The International Conference on Metamaterials, Photonic Crystals and Plasmonics (META) features every year the latest developments in the area of Nanophotonics, Metamaterials and related topics.

The conference program consists of plenary lectures, keynote talks, special sessions of invited talks, general sessions and high-profile poster sessions that typically cover a broad range of exciting physics, such as metamaterials and negative index materials, metatronics and graphene metamaterials, plasmonics and nanophotonics, plasmon-enhanced photovoltaics, photonic and plasmonic crystals and cavities, materials for photonics (Graphene, MoS2, WS2, etc), quantum photonics, nanobiophotonics, structured light, near-field optics and nano-optics, transformational electromagnetics and cloaking, acoustic metamaterials, optomechanics, nanofabrication technologies, etc.

The origin of the conference dates back to 2002 as a NATO Advanced Research Workshop at a time when many of the current topical research areas began to emerge from the field of complex electromagnetic materials.

Following a now well-established tradition META takes place every year in unique locations around the world.

Jeremy J. Baumberg  
*University of Cambridge, UK*

**Extreme nanophotonics : How to confine light below a cubic nanometre**

Jeremy J. Baumberg FRS, directs a UK Nano-Photonics Centre at the University of Cambridge and has extensive experience in developing optical materials structured on the nano-scale that can be assembled in large volume. He is also Director of the Cambridge Nano Doctoral Training Centre, a key UK site for training PhD students in interdisciplinary Nano research. Strong experience with Hitachi, IBM, his own spin-offs Mesophotonics and Base4, as well as strong industrial engagement give him a unique position to combine academic insight with industry application in a two-way flow. With over 20000 citations, he is a leading innovator in Nano. This has led to awards of the IoP Faraday gold Medal (2017), Royal Society Rumford Medal (2014), IoP Young Medal (2013), Royal Society Mullard Prize (2005), the IoP Charles Vernon Boys Medal (2000) and the IoP Mott Lectureship (2005). He frequently talks on NanoScience to the media, and is a strategic advisor on NanoTechnology to the UK Research Councils. He is a Fellow of the Royal Society, the Optical Society of America, and the Institute of Physics. His recent popular science book “The Secret Life of Science : How Science Really Works and Why it Matters” is just published by PUP; see np.phy.cam.ac.uk.

Alexandra Boltasseva  
*Purdue University, USA*

**Transdimensional Materials for Nanophotonics : From 2D to 3D**

Alexandra Boltasseva is a Professor at the School of Electrical & Computer Engineering at Purdue University. She received her PhD in electrical engineering at Technical University of Denmark, DTU in 2004. Boltasseva specializes in nanophotonics, nanofabrication, optical materials, plasmonics and metamaterials. She is 2018 Blavatnik National Award for Young Scientists Finalist and received the 2013 IEEE Photonics Society Young Investigator Award, 2013 Materials Research Society (MRS) Outstanding Young Investigator Award, the MIT Technology Review Top Young Innovator (TR35), the Young Researcher Award in Advanced Optical Technologies from the University of Erlangen-Nuremberg, Germany, and the Young Elite-Researcher Award from the Danish Council for Independent Research. She is a Fellow of the Optical Society of America (OSA) and Fellow of SPIE. She served on MRS Board of Directors and is Editor-in-Chief for OSA's Optical Materials Express.
Federico Capasso
Harvard University, USA

Metaoptics in the visible

Federico Capasso is the Robert Wallace Professor of Applied Physics at Harvard University, which he joined in 2003 after 27 years at Bell Labs where he was Member of Technical Staff, Department Head and Vice President for Physical Research. He is visiting professor at NTU with both the School of Physical and Mathematical Sciences and Electrical and Electronic Engineering. His research has focused on nanoscale science and technology encompassing a broad range of topics. He pioneered band-structure engineering of semiconductor nanostructures and devices, invented and first demonstrated the quantum cascade laser and investigated QED forces including the first measurement of a repulsive Casimir force. His most recent contributions are new plasmonic devices and flat optics based on metasurfaces. He is a member of the National Academy of Sciences, the National Academy of Engineering, the American Academy of Arts and Sciences. His research has focused on nanoscale science and technology encompassing a broad range of topics. He pioneered band-structure engineering of semiconductor nanostructures and devices, invented and first demonstrated the quantum cascade laser and investigated QED forces including the first measurement of a repulsive Casimir force. His most recent contributions are new plasmonic devices and flat optics based on metasurfaces. He is a member of the National Academy of Sciences, the National Academy of Engineering, the American Academy of Arts and Sciences. His awards include the King Faisal Prize, the IEEE Edison Medal, the SPIE Gold Medal, the American Physical Society Arthur Schawlow Prize in Laser Science, the Jan Czochralski Award for lifetime achievements in Materials Science, the IEEE Sarnoff Award in Electronics, the Materials Research Society Medal, the Wetherill Medal of the Franklin Institute, the Rank Prize in Optoelectronics, the Optical Society Wood Prize, the Berthold Leibinger Future Prize, the Julius Springer Prize in Applied Physics, the European Physical Society Quantum Electronics Prize.

Nader Engheta
University of Pennsylvania, USA

Analog processing with metastructures

Nader Engheta is the H. Nedwill Ramsey Professor at the University of Pennsylvania in Philadelphia, with affiliations in the Departments of Electrical and Systems Engineering, Materials Science and Engineering, Physics and Astronomy, and Bioengineering. He received his B.S. degree from the University of Tehran, and his M.S and Ph.D. degrees from Caltech. His current research activities span a broad range of areas including nanophotonics, metamaterials, nano-scale optics, graphene optics, optical metatronics, imaging and sensing inspired by eyes of animal species, optical nanoengineering, microwave and optical devices, and physics and engineering of fields and waves. He has received several awards for his research including the 2017 William Streifer Scientific Achievement Award from the IEEE Photonics Society, the 2015 Gold Medal from SPIE, the 2015 Fellow of US National Academy of Inventors (NAI), the 2015 National Security Science and Engineering Faculty Fellow (NSSEFF) Award (also known as Vannevar Bush Faculty Fellow Award) from US Department of Defense, the 2015 IEEE Antennas and Propagation Society Distinguished Achievement Award, the 2015 Wheatstone Lecture in King's College London, the 2014 Balthasar van der Pol Gold Medal from the International Union of Radio Science (URSI), the 2013 Inaugural SINA Award in Engineering, the 2012 IEEE Electromagnetics Award, 2006 Scientific American Magazine 50 Leaders in Science and Technology, the Guggenheim Fellowship, and the IEEE Third Millennium Medal. He is a Fellow of seven international scientific and technical societies, i.e., IEEE, URSI, OSA, APS, MRS, SPIE, and American Association for the Advancement of Science (AAAS). He has received the honorary doctoral degrees from the Aalto University in Finland in 2016 and from the University of Stuttgart, Germany in 2016.
Sir John Brian Pendry  
Imperial College London, UK

Singular plasmonic surfaces and their properties

Sir John B. Pendry is an English theoretical physicist educated at Downing College, Cambridge, UK, graduating with a Master of Arts degree in Natural Sciences and a PhD in 1969. He is a professor of theoretical solid-state physics at Imperial College London where he was Head of the Department of Physics (1998 – 2001) and Principal of the Faculty of Physical Sciences (2001 – 2002). John Pendry has made seminal contributions to surface science, disordered systems and photonics. His most famous work has introduced a new class of materials, metamaterials, whose electromagnetic properties depend on their internal structure rather than their chemical constitution. He discovered that a perfect lens manufactured from negatively refracting material would circumvent Abbe’s diffraction limit to spatial resolution, which has stood for more than a century. His most recent innovation of transformation optics gives the metamaterial specifications required to rearrange electromagnetic field configurations at will, by representing the field distortions as a warping of the space in which they exist. In its simplest form the theory shows how we can direct field lines around a given obstacle and thus provide a cloak of invisibility. John Pendry’s outstanding contributions have been awarded by many prizes, among which the Dirac Prize (1996), the Knight Bachelor (2004), the Royal Medal (2006), the Isaac Newton Medal (2013) and the Kavli Prize (2014).

Eli Yablonovitch  
UC Berkeley, USA

Optical Antenna Physics : Spontaneous Emission Faster than Stimulated Emission

Eli Yablonovitch introduced the idea that strained semiconductor lasers could have superior performance due to reduced valence band (hole) effective mass. With almost every human interaction with the internet, optical telecommunication occurs by strained semiconductor lasers. He is regarded as a Father of the Photonic Band Gap concept, and he coined the term "Photonic Crystal". The geometrical structure of the first experimentally realized Photonic bandgap, is sometimes called "Yablonovite".

Prof. Yablonovitch is elected as a Member of the National Academy of Engineering, the National Academy of Sciences, the American Academy of Arts & Sciences, and is a Foreign Member of the Royal Society of London. He has been awarded the Buckley Prize of the American Physical Society, the Isaac Newton Medal of the UK Institute of Physics, the Rank Prize (UK), the Harvey Prize (Israel), the IEEE Photonics Award, the IET Mountbatten Medal (UK), the Julius Springer Prize (Germany), the R.W. Wood Prize, the W. Streifer Scientific Achievement Award, and the Adolf Lomb Medal.

Eli Yablonovitch is the Director of the NSF Center for Energy Efficient Electronics Science (E3S), a multi-University Center headquartered at Berkeley. He received his Ph.D. degree in Applied Physics from Harvard University in 1972. He worked for two years at Bell Telephone Laboratories, and then became a professor of Applied Physics at Harvard. In 1979 he joined Exxon to do research on photovoltaic solar energy. Then in 1984, he joined Bell Communications Research, where he was a Distinguished Member of Staff, and also Director of Solid-State Physics Research. In 1992 he joined the University of California, Los Angeles, where he was the Northrop-Grumman Chair Professor of Electrical Engineering. Then in 2007 he became Professor of Electrical Engineering and Computer Sciences at UC Berkeley, where he holds the James & Katherine Lau Chair in Engineering.
KEYNOTE SPEAKERS

Konstantin Bliokh  
Theoretical Quantum Physics Laboratory - Riken, Japan  
Topological non-Hermitian origin of surface Maxwell waves  

Mark Brongersma  
Stanford University, USA  
Metasurfaces for Augmented and Virtual Reality  

Sven Burger  
Zuse Institute Berlin, Germany  
Computing resonances in nano-photonic devices using Riesz-projection methods  

Giulio Cerullo  
Politecnico di Milano, Italy  
Tracking ultrafast light-heat conversion in plasmonic nano-assemblies  

Manfred Fiebig  
ETH Zurich, Switzerland  
On the Search for Toroidal Order in Magnetic Materials  

Jean-Jacques Greffet  
Institut d’Optique Graduate School, France  
Electrical generation of surface plasmons with resonant nanoantennas  

Thomas Krauss  
University of York, UK  
Metasurfaces for sensing and imaging  

Stefan Maier  
LMU Munich, Germany  
Plasmonic hot electrons for nanoscale self-assembly and imaging
Sahin K. Ozdemir  
The Pennsylvania State University, USA  
Non-Hermiticity in Optics and Optomechanics

Nam-gyu Park  
Sungkyunkwan University, Korea  
Organic-inorganic Lead Halide Perovskite for High Efficiency Energy Conversion

Junsuk Rho  
POSTECH, Korea  
Artificial chirality evolution in micro-/nano-scale 3D metamaterials

Vladimir Shalaev  
Purdue University, USA  
Plasmonic Metamaterials Meet Quantum

David R. Smith  
Duke University, USA  
Optical Field Enhancement in the Nano-Patch Antenna for Lasing, Nonlinear Optics, and Other Nanophotonic Applications

Marin Soljacic  
MIT, USA  
Neural Networks in Nanophotonics

Jelena Vuckovic  
Stanford University, USA  
Optimized quantum photonics

Rachel Won  
Nature Photonics, UK  
Publishing in Nature journals

Nikolay Zheludev

Optical imaging and metrology with nanoscale resolution
META 2019 features several technical tutorials instructed by world-leading experts on various topics of interest to the META community. Tutorials are intended to provide a high quality learning experience to conference attendees. The tutorials address an audience with a varied range of interests and backgrounds: beginners, students, researchers, lecturers and representatives of companies, governments and funding agencies who wish to learn new concepts and technologies.

The tutorials are part of the conference technical program, and are free of charge for the conference attendees.

**ORGANIZER**

Prof. Ishwar Aggarwal, UNC Charlotte, USA

**Tutorials & Instructors**

**Prof. Nader Engheta**  
*University of Pennsylvania, USA*  

**Tuesday 23rd July**  
**11:40 - 12:40 — Auditorium I**  
**Near-Zero-Index Metamaterials**  
In this tutorial, I will present an overview of some of the fundamental principles and unique features of wave interaction with structures with effective refractive index near zero, which include epsilon-near-zero (ENZ), mu-near-zero (MNZ), epsilon-and-mu-near-zero (EMNZ) and Dirac-cone photonic media. I will then discuss some of the applications of near-zero-index metamaterials in photonics and microwave technologies. Possible future directions of research in this field will also be forecasted.

**Prof. Federico Capasso**  
*Harvard University, USA*  

**Wednesday 24th July**  
**10:50 - 11:50 — Auditorium I**  
**Flat optics**  
This tutorial focuses on how metasurfaces enable the redesign of optical components into novel thin and planar diffractive optical elements, that overcome the limitations of Fresnel and refractive optics, promising a major reduction in footprint and system complexity as well as the introduction of new optical functions. The planarity of flat optics will lead to the unification of semiconductor manufacturing and lens making, where the planar technology to manufacture computer chips will be adapted to produce CMOS-compatible metasurface-based optical components, ranging from metalenses to novel multifunctional phase plates.
Prof. Eli Yablonovitch  
UC Berkeley, USA  
Wednesday 24th July  
14:00 - 15:00 — Auditorium II  
The Electromagnetic Spectra of Ordinary Objects  

There is an aspect of Electromagnetics that has been somewhat overlooked. Common everyday objects can act as electromagnetic resonators. Indeed ordinary objects have a series of resonant frequencies extending from radio waves up to optical frequencies. These resonant modes can be modeled as LC circuits. Thus every object that we encounter is an LC resonator. Since LC circuits support ac currents, and since ac currents imply electron acceleration, they inherently radiate into the far-field. Therefore ordinary objects that we come across, in our daily lives, can act as electromagnetic antennas. This means that ordinary objects have a Q-factor and a radiation Q-factor for each resonant mode. The lowest frequency resonance is especially characteristic of the object geometry, but there is an entire spectrum of higher frequencies to work with, a spectral fingerprint for everyday objects. Many of the properties that have been attributed to plasmonic resonances are actually universal, and they arise already in ordinary electromagnetics. In communications technology, the antenna application is the most important. The antennas in cellphones, carried by almost everyone on the planet, are examples of multi-frequency resonant objects, enabling wireless connectivity.

Dr. Rachel Won  
Nature Photonics, UK  
Thursday 25th July  
11:00 - 12:00 — Auditorium II  
Writing and submitting your papers : Dos and Don’ts  

In this tutorial, Rachel will talk you through the detailed information and guidelines on scientific paper preparation and submission. Guidelines and tips for writing an abstract and a paper will be provided. Submission, editorial and peer-review processes will be discussed. At the end of the tutorial, you will walk away knowing how to write an informative cover letter, an outstanding abstract and a comprehensive scientific paper. You will also get to know where to submit your papers to, what editors seek, how your papers are reviewed and how to make an appeal.

Prof. Michael Fiddy  
DARPA, USA  
Thursday 25th July  
14:00 - 15:00 — Auditorium I  
DARPA’s interests in metamaterials  

Almost twenty years ago, some of the earliest research into metamaterials and their applications was funded by DARPA. The field has grown enormously since, and DARPA still supports fundamental research into improving our understanding and modeling of these engineered materials. This talk will provide the background and context for research of current interests. These include the study of new material properties, including bianisotropy and nonlinearity, advancing flat optics, and developing nonreciprocal and tunable components, all of which may impact imaging and remote sensing capabilities.
META 2019 will be held at the Congress Center of Instituto Superior Técnico (IST), situated at the Civil Engineering Building. All talks are scheduled for the Congress Centre of IST except for the Plenary talks which will be held in Culturgest, an independent conference center located 500m away from IST (see map).

Instituto Superior Técnico - Congress Center  
Civil Engineering Building (Pavilhão de Civil)  
Av. Rovisco Pais 1  
1049-001, Lisbon  
Website: https://tecnico.ulisboa.pt/en/

Culturgest  
Rua Arco do Cego 77  
1000-300  
Lisbon  
Website: https://www.culturgest.pt/en/
GETTING TO VENUE

Taxi
The quickest way to get from Lisbon Airport (LIS) to Instituto Superior Técnico is to taxi which costs 7€ - 9€ and takes 10mn.

Metro
Being close to the Lisbon city centre, IST is easily reached by metro (metro station "Alameda" - Red and Green lines; metro station "Saldanha" - Red and Yellow lines), from any location in town, including the airport (metro station "Aeroporto" - Red line).

Bus
The bus routes cover all Lisbon and extend to its outskirts. The tickets can be pre-paid, at the counters of Carris, the surface transportation operator for Lisbon, or bought aboard the bus, electric cars or funiculars. For IST hop off on one of the following bus stops:
- Av. Manuel da Maia
- Av. Rovisco Pais
- Arco do Cego

GENERAL INFORMATION

Registration
Registered participants may pick up their conference material at the registration desk which will be located:
- Monday, July 22 (15:00-18:00) : IST Civil Engineering Building
- Tuesday, July 23 (08:00 - 10:45) : Culturgest, in the foyer next to the Main Auditorium
• Tuesday, July 23 (10:45 - 18:00) : IST Civil Engineering Building
• Wednesday, July 24 (08:30-18:00) : IST Civil Engineering Building
• Thursday, July 25 (08:30-17:00) : IST Civil Engineering Building
• Friday, July 26 (08:30-11:00) : IST Civil Engineering Building

Plenary Lectures
Plenary Lectures will be held at the Main Auditorium of Culturgest, located 500m away from Instituto Superior Técnico Congress Center:
• Tuesday, July 23 (08:45-10:45)
• Thursday, July 25 (08:30-10:15)

Banquet
Schedule: Thursday, July 25 at 20:00.
Free Shuttle bus service will be provided between the Instituto Superior Técnico Congress Center and the KAIS Restaurant.
Pick-up time: 18:30 at the West IST Entrance located Av. Alves Redol (see map).
IST CONGRESS CENTER FLOOR PLANS

Civil Engineering Building - Level 0

Civil Engineering Building - Level 01

Civil Engineering Building - Level 01
Wi-Fi Instructions for META 2019 participants:

1. Browse available wireless networks and select as SSID "tecnico-guest";
2. Set IP to automatic (DHCP). This is usually the default setting, so you may probably skip this step;
3. Open your browser and try to access any external website. You will be automatically redirected to the page [https://wifi.ist.utl.pt/index_auth.php](https://wifi.ist.utl.pt/index_auth.php). Follow the link 'Web based login' at the top of the page concerning short-time, conference and meetings accounts. Enter the following username/password when requested:
   
   Username: META2019
   Password: jwvr2f

4. After step 3 you may freely browse and access the Internet. You may need to repeat the above steps if you close your browser or if the connection times out.

Guidelines for Presenters

**Oral Presentations**

Each session room is equipped with a stationary computer connected to a LCD projector. Presenters must load their presentation files in advance onto the session computer. Technician personnel will be available to assist you.

Scheduled time slots for oral presentations are 15 mn for regular, 20 mn for invited presentations, 30 mn for keynote talks and 35 mn for plenary talks, including questions and discussions. Presenters are required to report to their session room and to their session Chair at least 15 minutes prior to the start of their session.

The session chair must be present in the session room at least 15 minutes before the start of the session and must strictly observe the starting time and time limit of each paper.

**Poster Presentations**

Presenters are requested to stand by their posters during their session. One poster board, A0 size (118.9 x 84.1 cm), in portrait orientation, will be available for each poster (there are no specific templates for posters). Pins or thumbtacks are provided to mount your posters on the board. All presenters are required to mount their papers 30mn before the session and remove them at the end of their sessions. Posters must prepared using the standard META poster template (available on the conference website).

Metasurface Polarization Optics

Federico Capasso

John A. Paulson School of Engineering and Applied Sciences
Harvard University, Cambridge MA 02139

Abstract

The basic elements of polarization optics are polarizers and phase retarders (waveplates). Retarders most commonly take the form of bulk bi/uniaxial crystals whose birefringent properties allow for polarization conversion. These plates are, however, difficult to fabricate and process and are challenging to integrate. For example, current polarimeters use multiple optical components in sequence for polarization analysis and therefore often become bulky and expensive. The elements comprising a metasurface may possess tailored structural birefringence, making metasurface based flat optics a fascinating platform for new polarization optics to circumvent the above problems. A new class of phase plates has emerged from our research in this area along with major advances in polarimetry and polarization imaging, with greatly reduced complexity and increased functionality compared to existing technology.

Optical Antenna Physics:  
Spontaneous Emission Faster than Stimulated Emission

Eli Yablonovitch, Ming Wu, & Seth Fortuna

Electrical Engineering & Computer Sciences Dept.,  
University of California, Berkeley  
Berkeley California, 94720  USA  
*corresponding author, E-mail: eliy@eecs.berkeley.edu

Abstract

An optical antenna, like a radio antenna, can concentrate electromagnetic energy within a volume $\ll 1$ cubic wavelength. That same concentration factor applies to quantum zero-point electromagnetic energy. Intense pump radiation makes Stimulated Emission very fast. Likewise highly concentrated zero-point electromagnetic energy can make Spontaneous Emission very fast.

The question arises: Can zero-point electromagnetic energy be more intense than the strongest real pump fields? Real pump intensity in a laser is limited by various optical nonlinearities including saturation, hole-burning, gain-medium-damage, etc. Therefore optical antennas have a real opportunity to be faster than stimulated emission, but the Ohmic skin effect losses in the metals are a limitation.

We will describe the correct optical antenna conditions for making Spontaneous-faster-than-Stimulated emission, and we will review the improvements in our electrically pumped antenna Light Emitting Diodes.
Extreme nanophotonics: How to confine light below a cubic nanometre

Jeremy J Baumberg

1 NanoPhotonics Centre, Cavendish Laboratory, University of Cambridge, UK
*corresponding author, E-mail: jjb12@cam.ac.uk

Abstract

Coupling between coinage metal ‘plasmonic’ nano-components generates strongly red-shifted optical resonances combined with intense local light amplification on the nanoscale. I will show how we now create ultralow volume plasmonic cavities trapping light to the atom scale <1nm^3, and are routinely able to watch individual molecules and bonds vibrating. Using DNA origami we couple 1-4 dye molecules together optomechanically, and produce strong-light matter coupling that changes their quantum emission properties. We also watch redox chemistry in real time, watching single electrons shuttle in and out of single molecules, as well as 2D materials confined in the same gap. Prospective applications range from (bio)molecular sensing to fundamental science. I particularly focus on applications to nanomachinery actuation by light.

Fig. 1 Reversible nanoactuating systems under light, (a) ANT-on-mirror, (b) active metamaterial, (c) electro-plasmonic pixels, and (d) DNA origami nanomachines.

These concepts, which can be scaled up using bottom-up directed assembly, open up many new possibilities for applications of plasmonics and nano-optics.
Singular plasmonic surfaces and their properties

J.B. Pendry\(^1\)

\(^1\) The Blackett Laboratory, Imperial College London, London SW7 2AZ, UK
E-mail: j.pendry@imperial.ac.uk

Abstract
Plasmonic surfaces derive their properties from their structure. This is especially true when a singularity of some sort is present such as two touching spheres, or a sharp edge. Both these instances and many more give rise to intense concentrations of energy near the singularity. Singularities can be removed using transformation optics to relate properties of the singular structure to those of another structure in a higher dimensional space. The singularity can be regarded as a ‘compacted’, or ‘hidden’ dimension.
Transdimensional Materials for Nanophotonics: From 2D to 3D

Alexandra Boltasseva

School of Electrical & Computer Engineering and Birck Nanotechnology Center, Purdue University, 1205 West State St., West Lafayette, IN 47907, USA
*corresponding author, E-mail: aeb@purdue.edu

Abstract

The field of nanophotonics has recently seen a surge of new materials to address the need for tunable and durable nanophotonic components. In this talk, emerging photonic materials such as transparent conducting oxides, transition metal nitrides (TMNs), transdimensional (ultra-thin) materials (TDMs) and MXenes for photonic devices will be discussed. TDMs and MXenes are promising platforms for achieving actively switchable and tailorable metasurfaces, while TMNs are ideal for robust refractory plasmonic devices. Our recent progress on merging topology optimization with artificial intelligence assisted algorithms for designing photonic metasurfaces will also be covered.

1. Introduction

Due to their exceptional plasmonic properties, noble metals such as, gold and silver, have been the materials of choice for the demonstration of various plasmonic and nanophotonic phenomena. However, noble metals’ softness, lack of tunability, and low melting point, along with challenges in thin film fabrication, have prevented the realization of practical plasmonic devices requiring tailorable optical properties and durable metallic nanostructures. In response to these pressing requirements, investigations into new plasmonic materials that meet the need for tunable and robust nanophotonic devices have increased.

It has recently been predicted that as film thicknesses of plasmonic materials approaching the two dimensional (2D) regime can enable unusually strong tailorability of the optical properties. Transitioning from bulk, three dimensional (3D) structures to their 2D counterparts has uncovered truly new physics unattainable with 3D systems. However, the materials optical properties’ evolution in the transitional regime between 3D and 2D is still underexplored. The optical and electronic properties of these transdimensional materials (TDMs) which have thicknesses of only a few atomic layers are expected to show unprecedented tailorability, including strong dependences on the film thickness, composition, strain, and surface termination [1]. TDMs are also predicted to show extreme sensitivity to external optical and electrical perturbations [2]. TDMs and 2D materials may enable a variety of promising designs and demonstrations of miniaturized, tunable optical devices, owing to their extraordinary light confinement, tailorability of the optical properties and dynamic tunability.

In addition to tunable plasmonic devices, achieving durable metallic components for harsh environment applications has remained a challenge. Transition metal nitrides, such as titanium nitride (TiN), have emerged as a promising metallic material platform for nanophotonic devices operating at elevated temperatures for energy conversion, harsh environment sensors, and heat-assisted applications due to their refractory nature and remarkable plasmonic properties.

Alongside the development of new tunable and refractory metallic materials for plasmonic metasurfaces, novel approaches, such as topology optimization, have emerged as a successful method for the systematic design of photonic structures. Recently, it has been demonstrated that inverse design problems applied to metasurface and photonic crystal reconstruction can be efficiently solved using topology optimization techniques to obtain significantly improved performance in comparison with those obtained with direct optimization [3]. Combining topology optimization with new material development provides a synergistic approach for designing novel plasmonic metasurfaces.

2. New Materials for Tunable Plasmonics

The optical responses of atomically thin plasmonic films can be engineered by precise control of their structural and compositional parameters. This unique tailorability establishes TDMs as an attractive material for the design of tailorable and dynamically switchable metasurfaces. Due to their epitaxial growth on lattice matched substrates, TiN is an ideal material to investigate the tailorable properties of plasmonic films with thicknesses of just a few monolayers. The optical and electrical properties of smooth, epitaxial, ultra-thin TiN ranging from 2 to 10 nm have been characterized by ellipsometry and Hall measurements [4]. Although the metallicity decreases in smaller thicknesses, the thinnest film (2 nm) still retains a carrier density of 10^{12} cm^{-3} and is plasmonic properties at visible wavelengths (Figure 1). The role of quantum confinement, oxidation, and strain is explored through first principles density functional (DFT) calculations [5]. Gate dependent Hall measurements on a 1 nm film also reveals extreme tunability of the carrier concentration (up to 8.5%).

MXenes, a class of 2D nanomaterials formed of transition metal carbides and carbon nitrides, are yet another promising material platform for tailorable plasmonic metamaterials. They have the general chemical form
$M_{n+1}X_n$, where ‘M’ is a transitional metal, ‘X’ is either C or N, and ‘T’ represents a surface functional group (O, -OH or -F) and are chemically synthesized from a corresponding layered ternary carbides or nitrides phase known as MAX ($M_{n+1}AX_n$) phases [5]. Until now, MXenes have been widely explored in a variety of applications, such as electromagnetic shielding and SERS. However, investigations of MXenes in the context of nanophotonics and plasmonics have been limited leading to this current exploration of MXenes as building blocks for plasmonic and metamaterial devices. We have demonstrated an MXene based broadband plasmonic absorber and a dynamically tunable random laser (Figure 2).

3. Artificial Intelligence Assisted Photonics

Compared to other inverse-design approaches that require extreme computation power to undertake a comprehensive search within a large parameter space, topology optimization can expand the design space while improving the computational efficiency. We will discuss our studies on implementing deep-learning assisted topology optimization for advanced metasurface design development, focusing on highly efficient thermal emitter/absorber development for thermal-photovoltaics applications. We applied a topology optimization method to determine highly efficient metasurface designs with a non-trivial topology for efficient spectral reshaping of black-body radiation.

4. Conclusions

Ultrathin TiN and MXenes have been explored in the realm of tunable nanophotonics and plasmonics. As the material class and their synthesis techniques continue to mature, applicability in optics along with device performances are also expected to improve further. We have also coupled deep-learning-based techniques with the topology optimization of thermal emitters for TPV applications. The emerging classes of plasmonic materials in conjunction with machine learning assisted design optimization provide exciting opportunities for realizing novel metasurfaces with unprecedented functionalities.

Plasmonic chiral metamaterials has attracted significant attention at it provides a new route to intriguing optical properties such as negative refractive index, light polarization filters, and phase modulation. However, the fabrication regarding with limited resolution in conventional synthesis and complexity of asymmetric synthesis pose a major hindrance for further development. In this study, a new class of three dimensional chiral plasmonic nanostructures was successfully fabricated using molecular shape modifiers and crystallographic control of nanoparticle. Previously, we developed three-dimensional chiral metamaterials based on photolithography overlay and electron-beam lithography overlay for terahertz and near-infrared, respectively. We found scaling down them further to visible frequency is extremely difficult. As an alternative solution, we discovered a novel system that characteristic of molecule is transformed into distinctive gold nanoparticle shape. On the basis of this system, chirality transfer between molecular modifier and gold surface allow us to achieve numerous chiral morphologies of gold nanoparticle, named plasmonic helicoids. Particularly, enantiospecific interaction of molecule and high index plane plays pivotal role to provide asymmetric structuring process on the gold surface, forming distinct chiral morphology in single nanoparticle level. One of the representative shapes of helicoid structure showed gammadion-like structure, consisting of four highly curved arms of increasing width, in all six faces of cubic geometry. The unprecedented chiral morphology of plasmonic helicoid has remarkable optical activity (dissymmetry factor $\sim 0.2$ at 622 nm) even in a randomly dispersed solution, substantiated by direct visualization of macroscopic color transformation. Changes in molecular recognition and growth parameter led to different morphological evolution, and structural alterations provided a straightforward means of tailoring optical response, such as optical activity, handedness, and resonance wavelength. Also, our aqueous phase synthesis is readily scalable without losing exquisite chiral structure at nanoscale. In these aspects, our approach, chirality evolution in single nanoparticle, provides a truly new paradigm and valuable insight for chiral metamaterial fabrication. Such unique fabrication technique will provide the opportunity to achieve the significant step making metamaterials from science to technology.

Computing resonances in nano-photonic devices using Riesz-projection-based methods

Sven Burger$^{1,2}$, Felix Binkowski$^1$, Lin Zschiedrich$^2$

$^1$Zuse Institute Berlin, Takustr. 7, 14195 Berlin, Germany

Abstract

Nano-optics and quantum optics setups and devices typically rely on optical structures incorporating resonance effects. Advanced modeling and simulation methods are essential for an effective design of the experimental setups and for the interpretation of the physical results. In this contribution, we review simulation techniques for computing optical resonances. In particular, we point out Riesz-projection-based methods for computing the interaction of light emitters with resonance modes and for computing eigensolutions in dispersive systems.

1. Riesz projection expansion for computing coupling to light emitters

Nano-optical resonators have been demonstrated in various material systems [1, 2], including plasmonic [3] and dielectric structures [4]. Placing point-like sources in the vicinity of such nanoresonators or antennas enables exploration of new regimes of light-matter interaction. For quantifying the interaction, Maxwell’s equations can be solved directly to obtain solutions for the electromagnetic field. For a deeper insight into physical properties, an expansion using the eigenmodes of the systems, so-called quasi-normal modes (QNMs), can be used [5, 6]. The situation is depicted schematically in Figure 1. As indicated, the total electromagnetic field caused by any light source can be decomposed to resonance modes of the structure and to nonresonant components.

However, Riesz projections (RPs), well-known in spectral theory [7], are based on contour integration and provide a powerful means to analyze the spectrum of partial differential operators. RPs can be used to compute QNMs, the coupling of emitters to QNMs, and the coupling to a nonresonant background in an elegant way. Recently, we have presented a theory and a numerical implementation for modeling dispersive light-matter interaction based on RPs [8]. This approach has also been used in an investigation of emitters placed in the small gap between a plasmonic nanoantenna investigated numerically in a recent benchmark [12].

Figure 1: Schematic decomposition of the electromagnetic field caused by a dipole emitter in the vicinity of a nanoresonator. (a) Total electromagnetic field. (b) A resonance mode of the nanoresonator. (c) Nonresonant components of the electromagnetic field. This part includes also the singularity resulting from the dipole source. Figure 2: Visualization of the geometry, the finite-element mesh and the electromagnetic field distribution of a plasmonic nanoantenna investigated numerically in a recent benchmark [12].
monic nanoantenna and a metal surface [9]. In particular, it was studied under which conditions the strong coupling regime can be reached in such systems.

2. Riesz-projection-based method for computing photonic resonances

In a recent benchmark, a RP-based method for the computation of photonic resonances [10], as well as a specific auxiliary field approach [11], have been compared with other methods for approaching this simulation task [12]. We have used a finite-element based implementation (JCMsuite). Figure 2 shows a visualization of one of the benchmark problems: a silver cube with rounded corners placed on a thin polymer spacer above a gold substrate. An optical resonance with a strongly localized field in the polymer spacer material is also shown. Experimentally, such setups have been used to demonstrate large enhancements of light emission from optical sources placed in the spacer layer. In the benchmark, a general agreement of the results from most of the methods was demonstrated. The RP-based algorithm was shown to belong to the group of methods exhibiting high performance regarding accuracy and convergence for the computation of the eigenfrequency, quality factor, and mode volume of the resonance mode.

Utilizing plasmonic hot electrons for bridging top-down and bottom-up nanofabrication and for sub-wavelength absorption imaging

Stefan A Maier¹

¹Chair in Hybrid Nanosystems, Nanoinstitute Munich, Faculty of Physics, Ludwig-Maximilians-Universität München, 80539 München, Germany
* E-mail: Stefan.Maier@physik.uni-muenchen.de

Abstract

We demonstrate a novel approach towards the combination of top-down and bottom-up nanofabrication, based on controlled modification of the surface functionalization of plasmonic nanoantennas facilitated by hot electron bond cleaving.

Results

Plasmon decay in sub-wavelength metallic nanostructures leads to the generation of energetic, “hot” electrons, which can catalyze chemical reactions at the nanoparticle’s surface. Here we demonstrate two exciting applications of this phenomenon.

Firstly, we show how top-down nanofabrication of Au nanostructures (“nanoantennas”) can be combined with bottom-up self-assembly of colloidal units, thereby generating hybrid structures that bridge both fabrication methodologies [1]. This is achieved via controlled cleaving of thiol bonds on molecularly functionalized nanoantennas, allowing for refunctionalization with a second molecular unit (see picture) that links to the colloidal system of choice. Exploiting polarization and wavelength degrees of freedom hence enables to assemble the colloidal units to selected parts of the nanoantenna.

Secondly, we demonstrate how the thiol-bond cleaving can be utilized to map absorption sites in complex metallic nanostructures, utilizing fluorescence-based super-resolution localization microscopy on DNA-functionalized Au nanoantennas [2]. Spatially localized decay of hot electrons leads to thiol-bond cleaving only where optical absorption has occurred, allowing for spatial identification of absorption sites via monitoring changes in fluorescence.

These two examples demonstrate avenues to exploit plasmonic hot electrons beyond catalysis and Schottky-based photodetection. In particular, the combination of top-down and bottom-up nanofabrication facilitated by this approach should allow new approaches towards metasurface creation combining both nanoantennas and colloidal particles.

Abstract

This talk introduces you to all the existing and new journals in the family of *Nature*, and covers the detailed information and guidelines on scientific manuscript preparation and submission.

1. Introduction

Launched in January 2007, *Nature Photonics* is a monthly journal dedicated to optics and photonics that publishes top-quality, peer-reviewed research in all areas of light generation, manipulation and detection. Coverage extends from research into the fundamental properties of light and how it interacts with matter through to the latest designs of photonic devices and emerging applications that exploit photons. Both fundamental optical physics and applied photonics technologies, such as nonlinear optics, ultrafast photonics, quantum optics, plasmonics, metamaterials, nanophotonics, imaging, optical communications, optical storage, photovoltaics and optical communications, are covered. For more information: [https://www.nature.com/nphoton](https://www.nature.com/nphoton).

This talk, although with an emphasis on *Nature Photonics*, will introduce you to all the existing and new *Nature* journals, and cover the detailed information and guidelines on scientific manuscript preparation and submission. Also presented is an overview on the editorial and peer-review processes in all *Nature* journals. You will get to know what editors seek, how to write a good cover letter and a good scientific paper, the peer review process that your paper goes through and how to make an appeal. More importantly, you will find out how you can contribute to the journals apart from publishing your research.
Optical imaging and metrology with nanoscale resolution

Nikolay I. Zheludev

*corresponding author, E-mail: jean-jacques.greffet@institutoptique.fr

Abstract

We report the design, fabrication and characterization of antennas to emit surface plasmons by inelastic tunneling. The antenna controls the emission spectrum and enhance the emission efficiency by four orders of magnitude. We measure an emitted optical power of 10pW, four orders of magnitude larger than the power emitted by a scanning tunnelling tip. We introduce a theoretical model of the antenna in good agreement with the results.

1. Introduction

Surface plasmon polaritons are mixed electronic and electromagnetic modes propagating along the interface between a metal and a dielectric. The corresponding electromagnetic field can be confined to nanometer scale and has a decay time on the order of 10 fs so that a new generation of devices can be designed. An important limitation of surface plasmon is that in most cases, they are optically excited by a diffraction limited beam. In order to fully benefit from the field confinement, it is necessary to generate surface plasmon polaritons in the near field with a subwavelength device. This can be done using electronic inelastic tunneling through a tunnel junction.

Light emission by electrons tunneling inelastically through a planar tunnel junction was discovered by Lambe and McCarthy[1]. This process is rather inefficient with a typical efficiency on the order of one photon per a million electrons. Furthermore, light emission by inelastic tunneling (LEIT) has important advantages. Firstly, LEIT is intrinsically fast[2]. The fundamental limit is given by the tunneling time which is on the order of eV/h where e is the electron charge, V the applied voltage on the order of 1V and h is Planck’s constant yielding a time limit on the order of 4 fs. Secondly, LEIT can be a highly localized source. The source current density can be confined in a nanoantenna or in a metallic tip enabling electromagnetic excitation localized at the nanometer scale. Both photon and plasmon emission has been reported using scanning tunneling microscope tips[3,4]. More recently, surface plasmon emission has been reported with metallic nanostructures[5]. Hence, antenna surface plasmon emission by inelastic tunneling (ASPEIT) appears to be a suitable candidate for ultrafast and highly localized plasmon emission.

However, a number of issues need to be addressed before ASPEIT can become a practical source. It is required to control the emission spectrum, the angular emission pattern and to increase significantly the emission efficiency. In order to tackle these issues, resonant nanoantennas can be used. Photon emission in the visible by electrically driven optical antennas has been reported demonstrating a spectral control of the emission[6] and also a directional control[7]. So far, surface plasmon emission by inelastic tunneling has received comparably less attention. It was proposed[8] to use antennas to engineer the plasmon mode in order to increase the efficiency and to control the emission spectrum.

2. Results

Here, we report the design, fabrication and characterization of nanopatch antennas to emit surface plasmons, schematically shown in Fig. 1(a). The electrical excitation of propagating SPP (PSPP) can be launched along an air/Al interface, shown in Fig. 1(b). We design the antennas in order to control the emission frequency and we observe a narrow emission spectrum with an enhancement of the electron to plasmon conversion efficiency over three orders of magnitude.
Figure 1: (a) Schematic of the ASPEIT device consisting of an Au nanopatch antenna on an Al film with 3nm of AlOx layer in between. (b) Electroluminescence angular far-field distribution through the substrate. The inner dashed circle corresponds to $k=\omega/c$, and the outer dashed circle corresponds to $k=1.3k_0$; the yellow bright ring indicates the plasmon wave vector at the air/Al interface.

Optical Field Enhancement in the Nano-Patch Antenna for Lasing, Nonlinear Optics, and Other Nanophotonic Applications

David R. Smith¹, Patrick Bowen¹

¹Center for Metamaterials and Integrated Plasmonics and Department of Electrical and Computer Engineering, Duke University, Durham, North Carolina, USA

*corresponding author, E-mail: drsmith@ee.duke.edu

Abstract

The optical nanopatch antenna consists of a metal, planar nanoparticle spaced nanometers from a metal film. For symmetric nanoparticles (e.g., cubes or disks), semi-analytic expressions can be obtained for all relevant optical scattering properties, useful for describing such phenomena as perfect absorption, bistability, enhanced fluorescence and lasing. These analytical expressions enable the nanopatch system to be rapidly optimized for a wide variety of nanophotonic applications. We review the nanopatch antenna and discuss its role as a novel photonic device.

1. Introduction

The nanopatch geometry is illustrated in Fig. 1, which shows a periodic array of nanopatch antennas deposited on a thin insulating layer above a metallic film. As is well-known in plasmonics, two closely spaced, coupled nanoparticles (a dimer) will support a plasmon resonance in which the optical field between the nanoparticles can be enhanced by two orders of magnitude or more. This same enhancement can be achieved by a nanoparticle interacting with its electromagnetic image formed in a nearby conducting layer.

While the enhancement associated with a dimer and that between a nanoparticle and its image are similar, the ease of fabrication associated with the nanopatch geometry makes it a nearly ideal platform to study enhancement effects. With planar deposition techniques, the insulating layer can be precisely controlled to sub-nanometer dimensions, enabling the effective gap between nanoparticle and image to be carefully varied and optimized. In addition, by using colloidal methods to deposit the nanoparticles, time-consuming lithography can be avoided, and large surface areas patterned.

The nanoscale region between the nanoparticle and film where the fields are enhanced can be understood as a leaky cavity with moderate quality (Q-) factor (usually on the order of 10-30). While the Q-factor is quite low, the very small effective cavity volume makes the Q/V ratio large in comparison with other nano- and micro-cavity formats. This Q/V parameter is important for many quantum optical phenomena, including enhanced fluorescence and lasing, so that despite the low Q (arising from both radiative and resistive losses), plasmon nanocavities can be used to potentially achieve the strong coupling needed in many quantum optical devices.

2. Modeling the Nanopatch

The region between the planar nanoparticle and metal film of a nanopatch effectively behaves as a resonant cavity, with cavity modes closely resembling those corresponding to two planar electric conductors bounded by magnetic conducting walls. These modes can be found by solving a standard boundary value problem, including the plasmonic responses of the nanoparticle and metal film. The total field within the nanocavity region can then be expressed as an expansion over the cavity modes, $E_\mu(r)$, or [1]

$$E(\omega, r) = \sum_\mu e_\mu(\omega)E_\mu(r).$$  \hspace{1cm} (1)

Here, the cavity modes are lossless, which requires assuming the metal is lossless and that the boundary around the insulating region is terminated in a perfect magnetic conductor. Radiative and resistive losses are then taken into account via a perturbation approach. The coupling coefficients, $e_\mu(\omega)$, depend on the form of the excitation field and can be determined using coupled mode theory. For a plane wave incident on the nanopatch, the magnetic field incident on the surface of the gap between nanoparticle and film can be viewed as an effective electric current density source $K_x = \hat{n} \times H_{inc}$ that drives the cavity modes. The coupling coefficients can then be derived as...
\[ e_\mu(\omega) = -\frac{i\omega}{\omega^2 - \omega_\mu^2/\mu_\mu} \int_0^{\frac{d}{2}} |K_x E_x| dS \]  
where the mode-dependent Q-factor, \( Q_\mu \), can be determined using a perturbative approach.

The fields scattered from the patch result from effective magnetic currents excited on the gap surface. If the total electric field at the gap surface is known, then approximately \( K_m = (1 - r_{TM})\hat{E} \times \hat{n} \). From these effective surface currents, an effective dipole moment can be found from \( i\omega \mu_0 \text{Im} \int_{gap} K_m dS \), from which an effective polarizability is obtained:

\[ \alpha_\mu = \frac{4\mu_0 c^2 (1 - r_{TM})^2}{\omega^2 - \omega_\mu^2 - i\omega/\mu_\mu} \mu \text{odd}. \]

While Eq. 3 is simplified for an individual nanoparticle much smaller than the wavelength, the general form provides the basis for obtaining accurate analytical expressions for a wide variety of potential metasurface applications.

### 3. Examples

Once having obtained the complete scattering solution for a single nanopatch, the properties of arrays of nanopatches—or nanopatch metasurfaces—can be readily determined [2]. The closed form expressions that emerge for a variety of nanopatch surface applications provide key insights that guide design and allow performance metrics to be predicted. Two examples are summarized below.

#### 3.1. Reflectance of a Nanopatch Array

The reflectance from a nanopatch array can be determined by summing over the contributions from radiating effective magnetic dipoles at each nanopatch location. Near the fundamental resonance of the nanopatch, the reflectivity can be readily obtained as

\[ r = r_{TM} + \frac{i4k_0\lambda^2}{\omega^2 - \omega_\mu^2 + i\omega/\mu_\mu} , \]

where normal incidence is assumed (so that \( r_{TM} = -1 \)). The radiative Q-factor can be calculated as

\[ Q_r = \frac{k d^2}{2\mu_0 (1 - r_{TM})^2} \]

As a simple application, the above formulas can be used to design a nanopatch perfect absorbing surface. When the nanopatches are driven near their resonance, Eq. 4 reduces to

\[ r = r_{TM} + \frac{(1 - r_{TM})^2}{1 - r_{TM}^2} \frac{2Q_\mu}{Q_\mu + Q_\mu} , \]

where we have used \( Q_\mu = Q_r + Q_\mu \). Assuming the metal film has a reflectance close to \( r_{TM} = -1 \), Eq. 6 shows that perfect absorption occurs when the Ohmic losses are equal to the radiative losses. Using this condition, nanopatch surfaces with near zero reflectance can be designed.

#### 3.2. Bistability in a Nonlinear Nanopatch Array

If the gap region between the nanoparticle and film has a nonlinear polarizability, we can define a nonlinear current density of the form \( J_n = i\omega P_n \), which then appears as an additional volume source term in Eq. 2. Assuming the nanopatch has width \( a \), the total current density then has the form

\[ J = i\omega P_n + 2(\mathbf{H}_{inc} \times \hat{n})[\delta(x) + \delta(x + a)]. \]

Inserting the above current density into Eq. 2 leads to

\[ e_\mu(\omega) = \frac{i\omega}{\omega^2 - \omega_\mu^2 - i\omega/\mu_\mu} \frac{\int_0^{\frac{d}{2}} |P_n| E_\mu| dS}{\omega_\mu - \omega^2 - i\omega/\mu_\mu}, \]

Assuming a \( \chi^{(3)} \) nonlinearity, we have

\[ P_n(r) \approx \frac{2\mu_0 \chi^{(3)}}{4} e_\mu e_\mu^* |E_\mu(r)|^2. \]

Since the electric field of the fundamental mode in the gap has the form \( E_\mu = \hat{E} \cos(\mu \pi x / d) \hat{z} \), the above equations can be combined to yield the nonlinear equation

\[ x_\mu \left[ \alpha_\mu^2 - i\omega_\mu^2/\mu_\mu - \omega^2 (1 + \phi |x_\mu|) \right] = -8\omega Z_0 \frac{|E_\mu|}{k d}, \]

where \( x_\mu = e_\mu \hat{E} \), \( \phi = 9\chi^{(3)}/16 \), and \( Z_0 \) is the impedance of free space.

For a given excitation, the roots of Eq. 10 can be found and thus the effective polarizabilities of each nanopatch. Summing over these scattering dipoles yields a nonlinear reflectivity that exhibits bistability.

### 4. Conclusion

We have summarized the dipole approach to analyzing nanopatch metasurfaces, in which the polarizability of each nanopatch is computed using coupled mode theory. The accuracy of this basic approach can be improved by including additional effects, such as interactions among the nanopatches (coupled dipoles) as well as coupling of the nanopatches to surface plasmons. In addition, the expansion of Eq. 2 can be made in quasi-normal modes, which capture the Ohmic losses in a more natural and appropriate manner. The quasi-normal mode expansion is particularly relevant for predicting quantum optical phenomena, such as lasing and strong coupling, where obtaining accurate accounting of losses is crucial. Coupled-mode theory combined with coupled dipoles provides a foundation for functional metasurface design, particularly relevant for the co-design of tailored reflectance combined with enhancement effects.

Abstract
Since the first report on the high efficiency, stable solid-state perovskite solar cell (PSC) in 2012 by our group[1], following seed work on perovskite-sensitized liquid junction solar cells in 2011 [2], PSC demonstrated its power conversion efficiency (PCE) over 24% as of March, 2019. According to Web of Science, publications on PSC have been increased exponentially since 2012 and total number of publications reaches over 12,000, which is indicative of a paradigm shift in photovoltaics. Although small area cell exhibited superb efficiency surpassing the performance of thin film technologies, scale-up technology is required toward commercialization. In addition, further higher efficiency toward Shockley–Queisser limit of 31% based on bandgap of 1.6 eV is required in parallel. In this talk, the advent of solid state PSC is briefly introduced, which is followed by progress of PSC in terms of materials and devices. Issues in PSC such as current-voltage hysteresis, control of recombination and stability are also discussed based on doping approach, interface modification using post-treatment and additive engineering [3-6]. For scaling up, large-area coating technologies on perovskite cluster-embedded coating solution and D-bar coating process are discussed [7]. Bi-facial stamping method was developed for not only scale-up technique but also interface modification and low-temperature phase stabilization [8]. Commercially available perovskite powders were developed using precipitate method at ambient condition. With our perovskite powder, power conversion efficiency over 22% was reproducibly achieved. Recent advancements using organic-inorganic lead halide perovskites in X-ray imaging [9] and light emitting diode [10] are introduced.

Abstract

We investigate the photothermal properties of water-soluble hybrid organic-inorganic Au nanocrystal assemblies, comprising plasmonic nanocrystals embedded in a matrix of organic ligands, via a combination of ultrafast optical spectroscopy and semi-classical numerical modeling. We observe a complex transient optical response, with picosecond electron-phonon equilibration followed by heat release to the matrix on the 100-ps timescale. Our results indicate that assemblies operate as efficient nanoheaters exploiting the high absorption from the individual nanocrystals, enabled by the dilution of the inorganic phase.

1. Introduction

The last decade has witnessed an explosive growth of interest for the photothermal properties of nanostructures, both for fundamental and applied aspects [1]. Examples are photothermal therapy for cancer, in which light, following irradiation of nanocrystals, is converted to cytotoxic heat in order to selectively kill cancer cells and minimize the invasive injury to normal tissues [2, 3], as well as novel solar photodevices for water vapour generation [4] and direct light-driven desalination [5]. Particularly interesting in this respect are nanocrystal assemblies, as the interaction between nanocrystals and the heat transfer though molecular linkers can, in principle, strongly change their thermal properties and, subsequently, the dynamics of the photothermal energy conversion. Recently, some of the authors synthesized hybrid organic-inorganic nanoassemblies that are stable in water, paving the way to real-world in vivo applications [6]. These structures consist of hydrophobic inorganic nanocrystals that self-assemble in fcc structures thanks to the presence of hydrophilic organic materials.

Here we study the specific heat release properties of hundred-nm size Au clustered structures, ferrite (Fe₃O₄) supraparticles and Au/ferrite eggs, i.e. (Fe₃O₄)Au₁₃ assemblies trapped in ferrite colloidosomes. With the Au clustered structure we find that the hierarchical nanostructuring translates into a hierarchical mechanism for the energy flow that starts with the absorption of light in the metal phase, thanks to plasmonic resonances occurring at the individual nanocrystal level, and leads to the heating of the matrix ligands. The latter process, which we reveal by optical means thanks to thermo-optical effect, turns out to be comparatively fast because of the homogeneous distribution of the individual nanocrystals heaters in the assembly enabled by their periodic arrangement. A similar behavior is observed in Fe₃O₄ supraparticles and (Fe₃O₄)Au₁₃ nanoeys on the same time scale. This indicates that the light-heat conversion in these kind of nanomaterials is governed by a universal mechanism that relies on the intrinsic hybrid composition of the assembly involving optically-active inorganic nanocrystals and a matrix of organic ligands with relatively high heat capacity, embedded in a water environment [7].

2. Results and discussion

We studied clustered structures of Au nanocrystals with r = 2.75 nm radius coated with 1-octadecane-thiol, forming spherical assemblies with 160±50 nm diameter. The samples were excited by 100-fs pulses at 400 nm and probed by broadband white-light pulses covering the visible and the near-infrared (NIR) range. Figure 1A and 1B show differential transmission (ΔT/T) spectra, recorded as a function of probe wavelength and delay, in the visible and NIR, respectively. On the initial time scale of ten picoseconds, the transient signal resembles the typical ΔT/T map recorded for plasmonic nanoparticles. Cross sections at early time delays (black and red traces in the bottom panels of Figs. 1A and 1B) show the characteristic transient spectra of isolated nanocrystals which are dominated by shift and broadening of the plasmonic resonances. These spectra exhibit a decay constant of few ps, that is the timescale of electron-phonon scattering in noble metals. On longer times scales, surprisingly, the ΔT/T of Au clustered structures exhibits very distinct features: instead of a monotonic decrease over time, we observe the build-up of a positive signal which is red-shifted by about 100 nm (blue and magenta traces in the bottom panels of Figs. 1A and 1B) as compared to the early spectra.
To understand the unexpected transient optical response on the 100-ps timescale, we developed a model to simulate the optical experiments. The model combines finite element method (FEM) electromagnetic simulations of the optical response of the supracrystal to a semi-classical four-temperature model to describe the non-equilibrium optical response. The model considers the energy density of the out-of-equilibrium electrons in the metal nanocrystals, the temperature of thermalized electrons in the metal, the temperature of the metal lattice and the temperature of the organic subsystem embedding the nanocrystals. Using a negative thermo-optic coefficient of the organic matrix, the model reproduces the experimental results very accurately (see panels C and D of Fig. 1).

According to our model, the delayed build-up of the $\Delta T/T$ signal on the few hundred ps time scale is the signature of the final step in the light-heat conversion process, that ultimately results in the heating of the matrix of organic ligands. As such, this dynamical feature in the transient optical response is expected to be an intrinsic property of any hybrid assembly of hydrophobic nanocrystals, regardless the peculiar nature (i.e. plasmonic or not) of their building blocks, as observed in our experiments on non-plasmonic structures [7].

3. Conclusions

We have investigated the photothermal properties of water-soluble nanocrystal assemblies via a combination of ultrafast optical spectroscopy and semi-classical numerical modeling. Their hybrid composition at the nanoscale, comprising plasmonic (Au) nanocrystals embedded in a matrix of organic ligands, results in a complex transient optical response. Broadband pump-probe experiments in the visible and near infrared has allowed us track the whole chain of photothermal energy flow: (i) light absorption by the individual nanocrystals and subsequent excitation of out of equilibrium carriers; (ii) electron-phonon equilibration occurring in a few picoseconds; (iii) heat release to the matrix.

2D finite element method electromagnetic simulations of the composite nanostructure and multi-temperature modeling of the energy flow dynamics enable us to identify the mechanisms presiding over the light-heat conversion in this novel kind of nanomaterials. Our results indicate that hybrid (organic-inorganic) nanocrystal assemblies can operate as efficient nanoeaters by exploiting the high absorption from the individual nanocrystals, enabled by the dilution of the inorganic phase, that is followed by a relatively fast heating of the embedding organic matrix, occurring on the 100-ps timescale.

On the Search for Toroidal Order in Magnetic Materials

Manfred Fiebig

1Department of Materials, ETH Zurich, Vladimir-Prelog-Weg 4, 8049 Zurich, Switzerland
*corresponding author, E-mail: Manfred.fiebig@mat.ethz.ch

Abstract

Spontaneous long-range order of magnetic vortices is discussed as possible fourth form of primary ferroic order, called ferrotoroidicity. We define the underlying magneto-toroidal moment and discuss manifestations of the hallmark properties of ferroic order in magneto-toroidal materials: domains that are described by the orientation of an associated phase-transition-driving order parameter and that are switchable by a conjugate field. It turns out that "magneto-toroidal metamaterials" are ideal for elucidating the nature of the ferrotoroidic order and its conjugate toroidal field.

1. Magneto-toroidal moment and order

Although ferromagnetism is known to be of enormous importance, the exploitation of materials with a compensated (for example, antiferromagnetic) arrangement of long-range ordered magnetic moments is still in its infancy. Antiferromagnetism is more robust against external perturbations, exhibits ultrafast responses of the spin system and is key to phenomena such as exchange bias. However, there is no conjugate field for the manipulation of antiferromagnetic order, hindering both its observation and direct manipulation.

An interesting alternative to antiferromagnetism is a state with spontaneous long-range order of magnetic vortices called toroidal moments [1]. The toroidal moment is shown and defined in Fig. 1c as vortex-like head-to-tail arrangement of magnetic moments. The toroidal moment vector is given by

\[ \mathbf{t}_i = \sum \mathbf{r}_i \times \mathbf{m}_i, \]

where \( \mathbf{r}_i \) is the vector pointing from the center of the unit cell to the magnetic moment \( \mathbf{m}_i \) and \( i \) sums over all the magnetic moments in the unit cell. Spontaneous uniform long-range alignment of these toroidal moments yields a macroscopic toroidization \( \mathbf{T} = V^{-1} \sum \mathbf{t}_i \), where \( n \) sums over all the unit cells contained in the volume \( V \). Here, \( \mathbf{T} \) can be regarded as order parameter of a so-called ferrotoroidic state. Such ferrotoroidic order is discussed as complement to ferromagnetism, ferroelectricity and ferroelasticity as fourth type of a primary ferroic state.

The potential of ferrotoroidic materials is twofold. On the one hand, they represent a magnetically ordered state with compensated magnetization, yet, in contrast to antiferromagnetism, associated to an alternative field, the toroidization, that may be used to probe and switch domains despite their zero magnetization. On the other hand, the ferrotoroidic state involves a breaking of spatial and temporal inversion symmetries, which inherently allows the linear magnetoelectric effect: an electric field inducing a proportional magnetization and a magnetic field inducing an electric polarization.

2. Ferrotoroidicity as primary ferroic order

The existence of ferrotoroidic state has been discussed for many decades [2]. In order to establish it as genuine ferroic state, a variety of criteria have to be fulfilled [3]. A state can be called ferroic if it is reached by a non-disruptive phase transition involving a reduction of point symmetry. The phase transition is accompanied by the formation of domains where the domain states are distinguished by the respective orientation of the corresponding order parameter. A conjugate field acts on the orientation of the order parameter and can thus switch the domains in a hysteretic fashion. There has to be a macroscopic property diverging at the ferroic phase transition. Finally, in order to describe a proper manifestation of ferroic order, the order parameter needs to drive the phase transition instead of just following another phase-transition-driving order parameter in which case the ferroic state would be called improper.

2.1. Verified ferroic properties

Over the years, most of these criteria have been verified for the toroidal order in magnetic materials. A reduction of magnetic symmetry with the formation and hysteretic switching of domains was observed by optical second harmonic generation [3, 4]. A divergence of the magnetoelastic susceptibility at the phase transition has been detected [5] and indications for proper ferrotoroidic order have been identified by Landau theory and magnetoelectric susceptibility measurements [6].

2.2. The open issue of the toroidal field

A crucial, intensely debated point is the conjugate toroidal field. This is a field violating spatial and temporal inversion symmetry just as the ferrotoroidic order parameter does. Its
existence is yet unclear – there is no "toroidal field generator". Up to now, access to the ferrotoroidic domains and the two-fold breaking of inversion symmetry are almost always realized by the simultaneous application of static, orthogonal magnetic and electric fields [1]. Application of two fields would render the ferrotoroidic state a secondary ferroic state. Alternatively, it may be argued that the two fields are merely coupling to the actual, sole toroidal field, which would retain the notion of a primary ferroic state.

Figure 1: (a) Atomic force microscopy image of an artificial magneto-toroidal crystal built from permalloy nanomagnets on a silicon substrate. Unit cells comprising four nanomagnets are highlighted by the white boxes. (b) Corresponding magnetic force microscopy image revealing an as-grown toroidal domain structure with a domain boundary separating states of opposite toroidization. (c) The handedness of the arrangement of the magnetic moments in the unit cell determines the toroidal moment as $-t$ or $+t$.

3. Magneto-toroidal metamaterials

A way out of this dilemma is to upscale the magneto-toroidal order to length scales that can be probed more easily and directly than phenomena on the atomic-unit-cell level [7]. For this purpose, we created an artificial crystal consisting of mesoscopic planar nanomagnets. We designed this "magneto-toroidal metamaterial" to possess a magneto-toroidally ordered ground state as shown in Fig. 1b that we probe locally by scanning with a magnetic tip. Furthermore, by scanning the array with the magnetic tip in a suitable way, we can generate an effective toroidal poling field that we use to pole the toroidization of our nano-magnetic array locally, writing regions with the toroidization $+T$ or $-T$ as shown in Fig. 2. In this process, the magnetic tip catalyses the generation of the effective toroidal field, but it does not exert a poling field in itself. Thus, the experiment allows us, for the first time, to generate a toroidal field directly and apply it to set the toroidization of a sample.

Figure 2: Magnetic force microscopy images of two regions of an artificial magneto-toroidal crystal to which toroidal poling fields of opposite signs in (a) and (b) were applied. Colour codes as in Fig. 1.

4. Outlook

Our experiment on magneto-toroidal metamaterials brings us a significant step closer to consolidating the magneto-toroidal order as fourth form of primary ferroic order. Furthermore, the possibility to write specified regions with a uniform toroidization of defined orientation into a magnetic nano-array is the key to engineering unusual optical properties such as nonreciprocal directional dichroism up to unidirectional light propagation in the visible range.

Topological non-Hermitian origin of surface Maxwell and acoustic waves

Konstantin Bliokh
Theoretical Quantum Physics Laboratory - Riken, Japan
*corresponding author, E-mail: k.bliokh@gmail.com

Abstract
More than 60 years ago it was shown that interfaces between isotropic homogeneous optical media (including dielectrics, metals, negative-index materials) can support surface electromagnetic waves, which now play crucial roles in plasmonics, metamaterials, and nano-photonics. I will show that such surface Maxwell waves have a topological origin explained by the bulk-boundary correspondence. Importantly, the topological classification is determined by the photon helicity operator within the Weyl-like representation of Maxwell equations, which is generically non-Hermitian even in lossless optical media. The corresponding topological invariant, which determines the number of surface modes, is a Z4 number (or a pair of Z2 numbers) describing the winding of the complex helicity spectrum across the interface. I will also provide similar considerations and topological explanation of the surface acoustic wave that appears at interfaces between positive- and negative-density acoustic media. Instead of helicity, its properties are described by the effective non-Hermitian four-momentum operator within the Klein-Gordon representation of sound waves, which provides a single Z2 bulk index. Our theory provides a new twist and insights for several areas of wave physics: Maxwell electromagnetism, topological quantum states, non-Hermitian wave physics, and metamaterials.
Can plasmonics help outpace quantum decoherence?

Abstract

Photons are the primary candidates for implementing quantum networks, i.e. systems capable of distributing entanglement and transmit quantum information. Photonic modes must be coupled to matter in order to produce single photons or make them interact. However, naturally the interaction between light and matter is relatively weak, which is one of the reasons why most present photonic quantum technologies suffer from low bit rates. A targeted and strong enhancement of light-matter interaction based on plasmonic nanostructures has a potential to transform the way quantum photonic systems operate. It relies on speeding up processes beyond the rates of dephasing, rather than on achieving long coherence times in matter. We discuss our recent and planned work aimed at outpacing decoherence in quantum optical devices using nanoscale plasmonic metamaterials. We also outline future directions in the development of a platform for high-speed integrated quantum photonics and the application of machine-learning techniques for quantum optical measurements.

Abstract

Recent developments in metasurfaces, including the phenomenon of bound states in the continuum (BIC) have injected a new dynamics into the paradigm of guided mode resonances for sensing and imaging applications. We will discuss and compare the various geometries, both dielectric and plasmonic, introduce our silicon nanohole approach and demonstrate its superiority in terms of surface sensitivity, which is a key metric for label-free optical sensors yet one that is rarely discussed.
Non-Hermiticity in Optics and Optomechanics

Sahin K. Ozdemir

Department of Engineering Science and Mechanics & Materials Research Institute,
The Pennsylvania State University, University Park, PA, 16802, USA

In recent years, there has been a tremendous progress in the theory and experimental implementations of
the concepts rooted in non-Hermitian physics. This progress has led to a host of new intriguing results in
the physics of light–matter interactions with promising potential applications. One of the most notable
property of non-Hermitian systems is the emergence of non-Hermitian degeneracies known as
exceptional points (EPs) where complex eigenvalues and the corresponding eigenstates of the system
coalesce. The presence of an EP affects the system significantly, leading to nontrivial physics with
interesting features. In this talk, after briefly reviewing the related physics and the applications that have
been developed in the past few years, I will present the progress in our experimental and theoretical
studies towards a better understanding of optical processes and optomechanical interactions at EPs for
realizing photonic and phononic devices with novel functionalities. I will also present a brief perspective
on the developments and discuss possible future research directions that can benefit from the notion of
non-Hermitian engineering.

Abstract

We report on a new methodology for identifying the connectivity of a single molecule junction through the combination of surface enhanced Raman scattering and current-voltage response, with the density functional theory simulations. This new methodology discriminates three different atomistic connectivity for the benzenedithiol and aminobenzenethiol in the junctions, and uncovers the transition between different connectivity, which had never been detected. Using this methodology we reveal the changes in the atomistic connectivity as a function of applied voltage and time.

1. Introduction

Single-molecule circuits, in which individual molecules are wired into the circuit and act as the active electronic components, represent the ultimate limit to the miniaturization of electronic devices. Although conceptually simple, this goal has proven elusive. Up until then, charge transport properties of a variety of individual molecules have been investigated using the scanning probe microscopy and break junction techniques. Pioneering studies have demonstrated that unambiguous connection of a single-molecule to electrodes is difficult to confirm and achieve, as shown by large disparities in conductivities reported for identical molecules or similar molecules. On the single-molecule scale, conducting properties are strongly dependent on the atomistic connectivity of individual molecules to the external electrodes. The direct link between the connectivity and the device performance of the junction including the conductivity is very poorly revealed due to numerous experimental challenges. Thus, it is essential to achieve a detailed understanding and elucidation of the single-molecule connectivity at the molecule-electrode interfaces [1-4].

2. Experimental

Single molecule junctions were prepared using MCBJ, which offers high electrode stability and fine-tuning of the electrode spacing. This control is realized by bending a flexible substrate in a three-point bending geometry (Fig. 1). The free standing Au nano bridge (see scanning electron microscopy (SEM) image in Fig. 1) was fabricated on the bending phosphor bronze substrate with the electron beam lithography. Molecules were deposited on the unbroken Au nano bridge using self-assembly from 1mM ABT or BDT ethanol solution. On bending the substrate, the junction was stretched until it broke. The two sides of the broken Au nano bridge then acted as electrodes, the separation of which could be adjusted with picometer resolution using a piezo element. The electric current was monitored under the bias voltage application, Raman spectra from the junction was simultaneously measured with a Raman spectrometer using excitation wave length of 785 nm.

Figure 1: Scheme of a molecular junction under the Raman setup. Near-infrared excitation laser (\(\lambda_{ex} = 785 \text{ nm}\)) is focused by a lens on the molecular junction fabricated on the phosphor bronze substrate. The molecular junction is prepared by bending the Au nano bridge that is covered with molecules.

3. Results and Discussion

The SERS spectra observed in the single molecule junction regime show two distinct Raman bands, which are assigned to a C-S stretching mode (\(\sim 1060 \text{ cm}^{-1}\), \(\nu_{7a}\), and a C-C stretching mode (\(\sim 1560 \text{ cm}^{-1}\), \(\nu_{8a}\)). The appearance of Raman modes characteristic of ABT indicates the presence of ABT molecule in the gap. Dimerization reactions have been reported for ABT molecules on Au nano particles. However, the absence of 1380cm\(^{-1}\) and 1430cm\(^{-1}\) peaks corresponding to the ABT dimer indicates that dimerization reaction does not take place at the junction in the present experimental condition.
Figure 2 shows the two dimensional mapping for ABT of the metal-molecule electronic coupling $\Gamma$ and the Raman shift of the $v_{8a}$ mode for the SERS active samples i.e. samples for which the $v_{8}$ mode displays over 10 counts per second. The value of $\Gamma$ is obtained from fits to $I-V$ curves. In the mapping, we can clearly observe two intense regions corresponding to H and M states for both BDT and ABT. For ABT, the M region extends around $v=1582 \text{ cm}^{-1}$, $\Gamma=0.064 \text{ eV}$, and the H state extends around $v=1580 \text{ cm}^{-1}$, $\Gamma=0.14 \text{ eV}$. The $v_{8a}$ for the conductive H state is lower than for the M state. For comparison, we plot the statistical distribution of $\Gamma$ and $v$. Each distribution can be fitted by two Gaussian functions with different positions of the peaks, indicating the existence of two states with different $\Gamma$ or $v$. However, the two states overlap, and their boundary is not clear. These two states which cannot be separated by either electric coupling or Raman shift alone, can be well distinguished in the combined analysis of SERS and $I-V$ curves.

We calculated the metal-molecule electronic coupling $\Gamma$ and the Raman shift of the $v_{8a}$ mode by the theoretical calculation. The good match between calculation in both conductance, resonance broadening, and frequency trends suggests that the conducting state probed experimentally is the one described in the simulations. Based on these results, we conclude that the H, M and L conductance states relate to bridge, hollow and atop binding sites, respectively.

Having resolved the characterization of molecular adsorption geometry underlying the junction electrical characteristics through simultaneous SERS and $I-V$ characteristics and DFT simulations, we now address the dynamical fluctuations between these sites. We can see the transition from the hollow to bridge, and other way round, through changes in $\Gamma$ and $v$. Here, it is noted that some transitions cannot be detected by electrical or vibrational measurements alone.

Next, we address fluctuations in molecular adsorption site induced by the application of a bias voltage to the single molecule junction. As the bias is increased, the intensity of the bridge region decreases, and hollow regions become intense, indicating an increase in bridge to hollow site transitions.

4. Conclusions

We have demonstrated an adsorption site recognition technique based on an analysis combining SERS and measurements, with the aid of density functional theory calculations. This new methodology distinguishes multiple molecular adsorption sites, and uncovers the origin of conductance fluctuations, which had never been detected experimentally up to now. In the case of ABT and BDT single molecule junctions, electrical conductance can vary by up to a factor 100, a situation that hampers the development of clear, reproducible conductance signatures. The present study unambiguously monitors the changes in molecular adsorption geometry for the first time and demonstrates their significant role on junction conductance fluctuations. Using this new methodology we further monitored the changes in the population of adsorption sites as a function of time and applied voltage.

Hybrid Plasmonic Nanomaterials for Uranyl Detection

Hoa T. Phan¹ and Amanda J. Haes¹,*

¹Department of Chemistry, University of Iowa, Iowa City, Iowa USA
*corresponding author, E-mail: amanda-haes@uiowa.edu

Abstract
Reproducible detection of uranyl, an important biological and environmental contaminant, from complex matrices by surface-enhanced Raman scattering (SERS) is successfully achieved using hybrid plasmonic nanoparticles. Traditionally, non-specific binding of interfering species limits detection of molecules such as uranyl. Herein, this is overcome using materials design and rigorous sample analysis workflow design. Synergistic approaches for uranyl isolation and SERS detection is promising for real-world sample detection and eliminates the need of radioactive tracers and extensive sample pretreatment steps.

1. Introduction
Uranium, a radioactive material with a long half-life, accumulates in the environment in its oxidative form uranyl, which can contaminate soil and water [1]. Importantly, uranyl forms complexes with anions and cations thereby influencing solubility, toxicity, and fate of these heavy metal species. Furthermore, uranyl speciation varies with pH. The resulting complex speciation complicates detection and/or requires significant sample pretreatment. As such, methods that are capable of identifying trace uranyl species in complex samples are needed.

Herein, hybrid plasmonic nanomaterials (Figure 1) and experimental workflow implementation will be used to establish a rigorous protocol for uranyl detection [2,3]. Namely, localized surface plasmon resonance spectroscopy (LSPR), Raman spectroscopy [4], and surface enhanced Raman scattering (SERS) [5,6] serve as label-free and near real-time methods for identifying uranium species in complex aqueous solutions.

2. Experimental Approaches
A straight-forward protocol for spectral analysis will be shown using Raman spectroscopy and aqueous uranium samples. Raman excitation wavelength, pH, and coordinating ions are systematically varied. The spectral analysis results are rigorously validated using uranyl speciation models. Next, plasmonic nanomaterials are used to enhance the Raman signals for trace detection of low (and high) abundant species. Finally, an approach that promotes the reproducible detection of uranyl using SERS will be shown. All in all, the developed protocol provides an accurate and routine analysis of Raman spectra for uranyl species identification and relative abundance elucidation. These advances are expected to provide a straight-forward approach for uranium species identified using hybrid plasmonic nanomaterials.

Figure 1: Hybrid plasmonic nanostructures with tunable sizes, shapes and compositions are shown. Photographs and TEM images (width of each image = 50 nm) are shown. These are Au nanospheres (diameter = 12, 30 nm), Ag@Au nanospheres with 8 nm silver spheres coated with 4, 8, and 12 nm gold shells, Au nanorods with aspect ratios 3 and 5, and gold nanostars with branch lengths of 10, 15, and 20 nm.

3. Results and Discussion
Plasmonic nanomaterials offer many advantages over traditional methodologies in applications ranging from catalysis, sensing, and imaging. Despite these strengths, challenges arise including for both direct and indirect SERS detection of uranyl include nanoparticle stability, SERS spectral complexity, and variations in SERS intensities and vibrational frequencies. All of these challenges depend on intra- and intermolecular interactions at the plasmonic metal interface as well as the plasmonic nanomaterial stability in complex matrices.
Uranyl, unfortunately, exhibits poor affinity to traditional SERS substrates. Methods to promote molecule-metal interactions often lead to nanoparticle instability. Herein, gold nanostars and gold coated silver nanospheres are used. Implications of nanoparticle architecture are investigated for maximizing SERS responses and detectability of uranyl. Nanoparticle architecture and surface potential drive these interactions.

To promote detectability in complex matrices, both polymer and silica surface chemistries will be evaluated to initially “screen” unwanted interfering species for adsorbing to the metal surface while also permitted the adsorption and detection of uranyl for SERS detection.

Finally, solution conditions are used to identify key features that rationally promote uranyl-surface interactions without compromising the physical stability of the nanostructures. Solution composition induces changes in nanoparticle architecture and/or adsorption processes, yet systematic responses are observed. As a result, we expect these studies will broaden the scope of SERS and plasmonic-based assays as small molecules with weak affinity to metal nanostructures will be more readily detected.

4. Conclusions

While uranyl is a difficult molecule to detect in complex matrices, hybrid nanomaterial design and carefully designed experimental approaches facilitate detectability in a reproducible manner. By using polymers and silica hybrid materials, influences from interfering species are minimized and solution impacts reduced. Future advances in further reducing detection limits and integrating these materials with rapid sampling platforms have the potential to lead to a revolutionary sensor for heavy metal detection.

Abstract

A new design for hot-carrier solar cells is discussed in which a conventional semiconductor heterojunction is attached to a plasmonic medium. Our theoretical model indicates the opportunities and limitations of employing plasmonic hot-carriers for solar energy conversion. In addition, applications of plasmonic hot-carriers in photochemistry will also be introduced. The atomistic-scale mechanisms of tunable photochemistry via plasmonic hot-carriers will be discussed.

1. Introduction

Surface plasmon polaritons (SPPs) and localized surface plasmon resonances (LSPRs) are collective oscillations of electrons in conductors excited by electromagnetic modes. Surface plasmons result in concentration of light in the near-field around the particle interfaces, which enables efficient spatial control of charge and energy fluxes in a variety of applications. However, surface plasmons suffer from significant dissipation, with most of the plasmon’s energy loss due to Landau damping leading to hot electron-hole (e-h) pairs. Several recent efforts have proposed the possible extraction of these energetic carriers before dissipation takes place, which has simulated the application of hot carriers to several branches of applied physics, chemistry, and materials and energy sciences [1].

2. Plasmonic hot-carriers for solar energy conversion

In this work, we explore the opportunities and limitations for making plasmonic solar cells, here considering a design for hot-carrier solar cells in which a conventional semiconductor heterojunction is attached to a plasmonic medium such as arrays of gold nanoparticles. The underlying mechanisms and fundamental limitations of this cell are studied using nonequilibrium Green’s function method [2]. The numerical results indicate that this cell can significantly improve the absorption of solar radiation with energy lower than the gap (Fig. 1b) without reducing open-circuit voltage, as photons can be absorbed to produce mobile carriers in the semiconductor as long as they have energy larger than the Schottky barrier rather than above the bandgap. However, a significant fraction of the hot-carriers have energies below the Schottky barrier, which makes the cell suffer low internal quantum efficiency (Fig. 1d). Moreover, quantum efficiency is also limited by hot-carrier relaxation and metal-semiconductor coupling. The connection of these results to recent experiments is described, showing why plasmonic solar cells can have less than 1% efficiency.

3. Plasmonic hot-carrier-mediated tunable photochemistry

Even though our recent theoretical studies have shown that extracting hot carriers for solar energy conversion suffers from fundamental limitations [2], the opportunities for using plasmonic hot-carrier extraction to drive photochemistry are less-well known. In this work, we demonstrate the principles of plasmonic enhancement and control of chemical reactions by considering the photoinduced dissociation...
of an adsorbed molecule on a plasmonic nanoparticle and plasmonic dimer [3]. Non-adiabatic molecular dynamics were performed to model the bond dynamics of H$_2$ adsorbed on the surface of metallic nanoparticle (NP) with the NP treated in the Jellium approximation.

We start by examining the electronic structure of H$_2$ adsorbed on the NP. The bonding and anti-bonding (AB) state of the H$_2$ are 8.05 eV below and 1.48 eV above the Fermi energy. Because of the gap between the bonding and AB states of H$_2$, 9.53 eV, is much larger than the energy of a visible light quantum, no chemical reaction can be induced in the visible regime. However, in the coupled system, the AB state is only 1.48 eV above the Fermi level. Numerical simulations confirm that the hot-electrons generated in the metallic NP can indeed transfer to the AB state of H$_2$ and drive the H$_2$ dissociation.

In practical applications, an assembly of NPs is usually employed allowing for the formation of dimers and other aggregates that have more significant optical properties [4]. Thus, it is natural to consider if the stronger field-enhancement can facilitate H$_2$ dissociation. Consequently, we calculated H$_2$ dissociation in the plasmonic dimer for different geometrical configurations. As an example, we consider the H$_2$ molecule placed between the NPs shown in Figure 2(a). $D$ is fixed at 1.59 Å and $d$ is taken as a variable. The time evolution of H-H bond lengths for different $d$ is plotted in Figure 2(b-e). When $d=D=1.59$ Å, the H$_2$ is placed precisely in the center of the plasmonic dimer, with the stronger field-enhancement compared to larger values of $d$. However, no matter what the excitation energy is, the H-H bond never breaks as shown by the green curves in Figure 2. Our simulations further demonstrate that tuning the $d$ can affect the dynamics significantly. As shown in Figure 2, the H$_2$ starts to dissociate for some excitation frequencies when $d$ reaches 5.82 Å. An even larger distance $d$ more strongly favors dissociation of the H-H bond. These results demonstrate that chemical reaction can either be suppressed or enhanced by the plasmonic dimer depending on the relative position of the molecule between the dimer. Thus, hot-carrier mediated dissociation can be tuned by controlling the location of the molecule in the gap. We have further examined the charge dynamics of the H$_2$ molecule in the dimer. Overall we see that hot-carriers transferred from one NP to the H$_2$ will undergo another charge transfer to the other NP before H$_2$ dissociation can develop when $d=1.59$ Å. With increasing $d$, the charge loss from the H$_2$ molecule to the right NP is suppressed. At a certain distance, the charge accumulation on H$_2$ can be large enough to induce bond dissociation.

4. Conclusions

In summary, we have demonstrated the opportunities and limitations of extracting hot-carriers for solar energy conversion. In addition, we have performed TDDFT and NAMD calculations which enable us to directly look at the dynamic process of H$_2$ dissociation on the surface of a metallic NP. Our results illustrate the mechanism of plasmon-induced H$_2$ dissociation at the atomic scale and identify how hot-carriers can be transferred from a NP to the adsorbed molecule to drive photochemistry. Our results also demonstrate that the photochemistry can be tunable in the case of a plasmonic dimer.

Abstract
An efficient methodology based on scanning probe lithography technique to design complex metallic nanostructures on rigid or flexible substrates will be presented. Our results show that this methodology opens up new possibilities of applications for which an individual control of the height, shape, and periodicity of each printed nano(micro)structure is necessary. As the ability to control the 3D arrangement of gold nanostructures is of prior interest for plasmonics and surface-enhanced optical techniques we explored the potential of the substrate for biosensing and in particular for SERS measurements.

1. Introduction
Today, it remains difficult to detect, identify and quantify different analytes in complex mixtures and it is even more challenging if the pollutants are highly diluted. Among various analytical techniques, surface-enhanced Raman scattering (SERS) is among the most promising methods in detecting trace molecules due to its high molecular specificity (i.e., differentiation via molecular fingerprint characteristics) and high sensitivity thanks to the strong local field enhancements (« hot spots ») that can exist (under certain conditions) in the near-field region of nanostructured metallic surfaces.

2. Results
Recently we developed a new methodology for elaborating nanostructured metal supports based on soft lithography using an atomic force microscope as a tool of nanostructuration [1]. This original and patented [2] method allows on the same substrate to design different 3D architectures at the nanoscale (Figure 1). The discriminating advantage with respect to commercial substrates is the control and reproducibility of the patterns characterized by specific localized surface plasmon resonances which facilitates multi-wavelength analyses.

Figure 1: a) 3D AFM image of arrays of periodic gold nanostructures. b) The height profiles exhibit the different distances between the nanostructures.

Photoemission electron microscopy (PEEM) constitutes an alternative tool to investigate the optical near field at the nanometer scale. Indeed, Douillard et al. [3-5] show a direct evidence of the link between a localized surface plasmon excitation of metal nanoparticles and its electron emission counterpart as measured by PEEM. When the incident photons are resonant with the surface plasmon frequency the local field enhancement leads to an increase of the photoemission yield. Therefore, by collecting the photo-emitted electrons on the nanostructured gold pattern under illumination, PEEM allowed to reveal the distribution of the near-optical field at nanoscale in the visible and near-infrared ranges (400–900 nm) (Figure 2). The samples were illuminated by a femtosecond pulsed laser (Ti:sapphire ultrafast oscillator Chameleon Ultra II, Coherent Inc., repetition rate 80 MHz, hyperbolic-secant-squared pulse, pulse width 140 ± 20 fs). In PEEM-imaging mode, the measured brightness in a given
image area is proportional to the electron emission flux from this area. The spectral dependency observed in PEEM intensity was confirmed by calculating (using COMSOL Multiphysics) the local field enhancement of patterned arrays for different distances between nanostructures.

![Figure 2](image-url)

Figure 2: Calculated local field enhancement factor for a nanostructure as function of wavelength and experimental two-dimensional photoemission electron intensity maps (top)

Then, we showed that by tuning the geometrical parameters of the arrays at nanoscale we can modulate the SERS efficiently (Figure 3). This work was carried out on nanostructures with the same shape and the same size but with three different distances between them. A 785 nm excitation line was used to measure Raman spectra after immersion of the substrate in a $10^{-6}$ M solution of thiophenol.

The experimental phenomenon was confirmed by calculating the local field enhancement of arrays for different distances between nanostructures. The simulation made from a nanostructured profile, extracted from AFM images, shows the enhancement of the local field between gold nanoparticles and the effect of distance between structures.

![Figure 3](image-url)

Figure 3: a) Raman spectra of thiophenol recorded on three different nanostructures and smooth surface (black spectrum), b) Calculated local field enhancement as a function of spacing between nanostructures.

Works are in progress to detect and identify pesticides commonly found in water and emerging pollutants and we are focusing in particular on verifying the reproducibility, linearity and limit of detection of diluted multi-component solutions.

Materials for Photonics Beyond Noble Metals

Marina S. Leite

Department of Materials Science and Engineering, Institute for Research in Electronics and Applied Physics, University of Maryland, College Park, USA
*corresponding author, E-mail: mleite@umd.edu

Abstract

In this talk I will present how metallic materials beyond coinage metals have enabled us achieve materials with on demand optical responses ranging from the Vis to NIR. First, I will discuss the opportunities for developing optical components using metallic materials beyond noble metals for energy harvesting and superabsorption applications. Second, I will demonstrate a novel platform for transient, dynamic photonics based uniquely on earth-abundant materials: Mg and MgO.

1. Introduction

To date, different classes of materials have been explored for photonic applications, including metals, ceramics, intermetallics, semiconductors, and metallic alloys. Depending on the desired wavelength range of operation one of the abovementioned systems might be more suitable than others. There is still a pressing need for finding a material that with tailored optical response in the UV-NIR range of the electromagnetic spectrum. Despite all the work accomplished to date using noble metals, their predetermined permittivities and lack of CMOS compatibility currently limit their use in photonic devices.

2. Results and Discussion

2.1. Metal Alloys

We demonstrate how alloyed metals (Ag, Au, Cu, Al) enable optical materials with responses not achievable by its pure counterparts and, therefore, with superior performance. First, we build a library of their permittivity by mapping $\varepsilon$ as a function of chemical composition for a series of thin films formed by the binary combination of Ag, Au, Cu and Al. We combine transmission and reflection measurements using a B-spline model to resolve both $\varepsilon_1$ and $\varepsilon_2$ [1]. To corroborate the $\varepsilon_1$ measurements we compare the obtained values with SPP experiments using the Krechtmann configuration, and find an excellent agreement between the two independent methods.

For the Ag-Au model system, we resolve the alloys’ $d$ intraband electronic transitions by calculating their band structure through DFT. Our calculations are combined with XPS measurements of the valence band spectra and with transmission measurements of the Ag$_{60}$Au$_{40}$ thin films [2]. We identify the individual contribution of each metal, Ag and Au, to the band structure of the alloys, never resolved before.

Concerning alloyed nanostructures, we developed a scalable approach to obtain fully alloyed AgAu nanoparticles. For that, we expand the thin film deposition + annealing method, which provides a platform for lithography-free nanoscale building blocks. We characterize the optical response of these nanostructures by spectrally dependent near-field scanning optical microscopy (NSOM) – see Figure 1. We spatially resolve the ‘hot-spots’ of these nanoparticles: for Ag$_{60}$Au$_{40}$ we find a substantial local field enhancement at 600 nm, just underneath the nanostructures. Our experimental results are in very good agreement with 3D full-field simulations [2].

Figure 1: (a) NSOM measurement and (b) FDTD calculation for Ag$_{60}$Au$_{40}$ nanoparticle at 600 nm. (c) Field profile for the same nanoparticle showing ‘hot spots’ at 600 nm.

While Ag and Au represent an ideal model system to investigate the effect of alloying on the material’s optical
response, these noble metals are not CMOS-compatible and are high cost. Thus, we overcome these contrains by exploring the combination of earthabundament metals, such as Al and Cu. In particular, this combination is excellent for superabsorption. We numerically demnstrate the superior performance of thin film AlCu as the metallic layer of planar superabsorbers [4]. AlCu outperforms other metals commonly used in photonics, e.g. Ag, Au, and Cr. Si/AlCu shows >99% omnidirectional absorption across the Vis and NIR, as presented in Figure 2. The tunability of the high absorption peak primarily depends on the thickness of the semiconductor film. We validate our calculations by fabricating and testing this potentially CMOS–compatible system.

Figure 2: Near-unity (> 99%) absorption for (d nm) Si / 100 nm AlCu lithography-free, thin film superabsorber.

2.2. Earth-Abundant Metals

Reconfigurable photonic devices that can change in functionality can transform the design of next-generation optical devices such as modulators, sensors, and signal processors. We present the notion of transient photonic devices based on Mg, where we demonstrate color pixels formed by Mg/MgO/Mg thin films. Vivid colors ranging from blue to burgundy is obtained by varying the thickness of the dielectric spacer. The pixels vanish in hue in less than 10 minutes due to the dissolution of both Mg and MgO in water, at room temperature and neutral pH, as shown in Figure 3 [5]. We will also present transient devices based on Mg nanostructures.

Figure 3: (Top) Schematic of MIM structure for color pixels. (Bottom) Photographs of color pixels as a function of etching time in water, showing transiency.

Moreover, we have shown the near-unity (> 99%) absorption of thin-film formed Si/AlCu stacks. To elucidate how the optical behavior of the metal alloys differs from the linear combination of their pure counterparts we calculate their band structure by DFT, and identify the individual contribution of each metal.

3. Conclusions

In summary, metal alloys have recently emerged as an alternative material for photonics due to its tailored, on demand optical properties. We demonstrated that permittivity values not achievable by noble metals can be obtained by the binary mixture of Au, Ag, Cu, and Al.

**Abstract**

We demonstrate that prestructured metal nanogaps can be shaped on-chip to below 10 nm by femtosecond laser ablation (Figure 1 and [1]). We explore the plasmonic properties and the nonlinear photocurrent characteristics of such formed tunnel junctions. The photocurrent can be tuned from multiphoton absorption toward the laser-induced strong-field tunneling regime in the nanogaps, and gives rise to a field emission of ballistic hot electrons propagating across the nanoscale junctions. We demonstrate that a unipolar current of hot electrons is achieved by designing the plasmonic enhancement factors in the junctions to be asymmetric, which allows ultrafast electronics on the nanometer scale.

We particularly demonstrate that femtosecond optical pulses in the near-infrared (NIR) applied to such nanogaps can drive electronic circuits with a bandwidth of up to 10 THz [2]. The corresponding THz transients propagate on-chip in stripline circuits on a macroscopic, millimeter scale [3]. We discuss the effective diffraction index and attenuation of coplanar stripline circuits with microscale lateral dimensions on various substrates including sapphire, GaN, silica glass, and diamond grown by chemical vapor deposition. We show how to include dielectric, radiative and ohmic losses to describe the pulse propagation in the striplines to allow femtosecond on-chip electronics with frequency components up to 10 THz [4].

Moreover, we apply a similar THz time-domain spectroscopy to detect the electron dynamics in nanoscale materials [5]. In particular, we access the ballistic time-of-flight of photogenerated charge carriers in carbon nanotubes, as well as non-equilibrium thermo-electric currents, ultrafast lifetime limited currents, and non-radiative energy transfer processes in 2D materials [5-9].

Our results combine the advantages of ultrafast femtosecond optics with on-chip plasmonics to enable ultrafast nanoscale electronics on the way toward femtosecond electronics in waferscale circuits.

Abstract

We report the first experimental observation of a chiroptical effect that was predicted 40 years ago [1,2].

1. Introduction

Chiral nano/metamaterials and surfaces enable striking photonic properties, such as negative refractive index and superchiral light, driving promising applications in novel optical components, nanorobotics, and enhanced chiral molecular interactions with light [3]. In characterizing chirality, although nonlinear chiroptical techniques are typically much more sensitive than their linear optical counterparts, separating true chirality from anisotropy is a major challenge [4,5].

Optical Second Harmonic Generation (SHG) is a nonlinear optical effect whereby two photons at the fundamental frequency of light are converted into a single photon at the double frequency. Like all nonlinear optical effects, SHG scales as a power law of the fundamental electromagnetic field, which makes it very sensitive to near-field enhancements. However, among the nonlinear effects, SHG holds a special place; because it is the first term in the nonlinear optical expansion, it is often the largest nonlinear optical effect. Moreover, contrary to third harmonic generation for instance, SHG is forbidden in centrosymmetric materials (within the dipole approximation). As a consequence, SHG is exquisitely sensitive to symmetry breaking, such as the one caused by chirality.

2. Results

Here, we report the first observation of optical activity in second harmonic hyper-Rayleigh scattering (HRS). We demonstrate the effect in a 3D isotropic suspension of Ag nanohelices in water, see Fig. 1. The effect is 5 orders of magnitude stronger than linear optical activity and is well-pronounced above the multiphoton luminescence background.

Figure 1: Schematic diagram of the HRS OA effect upon illumination with left circularly polarized (LCP) and right circularly polarized light (RCP).

3. Conclusions

Because of its sensitivity, isotropic environment, and straightforward experimental geometry, HRS optical activity constitutes a fundamental experimental breakthrough in chiral photonics, for media including nano/metamaterials and chemical molecules.

Abstract

Periodic nanoripple patterns produced by ion-beam sputtering of dielectric surfaces (Si₃N₄ or Al₂O₃) are used as templates to elaborate self-aligned nanoparticles and nanowires arrays by deposition at glancing-angle of aluminum and refractory conducting nitrides (TiN, ZrN). From experimental and numerical investigations of their far-field and near-field optical properties, we will show that these alternative materials for plasmonics devices exhibit original dichroic properties.

1. Introduction

For the beginnings of plasmonics, most of the studies were focused on gold and silver nanoparticles because of their favorable bulk dielectric properties in the visible and near infrared (NIR) spectral range. However, gold and silver suffer from limitations such as low abundance on Earth, high cost, optical losses in the ultraviolet (UV) range due to interband transitions, as well as poor processing compatibility with silicon nanofabrication techniques and thermal instabilities. Hence, alternative plasmonic materials have received ever-growing attention these last years [1,2]. Among the most commonly suggested materials, aluminum [3] and transition metal nitride [4,5] nanostructures are currently at the focus of numerous studies and are suggested as a promising alternative for light absorption and near-field enhancement from UV (Al) to the visible and NIR (TiN, ZrN). However, until now, technical challenges make it difficult to achieve the production of such nanostructures over large areas with controlled morphology and composition. In this work, we present a two-step process for the formation of self-assembled non-noble metal nanostructures with substantial dichroic substantial plasmonic response. It is based on exploiting the shadowing effects during the glancing angle deposition (GLAD) of metallic species on pre-patterned rippled substrate.

2. Results

The first step of the elaboration process is the patterning of a dielectric buffer layer (silicon nitride or alumina films) by ion erosion with a collimated 1 keV Xe⁺-ion beam at oblique incidence to form periodic ripples [6,7] (Fig.1). The second step is the GLAD of Al, or TiN or ZrN on the rippled surface that enables the growth of self-assembled and well-aligned nanostructures along the ripples. For the GLAD two versions of sputter-deposition are used: ion beam sputtering for Al and magnetron sputtering for TiN and ZrN. For some samples, after deposition of the metal and prior to exposure to the atmosphere, the nanostructures are covered with a dielectric capping-layer. The nanostructures are deposited onto flat silicon and NaCl single crystal for structural characterizations with Atomic Force Microscopy (AFM) and Transmission Electron Microscopy (TEM) respectively, and onto fused silica substrate for absorbance measurements.

Figure 1: AFM topographic image of amorphous Al₂O₃ thin film deposited on Si after 1 keV Xe⁺-ion exposure

We will show that the elaboration process used with the pair (Al, Si₃N₄) leads to the formation of flat aluminum nanoparticles array with a core@shell Al@AlN structure (Figure 2a). The nanostructure exhibits surface plasmon resonances whose spectral positions depend on the polarization of the electric field with respect to the particles chains, as revealed by absorbance measurements (Figure 2b). Near-field calculations, performed using finite-difference time domain method, highlight the overlap...
between the surface plasmon resonance of the nanoparticles and the interband transitions of aluminum.

Figure 2: (a) Energy Filtered Transmission electron microscopy (EF-TEM) and (b) absorption spectra of Al nanoparticles embedded in silicon nitride.

ZrN and TiN nanostructures on rippled alumina surface in the form of nanowires arrays also exhibit polarization dependent absorbance spectra. As shown in Figure 3, the spectral position of transverse resonance of ZrN nanostructure takes place in the UV range and can be shifted in the visible region by covering the nanowires with a silicon nitride film (Figure 3).

Figure 3: Absorbance spectra of ZrN nanowires on rippled alumina buffer layer deposited onto fused silica substrate, as deposited (red) and after capping with a silicon nitride thin film (blue).

Abstract

In this invited talk, I will review our recent results on complex photonics materials created by warped spaces with application in energy harvesting, structural coloration, bio-imaging and broadband light control in nanoscale structures.

1. Introduction

Traditionally, photonics materials are assembled by carefully engineering dispersive properties of semiconductors, dielectrics or metallic structures. Recently, we demonstrated that it is possible to engineer materials with arbitrary complex responses by using suitably defined geometrical defamations and space warping. These structures opened new important applications in a variety of areas, ranging from energy harvesting to bio imaging. In Energy harvesting, photocatalytic conversion of solar energy to chemical fuels or feedstock is considered as an attractive strategy to solve the increasing demand of renewable energy sources. Typically, in a solar-conversion-system, semiconductors serve as photoactive materials, which capture, absorb and then transfer photo-excited electrons to catalytic sites to enable proton reduction reaction [1-3]. Direct photo-excitation of metal has emerged in recent years as a new promising strategy applied in photochemistry. Plasmonics is capable to provide the ultimate spatial and temporal manipulation over light and photo-derived chemical reactions, with help of an exquisitely designed metallic nanostructure network can efficiently enclose electromagnetic irradiation within a nanometric region. Surface plasmons, that charge-density oscillation, consequently are excited at the metallic surface and decay by photons reemission or through the creation of energetic electrons and holes. These photo-excited energetic carriers can be leveraged to trigger efficient photo-derived fuels and chemicals production, such as hydrogen evolution [4].

In this talk, I will illustrate a new efficient Photocatalysis in a material based on 3D multi-scale epsilon-near-zero (ENZ) nanostructures created by tree-like warped metallic geometries. This structure [5] achieves a hydrogen production rate of 9.5-μmol h⁻¹ cm⁻² that exceeds, by a factor of 3.2 that of the best previously reported plasmonic-based photocatalysts for the dissociation of H₂ with 50 h stable operation.

Tunable Shape-controlled Plasmonic Nanoparticles Superlattices for Surface-enhanced Raman Scattering Applications

Xing Yi Ling
Chemistry and Biological Chemistry Division, School of Physical and Mathematical Sciences, Nanyang Technological University, Singapore 637371

*corresponding author, E-mail: xyling@ntu.edu.sg

Abstract

A major challenge in nanoparticle self-assembly is programming the large-area organization of a single type of anisotropic nanoparticle into distinct superlattices with tunable packing efficiencies. In this talk, I will discuss how nanoscale surface chemistry is used to direct the self-assembly of shape-controlled silver nanoparticles into three distinct two-dimensional plasmonic superlattices at a liquid/liquid interface. Systematically tuning the surface chemistry of the silver nanoparticles leads to a continuous superlattice structural evolution, from close-packed to progressively open structures. Notably, silver octahedra standing on vertices arranged in a square lattice is observed using hydrophobic particles. The structure-to-function characterization reveals that the nanoparticle assembly with the least packing density generates plasmonic ‘hotstrips’, leading to nearly 10-fold more efficient surface-enhanced Raman scattering compared with the other more densely packed configurations.
Interface Design for Visible-Light Induced Photochemical Reactions Promoted by Refractory Transition Metal Nitride Nanoparticles Incorporated into TiO$_2$ Matrix

Abstract

Plasmonic nanoparticle (NP)-semiconductor interface plays crucial role in photocatalysis, in particular for separation of photo-generated carriers. Here, we explore two strategies to improve charge separation at the refractory transition metal nitride NP/TiO$_2$ interface: creating a Schottky barrier between the NP and TiO$_2$ by decorating the TiN core with a gold shell and application of an electric field at a ZrN NP/TiO$_2$ interface. Photoelectrochemical methanol oxidation is used to probe both interfaces under visible excitation. Computational analysis supports experimental observations.

1. Introduction

Refractory transition metal nitrides (RTMNs) such as TiN and ZrN are an emerging class of materials that have potential for harvesting energy of visible light for photocatalysis [1]. TiN and ZrN NPs can absorb efficiently at 450-1200 nm wavelengths, covering most of the solar spectrum. Their broad localized surface plasmon resonance (LSPR) indicates damped plasmons; this in contrast to conventional plasmonic materials, such as Au, Ag, Cu and Al [2]. Photo-excited carriers in TiN and ZrN can be generated both by intraband and interband transitions. Because plasmonic resonances of TiN and ZrN NP are weak and red-shifted compared to those of Au and Ag, RTMN NPs present a good platform to explore photocatalytic reactions driven by plasmonic carriers generated by interband transitions. Previous research has shown that interband transitions in TiN NPs play a major role in phoetochemical (PE) methanol (CH$_3$OH) oxidation at the interface between TiN and semiconducting TiO$_2$ support [3]. Here, we extend our analysis to the ZrN/TiO$_2$ photocatalyst that offer advantages over TiN/TiO$_2$ due to higher rates of hot carriers generation by ZrN vs TiN NPs [2]. An important feature of the TiN/TiO$_2$ interface is an absence of an electronic barrier between the plasmonic NP and a semiconductor support, which leads to a poor separation of photo-generated carriers. This issue can be addressed either by utilizing (1) a Schottky barrier by decorating the TiN core with a shell of a strongly plasmonic material (such as Au) or (2) a potential bias. Both strategies will be discussed in the presentation.

2. Experimental

2.1. Synthesis and characterization

ZrN NPs were synthesized by ammonolysis of Zr(NMe$_2$)$_4$, and all manipulations were done in a drybox under Ar or on a vacuum line. Clean Zr(NMe$_2$)$_4$ was prepared following a protocol from the literature [4]. A portion of the Zr(NMe$_2$)$_4$ (1.28 g, 4.78 mmol) was dissolved in heptane in a reaction bulb and 21.6 mmol NH$_3$ was condensed into the bulb at 77K. The mixture was stirred at room temperature for one day and then at 80 °C for another day. Solids were isolated by filtration. The solid was loaded into an alumina boat, inserted into a furnace, and heated under NH$_3$ flow first at 250 °C for 15 min, and then at 900 °C for 2.5 h. It was then cooled under N$_2$ flow once temperature dropped to 500 °C. A mostly black powder was isolated. Crystallite size was 11 nm, as determined by XRD. TiN/Au core-shell NPs were synthesized by (1) wet chemistry methods, and (2) hot-electron assisted photodeposition [5]. The wet chemistry method involved in situ generation of an oleilamine – Au (I) complex in heptane, followed by the addition of 20 nm TiN NPs (US Nano Research) and brief sonication. Then the vial was placed on a shaker table and allowed to gently agitate over 7 days. The hot-electron-assisted photodeposition method utilized 550 nm long-pass filtered broadband irradiation of TiN NPs to generate plasmonic hot electrons in the presence of Au (I) complex at a 1:1 ratio. CH$_3$OH was used as a sacrificial reagent to complete the oxidation half reaction. Following the synthesis of ZrN and TiN/Au NPs, they were incorporated into P25 TiO$_2$ matrix by mixing the NPs and TiO$_2$ powders in 50:50 (w/v) H$_2$O: ethanol mixture overnight. The ZrN/TiO$_2$, TiN/Au/TiO$_2$ and bare TiO$_2$ films for PE experiments were prepared as described elsewhere [3]. Experiments were conducted in a three-
electrode PE cell. The photocatalysts films deposited on FTO-coated glass substrates served as working electrodes, while Pt foil and Ag/AgCl in 3 M NaCl (BioLogic, Inc) were used as counter and reference electrodes, respectively.

2.2. Theoretical modelling

For this project, we performed both electromagnetic and quantum calculations. Using COMSOL and DDA, we computed both free-standing and embedded TiN and ZrN NPs. Simulations of NPs (TiN and ZrN) in solution agree with the solution experiments. The NPs embedded into the TiO$_2$ matrix show red shifted LSPRs due to the dielectric screening effect, as expected. Along with the classical electromagnetic calculations, we computed the rates of generation of over-barriers hot electrons using a quantum formalism [6]. Our classical and quantum calculations were used to interpret and understand the optical and PE data from experiments.

3. Results and Discussion

Figure 1 shows experimental extinction spectra of aqueous suspensions of TiN and ZrN NPs. The absorption maximum of ZrN NPs is broader than that of TiN NPs and shifted to the IR region. An increase in absorption below 500 nm is due to interband transitions in TiN and ZrN NPs. Figure 2 demonstrates how the interaction between the TiN/TiO$_2$ photocatalyst and visible light can be utilized for PE CH$_3$OH oxidation. Two important points come across when comparing incident photon to electron efficiencies (IPCEs) for CH$_3$OH oxidation on TiN/TiO$_2$ vs TiO$_2$. First, potential need to be applied in order to initiate CH$_3$OH photooxidation at the TiN/TiO$_2$ interface since it forms Ohmic junction. Second, increase in IPCE, observed for TiN/TiO$_2$ photocatalyst at wavelengths below 650 nm in Fig. 2, correlates with enhancement in optical absorption due to interband transitions in TiN NPs in CH$_3$OH oxidation.

IPCE vs wavelength curves depicted in Fig.2 will be used as a baseline for comparison of ZrN/TiO$_2$ and TiN@Au/TiO$_2$ to TiN/TiO$_2$ material.

4. Conclusions

We have developed novel approaches for synthesis of ZrN and TiN@Au NPs. ZrN NPs establish broader LSPR compared to that of TiN NPs, which makes them more efficient light absorber under the solar illumination and, therefore, holds promise for photocatalytic application. We demonstrate that the efficiency of photocatalytic reactions can be controlled by intelligent interface design.

Structural Alteration of Genomic DNA upon Interaction with Silver Nanoparticles

Luca Guerrini

Departamento de Quimica Fisica e Inorganica, EMaS, Universitat Rovira i Virgili,
Carrer de Marcel$l´ı Domingo s/n, 43007 Tarragona, Spain. E-mail: luca.guerrini@urv.cat

Abstract
The cooperative binding of cationic nanoparticles and duplex nucleic acids can alter the structural properties of the double-helix leading to strand separation. Still, the exact determinants and underlying mechanisms leading to such perturbation remain unclear. Here, we highlights new fundamental insights in this process by tackling the role of key variables, mainly surface charge and size/geometrical arrangement of DNA/nanoparticle clusters.

Introduction
The combination of DNA and nanoparticles has been generating a wealth of research in the field of bionanotechnology resulting in very diverse applications in areas such as biomedicine, sensing, and bioelectronics,[1, 2] These applications mostly exploit chemically modified oligonucleotides to impart unique biochemical properties to the nanomaterials. On the other hand, understanding the interaction of native DNA in its duplex form and nanoparticles has been far less explored, and often contradictory findings are found in the literature. This is most likely associated with the complex variability of the physicochemical properties of the metal-liquid interface that largely define the DNA/nanoparticle binding and the resulting impact on the biomolecular structure.

Surface-enhanced Raman scattering (SERS) spectroscopy profits from the localized-surface plasmon resonances (LSPR) generated by plasmonic nanoparticles to provide highly intensified Raman fingerprinting of molecules located in close proximity to the metallic surface (mainly, Ag or Au). Thus, SERS has the potential to be used as a highly sensitive and informative analytical technique for interrogating the union of genetic materials with plasmonic nanoparticles (NPs).[3, 4]

Nanoparticle surface charge plays a central role in determining the DNA/NPs interaction. In this regard, within the frame of SERS, it has been shown that negatively-charged nanoparticles show a limited affinity towards double-stranded DNA duplexes (dsDNA) as the surface binding typically requires direct interaction with nucleobases, which, in the double-helix, are sterically hindered.[5] Cationic nanoparticles activate, on the other hand, an adhesion route via purely electrostatic binding of the readily accessible phosphate groups. Notably, spermine-coated positively-charged silver nanoparticles (AgSp) has been successfully used as an efficient plasmonic substrate for the acquisition of highly reproducible and intense SERS spectra of DNA duplexes, which translated into multiple applications such as the detection of single-base mismatches and nucleobase lesions,[6, 7] quantification of base composition,[8] differentiation of tumour-related point mutations in K-Ras genes,[9] and, more recently, Trau and coworkers combined this SERS approach with RNA pre-amplification kits to generate target amplicons for prostate cancer (PCa) risk stratification.[10] Herein, we discuss the application of SERS to investigate the structural alteration of DNA duplexes resulting from the electrostatic binding with cationic silver nanoparticles of different ζ potential.

Discussion
AgSp nanoparticles of ca. 22 nm size and ζ potential tuned in the +20 to +40 range were exposed to both short (21 base pairs) and genomic (calf thymus) DNA duplexes (dsDNA21 and ctDNA, respectively). Regardless of the DNA size, intense and well-defined SERS spectra of short and genomic DNAs are obtained, revealing a progressive reshaping of the spectral profile for decreasing colloidal ζ potential and nanoparticle concentration (Fig. 1A). These spectral changes are associated with an increasing extent of base unstacking and unpairing. Among others, we highlight the spectral shifts cytosine+thymine (C/T) ring breathing mode at ca. 785 cm−1 which is informative of a larger degree of duplex separation. Both surface-charge (correlated with the ζ potential) and DNA/NP ratio (which affects the relative distribution of different particle clusters) play key roles in the alteration of the double-helix structure. Monitoring the spectral shifts of the C/T ring breathing at different DNA/NP ratios (fixed ζ potential) reveals minimal structural perturbation at intermediate ratios (Fig. 1B) when particle clustering is maximized. Accordingly, molecular dynamic simulations of model DNA-clusters suggest that size and geometrical architecture of particle clusters contribute at determining the extent of structural stress underwent by the duplex at the gap.[3] Specifically, larger aggregates appear to minimize the structural stress of the interparticle duplexes by favoring a more compact conformation. Subsequently, we fixed the DNA/NP at the
value providing minimal duplex perturbation and progressively varied the ζ potential of the colloids (Fig. 1C). In this case, both short and genomic DNA display a sudden red-shift of the C/T peak position at ζ potential below ca. 32-34 mV. This transition may be associated with the drop in concentration of spermine surface molecules under a critical level below which the reduction of anchoring points for DNA adhesion forces the adsorbed duplexes to significantly alter their local structure to efficiently bind a second nanoparticle.

Conclusions
This study provides new fundamental insights into the interaction of DNA duplexes and cationic nanoparticles. In particular, the key roles of both surface charge and cluster geometrical features on defining the integrity of the double-helix structure upon cooperative binding with nanoparticles have been demonstrated.

Abstract

In this paper, the gold nano-rod (GNR) with silica shell and quantum dots (QDs) adsorbed on the silica surface, i.e. the GNR@SiO2@QD hybrid structures were constructed to investigate the energy transfer between quantum dots. Two plasmon peaks of gold nano-rod are coupled with the emission peaks of donor and acceptor respectively, in fluorescent resonance energy transfer (FRET). The energy transfer efficiency from donor to acceptor is 35.34%, and the fluorescence intensity of acceptor is increased by 2 times.

1. Introduction

Localized surface plasmon has been widely used to enhance fluorescence, increase light absorption efficiency, enhance Raman scattering, and improve FRET efficiency[1, 2]. The FRET has a wide range of applications in the field of biosensors, such as ion detection[3], biomolecular conformations and so on. In addition, FRET has recently demonstrated potential applications in optoelectronic switches, light capture and LEDs[4,5]. When the local surface plasmon (LSP) couple with the FRET system, the energy transfer distance and efficiency can be improved effectively. Many metal nano-particles were used to study the LSP-coupled FRET, such as nano-sphere, nano-rods, nano-platelets and so on. To date, few articles utilize two plasmon peaks of GNR simultaneously. Therefore, it is expected to improve the energy transfer performance that two kinds of local surface plasmon resonance peaks couple with the luminescence peaks of donor and acceptor simultaneously.

In this paper, the transversal surface plasmon resonance (TSPR) peak and longitudinal surface plasmon resonance (LSPR) peak of the GNR couple with the donor and acceptor luminescence peak respectively. And the fluorescence intensity of the quantum dots increased by 15 times. In the meanwhile, the fluorescence enhancement increased from 1.3 times to 2 times. Time-resolved spectroscopy also proved this phenomenon, and the calculated energy transfer efficiency reached 35.34%.

2. Experimental section

GNR was prepared via modified seed growth method [6]. The new prepared GNR was centrifuged three times, and dissolved in a CTAB solution with a proper concentration. After standing at room temperature for more than 2 hours. The pH of the solution was adjusted to 10-11, using a 0.1 M NaOH aqueous solution. Then, adding appropriate tetraethylorthosilicate (TEOS) to the solution.12 hours later, the GNR would be coated with silica, and this structure was called GNR@SiO2. The GNR@SiO2 particles were first centrifuged twice with ethanol, and then centrifuged twice with toluene. Finally these particles were dispersed into 2 mL toluene. 100 μL 1 vol% 3-aminopropyltriethoxysilane (APTES) was added to the solution dropwisely. After stirring for 12 hours, solution was centrifuged twice with toluene and tetrahydrofuran (THF) twice, the solution was dissolved in 2 mL of THF. Then 1-100 μL of aliphatic-amine modified QDs solution was added to the solution. After stirring for 12 hours. The structure GNR@SiO2@QD was completed. The morphology of the particles was carried on transmission electron microscope (TEM, Philips CM200). The extinction spectra of nano-rods were measured by using UV-vis-NIR spectrophotometer (U4100, Hitachi). The photoluminescence and time-resolved photoluminescence were characterized by a multichannel photon counting system (Edinburg Photonics, Livingston, UK).

3. Results and Discussion

Fig.1 is the TEM image of GNR@SiO2 and GNR@SiO2@QD. It illustrates that the gold bar is coated with silica evenly as shown in Fig.1a. The thickness of silica is around 17 nm. After APTES treatment, silica surface has amino groups. In the meanwhile, surface of the QDs are absorbed by fatty amine ligand, so the QDs could adsorb on the surface of GNR@SiO2, via ligand exchange. The Fig.1b shows the structure GNR@SiO2@QD. The small black dots around GNR@SiO2 are QDs. The Fig.1c is the HRTEM image of GNR@SiO2@QD. The lattice of QDs can be seen from this image. Fluorescence of quantum dots coupled to different local surface plasmon resonance of GNRs simultaneously was shown in Fig.2. The brown dotted line is the extinction curve of GNR. The peaks of TSPR (536nm) and LSPR (605nm) overlap with QDs, whose fluorescence peaks are 525nm (QD525) and 605nm (QD605), respectively. The green short line is the fluorescence spectrum of QD525 (donor), and the
fluorescence spectrum of GNR@QD525+ QD605 is pink solid line. Compared GNR@QD525+QD605 and GNR@QD605. The fluorescence intensity of acceptor (QD605) is increased by 2 times. By adjusting the extinction peaks of quantum rods and the emission peaks of quantum dots, the coupling area between the peaks of quantum dots and gold rods is greatly improved. When the LSPR peak and TSPR peak couple with QD525 and QD605 respectively, the donor can deliver more energy to the acceptor. This makes the fluorescence enhancement of the acceptor more obvious.

Compared GNR@QD525+QD605 and GNR@QD605. The fluorescence intensity of acceptor (QD605) is increased by 2 times. By adjusting the extinction peaks of quantum rods and the emission peaks of quantum dots, the coupling area between the peaks of quantum dots and gold rods is greatly improved. When the LSPR peak and TSPR peak couple with QD525 and QD605 respectively, the donor can deliver more energy to the acceptor. This makes the fluorescence enhancement of the acceptor more obvious.

Fig. 3. The lifetime of donors in GNR@QD525+QD605 and GNR@QD525.

Fig. 4. The fluorescence spectrum and fluorescence lifetime of control group.

4. Conclusions

In conclusion, GNR@SiO₂@QD hybrid structures were constructed. When the two kinds of surface plasmon are coupled to two quantum dots with different fluorescence wavelengths, the energy transfer efficiency increases to 35.34% and the fluorescence intensity of acceptor increases 2 times. Taking into account the significant enhancement of energy transfer phenomenon, this structure has a guiding role in the design of energy transfer structures, and is expected to improve the efficiency of light harvesting and LED devices.

Abstract

Plasmonic metamaterials provide sub-wavelength light concentration and consequent localized heating, which holds great potential in the development of solar-thermal technologies. Here, we will present our recent efforts to fabricate large-scale refractory metamaterial films made by cylindrical plasmonic cavities of titanium nitride (TiN) and their use in various thermoplasmatic applications such as decomposition of molecules, synthesis of metal nanoparticles, conformal deposition of inorganic thin films, and steam generation.

1. Introduction

The use of nanostructures sustaining surface plasmons to control heat at the nanoscale, known as thermoplasmonics [1], has recently emerged as a subfield of plasmonics and holds great promises in several solar energy conversion applications including solar-thermophotovoltaics [2,3], fabrication of nanostructures [4], heterogeneous catalysis [5,6], optical trapping [7,8], and steam generation [9–11]. These demonstrations have been limited to nanostructures made of noble metals, which, despite showing outstanding optical properties for plasmonic applications, raise major issues related to their high cost and poor chemical and thermal stability.

In contrast, refractory TiN exhibits high chemical resistance to harsh environments, optical properties similar to Au and it can be utilized as plasmonic material in the visible and near-infrared regions [12–14]. Combining refractory material properties with broad plasmonic resonances, TiN offer a unique solution to material-related limitations in solar-thermal applications, where high temperature durability and/or chemical stability are needed.

Here we present our recent results on sub-wavelength plasmonic TiN nanocavities and their corresponding local heating properties. A new fabrication strategy to achieve broadband plasmonic absorbers will be outlined, while the solar-to-heat conversion efficiency along with examples of large-scale solar-thermal applications in chemistry will be discussed in detail.

2. Results and discussion

We start fabricating TiO2 nanocavities assembled in hexagonal lattice geometry through anodization of a titanium foil. After nitridation in ammonia atmosphere, TiO2 is completely converted to TiN nanocavities with diameter of 80 nm, length of 150 nm, wall thickness of about 20 nm, and period of 100 nm. The resulting TiN nanocavity films show near unity light absorption in the visible and near-infrared wavelength ranges as shown in Figure 1.

Figure 1: Experimental (black line) and simulated (empty blue dots) absorption spectra of TiN nanocavities, along with the normalized irradiance of the AM 1.5G solar spectrum (grey shaded area). The inset shows a schematic representation of the film stack composed by a Ti foil substrate, a TiN thermal layer, and TiN nanocavities.

In this talk, the results on experimental and simulated optical properties will be discussed and it will be shown that
both cavity modes and plasmonic resonances are supported inside the nanocavities. As a result, the plasmonic TiN nanocavity metamaterials are capable of generating intense local heating upon solar illumination. The opto-thermal properties and solar-to-heat conversion efficiency of our thermoplasmonic films will be analyzed, providing possible metamaterial designs to improve the performance of plasmonic TiN nanocavities. Finally, some examples of utilization of large-scale thermoplasmonic TiN films will be illustrated, including decomposition of metal-organic complexes, conformal deposition of ultrathin films, and steam generation.

3. Conclusions

Our results demonstrate the possibility of fabricating large scale refractory plasmonic metamaterials made by plasmonic TiN nanocavities through a simple and scalable strategy. These films provide efficient solar–to–heat energy conversion producing temperatures above 600 ºC under moderate concentrated solar power and can be conveniently utilized as nanofurnaces or nanoreactors to drive chemical processes with attolitre scale precision.

Abstract

The generation in artificial composites of a magnetic response to light comparable in magnitude with the natural electric response, may offer an invaluable control parameter for a fine steering of light at the nanoscale. In many experimental realizations however, the magnetic response of artificial meta-atoms is too weak so that there is a need for new designs with increased magnetic polarizability. Numerical simulations show that geometrical plasmonic nanostructures based on the ideal model of Platonic solids are excellent candidates for the production of strong optical magnetism in the visible range. Inspired by this model, we have recently developed a bottom-up approach to synthesize plasmonic nano-clusters made of a precise number of gold or silver patches around a central silica core. In this talk, we will compare the optical magnetic response of clusters made of twelve gold or silver patches located at the center of the faces of a dodecahedron and the one of disordered plasmonic clusters (“plasmonic raspberries”) of the same size. We will demonstrate that the regular organization of the satellites around the core is more efficient than a random distribution for the generation of a circular current mode. Controlling the uniform separation of the satellites in the regular distribution warrants a better control of the collective electromagnetic coupling which determines the strength of the circular plasmonic currents generating the magnetization.

Figure 1 – Sketch of the plasmonic raspberries (random distribution of the satellites around a dielectric core) and the gold dodecapod clusters (12 satellites symmetrically arranged around the dielectric core made of silica).

Introduction

Metamaterials are ensembles of nanoresonators that exhibit unusual optical properties that are otherwise attainable with natural materials. The first metamaterial was realized by Smith et al. in 1999 who produced a composite medium that had simultaneously negative electric permittivity and magnetic permeability, which constitutes a negative index material. Such a material has only been thought of purely theoretically by Veselago in 1968 and many profound physical implications had been predicted such as the reversal of the Cherenkov radiation. Since then, the metamaterials concept has been used to produce extraordinary devices ranging from invisibility cloaks to hyperlenses that enable imaging beyond the diffraction limit. Today, metamaterials have moved beyond electromagnetic waves and now includes acoustic, mechanical, thermal and seismic waves. When optics are concerned, most metamaterials produced thus far have been fabricated using top-down lithographic approaches which severely limits the total amount of nanoresonators that can be built. As a result, the total surface area that metamaterials typically cover rarely exceeds 100 µm². The bottom-up approach offers a serious alternative to tackle this hurdle, because it allows considering the nanoresonators and the metamaterial separately, in a way that we may refer to as hierarchical self-assembly. Indeed, nanotechnology tackles the problem of synthesizing complex nanoparticles with desired dispersions of the electric and magnetic polarizabilities, while soft matter self-assembly focuses on producing materials made of large volumes of these meta-atoms. Recently, we have proved that we could produced via bottom-up approach a bulk magnetic material exhibiting non-natural values of the magnetic permeability. In this material, the resonators consist of a set of plasmonic nanoparticles evenly, but randomly distributed around a dielectric core nanoparticle (plasmonic raspberries). The ratio of the magnetic to electric dipole scattering cross-section of a single raspberry is about 1/3 and the magnetic permeability of the assembled bulk metamaterial ranges from 0.8 to 1.45 µ0 units. In order to increase the magnetic response of the
metamaterial, we investigate in this work novel morphologies guided by numerical simulations. We show experimentally that a significant increase of the magnetic dipole can be obtained by a well-controlled geometrical organization of twelve plasmonic satellites onto the dielectric core. The highly symmetrical clusters were prepared by a multistep synthetic process from dodecahedral-dimpled silica particles. The details of the synthesis have been recently published. Figure 2 shows typical micrographs of the nano-objects produced in high yield, at the gram scale. The twelve gold satellites are symmetrically arranged around a silica core of 100 nm. The optical response of the golden dodecapods has been measured by a polarization-resolved static light scattering. The ratio of the magnetic to electric scattering is increased by a factor >3 when compared to plasmonic raspberries of the same size with the same amount of gold. These overall results validate the superiority of the dodecapod structure over the distorted distribution of a large number of satellites in the raspberry model. Changing the composition of the satellites toward silver-gold ones allowed to reduce the optical losses and strongly enhances the magnetic response. These new clusters are good candidates for the fabrication of Huyghens’ sources in which the electric and magnetic scattering display equal strength.

Conclusions

The bottom-up approach can be used to elaborate highly regular plasmonic clusters. The regular organization of the satellites around the core is more efficient than a random distribution for the generation of circular current mode. This observation is fully consistent with the initial inspiring models of resonant LC Inductor-capacitor nanocircuits. The bottom-up approach enables cost-effective, large-scale production of such magnetic resonators, hence opening the way to the fabrication of 2D and 3D magnetic metamaterials.

Surface-enhanced resonant Raman scattering and surface-enhanced fluorescence spectra of a strong coupling system between plasmon and molecular exciton

Tamitake Itoh

1 Health Research Institute, National Institute of Advanced Industrial Science and Technology (AIST), Takamatsu, Japan
*corresponding author, E-mail: tamitake-itou@aist.go.jp

Abstract
Surface-enhanced resonant Raman scattering (SERRS) and surface enhanced fluorescence (SEF) from single silver nanoparticle dimers under strong coupling regimes are investigated. Enhancement and quenching factors are derived from the Purcell factors, which are estimated by coupling energies obtained from the spectral changes in plasmon resonance based on a coupling oscillator model. The reproduced SERRS spectral changes are consistent with the experimental ones. The calculated SEF spectral changes reproduce the experimental ones by assuming transitions from ultra-fast SEF to conventional SEF.

1. Introduction
Thanks to the discovery of single-molecule (SM) detection of SERRS by single plasmonic nanoparticle (NP) systems like NP dimer, the electromagnetic (EM) coupling between plasmon resonance and molecular exciton has been investigated to clarify SM SERRS. Such single plasmonic NP systems enable us direct observation of relationships between plasmon resonance and SERRS. The observations have shown that the EM coupling in a field confined by plasmon within several cubic nanometers at junctions of NP dimers, called “hotspots”, facilitates such large enhancement [1]. SERRS hotspots have also revealed unique phenomena, e.g., strong coupling, in which the rates of EM coupling are larger than the dephasing rates of both plasmon resonance and molecular exciton resonance [2], ultra-fast SEF, in which the SEF rates exceed the molecular vibrational decay rates, resulting in emission from vibrationally excited states in the electronically excited state [3]. Various interesting hotspots have also developed to examine such unique phenomena e.g. Ref. 4.

The present EM model should assume strong coupling. Furthermore, the model should also include not only the quenching of fluorescence but also the quenching of resonant Raman scattering by higher-order plasmons. Such improvement in the EM model and experimental examination might enable us to gain deeper insights from experiments.

We develop a coupling oscillator model to treat the strong coupling between a plasmon and a molecular exciton, including its phonon replicas for representing the multi-level system of a molecule. By considering both enhancement and quenching factors due to the higher-order Purcell factors derived from the coupling energies, spectral changes in SERRS is successfully reproduced. In the case of SEF, we can successfully reproduce the spectral changes by assuming the transition from ultra-fast SEF to conventional one.

2. Experimental
The average diameter of the silver NPs was estimated to be 40 nm. The final concentrations of the R6G solutions and NP dispersion were 6.34×10⁹ M and 5.5×10¹¹ M, respectively. These mixed solutions were left for 30 min so that the R6G molecules could be adsorbed onto the NPs and the NPs could aggregate for SERRS activation. After the sample solution (50 μL) was dropped onto a slide glass plate, the drop was sandwiched by a glass plate to immobilize it on the plate. The plate was then set on the stage of an inverted optical microscope. The spectroscopic setup for detecting SERRS and SEF and the plasmon resonance spectra have been presented elsewhere [2].

3. Discussion
The model for evaluating the strong coupling system is developed by modifying a coupled oscillator model [2]. The model uses a Franck–Condon mechanism to yield phonon replicas of the exciton line. Thus, the coupled oscillator is composed of an oscillator representing a plasmon and multiple oscillators representing a molecular exciton and its phonon replicas. From the coupled oscillators one can derive scattering cross-section of the system. We evaluated the temporal spectral changes in plasmon resonance during the loss of SERRS activity using the scattering cross-section spectra. The plasmon resonance spectra exhibit blue shifts by 100–200 meV simultaneously with the disappearing SERRS activity. The origin of SERRS is EM coupling between a plasmon and a molecular exciton. Thus, the simultaneous blue shifts are due to the loss of the coupling energy. Figures 1(a) and 1(b) show the temporal changes in the experimental plasmon resonance spectra and the calculated ones, respectively. The blue shift and
SERRS with SEF spectra of the dimer [6]. The envelopes of the SEF spectra show clearly slow blue shifts; then, SEF finally disappears with rapid blue shifts. We try to reproduce the spectral changes in SERRS with SEF as a function of the coupling energy. Figure 2(b) shows the calculated SERRS and SEF spectra assuming transitions from ultra-fast SEF to conventional SEF with decreasing EM coupling energy [6]. These SERRS and SEF spectra are well reproduced in the experimental results in Fig. 2(a).

4. Conclusions

We analyzed SERRS and SEF under strong coupling conditions. The analysis involved the following: (1) evaluation of coupling energies using a coupled oscillator model, (2) derivation of mode volumes from the energies, (3) estimation of enhancement and quenching factors using the Purcell factors based on the volumes, and (4) reproduction of SERRS and SEF spectra using these factors. The derived factors reproduced the experimental SERRS and SEF spectra by considering ultra-fast SEF.

Abstract
We fabricated periodic diffractive arrays of Al, Ag and Si nanocylinders with the identical design and compared their photoluminescence (PL) outcoupling abilities. We deposited a polymer layer containing rhodamine 6G molecules and observed enhanced PLs from the layers on the arrays. The optical transmission with varied incident angle revealed the excitation the hybrid modes of diffraction and localized surface plasmon resonance in Al and Ag arrays and diffraction and Mie resonance in the Si array. The PL enhancements in the three arrays, which came from outcoupling, were explainable by the spectral and spatial profiles of the hybrid modes.

1. Introduction
An array of nanocylinders can modulate photoluminescence (PL) of emitters via simultaneous excitation of local resonances and light diffractions. Regarding the local resonance, localized surface plasmon resonance (LSPP) has been commonly applied[1, 2], while Mie resonance can be also a candidate. In recent years, there is a trend to change the material for nanophotonics including metamaterials and metasurfaces, from metal to high-refractive-index dielectrics in order to avoid large absorption losses of metal and deactivation of luminescent center due to energy transfer to metal. However, experimental comparison of PL enhancement between plasmonic and non-plasmonic nanocylinder arrays has hardly been verified. In this study, we compared the PL enhancement of the dye molecules by Al, Ag, and Si nanocylinder arrays. As an emitter we selected rhodamine 6G (R6G), which shows a high quantum yield, and designed the array to have a triangle lattice with a periodicity of 460 nm to show a resonance at the emission wavelength of the emitter.

2. Experimental section
2.1. Sample Fabrication
Al nanocylinders arranged in a triangle lattice with a periodicity of 460 nm were fabricated using nanoimprint lithography in combination with reactive ion etching (RIE), as described elsewhere[3]. Ag nanocylinder arrays were fabricated using nanoimprint lithography in combination with an electron cyclotron resonance Ar ion milling. Si nanocylinder arrays were fabricated by the combination of nanoimprint lithography and Si deep etching. The same mold was used so that the designs of the Al, Ag and Si arrays were identical to each other.

A film of polymethylmethacrylate (PMMA) containing 0.8 wt% R6G was spin-coated on the array. The thickness of the film was estimated with a surface stylus profiler (KLA Tencor) to be ca. 600 nm.

2.2. Optical Characterization
Zeroth-order optical transmission spectra were measured as a function of the angle of incidence in. For the measurement, the sample was placed on a rotation stage and white light from a halogen lamp was incident from the backside (substrate side). The zeroth-order optical transmission spectra were obtained by normalizing the transmission of the incident light through the sample to that through the glass substrate.

PL measurements were performed by illuminating the samples with a laser diode (excitation wavelength $\lambda = 460$ nm) at $\theta_{in} = 5^\circ$ from the backside. The PL was measured from the opposite side as a function of the angle from the surface normal $\theta_{em}$ by a fiber-coupled spectrometer (USB4000, Ocean Optics) mounted on a computer-controlled rotation stage, which could be rotated around the excitation spot.

3. Results and Discussion
Figure 1 compares the optical transmissions of the Al, Ag, and Si nanocylinder arrays with PMMA + R6G layer on the top. At $\theta_{in} = 0^\circ$, A dip appears at $\lambda = 460$ nm for the Al nanocylinder array due to LSPPs hybridized to the in-plane diffraction. Angular dispersion of the hybrid mode is largely modulated by the in-plane diffraction, i.e., Rayleigh anomaly, which is represented by dotted lines. Excitation of the hybrid mode is also obvious in the spectra for Ag nanocylinder array (Fig. 1(b)). Because of the less density of free carrier compared to Al, the hybridized mode is slightly redshifted for the Ag case. The transmittance of Si nanocylinder array is much higher and the resonance is sharper compared to those of Al and Ag nanocylinder arrays. The resonances follow the Rayleigh anomaly, indicating the
hybridization between Mie resonance and in-plane diffraction. Figure 2 compares PL enhancement, defined as PL intensity normalized to that from the PMMA with R6G layer on the flat silica substrate. PL enhancement follows the Rayleigh anomaly, indicating the enhancement comes from outcoupling, i.e., the PL generated inside the layer is scattered out into a direction predefined by the lattice pattern and periodicity. Because of the resonance of the LSPPs of Ag is redshifted with respect to that of Al, the PL enhancement occurs at longer wavelengths regions. The PL enhancement for the Si nanocylinder array is much sharper and directional, reflecting a sharper resonance in transmittance.

Figure 1: Optical transmittance of the PMMA layer containing R6G on the (a) Al, (b) Ag, and (c) Si nanocylinder arrays. The insets show top-view SEM images of the arrays with the coordination axes used in this study (scale bar: 500 nm), and the experimental configuration: $\theta_{in}$ is varied to provide momentum in the $x$-direction.

4. Conclusions

We experimentally compared the PL enhancements of the Al, Ag and Si nanocylinder arrays where the light diffraction could be simultaneously excited with LSPP or Mie resonance. PL enhancement occurred in all the arrays; however, it was more directive for the Si nanocylinder array and more omni-directional for the Al and Ag nanocylinder arrays. Outcoupling was the main mechanism of the directional increase of PL intensity for all the nanocylinder arrays.

Figure 2: PL enhancement, defined as the PL intensity of the sample normalized to that of the reference polymer layer without nanocylinder arrays, plotted as a function of the wavelength and angle of emission ($\theta_{em}$) with respect to the surface normal for the (a) Al, (b) Ag, and (c) Si nanocylinder arrays. The inset is a sketch of the experiment.

Nanoplasmonics for Terahertz Light

Luca Razzari

INRS Énergie, Matériaux et Télécommunications, 1650 Blvd Lionel Boulet, J3X 1S2 Varennes (Québec), Canada.

E-mail: razzari@emt.inrs.ca

Abstract: I will give a brief overview of our group activities on the use of plasmonic nanostructures to enhance terahertz radiation matter interaction.

Terahertz (THz) radiation has vast potentialities in characterizing specific features of various elementary excitations, such as phonons, excitons, and magnons. However, its long wavelength (300 µm at 1 THz) severely hinders its interaction with nano-objects, which has limited traditional far-field THz studies to macroscopic ensembles of nano-compounds. To overcome such limitation, during the last years we have explored the use of gold plasmonic nanostructures resonating in the THz frequency range [1,2]. These “antennas” can significantly enhance the THz electric field by confining it on a scale ~ 1000 times smaller than the wavelength. Using properly designed nanocavities made by antennas coupled end-to-end, we have demonstrated nanoantenna-enhanced THz spectroscopy [3], a technique that allowed retrieving the phonon spectral signature of a single layer of semiconductor quantum dots.

We have also shown that the phonon response of selected nanomaterials can be drastically modified inside such plasmonic nanocavities, without the need of any THz illumination, just exploiting the phonon strong coupling with the cavity “vacuum electric field” [4]. Such phonon response modification could open new avenues for altering the energy dissipation mechanism in nanosystems, towards the improvement of nanodevice performance.

In this talk, I will summarize the above results and also show how advanced nanoplasmonic architectures can be exploited in combination with intense THz sources for exploring strong-field physics phenomena in this frequency range.

1. Abstract

In this contribution, we show how it is possible to rigorously predict strain-related phenomena in case of plasmonic systems made of arrangements of metallic nanoparticles immobilized on a flexible elastomeric tape. This insight allows the study of the thermal response of the system and of the heat photogenerated at the nanoscale. Results evidence how the opto-mechanical control of the system depends on external parameters like incident light polarization, nanoparticle inter-distance, and distribution arrangement.

2. Introduction

A noticeable research interest is addressed to materials and methods to control the nanoscale response of resonant nanostructures. The potential for applications in tunable and reconfigurable devices is relevant. Typical approaches promote the interplay between external macroscale stimuli (mechanic, thermal, acoustic, electric, and chemical) and plasmonic systems to achieve nanoscale effects. An interesting case is to consider mechanical strains applied to a flexible substrate to induce plasmonic coupling between neighboring Au nanoparticles. Experiments performed by our group have already demonstrated the validity of the approach. One of the basic tests of materials in mechanics is a tension test, in which a strip or cylinder of the material, with a given length and cross-sectional area, is anchored at one end and subject to an axial load. In elastic regime, a tensile strain in one direction contributes a compressive strain in the other direction, just as stretching a rubber band to make it longer in one direction makes it thinner in the other directions. However, acquiring the information about the amount of local deformation of the involved material is more challenging. This insight can be quite useful if an ensemble of plasmonic subentities (Au nanoparticles) is immobilized on the surface of a flexible material and it is intended to compute the plasmonic response of the single nanoparticle as a result of the interaction with neighboring ones during light excitation. It is worth noting that the load applied at the extremities of the sample is not distributed uniformly along its volume so that the calculation of the overall plasmonic response of the system results quite complicated. Recently, we have considered this problem by exploiting the functionalities of a finite element method (FEM) simulation tool (COMSOL Multiphysics) which offers the possibility to compute the plasmonic response of the sample versus the applied strain and polarization direction of the exciting light. This enables the design and test of an extremely wide variety of possible geometries.

3. Discussion

The flexible substrate considered in experiments and numerical simulations is polydimethylsiloxane (PDMS) while the simplest geometry of AuNPs immobilized on its surface is a square one with 5 x 5 NPs (NP radius \( r = 20 \) nm) periodically distributed with relative distance \( 3r = 60 \) nm (center-to-center) in both \( x \) and \( y \) directions. This inter-particle separation has been chosen to be larger than the limit distance after which the particle-particle coupling can be considered negligible.

*Figure 1.* (left) Numerical cross-section extinction curves of a square geometry of AuNPs when the substrate supporting them is at rest or stretched of few percents (19%). In the inset, the sketch of simulated sample is reported indicating the distribution of the tensile stress along the sample area when identical loads are applied on its extremities; (right) thermal maps of the same sample respectively at rest (up) and under tensile stress (down) indicating the maximum temperature calculated on the sample surface.
In Figure 1, the extinction cross-section curves are reported, calculated for this geometry at rest and under tensile stress, in case of an exciting light with electric field oriented perpendicular to the tensile direction. Obtained results evidence a noticeable red-shift (about 5nm) of the localized plasmon resonance (LPR) wavelength deriving from the approaching of particles along the direction perpendicular to the stretching that gives rise to plasmonic coupling. This coupling has a direct consequence on the thermal response of the particles cluster [8-10] that has been calculated with the same simulation and reported in the inset of Figure 1. Indeed, the thermal maps of the sample at rest and under stretching show a noticeable difference in terms of photogenerated heat ($\Delta T=1.77\times10^{-10}$C).

The AuNPs belonging to the second considered ensemble are distributed in a radial, centro-symmetric, fashion as represented in the inset of Figure 2. Extinction cross-section curves and thermal maps of this particles configuration are reported in the same figure.

![Figure 2](image)

Figure 2. (left) Numerical cross-section extinction curves of a radial geometry of AuNPs when the substrate supporting them is at rest or stretched of few percents (19%). In the inset, the sketch of the simulated sample is reported indicating the distribution of the tensile stress along the sample area when identical loads are applied on its extremities; (right) thermal maps of the same sample respectively at rest (up) and under tensile stress (down) indicating the maximum temperature calculated on the sample surface.

In this case, upon tensile stress, the different particles distribution undergoes a sensitive overall displacement resulting in the formation of strongly coupled “chains” of particles. This is confirmed by the much larger redshift of the LPR wavelength (about 20nm). The calculated thermal behavior shows in this case an absolute maximum temperature value that is slightly smaller than the one observed in case of the square geometry. However, the photoheated area is now more confined suggesting a possible utilization of this geometry for precision temperature-dependent applications. Indeed, a suitable design of the particle configuration can be beneficial for realizing specific thermo-plasmonic functionalities. In more detail, a large area distribution of particles could eventually realize the presence of specific hot-spots with gradients of temperature able to drive complex multi-stage biological reactions.

4. Conclusions

In this communication, we have numerically investigated the plasmonic behavior of different AuNPs arrangements under an externally applied tensile stress. Upon excitation with linearly polarized light, the first geometry (square) reveals a strain-dependent plasmonic field enhancement that is mainly due to the AuNP coupling. This results in an increase of the extinction cross section amplitude with respect to the rest condition. This amplitude value can be changed by acting on the stretching percentage value. The thermal response of the plasmonic system is noticeable and reproduces the symmetry of the particles configuration. As an alternative to the square geometry, a radial one has been proposed showing a larger red-shift of the extinction cross-section curve under stretching with respect to the rest case. In terms of thermal response, there is a consistent advantage with respect to the square geometry for the possibility to concentrate the photogenerated heat in a smaller area. This result opens the way towards implementation of this concept to smart bio-chips where the efficiency of a biological reaction can be finely controlled through utilization of mechanical actions.

Synthesis of AgCl Nanoparticles and Their Plasmonic Replicas as Photocatalysts and SERS Probes

Han-Jung Ryu¹, Jang Ho Joo¹, and Jae-Seung Lee¹*

¹Department of Materials Science and Engineering, Korea University, Seoul, Korea
*corresponding author, E-mail: jslee79@korea.ac.kr

Abstract
We reported a rapid one-pot room-temperature aqueous synthesis of highly monodisperse sub-100-nm AgCl nanomaterials with various shapes and sizes. We successfully reduced the size of the AgCl nanomaterials which were replicated into metallic nanomesh structures that were small enough (~100 nm) to show intense surface-plasmon-absorption bands. The complex comprising semiconducting AgCl/metallic nanomesh replica exhibited excellent plasmonic photocatalysis properties for the complete removal of Cr(IV), and intense surface-enhanced Raman scattering (SERS) properties in a single-particle enhancing the electromagnetic field.

1. Introduction
The template-assisted growth method is one of the powerful, universal, and efficient strategies to synthesize noble metal nanostructures, because the shape and size of the nanostructures can be easily regulated by controlling the structural properties of the templates. Therefore, the morphology control of the templates and their replication into the metallic structures without deformation are the key factors to accurately design and synthesize the nanostructures with various shapes and sizes. AgCl nanomaterials are emerging as intact templates that are not associated with the galvanic replacement because they cannot be oxidized by the aforementioned replica precursors. Moreover, AgCl is one of the most promising materials for electrochemical and photocatalytic applications owing to their physicochemical properties. In particular, nano-sized AgCl is typically used in combination with Ag for outstanding photocatalysis under visible-light irradiation. However, AgCl nanostructures have been rarely used as building blocks or templates for synthesis, specifically compared to their metallic analog, AgNCs. This limited use of AgCl is attributed to insufficient studies to control the AgCl morphologies. In this work, we present a strategy for synthesizing sub-100-nm monodisperse AgCl nanostructures with elaborate controls of their shapes and sizes in aqueous media. Furthermore, we successfully synthesized replicated metallic nanostructures based on AgCl nanomaterials as templates and completely regulated the morphological properties of the final structures through the chemical control of AgCl nanotemplates and their surfaces. The detailed synthetic mechanism was investigated.

2. Results and Discussion
2.1. Synthesis of AgCl nanocubes
We successfully and easily controlled the size of AgCl nanocubes (AgCINC) by changing the mole ratio of AgNO₃ to HAuCl₄ (Figure 1). When the mole ratio was 11:1 (AgNO₃:HAuCl₄), the synthesized AgClNCs had sharp edges whose length was 210 nm on average (Figure 1a).
the mole ratio changed to 2:1, the highly monodisperse smaller AgClNCs with an edge length of 100 nm were obtained (Figure 1b). When the mole ratio further changed to 1:1, AgClNCs with a much smaller edge length (~80 nm) were observed (Figure 1c). Finally, the truncated and tiny AgClNCs (50 nm in size) were prepared at the mole ratio of 1:2 (Figure 1d). As the mole ratio of Ag\(^+\) to Cl\(^-\) decreased, the edge length of the products also decreased with narrower size distributions (Figure 1e). To the best of our knowledge, this work is the first demonstration of systematic size control of AgClNCs in aqueous media at room temperature. The results were similar to those previously obtained in organic media at much higher temperatures (>100 °C).

### 2.2. Metallic replica nanomesh structures

The mesh structures in the panels of Au/Ag cubic meshes (AuAgCMs) and Au/Ag spherical meshes (AuAgSMs) were further investigated in detail using the elemental mapping technique. In Figure 2, the distribution of the gold almost overlapped with that of the silver, indicating both metals were evenly distributed in the AuAgCMs and AuAgSMs.

![Figure 2](image)

**Figure 2.** (a) and (c) EDS elemental mapping images and scanning TEM (STEM) images of the AuAgCMs and the AuAgSMs, respectively. (b) and (d) Highly magnified EDS and STEM images of the AuAgCMs and the AuAgSMs, respectively. Au is shown in green and Ag in red (scale bars 25 nm). The atomic ratio of Au to Ag is 5.5 to 4.5 according to the EDS analysis.

### 2.3. Photocatalysis and SERS

Owing to the absorption properties of the metallic mesh structures in the visible and near-infrared ranges, and the hot electrons generated by the absorbed energy in AgClNCs, AgCl@AuAgCMs and AgCl@AuAgSMs were expected to exhibit photocatalytic activities. Therefore, we examined their photocatalytic performance for the reduction of Cr\(^{6+}\) under visible-light irradiation using a metal-halide lamp (Figure 3a). Potassium dichromate was used as a source of Cr\(^{6+}\), whose reduction progress was monitored by measuring the absorbance at 350 nm. We also obtained the single-nanoparticle SERS spectra of 1,4-benzenedimethanethiol (BDMT) that was absorbed by the individually dispersed AuAgCMs and AuNPs on a glass substrate (Figure 3b). As expected, two distinctive Raman bands of BDMT were observed at 1080 and 1572 cm\(^{-1}\) when individual AuAgCM was used as single-particle SERS substrate. On the other hand, the dispersed AuNPs nearly did not enhance any SERS signals of BDMT.

![Figure 3](image)

**Figure 3.** (a) UV-vis spectra obtained by monitoring the reduction of Cr\(^{6+}\) to Cr\(^{3+}\), which was photocatalyzed by AgCl@AuAgCMs. (b) SERS spectrum of 1,4-benzenedimethanethiol (BDMT)-coated AuAgCM (red) and 100-nm AuNP (black).

### 3. Conclusions

Silver halide (AgX) nanocubes have provided only specific facets in their metallic replication, mainly resulting in nanoframes. In this study, we carefully investigated the surface chemistry of AgCl and successfully overcame this limitation, demonstrating that not only faceted AgCl nanocubes but also almost facetless AgCl nanospheres could be the nanotemplates for their mesh-structured bimetallic replicas. The detailed synthetic mechanism has been thoroughly investigated. Moreover, unlike previous monometallic nanoframes, these metallic nanomeshes showed a high potential to enhance the SERS properties as single-nanoparticle substrates. Importantly, other mineral nanocrystals than AgX, such as faceted Ag\(_2\)PO\(_4\) nanocubes, were successfully replicated.

In Situ Surface-Enhanced Raman Spectroscopic Study of Chemical Reactions on Bifunctional Nanoparticles

Wei Xie

Key Lab of Advanced Energy Materials Chemistry (Ministry of Education), Renewable Energy Conversion and Storage Center, College of Chemistry, Nankai University, Tianjin, China
*corresponding author, E-mail: wei.xie@nankai.edu.cn

Abstract

Characterization of reactions catalyzed by nanoparticles (NPs) is challenging because the chemical transformation occurs only at the catalytic interfaces, where the many different components are difficult to separate and purify. Therefore, surface-selective analytical methods are required to monitor the reactions directly on the NP surface. Here, we show the use of surface-enhanced Raman spectroscopy (SERS) for in situ monitoring of catalytic reactions on bifunctional NPs.

1. Introduction

Surface-enhanced Raman spectroscopy (SERS) is very surface-selective and has high sensitivity plus chemical specificity which fulfills the requirements for in situ monitoring of molecular transformations in heterogeneous catalysis.[1] However, catalytically active materials such as Pt, Pd, Ni and small Au NPs do not provide sufficient plasmonic activity for the required SERS enhancement. On the other hand, conventional SERS substrates such as large Au or Ag NPs are not catalytically active. Bifunctional nanostructures that combine both plasmonic and catalytic activity can enhance the Raman signal of chemical species involved in the catalytic reactions. Au-Pt-Au core-shell nanoraspberries with both high Pt surface area and high plasmonic activity represent an example of bifunctional hybrid NPs for combined catalysis/SERS monitoring.[2] Reactions catalyzed by Pt can be monitored by SERS due to the plasmonic Au protuberances grown on the Pt surface. Alternatively, the small catalytically active NP satellites can be self-assembled onto a large plasmonically active core to form a plasmonic superstructure; in this case the chemical species on the catalyst surface experiences a sufficient SERS enhancement due to the plasmonic coupling between the small satellites and the large core.[3]

By using SERS, we characterized reactions catalyzed by different metals and found a couple of interesting interfacial chemical processes. For example, reduction in aqueous sodium borohydride solution is usually driven by H2, and the real hydride reduction occurs only in very basic solutions.[4] Another example is the hot-electron reduction on Ag NPs promoted by photodissociation of silver halides, which enables six-electron reduction without using conventional chemical reducers such as hydride and H2.[5,6] Recently, we studied C-C bond-forming reactions catalyzed by Pd and Ni NPs, respectively. According to the findings enabled by in situ SERS, the catalytic activity of the catalysts in the corresponding reactions was significantly improved.

2. Results and Discussion

To synthesize Au-Pd core-satellite superstructures with a SERS-active Au core inside and many small Pd NPs on the surface of the Au core. The 80 nm Au cores are first encapsulated in an ultrathin silica shell and then functionalized with thiol groups. Then 5 nm Pd satellites are added and anchor onto the core via strong metal-sulfur interaction. X-ray photoelectron spectra indicate the formation of Pd-S bond in the super-structures. The ~1.5 nm inert silica shell between the core and the satellites ensures the required SERS enhancement on the satellite surfaces and more importantly, isolates the Au core from direct contact with the reactants.

Figure 1: In situ SERS monitoring of Suzuki-Miyaura cross-coupling reaction between aryl bromides and phenylboronic acids.
We use the Suzuki-Miyaura C-C cross-coupling reaction as our model reaction for in situ SERS monitoring (Figure 1). Although this prominent reaction is extensively used in C-C bond-forming chemistry, in the presence of Pd NPs, it is not clear whether the coupling reaction is catalyzed heterogeneously (by solid-state Pd metal) or homogeneously (by thiolated reactants in solution). Via in situ SERS detection, solid evidence of heterogeneous catalytic Suzuki coupling has been found on the Pd nanoparticle surface. In contrast, the soluble Pd leaching out from the particle surface cannot catalyze the reaction, indicating that the direct contact between organohalide molecules and metallic Pd surface is prerequisite for the C-C cross-coupling. This finding highlights a key factor, in addition to the particle size, component and surface morphology (atomic defects), for rational design of nanoparticle catalysts: the increased molecule-metal contact will facilitate the C-C cross-coupling. As expected, the catalytic activity of Pd nanoparticles has been significantly enhanced when there is a proper electric attraction between the organohalide and the metal surface.

We monitor chemical reaction on metal NPs that are originally not SERS-active by using bifunctional nanostructure substrates. The surface-selective SERS directly focuses on the molecular conversions at the catalytic interfaces and enables many interesting findings which are very important for understanding the reaction mechanisms. These results show that SERS is a powerful technique for interfacial chemistry and can be utilized as a useful tool for the broad chemistry community.

Nanoscale Imaging and Control of Chiral Plasmons

Hiromi Okamoto

Institute for Molecular Science, National Institutes of Natural Sciences, Okazaki, Japan
*corresponding author, E-mail: aho@ims.ac.jp

Abstract
Novel near-field optical imaging methods were developed to visualize local optical activity and circularly polarized fields in the vicinities of metal nanostructures. We found not only chiral but also achiral gold nanostructures gave strong optical activity. Based on the result, we propose a method to generate highly circularly polarized local field with controllable handedness using an achiral nanostructure. We also found that chiral plasmon induces highly circularly polarized luminescence from achiral fluorescent molecules that interact with it.

1. Introduction
Chirality is a broad concept that characterizes structures of systems in almost all hierarchy of materials in natural sciences. Molecular chirality is sometimes essential in biological functions. In nanomaterials sciences, it is of fundamental importance to investigate internal structures (geometrical distributions) of chiral optical responses in nanomaterials, to design chiral characteristics of the materials and their functions. We developed a few types of near-field optical activity imaging methods that allow us to visualize local optical activity structures of nanomaterials: (i) Near-field CD imaging, where circularly polarized light (far-field) is incident on the sample and near-field scattering intensity in the vicinity of the sample is detected through the aperture near-field probe (in some cases, near-field circularly polarized illumination and far-field optical response detection was adopted). (ii) Near-field polarimetry imaging, where linearly polarized near-field radiation is incident on the sample through the aperture probe and the polarization state (ellipticity and azimuth angle) of the scattered light (far-field) is detected as the signal for imaging. These methods were applied to observe chiral plasmonic fields for two-dimensional gold nanostructures fabricated with electron beam lithography lift-off technique, and we found that chiral plasmons yield very strong local optical activity even for achiral nanostructures. Based on the results obtained with these methods, we proposed a simple method to generate highly circularly polarized local fields with an achiral nanostructure, with controllable handedness of the field. We also demonstrate that the locally highly chiral fields arising from plasmon resonances induce highly circularly polarized luminescence from achiral fluorescent molecules conjugated with the chiral plasmons.

2. Results and Discussion

2.1. Near-field optical activity imaging
We observed near-field optical activity images of two-dimensional chiral gold nanostructures. We found that the amplitudes of local CD signals were as large as 100 times the macroscopic CD signals of the same samples, for two-dimensional chiral ("S"-shaped) gold nanostructures [1]. Furthermore, even highly symmetric achiral structures, such as rectangles that never gave CD signals macroscopically, gave locally very strong CD signals [2,3]. In this case, average of the signal over the nanostructure yielded roughly null CD intensity. Figure 1 shows an ellipticity image of gold nano-rectangle obtained with near-field polarimetry imaging, which approximately corresponds to a CD image [4]. We also found that the observed spatial structure of the chiral field is qualitatively well reproduced by a simple dipolar excitation model. This result shows that any structure can have (local) chiral interaction with optical fields.

Figure 1: Top: Near-field ellipticity image (at 800 nm) of a gold rectangle [4]. Bottom: Line profile along the horizontal line indicated in the left panel. $\eta=\pm45^\circ$ for circularly polarized light.
2.2. Generation of controllable circularly polarized local fields with an achiral nanostructure

As an extension of the optical imaging study, we have shown that controllable local circularly polarized field can be generated by a combination of linearly polarized light and a gold nanorod (an achiral structure) [5]. When the polarization direction of the incident light is oblique to the nanorod axis, it was found that highly circularly polarized local field can be generated, and the handedness of the circular polarization and the ellipticity can be controlled by adjusting the oblique direction and angle of the incident polarization. The results obtained here provide basic principle to get highly chiral and switchable local optical fields, which may give us a chance to pioneer analytical applications of chiral optical fields and novel optical devices.

![Figure 2: Generation of highly circularly polarized local field with gold nanorod and linearly polarized light [5]. Degree of circular polarization (±1 for circularly polarized light) at the position above the center of the rod depends on the incident polarization angle, and the exceeds 0.5 around \( \theta_i \sim 45^\circ \).](image)

2.3. Highly circularly polarized luminescence from molecules conjugated with chiral nanostructures

We also demonstrate here that interaction between fluorescent molecules and chiral plasmons yield highly circularly polarized luminescence [6]. We used organic dyes as fluorescent emitters with luminescence enhanced by its near-field interaction with the chiral plasmons excited on a two-dimensional chiral metal nanostructure. The photoluminescence enhancement dissymmetry spectra showed maximum amplitudes in the wavelength region, which correspond approximately to the wavelength providing maximal circular dichroism of the plasmonic nanostructures. The dissymmetry factor of the luminescence exceeded \( g > 0.1 \) (as compared to those of the most of circularly-polarized emitters with chiral molecular structures, \( g \sim 0.001 \)). We discuss the physics behind the circularly polarized luminescence from such hybrid dye-doped chiral nanostructures with the aid of an electromagnetic model analysis. We found that the (two-dimensional) chiral structure of the resonant plasmon mode is the origin of the highly circular polarized luminescence.

3. Conclusions

By observation of local chiral field structures, we found that local optical activity of nanomaterials show some unique and valuable features compared to macroscopic one, which gives highly enhanced chiral natures of optical characteristics through near-field interactions. It may provide some useful applications in optical devices, chemical analysis, bioimaging, and so forth.

Photochemical properties of organic dye molecules under vibrational strong coupling regimes

Kosei Ueno

Abstract
The photochemical properties of dye molecules under vibrational strong coupling regimes have been studied by using plasmonic and microcavity structures which confines infrared light strongly. Fluorescence lifetime apparently shortened with increasing of the electromagnetic field intensity of the optical modes, which implies the decreasing of non-radiative rate constant in the energy relaxation process accompanying with the acceleration of vibrational relaxation due to vibrational strong coupling.

1. Introduction
Strong coupling has received considerable attention because molecular electronic states can be modulated by quantum mechanical interactions with optical modes such as microcavity, plasmon, and so on [1, 2]. If the electronic state is modulated by the strong coupling, it is expected to change the reactivity of molecules, so that it can work like a catalyst for promoting chemical reactions. On this basis, we have explored strong coupling between localized surface plasmon resonance (LSPR) and molecular excitonic states by using J-aggregate of molecules having relatively larger dipole moment [3, 4]. Ebbesen and co-workers recently demonstrated the strong coupling between microcavity and molecular vibrational modes in the infrared wavelength range and a possibility of modulating chemical reaction activities by the strong coupling [5, 6]. If the chemical reaction activity is changed by the vibrational strong coupling, it means that the transition state of molecule is influenced. Therefore, we study on the vibrational strong coupling and its influence on the electronic state of molecules under vibrational strong coupling. In the present study, we explored fluorescence properties of dye molecules in infrared plasmon–cavity strong coupling systems by several spectroscopic techniques.

2. Experimental
We constructed a modal strong coupling system in the infrared wavelength region utilizing LSPR and Fabry-Pérot cavity modes showing strong near-field enhancement in the wide wavelength range. The strategy for fabricating the strong coupling system is analogous to our modal strong coupling system in the visible wavelength range [7]. Only the resonant wavelength of plasmonic structures and the thickness of gold (Au) nanostructures and the thickness of titanium dioxide (TiO₂). Au-film with a thickness of 100 nm is deposited on the quartz glass (SiO₂) by sputtering, and subsequently TiO₂ film with a thickness of 450 nm is deposited on the Au-film/TiO₂ substrate by an atomic layer deposition (ALD) system. Au nanochains (AuNCs) which shows a dipole resonance band in infrared wavelength region were fabricated by electron beam lithography and lift-off processes on the TiO₂/Au-film cavity [8, 9]. Al₂O₃ with a thickness of 2 nm was additionally deposited on the AuNCs/TiO₂/Au-film substrate to improve the electromagnetic interaction between LSPR and Fabry-Pérot cavity modes as well as to not to directly contact between Au surface and fluorescence dye molecules for suppressing the fluorescence quenching. Fluorescence dye molecules of Eosin Y were adsorbed to the surface of the modal strong coupling system. Fluorescence spectra and decay curves were measured by spectrometer and time-correlated single photon counting. Absorption spectrum of the modal strong coupling system was obtained by measuring transmission (T) and reflection (R) spectra by Fourier-transform infrared (FT-IR) spectrometer and represented as 1-T-R spectrum.

3. Results and Discussions
A schematic illustration of the modal strong coupling system with fluorescence dye molecules on the surface is shown in Figure 1. Absorption spectra of the TiO₂/Au-film cavity substrate and AuNCs/TiO₂/Au-film structure are shown in Figure 2. As a reference, the broken line in Figure 2 shows a reflection spectrum of AuNCs on a TiO₂/SiO₂ substrate, whose TiO₂ thickness is 100 nm. The length of AuNC is set at 516 nm, which is corresponding to four chains.

Figure 1. A schematic illustration of the cross-section of the infrared modal strong coupling system with fluorescence dye molecules on the surface.
diagonally aligned Au nanoblocks (100 × 100 × 30 nm²). From the absorption spectrum of the TiO₂/Au-film substrate, it can be found that the fundamental Fabry–Pérot cavity mode is located around 2400cm⁻¹ when TiO₂ thickness is 450 nm. On the other hand, the LSPR band of AuNCs is closely to the cavity mode, the spectrum is modulated and the spectrum is divided into two peaks like a modal strong coupling system in the visible wavelength range due to the formation of hybrid modes [7]. When the LSPR band completely overlaps with the cavity mode by increasing the length of AuNCs from 750 nm to 2380 nm, the absorption in the wavenumber range of 2000–4000cm⁻¹ (2.5–5 μm as a wavelength) is dramatically increased. In the wavenumber range of 2000–4000cm⁻¹, OH stretching vibrational mode of the dye molecule is overlapped with the plasmon–cavity hybrid modes. Interaction between OH stretching vibrational mode and plasmon–cavity hybrid modes is expected. It is noteworthy that the high-order cavity mode exists also in the visible wavelength range. Therefore, Purcell effect cannot be ignored, which can be confirmed by the modulation of fluorescence spectrum and extremely fast fluorescence lifetime. Importantly, fluorescence lifetime changed with changing of the absorption in infrared wavelength range due to the degree of detuning between plasmon and cavity modes. There is a possibility that vibrational strong coupling affects the vibrational relaxation by OH group.

Figure 2. Absorption spectra of the TiO₂/Au-film cavity substrate and AuNCs/TiO₂/Au-film structure. The broken line shows a reflection spectrum of AuNCs on TiO₂/SiO₂ substrate whose TiO₂ thickness is 100 nm.

4. Conclusions

We investigated the photochemical properties of dye molecules in the infrared plasmon–cavity strong coupling system, which is composed of Au nanochains/TiO₂/Au-film structure. When the localized surface plasmon band of Au nanochains is closely to the Fabry-Pérot cavity mode of TiO₂/Au-film, the spectrum is modulated due to the formation of hybrid modes, and the absorption in the infrared wavelength region increased with decreasing the degree of detuning between plasmon and cavity modes. When OH stretching vibrational mode of the dye molecule is overlapped with the plasmon–cavity hybrid modes, fluorescence lifetime apparently changed. We speculate that vibrational strong coupling affects the vibrational relaxation by OH group.

Optical properties of plasmonic spiked particles as a function of their size and shape

Ramon A. Alvarez-Puebla
ICREA, Passeig Lluís Companys 23, 08010 Barcelona, Spain
Departamento de Quimica Fisica e Inorganica; Universitat Rovira i Virgili, Edifici N5, Carrer de Marcel·li Domingo s/n, 43007 Tarragona, Spain.

The anisotropy in the particle geometry determines the field distribution of the plasmon modes in the nanostructure [1]. Upon excitation with light of the appropriate energy, these structures can sustain large electromagnetic fields at ends (nanorods) [2], vertices (triangles) [3], or tip apexes (nanostars) [4]. Such field localization can be readily exploited for SERS and thus, for the fabrication of ultrasensitive devices. The intrinsic optical properties of nanostars were theoretically demonstrated by Nordlander and co-workers [5], indicating that the plasmon modes of a nanostar result from the hybridization of the individual plasmons of the core and the tips. The core would serve as a nanoscale antenna, dramatically increasing the excitation cross-section and the electromagnetic field enhancements of the tip plasmons. Recently, the efficiency of gold nanostars for SERS was as well experimentally evidenced [6-7].

Here we discuss the advantages of using different spiked particles for photonic and sensing applications including distant excitation, direct sensing and bioimaging through the use of encoded particles.

Abstract
The handedness of chiral TbPO₄ nanocrystals can be controlled by preparing the nanocrystals in the presence of certain natural chiral acids, such as tartaric acid. We use circularly polarized luminescence measurements to follow the handedness and enantiomeric purity of the produced nanocrystals. Using single particle circularly polarized luminescence microscopy we proved that we obtain enantiomerically pure terbium phosphate nanocrystals when prepared with tartaric acid molecules.

We have previously demonstrated on enantioselective synthesis of α-HgS [1], and Te, Se nanocrystals [2] using thiolated chiral ligands (cysteine, penicillamine, glutathione). Those nanocrystal ensembles exhibited strong circular dichroism, indicating that they were produced with significant enantiomeric excess. However, there was no experimental method to determine how large was this enantiomeric excess.

We have recently turned to another chiral crystal system: lanthanide phosphate hydrates (Rhabdophanes, LnPO₄·nH₂O). We synthesized Eu²⁺ doped TbPO₄·H₂O nanocrystals, which correspond to a chiral space group (P3121), in the presence of chiral ligands, such as tartaric acid. The nanocrystals were rod-shaped, about 0.5-1 µm long, and ~20-40 nm wide.

We have changed the enantiomeric excess of the tartaric acid used in the synthesis of the lanthanide phosphate nanocrystals and observed the change in the magnitude of the circular polarization in the emission lines of the Eu²⁺ ions. As shown in Figure 1, we have obtained an unusual behavior of the dependence of the circularly polarized luminescence dissymmetry factor

$$g_{\text{lum}} = \frac{I_L - I_R}{I_L + I_R}$$

on the enantiomeric excess of the tartaric acid molecules. $I_L$ is the emission intensity of the left-handed circular polarization component, and $I_R$ the right handed circularly polarized emission. A saturation of the $g_{\text{lum}}$ values at about $h=0.4$ indicates that already at that stage the formed nanocrystals are enantiomerically pure. This saturation phenomenon enabled us to normalize the relation between $g_{\text{lum}}$ and the enantiomeric excess of the formed nanorods (NRee), as seen in the inset of Figure 1.

Figure 1: Nanocrystal dissymmetry as a function of the enantiomeric excess of the tartaric acid ($h=x_L-x_R$, where $x_L$, $x_R$ are the mole fractions of the left- and right-handed tartaric acid). The $g_{\text{lum}}$ was measured at 699 nm emission line for the nanocrystals synthesized with different $h$ values. Both $g_{\text{lum}}$ and $h$ are shown in absolute value for simplicity. The inset compares the behavior of the tartaric acid-based synthesis to that of a glutamic acid-based one, where both are normalized by the saturation value of $g_{\text{lum}}$ observed for the TA-based synthesis. All syntheses in this figure were performed at 100°C. The solid lines are added as guides to the eye.

It can also be seen in Fig. 1 that glutamic acid is much less effective in directing the nanocrystal handedness. In order to prove that the saturation of the tartaric acid curve in Fig. 1 is indeed due to achievement of full enantiomeric purity of the nanocrystals we have performed single particle circularly polarized luminescence microscopy measurements [3]. Using a sophisticated spectral analysis to overcome the noise in the single particle circularly polarized emission spectra which involved a machine
learning algorithm, we have basically proven that indeed the samples prepared with pure L- or R-tartaric acid contained almost pure left- or right-handed crystals (with the exception of one particle out of ~140 particles sampled).

Abstract
In this work, we report a novel method to produce complex core-satellites SERS encoded nanoparticles (SEPs). Single codified NPs are produced in an easy and fast one-pot approach which, are further use as building blocks to produce the core–satellite SEPs. The presented protocol is very versatile allowing SERS codification with a wide variety of Raman active molecules and the use of different materials and shapes. Moreover, the core–satellite are designed to exhibit minimal interparticle distances (<2–3 nm) with maximum satellite loading, while positioning the encoding agents at the gaps. Thus, achieving a very high optical efficiency. In addition to such versatility, these fabrication methods are simple, cheap, scalable and robust, yielding stable SPEs in high yields.

1. Introduction
Nowadays, the use of SERS encoded nanoparticles (SEPs) is becoming a powerful method to solve analytical problems in complex media such as biological fluids1,5,7 due to their high-throughput screening, multiplexing capabilities, and large surface area for bioconjugation.5,7 In general, SEPs are made using a plasmonic core, responsible for the generation of the electric field necessary for the Raman amplification; a SERS encoding agent, responsible for the unique vibrational fingerprint of the encoded particle; and a protective layer which allows the attachment of biorecognition elements meanwhile preventing SEPs degradation.5,9 In this work, we propose an easy and fast approach to produce SEPs. This procedure allows the SERS codification of particles with a wide variety of Raman active molecules (more than 31 different encoded particles were produced). However, although SEPs composed of single plasmonic particles are desirable because of their homogeneous SERS signals, their efficiency is limited because they cannot form electromagnetic hot spots. Thus, hindering their applicability to other more demanding applications in which acquisition time or spatial resolution are of paramount importance. To solve this problem, we present a synthetic approach to produce SERS encoded core-satellites structures with maximum particle loading and minimal interparticle gaps (< 2-3 nm). Besides improving the SERS efficiency and keeping intensity homogeneity of the signals, these structures also keep the appropriate size ca. 100 nm for biological applications.10 The presented encoded core-satellites structures can be produced with cores of different materials (Au and Ag) and different shapes following the same protocol.

2. Results and discussion

2.1. Synthesis of SERS encoded building blocks
The successful production of SEPs, requires the simultaneous control of different experimental parameters which can be divided in four main different steps: 1) synthesis of plasmonic NPs; 2) mercaptoundecanoic acid (MUA) functionalization; 3) SERS codification; and 4) silica coating. Fig. 1 shows a schematic representation of the process.

Due to the low stability of colloidal solutions upon functionalization with SERS active molecules, a pre-stabilization step is required. Therefore, a molecule that binds covalently to the gold surface while providing particle stability (steric and electrostatic repulsion due to a long aliphatic chain and a terminal carboxylic group) was chosen. It is important that the selected molecule presents a negligible Raman cross-section to avoid undesired SERS signals. Therefore, MUA was used in a first step to functionalize the NPs8,10,11 Another crucial issue is that MUA should be added in an adequate proportion to avoid the formation of a compact monolayer that could passivate the metallic surface, preventing the retention of the SERS codes, and with extreme care to avoid heterogeneous adsorption of the molecule by some of the colloids in the solution. Thus, after the NPs synthesis, MUA was rapidly added under vigorous stirring at basic pH to functionalize the plasmonic nanoparticles with 0.8 MUA molecules nm−2, the minimal amount required to provide colloidal stability to the NPs9,10 After that, the SERS code can be added.
without inducing NPs aggregation. Finally, to ensure the SEPs stability for long periods and generate a readily external surface for further functionalization, the nanoparticles were encapsulated in a silica matrix using the well-known Stöber method.\textsuperscript{12,13,14} Fig. 2 shows representative example of the produced NPs.

Figure 2: Extinction spectra of Au particles after each step of the presented protocol. (B–D) Representative TEM images at different magnifications of the produced SEPs.

### 2.2. Synthesis of Core-Satellites SEPs

The assembling strategy for the fabrication of silica-coated SERS-encoded core-satellites is described in the following: plasmonic nanoparticles were first codified using the previously described MUA-mediated protocol\textsuperscript{8,10}, without the silica coating to use them as cores. Next, the negatively charged SEPs were wrapped with a single layer of positively charged branched polyethyleneimine (PEI) to yield the corresponding positively charged NPs. These NPs were subsequently exposed to a large excess of negatively charged small Au NPs which, via electrostatic interactions, are attached to the positive particles yielding the plasmonic assemblies. Finally, silica encapsulation was performed using a modification of the Stöber method directly on the mixture containing the core–satellites assemblies and the residual unbound satellites. In this specific synthetic approach, the silica coating allows the efficient separation of the light satellites from the clustered particles via post-centrifugation cycling with no risks of perturbing the aggregation state of the assemblies. Fig. 3 shows three different representative encoded core-satellite structures with cores of different materials (Au and Ag) and different shapes (spheres, rods, and stars).

Figure 3: Core-satellites structures with different core shapes, spheres, rods, and stars.

### 2.3. Optical enhancing properties

To test the optical enhancing properties of the materials produced and their usability for single particle detection, diluted solutions of the colloidal preparations were spin-coated on silicon slides to reach concentrations below one particle per µm\(^2\). The obtained results reveal that all the core-satellite materials yielded strong SERS signals for all lasers lines used (532, 633 and 785 nm) in the single particle regime. However, in the case of individual silver and gold nanoparticles, more concentrated films were required to provide a measurable signal, specifically, 18 and 5 particles per µm\(^2\) were required for gold and silver cores, respectively. In fact, the enhancement factors for the core-satellites are 4 orders of magnitude higher than those of the individual gold or silver SEPs.

### 3. Conclusions

In summary, we have developed an innovative and easy approach to produce SERS encoded nanoparticles which allows the use of a wide variety of Raman active molecules. This versatile strategy relies in the use of plasmonic NPs that are first stabilized with MUA for the further codification process. This approach allows for the further use of these nanoparticles as building blocks to produce core-satellites encoded structures. The obtained structures are highly brilliant SERS tags that allows for single particle detection.

Abstract

The synthesis of a hydrogel-based soft contact lens featuring laser shielding capabilities is reported. These light-protective properties are accomplished through the integration of gold-based plasmonic nanoresonators into the lens polymer network, which provides the hydrogel with a high optical density while preserving visible light transmittance. The implementation of these hybrid materials shows great potential in the eye care setting in terms of applications. Along these lines, the ability of the Au nanocomposites to act as efficient light concentrators renders this approach a cost-effective alternative to other less absorbing formulations which may also be toxic or degradable upon light irradiation. Furthermore, the use of these hybrid lenses would provide the wearer with an all day long protection and a minimal obstruction to perform common tasks in those scenarios where high powered light sources are operated.

Introduction

In the past few years, nanoscience has emerged as a source of innovative solutions to eye-related diseases and conditions.[1–3] In this line, the implementation of nanomaterials in the ophthalmologic field has propelled a vast array of applications including sensing,[4–6] imaging,[7–9] and ocular drug delivery,[10–12] Among these operational uses, electromagnetic shielding is also of great interest since, as known, excessive light exposure is a potential cause of ocular disorders such as cataracts or retinal damage.[13–15] In this context, high powered lasers constitute a major concern among the sources of artificial lighting given their widespread use in many industries as well as research, education, medicine and military.[16] For that reason, the current market of safety eyewear offers a wide range of products including spectacles, goggles and wrap-around glasses.[17] These accessories are aimed at protecting the human eye from laser irradiation by filtering specific (or a narrow range of) wavelengths depending on which applications they are intended for. This is usually accomplished through glass filters where heavy metal ions or colloidal particles are introduced. Polymer-based substrates (typically polycarbonates) can also be exploited to this end. In this case, this is achieved by the impregnation of the polymer with different dyes during the molding process, which enables the mimicking of the absorptive properties of glass laser filters.

Scheme 1. Illustration depicting the architecture of the plasmonic Au-based silica-shelled nanocapsules and their integration in a soft contact lens as an electromagnetic shielding component

Additionally, lamination of different glasses or hybrid combinations of glass and polymer substrates may be also employed in order to manufacture products offering protection against multiple wavelengths. However, despite the vast range of eyewear products available in the market,
no much efforts have been made from the field of nanoscience aiming at developing novel and more efficient strategies for the electromagnetic shielding in the eye care setting.[18] This lack of interest contrasts with the great progress made in the last years on the field of plasmonics, which has provided many technological opportunities due to the unprecedented ability of metallic nanostructures to concentrate light into deep-subwavelength volumes.[19]

The present work reports the fabrication of a hybrid soft contact lens featuring the integration of gold-based plasmonic silica-shelled nanocapsules (Scheme 1). Through this synthetic approach, the growth of the Au nanoparticles immobilized into these architectures can be chemically controlled thereby, allowing for a precise manipulation of the absorptive properties of the metal across the visible and infrared spectrum. In the end, this high degree of control enables the modulation of the optical behavior of the lens and thus, its exploitation as an electromagnetic shield.

Abstract

Strong light–matter interactions in two-dimensional transition-metal dichagenides (TMDCs) coupled with nanophotonic structures can have great potential in future high-performance nanophotonic and quantum devices which operate at room temperature. I will introduce our recent progresses on manipulation of this type of strong interactions using semiconductor as well as plasmonic nanostructures.

1. Introduction

Due to their intriguing optical and electrical responses, TMDCs with atomic thicknesses have attracted much attention in recent years, both from fundamental and application aspects. In particular, if the TMDCs are placed within an optical cavity, the coupling between the 2D excitons and cavity modes can lead to exotic photonic behaviors, such as Rabi splitting, Fano resonances, enhanced absorption and photoluminescence, and lasing. These processes are very important for nanophotonics devices and have attracted much attention in the past decade. From an application point of view, it is required that the strong interactions between the TMDCs and optical cavity can occur at room temperature and active control on such interactions is also strongly desired. The large exciton binding energies (0.3–0.9 eV), strong exciton transition dipole moments, and excitonic characteristics that are amenable to external stimulus in the TMDCs can well tackle these challenges.

In this talk I will introduce our recent works on manipulation of the coupling between the TMDCs with the plasmonic and dielectric nanocavities. Depending on the coupling strength and the cavity used, strong coupling phenomena, with a large Rabi splitting up to ~ 100 meV, and Fano-type resonances were observed at room temperature. The active control on these coupling processes were achieved using temperature scanning, electrostatic gating, and proton doping to the hybrid nanostructure. In particular, the modulation depth of the electric approach can be up to 17% (Fig. 1).

2. Results and discussions

2.1. Manipulation of strong coupling between plasmonic nanorods and 2D excitons in monolayer WS₂

By integrating the individual gold nanorods with the 2D WS₂ and WSe₂, we achieve strong coupling at room-temperature, where a Rabi splitting energy can reach up to 106 meV. In addition, the strong coupling can be tailored by applying temperature scanning, electrostatic gating, and proton doping to the hybrid nanostructure. In particular, the modulation depth of the electric approach can be up to 17% (Fig. 1).

2.2. Manipulation of resonance coupling between Si nanospheres and 2D excitons in monolayer WS₂

High-refractive-index dielectric nanostructures are another type of nanocavities capable of confining the free-space light into nanoscale volumes. We showed that resonance coupling could occur between the magnetic dipole mode of the Si nanosphere and two-dimensional excitons in monolayer WS₂ (ML-WS₂). For a silicon nanosphere coated with a ML-WS₂, a distinct mode splitting and anticrossing behavior with a splitting energy of 43 meV can be observed, which can be attributed to the coherent energy transfer between the magnetic dipole resonance and exciton transition. However, if a silicon nanosphere is deposited onto a flat ML-WS₂ flake, the resonance coupling is manifested by a Fano interference effect. In particular, such a Fano lineshape can be actively tailored by temperature scanning.

Fig. 1. Manipulation of the strong coupling in individual plasmonic nanorod coupled with monolayer WS₂.

Fig. 2. Resonance coupling between an individual silicon nanosphere and ML-WS₂.
3. Conclusions

In summary, I have reviewed our recent studies on manipulation of strong light–matter interactions between 2D excitons in monolayer WS$_2$ and nanophotonic structures. These results can not only further our understanding on light–matter interactions at the nanoscale, but also benefit the design of nanophotonic devices rely on 2D materials.

Abstract

Highly-absorbing, plasmonic-metal nanostructures offer a promising route to bandgap-less ultra-fast photodetectors and broadband solar photocatalysts, due to their tunable absorption characteristics and ability to generate hot carriers1-3. For this reason, fundamental knowledge of hot-carrier energy distributions as well as their dynamics and associated lifetimes are necessary to adequately harness these energetic, non-equilibrium carriers. To date, experimental studies of hot carrier devices have focused almost entirely on the exploitation of hot electrons to produce a photocurrent or initiate a chemical reaction. Furthermore, numerous efforts have been devoted to understanding the temporal evolution of hot electrons within photo-excited metal nanostructures and various metal-semiconductor assemblies4-6. In contrast, there have been very few realizations of hot-hole based plasmonic devices and the dynamics of hot holes in metal nanostructures have remained largely unknown, despite the favorable energetics of hot holes predicted by ab-initio calculations7.

Here, we report the construction, optoelectronic and photoelectrochemical characterization of plasmon-driven photodiodes and photocathodes based on a metal/p-type gallium nitride (p-GaN) heterostructure that operate within the visible regime via hot-hole injection. First, we report a photoelectrochemical platform for improving the selectivity of solar-to-fuel energy conversion via plasmonic hot-carriers8. Next, through solid-state measurements we elucidate the fundamental role played by the metal band structure in determining device performance9. Lastly, we use ultrafast transient absorption spectroscopy to show that plasmon-induced hot-hole injection from gold (Au) nanoparticles into the valence band of p-GaN occurs on a similar timescale as previous observations of hot-electron injection. Furthermore, we show that the thermalization process of hot-electrons is significantly affected by hot-hole collection by the p-GaN support10. Taken together, our studies substantially advance the understanding of hot-hole transfer in metal-semiconductor heterostructures and demonstrate new opportunities for expanding the scope of hot-carrier optoelectronics beyond hot-electron-based devices.

Abstract

We consider excitation of the plasmonic nanoparticle interacting with Raman active molecules by the external coherent field. We show that there is a threshold value of external field amplitude above which coherent generation both of surface plasmons and nuclei vibrations in the molecules arises. We find that the coherent generation of surface plasmons is always followed by the coherent generation of nuclei vibration in the Raman active molecules.

1. Introduction

The discovery of lasers gave a new impetus to the development of the Raman spectroscopy. The new phenomena such as stimulated Raman scattering, coherent (anti-)Stokes Raman scattering were discovered [1, 2]. The stimulated Raman scattering occurs when the Raman active molecules are illuminated by two coherent electromagnetic waves: a weak signal wave and a high pump one [1]. In the case when the pump frequency is greater than the signal frequency, and the frequency difference of the incident waves is close to the frequency of nuclei vibration of the molecule, the wave with signal frequency is amplified. If the Raman active molecules are placed in a resonator, then the role of a signal wave can be played by the resonator mode. In this case, when the system is illuminated with a coherent wave with high amplitude, the electric field inside resonator will exhibit self-oscillations. This device is called Raman laser.

In 2003, Bergman and Stockman introduced the spaser (Surface Plasmon Amplification by Stimulated Emission of Radiation), a quantum amplifier of surface plasmons by stimulated emission of radiation [3]. The spaser includes two parts: gain medium, that amplifies the electromagnetic field, and resonator, that provides the positive feedback. Principles of spaser operation are analogous to those for a laser with the role of photons played by surface plasmons localized at a metal surface. The main feature of the spaser is the strong subwavelength field localization that emerges due to the nature of the surface plasmons.

In this work, we consider the case of Raman laser when the role of the resonator mode is played by the plasmon resonance of a metal nanoparticle. We show that the nuclei vibrations can be coherently generated by self-oscillations of surface plasmons.

2. Results and Discussion

We consider Raman active molecules with the frequency of electronic transition $\omega_{\text{el}}$ placed in the vicinity of plasmonic nanoparticle with the frequency of dipole plasmonic resonance $\omega_{\text{pl}}$. Excitation of such a system is produced by external coherent wave with frequency $\omega_{\text{ex}}$. This coherent wave interacts with dipole moment of plasmonic nanoparticle. In turn, its near field excites the electron subsystem of the molecule through the dipole-dipole interaction. Nuclei vibrations of the molecules with eigenfrequency $\omega_v$ arise as a response to oscillation of molecule electronic subsystem. We assume that the condition $\omega_{\text{ex}} \approx \omega_{\text{pl}} + \omega_v \ll \omega_{\text{el}}$ is fulfilled. After second quantization procedure, the Hamiltonian of the system takes the form

$$\hat{H} = \hbar \omega_{\text{pl}} \hat{a}^\dagger \hat{a} + \hbar \Omega (\hat{a}^\dagger \exp (-i \omega_{\text{ex}} t) + \hat{a} \exp (i \omega_{\text{ex}} t)) + \hbar \omega_{\text{el}} \hat{\sigma}^\dagger \hat{\sigma} + \hbar \Omega_R (\hat{a}^\dagger \hat{\sigma} + \hat{\sigma}^\dagger \hat{a}) + \hbar \omega_v \hat{b}^\dagger \hat{b} + \hbar g (\hat{b}^\dagger + \hat{b}) \hat{\sigma}^+ \hat{\sigma} \quad (1)$$

Here, $\hat{a}$, $\hat{\sigma}$, and $\hat{b}$ are plasmon annihilation operators, lowering operator of electronic subsystem of a molecule, and annihilation operator of nuclei vibrations, respectively. $\Omega$, $\Omega_R$ and $g$ are interaction constants between external field and plasmonic nanoparticle dipole moment, between nanoparticle dipole moment and dipole moment of molecule electronic transition, and between molecule electronic subsystem and nuclei vibrations of molecule, respectively.

Using Heisenberg equation for the amplitudes of plasmon oscillations $\hat{a}$, electronic subsystem oscillations $\hat{\sigma}$ and nuclei vibrations $\hat{b}$, we obtain the following system of equa-
Numerical simulations of Eqs. (2) – (4) show that there is a threshold value of external field amplitude above which self-oscillations of both electric field of surface plasmons and nuclei vibrations arise. Coherent self-oscillations of surface plasmons in the considered system are analogous to surface plasmon self-oscillations in spaser proposed by Bergman and Stockman in [3]. Coherent oscillations of electric field of surface plasmons induced coherent vibrations of nuclei. The greatest number of nuclei vibration quanta is observed when the decay rate of nuclei vibrations is much smaller than the one of surface plasmon which usually takes place in most experiments.

3. Conclusions

In this work we propose spaser assisted coherent generation of nuclei vibrations in Raman active molecules. The Raman active molecules play the role of gain medium and coherent light source is used as a pump. It is shown that the coherent generation of surface plasmons is always followed by the coherent generation of nuclei vibration in the Raman active molecules. This provides the potential application in the vibrational spectroscopy as well as access the optically driven chemistry [4].

Abstract
We present a unified picture for Förster resonance energy transfer in hybrid nanostructures with mixed dimensionality and in assembly arrays. In addition to general classes of FRET, we will also discuss peculiar examples of FRET processes including the exciton migration from quantum well to an energy gradient structure and near unity energy transfer from Nanoplatelets to a monolayer of MoS2. The general effects of dimensionality and assembly, along with peculiar examples, show the richness of FRET phenomena.

1. Introduction
Today nanotechnology offers means to assemble and study hybrid nanostructures compose of metal and semiconductor materials. Each element of the nanostructure contributes to the overall structure with their distinctive properties resulting from quantum confinement and interactions between them, enhancing optical properties for the structure. The Förster resonance energy transfer (FRET) is an important mechanism for strong coupling between elements, based on the Dipole Coulomb interaction, where the exciton flows from the donor (D) to the acceptor (A) (D → A). Excitons play an important role in optical devices such as solar cell, lasers, photodetectors, and LEDs. Thus, understanding FRET in these nanostructures is crucial for high efficiency light generation and harvesting.

2. Discussion
We obtained the Förster resonance energy transfer (FRET) rates in the long distance asymptotic behaviour in the dipole approximation for all possible combinations with mixed dimensionality [1,2]. The FRET rate were calculated using the expression:

\[ \gamma_{\text{trans}} = \frac{2}{\hbar} \text{Im} \left[ \int dV \left( \frac{\varepsilon_1(\omega)}{4\pi} \right) \mathbf{E}_\text{in}(\mathbf{r}) \cdot \mathbf{E}_\text{out}^*(\mathbf{r}) \right] \]

where the integration is over the acceptor geometry, \( \varepsilon_1(\omega) \) is the dielectric function of the acceptor, and \( \mathbf{E}_\text{in}(\mathbf{r}) \) is the effective electric field created by an exciton at the donor side.

Table 1 shows the functional distance dependency for the FRET: (1) when the acceptor is an NP, FRET is proportional to \( d^{-4} \); (2) when the acceptor is an NW or 1D array structure, FRET is proportional to \( d^{-5} \); (3) when the acceptor is a QW or a 2D array, FRET is proportional to \( d^{-4} \), and when the acceptor is bulk or a 3D array, FRET is proportional to \( d^{-3} \). It is worth mentioning that the effective dielectric constant depends only on the donor's geometry its confinement effect is summary in table 2.

To illustrate the effect acceptor confinement on FRET rate, we discuss peculiar examples for FRET processes. For instance, the exciton migration from a quantum well (QW) to an energy gradient structure consisting of layer-by-layer assembled quantum dot (QD) bilayer [3]. The energy gradient of these QDs provides a substantial increase in the exciton transfer efficiency with respect to the bilayer of a single type of QDs. These results suggest that the energy difference between the QD layers significantly boosts the QW-QD exciton transfer rate compared to the monodispersed case. Another example is the near unity energy transfer between CdSe/CdS core/crown Nanoplatelets (NPLs) to a monolayer of MoS2 [4]. This systematic study suggested that the FRET rate decay as \( d^{-2} \), where \( d \) is the distance between the donor NPL and the acceptor MoS2 2D structure. We found that the strong field screening and the dipole electric field delocalization play a major role in modifying the energy transfer kinetics from \( d^{-4} \) to \( d^{-2} \) (Fig. 1).

3. Conclusion

In summary, we present a complete picture and unified understanding FRET in hybrid nanostructures with mixed dimensionality and in assembled nanostructures arrays. We obtain the analytical expressions for the energy transfer rate in the long distance approximation. Our findings show that the acceptor quantum confinement dimension sets the generic NRET distance dependence and the donor geometry dimension modifies the effective dielectric function. This generic distance dependence can be remodified by arraying (stacking) the nanostructures. Therefore, the functional distance dependency of the NRET rate is determined by the quantum confinement as well as array stacking dimensionality of the acceptor.

Probing optical chirality in the near-field of achiral nanostructures

Abstract
We study the optical properties of plasmonic oligomers with trigonal symmetry. Albeit achiral, such structures exhibit a near-field response that depends upon the handedness of the exciting light (i.e., left- or right-circular polarization). This effect stems from near-field interference between the modes sustained by the structure. Then, we experimentally demonstrate this effect by imprinting the local optical chirality into a photosensitive polymer.

1. Introduction
A structure is said to be chiral if it cannot be superimposed with its mirror image. Chirality leads to a number of fascinating effects, especially when light interacts with chiral objects. For instance, a chiral molecule exhibits different absorption coefficients under left- (LCP) and right-circular polarization (RCP), an effect known as circular dichroism. With the advent of nanotechnology, a variety of artificial nanostructures (metamaterials) have been designed to exhibit artificial chirality [1]. Such nanostructures can even exhibit a local chirality of higher magnitude than the chirality of a circularly polarized plane wave. This super-chirality could be used, for instance, to enhance opto-chiral interactions for molecular detection with enantiorecognition [2].

Interestingly, chiral-related optical effects can be observed in the near-field of achiral nanostructures. For instance, structures like nanorods [3] or V-shaped metallic nanostructures [4] do not show any circular dichroism (no far-field chirality) but do exhibit different near-field responses under LCP and RCP excitation. The effect stems from a near-field interference effect between the modes sustained by the nanostructure. In this Communication, we use a photosensitive azobenzene-containing polymer (PAP) to probe the near-field chirality with nanoscale resolution. We show that handedness-dependent effects can happen in symmetric plasmonic oligomers.

2. Near-field chirality in symmetric plasmonic oligomers
The structure under investigation consists of three gold nanodisks arranged as an equilateral triangle (Fig. 1a). The structure is symmetric and, at first sight, does not seem to exhibit any chiral effect. Its scattering spectra computed for LCP and RCP excitation are identical: as expected, the far-field optical properties of the plasmonic oligomer do not depend upon the handedness of the impinging light. However, the picture is different in the near-field of the oligomer. Figures 1b and c show that the electric field intensity computed in the near-field is different for LCP and RCP. Whereas the intensity distribution inside the gap is identical for both polarization, outside the oligomer the near-field intensity appears “twisted”, the sense of twist depending upon the handedness of the excitation.

To understand this phenomenon, it is necessary to use a rigorous representation of the plasmonic modes sustained by the oligomer. From the trigonal symmetry, group theory allows to retrieve the symmetry adapted coordinates (SACs). Each field distribution can then be projected onto the SACs [5]. For a specific wavelength, the phase difference between the excited modes reaches 90°. Once added to the ±90° phase-shift between the two linear components of circular polarization, this leads to handedness-dependent field distribution around the oligomer.

Figure 1: (a) Schematic of the structure: three gold nanodisks (diameter 140 nm), separated by a 30 nm gap and arranged into a triangle. (b) FDTD calculation of the near-field intensity inside the oligomer at λ=780 nm, for LCP excitation. (c) Same, for RCP excitation.
3. Experiment

This effect has been experimentally verified using an original approach based on a photosensitive azobenzene-containing polymer (PAP). The PAP consists of an azobenzene derivative (disperse red 1) grafted to a polymer backbone (PMMA). Under illumination, the azobenzene molecule undergoes trans-cis-trans isomerization cycles, leading to a “worm-like” movement and a global displacement of matter. The subsequent topographical changes can be mapped using atomic force microscopy (AFM), giving an insight of the field distribution inside the nanostructure [6]. We recently showed that the PAP could be excited using 2-photon excitation in the near-infrared, evidencing hot spots inside plasmonic gap antennas [7].

The plasmonic oligomer has been fabricated using electron-beam lithography. Then, it has been covered with a thin layer (45 nm) of PAP and exposed to circularly-polarized light at $\lambda=790$ nm. After illumination, the topography of the structure was imaged using AFM. Results of this procedure are shown in Figure 2a and b, for LCP and RCP excitation, respectively. A clear difference is observed between the two images, demonstrating handedness-dependence. The topographical maps also closely resemble to the field intensity maps of Figure 2b-c.

![Figure 2](image_url)

Figure 2: (a) Atomic force microscopy image of the PAP-covered plasmonic oligomer after illumination by LCP light. (b) Same, for RCP excitation.

4. Conclusions

We showed that a symmetric nanostructure, here a plasmonic oligomer with trigonal symmetry, can produce near-field intensity distributions that depend upon the handedness of the impinging light. This effect has been demonstrated experimentally using a photosensitive polymer, allowing us to imprint the chiral near-field into the polymer. Interestingly, after its interaction with light the initially achiral nanostructure is turned into a chiral nanostructure.

Abstract

Plasmonic properties of the surface lattice resonance (SLR) mode of the Au lattice structure were controlled by electrochemical potential. The energy and the lifetime of SLR are determined by the periodicity, diameter, and height of Au lattice structures. The structural factors were optimized through metal dissolution. Varying the density of electrons in metals also resulted in the change of SLR. In situ observation of the optical properties of Au lattice structures by electrochemical dark-field scattering microscopy proves the fine-tuning of the plasmonic SLR properties as the changes in the resonance energy and the spectral width. The present method successfully controlled the structure by controlled surface dissolution of the Au lattice structure at a rate of a few nanometers per minute to prepare the lattice structures showing a spectral width of 0.145 eV with a resonance maximum of 1.74 eV (714 nm). Characteristics of the strong coupling states using the structure with dye molecules were also evaluated.

1. Introduction

Precise tuning of plasmonic properties is an important target for the realization of effective plasmonic devices [1-3]. Generally it has been recognized that the tuning requires the controllability in an atomic scale. Even the top-down methods, including electron beam lithography, control of the metal structures in the size scale is difficult especially at room temperature. We have developed the methods for the electrochemical structural control of metals in that size range for the tuning of plasmonic properties. [4, 5] As an important properties of the plasmonic properties, it is known that the dephasing of the coherent oscillation is induced by electronic/vibrational excitation, radiation damping. For nanostructures with diameters larger than a few tens nm, radiation damping is predominant. To discuss the lifetime of the plasmonic excited state, evaluation of the linewidth, which is defined as the full width at half maximum (FWHM), is effective because the linewidth depends on nonradiative and radiative damping of the plasmon modes.

The values of plasmon lifetimes are 2–10 fs. The control of the lifetime could be characterized by the change in FWHM. Recently, two-dimensionally arranged metal nanoparticles have received much attention because of the advantage on the control of plasmon lifetimes. In a two-dimensional (2D) square grating of metal nanoparticles (lattice structure), the scattered light from one particle is absorbed by neighboring nanoparticles to excite the plasmon, resulting in a transformation from radiative to evanescent. By this suppression of radiative loss, strongly coupled nanoparticles in the lattice structures show the surface lattice resonance (SLR) mode with an extremely narrow linewidth (<0.15 eV). The lifetime of the excited state for the SLR mode reaches $\tau_{SLR} = ~200$ fs, which is ten times longer than that for LSPR ($\tau_{LSPR} = ~10$ fs). Thus the structural control of 2D lattice may provide the plasmonic field with superior lifetime.

2. Experiment

The Au lattice structures were prepared on indium tin oxide (ITO) substrates by the electron beam lithography method. The details of the sample preparation procedure are given in our previous report. [*] The lattice spacing ($a$), diameter ($D$), and height ($h$) of each particle in the lattice structure were varied to tune the lattice plasmon modes. The prepared structures were analyzed by scanning electron microscopy (SEM, JSM-6700FT, JEOL Ltd.) and atomic force microscopy (AFM, Nanoscope-IIIa, Digital Instruments). The electrochemical measurements were performed with a three-electrode system. The working, counter, and reference electrodes were a lattice-supported ITO substrate, a Pt plate, and a Ag/AgCl electrode, respectively. The electrolyte solution was 0.1 M NaClO4. For electrochemical dissolution, 10 mM KBr was added to the electrolyte solution. Before the electrochemical measurements, UV/ozone cleaning of the substrate was performed to remove the organic compounds on the surface. The electrochemical extinction and dark-field scattering measurements were performed in situ with an inverted microscope (IX-71, OLYMPUS Co.) equipped with a 100 W halogen lamp, a dark field condenser, and a 60×/0.7 numerical aperture objective lens. All of the spectra and images were obtained with a spectrometer (IsoPlane SCT-320, Princeton Instruments) and a charge-coupled device detector (PIXIS 100BR EX-M, SCIENTIFIC).
preparation of the substrates showing strong coupling states, controlled amounts of cyanine dye molecules S0366 were deposited on the lattice structures.

3. Discussion

The maximum resonance wavelength shifts from 693 to 730 nm with increasing $a$ with $D = 140$ nm and $h = 100$ nm. This intense peak can be assigned to the SLR mode because of far-field coupling in the 2D nanoparticle. The electrochemically controlled metal dissolution reaction was introduced to tune the lattice plasmon modes via fine structural control of a single disk unit. The extinction spectra during electrochemical potential polarization of the Au lattice structure ($a = 400$ nm, $D = 140$ nm, and $h = 100$ nm) at the potential 0.8 V for 600 s in 0.1 M NaClO4 containing 10 mM KBr. The significant change in the extinction spectrum indicates decreases in the extinction intensities for both SLR and LSPR. The correlation between the structural factors ($a, D,$ and $h$) and the lattice plasmon modes was investigated focusing on the resonance wavelength and FWHM of the spectra. The extinction spectra of Au lattice structures with $a = 300–460$ nm a showed a linear relationship between the blue shift and the $a$ value. Additionally, the FWHM values of respective structures showed similar behavior as the wavelength shift of a linear relationship between the FWHM and $a$. At the electrochemical dissolution, the FWHM decreases from an initial value of 0.165 eV to a minimum of 0.145 eV after polarization for 120 s, and it then increases to above 2.0 eV. At the FWHM minimum, the SLR resonance maximum is 714 nm (1.74 eV) [6]. This characteristic change in the FWHM suggests that that the lifetime of the excited SLR mode can be precisely tuned by decreasing $D$ and $h$ at a rate of a few nanometers per minute. This decrease in the FWHM could originate from the changes in the LSPR and lattice spacing, leading to a confined light field for long lifetime. It should be emphasized that the absolute minimum FWHM value achieved in the present system is comparable with those in previous studies. Real-time observation of the FWHM associated with controlled surface dissolution is important to obtain a lattice structure with tailored plasmonic properties for an extended lifetime. The structures with narrower FWHM provided the strong coupling states of plasmons and dye excitons at the deposition of dyes. Consequently, the present method can produce a confined light field with a relatively long lifetime excited state tuned to the target energy of the plasmon.

4. Conclusions

We have succeeded in tuning both the resonance wavelength and FWHM for the SLR mode by electrochemical potential control. By changing the electrochemical potential, the resonance wavelength can be tuned with precision below a few nanometers, which cannot be achieved by structural control techniques. The fine tuning the FWHM was also achieved by the control of the electrochemical metal dissolution to have a minimum spectral width of 0.145 eV at a resonance maximum of 714 nm (1.74 eV). This result indicates the possibility of application of the method to control plasmonic light confinement in the lattice structure, especially for the preparation of the strong coupling states.

Abstract
Silver nanowires are applied as a sensor for natural photoactive protein complexes. The surface of silver nanowires is modified in a selective way to detect specific fluorescent protein using wide-field fluorescence imaging, a fast technique, which gives information about sample morphology. In this work we studied and compared three methods of sensor design: mixing in solution, nanowires on glass substrate and in PDMS microchannels. Advantages and limitations of every approach are described and analyzed.

1. Introduction
Detection of biological substances, such as viruses, proteins, molecules, is important in many aspects of life. Research efforts are aimed at developing faster and more sensitive ways of searching substances. Another aspect of modern detection chips concerns also simplicity of an approach.

Silver nanowires (AgNWs) are highly advantageous as functional nanostructures in sensing design [1]. These structures are synthesized by wet chemistry and are very stable in water solution. They feature diameters around 100 nm and lengths around 50 μm, thus can be imaged using optical microscopy. Moreover, since they have the plasmon resonance around 400 nm, the AgNWs can be used for enhancing fluorescence of emitters. In order to facilitate such coupling, the surfaces should be chemically modified to enable specific conjugation with the analyte.

All the results were obtained using wide-field fluorescence imaging. This technique gives information about both the morphology and the fluorescence dynamics within the sample. For detection was used EMCCD camera, which allows to collect movies of fluorescence intensity.

The first type of our sensor is based on detecting photosynthetic molecules in a PDMS microchannel. In this approach biotynylated AgNWs are introduced into the channel through injection by a pump. Glass substrates are modified with streptavidin, facilitating attachment of AgNWs and simultaneous repulsion of PCP. The AgNWs are arranged along this same direction. Upon injecting protein solution into the channel we observe real-time attachment of PCP to AgNWs. The readout contrast is substantially improved after removal of unbound PCP.

The second strategy concerns the experiment in solution. We modify AgNWs surface and disperse them in water. In next step PCP solution was added. After few minutes AgNWs conjugated with PCP were deposited on a glass coverslip.

The last type of experiment is based on real-time fluorescence detection, where functionalized AgNWs are deposited on a glass surface in advance. Using transmission mode of a microscope we search for separated AgNWs. Then in a fluorescence mode, acquisition of kinetics is initiated, shortly before a droplet containing photosynthetic complexes is deposited on the surface with AgNWs.

2. Materials and Methods
Our sensor was tested for detecting photoactive proteins. First, Peridinin-Chlorophyll-Protein (PCP), equipped with streptavidin linker. PCP complex isolated from algae Amphidinium carterae and with a size of 4 nm, was used. The size of PCP is much less than the diameter of AgNWs. The absorption spectrum of PCP overlaps with the extinction spectrum of AgNWs. Second, we used green fluorescent protein (GFP) equipped with His-tag linker. GFP has similar size as PCP, although the different linker may lead to changes in attachment dynamics.
3. Discussion
In all cases we observed connection of PCP to silver nanowires. For high concentration of PCP the surface coverage of AgNWs is uniform and homogenous. At the same time we also quantify the enhancement of fluorescence of PCP attached to AgNWs.

Typical results obtained for our sensor are shown on Figure 1. First in a transmission mode we locate separated AgNWs and indicate their positions (Fig. 1A). Next fluorescence intensity of PCP complexes is measured, and usually the fluorescence pattern reflects the positions of AgNWs seen in the transmission mode (Fig. B).

![Figure 1. A Transmission picture showing the AgNWs. B Fluorescence map of single PCP attached to surfaces of AgNWs.](image)

In the experiment involving microchannels the whole process takes place in solution so detected molecules can be placed in the buffer. The most important advantage of this scheme is that the positions of AgNWs are known and every AgNW is at the same angle defined by the flow through the microchannel. Additionally, the AgNWs are attached to the glass surface. Using microchannels and the approach studied in this work, allows for using less sensitive imaging detectors in the experiments.

In the experiment carried out in solution we can catch all of the detected molecules in the sample. The effective surface of the AgNW sensor is bigger because PCP and AgNWs are swimming around in the solution. The detection also takes place in the buffer environment. Time which is needed for conjugation can be rather short (typically within minutes), but the molecules have to be attached to AgNWs.

Last but not least, the real-time imaging experiment is the fastest approach as the results can be seen directly during the kinetic acquisition. Sensitivity of this approach is determined – among others – by the number of AgNWs on the surface.

4. Conclusions
Functionalization of silver nanowires is simple, fast and cheap. Emitters need just a few seconds to find the AgNWs and efficiently conjugate with them. For highly concentrated solution of PCP in real-time we can see that all of the complexes are attached to the AgNWs. Plasmonic enhancement of fluorescence substantially improves the signal-to-noise ratio seen in the fluorescence images, enabling thus easier detection. Silver nanowires, as building blocks of sensor chip offer big potential in designing sensing platforms for commercial applications.

Quantum dot-cavity QED: Acoustic phonon-induced dephasing of polaritons

Egor A. Muljarov and Amy Morreau

School of Physics and Astronomy, Cardiff University, Cardiff CF24 3AA, United Kingdom

Phonon-induced optical decoherence in semiconductor quantum dots is a well-studied phenomenon which has been successfully explained within an exactly solvable independent boson model. This model picks up the major effect of a non-Markovian pure dephasing of a quantum dot exciton coupled to bulk acoustic phonons. In the case of a quantum dot embedded within an optical microcavity, this model does not work on its own as the exciton also interacts with an optical mode in the microcavity. Various approaches to this problem have been suggested in the literature, ranging from Born-Markov approximations to non-equilibrium Green's function techniques. However, to the best of our knowledge no exact solution to this problem has been found so far.

In this talk, we present an exact solution to the problem of the phonon-induced dephasing in a quantum dot-microcavity system, alongside simple analytic approximations [1]. Central to our approach is a Trotter decomposition of the full system Hamiltonian into two exactly solvable parts: a phonon-free Jaynes-Cummings model and a cavity-free independent boson model, thus taking into account the effects of the exciton-photon and exciton-phonon coupling on equal footing. Our approach is valid in a wide range of the exciton-phonon and exciton-cavity coupling parameters, covering regimes of weak, intermediate and strong coupling.

The obtained exact solution allowed us not only to confirm and rigorously prove results already known in the literature, such as temperature dependent renormalization of the vacuum Rabi splitting, but also to predict new important physical phenomena which have not been observed so far, such as phonon-assisted transitions between polariton states in the cavity and dephasing in the very strong coupling regime, in which the polaron and polariton timescales become comparable. We show that in this regime, the optical decoherence is determined by acoustic phonon-induced transitions between different polariton states of the quantum dot-cavity system and the polariton line broadening is well described by Fermi's golden rule.

Tailoring electric and magnetic dipole emissions by high-refractive index dielectric nanostructures

Abstract
Silicon nanostructures, providing well-separated electric and magnetic hot spots, are covered by thin films doped by Europium ions supporting both electric and magnetic dipole transitions. Photoluminescence mappings, obtained by raster scanning a laser beam at saturation over the sample, exhibit very distinct features corresponding either to the electric or magnetic dipole transition. They are interestingly comparable to the corresponding radiative electric or magnetic local density of optical states, calculated using the Green dyadic method.

1. Introduction
High-index dielectric nanostructures allow to manipulate optical Mie resonances through the material (e.g. silicon (Si), \( n \approx 4 \)), and the object size and shape. It has been shown that they offer the same ability to manipulate, concentrate or redirect visible light as plasmonic nanostructures made of noble metals, but with several key advantages such as much weaker absorption losses than in metals for wavelengths longer than the direct band gap (near UV to near IR for Si), and access to semiconductor (CMOS) technology for nanostructure fabrication.[1, 2] Furthermore, high-index dielectric nanostructures support both strong electric and magnetic resonances, giving the unique opportunity to separate and redistribute in the near-field the energy of the magnetic and electric parts of the electromagnetic field, inextricably connected in the far-field.[1] Rare-earth ions such as Europium (Eu³⁺) supporting electric (ED) and magnetic (MD) dipole transition of similar strength at close wavelengths, when positioned in the near-field of subwavelength Si nanostructures (Si-NS), can be used as probes of the relative electric and magnetic local density of optical states (LDOS).[2] Such results were usually obtained using a scanning near field optical microscope (SNOM) with emitters localized at the apex of the SNOM tip.[3] We propose an approach using a far-field optical set-up, allowing fast scanning, high signal-to-noise ratio and good spatial resolution, which is able to show spatially well-separated electric and magnetic dipole emission of an Eu³⁺-doped thin film deposited on top of isolated Si nanostructures.[4]

2. Results and discussion
Si-NS are obtained by electron lithography on a Silicon-On-Insulator substrate (SOI). They are then covered by a 30-nm thick film of Eu³⁺-doped Gd₂O₃ nanoclusters, obtained by Low Energy Cluster Beam deposition. Photoluminescence (PL) mappings are obtained by raster scanning the sample under a laser beam (\( \lambda = 532 \) nm) focused through a 0.9 NA microscope objective. A PL spectrum (see Fig.1) is acquired in each point, so that emission intensities corresponding to either the MD (\( \lambda \approx 590 \) nm) or ED (\( \lambda \approx 610 \) nm) transition are simultaneously recorded.

The signal of each contribution is normalized to its corresponding background intensity recorded far from the nanostructure. The laser power density is set to excite...
the emitters close to saturation, so that PL maps should be driven by radiative LDOS at the emission wavelength rather than by near-field intensity distribution at the excitation wavelength. Looking at Figure 1, it is obvious that MD and ED PL mappings are totally different. For a Si dimer (two elements of 300x300x90 nm$^3$ (LxWxH), gap = 100 nm), there is a clear contrast with a maximum of MD emission above the Si elements, while the maximum of ED emission is located around each Si-NS. First, it seems that this contrast is not due to the electric near-field intensity distribution (Fig. 1d).

The decay rate $\gamma_m$ ($\gamma_e$, respectively) of MD (resp. ED) transitions, proportional to the magnetic (resp. electric) LDOS, are calculated using the Green Dyadic Method (GDM). $\gamma_m$ being described in terms of mixed electric-magnetic field susceptibilities. [4, 5]

The maps of the decay rates are obtained by raster scanning a magnetic or electric dipole at 30 nm above the nanostructure to stay close to the experimental system. The total LDOS is obtained by summing two in-plane dipoles (the emission of an out-of-plane dipole is mostly in-plane, thus not detected by the microscope objective). We then compare the PL maps to the corresponding decay rates (convoluted with a Gaussian profile to model the finite size of the laser spot), assuming that radiative and total LDOS are the same due to negligible optical absorption of Si nanoantennas at the MD and ED emission wavelengths. The comparison between experimental PL maps and simulated radiative decay rates show a striking qualitative agreement, exhibiting unambiguously a separation of electric and magnetic LDOS above and around the Si-NS. The intensity ratios are also in good agreement.

3. Conclusions

In conclusion, we have shown that the ED an MD transition dynamics of quantum emitters such as rare-earth ions can be tailored when positioned in the vicinity of high-index dielectric nanostructures. There is also a qualitative agreement between far field PL maps and electric and magnetic LDOS. It should be interesting to design specific resonant Si-NS to control independently MD and ED radiation patterns and magnetic and electric Purcell effects.

Abstract

This study reports a metamaterial consisting of a nanofluidic channel sandwiched between plasmonic resonators and a metal film. This configuration enables a controllable delivery of molecules into the most enhanced field arising from the quadrupole mode of the structure, forming a strong plasmon–molecular coupled system. It offers an ultrasensitive IR spectroscopic platform for identification and quantitative detection of molecules. Moreover, the precise handling of molecules in a well-controlled nanogap allows us to study the molecular structures and physical properties of molecules confined in nanospaces.

1. Introduction

IR absorption spectroscopy is one of the most powerful biochemical analysis tools, as it extracts essential information of chemical bonds and molecular structures in a label-free fashion. It is especially useful in tracing subtle changes of the conformational structures in response to surrounding environment or probing the kinetics of chemical events. Recently, surface-enhanced and plasmonic metamaterials-based IR spectroscopies have emerged as promising approaches to improve the sensitivity, owning to the localized enhanced electromagnetic field (“hot-spots”) in plasmonic materials. It is of significance to control the spatial overlapping of molecules and hot-spots, yet it is a long-standing challenge, since it involves the handling of molecules in nanoscale spaces. Here we proposed and demonstrated a structure that significantly enhance the resonant coupling of molecules and plasmonic structures by combining molecules and plasmonic resonators in a heterogeneous configuration. It is composed of plasmonic resonators and a metal film sandwiched by a nanofluidic channel. The fluidic channel enables a controllable and effective delivery of molecules into the most enhanced electromagnetic field of the resonance arising from the interference between the top resonators and bottom metal mirror, which is known as “MIM absorber” structure. It is thus expected to perform as an ultrasensitive IR spectroscopic platform for molecular detection. Notably, the manipulation of molecules in 10–100 nm spaces also allows us to characterize the molecular structures and physical properties of molecules confined in nanospaces, which is crucial to understanding the chemical processes in biological or nanomaterial systems.

2. Results and Discussion

2.1. Principle and fabrication

The structure comprises of a metal mirror and a batch of periodic nano square-disks separated by a nanofluidic channel of several tens of nanometers in depth, as described in Fig. 1(a). The numerical calculation of the corresponding system carried out by the finite-element method (FEM) reveals that there is a strong resonant mode that exhibits the intrinsic property of trapping the plasmonic energy inside the gap between two metal layers (Fig. 1(b)) (i.e., quadrupole mode). When molecules are introduced into the channel, vibrational modes of molecules can strongly couple with this plasmon modes, resulting in a large change in the far-field spectral response of the system, and signals of molecules are apparently amplified. The nano square-disk arrays and the metal mirror were fabricated on two separate SiO₂ substrates prepared with fluidic channels in advanced, and the two substrates were bonded at room temperature to form a sealed fluidic device. The nanogap between two structures is well-controlled at nanometer precision in fabrication. The optical responses were measured at normal incident angle by using an FT-IR spectrometer equipped with a microscope.

Figure 1. (a) Concept and (b) Calculated field distribution in plasmonics-nanofluidics hybrid metamaterial
2.2. Ultrasensitive IR spectroscopy

To demonstrate the performance of our device in detecting and tracing the quantities of molecules, we used octadecane (C_{18}H_{38}) dissolved in CCl_{4} as target molecules. The device was purposely designed to exhibit the resonance at 2800–3000 cm\(^{-1}\) that covers the C–H vibrational bands of C_{18}H_{38} molecules. Fig. 2(a) shows the reflectance spectra of a channel filled with CCl_{4} and C_{18}H_{38}/CCl_{4} solution respectively. It unveils three C–H vibrational modes including the asymmetric, symmetric stretching of –CH\(_{3}\), and asymmetric stretching of –CH\(_{2}\) as distinct peaks in the broad reflectance dip of the quadrupole mode. The precise control of molecules inside the nanogap also allowed us to quantitatively determine the molecules with prominent reproducibility, as shown in the calibration curve in Fig. 2(b). The LOD estimated from the calibration curve shows an improvement of more than two orders of magnitudes, compared to reported metamaterials-based IR spectroscopies.

2.3. Characterization of nanoconfined water

2.3.1. Molecular structures by IR spectroscopy

The spatial distribution of the enhanced electric field indicates that the vibrational modes of the molecules confined in the nanogap can be selectively detected. Exploiting this characteristic, we have successfully measured the infrared absorption characteristic and elucidated the molecular structures of water confined in a 10–100 nm gap. The reflectance spectra when the filling liquid in a 10 nm gap is changed from D\(_{2}\)O to H\(_{2}\)O in Fig. 3(a) exhibits the asymmetric Fano line-shape, which is typical for the coupled systems. The drastic change of reflectance from less than 10% to more than 70% in the presence of water indicates the detection of water confined in 10 nm gap with a pronounced sensitivity, even it is equivalent to merely 30 layers of water molecules. The absorption spectrum of confined water is fitted from the coupled spectrum using the temporal coupled model theory, and the absorption spectrum of the confined water is retrieved from the fitting (Fig. 3(b)). The modes of wavenumber lower than 3200 cm\(^{-1}\) can be attributed to the so-called “network water” (NW), which corresponds to the strongly H-bonded water molecules. The component with wavenumber in the range of 3300-3550 cm\(^{-1}\) can be assigned to the “liquid water” (LW) representing the bulk water. The higher wavenumber higher than 3550 cm\(^{-1}\) can be assigned to interfacial water (IW) molecules with a small number of H-bonds. Our result reveals a high ratio of NW of water confined in ~10 nm, compared to the bulk one. Our method is also able to distinguish the subtle differences in the molecular structures, revealing the scaling behavior of confined water in 10-100 nm size regime.

2.3.2. Measurement of refractive index

The aforementioned quadrupole mode also carries information on the dielectric property of the molecules in the nanogap. It is applied to determine the refractive index (RI) of nanoconfined water. The device was designed to exhibit the resonance at 5000-6000 cm\(^{-1}\), which is “off-resonant” with vibrational modes of water and common organic solvents. Water and various organic solvents were introduced into the device, and the resonant wavelengths of the corresponding plasmon modes were measured and plotted against the published RI values of the corresponding solvents. The result unveils that the resonant peaks of confined water is significantly deviated and blue-shifted from the linear relationship. This result indicates that water confined 10 nm exhibits smaller RI with respect to bulk water. This property is in consistence with the molecular structures revealing the presence of a strongly H-bonded water under nanoconfinement. We also succeeded in determining for the first time the RI value of water confined in 10-100 nm gap.

3. Conclusions

A plasmonics–nanofluidics hybrid metamaterial that enables the handling of molecules at the nanoscale hot-spots of the electromagnetic field was demonstrated. It offered a platform for IR absorption spectroscopy that is not only superior in sensitivity but also able to address some critical issues in molecular detection. It also offers powerful method for in-situ study of nanoconfined molecules and chemical reactions, that gives us a fundamental insight into the nanoconfinement effects.

Abstract

The detection of biomolecules can be boosted by coupling them with field enhancing substrates such as plasmonic nanoantennas or photonics crystals. Many natural occurring molecules are chiral, thus detecting schemes have to discriminate from two opposite enantiomers. This can be obtained by suitable chiral substrate nanopatternig. Among different fabrication methods the self-assembly approach can lead to low cost, large area metasurfaces with desired functionalities. Here we present the optical circular dichroic behavior of some of these structures and possible applications.

1. Introduction

By proper design of basic elements, it is possible to realize metasurfaces that allow manipulation of the electromagnetic field in order to achieve desired functionalities [1]. Besides the top-down direct realization, through e-beam lithography, which gives precise and perfectly calculable results, bottom-up approaches techniques have also evolved allowing interesting reliable results with less effort for large scale metasurfaces. For example it is possible to obtain anomalous refraction [2], second harmonic generation (SHG) enhancement [3], chiral light polarization manipulation [4]. Here we present an overview of self-assembled metasurfaces that lead to an effective optical chiral response [5], that can be used as substrate for molecular recognition and enantiomer selectivity [6].

2. Nanostructured materials

2.1. Metal nano-antennas on polystyrene spheres

The self-assembled metasurface is composed by polystyrene spheres partially covered by few nanometers of metal (Cr, Ag, Au). The spheres (starting diameter of 530 nm), deposited on a glass substrate are self-organized in a hexagonal lattice. The diameter of the spheres are then reduced by selective etching up to 450nm and partially coated by 50 nm metal evaporated by an glancing angle of 45°. The 2-D periodical arrangement of the spheres can be seen in the fig.1.

Figure 1: (a) SEM image of the realized metasurface. (b) circular dichroism as a function of incidence angle for different metals (Cr, Ag, Au).

In this case we directly measured the selective absorption of circular polarized light of different handedness by using the photoacoustic absorption (PA) technique [7]. Extrinsic chiral behavior is evidence by the circular dichroism (CD) measured as a function of the incidence angle of light (fig.1).

Once the polystyrene spheres were removed, the substrate show an asymmetric nanopatterned metallic hole array that shows intrinsic chiral behavior and that can be used as ideal substrate for molecular sensing.

2.2. GaAs nanowires with asymmetric gold capping

Another metasurface consists of GaAs nanowires 5 microns long fabricated on Si substrate by a self-catalyzed approach (Fig.2). The wires are partially covered by gold that was evaporated at glancing angle [8].

On these sample we performed different measurements: photoacoustic (PA) measurements and nonlinear
measurements via second harmonic generation circular dichroism (CD-SHG).

Figure 2: (a) SEM image of the Au-coated GaAs wires; (b) scheme of the NWs structures with gold; (c) SHG-CD measurements.

The measurements were performed with different incident angles and polarization states of the light, in order to put in evidence the extrinsic chiral response of the samples.

3. Discussion

All samples here discussed show peculiar optical chiral properties due the coupling of light with the asymmetric geometrical features of metallic nanoantennas. Indeed, the geometrical arrangement of the metal clusters with high field confinement induced by metallic edges produces symmetry breaking and chiral response.

4. Conclusions

The potentiality of the self-assembled approach in the fabrication of low-cost nanostructured materials for photonics applications are here demonstrated and illustrated in some real cases. Different optical techniques, such as photacoustic absorption or nonlinear second harmonic circular dichroism are used in order to put into evidence the effective chiral behavior of such metamaterials, which can be utilized in different potential applications, such as selective molecular recognition.

Two-Photon Excitation of Biomolecules using Mid-infrared Surface-Plasmon Polaritons confined on Metasurfaces

Abstract

We explored the potential of using metasurfaces to excite and detect photoluminescence from biomolecules, in particular double-strained DNA (ds-DNA). The excitation of the genetic material placed over a metasurface can be mediated by surface plasmon polaritons (SPPs), that became responsible to excite the ds-DNA aqueous solution. In our case, two photon excitation (TPE) at 800nm was used to excited the molecule close by the metasurface generating spectral images recorded in the region of 400nm to 700nm. The DNA fluorescence intensity in the presence of nanostructure came out orders of magnitude as that obtained in the region without the nanostructure. The interaction between SPPs and DNA molecules happened to increase the optical activity (emission rate) of the molecules. The plasmonic fields generated by the nanostructures decreased the emission life time of the molecules and increased their fluorescence, which only happened in case of TPE.

1. Introduction

Two-photon fluorescence excitation is a very powerful method for enhancing the sensitivity and resolution in farfield light microscopy of biomolecules. To achieve the ideal conditions an intense light source must be focused to increase the density of photons per unit volume and per unit time becomes high enough for two photons to be absorbed into the same molecule. In our case the intense laser field was used to generates SPPs on a metasurface which consist in an array of concentric 50nm tick rings. The generated confined plasmons can enhanced the fluorescence [1] and is being applied in the last decades in many research areas in particular for bio-sensing. The transfer of energy between photonic molecules and metal surfaces is an ultrafast process (in the order of pico-seconds) and only can be effective if the molecule is close to the metal surface (< 60nm). The local electromagnetic field due to SPPs, enhance the fluorescence of photoexcited molecules to several orders of magnitude because SPPs can interact with the macromolecules that are in the vicinity of the surface, up to distances of around 300nm, which is the extension of the evanescent field. In this paper we used the plasmonic properties of a nanostructure to enhance the fluorescence signal of intrinsic DNA, whose week fluorescence intensity [2], makes it challenging to develop fluorescence-based DNA biosensors and devices [3, 4, 5]. No functionalization of a surface is needed to the excitation and detection. The goal of this work was towards making DNA a more viable material to be efficiently useful in photonic devices, such as photonic biosensors and was also to study the effects of two photons excitation.

2. Experimental Methods and Results

For the study of the interaction of plasmon-polaritons with ds-DNA molecules, concentric metallic nanostructures (CMN) were designed on a 200nm thick Silver film which was deposited on a Borofloat 33- Schott glass (refractive index around 1.45 in the study region of 450 to 850nm). The fabrication of nanostructures took place by using the ion beam lithography technique with a FEI Quanta 3D 200i microscope. The nanostructures were formed in to concentric arrangements of circular slits with circumferential diameter d, up to 20µm, width of 50nm for each circular slit and the separation between each two (that is, the periodicity) of 400nm. This geometric clear shows the SPPs by using polarized laser fields (see Figure 1). The excitation and detection was performed using a Zeiss DSM 700 confocal optical microscopy. The ds-DNA in aqueous solution (230µg/l) was dropped over the surface covering complete the nanostructure. The result shown on Figure 2 shows SEM of the CMN and horizontal and vertical polarized dark field images of extraordinary optical transmission. The transmitted spectra shows a transmission peak around 850nm, close to the laser excitation. The results shown on Figure 2 represents spectral images obtained with laser field set at 800nm. For the image with the aqueous solution of DNA (c) an increase of signal in the region of 450nm to 500nm is observed due to the emission of low energy states of the molecule. For images (a) and (b) we observe the luminescence from the generation of electronic excitation in the silver film. The increase in the emission signal detected in the nanostructure region can be observed by the decrease in the total lifetime of the radiative process. Figure 3 shows a Fluorescence Lifetime Images (FLIM), with laser excitation at 800nm. The image of Figure 3 (c) and the time spectrum observed in (d) shows clear that the mean lifetime for molecules close by the nanostructure is of the order of 250µs, whereas for molecules away from the metal surface this is on the order of 2ns.
Figure 1: (a) and (b) are the scanning electron microscopy images of the nanostructure. (c) and (d) shows the horizontal and vertical polarized dark field images of extraordinary optical transmission obtained through the nanostructure. (e) is the simulation spectrum of the EOT obtained through the CMN, without and with water over the surface. (f) is the schematic representation of the assembly detection for the experiment, where Ex is the excitation source.

Figure 2: Spectral images of the CMN with three different interfaces exposed to TPE excitation(800 nm). (d) Spectral decomposition of the images of the plasmonic CMNs (a),(b) and (c).

3. Conclusions

The use of two-photon spectroscopy though plasmonic nanostructures shows to be feasible for the detection of biomolecules, especially ds-DNA in aqueous solution, without the use of biomarkers. All optical process of excitation and detection occurs through the mediation of SPPs.

“Hot” electron generation in plasmonic nanostructures – thermal vs. non-thermal effects

Yonatan Sivan¹, Yonatan Dubi²

¹Unit of Electro-optic Engineering, Ben-Gurion University, Israel, ²Department of Chemistry, Ben-Gurion University, Israel, *corresponding author, E-mail: sivanyon@bgu.ac.il

Abstract
We present a self-consistent theory of the steady-state electron distribution in metals under continuous-wave illumination which treats both thermal and non-thermal effects. We show that reported faster chemical reactions likely originate from pure heating.

The possibility to use high energy (aka “hot”) electrons in illuminated plasmonic nanostructures for applications such as photo-catalysis, sensing, up-conversion attracts a lot of interest recently. A complete theoretical model of this problem should account for the non-equilibrium nature of the electron distribution, but also for the possibility of both the electrons and the underlying lattice to heat up. Furthermore, the theory should take into account that technologically important applications such as photocatalysis are performed under continuous wave (CW) illumination, driving the electron distribution into a non-equilibrium steady-state.

Surprisingly, to date, there is no comprehensive theoretical approach that takes all these elements into account. Typically, the transient electron dynamics are studied [1], focusing on an accurate description of the material properties, e.g., metal band structure and relaxation rates; some studies also accounted, to some extent, for the electron temperature and permittivity dynamics. However, it is not a-priory clear what can be learned from the transient case about the steady-state case. On the other hand, the few pioneering studies of the steady-state non-equilibrium (e.g., the most recent and comprehensive [2]) accounted for the electron distribution in great detail, but did not adjust the electron temperature, and ignored the heating of the phonons.

Here, we develop a coupled Boltzmann-heat equations formulation for calculating the electron distribution in plasmonic nanostructures under continuous wave illumination, taking into account non-equilibrium and thermal effects on the same footing. This is done by ensuring a total energy balance and basic thermodynamics. This allows us to determine self-consistently and uniquely the increase in electron and lattice temperatures above ambient conditions although the system is inherently away from thermal equilibrium. In particular, we show that the electron and lattice temperatures are nearly identical, providing, to our knowledge, the first ever justification for the use of classical single temperature models.

Our results also provide the first ever quantitative prediction of the high energy nonthermal electron densities, and show that close the Fermi level, the non-equilibrium is dominated by holes (rather than by electrons, as it usually claimed)! Most importantly, we find that most absorbed power causes heating, and only an extremely small fraction actually leads to high energy electron generation.

Finally, we develop a simple model for the catalytic enhancement for chemical reactions based on illuminated metal nanoparticles. It shows that the faster chemical reactions reported in many previous papers are extremely unlikely to originate from the high energy non-thermal electrons. Instead, the faster reactions very likely originate from a purely thermal effect.

![Fig. 1 (Left) Deviation from the equilibrium distribution at the ambient electron temperature as a function of electron energy for various incoming field levels; the system is an Ag](image-url)
nanoparticle illuminated at resonance. The dashed vertical line represents the Fermi energy. (Right) Power densities going into the thermal electron and lattice systems (green diamonds and orange triangles, respectively; indistinguishable), compared with the power going to the non-thermal electrons (blue squares), all as a function of local field. The power fraction that flows into the thermal channels is substantially larger than that going into generating non-thermal electrons.

Revisiting Plasmonic Photocatalysts Based on Titanium Nitride Nanoparticles

Diane Rawach¹, Peipei Liu¹, Peikui Wang¹, Jerome Claverie¹

¹Université de Sherbrooke, Dept of Chemistry, Sherbrooke, Canada

Abstract
The use of plasmonic nanoparticles has been limited to noble metal NPs such as Au, Ag because they exhibit strong resonances in the visible region but have poor chemical and thermal stability and are costly. An alternative is the use of transition metals such as TiN NPs which exhibit strong resonances in the red, high mechanical strength, durability, thermal and chemical stability. We have combined the TiO₂ nanobelts decorated with TiN NPs to achieve an enhanced photodegradation photocatalyst. Photodegradation of organic pollutants are performed on TiO₂ decorated with TiN NPs to study their photocatalytic efficiency.

1. Introduction
The rapid increase of environmental water pollution has seriously affected human health and the entire ecosystem [1-3]. Consequently, a green, cost-efficient method for removing the dissolved organic compounds (dye) from waste water is desired. Heterogeneous photocatalytic degradation technologies are one of the most promising method to purify the dye contaminated water [1]. The degradation efficiency depends on the type of photocatalyst. The plasmonic photocatalyst has been highly investigated to enhance the photocatalytic ability because of localized surface plasmon resonance (LSPR) effect which leads to the expansion of light absorption and enhance charge separation [4-5].

Titanium nitride nanoparticles (TiNx NPs) are hard materials with gold-like optical properties and significant plasmonic performance, allowing them to expand light absorption to visible and near-infrared light region [6-7]. In comparison with noble metals, TiNx NPs also possesses superior performance such as high temperature durability, chemical stability, low cost, which has great potentials for various environmental application [6]. Recently, the plasmonic enhancement of photocatalysts based on TiN has been reported [7-8]. Naldoni et al. have found TiN NPs injected into TiO₂ nanowires show superior performance for water splitting [7]. Edwin et al. show TiN/TiO₂ nanoparticle composites with plasmonic enhancement for H₂ evolution [8]. Therefore, the TiN-based photocatalyst is still of great interest for dye photodegradation.

TiO₂ nanobelts have unique one-dimensional (1D) structure and high crystallinity [9]. 1D favors the transport of electrons with high speed along the axial direction [9]. High crystallinity can decrease the recombination of electrons and holes because of low defects [9]. However, TiO₂ nanobelts with wide band gap is only active in UV light, which severely limits its photoactivity under solar irradiation. The decoration of TiO₂ NBs by plasmonic materials is one of most effective method to improve its properties. Here, the plasmonic TiNx NPs is combined with TiO₂ NBs, by a facile method through impregnation for photocatalytic degradation purposes.

2. Experimental Section
2.1. TiO₂ Nanobelt Synthesis
The TiO₂ NBs were prepared by a hydrothermal method. P25 (0.8 g) was added into a concentrated NaOH aqueous solution (10 M, 180mL) in a Teflon-lined stainless-steel autoclave which was subjected to 200°C for 24 h. The resulting white fluffy product was collected and abundantly washed with deionized water and 0.1 M HCl until the pH of the washing solution was less than 7. The as-washed samples were then calcinated at 600°C for 3h30.

2.2. TiN/TiO₂ preparation
The TiN/TiO₂ was prepared using the impregnation method. The TiN solution was added to the TiO₂ NBs in water and the pH was adjusted to pH=3 with HCl solution (0.1M). The mixture was washed thoroughly with water a few times and finally with EtOH. The as-washed mixture was then dried at 80°C for 12hrs.

2.3. Characterization
SEM images of the TiO₂ nanobelts decorated with titanium nitride nanoparticles (20 nm) were taken using a Hitachi S-4700 Field Emission SEM. Transmission electron microscopy (TEM) and high-resolution transmission electron microscopy (HRTEM) analyses were taken using a Jeol JEM-2100F. The AFM images were taken using a Bruker/VEECO Icon dimension 3100 with scan assyst.

2.4. Photodegradation
The photodegradation tests were done using the photochemical reactor Rayonnet RPR-200 equipped with sixteen lamps of a wavelength of 253.7 nm and a power of 12.5 mW/cm². Typically, 40 mg of the photocatalyst were dispersed in 40 mL of 40 mg/L methylene blue (MB). This solution was put under stirring in darkness for 1h. The solution was irradiated at room temperature by UV light.
3. Results and Discussion

3.1. Morphology

The morphology of the TiN\textsubscript{x}/TiO\textsubscript{2} nanobelts were characterized using different microscopy techniques as seen in figure 1. All three microscopy techniques show very well the nanobelt morphology: very long (>1μm) and very thin (a few nm). In figure 1 B) it is possible to see that the titanium nitride NPs are dispersed uniformly on the TiO\textsubscript{2} nanobelts.

Figure 1. A) SEM B) TEM C) AFM images of TiN\textsubscript{x} spherical NPs (20nm)/TiO\textsubscript{2} nanobelts.

3.2. Phase structure

The phase structure of the TiN\textsubscript{x}/TiO\textsubscript{2} nanobelts was measured using XRD as seen in figure 2. The XRD pattern clearly indicates that the TiO\textsubscript{2} obtained is pure anatase. However, for the TiN\textsubscript{x}/TiO\textsubscript{2} NBs, it was not possible to detect the titanium nitride nanoparticles due to the low quantity used (0.1 wt% of TiN NPs). Moreover, as seen in figure 3, the HRTEM-EDS clearly shows the presence of the titanium nitride nanoparticles adsorbed on the TiO\textsubscript{2} nanobelts.

Figure 2. XRD of TiO\textsubscript{2} NBs and TiO\textsubscript{2} NBs decorated with titanium nitride nanoparticles (20nm).

Figure 3. HRTEM-EDS of TiO\textsubscript{2} NBs decorated with titanium nitride nanoparticles (20nm).

3.3. Performance

The preliminary performance of the TiN\textsubscript{x}/TiO\textsubscript{2} nanobelts was measured by performing the photodegradation of an organic dye (in our case MB and MO). As seen in figure 4, the photodegradation efficiency of MB and MO by TiN\textsubscript{x}/TiO\textsubscript{2} nanobelts photocatalyst was 97.2% and 86.3% in an hour respectively which shows high photocatalytic activity.

Figure 4. Photodegradation of MB and MO by TiN\textsubscript{x}/TiO\textsubscript{2} nanobelts as the photocatalyst.

4. Conclusion and Perspective

TiN\textsubscript{x} NPs as an alternative plasmonic material is being actively investigated. The TEM and SEM images show that the TiN\textsubscript{x} NPs were roughly dispersed onto TiO\textsubscript{2} NBs. It also shows that the length of TiO\textsubscript{2} NBs and the size of TiN\textsubscript{x} NPs is 1μm and 20nm respectively. The TiN\textsubscript{x} phase could hardly be detected by XRD due to its low content. However, through the HRTEM-EDX analyses, the TiN\textsubscript{x} phase was confirmed. The preliminary photodegradation of MB and MO by the TiN\textsubscript{x}/TiO\textsubscript{2} photocatalyst shows promising results with the TiO\textsubscript{2} NBs. The performance of the TiN\textsubscript{x}/TiO\textsubscript{2} photocatalyst will be thoroughly investigated by PEC tests, H\textsubscript{2} evolution and compared with other photocatalysts.

Abstract

Nanoscale second harmonic generation (SHG) and photon pair generation is quantitatively investigated in hybrid nonlinear/plasmonic antennas by coupling quantum and numerical approaches. We demonstrate that the origin of SHG in plasmonic nanostructures are often not coming from the usually invoked local surface nonlinearity and that measurable photon pair production are reachable at the single nanostructure level.

1. Introduction

Although nonlinear photonics addresses many applications in the field of quantum optics, the realization of devices at the nanoscale raises major challenges. Reducing the size of a medium to a few tens of nanometers dramatically drops its optical nonlinear response. Among the different strategies that can be adopted to compensate that loss of efficiency, we chose to enhance the local fields with plasmonic nanoantennas. Such structure response depends on their shape, the presence of substrate, but also the tight focusing generally used, so that an in-depth investigation requires efficient numerical tools.

If simulations relying on a classical description are sufficient for up conversion processes, such as second harmonic generation (SHG), a quantum approach is required for the investigation of entangled photon pair production via spontaneous parametric down conversion (SPDC), where quantum fluctuations play a major role. In this context, we have developed for the first time simulation tools mixing quantum formalisms and numerical approaches solving Maxwell’s equations for investigating hybrid nanostructures. This allows a quantitative evaluation of the photons pair production yield in realistic experimental configurations.

2. Methods

Realistic experimental features such as laser specifications (polarization, wavelength and beam profile), excitation and collection optical path (through a high NA objective and several medium interfaces) are implemented analytically. The induced currents in the sample (at the excitation and the emission wavelengths) are computed numerically with a finite element method following classical equations \cite{1}. This approach has been validated by quantitative comparison with experimental data obtained by SHG in plasmonic nanoantennas.

In a second step, both up- and down-conversion processes were described through a quantum formalism based on measure theory. The former (SHG) was used to validate the overall approach, by comparing with the classical results discussed above, while the latter (SPDC) opens completely new horizons for investigating quantum optics at the nanoscale \cite{2}. This quantum approach requires the knowledge of the near-field distribution of the pump beam as well as the Green functions relating any point in the nanostructure to the two or four photon detectors, depending on the configuration (polarization resolved measurements as well as second order photon correlation investigation). Both are accessible using the numerical tools developed previously so that the absolute number of correlated photon pairs can be evaluated. Transmission efficiency through an experimental setup can also be included to match realistic constraints as close as possible. This is of fundamental importance as the actual correlation rate drastically drops down with increased losses.

3. Discussion

Using classical numerical simulations, we investigate the origin of the second harmonic signals in different nanostructures as arising from local surface or non-local bulk contributions depending on the metal (aluminum or gold) and its crystallinity. Through a quantitative comparison with experiments, we show that, most of the time, the source usually considered in the literature is not the dominant one and can even be overpassed by largely disregarded contributions.

With our quantum simulations, we demonstrate, for the first time, that photon pair creation is achievable in plasmonic nanostructures holding a nonlinear nanocrystal, under realistic experimental configurations \cite{2}. We show how plasmonic resonances tailor the SPDC spectral response and replace the phase-matching condition at the nanoscale. Optimized photon pair production rates are obtained by
tuning the antenna morphology for a given excitation and emission wavelength, yielding doubly resonant nanostructures. Huge (hundred- to thousand-fold) SPDC enhancement factors are reached by matching the nonlinear nanocrystal size with the near-field spatial distribution. As a consequence, a trade-off must be found between large enhancements and large emission rates, as the latter are intrinsically driven by the squared crystal volume. This work paves the way for investigating entangled photon pair generation at the nanoscale for an ultimate integration of quantum information and cryptography devices.

4. Conclusions

Thanks to numerical simulations accounting for all experimental features (presence of substrate, large numerical apertures, etc.), we have quantitatively inferred the origin of second harmonic generation in plasmonic nanostructures and demonstrated that the generally invoked mechanism is not the dominant one in the studied gold nanostructures. Extending these simulations to the quantum regime, we have shown that photon pair production is achievable provided that a nonlinear nanocrystal is inserted into the gap between plasmonic antennas. Although the net photon pair generation rate is still modest, this is a first proof of principle holding promise for future improvement.

Abstract

Hybrid plasmonic nanoparticles, designed to encompass dielectric or semiconducting coatings, whether of biological nature or not, are fundamental components in sensing platforms or photocatalytic substrates. While the overall properties of the nanomaterial define its performance, we argue that it is in general the interface between the metal and the surrounding medium that plays the most important role. Herein, we will discuss how studying and ad hoc tailoring interfaces can lead to achieving excellence in performance. We will discuss applications in both photocatalysis and surface enhanced Raman spectroscopy (SERS)-based sensing, demonstrating that only accurate assessment of the interfacial properties can push the boundaries and lead to unexpected results.

1. Introduction

Gold nanostars (NS) have recently emerged as powerful nanostructures for surface enhanced Raman scattering (SERS) [1-3], MRI imaging [4], and hot electron-driven photocatalysis [5]. In particular, numerical simulations and photocatalytic experiments have shown that, in nanostars placed in close proximity to TiO\(_2\), the location of the hot spots at the tip of the spike enables the localization of hot electrons at the metal-semiconductor interface, facilitating hot electron injection into the latter [6]. In biomedical applications, in particular those leveraging the gold nanoparticle both as field enhancer and as platform for oligonucleotide loading, proper bioconjugation schemes and surface coatings are necessary for sensitive, selective, and accurate detection of the biological targets. In both instances, careful design and control of the nanoparticle surface properties is mandatory. Herein, we discuss how the rational design and the careful synthesis of the gold-TiO\(_2\) interface leads to efficient injection of hot electrons generated at the tips of the nanostar into the thin semiconductor layer and how the presence of a perfectly realized interface leads to hydrogen production from water with yields that are seven times higher than those measured in systems with non-ideal interfaces. From the biological standpoint, we will show how the careful surface functionalization of gold nanostars with RNA strands and polymer shells allows for efficient cellular uptake, endosomal escape, and recognition of mutations in influenza A (IAV) RNA strands. Furthermore, we will report how the presence of a protein corona on the nanoparticles can affect their ability to recognize their viral targets, but not to the extent of completely cancelling their responsiveness to it.

2. Hot Electron Photocatalysis

Surfactant free gold nanostars were synthesized following traditional solution-based methods [7]. Because these nanoparticles have shown to be sensitive to high temperature and undergo restructuring at the tips, traditional protocols for crystallization of amorphous titania, which are carried out at least at 200°C, could not be followed. Therefore, we developed a new low temperature protocol leveraging titanium isopropoxide (TTIP) as the TiO\(_2\) precursor and running for 2 days in isopropanol at 70°C. While one could expect that carrying out the reaction at slightly higher temperature would have allowed us to reduce its length, this approach was not feasible due to the sensitivity of the nanostars to temperatures in excess of 80°C. The reaction time proved also to be a sensitive knob to tune the semiconductor shell thickness, allowing us to limit it to 4 nm, which is thin enough to enable effective hot electron transfer to the surrounding water environment. Furthermore, our protocol led to the epitaxial growth of TiO\(_2\) onto gold, further facilitating electron transfer owing to an unstrained interface. The overall lack of impurities at the metal-semiconductor interface further removed obstacles and freed-up the electron path. Finally, the synthesis produced an ideal mix of rutile and anatase in the thin titania shell, which has been hypothesized as ideal for band alignment with the water reduction reaction. Photocatalytic conversion experiments were carried out employing broad band illumination (200-1500+ nm) of a Xe-arc lamp. Using methanol as the sacrificial solvent for hole capture, we observed that the core-shell nanostars with the ideal interface produced at least 7-times more molecular...
hydrogen compared to the case in which the shell thickness was higher, the interface was not epitaxial, or the shell was not crystalline. Furthermore, comparison with published literature on similar systems, led us to calculate improved H$_2$ yields in excess of four-fold. Control experiments carried out on TiO$_2$-coated gold nanorods confirmed the need of realizing an ideal interface for efficient hot electron-based photocatalysis [8]. Because gold nanorods are synthesized employing cetyltrimethylammonium bromide (CTAB) as shape inducing surfactant, and because the micelle it forms is sensitive to alcohols, we needed to carry out the reaction in water. We could have employed protocols reported in the literature in which polymer shells are introduced to replace CTAB, but those would have introduced steric hindrance against electron transfer. Because TTIP is very reactive in water, we introduced acetic acid to slow down its kinetics. Nonetheless, the synthesis was not as effective as what observed in nanostars, producing only partial titania coating on the nanorods. Even so, our approach led to yields of hydrogen higher than reported in the literature, suggesting once more the importance of unhindered interfaces in hot electron-based photocatalysis.

3. Detection of Viral RNA

The influenza A virus (IAV) is a segmented RNA virus whose high rate of mutation affects our ability to design and develop vaccines with broad spectrum effectiveness over long-time scales. This issue is similarly encountered for other RNA viruses, such as HIV, dengue, Ebola, etc. When IAV replicates, the high degree of mutations produced leads to the generation of highly defective genomes, some of which lacking the majority of the genes. It has been hypothesized that these products, called defective interfering particles (DIPs), could be important allies against the virus, as their presence has been associated to reduced pathogenicity. We demonstrate here that gold nanostars and surface enhanced Raman spectroscopy (SERS) can be employed to study viral mutations in intact cells at the single cell level. This single-cell approach could be interesting to understand viral superspreaders and associate viral evolution dynamics to environmental conditions and interactions. We synthesized gold nanostars using a known surfactant free protocol [7] and functionalized them with an RNA beacon carrying a fluorophore at the 3’ terminus. Fluorophores are known to have good Raman cross sections as well and can be useful for dual modality imaging. The proximity of the dye to the nanostar surface, achieved upon hybridization with the targeted strand, yields intense SERS signals unique to the fluorophore. The signal intensity is the highest in the presence of the perfectly complementary target, and linearly decreases with the number of mismatches. Importantly, no signal is observed when a random target is introduced, as expected. To achieve these results and render them quantitative, it was necessary to carefully understand the metal-RNA interactions, model the distance dependence of the E-field enhancement, and ensure that proteins in the surrounding medium, forming a thick shell on the nanostar, also known as protein corona, would not affect the performance of the sensor. To assess this hypothesis, we spiked cell lysates with target RNA and determined that while the signal was slightly reduced, the sensitivity and selectivity were not affected. Studies in individual intact cells further proved the validity of the assay. However, to avoid retention in the endosomes upon uptake, we needed to further engineer the surface with a polymer coating layer enabling endosomal escape. This functionalization step proved to lead to increased retention in the cytosol with minimal loss of signal intensity. Similar results were observed when studying the effect of protein corona using fluorescence as the transduction mechanism. Overall, these results are promising and suggest that hybrid plasmonic nanoparticles could be relevant sensing platforms for the SERS-based detection of intracellular events.

4. Conclusions

Hybrid nanostructures based on the use of gold nanostars have shown promising applicability in studies involving electric field enhancements and hot electrons. In both cases, the need to carefully design, engineer, and realize a perfect metal-nonmetal interface is mandatory to optimize performance and achieve expected or transformative results, especially if quantification is needed.

Abstract
In this talk, we will overview the sensing applications of plasmonic metamaterials including Au nanorod arrays and metal-dielectric multishells.

1. Introduction
Surface plasmons are the collective oscillations of electron gas at a metal-dielectric interface, which have the ability to concentrate light on subwavelength scales, produce high local-field intensities and generate energetic hot electrons. Benefiting from the high sensitivity of plasmonic modes to changes in the local dielectric environment, surface plasmons are very promising for optical sensing applications. In this talk, we will overview the sensing applications of plasmonic metamaterials including Au nanorod arrays and metal-dielectric multishells.

2. Results
Firstly, we will discuss the enhanced sensitivity (more than 30,000 nm per refractive-index unit) of Au nanorod array to refractive-index variations of the medium between the rods for (bio)chemical[1] and ultrasound[2] sensing, benefiting from a substantial overlap between the probing field and the analytes incorporated between the nanorods and a strong plasmon-mediated energy confinement inside the porous nanorod layer, as shown in Fig. 1a.

Secondly, we will discuss the extension of sensing capabilities of the nanorod metamaterials by functionalization, for example, high-sensitivity optical hydrogen gas sensing by coating the surface of Au nanorods with a thin layer of palladium[3], as shown in Fig. 1b.

Thirdly, we will introduce an extremely compact and versatile sensing platform based on plasmonic tunnel junction array constructed on a nanorod metamaterial[4], as shown in Fig. 1c. During the tunnelling process, inelastic electron tunnelling excites plasmonic modes in the nanorod metamaterial, while elastic electron tunnelling produces energetic hot electrons in the nanorod tips. The hot electrons are harvested to activate chemical reactions in the tunnel junctions with analytes, while the radiative decay of plasmons which can be observed as a light emission from the metamaterial is used for the high-sensitivity detection of the highly-confined reactions.

Finally, we will show hyperbolic metaparticles based on metal-dielectric multishells (Fig. 1d)[5], which are promising for applications such as sensing and plasmon-enhanced spectroscopy.

Fig. 1. (a) Schematic of the nanorod metamaterial for (bio)chemical sensing. (b) Schematic of nanorod metamaterial for hydrogen sensing based on an Au/Pd nanorod array. (c) Plasmonic tunnel junction based sensing platform. (d) TEM image of gold-silica multishells.
3. Conclusions

In conclusion, plasmonic metamaterials including Au nanorod arrays and metal-dielectric multishells are promising platforms for high-sensitivity sensing applications.

Folding a 2D material into a W-shape periodic nano-structure: the case of a gold nano-layer and the consequences on its plasmonic and photonic properties

Abstract

Our experiments and simulations show notable effects in the photonic and plasmonic properties when transitioning from a single flat gold layer to a periodically folded layer. In particular the coupling of surface plasmon polaritons to free-space propagating waves becomes possible through the refraction orders, some localized resonances along the segments created by the folding are observed and result in an increased absorption, wedge/corner resonances with a strongly localized enhanced electric field are also observed.

1. Introduction

We managed to fabricate and study theoretically gold nano-structure with a shape of a periodic W. These structures are interesting for possible applications such as control of the LDOS, application to sensors and control of SPP. And we were also interested in the more fundamental aspect of the study of the transition between a single layer and a folded W-shape gold layer, since this is a way to structurate a 2D material.

2. Sample fabrication and measurement

The first part of the sample fabrication consists in fabrication of a silicon matrix in which the metallic structure will be later deposited. The grating structure is projected onto a silicon nitride (Si₃N₄) mask layer above the silicon substrate. Reactive-ion etching (RIE) is used to create the grooves and because of the silicon anisotropy, the etching rate is not the same along the different crystal axes. At the beginning of the etching process, trapezoidal grooves appear; And with a precisely matched etching time, the trapezoidal grooves change into triangle grooves. Figure (1) shows an example of such a silicon matrix. After the silicon mould is finished, metal is deposited on the surface. Template stripping is used to do metal lift-off, and metal is easy to remove due to the bad adhesion between metal layer and Si surface.

The resulting metallic structure on its polymer substrate was then put in an optical bench to measure its transmission in the visible range (400-900nm), for various angles of incidence and both linear polarizations.

Figure 1: One of the silicon matrices used for the moulding of the gold nanostructure.

3. Theoretical study

The gold W-structures are characterized by complex spectra that only rigorous electromagnetic numerical methods are able to fully describe accurately. However we were interested in understanding the underlaying phenomena that distinguish these folded structures from a single flat gold layer. For this study we used the differential method for gratings [1],[2] and Chandezon [3] method as theoretical tools to explore further the properties that are more difficult to access experimentally, such as the near field and for extensive parametric studies. And we were able to distinguish at least 3 of different types. First the periodic nature of the structure create diffraction orders which play a fundamental role in the patterning of the spectra and also importantly, allow the coupling of SPP even for free space propagative waves (Fig.2). Another interesting phenomena is the presence of localized plasmon resonances along the segments created by the folding (Fig.3)). Lastly, a sharp field resonance can occur at the edges of the structure. A very localised enhancement of the electric field can be obtained, up to a factor x20 in the case corresponding to one of our sample of 400nm period and a folding angle of 54.7.
Figure 3: Local field map of a gold W-structure with a 600nm period and 50nm height, for a wavelength of 770nm corresponding to a 2nd order segment resonance. Notice that the phenomena which corresponds to the propagation of a surface plasmon along one segment of the W, depends little on the angle of incidence.

Figure 2: Absorption map as a function of the incidence angle and wavelength in the case of a slightly folded gold layer slightly with an angle of 10 degrees from the flat surface. The surface plasmon polariton coupling with (-1) and (+1) orders is clearly visible in the upper left corner, where increased absorption above the limit of (-1) (dark dashed line) and (+1) (white dashed line) orders. A similar signature as the plasmon in Kretschmann configuration for a single layer also appears on the right side of the vertical yellow line representing the total internal reflection limit.

4. Conclusion

Now that our fabrication method is validated and we have some theoretical elements of understanding regarding the transition from a flat layer to a periodically folded structure, we would like to explore other original 2D materials such as graphene.

Ultrafast Nanophotonics and Quantum Optics in Nano-bio Assemblies, Colloidal Nanostructures, and Metamaterials

Gary P. Wiederrecht *

1Center for Nanoscale Materials, Argonne National Laboratory, Lemont, Illinois 60437, USA
*corresponding author, E-mail: wiederrecht@anl.gov

Abstract

We describe the ultrafast dynamics and quantum optic behavior of three different light-activated hybrid nanostructures. These include colloidal semiconductor nanoplatelets, chromophore-doped peptide bio-assemblies, and plasmonic gap-mode metamaterials. Ultrafast transient absorption and photoluminescence studies, as well as single photon correlation studies, are described. Insight into the design considerations for cooperative nanoassemblies for efficient light-activated structures is given.

1. Introduction

Light-matter coupling in excitonic or plasmonic nanostructures has produced phenomena of interest for nanophotonics applications, including the realization of single photon emitters for quantum optics and the generation of energetic carriers in plasmonic metamaterials for enhanced light harvesting or ultrafast nonlinear optics. A detailed understanding of the ultrafast processes produced in these nanostructures following photoexcitation is important for realizing and improving the efficiency of a desired nanophotonic application. In this talk I will first describe recent efforts to produce high quality single photon emitters using colloidal CdSe/CdS semiconductor core/shell nanoplatelets.[1,2] Interestingly, these structures show size dependent biexciton production with a quantum yield that can approach unity under ideal conditions. The emission of correlated photons is of interest for the possibility of producing entangled photon pairs from a single nanostructure for quantum information science applications. We explore the necessary parameters to produce efficient biexciton production, and also how to improve polarized, directional emission from the nanostructures. These properties are ultimately important for coupling the emission to photonic networks. In the second part of the talk, I describe our efforts to design chromophore-doped peptide nanoassemblies for long range, one dimensional exciton transport.[3] In the third part of the talk, I describe our work in generating a large number of hot electrons following ultrafast photoexcitation of nanostructured gap-plasmon metamaterials.[4,5] In this work, efforts to alter the size, shape, composition, and gap-plasmon spacing to improve hot carrier production are described. As a result of greater hot carrier production and improved signal to noise, we are further able to spectroscopically characterize the decay pathways for energetic plasmonic electrons. Evidence for anisotropic decay of nonthermal electrons is presented. I conclude by introducing some of the new user science capabilities at the Center for Nanoscale Materials, particularly for quantum optics and quantum information science.

2. Light-activated nanoscale structures

Below are some of the examples of light activated hybrid nanostructures used in these studies.

2.1. Colloidal semiconductor nanoplatelets

A new class of semiconductor quantum materials, nanoplatelets is studied for quantum optical behavior, using photon correlation optical spectroscopic methods. Semiconductor nanoplatelets are nanostructures with quantum confinement in the thickness direction. Compared to conventional semiconductor quantum dots, the lateral sizes of the nanoplatelets can be tuned from medium confinement to weak confinement. This tuning indicates that the excitonic properties of the nanoplatelets can also be adjusted. Using single particle spectroscopy, we show that with the increase of the nanoplatelet lateral sizes, the radiative decay rate, which is proportional to the oscillator strength of the nanoplatelets, first increases and then flattens out, whereas electric dipole approximation predicates a monotonic increase.[1,2] This deviation can be explained by the strong exciton-phonon coupling in the nanoplatelets at room temperature, which limits the coherent size of the excitons to a value that is smaller than the nanoplatelets lateral sizes. We also show that with the increase of the nanoplatelet lateral sizes, the photon correlation statistics, which are measures of the single photon and biexciton emission probabilities, also increase. This finding indicates that nanoplatelets with large lateral sizes accommodate more biexcitons.

2.2. Exciton transport in bio-assemblies

Light harvesting proteins are the primary light capturing entities in photosynthesis. Motivated by nature’s ability to orient and control molecular coupling in photosynthesis, we have designed peptides to not only self-assemble into 1D
nanofibers, but also coordinate a light activated chromophore, zinc porphyrin. We report an in depth study of the photophysical properties of our bioinspired light harvesting material.[3] By varying the amount of porphyrin added to the assembly, we showed the formation of an excimer complex that increased as concentration increased. Time resolved photoluminescence studies clearly show that the exciton hopping distance along the 1D nanofiber was short (~3.5 nm) when the porphyrin concentration was high. The hopping distance increased as we decreased the amount of porphyrin (~60 nm). Our investigation revealed that the excimer functioned as an energy trap, and was more likely to form in high concentrations of porphyrin, thereby reducing the exciton propagation.

2.3. Energetic carriers in plasmonic metamaterials
The creation of energetic electrons through plasmon excitation of nanostructures before thermalization has been proposed for a wide number of applications in optical energy conversion and ultrafast nanophotonics. However, the use of "nonthermal" electrons is primarily limited by both a low generation efficiency and their ultrafast decay. We report experimental and theoretical results on the use of broadband plasmonic nanopatch metasurfaces comprising a gold substrate coupled to gold or silver nanoparticles that produce large concentrations of hot electrons, which we measure using transient absorption spectroscopy.[4,5] We find evidence for three subpopulations of nonthermal carriers which we propose arise from anisotropic electron-electron scattering within sp-bands near the Fermi surface. The bimetallic character of the metasurface strongly impacts the physics, with dissipation occurring primarily in the gold whereas the quantum process of hot electron generation takes place primarily in both components. Our calculations show that the choice of geometry and materials is crucial for producing strong ultrafast nonthermal electron components. Theoretical efforts to directly extract hot carrier populations from transient absorption spectra are also described.[6]

3. Conclusions
We described the unusual nanophotonic and quantum optical behavior of three different hybrid nanostructures. A broad range of synthetic or fabrication approaches are used, including colloidal synthesis, biomimetic peptide assembly, and top-down fabrication approaches are used. Predictions and guidelines for improving the efficiency of light-activated nanostructures are given.

Polariton chemistry: thinking inside the (photon) box

Joel Yuen-Zhou

1Department of Chemistry and Biochemistry, University of California San Diego, La Jolla, CA 92093

Abstract

In this talk, I will showcase recent theoretical and computational studies that my group has carried out in terms of controlling the physicochemical properties and processes of molecular ensembles that undergo strong light-matter coupling with confined electromagnetic modes in the mid-IR range. Examples include enhancement of thermally-activated ground-state chemical reactions, design of exotic optical nonlinearities, and remote control of chemical reactions.

1. Introduction

The usual suspect of cavity quantum electrodynamics (CQED) is a “photon box” containing pristine atomic and molecular systems with highly controllable degrees of freedom, to be manipulated for quantum information purposes. In contrast, in recent years, there has been a big effort to sacrifice the simplicity of these well-defined quantum optical systems and import the CQED toolbox into the context of complex molecular materials with the idea of endowing the resulting hybrid light-matter systems with drastically different physicochemical properties and phenomena than the bare molecular counterparts [1, 2].

In this talk, I will focus on systems like the one depicted in Fig. 1, which can be described by a single mid-infrared (IR) cavity mode which can couple to \( N \approx 10^6 - 10^{10} \) molecules, each supporting a high-frequency vibrational mode (other studies involving UV-visible molecular excitations will be briefly mentioned). The low energy excitations of this problem are given by the Tavis-Cummings (TC) model. At light matter resonance (\( \omega_{ph} = \omega_{exc} \)), the cavity mode chooses a totally symmetric linear combination of molecular excitations (the “bright” state) \(|B\rangle\) with which to pair, forming hybrid light-matter modes \(|\pm\rangle = \frac{1}{\sqrt{2}}(|B\rangle \mp |ph\rangle)\) called upper and lower polaritons (UP, LP), whose energies at resonance are given by \(\omega_{\pm} = \omega_{ph} \pm 2\sqrt{Ng}g\), where \(g\) is the single molecule light-matter coupling. Note that when \(\sqrt{Ng} \gg \kappa, \Gamma\) (the photonic and molecular linewidths), the polariton states are separated in energy by a large Rabi splitting \(\Omega = 2\sqrt{Ng}g\), signaling the onset of (collective) strong light-matter coupling. However, it is important to emphasize that this superradiant enhancement of coupling comes at the expense of having a macroscopic reservoir of \(N - 1\) “dark” (subradiant) states \(|\{D_i\}\rangle\), \(i = 1, \cdots, N - 1\) that are parked at the bare molecular energy \(\hbar \omega_{exc}\) and do not mix with light [3].

2. Enhancement of thermally-activated reactions via vibrational polaritons

Recently, it has been experimentally shown that kinetics of thermally-activated reactions can be enhanced or suppressed by formation of vibrational polaritons between high-frequency molecular vibrations and optical cavities [4]. From the explanation above, it is not obvious that this strategy should work at all given that, at thermal equilibrium, most excitations are dark and not polaritonic. However, in recent work[5], we have theoretically shown, using a Marcus-Jortner electron transfer model [6, 7], that a judicious arrangement of polaritonic channels can lead to smaller activation energies that can outcompete the entropy associated with the dark reservoir (see Fig. 2). We believe that this mechanism is universal and might be able to explain the experiments described above.

3. Exotic vibrational polariton optical nonlinearities

In recent work together with our experimental colleagues[8], we have shown that optical nonlinearities vibrational polaritons exhibit anomalies with respect to their bare molecular counterparts. At fixed pump and probe fluences as well as fixed molecular concentrations, the cavity with twice the longitudinal length shows a weaker nonlinearity than the original one. This result can be interpreted as follows: Since the cavity length sets the polariton wavefunction lengthscale, the longer cavity features a smaller density of anharmonic transitions to be probed. This is an usual situation that does not occur
with regular molecular samples, and crucially inherits essential physics from both matter (anharmonicities) and light (delocalization).

4. Remote control of chemistry

Harnessing our recent understanding of polariton nonlinearities, we have recently developed the concept of remote control of chemical reactions[9] mediated by optical microcavities: the idea is that pumping molecules in one cavity can affect the chemical reactivity of molecules in another one. This idea opens doors to spatially nonlocal concepts in control of chemical reactivity.

Abstract

High integration density, high responsivity, and multifunctional Silicon photodetectors are the long term goals in the field of light detection. The photothermoelectric (PTE) effect provides a promising way towards the requirement above. Here we report a plasmon modulated silicon nanostripe PTE detector with an open-circuit photovoltage responsivity ~82 mV/μW. The gold subwavelength nanogratings provide enhanced optical absorption and polarization and wavelength sensitivity. This plasmon enhanced silicon PTE effect would pave the way for high integration, CMOS compatible light harvesting devices.

1. Introduction

Light induced temperature gradient can drive the consequent photocarriers diffusion process, thus produce a detectable photovoltaic signal, which is named as the photothermoelectric (PTE) effect. The PTE effect have been reported in carbon nanotubes¹-², semiconductor nanowires³, graphene⁴-⁵ and two dimensional metal dichalcogenide materials⁶-⁷. For further applications, it will be useful to combine plasmon structure with PTE device, such as silicon nanostructures, which have much potential both in optoelectronics and thermoelectric devices. Though the silicon PTE photodetectors is reported in ref⁸, further reducing the silicon structure to the nanometer scale and utilizing surface plasmons to enhance the silicon nanostructure photoresponsivity still need to be explored towards high integration density, high sensitivity and low cost silicon photodetectors.

Here we report a plasmon modulated silicon PTE photodetector, which combines the gold subwavelength slit gratings with silicon nanostripes. An open-circuit photovoltage responsivity of as high as ~82 mV/μW was achieved with a 633 nm laser illuminating the nanograting region. This originates from the large Seebeck coefficient of the silicon nanofilm and the plasmon enhanced optical absorption (~10 fold) in the silicon film. The polarization and wavelength sensitivity of the photoresponse due to the plasmon resonance were demonstrated. The reversed sign of the Seebeck coefficient of silicon due to the Cr/Si contact was discovered and explained by the charge injection from the Cr adhesion layer.

2. Results and discussion

Figure 1a shows the false color SEM image of the device. An enlarged SEM image of the plasmonic nanograting is in the inset. Our device is composed of Si nanostripes and a Au grating with a 350 nm period and 25 nm slit width. For utilizing the PTE effect in silicon nanofilms experimentally, we need to carefully design the electrode/silicon contact to minize the PV effects. This was achieved by forming an Ohmic contact instead of a Schottky contact. The Ohmic contact was achieved by using 5 nm thick Cr as an inter-layer between Au and Si and was confirmed by the measured current-voltage measurement. The Ohmic contact is due to the energy matching between the fermi energy of Cr and the lightly doped p-type Si. The measured conductance verified a boron doping level of $1.52 \times 10^{12} \text{cm}^{-2}$.

Figure 1: (a) False colour SEM image of the prepared sample. The inset shows the detailed grating structure with a 350 nm period and 25 nm slit width. (b) Fabrication process of the device. In the cross-section of the final sample, close to the right end, a gold nanograting is integrated on the silicon nanostripe.
Figure 2. (a) Spatially resolved photocurrent and photovoltage along the Si nanostripe with on-resonance grating excitation. The polarization of the incident laser is perpendicular to the grating slits. (Laser wavelength 633 nm, power 0.09 μW) (b) The Photocurrent in the grating region exhibits a angular dependence as a function of the polarization angle $\alpha$ of the incident light. (c) Spatially resolved photocurrent with 800 nm and 850 nm incident laser light.

The Seebeck effect, $\Delta T = -\frac{E_J}{J} = -\alpha S\Delta T$, predicts that when the laser illuminates the “left” (“right”) sides, the voltage of left side should be lower (higher) than that on the right side, leading to a negative (positive) photovoltage or positive (negative) photocurrent detected by the sourcemeter. The measured spatially resolved short-circuit photocurrent and open-circuit photovoltage are plotted in the Figure 2a, with incident 633 nm laser light polarized perpendicular to the grating slits (p-polarization). The laser power was 0.09 μW. A distinct photocurrent occurred for laser illuminating on the nanograting region under p-polarization, compared with the photocurrent response under s-polarization. The polarization dependence of the short-circuit photocurrent exhibit a $\cos^2 \alpha$ angular dependence and verified the contributions by SPPs excitation, as seen in Figure 2b. $\alpha$ is the incident polarization angle with 0 degree corresponding to p-polarization. The photocurrent polarizability $p = 0.95$ , revealed a sensitive photoreponse to the polarization of the incident laser. We studied the wavelength dependence of the short-circuit photocurrent by the tunable laser wavelength from a supercontinuum laser. The spatially resolved short-circuit photocurrent for 800 nm and 850 nm wavelengths show a distinct photocurrent response in the grating region, as seen in Figure 2c. The photocurrent under the 850 nm wavelength laser is ~10 times higher than the photocurrent under the 800 nm wavelength laser.

Although the gold gratings offered a plasmon enhanced optical absorption in the silicon film, the maximum photocurrent response in the grating region was only ~40% of the maximum photocurrent in the silicon stripe region under 850 nm wavelength. In addition, the sign of the photocurrent was reversed compared with the silicon located nearby. The reversed sign of the photocurrent means that the Seebeck coefficient turns to a negative value and is different to the original positive value of the Seebeck coefficient in p-type silicon. The influence of Cr/Au coating on the Seebeck coefficient of Si is explained by the work function. The adhesion layer material Cr has Fermi energy $E_F = -4.5$ eV and is slightly smaller than the Fermi level for the weakly p-doped Si $E_F = -4.74$ eV. Therefore, Cr has doped the Si film with electrons and turned the lightly doped p-type Si into intrinsic n-type. This implicates a careful design of the contact barrier and the doping level is important for optimized PTE photodetection. With further efforts to explore the plasmon enhanced silicon PTE effects in the infrared region and achieving higher integration density, the plasmon enhanced Si nanostructures are promising for silicon based multifunctional on-chip subwavelength photodetection.

Abstract

Hybrid bionanomaterial comprised of Enhanced Green Fluorescent Protein covalently bound to 20 nm thick perforated Al film has been created. The short-ordered arrays of nanoholes with diameter in range 65–120 nm have been fabricated using sparse colloidal lithography. By changing the diameter of the nanoholes, the plasmon-polariton frequency has been tuned across the spectrum. The strongest plasmon-enhanced fluorescence has been observed for the systems with 120 nm nanoholes, reaching the 2.75 enhancement factor.

1. Introduction

Single-molecule imaging is a fast-growing area of research, which offers unique experimental tools for studying various microscopic processes with high sensitivity and unprecedented resolution. In this technique, spatially isolated fluorescent molecules conjugated to biomolecules of interest serve as point light sources. The position of each dye molecule can be determined with nanometer precision by fitting the diffraction-limited emission profile. Despite lower brightness and stability compared to many organic dyes, fluorescent proteins (FPs) are widely used as tags for labeling proteins in vivo, since they can be genetically encoded with high specificity inside the cell. Therefore, it is important to improve the brightness and the lifetime of normally dim FPs. One of the promising approaches is to utilize the plasmon-enhanced fluorescence by placing the FP near the surface of a plasmonic nanostructure. However, it is not a straightforward task. At short distances between the fluorophore and metal the non-radiative energy transfer prevails, thus one has to carefully design the spacer and immobilization route. Additionally, FPs are more sensitive to the environment and can denature when adsorbed on the surface. In this work we demonstrate the successful immobilization of EGFP on surface-oxidized perforated Al thin films and the observation of plasmon-enhanced fluorescence in this hybrid system.

2. Experiment

2.1. Nanofabrication

Hybrid Al–Enhanced Green Fluorescent Protein (EGFP) bionanosystems have been constructed using the following strategy. First, aluminum nanostructures have been fabricated using sparse colloidal lithography approach, described in detail elsewhere [1]. Samples with average diameter of nanoholes of 60, 80 and 120 nm have been obtained.

The protein binding step has been carried using the (3-Glycidyloxypropyl)trimethoxysilane (GLYMO) as an anchor. Covalent binding of EGFP has been achieved via the reaction of GLYMO epoxy-groups with one of the protein’s surface amine groups. For each sample, a 20 µL droplet of 0.25 M EGFP solution in phosphate buffered saline (PBS) has been placed on top of the GLYMO-modified surface and covered by a microscope slide to prevent water evaporation. After 20 min, the sample has been rinsed by PBS to remove the unbound protein molecules and studied.

2.2. Spectroscopy

Extinction (1-T) spectra of the perforated Al films have been recorded in range of 300–700 nm using UV-vis-NIR spectrometer (Jasco V-770). Spectra have been registered in two-beam mode using a clean glass slide as a reference. Fluorescence emission spectra have been registered using a custom-built optical setup. Femtosecond laser pulses with a 80 MHz repetition rate, 950 nm central wavelength, and energy up to 25 nJ were generated by a Titanium-Sapphire oscillator (Tsunami, Spectra-Physics). Frequency-doubled pulses at 475 nm were focused on the sample’s bottom surface. Fluorescence was filtered with 500 nm long-pass filter and coupled to an Acton SP300i monochromator and then to a PI-MAX 2 CCD camera (Princeton Instruments), which recorded fluorescence emission spectra.

3. Results and discussion

Nanohole arrays, fabricated using sparse colloidal lithography, are characterized by short-range order (SRO), while the long-range order in such systems is absent [1]. Optical properties of SRO nanohole arrays are defined by a combination of two contributions: the surface plasmon polari-
tons (SPPs) between the holes, and the localized surface plasmon resonance (LSPR) in the holes. The former manifests itself as an extinction maximum (peak), while the latter — as an extinction minimum (dip) in the spectra [2, 3]. By increasing the diameter of nanospheres used for fabrication, the diameter of the holes and the distance between them are gradually increased, thus allowing one to tune the plasmonic resonances to longer wavelength. The extinction spectra of perforated Al films fabricated in this work clearly demonstrate such behavior, as depicted in Fig. 2. The fluorescence emission spectrum of EGFP is presented in the same graph for comparison.

Fluorescence emission spectra have been normalized by the intensity of EGFP immobilized on glass surface (without Al layer). Additionally, to take into account the extinction of light by metal reflection and absorption, the spectra are divided by the transmission at the excitation wavelength (475 nm). The resulting fluorescence intensity at EGFP emission maximum (510 nm) are presented in Fig. 2. One can see that the fluorescence intensities on glass and on Al film without nanoholes are almost the same, which suggests that 1) the amount of EGFP molecules immobilized on glass and on Al are close, and that 2) there is no significant fluorescence quenching by Al in these conditions. Introducing plasmon resonances by adding nanoholes to Al films leads to stronger fluorescence, which reaches factor 2.75 for the 120 nm holes.

4. Conclusions

We have created a hybrid nanobiosystem based on Al short-ordered nanohole arrays and the covalently attached fluorescent protein molecules EGFP. The natural oxide layer on Al surface serves as an efficient spacer between the metal and the protein’s chromophore, allowing to decrease the non-radiative energy transfer. The observed fluorescence intensity has increased by the factor of 2.75 compared to the protein, immobilized on a glass surface. The advantage of the proposed approach is in relative simplicity of the immobilization procedure as well as in its low cost.

Plasmonics in complex geometries:

Modal optical properties and coupling with nanoscale emitters

Abstract

Plasmonics deals with the properties and the control of localized and delocalized surface plasmons at the subwavelength scale. It has highly potential applications for nanoscale ultrafast photonics and for ultrasensitive sensors. Two types of resonances exist, Surface Plasmons Polaritons (SPP) and Localized Surface Plasmons (LSP). Understanding the coupling properties between quantum emitters and surface plasmons resonances and/or nanonanantennas is a key step towards realistic applications in the near future. We will present in this paper our latest experimental and theoretical results on the optical properties of different plasmonic systems exhibiting complex resonant modes and applications for the sensitive detection of molecules Surface Enhanced Spectroscopies, such as Surface Enhanced Raman Spectroscopy (SERS) and Surface Enhanced Fluorescence (SEF).

Main

Plasmonics is a now well-established field finding numerous applications in pharmacology, biology, optoelectronics and metamaterials among others. Two types of resonances exist, Surface Plasmons Polaritons (SPP) and Localized Surface Plasmons (LSP). SPPs are delocalized waves, which can be launched either on thin metallic films or on nanoscale waveguides [1]. LSPs are confined modes at the subwavelength scale, which are localized in metallic nanoparticles. Electric dipolar modes are the simplest modes observed, whose resonance wavelength depend on the size and shape of the nanoparticles (Fig.1) [2]. They also depend on their environment, such as the presence of a substrate, and on the mutual interactions between nanoparticles, both in near-field and in far-field. These optical properties are extensively used in Localized Surface Plasmon Resonance sensing. The incident field spatial distribution, through its amplitude, phase and polarization variations, can excite more complex modes of nanoparticles, multipolar modes, such as electric quadrupoles or magnetic dipoles, but also hybrid modes, which result from the coupling of two or more modes. All these modes can be observed in extinction spectroscopy for ensembles of nanoparticles, or in scattering and photoluminescence spectroscopies for single nanoparticles [3-5]. Even more complicated plasmonic systems, such as metal-insulator-metal nanostructures, can sustain both LSPs and SPPs and other modes whose intense field is confined in the gap between the two metals [6].

Figure 1: Normalized extinction of arrays of gold ellipsoidal nanoparticles [2]
For the sensitive detection of molecules or nanocrystals, organic or inorganic, Surface Enhanced Spectroscopies, such as Surface Enhanced Raman Spectroscopy (SERS) and Surface Enhanced Fluorescence (SEF), are widespread and the most used for applications. Both these enhanced spectroscopies rely on local field enhancements in the near vicinity of resonant metallic nanoparticles when one or several Surface Plasmon oscillations are driven for a specific optical wavelength. Double enhancement can be achieved if surface plasmons resonances coincide with both excitation/emission wavelengths for fluorescence or with both excitation/scattering wavelengths for Raman scattering.

SERS can achieve a high sensitivity, detecting traces of a species, even reaching single molecule detection. Such sensitivity is obtained with specific systems of plasmonic nanoparticles, especially when two or more metallic nanoparticles are coupled through their optical near-fields, resulting in huge enhancements usually ranging from 4 up to 10 orders of magnitude [7]. Even if most SERS studies have been made on organic molecules, it has also been recently showed that significant enhancement can be observed on semiconductor nanocrystals [8]. In order to detect few amounts of inorganic nanocrystals or organic molecules specific large-scale plasmonic systems have been developed, which incorporates monometallic or bimetallic nanoparticles on substrates, separated by small gaps [9-10].

Less enhancement of the spectroscopic signal is obtained with SEF. In SEF one has to take into account the quantum yield modifications in the presence of the metallic nanoparticles. Quantum yield can be enhanced or even reduced, although always resulting in a decrease of the excited level lifetime. In the former case double resonance enhancement can be achieved while leading in the latter case to a competition between local field excitation enhancement and quantum yield reduction. In that case the possibility of quenched fluorescence from the emitters can be observed but the effect is also dependent on the distance between the emitter and the metallic nanoparticle. Double resonant enhancement of the fluorescence of single photosystems has recently been observed with large-scale plasmonic platforms both at room and low temperatures [11]. More complex systems of emitters, mixing organic photochromic molecules and inorganic quantum dots, have also been studied where the organic absorbing species can induce a switch from quenching to enhancement of the nanocrystals luminescence [12].

Broadband Mid-Infrared Absorber Using Gosper Curve

Abstract
Designing broadband metamaterial perfect absorbers is challenging due to the intrinsically narrow bandwidth of surface plasmon resonances. Here, we designed an ultrabroadband metamaterial absorber by using space filling Gosper curve. The optimized design shows an average absorption up to 95.78% from 2.64 to 9.79 μm across the entire mid-infrared region. Meanwhile, the absorber shows a great insensitivity to polarization and the angle of light incidence. The broadband perfect absorption can be attributed to the defined Gosper curve with different segments that support electric resonances at different wavelengths. This work provides a new concept for the design of broadband absorbers and sheds light on practical applications, such as broadband infrared photodetection and biomedical sensing.

1. Introduction
Metamaterials have intriguing electromagnetic response with tailored permittivity and permeability that are not available in naturally occurring materials, promising for perfect lenses, holographic display and invisible cloaking. Metamaterial absorbers (MMAs) demonstrated a variety of applications at different frequencies,[1] such as thermal imaging,[2-5] thermal emitters, [2],[6] solar photovoltaics, [7-9] plasmonic sensors,[10] and single photon source. [11] MMAs can be divided into two types—narrow band and broadband.[1] Narrow band MMAs have been demonstrated extensively, such as single-band[1],[4],[12-13], dual-band, [6],[14-16] triple-band,[17-18] and multi-band.[19-21] However, achieving broadband MMAs at a higher frequency—still remains a challenge, due to the intrinsically narrow bandwidth of localized surface plasmon resonances (LSPRs) or surface plasmon polaritons (SPPs) generated on metallic structure.[1] Gao et al. proposed a MMP with binary-pattern which demonstrated absorption over 95% from 3 to 3.9 μm. However, achieving perfect absorption in the entire mid-infrared (MIR) region, 3-8 μm, has so far remained as a challenging task.
Here, based on the space-filling Gosper curve, we propose a broadband MIR MMAs that demonstrates a nearly-perfect absorption covering the entire MIR—over 95% absorption spanning from 2.6 to 9.8 μm. Simulation shows an angle-independent absorption greater than 90% over 60° range under either transverse electric (TE) or transverse magnetic (TM) polarization. Our device may have applications on surface-enhanced infrared spectroscopy—infrared vibrations of molecules located in these fields can be boosted by orders of magnitude and permitting a spectroscopic characterization with unprecedented sensitivity.

2. Simulation
2.1. Method
The finite-difference time-domain (FDTD) and Finite Element Method (FEM) were employed to simulate the MMAs. Numerical and COMSOL Multiphysics were used, respectively. In the z direction, we used perfectly matched layers (PML) boundary conditions to eliminate the boundary scattering. A single unit of the MMAs is simulated with periodic boundary in the x and y directions. A single unit of the space-filling Gosper curve is shown in Fig. 1.

2.2. Figures

Figure 1. The diagram of absorber structure.

Figure 2. The absorption spectrum of the absorber.
3. Results and Discussion

We simulated first three stages in the construction of a fractal array based on Peano-Gosper space-filling curve as shown in Fig. 1. Polyimide, a dielectric superstrate is used to tailor the impedance match to free space in order to minimize reflection and maximize absorption in the MIR region. Platinum (Pt) is used to replace conventional gold resonator to extend the bandwidth of MMAs. The proposed MMA exhibits a nearly perfect absorption with an average absorbance of 95.78% and 90% absorption bandwidth over 7.15μm from 2.64 to 9.79μm, as shown in Fig. 2. Meanwhile, the MMA is insensitive to the incident angle. Especially for TM mode, 90% absorption bandwidth still maintains as high as 3.53μm at the incident angle of 60°, the average absorptivity is 97.64% from 2.87 to 6.40μm. The broadband MIR perfect absorption can be attributed to the defined Gosper curve with different segments that support multipole resonances at different wavelengths. Interestingly, the electric resonances dominates in the MMA while its conventional counterparts have electric and magnetic resonances.

4. Conclusion

In this paper, we reported an ultra-broadband based on space filling Gosper curve and it demonstrates the highest bandwidth in the near-mid infrared region with nearly perfect absorption among their single layer counterparts. This work provides a new concept for the design broadband MMA and paves the way for its practical application, such as infrared imaging, broadband photodetection and biomedical sensing, etc.

Plasmonic Aluminum Nanohole Arrays for ITO-Free Ultraviolet Photodetectors with Improved Response Stability and Tunability

Monica Esopi and Qiuming Yu*
Department of Chemical Engineering, University of Washington, Seattle, WA, USA
*corresponding author, E-mail: qyu@uw.edu

Abstract
Incorporating plasmonic nanostructures into photodetectors provides an avenue for enhancing photoresponse strength, selectivity and tunability. Here, aluminum nanohole arrays (Al-NHAs) were incorporated as transparent electrodes into ultraviolet photodetectors. The optimal gap/pitch were determined to be 175/200 nm by 3-dimensional finite-difference time-domain (3D-FDTD) simulations. Devices incorporating these Al-NHAs had comparable photoresponse, under reverse biases, compared to ITO-based control devices. Under forward biases, improved, spectrally distinct photoresponse was obtained by the Al-NHA-based devices, enabling a new bias-dependent response tunability.

1. Introduction
Nanostructured films incorporated into optoelectronic devices, including photodetectors, have attracted attention for their ability to support surface plasmon polaritons (SPPs), which can enhance optical absorbance, internal electric field, and ultimately device performance[1, 2]. Metal films can also serve as a transparent device electrode, making them a cost-effective, flexible, high-performance alternative to the commonly used indium tin oxide (ITO), which is expensive and brittle[3]. Photodetectors, particularly those that are selective to ultraviolet (UV) light, are important in a variety of applications including environmental monitoring, imaging, and flame and missile detection[4, 5]. Despite this applicability, extension of plasmonic enhancements to UV-selective devices has been relatively slow. Although oxide formation on the surface can cause a redshift in its plasmonic properties, Al provides an abundant, low-cost option for supporting SPPs in the UV spectral range due to its carrier concentration and dielectric function[6-8].

In this work, Al nanohole arrays (Al-NHA) were designed using 3-dimensional finite-difference time-domain (3D-FDTD) simulations and employed as transparent electrodes in conventional UV photodetectors. These photodetectors utilize organic active materials, which provide a low-cost, flexible alternative to inorganic materials. The active layer consists of the UV-absorbing polymer poly(9,9-diocetylfluorene-alt-bithiophene) (F8T2) and the electron acceptor phenyl-C71-butyric acid methyl ester (PC71BM) blended in a 100:4 weight ratio. The hole and electron transport layers were Poly(3,4-ethylenedioxythiophene) :poly(styrene sulfonate) (PEDOT:PSS) and LiF respectively.

The substitution of Al-NHA for ITO as a transparent conducting electrode resulted in similar photoresponse under reverse bias, improved response under forward bias, and new bias-dependent response tunability.

2. Discussion

2.1. Evaluating Al-NHAs with 3D-FDTD Simulations
To design the Al-NHA electrodes, a broad range of gap/pitch combinations were tested in 3D-FDTD simulations. The full device structure was glass/ITO or Al-NHA/PEDOT:PSS/F8T2:PC71BM/LiF/Al, and is shown in Fig. 1a with an Al-NHA electrode. The simulated active layer absorbance was used to distinguish between different nanopattern geometries and determine that, considering fabrication constraints, a hexagonal NHA with a gap/pitch of 175/200 nm was optimal. The internal electric field distribution calculated for a simulated device on an optimal Al-NHA is shown in Fig. 1b, and corresponds to an x-y point at the edge of a nanohole. The field is mapped in the z direction at various wavelengths of incident light, which are plotted on the x axis. The electric field distribution for an ITO-based device is shown in Fig. 1c for comparison, illustrating the enhancement provided to the simulated, particularly in the lower portion of the device, upon incorporation of the Al-NHA electrode.

Figure 1: (a) device schematic, (b) simulated electric field distribution for an Al-NHA-based device, and (c) simulated electric field distribution for an ITO-based device.

2.2. Incorporating Al-NHA Electrodes into Devices
Devices with a structure of glass/ITO or Al-NHA/PEDOT:PSS/F8T2:PC71BM/LiF/Al were fabricated and evaluated experimentally. A nanosphere lithography process, beginning with a monolayer of nanospheres, illustrated in Fig. 2a, followed by etching, Al deposition and chemical liftoff, was used to produce the Al-NHAs, an SEM of which is shown in Fig. 2a. Devices were evaluated based...
on their photoresponse strength, speed, UV-selectivity and tunability under both reverse and forward biases. The specific detectivity (D*) encompasses many of these criteria, so it was calculated and is shown in Fig. 2b-c.

Under reverse biases (Fig. 2b), both ITO- and Al-NHA-based devices produce photoresponse spectra with two peaks, around 360 and 510 nm, which correspond to the edges of the F8T2 absorption spectra. Light with these wavelengths is absorbed weakly, so it penetrates the active layer and is absorbed in the top portion, engaging a photomultiplicative response mechanism based on holes injected from the top electrode, which has been previously reported for the ITO-based devices[9]. The Al-NHA electrodes have lower transmittance than ITO, yielding a lower photoresponse, but the noise in Al-NHA-based devices is also lower than ITO-based-devices, so the D* values are comparable. Thus, an ITO-free device is obtained without diminishing the reverse-bias photoresponse.

Al-NHA-based devices exhibit a spectrally distinct, broad photoresponse under forward biases (Fig. 2c), unlike the ITO-based devices, whose behavior is unstable under forward biases because they rely on hole injection from the top electrode, which is more difficult under forward bias. The electrode symmetry of the Al-NHA-based devices enables them to produce photoresponse from photons within the F8T2 absorption peak, which are absorbed strongly in the lower portion of the active layer and result in photogenerated holes being collected at the top electrode. This mechanism produces a spectrally distinct, stable photoresponse, enabling the Al-NHA-based devices to improve upon the photoresponse of ITO-based devices under forward bias, and to unlock a response tunability based on the bias applied during testing.

3. Conclusions

In this work, Al-NHA electrodes were designed by 3D-FDTD simulations and incorporated into conventional, organic ultraviolet photodetectors. The hexagonal NHA had a gap and pitch of 175 and 200 nm, respectively, and was successfully fabricated by nanosphere lithography. Upon incorporation into devices, the reverse-bias photoresponse was maintained at a comparable level due to the low noise levels in the Al-NHA-based devices. Additionally, under forward biases, the photoresponse was improved compared to the ITO-based control devices, and a new bias-dependent tunability was enabled. To further investigate the mechanisms of this photoresponse, devices based on planar Al electrodes and hole-only devices based on ITO, planar Al, and Al-NHA electrodes were also fabricated and tested, to isolate the impact of the NHA from the impact of the electrode material and the impact of external and internal biases. These devices provide an example of ITO-free devices utilizing cost-effective materials resulting in UV photodetectors with improved photoresponse strength, stability, selectivity and tunability.

Nanostructuring of functional polymers for the directed assembly of nano-objects and the integration of hybrid nanosources

Abstract

In this work, we show a general strategy of directed assembly of nano-objects. This assembly concerns a wide range of colloidal nanoparticles including Gold, Silver, Iron Oxide, Fluorescent polystyrene and CdSe/ZnS Quantum Dots. We show the possibility to integrate nano-emitters into plasmonic nano-antennas (gold nanocubes, nanowires), optical waveguides and optical fiber tips with a spatially controlled manner.

The integration of efficient single photons in on-chip optical circuits is one of the main challenges in quantum optics. In this context, we developed a new approach of integrating nano-emitters. This approach is based on the use of a specific home-made functional photopolymer to make nanolithography followed by colloidal deposition in order to trap single nanoparticles with a highly selective manner. This “nano-patch” of polymer can be integrated at the extremity of plasmonic nano-antennas either by 2-photon polymerization or by near-field plasmon induced photopolymerization.

First, the multidimensional directed assembly of gold, silver, iron oxide and polystyrene nano-spheres is demonstrated. In particular, 50 nm gold nano-spheres are assembled into 1D, 2D and 3D (Figure 1).

This directed assembly results in the formation of monolayer of NPs with tunable coverage rate depending on the immersion time and concentration of functionalizing molecules. Thus, tuning the intensity of the plasmonic resonance band and the coupling between nano-spheres within 3D microstructures is demonstrated. The potential application of the obtained 3D microstructures in sensing and as metamaterials is illustrated.

To make it possible the integration of the functionalized polymer with sub-100 nm resolution, the photopolymer is optimized in order to chemically confine the polymerization volume (Figure 2).

Figure 2: Polymer nano-pillars (PNPs) fabricated by two photon polymerization under various conditions: (a,b) decreased laser power and decreased exposure time, following Y and X respectively. (c,d) Adjusting the laser
focal plane. (e) Diameter and height of the PNPs as a function of the laser power.

Using this approach, single fluorescent polystyrene nanospheres (PSNS) and few quantum dots are selectively trapped by the polymer nano-pillars (PNPs) (Figure a). The same approach is used in order to fabricate new active nano-probes for scanning near field optical microscopy by trapping single fluorescent PSNS at the extremity of PNP, itself integrated at the extremity of an optical fiber (Figure 3-d and Figure 3-e).

Abstract

Plasmonic hot electrons can carry up to the full energy of the photons impinging in a nanostructure, allowing them to be emitted or injected into adjacent media. They can be used to induce secondary processes relevant in, e.g., photodetection and energy conversion processes. We present work intended to further our fundamental knowledge on hot electron excitation dynamics, provide guidelines to improve their generation efficiency and highlight new research avenues for their study.

1. Introduction

Plasmonic resonances couple strongly with light and provide great local field enhancement, so that plasmon-supporting structures have become rich scientific tools for research in Nanophotonics, [1] proving useful in a variety of technological applications. Among them, the capability of plasmonic nanocrystals and metastructures to harvest light’s energy and convert into other forms of power is particularly promising, as this can be used for purposes ranging from photovoltaics to photodetection. [2,3]

The generation of energetic (hot) electrons is one of the different physical mechanism by which plasmonic systems can operate this process, as these carriers can be injected into neighboring systems to contribute to the output of other photoconversion processes in the device, as depicted in Fig. 1. [4,5]

On the other hand, hot electrons typically make a small percentage of the total excited electrons in a plasmonic system, with the majority being low-energy carriers. Therefore, to take full advantage of their scientific and technological promise, we should fully understand the mechanisms underlying their fast excitation and decay, and seek ways to increase their overall energy contribution to secondary processes.

2. Model

We describe the process of generation of single-particle excited states in a plasmonic materials through the equation of motion for the density of electronic states, perturbed by an external driving field, and study its linear regime. [4-6] This model can be formulated such that it can be connected with classical methods to obtain the plasmonic response of large nanoparticles, allowing the study of hot electron generation in relatively large nanoparticles, complex geometries or systems with interacting structures. [5] Such a computational approach opens up the possibility of studying the relevance of hot spots in the generation of hot electrons, [7] and how to take advantage of them to create more efficient systems utilizing hot electrons for, e.g. photocatalysis. [5,8,9]

Importantly, this model offers a picture for the energy distribution of populated excited states in a plasmonic nanostructure that is different to the traditional one found in the literature (Fig. 2), which becomes relevant both when studying the ultrafast response of the system under short excitations [7] and when predicting the rates of hot electron generation under continuous wave excitation. [3-6,8,9]
3. Alternative materials

The most commonly studied materials in plasmonics are noble metals, due to their sharp and strong resonances around the visible and near IR spectrum. We have theoretically explored the potential of different plasmonic materials in the context of photocatalytic applications, contrasting non-interacting nanoparticles with metamaterial structures, and materials with sharp and broad resonances, finding that materials such as TiN and ZrN can offer good hot electron generation efficiencies at cheaper prices than strongly-plasmonic materials such as Ag and Au. [8]

4. Chiral photocatalysts: circular polarization-sensitive photochemistry

The field of chiral photocatalysis focuses on creating differential reaction rates for chiral enantiomers at the molecular level. We propose a different approach, setting the differential chiral response at the scale of the plasmonic nanoparticles. Due to their large interaction cross sections and strongly chiral geometries, plasmonic complexes can show circular dichroic signals orders of magnitude larger than those of molecules, and can be used to create functional setups showing chiral plasmonic nanoparticle growth, polarization-sensitive photochemistry, and chiral recognition or separation. [9]

5. Conclusions

Research on the generation of hot electrons has already produced useful applications and insights on their ultrafast generation. Our work elaborates on its fundamental understanding, develops useful design techniques to improve hot electron-based device efficiency and sketches different novel research directions.

Metamaterial Absorber-empowered Light-harvesting Devices

Peng Yu¹, Zhiming Wang¹, and Alexander O. Govorov¹,²,*

Abstract
Absorption of light is critical to light-trapping devices such as photovoltaics, biosensors, photodetectors, etc. Naturally occurring materials have weak absorption, while perfect absorbers based on metamaterials are developed to solve the weak light absorption of light-harvesting devices. This presentation will provide an overview of metamaterial absorber enhanced light harvesting devices and our recent research progress on metamaterial absorbers.

1. Introduction
Naturally occurring material-based absorbers are unsatisfactory for many modern photonics and optoelectronic applications due to their large impedance mismatch \( z = \sqrt{\mu / \varepsilon} \) between the material and free space. Artificial metamaterial absorbers (MAs) have opened a new door for light-harvesting devices operating from optical regimes to microwave—deliberately engineered resonators can collectively serve as a metasurface, creating impedance matching to free space with an effective electric and magnetic response. The structure is typically composed of three layers: a continuous metallic ground layer to block the light transmission, a dielectric spacer layer and periodically arranged metallic resonators. After a seminal demonstration by W. Padilla et al., this concept has been extended to other frequencies, researches on the fundamental investigation and a variety of applications are mushroomed.[1] MAs with single-band, dual-band, triple-band and more are experimentally and theoretically demonstrated. Also, according to their bandwidth, they are divided into two types—narrow and broad bandwidth. Achieving a narrow and broadband for special applications is a challenge. MA with a narrow absorption is desired for applications such as refractive index sensing, biomolecular sensing, strain sensing, coloration of imaging, data storage, and so on. On the other hand, broadband absorption is critical for applications such as photovoltaics, bolometry, photodetection, stealth technology, mechanical manipulation, etc. However, a typical line width of surface plasmon polaritons (SPPs) or localized surface plasmon is several tens of nanometers. Therefore, achieving ultra-narrow and broadband MAs is one important research direction in the field of MAs. Based on the MAs, many light-harvesting devices are demonstrated with satisfactory performance, such as sensors, solar thermophotovoltaics, imaging devices, photodetectors, infrared emitters, optomechanical converters, and single photon sources.

2. Recent progress and main results
2.1. Metamaterial perfect absorber with unabated size-independent absorption
The top resonators in MAs are critical for tuning resonant frequency, bandwidth, and maximum absorption—one can define their material, shape, and size. The maximum absorption is usually decreased as the size of the resonator changes, due to the high sensitivity of impedance matching with the medium. We experimentally demonstrated an MA using a metal square inscribed with a hollow square (MSIHS) with unabated absorption robust to resonator’s size changes, as shown in figure 1(a).[2] The maximum absorption maintains above 98% as the size changes from 600 to 1500 nm in the mid-infrared region, in accordance with simulated absorption of ~100%. We adopted the equivalent circuit theory to explain the unabated absorption. The structure is less sensitive to size change while its square counterpart only shows maximum absorption at size=800 nm, as shown in figure 1(b)-(d).
2. Metamaterial Absorber for Photodetection

In a metal-dielectric interface, a Schottky barrier is formed. If a hot electron has enough energy, it can transport to the junction interface and then be injected into the conduction band of the semiconductor. Therefore, the photodetection bandwidth is determined by Schottky barrier height rather than the bandgap of semiconductor, as shown in Figure 2.[3]

Figure 2: Schematic diagram for energy band transport.

We simulated a dual-band absorber, potential for multispectral plasmon-enhanced infrared photodetection, as shown in Figure 3.[4] The dual-band MA is based on two gold nanorings. Two perfect peaks can be readily tailored in 3-5 µm and 8-14 µm via changing the geometric parameter of the MA.

Figure 3: (a) Schematic illustration of the dual-band MAs; (b) Absorption spectra of MAs in 3-5 µm and 8-14 µm.

2.3. Ultra-broadband MA Using Space-filling Gosper Curve

By integrating different-sized or shaped geometries into a unit cell, multiple resonances can be merged into a broadband resonance; the second method is staking different dielectrics and metals as an individual bilayer and then merge resonances into a broadband one or leverage slow-light mode of the MAs; the third method is introducing lumped elements into the MAs to reduce their Q-factor in GHz region; finally, due to the localized surface plasmon resonances of metallic nanoparticles in nanocomposite, the metal-dielectric nanocomposite system can offer impedance matching of the medium to free space. We designed an unconventional MAs by using a space-filling Gosper curve. The MA has an average absorption of 95.78% from 2.64 to 9.79 µm (bandwidth 7.15µm) across the mid-infrared region, as shown in Figure 4. According to our knowledge, this is the broadest MAs among their single layer counterparts.

Figure 4: Broadband MA based on a space-filling Gosper curve. (a) stage 1; (b) stage 2; (c) stage 3; (d) cross-section view of the MA; (e) absorption spectra of stage 1-3; (f) detailed absorption and bandwidth of stage 3 MA.

3. Conclusions

Although MA opens an avenue for light-harvesting devices, there are still some challenges to overcome, including achieving ultra-narrow and broadband absorption, addressing the parasitic loss of metal, developing more devices via trapping light and convert it into physical effects such as force, electric, acoustics, and heat.[5-6] If these problems are addressed, the MAs will renew light-harvesting devices for industrial application.

Abstract

Using simulations from first principles we study the optoelectronic and plasmonic properties of Titanium Nitride, a refractory compound that has been proposed as a feasible route to substitute gold in harsh environment applications. The microscopic origin of the plasmon resonances and their dispersions are discussed on the basis of the analysis of the electronic structure and of the interplay between collective and single-particle excitations. The effects of nanostructuring and the formation TiN/dielectric interfaces are also deeply investigated.

Introduction

The development of plasmonic and metamaterial devices requires the research of high-performance materials alternative to standard noble metals. Recently refractory Titanium Nitride has been proposed as a valid alternative to gold, [1] even for application in harsh and high-temperature environments. Indeed, being refractory this compound exhibits extraordinary mechanical stability over a large range of temperatures (∼2000°C) and pressures (∼3.5 Mbar), well above the melting point of standard noble metals (∼800°C). This material is furthermore resistant to corrosion and compatible with silicon technology. TiN has optical and plasmonic properties (color, electron density, plasmon frequency) very similar to gold and has been exploited for the realization of waveguides, broadband absorbers, local heaters, and hyperbolic metamaterials in connection with selected dielectric media (e.g., MgO, AlN, sapphire, etc.).

Even though the fundamental mechanical and optoelectronic properties of TiN have been largely studied so far from experimental and theoretical points of view, very little is known about its plasmonic behavior. Here, we present a fully first principles investigation, based on time-dependent density functional theory (TDDFT), of the plasmon properties of stoichiometric titanium nitride [2]. The microscopic origin of plasmonic excitations are analyzed in terms of the fundamental collective and/or radiative excitations of TiN electronic structure. From the simulation of energy-loss spectra at different momentum transfer, we derive the TiN plasmon dispersion relations that are directly accessible by experimental measurements.

We also investigated the optoelectronic characteristics of the compound in relation to the crystal phase transition, experimentally observed at very high pressure or in the case of ultrathin TiN films [3]. Finally, we furthermore analyze different interfaces between TiN and conventional semiconductors in order to describe TiN surface-plasmon polaritons for the realization of waveguides [2] or the growth of hyperbolic metamaterials for photonics [4]. The similarities and the differences with other noble metals, in particular with gold, are thoroughly discussed.

Results and discussion

We investigate the plasmon dispersion relations of TiN bulk in the different range of the electromagnetic spectrum (0-30 eV). In agreement with experimental results, TiN exhibits a low-energy plasmonic resonance in the visible range at $E_p \approx 2.5$ eV. The microscopic origin of this plasmonic excitation is analyzed in terms of the fundamental collective and/or radiative excitation of TiN electronic structure: TiN is not a purely free-electron metals, but a partially lossy materials where absorption processes take place over a large section of the electromagnetic spectrum.

![Fig. 1](image-url) (a) Simulated loss function for TiN bulk at increased transferred momentum $|q|$ in units of $2\pi/a_0$. Dotted-dashed line follows the low-energy single-particle (el-phonon) contribution at increasing $|q|$. Two sets of experimental EELS spectra (gray curves) are superimposed for comparison. (b) SPP dispersion relations at TiN/dielectric interfaces. Dashed lines are the dispersion relations for light in the corresponding dielectrics. Image adapted from Ref. [2].

The overall plasmonic properties result from a complex balance between intraband and interband transitions that act as screening term of the global electron gas. From the simulation of energy loss spectra at different momentum transfer we derive also the plasmon dispersion of TiN (Figure 1a). We demonstrate the retention of TiN optical
proper ties against the applied pressure and we prove a universal scaling law that relates the bulk modulus and the plasmonic properties of TiN. The dissipative contributions to TiN surfaces have also a critical effect on the stability and the spatial properties of surface-plasmon polaritons (SPP) [2] at the TiN/dielectric interfaces as well as on the overall optical response of metamaterial TiN/dielectric heterostructures [4].

The dissipative contributions to TiN surfaces have also a critical effect on the stability and the spatial properties of surface-plasmon polaritons (SPP) at the TiN/dielectric interfaces as well as on the overall optical response of metamaterial TiN/dielectric heterostructures [4].

The simulated dispersion relations of Fig. 1b show an increase of the stability of SPP at TiN/dielectric interfaces, as the dielectric constant is increased. Air is not able to stabilize a SPP at the TiN surface, and the TiN/air interface is not suitable for realistic applications. However, as dielectric constant of non-metal part is increased, the SPP can be progressively stabilized, giving rise to oscillating waves that propagate along the metal surface, with a wavevector sensitively larger than light (i.e. non-radiative mode). MgO and nitride compounds (AlN and GaN) in particular seem the best choices for the generation of SPP in TiN, in agreement with the recent experimental studies of these interfaces.

![Fig 1](image)

**Fig 1** (a) Side view of 1–10, 15, and 20 layer thick TiN(100) slabs used in the simulations. (b) Real part of the dielectric function as a function of the number of layers NL. Inset shows the comparison between theoretical (thick straight lines) and experimental (thin dashed lines) for 2 (blue) and 4 nm (red) films, respectively. Image adapted from Ref. [3].

Finally, by combining first-principles theoretical calculations and experimental optical and structural characterization techniques, we study the plasmonic properties of ultrathin TiN films (2–10 nm) at an atomistic level for the realization of ultrathin metasurfaces with plasmonic nonlinear properties [3]. Our results indicate a remarkably persistent metallic character of ultrathin TiN films and a progressive red shift of the plasmon energy as the thickness of the film is reduced, which is consistent with recent experimental studies (Fig. 2). Surface oxidation and substrate strain are also investigated to explain the deviation of the optical properties from the ideal case.

**Conclusions**

Our ab initio results confirm that at standard conditions TiN exhibits plasmonic properties in the visible regime, very close to gold, in agreement with experimental data. In contrast with malleable noble metals, the hardness of refractory ceramics allows for the exploitation of plasmonic properties also at high temperature and under pressure, conditions where standard plasmonic materials cannot be used. We also study on the plasmonic behavior of ultrathin (down to a few atomic layers) TiN films to determine the role of thickness, surface oxidation and interface strain on TiN optical properties. The observed plasmonic properties, in combination with the confinement effects, make TiN ultrathin films a promising material for the realization of plasmonic metasurfaces with enhanced nonlinearities and electrical tunability.

Nonlinear Chiral Response of Planar Plasmonic-Photonics Hybrid Metasurfaces

Feng Wang¹ and Hayk Harutyunyan¹,*

¹Department of Physics, Emory University, Atlanta, GA 30322, USA
*corresponding author, E-mail: hayk.harutyunyan@emory.edu

Abstract
Planar structures that can exhibit chiral response are highly desirable because of their facile fabrication, however fundamental challenges arising from the 2-dimensional nature of these systems prevent the generation of strong chiro-optical effects. In this work, giant enhancement of the handedness-dependent optical response in planar metallic nanostructures is shown by exploring the hybridization of plasmonic-photonic modes in a chiral metasurface.

1. Introduction
The advent of nanotechnology have made it possible to engineer sophisticated chiral platforms at the nanoscale [1, 2]. Importantly, such sample preparations require complex nanofabrication processes due to the 3-dimensional (3D) nature of chiral materials. Over the past two decades various approaches have been implemented including fabrication of nano-helices and layer-by-layer deposition of chiral materials. 2-dimensional (2D) fabrication, on the other hand, represents a more facile sample preparation method since materials can be simply fabricated in a single step, e.g. after lithographic patterning of the substrate. However, strictly 2D objects with rotational symmetry do not possess chiral properties because the sense of twist is reversed when light propagation is reversed. This leads to a diminished chiral response for planar plasmonic samples and metamaterials. Indeed, the experimental observation of spin-dependent optical effects for right circularly polarized (RCP) and left circularly polarized (LCP) light in planar samples have been attributed to such 3D effects as the presence of the substrate and off-normal illumination conditions. Here, we demonstrate an alternative approach to enhance the chiral optical effects in planar plasmonic systems by coupling them to photonic modes of a dielectric waveguide.

2. Results and Discussion
The hybrid modes of the plasmonic-photonic metasurface exhibit some unique properties that enable not only a strong enhancement of Third Harmonic Generation (THG) but also the observation of giant spin-dependent nonlinear chiral response, Figure 1. The metasurface is based on a straightforward planar lithography process and a standard nanophotonic platform, Silicon-on-Insulator (SOI) wafer, which makes its fabrication accessible for any potential applications. By tuning the periodicity of the plasmonic arrays and geometric parameters of the chiral unit cell facilitates full control of the spin-dependent optical response.

Figure 1: Chirality-dependent response of third harmonic generation in nonlinear hybrid metasurface.

Our demonstration opens up a novel approach for enhancing the chiral optical properties in metamaterials and nanostructures by coupling them to judiciously engineered photonic modes of the substrate. We believe that our results will pave the way for better fundamental understanding of planar chirality and spin-dependent optical response at the nanoscale.

Abstract

Metal nanoparticles are very interesting and important nanomaterials with a number of applications. The main goal of our work is to develop new anisotropic metal nanomaterials and explore their properties and potential uses. We have prepared a range of homo- and bi-metallic noble metal based anisotropic nanomaterials with a complex morphology. The materials have been characterized by various instrumental techniques and their biological behavior and catalytic activities in selected reactions have been tested. We believe that new nanomaterials developed in this work will find various applications in biomedical research, photonics and energy science.

1. Introduction

The optical properties of metal nanoparticles are highly dependent on their size and shape and as a result anisotropic plasmonic nanostructures have attracted much attention in recent years. These nanomaterials have been widely investigated due to their unique optical and electronic properties enabling important potential applications including biological sensing, catalysis, drug delivery energy harvesting and optoelectronics amongst others [1-5]. The main attraction of metal nanostructures resides in their surface plasmon resonance (SPR) phenomenon, which can be tuned both in wavelength and intensity by varying the size, shape and composition of metal nanoparticles. That collective oscillation of electrons creates a strong enhancement of the electromagnetic field in the vicinity of the nanoparticles upon photo-excitation. This in turn is the basis for many applications. It has been successfully employed to enhance Raman signals in Surface Enhanced Raman Spectroscopy (SERS). Raman spectroscopy is a characterization technique based on the inelastic scattering of photons by certain molecules. The photon sets the material into vibration and is scattered with a different frequency, or energy, and that shift is measured. SERS arises from the presence of metal nanoparticles on the substrate. The SPR-induced enhancement of the electromagnetic field in the vicinity of the surface strongly enhances the vibrational modes. A charge-transfer complex may also be formed between the surface and the analyte molecule, with electronic transitions in the visible range. It should be noted that the SERS effect does not occur on smooth surfaces, but only on rough, nanoparticulate ones. Although initially developed with spherical nanoparticles, SERS has been proven to be influenced by the particle size and shape [1-3]. Furthermore, there is a growing interest for gold nanoparticles in the fields of drug delivery and biological imaging. They are indeed a biologically inert material which also provides opportunities for functionalization as well as plasmonic imaging [4]. They can also be triggered by an external stimulus to release their cargo or produce heat [5]. The main aim of our work is the synthesis of a variety of anisotropic metal nanostructures and the investigation of their properties for potential biomedical and catalytic applications.

2. Results and Discussion

A variety of anisotropic nanostructured materials were produced based on the reduction of silver and gold salts, in a rapid synthesis at room temperature. TEM images of some examples of our anisotropic plasmonic nanostructures are shown in Fig. 1 below.

Silver nanoprisms were successfully synthesised and coated with a protective layer of gold according to published procedure [6]. As-synthesised silver nanoprisms were also used as templates to form gold nanorings. This was achieved by depositing a layer of gold at the edges of silver nanoprisms and subsequently etching away the remaining silver. It resulted in the formation of closed shapes from triangles to circles, best described as toroidal polyhedra. In common parlance, a ring designates a band-like object with a vacant centre, usually of circular shape. By extension, the closed triangles may be viewed as degenerated rings with nanometric dimensions. For simplicity, such materials are referred to as nanorings.

Addition of a large amount of gold and ascorbic acid in excess to initial silver nanoprisms resulted the formation of a hollow triangular nanostructure which was designated as nanobox. The postulated growth mechanism for these nanoboxes is through the galvanic replacement of silver by gold despite the presence of excess ascorbic acid. After the initial oxidation, Ag⁺ ions are believed to be co-reduced with HAuCl₄ by ascorbic acid and to form an alloy at the Au/Ag interface that reforms the particle shape while leaving a hollow space in the middle.

Then the deposition of gold onto silver nanowires was achieved through galvanic replacement using a solution of chloroauric acid which was added to the nanowires resulting in gold/silver nanotubes.
using temperature control the protocol was further optimised, reducing the poly-dispersion of the products and shortening the reaction time. These 1D ultrathin AuAg nanomaterials exhibit remarkable catalytic performance for the electro oxidation of ethylene glycol. Then we have developed ligand induced chiral modification of these 1D ultrathin materials using a ligand exchange method.

Finally, we have developed and investigated novel plasmonic-excitonic nanowire-quantum dot hybrid structures in which the quantum dots form a helical self-assembly around the metal nanowires.

3. Conclusions

We have prepared a range of anisotropic gold and silver nanostructures and investigated the influence of a number of parameters on their final shape and size. Deposition of gold on silver templates and galvanic replacement reactions led to the formation of hollow nanostructures. Precise control over the ratio of gold to silver allowed us to selectively retain or remove the initial silver nanoparticle. Gelatin was used to prepare a series of nano-composites with CdTe QDs and silver nanoprisms which have been characterised in terms of their cellular behaviour and structural features. We believe that new nanomaterials developed in this work will find applications in biomedical research, photonics and energy science.

Wafer-scale gold nanocube arrays for tuneable absorption and refractive-index sensing

Shaolong Wu*, Liang Li1, Liujing Li1, Zhongyuan Zhou1, Su Shen1, and Xiaofeng Li1

1 School of Optoelectronic Science and Engineering, Soochow University, Suzhou 215006, China.
*corresponding author, E-mail: shaolong_wu@suda.edu.cn

Abstract
Here, we have cost-efficiently prepared the large-area Au nanocube arrays (NCAs) only with the help of electrostatic force interacting. This method provides a flexible way for obtaining the controlled Au NCAs with various fill fractions and sizes, leading to a significant and tuneable light absorbance from visible to near-infrared spectrum. Besides, the as-prepared Au NCAs used as a prototype refractive-index (RI) sensor perform excellent stability and a sensitivity over 560 nm per RI unit.

1. Introduction
Over the last one to two decades, nanoscale particles, especially metallic nanostructures, have attracted extreme attention for exploiting new applications due to the novel properties strongly distinguished from the bulk counterparts. In particular, two-dimensional (2D) arrays of the metallic nanoparticles have been applied to a wide range of fields, involving biosensors, solar cells, photodetectors, nonlinear optics, and surface-enhanced Raman scattering (SERS). In these systems, precisely controlling the intervals between neighbouring elements in nanoscale is the key point for the specific applications. Currently, much more endeavours have been devoted to the synthesis of a wide range of nanoparticles in various shapes, sizes, and materials; nevertheless, less attention has been paid for the fabrication of large-area nanoparticle arrays with a reduced-cost method.

The patterned template, made from these techniques such as electron beam lithography, focused ion beam, and double-exposure interferometry, are the most common approaches to prepare 2D arrays of nanostructures. These methods usually involve a top-down nanofabrication technology integrated with evaporation deposition and lift-off processes. Nevertheless, direct etching and nanolithography methods are resisted by the high cost of experimental instruments and the scalability to large area. In addition, evaporation deposition technology has its limitation on roughness and choice of target materials.

Here, low-cost realization of the Au nanocube arrays (NCAs), via directly assembling the as-synthesized colloidal Au NCs atop of a polyelectrolyte (PE) spacer without any lithographic process, is reported. When these Au NCAs are coupled to a metallic film, the optical resonance inside the gap can excited and manipulated from visible to near-infrared spectrum by varying the Au NC size as well as the spacer thickness, leading to a narrow-band tuneable absorbance. Furthermore, a prototype refractive-index sensor based on the prepared Au NCAs is demonstrated to be with a considerable sensitivity and excellent stability.

2. Results and Discussion
Fig. 1a illustrates the diagrammatic drawing of the Au NCAs atop an Au film with a spacer. Fig. 1b shows the top-view SEM image of the prepared Au NCAs with fill fraction (ff) of ~12.4%. High-resolution SEM image of the as-synthesized Au nanocube powder centrifuged from colloidal solution is also given in the set of Fig. 1b, from which one can see that the nanocubes are relatively uniform in size and shape. The measured reflectance spectrum of the prepared Au NCAs is plotted in Fig. 1c, and an obvious and narrow-band reflection dip is observed.

Figure 1: Experimental and simulated result of Au nanocube arrays (NCAs). (a) Schematic of the disordered Au NCAs assembled atop an Au film with a polyelectrolyte spacer. (b) SEM image of the prepared NCA with a surface fill fraction of 12.4%, an edge length of 85 nm and a spacer of 8 nm. The scale bar is 1 μm. Inset is the high magnification SEM image of nanocubes and the scale bar is 100 nm. (c) Measured reflection spectra (solid line) of the prepared disordered Au NCAs coupled with Au film, with a comparison of the simulated ordered one (dotted line). (d) Cross profiles of the normalized magnetic field of the simulation cell at wavelength of 770 nm.

To reveal the underlying reason for the reflection dip, we performed the optical simulation and examined the
electric/magnetic field profiles. The Au NCAs are simplified to be periodically arranged in the simulation, and the main structure parameters of the simulated unit are indicated in Fig. 1d. One can see that the two reflection dips are nearly overlapped, implying the cause for the observed reflection dip can be explained by the optical simulation. Fig. 1d shows that the normalized magnetic field (|H/H₀|) is intensively confined inside the gap, while there is no electromagnetic coupling between the neighbouring nanocubes, that is, the optical resonance inside the gap (named as plasmonic gap mode) is excited and the in-plane coupling mode is not excited at the present conditions.

Furthermore, we demonstrated the superiority of the Au NCAs relative to the Au nanorod and nanosphere arrays, and observed that there is no obvious reflection dip for the two references [1]. The tuneable absorption is realized by varying the spacer thickness and the edge length of Au nanocubes. It should be noted that when the ff increases, the reflection dip does not shift, but the value of the reflection dip gradually decreases.

Figure 2: (a) Schematic configuration of a prototype device base on the Au NCAs for the bulk solution sensing. (b) Measured reflection spectra of the prepared sensor measured in the solution of different glucose concentrations. (c) Reflectance spectra of the prepared sensor repeatedly measured for three times. (d) The sensing performance of the Au NCs dispersed in an aqueous solution with different glucose concentrations as a comparison.

Finally, we fabricated a prototype device for refractive index sensing based on the above-mentioned Au NCAs. The working principle of the sensor is the optical resonance dependent on the background-material refractive index (n₀). As shown in Fig. 2a, when the PDMS cave is filled with various solutions, the pre-loaded Au NCAs would be surrounded by different n₀. Here we discretely used aqueous solutions of glucose in different concentration (i.e., 0, 9.1%, 16.7%, 23.1% and 28.6%), the corresponding refractive indices were 1.3328, 1.3437, 1.3519, 1.3597 and 1.3676, respectively. When the Au NCAs with L = 85 nm, b = 8 nm and ff = 5.5% are employed, we observed a red shift in the reflection dip as the glucose concentration increases (as shown in Fig. 2b), similar to previous refractive-index sensor [2]. The fitted linear relationship is shown in the inset of Fig. 6b, and a sensitivity (S) of 560 nm/RIU is calculated.

To assess the stability of the Au NCAs based sensor, the reflectance spectra of one device was repeatedly tested after being preserved for 0 day, 30 days and 120 days, separately. Fig. 2c show that all the dip positions and values are nearly the same, implying that the device possess excellent stability and repeatability. As a comparison, the sensing performance from the colloidal Au NC solution with varying glucose concentrations is also evaluated via optical density spectrum (as shown in Fig. 2d). One can see the peak wavelength of the OD spectrum shows a slight redshift as n₀ increases. A much smaller S (341 nm/RIU) for colloidal Au NC solution confirms the advanced performance for the Au NCAs-based sensor.

3. Conclusions

We have facilely fabricated Au nanocube arrays and investigated its potential application for refractive index sensing due to the strong optical resonance between the upper Au nanocube arrays and the lower Au film. The gap-mode resonance can be tailored by controlling the cube sizes and the gap thicknesses according to the reflectance dip change. The surface fill fraction can also be tuned by controlling the nanocube solution concentration. Long-term stability and repeatability for the optical response can be achievable. The refraction index sensing experiments show that the sensitivity can be up to 560 nm/RIU. This work gives a cost-efficient route to prepare the large-area Au nanocube arrays and point out a potential application.

References

In this seminar, I will present our team’s effort in fabricating a stable super-hydrophobic surface-enhanced Raman Scattering (SH-SERS) platform for trace molecular sensing [1-2]. The design strategy of our SH-SERS focuses on integrating the intense electromagnetic field confinement generated by highly crystalline Ag nanocubes or nanowires with a superhydrophobic surface capable of analyte concentration to lower the molecular detection limit. These single crystalline Ag nanocubes or nanowires are assembled using the Langmuir-Blodgett technique to create surface roughness followed by chemical functionalization with perfluoro-decanethiol. The resulting substrate has an advancing contact angle of >150° and an analyte concentrating factor of 10-100 fold for water and 8-fold for toluene, as compared to a hydrophilic surface. Our protocol is a general method that provides a simple, cost-effective approach to develop a stable and uniform superhydrophobic SERS platform for trace molecular sensing.

Generation, thermalization and extraction of hot carriers in metallic nanoparticles

Johannes Lischner
Department of Materials, Imperial College London, London, United Kingdom

Abstract
Plasmon-induced hot carriers in metallic nanostructures have attracted significant attention as they can be harnessed for applications in sensing, photovoltaics and photocatalysis. To study hot carrier properties, I have developed a material-specific approach that combines quantum-mechanical calculations of large nanoparticles with a classical electrodynamic treatment of localized surface plasmon excitations. I have used this approach to study hot-carrier generation in both mono-metallic nanoparticles and also in bi-metallic core-shell nanoparticles. Combining this approach with the Boltzmann equation and Marcus theory of electron transfer allows me to capture also the thermalization of hot carriers and their extraction.

1. Introduction
There has been significant interest in energetic or “hot” carriers generated from the decay of localized surface plasmons in metallic nanostructures. Potential applications of such systems involve sensing, optoelectronics, photovoltaics and also photocatalysis. Recently, there has been an active debate about the physico-chemical origin of the photocatalytic activity of metallic nanostructures. Specifically, the question is whether hot carriers are relevant to nanoplasmonic photocatalysis or if experimental observations can be explained by the local heating of the nanoparticle leading to enhanced rates of chemical reactions according to the Arrhenius law.

2. Methods
In this section, we describe the techniques used to model hot carrier generation in metallic nanoparticles as well as hot carrier extraction and thermalization.

To calculate the rate of hot carrier generation in an illuminated nanoparticle, we employ Fermi’s golden rule. To calculate the electron-plasmon coupling constant, we use the plasmon potential from the quasistatic approximation and electron wavefunctions from a spherical well model of the nanoparticle, where the depth of the well is adjusted to reproduce the experimentally measured workfunction of the material. Finally, we obtain transition linewidths by adding the quasiparticle linewidths of electrons and holes involved in the transition which include contributions from electron-electron and electron-phonon interactions [1]. To model core-shell nanoparticles, a spherical two-step potential is solved where the energy difference between the potential steps is given by the experimentally measured contact potential between the two metals [2].

To study the photocatalytic activity of nanoplasmonic systems, we focus on water splitting. The total number of photocatalytically active electrons is obtain by calculating the number of hot electrons with energies larger than the redox potential of the hydrogen evolution reaction. Similarly, photocatalytically active holes must have an energy lower than the oxygen evolution reaction.

To study the thermalization and extraction of hot carriers, we solve Boltzmann’s equation. We include scattering terms that capture the effects of electron-electron and electron-phonon interactions. We assume a continuous wave illumination. We also include the extraction of hot carrier due to redox reactions at the surface of the nanoparticle. Electron transfer is described using Marcus theory.

2.1. Results
Figure 1 shows the total rate of plasmon-induced hot carriers that are photocatalytically active for water splitting. Results are shown for different materials and different dielectric environments. We find that hot holes are predominantly produced by transition-metal nanoparticles, such Ag and Au. In contrast, alkali and alkaline-earth nanoparticles exhibit the best performance in producing hot electrons for the hydrogen evolution reaction.

Figure 2 compare the performance of various bimetallic core-shell nanoparticles for water splitting. We find that core-shell systems perform better than mono-metallic systems, which are the diagonal elements. In particular, core-shell nanoparticles with thin transition-metal shells and alkali metal core exhibit the best performance.

3. Conclusions
We have developed a new material-specific approach to study the generation, thermalization and extraction of hot carrier in nanoplasmonic materials. In particular, we have studied the performance of mono-metallic and bi-metallic core-shell nanoparticles for water splitting and have discovered novel material combinations as promising photocatalysts.
Figure 1: Total number of plasmon-induced hot electrons and hole in different mono-metallic nanoparticles that can trigger the hydrogen evolution reaction (HER) and oxygen evolution reaction (OER), respectively. Results are shown for different dielectric environments.

Figure 2: Comparison of different bi-metallic core-shell nanoparticles for water splitting. The figure of merit (FOM) is given by the lower of the hot electron and hot hole generation rates. Crosses denote systems which are not stable in aqueous environments and purple frames indicate systems where the formation of an oxide layer is expected.

Abstract
Surface enhanced Raman scattering (SERS) for amplification of Raman signals has been studied for several decades [1-3]. Nevertheless, a mechanism of chemical enhancement, one of the mechanisms of SERS, is not yet completely understood [4-7]. We investigated the chemical contribution of the SERS effect of 4-Mpy molecules deposited on ZnO nanostructure by resonance Raman scattering with incident photon energy ranging from 1.7 eV to 5.7 eV. Through this study, we provide theoretical and experimental means to study chemical enhancement mechanism for SERS.

1. Introduction
SERS is a tool that amplifies small Raman signals [4-9]. In particular, many studies have been made as a very attractive tool in that signals from single molecules can be detected. SERS has two major mechanisms. One is the electromagnetic mechanism originated from surface plasmon resonance. This occurs when the energy of excitation laser matches the surface plasmon energy of a metal substrates and is most strong at hot spots between metal substrates, leading to a very large enhancement factor up to $10^{12}$ [8]. The other is the charge transfer enhancement, also called chemical enhancement, which is associated with charge transfer between the molecule and the substrate [9-12]. Although there have been a lot of studies on SERS, the chemical mechanism has yet to be completely clarified. This study suggests theoretical and experimental methods to study the mechanism of chemical enhancement of SERS in depth. We have used semiconductor substrates in order to exclude the contribution from surface plasmon resonance as Raman enhancement mechanism.

2. Results
Figure 1 shows Raman spectra of 4-MPY molecules adsorbed on ZnO nanostructure as a function of excitation energy. The range of excitation energies is from 1.96eV to 5.64eV, which contains both the transition energy between the highest occupied molecular orbital (HOMO) of the molecule and the conduction band (CB) of the ZnO (in UV range) and the transition energy between the valence band (VB) of the ZnO and the lowest unoccupied molecular orbital (LUMO) of the molecule (in visible range).

Figure 1: (a) Raman spectra of a monolayer of 4-Mpy deposited on nanostructured ZnO rod arrays for four exemplarily laser energies in the deep UV range between 5.64 eV (220 nm) and 4.96 eV (250 nm). (b) Raman spectra of a monolayer of 4-Mpy deposited on ZnO rod arrays for excitation energies covering from mid UV to visible spectral range.

Figure 1 also shows that the ring-breathing mode of molecules near 1000 cm$^{-1}$ is greatly increased at 5.14 eV excitation, starting from 4.96 eV. In the visible range, the signal gradually increases from 2.54 eV to 2.33 eV. However, the signal is not observable at 3.76 eV and at 1.96 eV. We observed that the Raman intensities of 4-Mpy peaks at 5.14 eV in the UV region is about 20 times
larger than that in the visible region, due to resonance transition of HOMO to LUMO of 4-MPY molecule itself.

3. Discussion

We also calculated the Raman susceptibility profile by using the four-photon Green’s function [13] in the resonant Raman scattering process, which showed a good agreement with our experimental results as shown in Fig 2 (a). As expected, we observe two major resonances that visually convert from molecular HOMO to CB and from semiconductor VB to molecular LUMO in UV. Each arrow in Fig. 2 (a) is the result of each charge transfer transition in the same color in Fig. 2 (b). Surprisingly, the UV resonance consists of two contributions. These two are ~400 meV apart from each other as shown in Fig. 2 (a). Considering the energy difference shown in Fig. 2 (b), we could see that the charge transfer from 4-Mpy HOMO to the excitonic state of ZnO exhibits a very strong Raman signal.

Figure 2: (a) SERS Raman susceptibility (Intensity of the Raman response of a 4-Mpy monolayer on ZnO rods) of the mode at 1000 cm\(^{-1}\) as a function of excitation energy. (b) Pictorial model of the investigated system, outlining the observed resonances in (a) due to the indicated optical transitions.

4. Conclusions

We studied the chemical SERS effect of 4-Mpy adsorbed on semiconducting ZnO rods by resonant Raman spectroscopy in the ultraviolet and visible spectral region. We describe the observed resonance using a model based on a four-photon Green’s function calculation. In addition to the two resonances of 5.15 eV and 5.55 eV in UV, one resonance is observed at about 2.43 eV. The strongest resonance is found at 5.15 eV ultraviolet radiation and is the result of transitioning to an exciton-related state below the ZnO CB. Our findings suggest that consideration of every possible charge transfer route should be needed for studying chemical enhancement of SERS and from the consideration deeper understanding of enhancement mechanism can be attained.

Abstract

We focus on less studied effect in SERS of chemical enhancement responsible for selective enhancement of Raman response of different analyte molecules adsorbed on same substrate materials. We incorporate finite-difference time domain (FDTD) simulations to discuss how the design of structures attributes to electric field and absorption of non-metallic SERS system which does not involve surface plasmonic resonance. Comparing to our experimental results, we suggest optimization conditions for chemical enhancement in SERS without involving surface plasmon resonance.

1. Introduction

There have been large number of theoretical and experimental studies of Surface enhanced Raman spectroscopy (SERS) over several decades for its huge enhancement. Huge enhancement factors of up to over $10^{10}$ is explained to be mainly due to surface plasmon resonance between substrate materials and incident laser light. However, chemical enhancement, another of the SERS mechanisms, has not yet been described for its obvious mechanism. Chemical enhancement can be very fascinating and highly available in that it plays a role in selectively enhancing the Raman reaction of different analyte molecules adsorbed on the same substrate material. In this study, We discussed the mechanism of this chemical enhancement. We incorporate finite-difference time domain (FDTD) simulations to calculate electric field intensity and absorption profile on the surface while varying design of models. As a result, we can exclude the electric effect generated by the structure from the experimental results so that we can solely study the chemical enhancement mechanism. In a previous study, we found that the shape of the semiconductor substrate structure affects the enhancement factor[1]. Furthermore, in this study, we suggest optimization conditions for the chemical enhancement of SERS without including surface plasmon resonance by comparing FDTD simulation results to our experimental results.

2. Discussion

2.1. Simulation of substrate structure effect

First, to investigate the electric field effect of the substrate structure before the molecule was adsorbed, we built the model similar to the actual structure we used for experiments in the FDTD simulation program as shown in Figure 1. Figure 1-(a) shows optical image of the actual structure of ZnO rods on the substrate and Figure 1-(b) is the model we made in the FDTD simulation program to calculate the electric field distribution and the absorption. We set the frequency-domain field monitors above the rod, on the surface of the substrate and also in the rod to record electric field and the power passing through the monitors. The laser beam in the actual experiments was considered to be a plane wave source in this simulation.
The electric field intensity distribution of four different wavelength source by FDTD simulation (a) at 300 nm (b) at 488 nm (c) at 532 nm (d) at 633 nm

The results of this FDTD simulation are shown in Figure 2. Figure 2 shows the electric field intensity distribution of four different wavelength source. The most concern in chemical SERS experiments at various wavelengths is the overlap of SERS effects due to penetration depth and reflection at each wavelength. However, as the result of simulation, although the electric field intensity inside the rod seems to be larger at longer wavelength sources, the electric field intensity outside the rod has little difference depending on the wavelength of source. This result excludes the possibility that it is the wavelength that makes the difference in enhancement of Raman signal. In other words, although the reflection by the substrate occurs more intensely in longer wavelength because of its longer penetration depth, the reflection is only confined to the rods and doesn’t affect Raman signal.

2.2 Simulation of molecularly adsorbed ZnO rods

(a) Measured complex refractive index of 4-MPY by ellipsometry (b) Model of adsorbed 4-MPY molecules on ZnO rod substrate in FDTD simulation

The chemical enhancement effect was observed when 4-MPY molecules were adsorbed on ZnO rod substrate which the combination has been widely used in chemical enhancement experiments. However, the FDTD simulation of adsorbed 4-MPY molecules on a substrate had not been conducted before, therefore, we measured the refractive index of 4-MPY using ellipsometry so that we can calculate FDTD simulation. As a result, we could obtain a complex reflective index of the 4-MPY molecule as shown in Figure 3-(a). Figure 3-(b) shows the model of adsorbed 4-MPY molecules on ZnO rod substrate in FDTD simulation. The molecules on the substrate were considered to be thin film. By running FDTD simulation, we could find what kind of combination of a structure and molecule can enhance the SERS signal effectively.

3. Conclusions

We calculated the absorption and electric field profile using finite-difference time domain (FDTD) simulation and compared to our experimental data. The results of the simulation indicate that the reflection by the substrate is only confined to the rods and it is not the reflection that enhances the raman signal, hence, we were able to effectively eliminate the electric effects of wavelength and substrate structure when analyzing chemical SERS experiments which use various wavelengths.

Furthermore, we measured complex refractive index of 4-MPY molecules by ellipsometry to obtain FDTD simulation results for molecule-adsorbed ZnO rod substrates. Our study would be very interesting in that we measured the refractive index of 4-MPY molecules for the first time, which are widely used in chemical SERS experiments, and applied to the FDTD simulation to suggest optimized models for larger enhancement.

Cooperative emission by quantum plasmonic superradiance

Hugo Varguet, Stéphane Guérin, Hans Rudolf Jauslin, and Gérard Colas des Francs

Laboratoire Interdisciplinaire Carnot de Bourgogne (ICB), UMR 6303 CNRS, Université Bourgogne Franche-Comté, 9 Avenue Savary, BP 47870, 21078 Dijon Cedex, France

Abstract

We investigate the correlated emission from an assembly of emitters coupled to a plasmonic particle, in a quantized model. We observe burst of emission but demonstrate that modal destructive interferences can inhibit the cooperative behaviour.

1. Introduction

Superradiance refer to the collective emission from N emitters gathered in a subwavelength volume. In such configuration, their emission is coupled to the same electromagnetic mode so that fast decay rate (proportionnal to the number of emitter; \( \Gamma_N = N\Gamma_1 \)) and bright emission (proportionnal to \( N^2 \)) occur. It originates from spontaneous phase-locking of the atomic dipoles through an electromagnetic mode and is very similar to the building of cooperative emission in a laser amplifier [1]. Using a classical approach, it has been proposed to realize plasmon analogous of superradiant states by coupling an ensemble of emitters to a metal nanoparticle to further increase the brightness and miniaturization of the collective nanosource [2, 3]. In this work, we discuss the properties of plasmonics superradiant and subradiant states (Dicke plasmonic states) with particular attention devoted to describe the construction of the cooperative behaviour, a fully quantum characteristic of superradiance [4].

2. Discussion

Figure 1a) represents the dynamics of correlated emission for 6 radial emitters coupled to a silver nanoparticle and its comparison with two limits cases: ideal superradiance and incoherent emission. Ideal superradiance is obtained when all the emitters are located at the same position. We observe a short burst of emission, on a timescale \( \tau_N \approx \tau_1/N \), characteristics of superradiance collective emission (blue curves). On the opposite, independent emitters emission gives the well-known Purcell enhanced spontaneous emission with an exponential decay (red curves). In case of homogeneous repartition of azimutal emitters around the MNP, we still observe the burst of emission since the LSP symmetry leads to identical coupling of the emitters. In case of radial emitters (Fig. 1b), the cooperative process is degraded because of the coupling to high-order modes. The

Figure 1: Collective rate for 6 emitters coupled to a 16 nm silver nanoparticle. a) azimuthal orientation. b) radial orientation. Blue curves corresponds to ideal superradiance with the emitters located at the same position. Red curves present the incoherent emission. Green and black curves refer to the configuration schemed on the graph (emitters on the MNP poles or homogeneously distributed). The emission wavelength is resonant with the dipolar mode LSP \(_1\) (\( \omega_0 = \omega_1 = 2.789 \) eV) and the separation distance between the mitterand the MNP is \( h = 20 \) nm.
apparent quantum yield of the collective emission, defined as the ratio between the far-field scattering and the total superradiance emission, is about 15% for 30 nm silver MNP.

3. Conclusions

We derive a quantum approach for plasmonic superradiance and discuss the dynamics of cooperative emission. The system follows the plasmonic Dicke ladder and strong correlations build up between the emitters, LSP mediated, so that superradiance can be Purcell enhanced. However, superradiance blockade occurs at small distances. We emphasize that the origin of superradiance degradation at short distances is different from the mechanism of fluorescence quenching. Superradiance cooperativity is jeopardized because of modal destructive interferences whereas fluorescence quenching originates from an increase of the non radiative rate. We expect that plasmonic superradiance could be experimentally investigated on metallo-dielectric nanohybrids [5, 6, 7, 8]. This constitutes ultrafast and extremely bright optical nanosources of strong interest for integrated nano-optics platforms.

Abstract
Using a spatial light modulator, a pre-calculated heat source distribution is projected on a plasmonic nanoparticle carpet to produce a fast, reconfigurable and accurate temperature distribution in an arbitrarily-shaped 2D region. The temperature maps induced by the thermoplasmonic effect are deduced from images obtained using two types of wavefront sensors, a shearing interferometer and a thin-diffuser-based imaging approach.

1. Introduction
Temperature is often a critical factor, in physics as well as biology. Most existing techniques (e.g. ovens, incubators…) only provide global temperature control and incur strong inertia. Thermoplasmonic heating can give access to fast, local and contactless optical temperature control. However, tailoring temperature at the micro-scale is not straightforward since heat diffusion alters temperature patterns. In this study, we propose and demonstrate an accurate and reconfigurable microscale temperature shaping technique by precisely tailoring the illumination intensity that is sent on the sample. A homogeneous array of absorbing plasmonic nanoparticles is used to efficiently convert light into heat through thermoplasmonic effects.

2. Light and heat structuration
The method consists in (i) calculating the distribution of heat sources, also named Heat Source Density (HSD), which pre-compensates heat diffusion effects [1] so as to produce the desired temperature distribution, and (ii) using a Spatial Light Modulator (SLM) and a Gerschberg-Saxton calculation of the appropriate phase pattern in order to shape the illumination and reproduce this HSD in the nanoparticle plane. After heat diffusion, the tailored heat source distribution produces the desired microscale temperature pattern, as illustrated in Fig.1.

The resulting temperature distribution is measured using wavefront-sensing-based temperature imaging microscopy [2,3] using a shearing imaging interferometer. Beyond this interferometer, we will present a wavefront imaging technique based on the use of a simple thin diffuser in order to measure speckle changes using the memory effect. We will show how this type of cost-efficient wavefront sensing system can be used to derive temperature distributions, particularly in the context of thermoplasmonic effects.

Figure 1: Schematic representation of the Spatial Light Modulator-based projection of an optical pattern calculated to pre-compensate heat diffusion. After photothermal conversion by a gold nanoparticle array, heat diffusion induces the desired 2D temperature distribution.

Figure 2: Reconfigurable temperature-shaping workflow (calculated images). ΔT is the targeted temperature increase distribution; Q is the associated HSD distribution; Φ is the corresponding phase distribution in the Fourier plane of the illumination pattern; I is the light intensity distribution in the
sample plane; $\Delta T'$ is the resulting temperature increase distribution.

Fast (sub-ms) thermalisation is possible when addressing microscale domains, and we demonstrate accurate, and reconfigurable temperature patterns over arbitrarily-shaped regions. In the context of cell biology, we present a methodology combining fluorescence imaging with reconfigurable temperature shaping to thermally target a given population of cells or organelles of interest, opening new strategies to locally study their response to thermal activation [4].

Finally, we will illustrate applications of microscale heat shaping, using resistors with optimized shapes, in order to engineer thermal landscapes and manipulate the phase of light. Various adjustable optical functions including lenses, phase pistons, axicons or Zernike polynomial-type phase shaping can be generated by calculating the appropriate heat source density and the corresponding resistor design. Using this electro-thermo-optical approach, we will show that a broad range of optical elements can be reproduced and electrically controlled, opening a broad range of imaging applications.

Abstract

For decades, many studies have been conducted to improve the efficiency of photovoltaic devices. In this study, we focused on structural properties, especially phase transition behavior as a result of temperature changes in methylammonium lead halide perovskite (CH$_3$NH$_3$PbX$_3$, X-I, Br, and Cl) to understand fundamental properties in these materials. The properties of perovskite materials on halogen elements, and Raman scattering can show that the contribution to the structural phase transition from each atomic/molecular vibration varies from compound to compound.

1. Introduction

Inorganic-organic hybrid lead halide perovskites have been getting huge attention because of its various merits; low cost to make, earth abundant, tunable bandgap etc. In addition, the efficiency of solar cells made of these materials is quite high (~23%), which promotes more studies towards next generation photovoltaic devices. However, perovskite thin films are unstable in ambient conditions, especially under UV illumination or presence of water vapor so in order to minimize stability issues, we used single crystal samples in this study of fundamental properties. The perovskite materials exhibit different properties upon the halogen elements (chlorine, bromine and iodine), so the temperature at which phase transition occurs changes with different compounds. For example, CH$_3$NH$_3$PbBr$_3$ exhibits a structural phase transition from a cubic to a tetragonal structure at $\sim$236K and CH$_3$NH$_3$PbCl$_3$ shows the similar phase transition at $\sim$179K. To understand the basic properties leading to photovoltaic mechanism of CH$_3$NH$_3$PbX$_3$, first we focused on phase transition behavior of materials. Raman scattering spectroscopy observes small changes in phonon spectrum that reflect microscopic environments and configurations, so it is useful as a research mean and a sensitive monitoring tool to study structural changes that lead to understand fundamental properties of materials.

2. Results

There are 2 groups of vibration modes in MAPbX$_3$; external vibration mode of inorganic (PbX$_3$) anion, internal vibration mode of MA (CH$_3$NH$_3$) cation. The internal vibration modes of MA cation range from 400-3300cm$^{-1}$.

2.1. CH$_3$NH$_3$PbBr$_3$,

![Figure 1: Temperature dependent Raman spectra of CH$_3$NH$_3$PbBr$_3$ single crystal from 80 K to RT. The spectra range from 300 cm$^{-1}$ to 3100 cm$^{-1}$.](image-url)
II phase is \( P4/mcm \). At 145K, another phase transition from tetragonal II to orthorhombic phase occurs. As can be seen clearly in our results, some peaks show an abrupt change at \(~140\)K in frequency and/or intensity.

### 2.2. \( \text{CH}_3\text{NH}_3\text{PbCl}_3 \)

![Image](http://via.placeholder.com/150)

Figure 2: Temperature dependent Raman spectra of \( \text{CH}_3\text{NH}_3\text{PbCl}_3 \) single crystal from 80 K to RT. The spectra range from 100 cm\(^{-1}\) to 3300 cm\(^{-1}\).

\( \text{CH}_3\text{NH}_3\text{PbCl}_3 \) also has 3 phases: cubic, tetragonal, orthorhombic depending on temperature. In case of chloride, space group of tetragonal phase is \( P4/mcm \) and the window of phase transition temperatures is narrow: The phase transition from cubic to tetragonal phase is done at 178.8K and the subsequent phase transition from tetragonal to orthorhombic phase occurs at 172.9K. In \( \text{CH}_3\text{NH}_3\text{PbCl}_3 \), more changes are observed shown especially at high frequency than Bromine. There are two peaks at 3150 cm\(^{-1}\) and near 2900 cm\(^{-1}\) appearing in orthorhombic phase, and they abruptly change around 160K.

### 3. Discussion

Comparing \( \text{CH}_3\text{NH}_3\text{PbBr}_3 \) and \( \text{CH}_3\text{NH}_3\text{PbCl}_3 \), both materials show abrupt change in each phonon spectra. Each change is associated with phase transition from tetragonal to orthorhombic phase at their respective temperatures, \(~140\)K for bromides and \(~160\)K for chlorides. Though the two materials exhibit qualitatively similar changes with respect to temperature change, there are differences that reflect differences in microscopic environment, especially in MA configuration.

### 4. Conclusions

MA perovskites are known to possess different phases with respect to temperatures. They also show phase transition behavior accordingly. For understanding structural characteristics, study of various phases and relation between them is essential. However, thin film perovskite is unstable at ambient conditions. We used single crystalline samples to study structural properties and did not find any stability issues. By measuring temperature dependence in Raman spectra, it was observed that the contributions to the phase transition from each atom/molecule vibration were qualitatively different. We also show that Raman scattering spectroscopy is a very effective mean to monitor different phases by observing abrupt and/or gradual changes in phonon spectra that sensitively reflect microscopic environmental changes.

Abstract

Cavity quantum electrodynamics calculations are used to elucidate how quantum dots can become entangled in hybrid systems composed of quantum dots and plasmonic resonators. By coupling the quantum dots to photonic cavities it is further shown how measurement of the two-photon correlation function can be used to verify the entanglement.

1. Introduction

There is much interest and research activity in quantum computing, quantum communication and quantum sensing, collectively known as quantum information science (QIS). Entanglement between or among systems is a highly quantum mechanical state that cannot be written as a separable product of component states and is a key component of a lot of QIS protocols. For example, entanglement can improve the sensitivity of measurements beyond what can be achieved classically [1].

A number of simple models and calculations, e.g., Refs. [2-5] have suggested that quantum dots, taken to be simple two-level systems, interacting with plasmonic structures (waveguides, nanoparticles and cavities) can become entangled due to their coupling through the plasmonic structure. One can imagine laser excitation or driving of one of the quantum dots in a two quantum dot/plasmonic system, and the second quantum dot becoming excited and exchanging energy with the first quantum dot via their mutual coupling with the plasmonic system. A significant degree of entanglement, as characterized by concurrence, also can result [6]. An important question to address is how one could experimentally verify entanglement in such systems. One measure, proposed by Dumitrescu and Lawrie [5], is to measure photon coincidences associated with the emission from the quantum dots, with these coincidences exhibiting features characteristic of anti-bunching (a dip in the steady-state, same-time two-photon correlation function or \( g^{(2)} \)). In this contribution a different, time-dependent approach is suggested that leads to \( g^{(2)} \) exhibiting maxima when the quantum dots are entangled [7].

2. Results and Discussion

We consider the system depicted in Figure 1, which is composed of two quantum dots, each placed or interacting with a photonic cavity and a plasmonic nanoparticle.

Figure 1: Schematic diagram of the proposed system for verifying quantum dot entanglement.

We imagine that the photonic cavities are connected to detectors in the fashion of a Hanbury Brown Twiss experiment [8]. In addition, we imagine a femtosecond pulse exciting quantum dot 1 (QD1), which leads to the second quantum dot (QD2) becoming entangled with QD1. Our cavity quantum electrodynamics calculations of this system yield results such as those depicted in Figure 2. In this figure we plot the concurrence associated with entanglement of the two quantum dots (left-hand axis) as well as \( g^{(2)} \) (right-hand axis). As time evolves after the initial excitation the concurrence oscillates from small or zero values to moderately large values (a concurrence of 1 is maximal entanglement), and the two-photon correlation function is seen to exhibit significant spikes whenever the concurrence is close to or reaches a maximum.

This remarkable correlation between concurrence and two-photon correlation function, as well as the periodic oscillations in time, can be understood in terms of the entanglement passing between the two quantum dots and the two photonic cavities. The overall entanglement (sum of entanglement of the cavities and the quantum dots) remains
a constant. An analytical model can also be constructed to show this behavior [7].

Figure 2: Strong correlations are exhibited between the concurrence of QD1 and QD2 (a measure of entanglement) and photon coincidences associated with photon emission from the photonic cavities.

The transparency and tunable electrical, optical, and magnetic properties of metal oxide thin films make them very attractive for many applications in electro-optical devices. However, the integration of such materials at the micro or nanoscale is still challenging. In recent years, solution processing combined with direct-patterning techniques such as micro-/nanomolding, inkjet printing, e-jet printing, e-beam writing, and photopatterning has drawn much attention because of the inexpensive and simple fabrication process that avoids using capital-intensive vacuum deposition systems and chemical etching. [1]

We present here our latest results on the laser direct writing of metal oxide micro and nanostructures. The key step is to develop photosensitive metal-oxo precursors solutions that can be patterned with high resolution. Stable solution of metal-oxo clusters were prepared by reaction between metal alkoxide precursors (Zn, Ti, Zr) and ligands (mostly carboxylic acids). These solutions were doped to tune the electrical or magnetic properties (In, Al, Co) and thin films were prepared by spin-coating.

Photocrosslinking was studied by spectroscopy (FTIR, Raman), spectroscopic ellipsometry with irradiation wavelength in the deep-UV range (193 nm and 266 nm). It was demonstrated that the Deep-UV irradiation is very efficient to induce the elimination of the organic molecules complexing the metal and then provoke crosslinking by condensation reaction.[2]

These materials were evaluated for photopatterning with resolution between 50 nm to several hundreds of microns.[3, 4] Furthermore, practical applications are demonstrated in thin-film transistors and biochemical sensors on a wide range of substrates. We show in particular application of these metal oxide nanostructures as gas sensors and for magnetic properties. [5]

Since direct-patterning techniques enable low-cost fabrication of nanoscale metal oxide structures, these methods are expected to accelerate the development of nanoscale metal oxide devices and systems based on metal oxide components in important application fields such as flexible electronics, the Internet of Things (IoT), and human health monitoring. Abstract

Metallic nanoparticles exert a strong influence on the electrodynamics and mechanical dynamics of nanoemitters in their vicinity. Transformation optics can provide analytical descriptions and physical insight on these scenarios. As a case of study, we discuss the use of conformal transformation to understand the nonradiative Purcell enhancement and the optical forces experienced by nanoemitters nearby bowtie nanocavities and nanoantennas.

1. Introduction

Recent advances in nanofabrication has made it possible to fabricate nanostructures with a wide range of topologies [1]. This flexibility in attainable topologies opens endless possibilities, but at the same time makes the optimization of designs more challenging. Full-wave simulations can assist in the design process, but they have two main disadvantages compared to analytical solutions: computational burden that can potentially be unaffordable and limited physical insight.

Among the limited number of existing analytical techniques suitable for nanoplasmics, transformation optics [2] is becoming the norm given its rigor and accuracy, which have made it possible to have analytical electromagnetic descriptions of crescent-shaped [3], cylindrical sector [4], bowtie [5] and tripod nanoantennas [6], as well as ring-disk [7] and crescent-shaped nanocavities [8]. This success should not come as a surprise though since conformal transformation was already used successfully in microwave engineering to provide analytical description of planar transmission lines [9].

Inspired by [2]-[8],[10] we investigate analytically and numerically the Purcell enhancement and the optical forces experienced by a nanoemitter (modelled as a point dipole) inside a 20 nm inner diameter bowtie nanocavity [11] and we also unveil hidden symmetries in bowtie nanocavities and 20 nm outer diameter nanoantennas.

2. Conformal mapping

Given the subwavelength diameter of the plasmonic structures under study, we assume a quasi-static problem. In this case, the electric and magnetic fields are decoupled and the former can be described by an electrostatic potential satisfying Laplace’s equation.

By applying the conformal transformation $z = \ln(z'/a)$, the bowtie topologies shown on the left-hand side of Fig. 1 can be transformed into the geometries shown on the right-hand side of Fig. 1. Here $z = x + iy$ and $z' = x' + iy'$ correspond to the spatial coordinates in the transformed and original frames, respectively, and $a$ is the distance between the nanoemitter and the coordinate origin. Notice that the nanocavity in panel (c) and the nanoantenna in panel (e) have mirror symmetric transformed spaces (see Fig. 1(d,f)).

![Figure 1](image-url)

Figure 1: (a, c, e) bowtie nanocavities and nanoantenna. (b, d, f) electromagnetic equivalent transformed scenario that is analytically solvable.

The transformed space preserved the physics all the original space. Hence, the potential and power dissipation in...
the transformed space, $P_{\text{abs}}^{(x'y')}$, are the same as those of the original space. Given the simplicity of the transformed space,

$$P_{\text{nr}}^{(x'y')} = P_{\text{abs}}^{(x'y')} = -\frac{1}{2} \omega c \text{Im}\{\vec{p}^\ast \vec{E}^0_n(x,y)\} = -\frac{1}{2} \omega c \text{Im}\{\vec{p}^\ast \vec{E}_x^0(x,y) + \vec{p}^\ast \vec{E}_y^0(x,y)\},$$

where $P_{\text{nr}}$ is the nonradiative power emission by the dipole source, $\vec{p}^\ast$ is the dipole moment of the nanoemitter, $\omega = 2\pi c / \lambda_0$ is the angular frequency at the operation wavelength $\lambda_0$ and $c$ is the velocity of light in vacuum. Additionally, the nonradiative Purcell enhancement spectra is given by $P_{\text{nr}}(\omega)/P_{\text{abs}}(\omega)$, where $P_{\text{abs}}(\omega)$ is the power radiated by the dipole in free space. From the potential one can compute the electric field and then the optical force using the Maxwell stress tensor.

### 3. Results and Discussion

The nonradiative Purcell enhancement for a horizontally- and vertically-polarized dipole nearby the different geometries described in Fig. 1 is shown in Fig. 2. One can see the strong influence that the center of the nanostructure plays. Full-wave simulations (Comsol Multiphysics®) of the original space (Fig. 1(a, c, e)) agree very well with the analytical calculations (Fig. 1(b, d, f)).

![Figure 2](image)

**Figure 2:** Numerical (solid lines) and analytical (symbols) results of the nonradiative Purcell enhancement under vertical (first column) and horizontal (second column) polarization of the dipole placed at different positions along the $x'$-axis. (a, b) bowtie nanocavty with connected metal arms; (c, d) bowtie nanocavity with disconnected metal arms; (e, f) bowtie nanoantenna with connected arms.

### 4. Conclusions

Conformal transmission is utilized to understand the physics in nanoplasmonic scenarios involving a nanoemitter and bowtie-shaped plasmonic nanostructures. The underlying mechanisms are easily unveiled by inspection of the transformed space. Also, within the transformed space a hidden symmetry between the bowtie nanocavity with disconnected metal arms and the bowtie nanoantenna with connected arms is clearly shown.

On-chip fabricated non-transfer plasmonic nanolaser

Ya-Lun Ho¹, J. Kenji Clark¹, A. Syazwan A. Kamal¹, Jean-Jacques Delaunay¹

¹School of Engineering, The University of Tokyo, Tokyo, Japan
*corresponding author, E-mail: jean@mech.t.u-tokyo.ac.jp

Abstract

We demonstrate a monolithically fabricated plasmonic-waveguide nanolaser. This is the first report showing a non-transfer plasmonic-waveguide nanolaser with a structure size (not only the mode size) in the sub-wavelength regime. A plasmonic waveguided mode capable of sustaining lasing is carefully designed so that top-down fabrication techniques can be used (no need of nanostructure transfer) to simultaneously fabricate the nanolasers together with waveguides for an optical circuit. Moreover, the design supports a lasing mode with a large effective area and confines the absorption of the pump light to the area in which the plasmonic-waveguide mode is most intense, reducing the lasing threshold. Lasing up to room temperature with a low threshold intensity of 0.20 mJ/cm² is demonstrated.

1. Introduction

Due to the strong demand for photonic computing, on-chip optical communication, medical imaging, and biosensing at the nanoscale, interest in nanolasers has grown dramatically in recent years. Plasmonic lasers are promising as nanoscale laser sources [1] and have been widely studied using semiconductor nanowires on metal surfaces synthesized by bottom-up techniques [2,3]. However, these nanowire plasmonic lasers require transfer and positioning after fabrication, making their use in practical on-chip devices difficult.

Here, we propose a plasmonic structure, as shown in Figure 1, consisting of ZnO cavities with Al top layers directly grown on a sapphire substrate [4]. The ZnO cavities are directly fabricated on the sapphire wafer using pulsed laser deposition for ZnO, ion beam sputtering for Al, and top-down fabrication techniques such as electron-beam lithography and reactive ion etching. Due to the use of top-down techniques, the dimensions, positions, and alignment of nanolaser cavities can be controlled without transfer and manipulation processes. As a result, the nanolaser device was fabricated on the sapphire wafer coated with Al/ZnO without the need for transfer of nanostructures, which is needed for other reported nanostructures-on-a-film devices.

Figure 1: (left) Illustration of the on-chip fabricated ZnO/Al plasmonic nanolasers. ZnO open-ended cavities with Al top layers are directly grown and fabricated on a sapphire substrate. (right) Fabrication process of the plasmonic nanolaser.

2. Results and discussion

Figure 2 shows a comparison between the electric field enhancement achieved by the proposed Al/ZnO plasmonic cavity and the conventional nanowire-on-a-film structure. For the Al/ZnO plasmonic structure, the electric field enhancement is calculated for the wavelength $\lambda = 372$ nm and the absorption distribution for the wavelength $\lambda = 343$ nm (the structure is pumped from the bottom through the sapphire substrate). For comparison purposes, the electric field enhancement of the fundamental plasmonic mode in the ZnO nanowire laser sitting on the Al surface at wavelength $\lambda = 372$ nm and the absorption distribution at wavelength $\lambda = 343$ nm (pump light from the top of the structure) are also shown. It is noted that the mode distribution and the absorption have good overlap in the
case of the on-chip plasmonic cavity nanolaser. In contrast, the nanowire laser cavity exhibits a mismatch between its strong field enhancement near the bottom of the cavity and its absorption maxima near the edge of the cavity bottom and close to the center of the cavity. This mismatch suggests inefficient exciton-plasmon coupling for the nanowire-on-a-film structure.

Figure 2: (top) Comparison between simulated distributions of the electric field and absorption for (left) the Al/ZnO cavity on a sapphire substrate and (right) the ZnO nanowire on an Al surface. (bottom) Absorption of the pump light in both structures. Note that the absorption for the Al/ZnO cavity structure is obtained for the light pump coming from the bottom of the structure through the sapphire substrate.

The variation in the emission intensity with the pump energy density for the fabricated plasmonic nanolaser is shown in Figure 3 as a log-log plot. When the pump energy density reaches 0.09 mJ/cm², the emission intensity increases nonlinearly. The nonlinear region ranges from 0.09 to 0.12 mJ/cm² and represents the threshold region between spontaneous emission and lasing. The bandwidth of the emission decreases drastically in the nonlinear region confirming the lasing of the structure. It was also found that the emitted light was polarized along the cavity axis as expected for a plasmonic mode. Finally, lasing was observed at 330 K confirming the possibility for this structure to sustain lasing at room temperature.

Figure 3: (left) Emission spectra at 147 K of the fabricated ZnO/Al plasmonic cavity with a width of 100 nm. (right) Emission intensity versus pump energy together with the emission bandwidth.

3. Conclusions

We demonstrate a monolithically fabricated ZnO/Al plasmonic-waveguide nanolaser compatible with the fabrication requirements of on-chip circuits. The nanolaser is designed with a plasmonic metal layer on the top of the laser cavity only, providing highly efficient energy transfer between photons, excitons, and plasmons, and achieving lasing in the ultraviolet region up to 330 K with a low threshold intensity. This work demonstrates the realization of a plasmonic-waveguide nanolaser without the need for transfer and positioning steps, which is the key for on-chip integration of nanophotonic devices.

Abstract

We report on easy and robust strategies for the versatile integration 2D material flakes on plasmonic nanostructures by means of site selective deposition of MoS$_2$. The methods can be applied both to simple metallic flat nanostructures and to complex 3D metallic structures comprising nanoholes. The deposition methods allow the decoration of large ordered arrays of plasmonic structures with single or few layers of MoS$_2$.

1. Introduction

In the last decade, intensive research efforts have been devoted to the investigation of two-dimensional (2D) materials, such as graphene and various transition metal chalcogenides (TMDCs).[1–2] Molybdenum disulfide (MoS$_2$) is a typical representative of TMDCs materials family, which consists of S-Mo-S layers bonded by van der Waals interaction. MoS$_2$ offers a powerful platform for applications in nanophotonics and optoelectronics due to its remarkable optical properties. In fact, MoS$_2$ behaves like a semiconductor with direct band gap electronic structure, notable flexibility, and tunable optical emission.[3] An extensive interest from researchers raised in the last years to explore potential physical phenomena, especially on light–matter interaction, such as multie exciton photoluminescence (PL), interlayer exciton coupling, strong coupling and valley polarization effect.[4] Great efforts have been devoted to realize the active control of MoS$_2$ by utilizing photonic cavity modes and metallic surface plasmons.[5] However, most designed structures must be fabricated precisely with the structure geometries and the coupling distance, which limits the development of active-controlled optoelectronic devices in the future. Moreover, one of the main limitation of MoS$_2$ application in photonics and plasmonics is related to the challenging alignment between nanostructures and the 2D material. New approached for easy and controlled integration of 2D materials with metallic or semiconductor nanostructures can now represent a significant help in the cited field of research. We have recently proposed and demonstrated the possibility to control the deposition of single layer MoS$_2$ flakes on metallic nanostructures by means of chemical conjugation and electrostatic deposition process.[6,7] Here we illustrate a direct comparison between the two methods. As we will show, both the procedure are reliable and allow high yield controlled deposition in both flat nanostructures and 3D elements.

2. Materials and Methods

2.1. Exfoliation of MoS$_2$

In a glove-box (water < 1 ppm, O$_2$ < 10 ppm), LiBH$_4$ (0.109 g, 5 mmol) and MoS$_2$ (0.320 g, 2 mmol) were ground in a mortar and subsequently transferred in a Schlenk-tube, which then was brought outside of the glove-box and connected to a Schlenk-line. This mixture was heated in a sand bath at 330°C for 4 days under nitrogen. Afterwards, the Schlenk-tube was brought again inside the dry-box, where it was newly grounded with additional LiBH$_4$ (0.109 g, 5 mmol). The sample was subsequently heated for 3 days at 330°C under nitrogen. The intercalation product was added in a single shot in 270 ml of degassed water and the resulting suspension was bath-sonicated for 1 h to facilitate the exfoliation. In order to remove the LiOH produced, the suspension was equally divided into six centrifugation tubes (45 ml/tube) and centrifuged at 10000 rpm (23478 g) for 20 min for three times, replacing the supernatant with clean solvent.

2.2. Fabrication of plasmonic nanostructures

The fabrication of the metallic nanoholes follows simple and robust procedures for the 2D and 3D geometry. In both cases the substrate was a Si$_3$N$_4$ membrane (100 nm thick) prepared on a Silicon chip. [8-10].

2.3. Electrostatic deposition

The electrostatic method has been already proposed for MoS$_2$ nanosheet deposition for several applications, here, with respect to the previous reported cases, the substrate where the flakes are deposited is not used as electrode. On the contrary, in order to obtain a controlled deposition only over our nanostructures, the substrate is placed in the middle of a fluidic chamber where two Pt electrodes are present. In particular, the nanoholes present in the substrate allow the flow of ions though them and at the same time they
represent an obstacle for the MoS₂ flakes that are there forced to stop and deposit.

2.4. Chemical conjugation deposition

The method used for the deposition is based on the conjugation between a gold (or another noble metal) surface and a dithiol-terminated organic chain as well as the same conjugation between the MoS₂ flake and the dangling –SH group of the same molecule. In particular, to perform a controlled deposition of MoS₂ over metallic holes, we used a 1,12-dodecanedithiol molecule as a linker between the gold surface and local –S vacancies in MoS₂ flakes.

3. Results and discussion

Micrographs of the deposited MoS₂ flakes on flat and 3D plasmonic nanoholes are shown in Fig. 1. In left panels examples of different samples deposited by means of chemical conjugation are reported. In the right panels similar depositions performed by means of electrophoretic process are reported.

![Figure 1: SEM micrographs of the prepared MoS₂ hybrid structures.](image)

To verify the deposition of MoS₂ flakes and to compare the two processes, we performed Raman spectroscopy on our samples at wavelength of excitation of 532 nm.

![Figure 2 – Raman map integrated between 400 and 410 cm⁻¹ (A₁g mode). (a) Sample deposited by means of thiol conjugation (b) Sample deposited by means of electrophoretic force.](image)

4. Conclusions

In conclusion, we presented methods for hybrid plasmonic 2D material structure preparation. The fabrication procedure allows to obtain ordered structures over large array using a low-cost procedure and without the use of complex lithographic processes. This strategy can be applied to not only MoS₂ but also to other 2D materials. We believe that such an approach can be interesting for the realization of new hybrid devices for use in several applications, including photoluminescence, strong coupling and valley-polarization studies. With respect to previously reported hybrid plasmonic nanostructures, our scheme significantly reduces the complexity of fabrication, leading to a more robust and low-cost approach for the integration of 2D materials with plasmonic nanopores.

In this talk we present an optoelectronic switch for functional plasmonic circuits based on active control of Surface Plasmon Polaritons (SPPs) at degenerate \( p^n++ \) - junction interfaces. Self-consistent multi-physics simulations of the electromagnetic, thermal and IV characteristics of the device have been performed. The lattice matched Indium Gallium Arsenide (In\textsubscript{0.53}Ga\textsubscript{0.47}As) is identified as the best semiconductor material for the practical implementation of the optoelectronic switch providing high optical confinement, reduced system size and fast operation. The optimal device is shown to be capable of providing SPP signal modulation surpassing -20dB and switching rates up to 50GHz, thus potentially providing a new pathway toward bridging the gap between electronic and photonic devices. Experimental validation of the device performance and specifically it potential for strong bias modulation is presented.

Photonics and in particular plasmonics has been recognized as a key technology for fast data communication and computing\textsuperscript{1-3}. Here we propose a fast optoelectronic switch termed Surface Plasmon Polariton Diode (SPPD)\textsuperscript{2}, shown in Fig. 1a. The device consists of a degenerate \( p^n++ \) - junction with an active drift-diffusion region formed between two control electrodes. Under forward bias minority carriers (electrons) are injected in the \( p^- \) doped layer and for applied voltage higher than a critical value \( V > V_c \) the \( p^- \) layer acquires a metal like characteristics impeding the propagation of the SPP across the active region and establishing the OFF state of the device. A steady-state SPP signal modulation higher than \(-20\)dB is predicted, and responsivities in excess of \(-1000 \, \text{dB} \cdot \text{V}^{-1}\) for Si and \(-500 \, \text{dB} \cdot \text{V}^{-1}\) are expected for applied bias close to a critical values \( V_c = 1.14V \) for Si and \( V_c = 0.81V \) for In\textsubscript{0.53}Ga\textsubscript{0.47}As. The fast response of the devices under step type of input voltage is studied, see Fig. 1b. The numerical results show a well-defined distinction between the OFF and ON response times, with the former being substantially faster. This distinction can be attributed to the drastically different physical processes that are involved, with the OFF times governed by the electric field facilitated injection of minority carriers while the ON times are set by charge diffusion. Consistently, a faster response is observed for the In\textsubscript{0.53}Ga\textsubscript{0.47}As device. Moreover, the modulation rates are revealed to dependent on the acceptor doping, with higher doping’s leading to faster signal modulation with 3dB data rates in excess of 50Gbit/s for In\textsubscript{0.53}Ga\textsubscript{0.47}As and up to 10Gbit/s for Si.

A proof of concept experimental study has been performed to assess the main switching mechanism behind the SPPD operation. A degenerate \( p^-n^+\) junctions are grown epitaxially on InP and fabricated by spin-doping on Si-on-insulator (SOI) wafers, see Fig. 1c. The devices are characterize both electrically and optically as a function of applied forward bias (Fig. 1c), with the measured change in reflectivity compared to the theory, see Fig. 1d. Our simulations match our experimental data with excellent agreement, and indicate the potential of the presented device architectures for integration into an actual SPPD.
Figure 1. (a) Basic schematic of a Surface Plasmon Polarization Diode (SPPD). Abstract
An intuitive semi-analytical model is proposed to describe the channel plasmon polaritons (CPPs) guided by a subwavelength rectangular groove cut into a metal substrate. The model is built up by considering an intuitive multiple scattering process of gap surface plasmons (GSPs) bouncing between the mouth and the bottom of the groove. The evolution of the CPPs from guided, quasi-guided to evanescent modes with the increase of wavelength is explained with the model.

1. Introduction
CPPs supported by plasmonic channel waveguides (such as a metallic V-groove or rectangular trench) can simultaneously realize a strong confinement of field and a low propagation loss, and have important applications such as plasmonic nanocircuit components \cite{1}, quantum plasmonics \cite{2}, and nanolasers \cite{3}. To analyze the channel waveguides, full-wave numerical methods such as the finite-difference time-domain method and the finite element method have been used. However, these numerical methods are lack of intuitive physical pictures on the formation of the CPP supported by a rectangular trench \cite{4,5}. The model-channel waveguides. However, the EIM turns to be less accurate as the frequency approaches the cut off and cannot provide the field distribution of CPPs \cite{5}. The model-matching method is able to provide analytical expressions for the mode fields and to determine the mode dispersion numerically \cite{6}.

In this talk, we introduce an intuitive semi-analytical model for the CPP supported by a rectangular trench waveguide \cite{7}. The model can comprehensively reproduce all the features of the CPP including the dispersion relation, the electromagnetic field, and the critical parameters for identifying the guided, quasi-guided and evanescent CPP modes. With the model, the two-dimensional (2D) field distribution of the CPP in the waveguide transverse section can be reproduced with the 1D field distribution of the GSP, which decreases the computational amount compared to the full-wave numerical methods.

2. Results and discussion
As sketched in Fig. 1(a), the considered waveguide is formed by a rectangular air groove (with depth \(h\) and width \(w\)) cut into a gold substrate. To achieve a strong confinement of field, we consider a subwavelength groove (\(w=0.5\lambda, \lambda\) being the wavelength). In the model, by only considering the fundamental propagative GSP mode supported by the metal-insulator-metal (MIM) structure and neglecting all other higher-order evanescent GSP modes, a set of coupled-GSP equations can be written,

\begin{equation}
\begin{aligned}
a &= b u_r, \\
b &= a u_r,
\end{aligned}
\end{equation}

where \(a\) and \(b\) are the unknown complex coefficients of the up-going and down-going GSPs [Fig. 1(b)], \(r_s\) and \(r_w\) are the reflection coefficients of the GSP at the mouth and the bottom of the groove, respectively [Figs. 1(c) and 1(d)], and \(u=\exp(ikz)\) is the \(z\)-direction phase shift factor of the GSP travelling over one groove depth \(h\). Equation (1a) can be understood intuitively in view that the down-going GSP (with coefficient \(a\)) should result from the reflection of the up-going GSP (with coefficient \(b\) and phase shift factor \(u\)) at the groove mouth. Equation (1b) can be understood in a similar way. The CPP modes are the nonzero solutions of Eq. (1) and thus satisfy a resultant eigenequation \(u^2r_s^2r_w^2=1\), which can be rewritten as

\begin{equation}
k^2_z = \frac{2m\pi}{2h} - \arg(r_s r_w) + i \frac{\ln |r_s r_w|}{2h},
\end{equation}

where \(m\) is an integer corresponding to different orders of CPPs. With Eq. (2) and \(k_z^2 + k_y^2 = k_{GSP}^2\), one can solve the dispersion relation \(k_z=k_{yz}(\lambda)\) of the CPP modes for a given \(\lambda\), where \(k_z\), \(k_y\) and \(k_{GSP}\) are the \(y\)-direction, \(z\)-direction and total GSP propagation constants, respectively. The electromagnetic field of the CPPs can then be obtained with
the use of the GSP field in the groove and of the transmitted fields $\boldsymbol{\Psi}_{sl}$ and $\boldsymbol{\Psi}_{sr}$ out of the groove for an incident GSP with unitary coefficient [Figs. 1(c) and (d)].

As shown in Figs. 2 and 3, the model can accurately reproduce both the dispersion relation and the electromagnetic field of the CPPs obtained with the full-wave aperiodic Fourier modal method (a-FMM). Figure 2 shows that with the increase of the wavelength $\lambda$, the CPP evolves from the guided mode first, then the quasi-guided mode [$Re(k_{0})<k_{0}$], and finally to the evanescent mode [$Re(k_{0})>Re(k_{\text{GSP}})]$. The exceptional case is the fundamental CPP mode ($m=0$) which is always a guided mode. With the model, the critical wavelengths $\lambda_{c}$ and $\lambda_{e}$ among the guided, quasi-guided and evanescent CPPs can be derived to be

$$\frac{2\pi}{\lambda_{c}} \approx \frac{(2m+1)\pi}{2h\sqrt{n_{GSP}^2 - 1}}$$

and

$$\frac{2\pi}{\lambda_{e}} \approx \frac{(2m+1)\pi}{2hn_{GSP}}$$

with $n_{GSP} = \frac{k_{GSP}}{k_{0}}$.

Figure 1: Definition of quantities used in the model.

Figure 2: Dispersion relation $Re(k_{y})$ and $Im(k_{y})$ as a function of $1/\lambda$ for the considered trench waveguide. The results are obtained with the model (solid and dashed curves for the lossy and lossless metal, respectively) and with the full-wave a-FMM (circles, for the lossy metal) for groove width $w$=50nm and depth $h$=1μm and for different orders of CPPs ($m=0,1,2,\ldots$ from bottom to top). The red dash-dotted line in (a) denotes the dispersion relation $k_{y} = kv = 2\pi/\lambda$ of light in air. (b) takes a logarithmic scale of $Im(k_{y})$ to show the slight increase of $Im(k_{y})$ from the guided CPPs to the quasi-guided CPPs. The critical wavelengths $\lambda_{c}$ and $\lambda_{e}$ for distinguishing the guided, quasi-guided and evanescent CPP (of order $m=3$) are marked with the two horizontal black dashed lines.

Figure 3: Modulus $|E_{x}|$ of the $x$-component of the electric field (the dominant electric field component in the groove) for the first five orders of CPPs ($m=0,\ldots,4$). The results are obtained with the full-wave a-FMM (a1)-(a5) and the model (b1)-(b5) for $h$=1μm and $\lambda$=0.75μm.

Abstract
Cat’s eye antennas have been designed and fabricated to modify the emission efficiency and profile of InP nanowire lasers. Narrower emission angle, higher polarization degree, increased internal quantum efficiency and lower lasing threshold were achieved from the antenna-coupled system, in comparison to bare nanowire lasers.

1. Introduction
Semiconductor nanowires have undergone a significant expansion and became a highly active research area within the nanoscience community. As one of the most promising applications, nanowire lasers provide both gain medium and photonic cavity, but still suffer from high threshold and poor directionality. In this work, InP nanowire lasers are demonstrated by integrating with Cat’s eye (CE) antenna, aiming at tailoring and enhancing the emission properties, including focused far-field distribution, enhanced polarization degree, increased internal quantum efficiency (IQE), and reduced lasing threshold [1].

2. Modeling and design
2.1. Guided modes in InP nanowires
The nanowire geometry, including diameter \( w \) and length \( L \), was optimized to support guided optical modes at the wavelengths of 750 and 870 nm, these being the near-band emissions of InP nanowires at low (\(-7 \text{ K}, \text{ LT}\)) and room temperature (RT), respectively. RT-lasing would be observed from nanowire lasers with \( w = 600 \text{ nm}, L = 7.5 \text{ \mu m} \). While for the case of \( w = 290 \text{ nm} \) and \( L = 900 \text{ nm} \), the required minimum threshold gain for lasing is calculated to be \( 2400 \text{ cm}^{-1} \), which indicates that lasing action would be hard to be obtained at RT or even LT.

2.2. Design of the CE antennas
The design of the CE antenna was divided into two steps. First, the inner circular grating, located at a distance \( s \) from the antenna center, was designed to form an enhanced Q-factor metal resonant cavity for the nanowire guided modes. The second step was then to optimize the periodical circular grating of the antenna to guarantee efficient surface plasmon (SP) coupling resonance and also function as a lens, focusing the emission. The parameters of grating period, \( p = 650 \text{ nm} \), metallic concentric grating width \( b = 200 \text{ nm} \) and depth \( d = 300 \text{ nm} \), split-gap width \( g = 200 \text{ nm} \), and inner circular grating distance, \( s = 900 \text{ nm} \), are finally chosen for the nanowire with a diameter \( w = 290 \text{ nm} \) and a length \( L = 900 \text{ nm} \) by considering SP excitation, maximum \( E \) intensity at the focal point, minimal footprint of the device, as well as the feasibility in fabrication. Similarly, \( p = 650 \text{ nm} \), \( b = 200 \text{ nm} \), \( d = 600 \text{ nm} \), \( g = 700 \text{ nm} \), and \( s = 800 \text{ nm} \) are chosen for the case of nanowire with \( w = 600 \text{ nm} \) and \( L = 7.5 \text{ \mu m} \).

3. Nanowire growth and device fabrication
The InP nanowires were grown on (111)A InP substrates by selective area epitaxy (SAE). Fabrication for Sample A (Fig. 1a) with \( w = 290 \text{ nm} \) and \( L = 900 \text{ nm} \) began by first transferring InP nanowires from growth substrate onto quartz substrate. Then a layer of 300 nm-thick SiO\textsubscript{2} was deposited by plasma enhanced chemical vapor deposition, followed by a 30 nm Al deposition via e-beam evaporation. The antenna design was then imported by intaglio printing into the SiO\textsubscript{2}/Al structure around the InP nanowire with depth of \(-330 \text{ nm} \). Finally, another 1 \( \mu \text{m} \)-thick Al layer was deposited to form the CE antenna. Two additional reference samples (B and C) were also fabricated. Sample B was consisted of an InP nanowire laying horizontally on a bare quartz substrate, whilst Sample C was formed by an InP nanowire coated with a 1 \( \mu \text{m} \)-thick Al film on a 300-nm thick un-patterned SiO\textsubscript{2} cladding layer. The fabrication process of Sample D (Fig. 1d) with larger nanowire \( w = 600 \text{ nm} \) and \( L = 7.5 \text{ \mu m} \) embedded in CE antenna was similar with Sample A. For comparison purposes, Sample E was also fabricated by a bare InP nanowire laser \( w = 600 \text{ nm} \), \( L = 7.5 \text{ \mu m} \) placed on Al substrate.

4. Results
4.1. Focused far-field distribution
The far-field angular distribution of the emitted light from Samples A and C was characterized when a pumping fluence of 0.8 mJ/cm\textsuperscript{2} was utilized at RT (Fig. 1b, c). When compared to Sample C, the far-field distribution of Sample
A shows a narrower emission angle which indicates that the integrated CE antenna strongly governs the propagation direction of the nanowire emission. For Samples D and E, lasing can be obtained at RT. As shown in Fig. 1e,f, interference patterns were observed in the far-field intensity distribution of both Samples D and E at a pumping fluence of 12.8 mJ/cm². The comparison of the far field patterns further confirms that the InP nanowire laser with CE antenna exhibits a much improved vertical emission directionality above the threshold.

Figure 1: (a,d) SEM images of the fabricated Samples A and D before Al deposition. (b,c) Directionality characterization of light emission from Samples A and C below threshold at RT. (e,f) Directionality characterization of lasing from Samples D and E above threshold at RT. (g) Statistical results of IQE as a function of pumping power for Samples A-C at RT. (h) Lasing characterization from nanowire Samples A and B at LT.

4.2. Enhanced polarization degree

As measured, a degree of polarization (DOP) of 0.7 is obtained at 870 nm from Sample A, which is higher than the value of 0.5 from Sample B. To exclude the influence arising from reflections at the Al layer, we have also measured the polarization-dependent emission spectrum from Sample C. As a result, no distinct DOP enhancement can be observed from Sample C as compared to Sample B. It is therefore concluded that the improved DOP of Sample A is a direct result of the polarization sensitivity of the integrated split-gap CE antenna due to the cylindrical symmetry breaking.

4.3. Increased internal quantum efficiency (IQE)

The RT IQE (Fig. 1g) was measured and extracted from the variation in the integrated photoluminescence (PL) intensity as a function of excitation power density and based on rate-equations analyses. Clear improvement in IQE was obtained from Sample A, as compared to Samples B and C, which further verifies the distinct localization of optical energy densities in the nanowire.

4.4. Lasing characterization

Figure 1h shows the micro-PL spectra obtained from Samples A and B by optically pumping a pulsed laser (\(\lambda = 522\) nm) at LT under different pumping fluences from 1.0 to 18.0 mJ/cm². At low pumping fluences, a single broad peak around 840 nm appears in both samples. With increasing fluence up to 18.0 mJ/cm², the PL intensity increases almost linearly but lasing is not observed from Sample B. On the other hand, for Sample A, upon exceeding a lasing threshold of only 5.8 mJ/cm², an additional peak emerges at 775 nm showing a dramatic increase of output intensity and a sudden linewidth narrowing. The observed spectral clamping indicates transition from spontaneous to amplified spontaneous emission and finally reaching lasing.

5. Conclusions

CE antenna has been designed to modify the emission characteristics of InP nanowires. The emission efficiency and profile were largely improved in following aspects: enhanced narrower emission angle, higher polarization degree, enhanced internal quantum efficiency, and reduced lasing threshold. It provides a promising solution to achieve high-performance nanoscopic light sources and other integrated nanophotonics applications.

Abstract

We present a theory for quantum nanoplasmonics that incorporates nonlocality and quantum effects like electronic spill-out and surface-enabled Landau damping, while also including retardation. Focusing on the planar and sphere geometries, we derive analytical expressions for the non-classical scattering coefficients, from which the optical response of the systems can be unambiguously determined. We compute the systems’ plasmonic excitations and investigate the role of quantum surface corrections to plasmon–emitter interactions, e.g., Purcell enhancement, dipole-forbidden transitions rates, and plasmon-mediated energy transfer.

1. Introduction

In this work, we provide a theoretical framework that remedies the shortcoming of classical electrodynamics in the mesoscopic regime, and, crucially, whose validity spans the intermediate regime where both quantum and classical effects coexist.

2. Results and Discussion

We develop a theory which rigorously accounts for quantum nonlocal effects in quantum nanoplasmonics, specifically, nonlocality, electronic spill-out, and surface-assisted electron-hole pair generation (known as Landau damping).

Figure 1: Illustration of the $d$-parameters obtained from TDDFT for a $r_s = 4$ jellium, together with an artistic impression of the quantum mechanical spill-out of the induced charge density in response to an external potential. a–b) Classical and quantum plasmon dispersion diagrams for a half-space, in the case of a a) simple metal and b) silver. c–d) Classical and quantum extinction cross-sections for a c) jellium and d) silver sphere. Classical and quantum Purcell enhancement experienced by a dipole emitter at different emitter–metal separations: e) planar interface; f) $R = 5$ nm jellium sphere.
In particular, we further develop and extend the formalism of Feibelman’s $d$-parameters [1–3], and derive analytical expressions for the nonclassical scattering coefficients—{$r_{TM}$, $r_{TE}$} and {$a_{TM}^{l}$, $b_{TE}^{l}$}, for the planar interface and for metal spheres, respectively—with TDDFT-level accuracy to leading-order. Using these nonclassical scattering coefficients, we unambiguously determine the far- and near-field optical responses of the considered plasmonic structures. Our approach allows a simultaneous account of both quantum mechanical phenomena and retardation effects. Our calculations show that the simultaneous treatment of quantum effects and retardation is indeed essential for an accurate description of plasmons and plasmon-enabled phenomena in systems located in the blurred “classical–quantum boundary”. In good agreement with experiments [1, 4], we predict nonclassical redshifts (blueshifts) of the plasmon resonances in simple (noble) metals accompanied by nonclassical damping, the latter being consequence of surface-enabled plasmon decay into electron-hole pairs. Moreover, we further investigate the impact of the above-mentioned quantum surface corrections in the context of plasmon–emitter interactions, where we find that these effects impose bounds to the enhancement of the electromagnetic local density of states (LDOS), modify dipole-forbidden transitions (namely, electric multipolar and two-photon processes), as well as plasmon-mediated energy transfer between two emitter.

3. Conclusions

In summary, our theoretical framework provides a comprehensive account of both plasmons and plasmon–emitter interactions at the nanoscale, that is, in the regime of quantum nanoplasmonics. Therefore, we show that our theory constitutes a simple, rigorous, and unified platform to incorporate quantum effects in nanoplasmonics.

ABSTRACT
A computationally efficient new approach based on deep-learning techniques for analysis, design, and optimization of electromagnetic nanostructures will be presented. Using the strong correlation among features of an electromagnetic design problem, deep-learning techniques are employed to considerably reduce the dimensionality of the problem and thus, the computation complexity, without imposing considerable error. This approach reduces the computational complexity in both solving the forward problem (or analysis) and inverse problem (i.e., design) by orders of magnitude compared to conventional approaches. In addition, it provides analytic formulations that, despite their complexity, can be used to obtain intuitive understanding of the physics and dynamics of electromagnetic wave interaction with nanostructures with minimal computation requirements. In addition to explaining the fundamental properties of this approach, its application to designing a series of photonic metastructures, especially a new class of on-demand reconfigurable optical metasurfaces will be discussed and compared with more conventional design approaches.

Abstract
We realized active tunable photonic topological states in photonic crystal topological insulators based on the thermo-optic effect and electro-optic effect. This may provide a useful way for the practical applications of photonic topological insulators in integrated optical devices.

1. Introduction
Photonic crystal topological insulators play an essential way in the realization of novel integrated photonic devices, because of their unique properties of controlling propagation states of photons. The topological protection properties are very important for the device fabrication. However, active control of the topological state is also a basis for the realization of device function. Therefore, the contradiction between the topological protection and active control has limited the applications of photonic crystal topological insulators.

2. Results and discussion
We realized active tunable photonic topological states in photonic crystal topological insulators based on the thermo-optic effect and electro-optic effect. We firstly realized an one-dimension photonic crystal topological insulator in the optical communication range thermo-optic effect. A one-dimensional silicon dioxide/vanadium dioxide photonic crystal heterostructure etched in a silicon waveguide, sandwiched between two gold films, was fabricated using electron-beam lithography etching. A photonic topological edge state centered at 1550 nm was obtained. The topological state could be switched on or off based on insulator-to-metal transition of VO2. We also realized an electro-optic tunable two-dimensional photonic crystal topological insulator made of TiO2 and BaTiO3. The refractive of BaTiO3 could be adjusted by using an external applied voltage. Then the band inversion was achieved and the resonant frequency and propagation direction of the topological state changed.

Abstract

We demonstrate efficient optical switching of the second harmonic generation (SHG) in AlGaAs nanoantennas. We observe more than 50% enhancement/suppression of the SHG excited at telecom wavelength, when simultaneously illuminating with a control beam at an energy above the material bandgap. By means of pump-probe experiments, where the control beam serves as pump, we addressed the temporal evolution of this process revealing ultrafast build-up times (< 300 fs) and slower recovery times above 10 ps.

1. Introduction

Metal-less nanophotonics has recently raised an increasing interest because the optical response of high-permittivity dielectric nanoparticles exhibits negligible dissipative losses and strong magnetic multipole resonances in the visible and near-IR [1–3]. Semiconductors such as GaAs are extensively studied and employed in photonics due to their pronounced second order nonlinear properties [4]. In this context, we have recently devised [5] and realized [6] a nanophotonic platform characterized by an unprecedented second harmonic generation (SHG) conversion efficiency. This is an all-dielectric platform composed of 400nm-high AlGaAs nanopillars suspended on a low-refractive-index AlOx substrate fabricated from an aluminum-rich (100) GaAs wafer [6]. The result is an array of nanopillars on an aluminum-oxide (AlOx) substrate. We report SHG conversion efficiency higher than 10⁻⁵ when individual nanoantennas are illuminated with femtosecond pulses (150 fs pulses, 80 MHz repetition rate, 1554 nm wavelength) with an intensity of about 1.6 GW/cm², in excellent agreement with our simulation [5-8]. Such a remarkable efficiency is achieved thanks to the exploitation of magnetic and electric resonances emerging at coincidence with both the illumination and the SHG wavelength, which are characterized by sizeable quality factors due to the relatively low refractive index of the substrate. The choice of the fundamental wavelength and, consequently, of the SHG (about 777 nm) wavelength, both set below the energy of the material bandgap, allows minimizing the two-photon absorption of the pump and the re-absorption of SHG.
2. Results & Discussion

Here, we study the behavior of the SHG signal excited at 1550 nm, when the nanoantennas are concurrently illuminated with a low-power (below 300 µW average power) control beam with energy above the bandgap (either 405 or 510 nm wavelength, i.e. about 3.2 or 2.5 eV). Figure 1 shows the comparison between a SHG intensity map and a SHG differential map (ASHG) acquired on an array of nanopillars with variable radius (along the horizontal axis), from 200 to 240 nm. The ΔSHG map is the difference between the SHG map obtained under simultaneous irradiation with a continuous wave (CW) control laser at 405 nm and the SHG map retrieved with the control laser is off (Figure 1b). In this way, we observe a variation in the SHG yield of the nanoantennas up to 60% with 300 µW power impinging on the nanoantenna. More importantly, depending on the nanoantenna radius, we observe that, while the SHG from the smaller nanopillar (r = 205 nm) is decreased, larger nanopillars (i.e. 220-nm-radius nanopillar) show a SHG yield enhancement when the control beam is on. A similar behavior is observed when the control wavelength is set at 532 nm (here not shown), while no sizeable ΔSHG has been measured using a control laser photon energy below the bandgap of the material (λ = 980 nm laser wavelength, not shown here).

We also investigated the ultrafast modulation of the SHG in a pump-probe experiment, where an ultrashort control pulse at λ = 510 nm (above material bandgap) acts as the pump, while the probe is a time-delayed pulse at λ = 1550 nm generating the SHG. In this way, we could study the SHG dynamics when the pillars are brought out of equilibrium and a transient plasma is photoinjected in the dielectric. Time-traces of the SHG as a function of the pump-probe delay are shown in Figure 2. We measured an ultrafast SHG quenching (< 0.5 ps) and a slower (10 to 100 ps) recovery times, which strongly depend on the nanopillars, hence on the resonances involved.

Figure 2. Time traces of SHG yield from different pillars using an ultrafast (∆t < 100 fs) pump beam at 510 nm (above bandgap). The timetraces refer to the pillars whose behavior was already assessed in the CW pump measurements.

3. Conclusions

We report efficient (more than 50%) modulation of the SHG yield in all-dielectric Al₀.₆Ga₀.₄Oₓ-As-on-AlOₓ nanodisks when an additional control beam with energy set above the material bandgap is concurrently illuminating the nanodisks. Pump-probe experiments employing an ultrashort control beam with energy above the material bandgap as pump indicate also the possibility to achieve an ultrafast modulation of the SHG (hundreds of fs) in these nanostructures with recovery times above 10 ps. Our results allow gaining further insight in the photophysics of the nonlinear emission in AlGaAs-on-insulator all-dielectric platforms and pave the way to the realisation of nanoscale devices for all-optical data storage and quantum information processing.

Abstract
We demonstrate the versatility of dielectric metasurfaces to (i) shape the temporal evolution of ultrafast optical pulses, and (ii) discuss their applications towards creating integrated photonic interfaces with quantum systems.

1. Introduction
Over the last decade, flat optical elements composed of an array of deep-subwavelength dielectric or metallic nanostructures of nanoscale thicknesses – referred to as metasurfaces – have revolutionized the field of optics and nanophotonics \cite{1-2}. Because of their ability to impart an arbitrary phase, polarization or amplitude modulation to an optical wavefront as well as perform multiple optical transformations simultaneously on the incoming light, they promise to replace the traditional bulk optics in applications requiring compactness, integration and/or multiplexing. The primary focus of research in this area has been on applications requiring arbitrarily manipulation of light in the spatial domain such as high numerical aperture focusing or generation of novel polarization states.

2. Metasurface enabled spatio-temporal beam shaping

2.1. Ultrafast pulse shaping
In this talk, we discuss the ability of metasurfaces to arbitrarily shape instead the temporal evolution of ultrafast optical pulses. This requires independent control over the amplitude, phase and/or polarization of the spectral lines covering the entire bandwidth of an optical pulse. We achieve this by designing a metasurface to operate on the spectral components of an ultrafast pulse that are separated spatially using a Fourier transform setup (Fig. 1). By designing metasurface elements to act as individual half wave plates, and combining it with an integrated broadband polarizer – we demonstrate the ability to shape $<$10 fs pulses with a spectral resolution of approx. 140 GHz.

Figure 1: Metasurface-enabled Fourier-transform optical pulse shaper embedding one or more metasurfaces and a polarizer. Inset shows the SEM image of a typical metasurface composed of Si rectangular pillars on a fused-silica substrate. Scale bar represents 500 µm.

As an example requiring simultaneous and independent control over the spectral amplitude and phase, we demonstrate the ability to split an optical pulse into two time separated replicas (Fig. 2). Other examples such as dispersion compensation to arbitrarily higher orders including mechanical approaches towards dynamic control will be presented. We discuss the advantages of the metasurface approach to pulse shaping over the more traditional use of spatial light modulators to do the same. Finally, ongoing work on extending the spectral resolution of the system to sub GHz range enabling control of individual frequency comb lines from an ultrafast oscillator for applications in optical arbitrary waveform generation will be presented.
2.2. Metasurface enabled integrated photonic interfaces to quantum systems

In the second part of the talk, we will demonstrate the versatility of spatial shaping metasurfaces to be directly integrated on integrated photonic chips for their applications as an interface to quantum or biological systems (Fig. 3). Through spatial multiplexing of metasurfaces integrated with grating out-couplers directly on a nanophotonic chip, we show the ability to create arbitrary optical fields in the far-field that may enable applications such as optical trapping, biosensing or LIDAR.

3. Conclusions

In conclusion, we show the versatility of dielectric metasurfaces as replacement for traditional spatial light modulators both for temporal and spatial domain shaping of optical fields. The ability to directly integrate them, monolithically in a CMOS platform, with photonic chips will enable novel applications in the areas of biosensing and quantum optics.

Abstract

We explore current-driven plasmon dynamics including perfect transparency and light amplification in monolayer graphene metasurfaces. Current-induced complete suppression of the graphene absorption is experimentally observed in a broad frequency range followed by a giant amplification (up to ~ 9 % gain) of an incoming terahertz radiation at room temperature.

1. Introduction

The generation and amplification of electromagnetic waves by plasmonic instabilities in conventional two-dimensional (2D) electron systems (2DESs) have been actively investigated since 1980 [1]. However, after about forty years, we are still a long way from the realization of efficient emitters and amplifiers based on those plasmonic instability-driven mechanisms. The intensity of radiation reported experimentally so far is weak, the plasmon resonances too broad and not tunable enough to be promising for device applications [2]. The rise of graphene and its extremely strong light-plasmon coupling and superior carrier transport properties [3] make this work worth to be revisited. We investigate dc current driven plasmonic instabilities in high mobility graphene metamaterials that combine the advantage of an efficient tunable absorber, emitter and amplifier at room temperature (RT).

2. Device structure and physics

Plasmon modes in our devices are excited in monolayer graphene on hexagonal boron nitride (hBN) with a periodic dual-grating gate structure [4] positioned above the graphene sheets. The grating gate modulates the incoming electromagnetic wave and defines the plasmonic wave vectors. The samples are fabricated as field effect transistors (Fig. 1) with structures featuring an interdigitated asymmetric-dual-grating-gate (ADGG) [5]. The plasmonic cavities are formed below the gates electrodes and designed with symmetric or asymmetric boundaries and electron mobilities around 50,000 cm²/Vs at RT. ADGG-bias-dependent electron density modulation causes spatial complementary modulation of the plasmon and drift velocities. This may cause Doppler-shift (DS) type, transit-time-modulation (TTM) type, Cherenkov (CK) type, and/or plasmonic boom (PB) type instabilities under asymmetric cavity boundaries [6][8]. When the instability-driven gain surpasses the Drude loss, the system yields the net gain, resulting in plasmon self oscillation at the resonant frequencies. The ADGG works as a broadband antenna that can convert the non-radiative plasma oscillations to radiative THz waves. This, in turn, enables spontaneous THz emission of radiation as well as coherent light amplification to the incident THz waves.

3. Experimental results and discussion

We examined three samples: two ADGG type (ADGG1 (Fig. 1(b)) and ADGG2) and one symmetric DGG type (SDGG) alignment (Fig. 1(c)). With the applied gate
voltage $V_d$ and $V_g$, each device supports the formation of two different plasmonic cavities (types C1 and C2) below the fingers of Gate 1 and Gate 2 in the DGG device structure (top part of Fig. 1). Terahertz (THz) time-domain spectroscopy (THz-TDS) was employed to measure the changes in the THz pulses transmitted through the graphene plasmonic cavities of type C1 (C2) when sweeping $V_{gl}$ ($V_{g2}$) and keeping the voltage on the other gate electrode constant at the charge neutral point (CNP) $V_{CNP} = V_{CNP1}$. The source-to-drain voltage ($V_d$) dependent measurements were also conducted at a constant $V_g$. The transmission coefficient at a given $V_g$ and $V_d$ is referred to as $T$ while $T_{CNP}$ is the transmission coefficient at $V_g = V_{CNP}$. The measured extinction spectra ($1/T/T_{CNP}$) at $V_d = 0$ V exhibited similar tendencies of polarization-sensitive resonant absorptions among the three samples (Fig. 2).

When $V_d$ increases, the absorption peaks weakened with red shifting, only ADGG samples approaching perfect transparency over the measured entire frequency range (at $V_d = 370$ mV for C2 of ADGG1). Further increase in $V_d$ for only ADGG samples gives rise to negative absorption peak, i.e. resonant amplification, appears in the extinction spectra with a noticeable blue shift, reaching the maximal gain (9%) which is far beyond the interband-transition-limited quantum efficiency (2.3%) (Fig. 3(a)). The measured frequency dependence of the extinction peaks perfectly traces the theory with sharp gain thresholds [7] (Fig. 3(b)). Considering the extracted plasmon and drift velocity relations, a mixture of DS and TTM instabilities may cause such phenomena.

4. Conclusions

We explored current-driven plasmon dynamics in monolayer graphene active metamaterials. Frequency tunable THz light amplification up to 9% gain at RT by current-driven plasmon instabilities produced in an ADGG-GFET structure has been successfully demonstrated.

Abstract

In order to exploit the plasmonic properties of metal nanoparticles in actual applications convenient methods must be developed for the production of ordered assemblies covering macroscopic surface areas. Our work addresses this goal through the directed assembly of metal nanoparticles within periodic block copolymer templates. This self-assembly method allows for the preparation of unique arrangements, such as nano-rings and hybrid core-satellite structures. The optical properties of these individual nanostructures are characterised by combining hyperspectral imaging and scanning electron microscopy.

1. Introduction

Metal nanoparticles can interact with light in a unique way, offering exciting new possibilities for both fundamental science and the design of novel optical materials. This interaction is dominated by the collective excitation of free electrons, known as the surface plasmon. Plasmon excitation is in fact the most efficient process by which light can interact with matter, conferring to metal nanostructures the unique ability to concentrate and manipulate light at dimensions well below the diffraction limit. Because of these new capabilities, the field of plasmonics has grown rapidly, being identified as a potential pervasive technology capable of achieving unprecedented optical functionalities.

Nanoparticle assemblies, as opposed to single particles, offer multiple advantages for the fabrication of plasmonic devices. Excitation of the surface plasmon leads to local electromagnetic field enhancement that is at the basis of surface enhanced spectroscopies. In the case of assemblies, strong interparticle interactions can increase this field enhancement by up to several orders of magnitude as compared to that of isolated particles. Furthermore, interparticle coupling provides a way to tune the plasmon frequency through the characteristic redshift associated with particle aggregation. Of particular relevance to sensing applications, is the observation that the plasmon frequency of coupled modes shows a stronger response to local refractive index changes than does that of single particles.

2. Objective and Experimental Approach

When spread at the air-water interface, amphiphilic block copolymers self-assemble into a periodic array of surface micelles, such as those illustrated in Figure 1, composed of circular hydrophobic domains surrounded by coronas of hydrophilic segments.

[Figure 1: AFM image of surface micelles formed by poly(styrene)-b-poly(methyl methacrylate). The sample was prepared by self-assembly at the air-water interface followed by transfer to glass substrates.]

We have prepared composite films by co-spreading thiol-capped gold nanoparticles with poly(styrene)-b-poly(2-vinylpyridine) (PS-b-P2VP) and found that particle size, capping ligand length, and particle loading all have an impact on the precise spatial distribution of the particles within the block copolymer template. Of particular interest is the formation of ring assemblies resulting from the spontaneous relegation of the nanoparticles to the periphery of the circular hydrophobic domains.
Although the self-assembled rings exhibit significant plasmon coupling, the extinction spectra recorded for ensembles of nanostructures are very broad [7]. This can be attributed to variations in the details of particle organisation from one ring to another. To address this heterogeneity, we have combined scanning electron microscopy with hyperspectral imaging to characterise the plasmonic properties of individual structures.

3. Results and Conclusions

In order to image individual nanostructures with dark field hyperspectral microscopy the structures must be separated at distances greater than the diffraction limit. The addition of P2VP homopolymer to the PS-b-P2VP matrix results in a loss of periodic order and an increase in the distance of separation between the hydrophobic domains and, consequently between the metal nanoparticle rings that surround them. This is illustrated in Figure 2.

Using dark field hyperspectral microscopy, plasmonic scattering spectra were recorded from individual rings such as those shown in Figure 2. Through the use of marked substrates, the corresponding structures were imaged by scanning electron microscopy. Typically, scattering spectra exhibit more than one resonance, as shown for the example provided in Figure 3. Furthermore, the spectral features recorded from individual structures are much narrower than those of ensemble measurements. As anticipated, significant structure-to-structure variation is observed and the plasmonic spectral signature is very sensitive to structural details. These results clearly indicate the importance of coupled modes. Further investigation will be required to assign specific resonances to specific modes.

Nanoplasmonics in Embedded CMOS Electronics: Future mm-scale Complex Nano-optical Sensory Systems

Kaushik Sengupta

1 Department of Electrical Engineering, Princeton University, NJ 08544.

Abstract

Here we demonstrate for the first time massively parallelizable nanoplasmonic structures exploiting the sub-wavelength lithography of embedded copper-based interconnect layers in an industry standard CMOS process with 65-nm feature size. We show this in the context of a fully integrated, fluorescence based CMOS bio-molecular sensor array with integrated angle and scattering insensitive nanoplasmonic filters. The nano-optics and the all the readout analog and digital electronics are all co-designed and co-integrated in a single 2 mm² CMOS chip with absolutely ‘no change’ approach to the CMOS foundry processes.

1. Introduction: Why CMOS and Nano-optic co-integration matters?

The ability to integrate multi-functional, complex and robust nanoplasmonic structures operating in the visible and near-IR domain, with embedded electronics in the same substrate can allow a new class of intelligent, connected, ultra-miniaturized and low power nano-optical systems on chip. This is particularly true for CMOS-based foundry platforms that allows complex systems with high levels of integration in a single chip at low cost, high yield, small form factor and with low power dissipation.

In this paper, we show how the lowest metal layers in modern day CMOS processes that typically carry electronic information within the chip can be exploited to realize massively parallelizable and robust nano-photonic structures. With Moore’s law in scaling, as transistors have reached 20-nm in dimensions, the embedded copper-based electronic interconnects have also reached deep sub-wavelength regime in the visible and near-IR. Understandably copper nanostructures can be more lossy compared to gold. However, the critical point to note is that the co-integration of the optics and the electronics in the same substrate potentially with billions of transistors opens up a new design space and system capabilities. This is expected to be well beyond the traditional partitioned design approach that locally optimizes at a component level. An analogy can be drawn with modern-day wireless connectivity that relies on highly sophisticated and integrated radio-frequency integrated circuit (RFIC) technology in CMOS. The components realized in silicon RFICs are not the most efficient. However, collectively, with the integrated signal processing, digital control and high levels of integration, the approach has revolutionized our use of the RF spectrum. The nano-optic and CMOS co-integration can viewed as an enabling technology for the next generation of sensing and imaging systems.

2. CMOS Nano-optical System: Electronic and Photonic Co-design

In this paper, we demonstrate this approach in the context of a fully integrated, optics-free, 96-sensor multiplexed CMOS fluorescence biosensor array. This has been extremely challenging for nucleic acid and protein assays, since detection of fluorescence emission from tagged trace bio-molecules can be typically 70-80 dB lower than the excitation signal. Processing of such levels of signal typically requires a series of optical components including multiple filter sets, lenses, collimators, and photo-multiplier tubes that can be large, complex, bulky and expensive. Prior efforts in miniaturizing these systems have focuses on the same components in tighter packaging systems.

We achieve this with integrated nanofilters realized with lowest metal layers in a 65-nm CMOS process. The scattering and angle-insensitive nature of the filter eliminates all optical components and allows us to incorporate the entire biosensor interface, sensor array and the optics into a 2 mm² chip and the packaged system into a volume small enough to fit inside a pill(Fig. 1a). In spite of this, the system demonstrates sensitivities of 100 fM for DNA and 5 pm for proteins, comparable to, if not better than commercial reader and ELISA systems. This is achieved through co-design of the electronic and photonic front-ends where 50 dB of rejection is achieved optically, and 27 dB is achieved electronically allowing us to reach sensitivity of fluorescence detection that is 77 dB below the excitation (Fig. 1a).

3. Nano-waveguide based Filters

The nano-waveguide based filters are realized with four metal layers inside the CMOS chip with 100 nm width and 130 nm spacing. The filter sheet spreads over the entire 2 mm² chip. As shown in Fig. 1, when the excitation field (405 nm) is incident on the fluorescence tags on the chip surface, the tags act as optical nano-antennas and they emit randomly polarized fluorescence signal in a complex radiation pattern. Therefore, by removing all the collimating elements in a classical fluorescence set up to allow for true miniaturization, the filters need to be robust against all un-
Figure 1: **a.** A 96-sensor, multiplexed, optics-free CMOS chip with a disposable bio-interface, occupying 0.1 cc of volume. **b.** Integrated nanoplasmonic filters and simulated and measured performance [2, 3].

Figure 2: **a.** Nano-waveguide filter design and measured angle-insensitiveness eliminating the need for collimation and lenses. **b.** Measured DNA and protein sensitivity in sandwich assay and multiplexing ability in a hybridization assay [2, 3].

angles of incidence in a highly scattered background. The incidence excites multiple modes in the vertical waveguides, and the fundamental propagating mode (TM0) or the coupled surface plasmonic polariton mode constitutes the lowest losses. The filter operates by exploiting the differential absorption losses of the SPP modes between the excitation and the incident wavelengths, and the design of the sub-wavelength spacing suppresses the higher modes even more strongly between 60-120 dB [2]. The non-resonant nature of the filter is key towards the angle-insensitive nature of the filtering allowing it to operate in presence of uncollimated and scattering environment. This is illustrated in the measurement result in Fig 2a.

4. CMOS Nano-optic Biosensor Array

Under the plasmonic filter sheet, we implement a highly multiplexed 96-sensor photodetector array, low-noise read out circuitry and digital control all integrated in the same chip. The ability to detect 96 different bio-molecules simultaneously over the same chip is key for robust diagnostics and better statistics, reducing false positive and false negatives. A packaged LED and a disposable bio-interface over the chip with printed capture probes (for proteins and DNAs) (Fig. 1a) allows the entire system to have a volume less than 0.1 cc, small enough to fit inside a pill. In spite of the miniaturization, this demonstrates measured sensitivities of 100 fM for DNAs and 5 pM for proteins, the latter being comparable with the gold standard ELISA systems. To the best of our knowledge, this is the first demonstration of a multiplexed, fully integrated and optics-free fluorescence system in a CMOS chip with integrated nanoplasmonic filters [1]. More importantly, it demonstrates the feasibility of utilizing the co-design space to allow scalable and complex sub-wavelength optical field and electronic integration for future mm-scale nano-optical systems.

Abstract
Nanostructured dielectric and metallic photonic architectures can concentrate the electric field through resonances, increase the light optical path by strong diffraction and exhibit many other interesting optical phenomena that cannot be achieved with traditional lenses and mirrors. The use of these structures within actual devices will be most beneficial for enhanced light absorption in thin solar cells, photodetectors and to develop new sensors and light emitters. However, emerging optoelectronic devices rely on large area and low cost fabrication routes such as roll to roll or solution processing, to cut manufacturing costs and increase the production throughput. If the exciting properties exhibited photonic structures are to be implemented in these devices then, they too have to be processed in a similar fashion as the devices they intend to improve.

In this presentation, I will show how we use soft nanoimprinting lithography to mold unconventional materials such as polymers, cellulose or metal colloids to produce a variety of photonic architectures exhibiting exciting optical properties with tremendous applications as inexpensive disposable photonic components and sensors.

By nanostructuring these unconventional materials, we combine the complex optical properties of the nanostructure with the properties of the original materials: biodegradability (cellulose), electrical transport (conductive polymers) and sensing (Au colloids).

In particular, to the extraordinary properties of the cellulose, we incorporate enhanced photonic functionality by shaping it into photonic and plasmonic crystal structures via nanoimprinting lithography (Fig 1a,b), the most promising method for mass-produced nanostructures. [1] This combination opens up new venues in the field of cellulose based photonic architectures, offering a smart opportunity for the ecofriendly production of color in packaging systems or in photonic papers, anti-counterfeiting technology, washable and edible detectors or labels for the food industry. In addition, I will demonstrate further uses of the cellulose derivatives as water processable and environmentally friendly nanoimprinting resists. I will demonstrate the patterning of silicon wafers and the fabrication of metal nanoparticles with the aid of cellulose and water as only chemicals. [2]

To conclude, I will demonstrate how gold colloids can be assembled into hierarchical plasmonic crystals (Fig 1c,d), allowing the interplay of the optical response of the colloid with that of the plasmonic lattice. [3]

Abstract— We report on the photon drag effect of Bose-Einstein condensates. We develop a microscopic theory of this effect, which occurs in a general system containing Bose–Einstein-condensed particles, possessing an internal structure of quantum states. Analyzing the response of the system to an external electromagnetic field, we find that the drag results in a flux of particles constituting both the condensate and the excited states. We show that in the presence of the condensed phase, the response of the system acquires step-like behavior as a function of the electromagnetic field frequency with the elementary step determined by the internal energy structure of the particles.

1. INTRODUCTION

Light acting on atoms, molecules and other particles might result in a momentum transfer between light and matter particles [1]. This phenomenon is called the radiation pressure. In condensed matter, light pressure results in a current of charge carriers and it is called the Photon Drag Effect (PDE). Charge carriers, such as free electrons and holes, can absorb radiation by means of interaction with an electromagnetic field (EMF), and they move in a direction of the wave vector of light. PDE has been studied in semiconductors [2], dielectrics [3], metals [4], and other systems.

In classical description, the PDE current reads \( \mathbf{j}(\omega) \sim k \alpha(\omega) I \), where \( k \) is the photon wave vector, \( I = c E^2/8\pi \) is the intensity of the electromagnetic wave and \( \alpha(\omega) \) is the absorption coefficient of light by the charge carriers. Evidently, the frequency dependence of the drag current is determined by the spectrum of the absorption coefficient. In the majority of cases, this dependence is monotinous or resonant if the frequency of the EMF \( \omega \) is close to the energy of quantum transitions in the system. However, there are exceptions.

2. THEORY

We study the radiation pressure phenomenon in a system of bosons, containing particles in the BEC state [5, 6]. The spectrum of a single boson with an eigenfunction \( |\eta, \mathbf{p}\rangle \) reads \( \varepsilon_\eta(\mathbf{p}) = \varepsilon(\mathbf{p}) + \Delta_\eta \), where \( \varepsilon(\mathbf{p}) = \mathbf{p}^2/2M \) is a kinetic energy of the particle center-of-mass motion, and \( \Delta_\eta \) is the energy spectrum of the internal motion. Here index \( \eta \) stands for the full set of quantum numbers, characterizing the internal spectrum of the particle and the value \( \eta = 0 \) refers to the ground state of the internal spectrum of Bose particles.

The electric field of light depends on the center-of-mass coordinate \( \mathbf{r} \) only, \( \mathbf{E}(x) = E_0 e^{ikr - i\omega t} + E_0^* e^{-ikr + i\omega t} \), and the light–matter coupling can be described by the matrix elements \( \mathbf{d}_{21} \cdot \mathbf{E} \). Here the indices 1, 2 stand for the ground and excited quantum states of the internal particle motion, \( |1\rangle \equiv |\eta = 0\rangle \) and \( |2\rangle \equiv |\eta \neq 0\rangle \). Then \( \mathbf{d}_{12} = \langle 1| \mathbf{d} |2\rangle \) is a matrix element of the dipole moment operator of the particle. The system response to a pressure of the external EMF is a current of particles which is determined by the light absorption coefficient. The BEC–EMF interaction Hamiltonian reads

\[ H_I = \mathbf{d}_{21} \cdot \mathbf{E}_0 \sum_\mathbf{p} c_{\eta, \mathbf{p}}^\dagger \mathbf{a}_\mathbf{k}(t) c_{\eta, \mathbf{p}}(t) + \text{h.c.}, \]

where \( c_{\eta, \mathbf{p}}(t) = c_{\eta, \mathbf{p}}(0) \exp(-i\varepsilon_\eta(\mathbf{p})t) \) and \( \mathbf{a}_\mathbf{k}(t) = \mathbf{a}_\mathbf{k}(0) \exp(-i\omega t) \) are the annihilation operators for the Bose particle and EMF photon, respectively. The theoretical description of BEC is based on the Bogoliubov theory of a weakly interacting Bose gas [7]. To describe the dynamics of the BEC, we will use the Gross-Pitaevskii equation. Then low-energy excitations of the BEC represent Bogoliubov quasiparticles (bogolons) with the dispersion

\[ \omega_\mathbf{p} = \sqrt{\varepsilon_\mathbf{p} + 2gn_c} = sp\sqrt{1 + (p\xi)^2}, \]

where \( s = \sqrt{gn_c/M}, \xi = 1/(2Ms) \) are the sound velocity and the healing length, \( g \) is interparticle interaction strength, \( n_c \) is density of particles in the
BEC. In a long-wavelength limit $\xi_p \ll 1$ (that is equivalent to $\varepsilon_p \ll g_n$) the dispersion law of the bogolons becomes linear, $\omega_p = sp$. We will consider $T = 0$ thus disregarding the processes of thermal excitation of bogolons. Further we present $c_{0,p}$ in the form $[?]$ $c_{0,p}(t) = c_{0,0}\delta(p) + u_pb_p(t) + v_p b_p^\dagger(t)$, where $c_{0,0}$ describes the particles in the BEC state with zero momentum and $|c_{0,0}|^2 = n_c$. Here $u_p$ and $v_p$ are the Bogoliubov transformation coefficients and $b_p(t) = b_p(0) \exp(-i\omega_p t)$ are Bogoliubov excitation operators. Summing up, we come up with several principal quantum channels of the EMF absorption.

3. RESULTS

The first term of current describes a transition of a Bose particle from the BEC to an excited state $\eta \neq 0$ with the energy conservation law $\omega = \varepsilon_k + \Delta_{\eta} \approx \Delta_\eta$, see Fig. 1 transitions I. Beside these, there exists another type of transitions described by the second and third terms of the current density. They can be referred to as the Belyaev processes and happen when the light absorption is accompanied by not only excitation of the particle but also the emission or absorption of a Bogoliubov excitations of the condensate, see Fig. 1 transitions II. Such processes result in the step-like behavior of the BEC response (right panel). Therefore taking into account the internal structure of the particles leads to the “quantization” of the response of the system to the external light pressure in a 2D condensate.

Abstract

We report a broadband metalens that can realize wavefront modulation with high energy efficiency. Based on the impedance-matched gradient material, we theoretically and experimentally study a gradient index helical-structured metamaterial that can modulate sound wavefront with near perfect transmission over a broad bandwidth. A thin flat metalens is constructed to demonstrate sound focusing with the extraordinary transmission for more than 1/3 octave band. It is anticipated that this engineered material may be used in ultrasonography, ultrasound surgery, and DNA fragmentation.

1. Introduction

Acoustic metasurfaces developed rapidly in recent decades, enriching the acoustic wave control technology, offering abundant unique wavefront modulation functionalities in different application scenarios. There are two reasons limiting their bandwidth and performance. First, many approaches utilize cavity-resonance-based structures to generate phase delay, which only works ideally near the resonant frequencies. Secondly, for those who resort to coiling up space to obtain the high effective refractive index, accompanied by impedance mismatching with host media and Fabry–Pérot resonances that lead to a dramatical decrease of transmission coefficients. To extend the working frequency range, for reflected wave modulation, corrugated surface and circular-holed cube have been adopted. For the transmitted wave control, metamaterials with varying geometrical shape were introduced being an ideal model as it can decrease the reflection with a better impedance matching behavior, while the high index region is restricted by the viscous or structural loss because of the structural complexity. Moreover, many approaches are in primary stage, and more experimental investigation is needed. Notably, by compressing space by using helicoid surface, a dispersion-free metamaterial\textsuperscript{[1]} has been developed with higher space utilization rate compared with previous designs. Former works attempted to make an impedance-matched layer by using gradient pitch distribution and sound devices with diverse functionalities\textsuperscript{[2-4]}. A systematic investigation as well is experimental study is highly desirable to evaluate the effect of viscous and thermal loss and demonstrate the broadband sound wavefront modulation with high energy transitive ratio.

In this work, we introduce linearly distributed pitch to helical-structured metamaterials, matching the impedance of air with small helicity density at both ends. A transfer-matrix-based model is established to describe its behavior in frequency domain. To verify the performance practically, a flat meta-lens has been constructed to realized broadband focusing, showing excellent experimental results\textsuperscript{[5]}.

2. Design of elements

Different from the former approaches, we developed a helicoid structure with gradient pitch distribution. A theoretical model of the inhomogeneous medium has been conducted to calculate the phase and transmission spectra of the element. The unit element of the proposed helical structure has the largest pitch at both ends and the smallest pitch in the middle, symmetric about the middle point. The effective acoustic parameters of such a gradient structure are no longer uniformly distributed but instead decided by the on-site pitch value. The effective impedance, dynamic density and refractive index of an element are in the same variation trend that is against the pitch change. From the end to the middle point along the Y-axis, they all increase gradually with decreasing pitch value and a tighter arrangement of the blades.

![Figure 1: Photo of the newly designed gradient helicoid metamaterials. (manufactured by 3-D printing)](image_url)

Because of the distribution of the acoustic parameter can be expressed analytically. The wave propagation equation can be used to establish the theoretical model of the elements, as well as paves the way to design reversely based on the model. For the host media, we use the one-dimensional monochromatic wave equation, while for the effective media, with inhomogeneous properties, the governing equation can be

\[
\frac{d^2 p_i(y)}{d y^2} + \left( \frac{\omega}{c} n_{\rho i}(y) \right)^2 p_i(y) = \left( \frac{d \ln \rho_{\rho i}(y)}{d y} \right) \frac{d}{d y} p_i(y) = 0
\]

(1)
By using the analytical solution of the host media and the inhomogeneous effective model layers, a transfer matrix description can be built to predict the frequency response.

Figure 2: Transmission and phase spectra of an element. Calculated by using different methods, the results’ good agreement indicates the rationality of the theoretical method. The high transmission coefficient and gentle phase shift over spectra allow the elements to work together to generate unchanged lead-and-lag of phase in wide frequency range. Hence a broadband meta-lens can be achieved.

3. Experimental results

3.1. Measured effective index

The experimental results verify the slight dispersion of an element. The imaginary part – the attenuation coefficient— is near to zero and keeps flat during the calculated frequency range. Hence the gradient-pitched helical structure can be described by a lossless model reasonably.

Figure 3: Experimentally tested the complex refractive index of a single element (same one as Figure 2)

3.2. A broadband focal lens

We design a focal lens based on

\[ \phi(x) = \frac{2\pi f}{c} \left( \sqrt{x^2 + F^2} - F \right) \]

where \( \phi \) denotes the phase delay at any specific location \( x \), \( f \) is the operating frequency, \( c \) is the sound speed in the air (343.2 ms\(^{-1}\)), and \( F \) is the focal length. In the design procedure, we use 4000 as the target frequency. In this wide frequency range, which is tested from 3500Hz to 4500Hz, about 1/3 octave.

4. Conclusions

In this study, we theoretically and experimentally investigated the acoustic characteristic of the graded helicoid metamaterial and constructed a broadband focal lens with the studied element cell. The lossy property of the element has been evaluated in the experiment, and the broadband performance of the lens has been measured. The theory work paves the way of inverse design of metasurfaces while the experimental work studied the properties of such kind of metamaterial, providing valuable references for research and engineering.

Figure 4: Measured focusing field (a-c) and the cross-section distribution of sound intensity (d-f) realized by the meta-lens.

Abstract
We propose a new type of metasurface, which builds on the extended coherent states associated to plasmon/exciton polaritons. For this purpose, periodic stripes of organic dye are deposited on a continuous silver film. With a structuration exceeding the polaritonic wavelength by more than one order of magnitude, we demonstrate anisotropy generation in transition energies and emission patterns. These findings pave the way towards a novel type of artificial materials which require micro- instead of nano-structuration.

1. Introduction
The strong-coupling phenomenon that occurs when light-matter interaction prevails over damping leads to remarkable changes in the optical properties of matter, modifying both the spectrum [1] and dynamics of excitations [2]. When a large number of emitters is involved, a coherent coupling of the emitters through the electromagnetic mode occurs [3, 4]. In metal semiconductors systems, the strongly-coupled state (polariton) arising between molecules and a propagating plasmon has an extension ranging from a few [4, 5] to several tens of microns [6]. Polariton states have previously been tailored by confining either their electromagnetic [7,8] or excitonic parts [9]. Here, we will show that by patterning the emitters at the micron scale, it is possible to generate a new type of metasurface that builds on the polariton extended coherence.

2. Results
The sample consists of stripes of active dye, periodically deposited (period p) on a continuous silver film. The inactive stripes have been created in a homogeneous cyanine dye film (TDBC, 17 nm thick with a sharp absorption peak at 2.1 eV) by photobleaching the dye molecules using local UV-irradiation. The UV-irradiated material has the same optical index as the cyanine dye film, except around 2.1 eV where the Lorentzian peak related to the sharp absorption is eliminated. On the sample thus coexist regions where the material is non-absorbing (forbidding the strong coupling regime), and regions with strong material absorption (Fig. 1a).

Figure 1: a. Sketch of the sample b. Fourier image of the emission. The dotted line indicates the position of the beam-blocks inserted in the Fourier plane for the direct emission images. c-e. Direct images of the emission by keeping only (c) the central part of the Fourier plane (incoherent states); (d, e) the outer part of the Fourier plane (polaritonic states.

In order to first analyze the impact of a micron-size structuration on the polaritonic state, the spatial distribution of the emission for a p=2µm stripe array is presented Fig. 1. To separate the contributions of uncoupled TDBC states from those associated with polaritonic states, Fourier-space filtering is performed using a circular or ring-shaped mask (Fig. 1b). Figure 1c shows the emission in the recorded direct space by conserving only the small wave vectors associated with the incoherent states. In this configuration, the dye stripes appear distinctly, and no emission is recorded in the irradiated areas. When only large wave vectors, associated with polaritons, are conserved, the emission behavior is radically different. For a horizontal polarization (along x), that is to say when considering only
the wave vectors associated with a propagation perpendicular to the lines, a uniform emission is obtained (Fig. 1d). In the case of propagation parallel to the lines, the emission takes place only on the dye stripes (Fig. 1e). This experiment highlights the formation of a coherent state: the patterning having a characteristic size smaller than the extent of the polaritonic state, the structured system behaves like a homogeneous effective medium for a propagation perpendicular to the lines, and as the sum of two distinct modes for propagation parallel to the lines.

This effect is also confirmed by reflectometry measurements obtained on a sample with a 5 µm stripe period. For a propagation direction along the lines (Fig. 2a), the dispersion relation simultaneously reveals a surface plasmon and a polariton. The Rabi splitting in this case is about 160 meV. However, for propagation perpendicular to the lines, only the polariton exists (Fig. 2b), with a Rabi splitting of the order of 100 meV. This reduction in the Rabi splitting is close to the factor \( \sqrt{2} \) expected for a filling factor \( \frac{1}{2} \).

In the energy range corresponding to dye absorption (2.1 eV nm), the surface plasmon mode is present only for directions of propagation contained in a cone of ± 20 ° around the y axis (along the stripes). For higher angles, the plasmon disappears, and no mode remains in this energy range since it corresponds to the exclusion band of the polariton. Our approach thus allows the generation of anisotropic dispersions relations in a given energy band, the system remaining isotropic outside this band.

Figure 2: Dispersion relations in reflection for a sample with p=5µm, associated with propagation: a. parallel to the stripes and b. perpendicular to the stripes. c. Reflection dips energies as a function of the orientation of the propagation with respect to the lines, measured between 0 and 360 °.

In this talk, simulation results as well as a study of the period effect on the metasurface behavior will in addition be discussed. Finally, we will also show that by changing the stripes filling factor it is possible to generate anisotropic polaritonic emission.

3. Conclusions

In conclusion, we have shown that the properties of molecules strongly coupled to surface plasmons can be drastically modified by structuring the sample on distances which are large compared to wavelengths. The modified material band structure can find applications in polarization controlled sources, as well as in topological photonics based on anisotropic dispersions and Dirac cones [10] or exceptional points [9]. The active polaritonic metasurfaces we propose are not restricted to plasmonic modes nor organic dyes alone, but can be extended to a large variety of structures in strong coupling such as cavity polaritons which have similar extended coherence lengths [11].

(Chiro)-optical properties of chiral inorganic-plasmonic nanocomposites

Thierry Verbiest\textsuperscript{1*}, Ward Brullo\textsuperscript{1}, Tom Swusten\textsuperscript{1},

\textsuperscript{1}University of Leuven, Department of Chemistry, Belgium

*corresponding author, E-mail: Thierry.verbiest@fys.kuleuven.be

Abstract

We will discuss the chiro-optical properties of chiral self-assembled nanostructures that are composed of superparamagnetic iron oxide and plasmonic nanoparticles.

1. Introduction

We recently developed a self-assembly method to prepare multi-layered materials composed of inorganic and metallic nanoparticles coupled together by organic molecules \cite{1}. Due to their hybrid character they exhibit peculiar optical properties. For example, multi-layered structures composed of plasmonic gold nanoparticles and superparamagnetic nanoparticles exhibit unusually strong magneto-optical effects, asymmetric optical transmission and optical activity effects \cite{2,3}. Instead of using self-assembly, these structures can also be prepared via spray coating techniques, making it possible to prepare them on a larger scale \cite{4}. Here we will investigate the chiro-optical properties of chiral self-assembled nanostructures.

2. Results and discussion

2.1. Preparation of self-assembled nanostructures

The self-assembled nanostructures were prepared according to a procedure described by Brullot \textit{et al.} \cite{1}. In brief, gold nanoparticles prepared via the well-known Turkovich method are deposited onto a glass slide that was coated with APTMS by soaking the glass slide in a dispersion of gold nanoparticles. After rinsing with water and methanol, the glass slide covered with gold nanoparticles is immersed into a dispersion of APTMS coated iron oxide nanoparticles. After rinsing with solvent, we now have a double layer of gold and iron oxide nanoparticles that are covalently bonded together by the APTMS linker. By repeating this procedure, several of these nanoparticle double layers can be deposited onto the glass slide. Note that via this procedure, nanoparticles layers are deposited on both sides of the glass. For our experiments we always mechanically removed one side of the coating. These nanocomposites can be made chiral by immersing them into a solution of D- or L-proline.

2.2. Optical rotation experiments

Optical rotation experiments were done using a home-made experimental set-up. Light from a semiconductor laser (785 nm) is sent through a polarizer and focused onto the sample perpendicular to the substrate. After the sample, the light is split into an s- and p-polarized component via a Wollaston prism and send to two photo diodes. The whole system is aligned in such a way that in the absence of optical rotation, the intensities on the two photodiodes are equal. Hence, any optical rotation in the sample will result in an imbalance in light intensity on the photodiodes from which the optical rotation can be calculated.

For our first experiments we used a sample composed of alternating layers of gold nanoparticles and iron oxide nanoparticles with 9 nanolayers in total and impregnated with L-proline. The optical rotation was found to be +0.0024°. For samples impregnated with D-proline the optical rotation -0.0044°. We realize that the optical rotation for D- and L-enantiomer should only differ in sign, not magnitude. However, we found that impregnating the samples is not always reproducible, since it depends on a variety of parameters. Nevertheless, the difference in sign for both enantiomers is clearly present. While these optical rotations may seem very small we have to consider the fact that the thickness of the samples is only 40 nm. Hence per mm, this amounts to an optical rotation of 11°/mm, much higher than what is typically observed in concentrated solutions of proline. Probably, this high optical rotation is due to plasmonic effects.

Even more peculiar was the following observation: the optical rotation was found to be different when the sample was illuminated from the front or from the back. For front side illumination the optical rotation for the L-proline sample was 0.0024°, while for back side illumination the optical rotation was -0.0055°, a difference of 0.0079°. For the D-proline sample, front side illumination resulted in 0.0044°, while back side illumination yielded -0.0018°. In principle anisotropy or a heterogeneous sample could account for such observation, but polarized UV/Vis spectroscopy clearly indicates that the sample is perfectly in-plane isotropic and optical microscopy reveals no heterogeneities. We currently do not have a solid explanation for this behavior, but interestingly, a similar phenomenon was observed by Zheludev \textit{et al.} in a chiral crystal and the effect was called nonreciprocal natural optical rotation. The authors attributed the effect to the presence of a nonvanishing symmetric part of the nonlocality tensor.
3. Conclusions

We have observed extremely strong optical rotation in chiral self-assembled nanostructures composed of plasmonic gold nanoparticles and iron oxide nanoparticles. Furthermore, the optical rotation was found to be asymmetric in the sense that forward and backward propagation of light through the sample yields a different optical rotation.

Abstract

Self-assembled diblock copolymers were used as templates to produce well-defined gold nanostructures in 3D or 2D, with so degree of order. Resulting structures were shown to present specific and tunable optical resonant properties, and include hyperbolic metamaterials and high-index metasurfaces.

1. Introduction

Optically resonant nanostructures provide unprecedented capacities to manipulate light at a sub-wavelength scale. Their applications span the whole range of optical functions (filters, modulators, polarizers, absorbers, etc) while being accessible at sub-wavelength dimensions with the benefit of enabling miniaturized devices. In spite of tremendous recent progress in the nanofabrication methodologies, such nanostructures usually require complex fabrication processes via top-down approaches of low scalability. To circumvent these technological issues, bottom-up approaches including colloidal assembly, micellar-induced assembly, or self-assembly of diblock copolymers (dBCPs) have been successfully introduced as alternative methodologies since they give access to various 3D or 2D metal, dielectric or metal/dielectric nanostructures. In particular, the selective hybridization of dBCP thin films with metallic species is known as a fabrication methodology for visible range metamaterials [1-4]. Indeed, dBCPs self-assemble into metamaterials with well-defined morphology. They are macromolecules made of two molecular chains of distinct chemical nature linked together, called the blocks, and present solid state spontaneous organizations with long-range order and tunable characteristic sizes, ranging typically from a few nanometers to a few hundred nanometers. The accessible morphologies include hexagonally packed cylinders and lamellae. Here, we report on the use of dBCPs presenting a lamellar morphology to produce two types of plasmonic structures. The first one is a uniaxial 3D multilayer stack, in which we show that the optical anisotropy allows reaching hyperbolic permittivities. The second is a 2D nanostructure, in which out-of-plane lamellae lead to an azimuthally isotropic resonant thin film reaching high refractive index.

2. 3D plasmonic lamellar nanomaterials

2.1. Fabrication

Here, we use a lamellar poly(styrene)-block-poly(2-vinylpyridine) (PS-b-P2VP) copolymer with both blocks of molar mass 25 kg/mol, which spontaneously develops a multilayered structurally uniaxial thin film of alternate PS and P2VP layers with a period of 37 nm in the bulk. We use a process combining spin-coating of a polymer solution on a selective surface and thermal annealing, which produces a flat and homogeneous film with a parallel alignment of the organized structures, throughout the thickness of the film between 200 and 700 nm. This ordered structure spans an area as large as the spin-coating process can produce (we use 15 x 15 mm² wafers). In order to induce dielectric permittivity contrast depending on the probed direction, we dope one of the polymer phase with metallic nanoparticles of radius 5 nm. For this, we use an impregnation methodology, in which a previously ordered and aligned copolymer nanostructure is selectively swollen with a gold precursor solution. After action of a reducing agent, Au nanoparticles form selectively within the P2VP layers, thus producing alternate stacks of pure PS layers, and composite...
layers of gold nanoparticles and P2VP (see Fig. 1). We can increase and control the volume fraction of nanoparticles in the composite layers, by repeating the impregnation process and we can then follow the structural and optical evolution of the material.

2.2. Optical properties

We determine by spectroscopic ellipsometry that the dielectric functions $\varepsilon_\parallel$ and $\varepsilon_\perp$ both present a resonance at the wavelength $\lambda \sim 580$ nm, close to the plasmon resonance of the gold nanoparticles. This resonance amplitude for $\varepsilon_\parallel$, is limited and varies only little while the resonance of $\varepsilon_\perp$ is stronger and its amplitude significantly increases with the gold loading, reaching a regime of negative values for gold volume fractions beyond 30%. These results demonstrate the capacity of our bottom-up self-assembled multilamellar stack to respond as a hyperbolic effective medium in a given region of the visible spectrum ($520 < \lambda < 560$ nm). In the hyperbolic region, the dispersion relation allows propagative modes for large values of $|k_\parallel|$, potentially providing super-resolution.

3. 2D plasmonic fingerprint nanostructures

3.1. Fabrication

A thin (~40 nm) film of a lamellar PS-b-P2VP dBCP, with $M_{nPS} = 102.0$ kg/mol and $M_{nP2VP} = 97.0$ kg/mol, was directly deposited by spin-coating onto a silicon wafer, chemically modified by a polystyrene-Star-poly(methyl methacrylate) copolymer ($f_{PS} = 0.63$) to promote the out-of-plane alignment of the dBCP. The films were then impregnated with a gold precursor solution, and exposed to a reactive ion etching (RIE) O$_2$ plasma, in order to remove the BCP template and reduce the gold salts. The as-cast copolymer films, as well as the resulting gold decorated surfaces, present a lamellar morphology (of period 64 nm), (see Fig. 2). Interestingly, there is no defined azimuthal orientation, leading to characteristic fingerprint patterns. The shape of the produced gold nanostructures was tuned by varying the metal content within the P2VP lamellae, using different impregnation durations. This resulted in different gold nanofeature shapes from well-defined Au dots to rodlike particles of increasing aspect ratio.

3.2. Optical properties

The evolution of the measured ellipsometric angles $\varphi$ and $\Delta$ as a function of the photon energy reveals a clear resonance feature in the region near 540 nm, which is attributed to the LSPR of the Au NPs templated from the P2VP domains. The effective refractive index of the thin film was extracted from the spectroscopic ellipsometry measurements, using a Maxwell-Garnett effective medium approximation with either spherical or ellipsoidal inclusions. High-refractive index surfaces (up to 3.2) with relatively low extinction coefficient (1.4) are obtained with the film of high aspect ratio particles. Finally, the precise control on the shape, structure and volume fraction obtained with the fabrication process, along with the effect of the localized surface plasmon, allows modulating the optical response while keeping a low gold content and little plasmonic coupling effects.
Topological Photonic Metamaterials with Honeycomb Structure

Xiao HU

International Center for Materials Nanoarchitectonics (WPI-MANA)
National Institute for Materials Science (NIMS), Tsukuba, Japan

Abstract

We propose a generic way to create topological metamaterials. The strategy of our approach is of two steps: (1) create the Dirac-type linear dispersion with the honeycomb lattice, which may be called artificial graphene, and (2) open a band gap and carry out band engineering based on real-space manipulations. Our work shows that fascinating topological functionality can be created using the advanced nanotechnology.

1. Introduction

A couple of years ago, we proposed theoretically that topological electromagnetic transportations can be realized in honeycomb-type photonic crystals of dielectric cylinders [1]. Recently, the proof-of-concept experiment has been carried successfully in microwave regime using Al₂O₃ [2]. The strategy of our approach is of two steps: (1) create the Dirac-type linear photonic dispersion with the honeycomb photonic crystal, which may be called artificial graphene, and (2) open a frequency gap and carry out band engineering based on real-space manipulations.

Crystalline symmetries play the crucial roles since the Dirac-type dispersions in honeycomb lattice are guaranteed by the C₆₅ symmetry with respect to the center of hexagonal unit cell, and the C₃ symmetry with respect to individual sites. Breaking the C₃ symmetry opens a gap accompanied by the lifting of degeneracy between the p and d bands.

We reveal that there are always two conjugating ways in breaking the C₃ symmetry where the p and d bands are inverted in the order of frequency (or energy), which induces the nontrivial topology.

2. New topological metamaterials

Along this line, we have designed a couple of new topological metamaterials of honeycomb structure.

2.1. Topological LC circuit

We design a topological LC circuit with L₁>L₀ as shown schematically in Figure 1, where the C₃ symmetry is broken by the texture in inductance. The design has been realized successfully in microstrips, a typical transmission line [3].

2.2. Topological photonic crystal of dielectric cuboids

As another example, we propose to achieve topological electromagnetic propagations by using honeycomb lattice of dielectric cuboids, where the C₃ symmetry is broken by the shape of cuboids [4]. A transition between trivial and topological photonic states is achieved by merely rotating the cuboids around their centers.

3. Conclusions

We propose a generic way to create honeycomb-type topological metamaterials. Our approach is based on the Dirac-type linear dispersion, where the C₆₅ symmetry with respect to the center of hexagonal unit cell, and the C₃ symmetry with respect to individual sites are crucially important. We have revealed that there are always two conjugating ways to break the C₃ symmetry, which lifts the degeneracy of the p and d orbitals and invert them in the order of frequency or energy, and thus induces the nontrivial topology with time-reversal symmetry. Our approach requires only local real-space manipulations, without resorting to spin-orbit coupling, and other special materials. Therefore, our approach is applicable to both
bosonic and fermionic systems, as well as all physical waves. Our work bridges the brand-new topology physics and the advanced nanotechnology.

Abstract

Fano-resonant structures that exhibit sharp spectral resonances are demonstrated employing shape memory polymers. When heated above the glass-transition temperature, disordered lattices are transformed into an ordered lattice, resulting in a drastic change in photonic response. This could be useful for long-distance environmental monitoring.

1. Introduction

Four-dimensional (4D) printing combines smart materials with 3D printing and can thus realize a complex geometry of smart materials with fine details [1, 2]. Therefore, it is a very interesting route for various stimuli-responsive structures with highly enhanced functionalities. 4D-printed structures are also called ‘programmable matter’, because their response can be programmed into materials by structural and compositional design. However, 4D printing studies have thus far been limited to relatively simple demonstrations. No active or reconfigurable photonic structures with remarkable spectral responses have been reported. Here, we demonstrate 4D printing of shape memory polymers to realize stimuli-responsive, Fano-resonant lattice structures. The optimized lattice structure can exhibit sharp Fano resonances in the microwave region. Deformed lattices can be transformed to the original, ordered lattice upon heating, resulting in a drastic change in photonic response. This could be useful for long-distance environmental monitoring.

2. Results and Discussion

An SMP beam array was fabricated by fused deposition modeling (FDM) 3D printing. After thermomechanical programming, the SMP lattice was randomized. This disordered lattice does not show a sharp spectral resonance. Later, when it was heated again, the lattice returned to its permanent, ordered structure (Figure 1a). A sharp Fano resonance then appeared and we obtained a drastic change in the microwave spectrum (Figure 1b-d). In our dielectric lattice structure, sharp Fano resonances occur because of guided resonances in the periodic, dielectric beams, which interfere with a slowly varying, background Fabry–Perot resonance. Upon heating, the sharp spectral change occurs because the Fano resonance in the ordered lattice structure is induced by a collective, coherent mode distributed over the whole lattice, not by localized resonances in individual beams. Figure 1 below summarizes our sample and microwave measurement results.

In conclusion, 4D printing of shape memory polymers that enable a drastic change in photonic response is demonstrated. Shape-memory-polymer lattices are designed, implemented (by 3D printing), and characterized. The sharp Fano resonance and spectral collapse are measured and analyzed. The effect of the degree of disorder on the Fano resonance is investigated.

Mid Infrared Metasurfaces

Yoshiaki Nishijima¹, Naoki To¹, and Takuhiro Kumagai¹

¹Faculty of Engineering, Yokohama National University
*corresponding author, E-mail: nishijima-yoshiaki-sp@ynu.ac.jp

Abstract
Mid infrared wavelength is unique to detect the molecular vibration mode. Especially absorption type of frequency selective meta surface can be used for thermal light source, detector and sensing material. Here we demonstrate the recent advances of plasmonic meta surfaces in mid infrared wavelength region. The experimentally measured optical properties were compared with simulations by Finitedifference time-domain calculations. Also, we demonstrate applications of these structures for the plasmonic IR-light sources and detectors.

1. Introduction
Plasmonic metasurface become essential material to control optical transmission, reflection and absorption. One of the popular trends in plasmonics and metamaterials are mid infrared applications. Recent progress in mid infrared metasurface are broad band light absorber for energy harvester, thermal light emitter/absorber and so on [1–4]. The simple configuration of the metal-insulator-metal(MIM) are easy to design and to make by a well-established semiconductor nanofabrication processes or self assembly of nano particles. We focused on PPA structures as the photo-thermal light emitter and detector in mid-infrared (IR) wavelengths for constructing plasmonic non-dispersive infrared (NDIR) gas sensors. The Kirchhoffs law of the thermal radiation defines the absorption and emission efficiencies being equal to each other.

In mid infrared wavelength region, metasurface can be fabricated with well established technology, such as reduction projection photolithography and electron beam lithography techniques, still it requires expensive semiconductor equipment. Therefore the requirement of lithography free plasmonic absorber is enhanced. Here, I will present the methodology for realizing real perfect absorption with plasmonic metasurface, and FabryPero type of metasurfaces and their thermal radiation properties, hydrogen sensing applications.

2. Experiments
Sub-micrometer structure dimensions are required for the MIM structures functional at the IR wavelength range. Therefore, EB lithography with low resolution, high trough put mode or the reduction projection photo lithography is suitable for the mass production of devices. 200 nm Au film was deposited on top of Si substrate, which both side was polished mirror grade. After lithography process (EB or stepper), development and metal deposition, a lift-off was performed in an organic solvent to obtain final plasmonic metasurface structures. Lithography free metasurface has been obtained with EB deposition of metal and insulator layers.

Optical reflection spectroscopy has been performed with the combination of the FT-IR (FT-IR 4200, JASCO CO.) and microscope unit (IRT-1000). As a reference for the reflectance spectra, a Au mirror with the 98reflectance has been used. For the thermal radiation spectroscopy, specially modified FT-IR system was implemented. The light from the outside was coupled into the FT-IR setup from an optical side port. The light passed through the interferometer and directed to the HgCdTe (MCT) detector. Samples were contacted to the ceramic heaters on a Al plate with ceramic glue.

3. Results and discussions
Figure 1 shows reflection spectra of plasmonic metasurfaces. Exhaustive FDTD simulation predicts over 90% absorption in various points. In the experimental aspect, resonance wavelength is well agreed with FDTD, but absorption value is not completely suit with FDTD. However controlling the thickness of insulator layer and nanodisks, diameter of nanodisks, distance between two nanodisks (periodicity), we have realize 95% absorption.

Figure 2 shows reflection and emission spectra of Fabry Pero metasurface. Absorption peaks have appeared around 1.5, 2.5, 7 µm. These peaks comes from multiple reflection in Fabry Pero resonance. In FDTD simulation well agreed with sharp shorter wavelength peaks. However, around 7 µm has not reproducible by FDTD. In the emission spectra, we have observed this broad band emission spectra. According to the Kirchhoff’s emission law, only real absorption mode can be realize photo-thermal energy conversion. Detail analysis of this mode is now under consideration, but we have successfully realized near perfect absorption and emission in the mid infrared wavelength region.

4. Conclusions
In this study, we have demonstrated the optical absorption properties of various kinds of plasmonic and label free absorbers in mid-IR wavelengths. Still further improvement is needed to realize real perfect absorber in mid infrared wavelength region. Mid infrared plasmonics and metasur-
Figure 1: Reflection spectra of plasmonic metasurface with 60 nm of insulator thickness, 50 nm of metal nanostructure thickness and 800 nm of diameter, with 100 to 1200 nm of distance between two disks.

Electrically Tunable Mirror Arrays for Spatial Modulation of Terahertz Radiation over a Wide Frequency Range

Jan Kappa¹, Dominik Sokoluk¹, Steffen Klingel², Corey Shemelya¹, Egbert Oesterschulze², and Marco Rahm¹

¹Department of Electrical and Computer Engineering, Research Center OPTIMAS, Technische Universität Kaiserslautern, Kaiserslautern, Germany

Abstract

We demonstrate spatial modulation of terahertz waves in a frequency range from 0.97 THz to 2.28 THz by means of an electrically tunable multi-mirror grating. The terahertz spatial light modulator (THz-SLM) consists of 768 actuating mirrors with each a length of 220 µm and a width of 100 µm. Within the investigated frequency bandwidth, the modulation contrast exceeds 50% with a maximum modulation contrast of 87% at a frequency of 1.38 THz. The THz-SLM can be used to generate almost arbitrary spatial pixel sizes by changing the groupings of the mirrors that are collectively addressed as a pixel. The mirrors are fabricated as a chrome-copper-chrome multilayer material. Due to intrinsic stress in the structure, the mirrors incline to an upstanding position at an angle of 35°. By application of a bias voltage of 35 V, the mirrors can be individually addressed and be pulled down to a ground electrode on the substrate. In addition, hysteretic switching enables spatial light modulation at arbitrary pixel modulation patterns without the necessity to electrically address each individual mirror in the array.

1. Introduction

Terahertz radiation attracts the interest of scientists and industrial developers due to its favorable property of penetrating through almost all dielectrics without a significant attenuation. Furthermore, terahertz pulses with a multi-THz spectral bandwidth can be generated and measured in amplitude and phase. Merging these assets renders terahertz technology an ideal candidate for non-invasive spectroscopy that is urgently needed for quality control and security technology. However, terahertz systems suffer from two major drawbacks. First, imaging terahertz spectroscopes are sophisticated measurement instruments that cannot be fabricated at low cost. Second, terahertz imagers only enable monitoring at low data acquisition rates. The latter especially carries weight when amplitude and phase and thus the whole spectrum is measured for each image pixel. A possible method for faster terahertz imaging is the coded aperture technique, in which a variety of projections of a scene are imaged onto a single-pixel detector [1]. The scene is then reconstructed by either fast direct matrix inversion [2] or compressive computation [3,4]. In contrast to multi-pixel cameras that usually only record the pulse amplitude, the single-pixel detector can be a commercial terahertz antenna that measures amplitude and phase and thus the whole frequency spectrum of the pulse. Yet, coded aperture imaging require THz-SLMs for the encoding of the spatial projection masks. Among a great variety of different approaches for the realization of THz-SLMs, reconfigurable metamaterials have proven to achieve fast dynamic spatial modulation, but only for limited spectral working range [5-10].

Here, we report the fabrication of a THz-SLM that allows spatial terahertz light modulation over a frequency bandwidth of more than 1 THz. The THz-SLM is based on an electrically tunable grating that consists of actuating mirrors. The THz-SLM can be used to modulate the projection masks for coded aperture imaging without sacrificing the spectral bandwidth in the measurement process.

2. Results and Discussion

Figure 1 shows a photograph of the fabricated THz-SLM. The THz-SLM is mounted on a circuit board that contains the contact pads for applying the bias voltage patterns to the multi-mirror array. Without biasing, the mirrors of a pixel are inclined at an angle of 35° and form a grating that diffracts incident terahertz radiation away from the position of the single-pixel terahertz detector. The detected terahertz electric field is therefore minimal, when no bias voltage is applied. For a bias voltage of 35 V, the mirrors of a pixel are pulled down to the ground electrode and lie flat on the substrate. In this position, the mirrors of a pixel reflect the incident radiation directly into the direction of the position of the detector and the detected terahertz field is maximal.

In the experiment, we investigated the spectral dependence...
of the achievable modulation contrast of the THz-SLM by simultaneously switching all pixels between the flat and inclined mirror position. Figure 2 depicts the plot of the modulation contrast vs. frequency. We observed that the modulation contrast exceeds a value of 0.5 for frequencies between 0.97 THz and 2.28 THz, corresponding to a frequency working range of about 1.3 THz. As shown in a great number of publications, a modulation contrast of 0.5 is sufficient for application of the THz-SLM in a terahertz coded aperture imager. Due to the wide spectral working range, the THz-SLM is not only suited for reconstruction of intensity images in a coded aperture imager, but also for spatially resolved terahertz spectroscopy [11].

3. Conclusions

We experimentally demonstrated spatial terahertz wave modulation with a modulation contrast exceeding a value of 0.5 over a frequency working range from 0.97 THz to 2.28 THz. Due to its wide working range, the terahertz spatial light modulator is very well suited for spatially resolved terahertz spectroscopy based on the coded aperture imaging method.

Abstract

We show both experimentally and theoretically that dielectric nanowires (Si-NW) are an efficient platform to transfer visible light from quantum emitters. We first study the effect of high index dielectric nanowires on the spontaneous emission of the emitters positioned in their vicinity. Then, we demonstrate that the 1D propagation of light can be efficiently controlled by the geometry of the wire. These emitter-nanowire hybrid structures might be good candidates as building blocks for the design of complex optical nanodevice architectures working in the single photon regime.

1. Introduction

For a couple of decades, nanoscale optics has mainly been driven by plasmonics since noble metal nanostructures sustain strong resonances that can be used to enhance, confine, propagate or redirect visible light. Such properties have led to numerous actual or potential applications in integrated optics, sensors, nonlinear optics, field-enhanced spectroscopies, or photovoltaics. Recently, an alternative to plasmonics emerged with high refractive index dielectric nanostructures, which offer the same range of applications as plasmonics by manipulating waveguide and Mie optical resonances instead of plasmonic ones [1]. These resonances can be efficiently tuned by modifying the size, shape, and material of those nanostructures (e.g. silicon, optical index $n=4$). Furthermore, high index dielectric nanostructures offer several advantages when compared to their metallic counterparts: absorption losses are far weaker for wavelengths greater than the direct gap, access to semiconductor (CMOS) technology for nanostructure fabrication, and presence of intrinsic strong electric and magnetic resonances [2,3].

In the context of quantum nanophotonics, which aims to combine the confinement and propagation of light at the nanoscale along with quantum properties of light, their appealing properties make Si nanostructures an interesting platform to investigate classical to quantum optics transition in coplanar devices.

2. Discussion

First, we discuss the effect of high index dielectric nanowires on the spontaneous emission of quantum emitters placed in their optical near field. The local density of photonic states (LDOS), therefore the emission rate of punctual emitters, are driven by the presence of the nanostructure. With time-resolved photoluminescence acquisitions, we show that the photodynamics of the quantum emitters are modified in the vicinity of Si wires. The experimental data are systematically compared to decay rate and LDOS maps computed with the Green Dyadic Method (GDM).

![Figure 1: (a) SEM image of a silicon wire (cross-section: 200 nm). (b) Corresponding photoluminescence map recorded in the image plane which reveals the propagation of single photons in the Si-NW.](image)

In a second stage, we show that visible photons emitted by a single emitter coupled at one extremity of Si nanowires is guided efficiently by the waveguide modes up to the second extremity, located several micrometers away. By performing image plane acquisitions (as illustrated in Figure 1) on a set of emitter-wire hybrid structures, we observed in good agreement with numerical experiments that the geometrical parameters of the wires plays an important role in the efficiency of the transfer.

Abstract

High-index dielectrics such as silicon are an exciting alternative to plasmonic materials for the design of optical nanoantennas with low ohmic losses. We review our recent results on the use of Si-based nanoscale resonators to manipulate magnetic and electric spontaneous emission processes.

Results and discussion

Thanks to their enhanced and confined optical near-fields, broadband subwavelength resonators have the ability to enhance the spontaneous emission rate and brightness of solid-state emitters at room temperature. Over the last few years, high-index dielectrics have emerged as an alternative platform to plasmonic materials in order to design optical resonators with low ohmic losses (Figure 1-a) [1]. In particular, we recently demonstrated experimentally that silicon-based nanoantennas can enhance or inhibit spontaneous emission from fluorescent molecules [2]; but also enhance specifically magnetic decay processes from rare-earth based emitters [3]. In practice, the interaction between silicon nanoantennas and solid-state emitters is controlled using scanning probe microscopy, either by grafting fluorescent emitters or milling a nanoscale resonator (using a focused ion beam) at the tip of a tapered optical fiber.

By coupling a 100 nm fluorescent sphere to silicon nanodisks, we observe that matching the antenna resonance to the fluorescence emission wavelength leads to enhanced decay rates at short distances; while, for an out-of-resonance antenna, the fluorescence lifetime is locally increased (Figure 1-b). Furthermore, these experiments highlight the ability of silicon antennas to increase far-field collection efficiencies, in agreement with numerical simulations.

To study the enhancement of magnetic spontaneous emission processes, we couple oxide nanoparticles doped with trivalent europium cations to cylindrical silicon antennas. By monitoring the relative intensities of the electric and magnetic transitions of europium while scanning the nanoparticle in the vicinity of the nanoantenna, we demonstrate strong nanoscale modulations of the local densities of magnetic or electric optical states, allowing a local enhancement of magnetic emission over its electric counterpart (Figure 1-c).

These results demonstrate the potential of silicon antennas for the manipulation of solid-state emitters at the nanoscale and at room temperature.

Abstract
We analyze ultrafast hot electron dynamics in the time domain upon optical excitation of propagating surface plasmon-polaritons in metal-dielectric heterostructures. Considering both local and non-local hot electron relaxation on equal footing, we develop a kinetic model elucidating the role of surface plasmon-polaritons in an apparent slowdown of electron transport. We show how the time-transmissivity data can be employed for the direct measurement of surface plasmon lifetimes at arbitrary corrugated interfaces with unknown losses.

1. Introduction
Ultrafast dynamics of electronic excitations is of growing fundamental interest in modern physics. Femtosecond electron dynamics after an ultrashort optical excitation cannot be accurately described within the thermal equilibrium models. Instead, non-equilibrium electron distributions should be considered on the timescale of a few hundred of femtoseconds \cite{1-2}. Small penetration depth of the optical field in metals ensures inhomogeneous excitation profile and the in-depth transport of hot laser-excited electrons in the ballistic regime \cite{3-4}. Interestingly, the SPP lifetime in plasmonic metals usually resides on a similar timescale, enabling an interplay of these excitations with the relaxation of hot electrons. It is thus intriguing that the role surface plasmon-polariton (SPP) excitations in the hot electron dynamics has not yet been clearly identified.

2. Results
Femtosecond laser excitation of a metal results in the generation of hot electrons above the Fermi level. The population of these non-thermal electrons evolves by means of ballistic transport and electron-electron scattering, constituting non-local and local relaxation, respectively. We employed 40 fs-long laser pulses for studying transient transmittance of a periodically corrugated Au/Co-doped yttrium iron garnet (YIG:Co) magneto-plasmonic crystal (period 800 nm, gap width 100 nm, Au thickness 50 nm). The Au grating enables phase-matched free-space excitation of propagative SPPs at the metal-dielectric interface. In the time-resolved experiments, the pump (fluence 1 mJ/cm\textsuperscript{2}) angle of incidence and wavelength were tuned in the near-IR spectral range around the SPP resonance at the Au/garnet interface at about 1300 nm and 24 degrees of incidence. The weak probe pulses at 800 nm monitored the transient transmittance variations. The experimental data were fitted with a bi-exponential function, allowing to extract the characteristic relaxation timescales at each pump wavelength and incidence angle. We found the local relaxation rate of hot electrons on the order of 1.5 ps, whereas the non-local (fast) relaxation demonstrated a consistent retardation at the SPP resonance (from 50 to 200 fs) in both experimental approaches. No spectral variations of these timescales were detected on a continuous Au film.

To explain this behavior, we employ rate equation for the non-thermal electron population and incorporate the SPP dynamics into the source term. This approach is further corroborated by the excellent agreement of the retardation of the hot electron dynamics and the SPP lifetime estimated from the linewidth of the resonance (~150 fs). Furthermore, this value is very close to the half of the SPP lifetime on a continuous Au/garnet interface (310 fs), as expected if the radiative losses are added up to the intrinsic (Joule) ones. We thus conclude that the hot electrons can be employed for measurements of the SPP lifetimes at interfaces with arbitrary losses. Allowing for external engineering of their losses, SPPs can be envisioned as flexible photonic tools for the spintronic functionality, as well as other applications of the hot electron science and technology.

Abstract

Spherical, crystalline silicon particles, smaller than the wavelength of incident light, demonstrate intense dipolar electric and magnetic resonances. A new bottom-up route has been developed allowing us to produce mass quantities of these meta-atoms. Thanks to their large diameter (80-115 nm), high degree of crystallinity, purity and the absence of pores, both electric and magnetic Mie resonance has been measured using static light scattering. The scattering properties of these particles have been additionally characterized by single particle dark field scattering. The silicon particles were organized on 2D substrates via dip-coating with the aim of manufacturing metasurfaces.

1. Introduction

All-dielectric optical metamaterials and metasurfaces have attracted interest in recent years due to the short-comings of plasmonic metamaterials [1,2]. Plasmonic resonators often possess weak magnetic scattering, which cannot compensate for the strong losses due to friction between electrons during plasmonic resonance. Among all-dielectric metamaterials, silicon is the favourite candidate as it supports intense Mie resonances at optical frequencies, has low losses and will be easily interfaced with existing silicon electronics technologies [3]. In silicon, the magnetic dipole scattering is the most intense resonance mode and occurs slightly red-shifted compared to the electric dipole scattering. To exhibit Mie scattering at visible frequencies, silicon particles should have a particle diameter between 75 and 200 nm, they should be non-porous, pure in composition and crystalline [3]. Zywietz et al. experimentally showed the interest in silicon particles as meta-atoms, by laser printing particles with controlled diameters and degrees of crystallinity one by one [4]. Thus chemists are now given the challenge of producing these resonant particles via bottom-up methods capable of producing sufficient quantities of particles to assemble a material. Silicon is a particularly difficult material for synthetic chemists as silicon precursors are highly reactive, often dangerously so, and silicon quickly oxidizes to silica. Silica possesses a low refractive index, and thus must be avoided. We explored a modification of the synthesis published by A. Thiessen et al. [5] in order to produce Si particles with larger diameter, possessing visible magnetic and electric scattering. We then have begun assembling these silicon particles on 2D substrates to produce all-dielectric metamaterials.

2. Experimental

Silicon nanoparticles were prepared via a modification of an established and widely embraced synthetic route involving the thermally-induced disproportionation of hydrogen silsesquioxane (HSQ) to produce bulk quantities of silicon particles having Mie resonance [5]. Silicon nanoparticle size was tuned via controlling the thermal processing conditions of HSQ. Silicon meta-atoms between 80 and 115 nm have been prepared. The resulting SiNPs were liberated from the oxide matrix via alcoholic HF etching. Silicon nanoparticles were evaluated for crystallinity and purity using X-ray diffraction, X-ray photoelectron spectroscopy, TEM, SEM, SAED, EDX, and FTIR spectroscopy.

Dip-coating experiments were performed on an ACEdip 2.0 dip-coater obtained from SolGelWay. The withdrawal speed and the chamber temperature were controlled using the software ACEdip 2.0 SOLGELWAY. Boron-doped prime CZ silicon wafers with (100) orientation were obtained from Siltronix. The wafers were cleaned, rinsed with absolute ethanol and wiped dry with a Kimwipe paper, before use as the substrate for silicon nanoparticle self-assembly.

3. Results and discussion

In this work, we produced Si meta-atoms via the thermal decomposition of HSQ. This method produces spherical, dense, crystalline silicon particles that have Mie scattering resonances in the visible spectrum (Figure 1). The particles were characterized for optical magnetism using single particle dark field microscopy and static light scattering. These are among the best silicon meta-atoms produced via bottom-up chemistry to date.
The silicon nanoparticles were then suspended and dip-coated onto silicon wafers. Critical to a good deposition is a stable colloidal solution. Thus solvent properties were studied to obtain a dispersion with several hours of shelf-life. Although this was sufficient for film processing, the particles were then sterically stabilized to further increase the colloidal stability and decrease particle aggregation. Films were then created, maximizing the degree of compactness via changing the evaporation conditions and the deposition rate. Stick-slip deposition lines were observed at withdrawal rates equal to or slower than 25 μm/s (Figure 2). Continuous films were obtainable by tuning the processing conditions. These films are currently being characterized using ellipsometry.

4. Conclusions

Si particles can be produced on the gram scale using HSQ as a silicon precursor. The silicon particles released from the oxide matrix are stable in air, even after several months of storage, attesting to their density. Due to the optimum parameters of these beads, Mie scattering resonance was observed via static light scattering measurements of dilute suspensions of silicon particles. These particles were then deposited onto 2D substrates using dip-coating. Dip-coating is an effective technique for silicon nanoparticle deposition, giving rise to tightly packed films of controllable thickness. These materials are unique to date, prompting us to study these films using ellipsometry in order to extract μ_eff and ε_eff. In the future, complex clusters will be explored in order to spectrally overlap the magnetic and electric scattering properties [6].

Abstract

Multiple surface lattice resonances generated under normal incidence suppress radiative losses effectively around several spectral positions, and it is important to develop reliable methods to generate multiple surface lattice resonances. In this work, we propose an approach to excite multiple surface lattice resonances with rationally designed plasmonic molecule arrays. It is demonstrated that owning to the formation of various hybridized localized surface plasmon resonances (LSPRs) with a plasmonic trimer, multiple surface lattice resonances can be excited with plasmonic trimer arrays caused by the hybridization between parallel and orthogonal surface lattice resonances.

1. Introduction

Compared with that of a single surface lattice resonance, metallic nanoparticles arrays that support multiple single surface lattice resonances suppress radiative losses around several spectral positions simultaneously. Therefore, multiple single surface lattice resonances are promising for multi-wavelength related applications. It is shown that multiple surface lattice resonances are excited in plasmonic nanoparticle superlattices caused by the coupling between single patch surface lattice resonances and Bragg modes [1]. Similar as the plasmon hybridization theory, hybridization of individual lattice resonances results in the formation of multiple surface lattice resonances in overlapped nanoparticle arrays with multi-particle unit cell [2]. Not long ago, the realization of multi-modal nanolasering and lasing at K points has been demonstrated with multiple surface lattice resonances [3, 4]. In this study, we show that the symmetry of single oligomer clusters plays an important role for the collective responses of plasmonic molecule arrays. We experimentally and theoretically demonstrated that multiple surface lattice resonances can be generated with plasmonic oligomer cluster arrays.

2. LSPRs with single trimers

Depending on the structural symmetry, the collective optical responses of single plasmonic molecules are constructed from linear combinations of the plasmon modes of individual nanoparticles. Therefore, the optical responses of a plasmonic molecule such as the gold nanodisk trimer can be strongly modified by manipulating the structural symmetry [5]. When the trimer symmetry is lowered to Cnv point group [6], the symmetry breaking lifts the degeneracy of the resonances, where the E modes of a symmetric trimer evolve into four non-degenerate A1 and B2 resonances. Besides that, the ring-like dipole arrangement of the dark A2 mode for the D3h trimer is perturbed by the symmetry breaking, and the resonance evolves into another bright B2 mode for the C2v trimer.

3. Hybridization between parallel and orthogonal surface lattice resonances

Since plasmonic trimers possess various LSPRs, and the spatial arrangements of the equivalent dipoles for individual resonances are different with each other, it is expected that the coupling between these LSPRs and RAs may occur simultaneously for plasmonic molecule arrays, which makes it possible to generate multiple surface lattice resonances.

To that end, a series of Cnv gold trimer arrays with different lattice spacing along the x-axis have been fabricated (the middle panels of Figure 1). A home-built optical setup was used to measure the transmission spectra, where the NA of the incident beam is reduced to about 0.03. In this way, the diffraction coupling between the unit cells and the excitation of SLRs can be observed in the transmission spectra due to the near-normal incidence. The left and right panels of Figure 1 show the measured and calculated transmission spectra under x-polarized incidence, respectively. When the lattice spacing Px = 650 nm, the hybridization between the parallel and orthogonal surface lattice resonances leads to the formation of two hybridized collective resonances.
4. Conclusions

In conclusion, we propose and demonstrate that plasmonic molecule arrays are promising platforms to generate multiple surface lattice resonances under normal incidence. Depending on the plasmon hybridization and the structural symmetry, plasmonic molecules such as the trimer possess various localized plasmon resonances belonging to different irreducible representations. The coupling between these LSPRs and RAs occurs for plasmonic molecule arrays by manipulating the lattice spacing, which leads to the formation of multiple surface lattice resonances. It is interesting to find that in addition to the conventional orthogonal surface lattice resonances, a spectral feature related to the excitation of the parallel surface lattice resonance is observed in the transmission spectra, which is attributed to the formation of equivalent dipoles perpendicular to the incident polarization. What’s more important is the plasmon hybridization theory reveals that the collective resonances of plasmonic molecules are non-orthogonal with each other. Therefore, even though the parallel surface lattice resonance is very weak, the resonance coupling between the parallel and orthogonal surface lattice resonances occurs when the two kinds of surface lattice resonances are approaching to each other, and a pronounced anti-crossing behavior is observed in the energy diagram, thereby forming two new eigenmodes that possess the characteristics of both parallel and orthogonal RAs.

Invisible Dielectric Cylinders at Optical Frequency

Kotaro Kajikawa, Yusuke Kobayashi

Department of Electrical and Electronic Engineering, School of Engineering, Tokyo Institute of Technology, 4259 Nagatsuta, Midori-ku, Yokohama 226-8502, Japan

Abstract

Reported here is invisible circular cylinders at optical frequency, with no coating, on the basis of analytical and numerical calculations. We can realize this, using a dielectric cylinder with its refractive index ranging from 2.7 to 3.8. According to our FDTD calculations, the invisibility stems from cancellation of the dipoles generated in the cylinder.

1. Introduction

Optical cloaking is one of the methods to be an object invisible. In most cases, the object becomes invisible by wrapping with a cloaking medium. There are two major mechanisms for cloaking: one the cancellation of the polarizations arising in the object and in the cloaking medium[1], the other the detouring of light in the cloaking medium having designed distribution of refractive index[2, 3]. Although many studies on the cloaking have been reported, no reports have appeared on an invisible object at optical frequency. In this paper, we report invisible circular cylinders with no cloaking, at optical frequency, on the basis of analytical and numerical calculations.

2. Results and discussion

We investigated optical parameters for invisibility of a cylinder, with a radius \( r \) and a refractive index \( m \) at an optical wavelength \( \lambda \). Analytical calculations on the basis of the Mie theory were carried out to find the invisible condition. Figure 1(a) shows a contour plot of scattering efficiency \( Q_{sca} \), as a function of the size parameter \( \alpha = \frac{2\pi r}{\lambda} \) and the refractive index \( m \), for TE polarization, defined as a polarization perpendicular to the axis of the cylinder. As expected, the scattering efficiency is low at \( m \sim 1 \) and at a small size parameter. There are a few regions of low scattering efficiency other than those. In the region pointed out with a red arrow, there are points with the lowest scattering efficiency \( Q_{sca} \sim 0.08 \), where the refractive index ranges from 2.7 to 3.6. The natural materials with these indexes are exemplified by Si, GaAs and AlAs. Therefore, we can realize the invisible cylinder with these materials, experimentally.

Figure 1(b) shows a contour plot of scattering efficiency \( Q_{sca} \) for TM polarization, defined as a polarization along the axis of the cylinder. Although there are some regions of low scattering efficiency, the lowest efficiency is not very low, \( Q_{sca} \sim 0.4 \). Figure 1(c) shows the scattering efficiency of a sphere. The profile is similar to that of the cylinder for TM polarization, indicating that there exists no condition of the low scattering efficiency at optical frequencies. Thus, we conclude the invisibility can be made only for a cylinder with high refractive index, on the illumination of TE polarization.

FDTD calculations were made to clarify the mechanism of the invisibility. At the low scattering condition, the wavefront was scarcely distorted by the invisible cylinder. The calculated field distribution in the cylinder is symmetric, indicating that the radiation is canceled in the cylinder.

3. Conclusions

We reported invisible circular cylinders with no coating, at optical frequency, on the basis of analytical and numerical
calculations. This condition can be achieved using a dielectric cylinder with the refractive index of the dielectric cylinder ranges from 2.7 to 3.8. This can be realized with natural materials, such as Si, GaAs and AlAs. According to the calculations based on FDTD, the invisibility stems from cancellation of the dipoles generated in the cylinder.

Abstract

We report the direct experimental observation of photonic nanojets created by single Si₅N₆ microdisks illuminated by a waveguide. High intensity sub-wavelength spots and low divergence nanojets are observed at a wavelength of 1550nm. Light scattered from the disk is observed by imaging from above. The electromagnetic distributions inside and outside the microdisk are calculated by using finite-difference-time-domain method and compared to the experimental image.

1. Introduction

The effect of enhanced and subwavelength focus of visible light by dielectric microspheres and microcylinders has been recently the subject of several papers [1-4]. These investigations predict, under specific conditions, the existence of a subdiffracted-waist beam that emerges from the structure with high intensity and low divergence. This beam, inaccessible with a classical Gaussian laser beam focused by a high numerical aperture objective, has been named photonic nanojet (PNJ) [4]. However, much of the experimental work has been focused on PNJs from dielectric spheres and cylinders. The use of a planar disk based configuration offers many advantages. The disks size and shape and position can be easily controlled to high precision in a lithography microfabrication process. We report the direct experimental observation of photonic nanojets created by single Si₅N₆ microdisks illuminated by a waveguide. Microdisks with diameters of 5µm have been fabricated and incident wavelengths of 1550nm has been used. By simply imaging the disks from the top, many of the properties of light scattering have been confirmed.

2. Device fabrication

A 900nm layer of non-stoichiometric – low index Si₅N₆ was deposited on a 2 µm layer of thermally grown SiO2 on a Si wafer. The 2 µm thick low refractive index oxide layer acts as an optical spacer between the Si₅N₆ guiding layer and the Si base wafer. The microdisks and waveguides were then patterned using a 30 kV FEI- ebeam lithography system under a PMMA/MMA bilayer positive tone resist. A 100nm thick chromium hard mask is then deposited followed by a lift-off process. The sample was etched using an RIE with a mixture of SF6 and CHF3 gases to reveal patterns with smooth sidewalls. Finally, a wet etching process step was used to remove the remaining chromium from the surface.

3. Experiment

Samples were characterized with a linearly polarized tunable laser set to the desired wavelength (1550 nm) and light was injected by buttcoupling into the waveguide. The waveguide has been designed to produce a nearly plane wave excitation of the disk. The scattered light is observed from above using a long working distance, flat field corrected, 100x microscope objective with an NA of 0.7 (Mitutoyo). The objective is infinity corrected, thus a tube lens of focal length 200mm is used to form the primary image directly on the CCD. The result is a gray-scale pixel image of the scattered light distribution as shown in Figure 1.

4. Conclusions

We proposed and demonstrated a new platform for the integration of photonic nanojet on a chip. The scattering properties of a microdisk have been fully investigated and revealed a localized PNJ generated at the shadow-side surface of the SiN based microdisk illuminated by the waveguide.

Cooperative emission mediated by energy transfer to plasmonic antenna

Tigran V. Shahbazyan
Department of Physics, Jackson State University, Jackson, MS 39217 USA
E-mail: shahbazyan@jsums.edu

Abstract
We describe a new cooperative mechanism of spontaneous emission by an ensemble of quantum emitters near a plasmonic nanostructure based on cooperative energy transfer to plasmonic antenna from collective states formed due to plasmonic correlations.

1. Introduction
Spontaneous decay of a quantum emitter (QE), such as dye molecule or semiconductor quantum dot, placed near a metal nanostructure supporting surface plasmons in the same spectral range can be greatly enhanced due to new efficient energy transfer (ET) channel from the QE to resonant plasmon mode. The enhancement of spontaneous emission (SE) rate is characterized by the Purcell factor [1] $F_p = \frac{6\pi Q \omega^3}{c^3 V}$, where $Q$ is the plasmon mode quality factor and $V$ is the mode volume characterizing field localization ($\omega$ and $c$ are the frequency and speed of light). If the system size is not too small, a considerable part of transferred energy is radiated away by the plasmonic antenna, resulting in strong enhancement of radiated power spectrum observed, e.g., in plasmon-enhanced fluorescence experiments [2,3], while the rest of transferred energy is dissipated mainly through the Ohmic losses in metal. Note, however, that the plasmon local density of states (LDOS), which characterizes ET rate, is limited by nonlocal effects in the electron optical response near the metal surface.

At the same time, SE by an ensemble of QEs can be greatly accelerated through electromagnetic correlations between QEs. A prominent example of cooperative emission is Dicke superradiance [4] of QEs interacting with a common radiation field, which leads to emergence of collective states radiating at a rate proportional to the full ensemble size (even if only a few QEs are excited). In the presence of plasmonic structure, superradiance is modified: while the QEs’ correlations are enhanced due to resonant Mie scattering, thus reducing the negative impact of direct dipole interactions, the Ohmic losses in the metal suppress correlations for QEs located too close to the metal surface [5]. Observation of plasmon-enhanced superradiance remains a challenge as it hinges on delicate interplay between QEs’ direct interactions, plasmon-enhanced radiative coupling, and metal losses.

2. Results and discussion
On the other hand, strong absorption by a plasmonic nanostructure gives rise to another collective effect – cooperative energy transfer (CET) from an ensemble of QEs to resonant plasmon mode [6]. Namely, if the emission frequencies of $N$ excited QEs lie within the plasmon spectral band, the plasmonic correlations between QEs lead to emergence of a collective state that transfers its energy at a rate $\gamma^c_{et} = \sum_i \gamma^i_{et}$, where $\gamma^i_{et}$ are individual QE-plasmon ET rates determined by the plasmon LDOS at the QE positions (see Fig. 1). If radiation efficiency of a plasmonic antenna is sufficiently high, this energy is radiated away at the same rate $\gamma_{et}$ it is being received from the QE ensemble. Importantly, CET mechanism is insensitive to natural variations of QE frequencies due to, e.g., direct dipole interactions or, in the case of QDs, their size variations, if QEs’ frequencies stay within plasmon’s broad spectral band. Furthermore, the power spectrum retains the plasmon resonance lineshape and, therefore, is also largely independent of QEs frequency variations within the ensemble.

![Figure 1](image)

Here we present a theory of cooperative spontaneous emission by an ensemble of QEs coupled to a plasmonic resonator mediated by CET mechanism. For an ensemble of $N$ excited QEs coupled to plasmonic resonator, we pinpoint the collective state that saturates the ensemble ET rate to the plasmon mode and derive cooperative Purcell factor as the sum of individual factors, $F^c_p = \sum_i F^i_p$ (see Fig. 2a). The power spectrum enhancement factor for cooperative emission has the form $M_c = F^c_p \eta$, where $\eta$ is the antenna radiation efficiency (see Fig. 2b). For comparable individual ET rates, e.g., if QEs are confined within a plasmonic cavity, the CET
rate scales with the ensemble size. In contrast, if QEs are distributed outside the metal structure, the local fields that determine the individual ET rates rapidly decrease as the distance to metal surface increases, so that the remote QEs are not coupled to the plasmon mode. In this case, if QEs are uniformly distributed in an extended region that saturates the plasmon mode volume, the cooperative Purcell factor is independent of local fields and is determined solely by the system parameters measured in experiment [7].

Fig. 2. Numerical calculations of SE from an ensemble of QEs uniformly distributed at concentration \( n \) within dielectric shell of a core-shell nanorod, modeled by two confocal spheroids with semi-major and semi-minor axes \((a, b)\) and \((a_1, b_2)\). (a) Cooperative Purcell factor is shown with increasing QE region at different nanorod overall sizes. (b) Same for enhancement factor of radiated power spectrum.

Advances in Sub-Wavelength Nanophotonic Devices

(Invited Talk)

Jian Wang

Wuhan National Laboratory for Optoelectronics, School of Optical and Electronic Information, Huazhong University of Science and Technology, Wuhan 430074, Hubei, China. *Corresponding author, E-mail: jwang@hust.edu.cn

Abstract

In this talk, we review our recent progress in sub-wavelength nanophotonic devices and their wide applications. We discuss a variety of sub-wavelength structures on different platforms (silicon, metal, fiber): 1) microring resonator and photonic crystal nanocavities for linear and nonlinear optical signal processing; 2) slot, hybrid plasmonic slot and sub-wavelength slot waveguides for on-chip optical interconnects; 3) surface grating structures, plasmonic and dielectric metasurfaces for spatial light manipulation. The demonstrations show impressive performance in diverse implementations of sub-wavelength nanophotonic devices.

1. Introduction

Analogous to the importance of electronic integrated circuits, Photonic integrated circuits are the trend of optoelectronic devices. Photonic integration can be implemented on different platforms such as silicon, metal and fiber. In particular, silicon photonics is one of the most promising photonic integration platforms owing to its high-index contrast, small footprint, low power consumption, and availability of complementary metal-oxide- semiconductor (CMOS) fabrication technology for low-cost mass production [1]. Very recently, the emerging opportunity to design and fabricate photonic integrated devices at the sub-wavelength scale, enabling wide applications with favorable performance, has attracted increasing interest [2]. Remarkably, most of the sub-wavelength nanophotonic devices can still be fabricated using the similar fabrication techniques to conventional photonic integrated devices, such as electron-beam lithography (EBL) followed by induced coupled plasma (ICP) etching, focused ion beam (FIB), etc. Figure 1 shows typical sub-wavelength nanophotonic devices on different platforms (silicon, metal, fiber) fabricated in our lab, including microring resonator, photonic crystal nanocavity, slot waveguide, hybrid plasmonic slot waveguide, sub-wavelength slot waveguide, grating coupler, tilted grating, surface hologram, plasmonic metasurface on metal, dielectric metasurface on silicon, and metasurface on fiber facet. In this talk, we review recent advances in these sub-wavelength nanophotonic devices and their diverse applications.

2. Microring resonator and photonic crystal nanocavity for optical signal processing

Using nonlinear four-wave mixing (FWM) in fabricated silicon waveguides, we demonstrate chip-scale wavelength conversion of orthogonal frequency division multiplexing m-ary quadrature amplitude modulation (OFDM m-QAM) signals [3], regeneration of 4-ary pulse amplitude modulation (PAM-4) signals [4], and chip-scale high-base optical computing (quaternary/decimal addition/subtraction) [5]. Using enhanced nonlinearity in graphene-assisted microring resonator, we demonstrate efficient wavelength conversion of advanced modulation signals [6]. Using enhanced resonance in photonic crystal nanocavity, we demonstrate linear and nonlinear microwave photonic signal processing functions [7].

3. Slot, hybrid plasmonic slot and sub-wavelength slot waveguides for on-chip optical interconnects

Using reduced nonlinearity in slot waveguide and tight mode confinement in hybrid plasmonic slot waveguide, we demonstrate chip-scale data transmission with advanced multi-carrier multi-level modulation signals. Ultrahigh-bandwidth low penalty 1.8-THz/s (161 WDM 11.2-Gbit/s OFDM 16-QAM) data transmission is demonstrated in the experiment [8, 9], showing great potential of on-chip optical interconnects. Additionally, we also propose and demonstrate sub-wavelength grating slot (SWGS) waveguide on silicon platform. The SWGS waveguide combines the advantages of sub-wavelength grating (SWG) and slot waveguide, showing greatly reduced nonlinearity compared to the slot waveguide by pushing mode out of the silicon region [10]. Moreover, we also propose, fabricate, and demonstrate SWGS microring resonator for athermal and sensing applications with impressive performance.

4. Surface grating structures, plasmonic and dielectric metasurfaces for spatial light manipulation

The conventional surface grating structure is widely used for fiber-chip-fiber vertical coupling. The modified surface grating structure can be also applied to other emerging applications. We design, fabricate and demonstrate an on-chip optical vortex lattice emitter consisting of three parallel waveguides with etched tilted gratings [11]. The tilted gratings facilitate flexible light emission in a wide range of directions, enabling the generation of an optical vortex lattice above the silicon chip. The optical vortex is also known as orbital angular momentum (OAM) mode having helical phase front. We propose and demonstrate chip-scale generation and synthesis of ultrabroadband optical vortices (OAM modes) on silicon platform [12]. By introducing a sub-wavelength holographic fork grating on top of a silicon waveguide, the in-plane guided mode is converted to the free-space OAM mode. Inputs from both sides of the waveguide enable the synthesis of OAM modes. The chip-scale ultrabroadband OAM generator and synthesizer may find potential applications in multidimensional optical communications and quantum key distribution. Moreover, we propose and demonstrate...
plasmonic metasurfaces on metal and fiber facet and dielectric metasurface on silicon for flexible spatial light manipulation [13-16]. The obtained results show impressive performance of metasurface structures.

Figure 1: Measured scanning electron microscope (SEM) images of the fabricated typical sub-wavelength nanophotonic devices. (a) Si waveguide (building block of other devices); (b) microring resonator; (c) photonic crystal nanocavity; (d) slot waveguide; (e) hybrid plasmonic slot waveguide; (f) sub-wavelength slot waveguide; (g) grating coupler; (h) tilted grating; (i) surface hologram; (j) plasmonic metasurface; (k) dielectric metasurface; (l) metasurface on fiber facet.

5. Conclusions
We give an overview of recent advances in sub-wavelength nanophotonic devices (microring resonator, photonic crystal nanocavity, slot waveguide, hybrid plasmonic slot waveguide, sub-wavelength slot waveguide, grating coupler, tilted grating, surface hologram, metasurface) on different platforms (silicon, metal, fiber) and their wide applications (linear and nonlinear optical signal processing, on-chip optical interconnects, spatial light manipulation). The demonstrations show great significance in developing sub-wavelength nanophotonic devices.

Abstract

We have demonstrated that planar chirowaveguides made of chiral hybrid material can propagate circularly polarized light. These chirowaveguides require symmetric structure with low refractive index mismatch. We show that chiral propagation behavior is the result from the balance between circular and modal birefringence. Based on coupled mode theory, we numerically simulate the performance of rib chiro-waveguide in air and show that circular polarization can be obtained by tailoring the dimensions of the waveguide.

1. Introduction

The transverse polarizations propagating in integrated photonic devices are the two well known linear TE and TM polarizations. As a consequence, any set-up requiring other polarizations, especially the circular polarization (chiral sensing, 3D-display, quantum optics...), can not take the full advantage of integrated optics. However, chiral materials, via the optical rotation, can overcome the geometrical properties of the waveguides to produce new states of polarization for the guided light as stated by Engheta in the last 80’s\textsuperscript{[1]}. We have recently demonstrated the proof of concept of the simple fabrication of chirowaveguides allowing the propagation of any polarization from elliptical to nearly circular, along a few centimeters with losses lower than 1dB/cm\textsuperscript{[2]}. These results have been obtained for waveguides made of a new chiral Ormosil (Organically Modified Silica) based on binaphthyl organic molecules bonded to a silica network.

The best results (i.e. quasi circularly polarized modes) are obtained for symmetric waveguide (core layer sandwiched between two identical layers) with low refractive index contrast $\sim 10^{-3}$. This requirement is a serious limitation to the use of planar chirowaveguides in the area of chiral sensing. Indeed, evanescent wave sensing implies highly non symmetric waveguide\textsuperscript{[3]}.

In this work, we will numerically show how channel waveguides can be optimized to achieve circular polarization even with air top cladding. In the first part, we introduce the two relevant parameters describing the chirowaveguides: the circular birefringence (CB) and the modal birefringence $\Delta N_m$. A simple equation from the coupled mode theory can then be used to quantify the polarization propagation in chirowaveguides\textsuperscript{[4, 5]}. Our results on planar chirowaveguides are presented in the first section with respect to the relevant birefringences CB and $\Delta N_m$ showing a qualitative good agreement with the coupled mode theory. In the last part, we numerically simulate the performance of raised strip chirowaveguides in term of polarization eccentricity (ratio of the main axes of the polarization ellipse).

2. Theoretical considerations

The transition from an achiral waveguide (linearly polarized modes) to a chirowaveguide with circularly polarized (CP) modes requires special conditions. Indeed, chirowaveguides are devices combining both the isotropic circular birefringence (CB) coming from the core chiral material characterized by its optical rotation OR=$\frac{CB}{2\pi c}$ and the modal linear birefringence ($\Delta N_m$) which denotes the difference between the effective indices of TE and TM modes.The eigenpolarizations in chirowaveguides result from the competition between these two birefringences.

Different theoretical approaches can be used to quantitatively study chirowaveguides. Here, we will use the simple coupled mode theory to explain the general trend of our chirowaveguides. In this framework, $\Delta N_m$ is calculated for the chirowaveguide structure but without chirality (OR=CB=0). The effect of the chirality is described as a weak cross coupling between the two TE/TM modes of the achiral structure leading to two new eigenmodes of eccentricity $e_c$ given by\textsuperscript{[5]}:

$$
\epsilon_{c\pm} = \frac{\text{CB}}{\Delta N_m \pm \sqrt{\text{CB}^2 + \Delta N_m^2}} \tag{1}
$$

3. Planar chirowaveguides results

We have made different series of planar chirowaveguides and characterized the mode polarization for monomode waveguides\textsuperscript{[2]}. The evolution of the first mode eccentricity $\epsilon_{c0}$ versus CB can be estimated by changing the work-

ing wavelength. Indeed, the different layers being made by nearly the same material[2], the refractive index contrast does not change significantly compared to the CB. \( n_{c0} \) increases with CB as shown in Fig. 1-left. The coupling theory –green curve–, assuming a constant \( \Delta N_m = 4.5 \times 10^{-3} \), fits quite well the results.

By tailoring the refractive indices and the core thickness of the devices different \( \Delta N_m \) are obtained. The corresponding eccentricities are drawn in Fig. 1-right for a given CB\( (\lambda = 633nm) \). \( n_{c0} \) requires \( \Delta N_m \) in the same order of CB to reach significant values. Again, there is a good qualitative agreement with the simple mode coupling theory.

![Figure 1: Measured polarization eccentricities and corresponding polarization ellipses in planar chirowaveguides. Left: Measurements on a given waveguide Right: \( \lambda = 633nm \). CB=3 \( 10^{-6} \) planar waveguides with different parameters leading to different \( \Delta N_m \).](image)

Abstract

Strategies for ultrafast optical control of magnetism have been a topic of intense research for several decades because of the potential impact in technologies such as magnetic memory, spintronics, and quantum computation, as well as the opportunities for non-linear optical control and modulation in applications such as optical isolation and non-reciprocity. Here we report the first experimental quantification of optically induced magnetization in plasmonic Au nanoparticles due to the inverse Faraday effect (IFE). The induced magnetic moment in nanoparticles is found to be ~1,000x larger than that observed in bulk Au, and ~20x larger than the magnetic moment from optimized magnetic nanoparticle colloids such as magnetite. Furthermore, the magnetization and demagnetization kinetics are instantaneous within the sub-picosecond time resolution of our study.

1. Introduction

This The IFE is an opto-magnetic phenomenon that manifests as an induced magnetization, that is parallel or anti-parallel with the axis of circularly polarized excitation based on the helicity of the radiation (Fig. 1b). The IFE has been studied extensively in materials with large Verdet constants, such as Tb,TiO, and TaGaO for application in optically-written magnetic hard drives. Notably, strong resonant field concentration from plasmonic metasurfaces interfaced with these materials can further enhance sub-wavelength magnetization. Circularly polarized femtosecond laser pulses can also be used to non-thermally align electron spins in magnetic materials via the IFE. However, there has been limited research studying magnetization that occurs within non-magnetic plasmonic metals due to the IFE, without other magnetic structures, despite compelling theoretical studies that suggest plasmonic nanomaterials may out-perform more conventional magnetic materials in terms of induced magnetic field strength, spatial confinement, ultrafast time response, and other technologically relevant optoelectronic behavior. Several studies have also reported anomalously large Verdet constant in plasmonic colloids, further suggesting strong enhancement of the IFE may also be possible.

2. Results

The maximum induced optical rotation as a function of peak pump intensity is plotted in Fig. 2. The optical rotation shows a linear dependence. These observations provide further confirmation that the optical rotation of the probe beam is due to the optically-induced magnetic field. The effective induced magnetic field of the AuNP during excitation can be estimated by the induced optical rotation angle in the pump-probe experiments (Fig. 2). This value can be thought of as the strength of an externally applied magnetic field that would be required to induce the same optical rotation in the pump-probe measurement. The value of can be further analyzed to determine the magnetic moment of each Au nanoparticle by applying the following relation

We observe up to 0.032 T at a peak pump intensity of 4.9 x 10¹³ W/m². If we consider that the individual Au nanoparticles act as small bar magnets with rotation and diffusion that is much slower than the pulse duration, the of the ensemble corresponds to an induced magnetic moment per particle of 2.5 x 10⁻⁷ μB or 8.0 x 10⁻¹ μB per Au atom, where μB is Bohr magneton. This induced magnetic moment is approximately one order of magnitude larger than the magnetic moment in other magnetic nanoparticles such as magnetite or CoFe₂O₃ colloidal nanoparticles.
Further, the induced magnetic moment per Au atom in bulk Au films due to the IFE at the same incident power density and wavelength is reported to be $3.9 \times 10^{-4} \mu_B$, verifying the extraordinary $>1,000$-fold plasmonic enhancement of the optically induced magnetization measured here.\textsuperscript{8,14}

Figure 2: Dependence of Optical Rotation on Pump Intensity and Corresponding Effective Magnetic Field. Optical rotation as a function of peak pump intensity. The fit shows a linear trend.

3. Conclusions

In summary, we report the first experimental observation of optically-induced magnetization in Au nanoparticles due to the IFE. By controlling the relative polarization difference between the pump and probe beams in an ultrafast time-resolved study, the contribution of the IFE and OKE was clearly distinguished. Our experiments measured optical rotation indicative of magnetization that is parallel or anti-parallel with a pump beam depending on the helicity of the excitation. Additionally, we observe optically induced magnetization that is $\sim1,000$ times larger than in bulk Au. We anticipate these results may be of great interest in the photonics community for application in ultrafast optical control of magnetic properties, and for all-optical methods of optical isolation that do not require externally applied magnetic fields.

Abstract

Based on a novel analysis of pulse spectral broadening experiments in graphene-covered silicon nitride waveguides, we show that, contrarily to a long-standing belief, self-phase modulation in such waveguides does not rely on the Kerr effect. The unconventional spectral broadening behavior observed in our experiments is successfully explained by means of the saturable refraction of free carriers produced by one-photon absorption in graphene.

1. Introduction

Along the lines of further miniaturization of nonlinear-photonics technologies, different research groups have succeeded in increasing the nonlinear response of on-chip devices covering them with graphene, a single atomic layer of carbon atoms, which can notably reduce the device length demands for nonlinear applications [1, 2]. Despite being a one-atom-thick layer, graphene shows an extremely large third-order nonlinearity [3], which can still enhance the nonlinear performance of a device. The potential of graphene for nonlinear optics motivated \textit{ab-initio} calculations of the third-order nonlinearities of this 2D material within a perturbation theory frame [4]. However, the Kerr nonlinear response led to a divergent result for photon energies allowing one-photon absorption (1PA) [4]. Moreover, recently we experimentally demonstrated a negative graphene’s nonlinearity through pulse spectral broadening experiments in graphene-covered silicon waveguides [2]. These results called for further investigations about the underlying mechanism of pulse spectral broadening in graphene-cladded waveguides.

In this work, we show exponentially growing spectral broadening in graphene-covered silicon nitride waveguides that cannot be explained through the Kerr effect and thus provide evidence of the different nature of this nonlinear response of graphene. Subsequently, we demonstrate that spectral broadening observed in our experiments can be still attributed to a self-phase modulation (SPM) process. Finally, based on a nonperturbative theory that accounts for the pulse chirp generated through saturable photoexcited carrier refraction (SPCR), we explain the most important features of our experiments [6].

2. Results

We investigate how the width of the spectrum of picosecond pulses —quantified by means of the spectral variance $\mu$— evolves along different graphene lengths on silicon nitride waveguides fabricated in a multi-project wafer run of the LioniX foundry [see Fig. 1(a)]. According to Kerr-based SPM, the broadening factor $\mu_{\text{out}} / \mu_{\text{in}}$ should increase until a distance around $\alpha^{-1}$, $\alpha$ being the linear loss coefficient, where the broadening factor should level off. Transmission measurements indicated that this length was around $220 \mu m$. Contrarily, our experiments showed an exponential-like growth of the broadening factor beyond this distance [see Fig. 1(b)].

These results demanded a careful revision of the nonlinear response of our waveguides. On the one hand, we conceived an experiment to test whether the pulse spectral broadening still relied on a SPM process. In [2], we developed a method to control the sign of the pulse chirp. Here this approach allowed us to observe a significant dependence of the broadening factor on the input pulse chirp, which clearly pointed out a SPM mechanism. At the same time, these results also indicated a negative nonlinearity, in agreement with our previous work [2]. On the other hand, inspired by [5] —where the negative nonlinearity produced by the refraction of free carriers induced by two-photon absorption in silicon waveguides was modeled— we proposed the following phenomenological theory to describe the chirp, and hence $\mu$, induced by the saturable refraction of free carriers excited through 1PA in graphene [6]:
3. Conclusions

We have demonstrated that SPCR is responsible for pulse spectral broadening in graphene-cladded waveguides. Our novel SPCR theory explains both quantitatively and qualitatively the experimental data reported here. These insights constitute a key step towards the optimal use of graphene-covered on-chip waveguides for nonlinear applications.

Abstract

We investigate theoretically the conversion of surface acoustic waves generated on a substrate by means of interdigital transducers to the guided modes of a phononic nanobeam. An efficiency of -23 dB is demonstrated. We study the interaction of these converted modes with a structured phononic crystal nanobeam containing a cavity and evaluate the transmission through localized cavity modes. We also discuss the optomechanic interaction of the phononic cavity with an external optical waveguide and the emission of phonons into the nanobeam.

There is a growing interest in the development of new structures and devices using phonons for the purpose of carrying and processing the information \cite{1,2}. Among these, the study of cavity optomechanics (OM) and their potential applications from sensing to quantum information has known a great deal of attention during the last decade \cite{3}. Currently, the design of new phononic circuits, based on the coupling between several OM cavities connected through waveguides, for the purpose of generation and detection of coherent phonons is of high interest. In parallel, some works have been devoted to the excitations of phonons in an OM cavity by means of Surface Acoustic Wave (SAW) generated on a piezoelectric substrate \cite{4,5}. In this paper, we demonstrate the conversion of SAW generated on a substrate by means of interdigital transducers (IDT) into the guided modes of a phononic nanobeam (NB). Then, we study the interaction of these converted modes with a nanobeam phononic crystal containing a cavity and evaluate the transmission properties of the structure. Finally, we discuss the OM interaction of the cavity with an external optical waveguide and the emission of phonons into the NB.

A schematic presentation of the device is presented in Fig. 1. The SAWs are generated on a Si substrate supporting a three-layer structures consisting of a SiO2 layer, a thin 220nm Al layer and a piezoelectric AlN layer over which the Al interdigital transducers (IDT) are deposited. The substrate is connected to a Si nanobeam of 220 nm thickness where the guided modes should be generated. The geometrical parameters of the structure are optimized in order to generate SAW at 2 GHz sufficiently confined in the Si layer. Then, the focusing of SAW by means of radially curved-shaped IDT’s and the utilization of a taper at the entrance of the NB allow a conversion efficiency of -23 dB into the guided modes of the NB. We show in Fig. 2 the excitation of the acoustic modes inside the NB together with its decomposition into the eigenmodes of the NB, namely a longitudinal mode (1) and a flexural mode (4) in the geometry of our design. The conversion efficiency is calculated as the ratio between the time-averaged Poynting vector integrated over the section of NB and the apparent electric power consumption.

Figure 1: Schematic representation of a prototype device for the phonon generation and detection by electrical means using IDT on a piezoelectric AlN film deposited on the Si membrane. The surface acoustic wave generated by the IDT propagates through the Si-membrane or through the nanobeam (where optomechanical effects can occur) and can be detected by another IDT system.
In conclusion, this work presents the design of an electromechanical device for an efficient conversion of SAW into the guided modes of a NB. Then, the interaction of these modes with a structured phononic crystal and the transmission properties through an OM cavity are investigated.

Enhancing Light Absorption with a Complex Environment: What Are the Limits of the Playground?

Emilie Sakat, Léo Wojszvzyk, Jean-Jacques Greffet, Jean-Paul Hugonin, and Christophe Sauvan

1Laboratoire Charles Fabry, Institut d’Optique Graduate School, CNRS, Université Paris Saclay, 91127 Palaiseau, France

Abstract
We have studied light absorption by a subwavelength particle in a complex environment. We have derived an upper bound for the absorption, which is valid for any environment and any illumination. The upper bound allows decoupling the choice of the environment from the one of the absorber. It provides a meaningful figure of merit to compare the ability of different systems to enhance absorption. In the scalar approximation, the relevant physical parameter is the ratio between the field enhancement and the local density of states. Consequently, a plasmonic structure supporting hot spots is not necessarily a good choice to enhance absorption. Furthermore, we have applied our theoretical results beyond the scalar approximation and the case of plane-wave illumination.

Light absorption and emission are two fundamental processes of light-matter interaction. Absorption converts electromagnetic energy carried by photons to internal energy of matter carried by electrons or phonons. Controlling the absorption in small volumes is a major issue for a vast array of applications, such as photovoltaics [1,2], sensing by surface-enhanced infrared absorption (SEIRA) [3], photothermal cancer therapy [4], thermoplasmonics and thermal emission [5,6].

Absorption inside subwavelength objects is in general weak but different strategies can be used to circumvent this limitation. First, the absorber properties can be engineered. Many works have been dedicated to the optimization of the absorption by a single nanoparticle. For an absorber in a homogeneous medium, the physical bounds of the problem are known; they are driven by the multipolar character of the particle [7-10]. The maximum absorption cross-section of a molecule or a nanoparticle that can be assimilated to an electric dipole is $3\lambda^2/(8\pi n^2)$, with $\lambda$ the wavelength and $n$ the surrounding refractive index [7,10]. This upper bound can only be reached if the absorber polarizability $\alpha$ matches a precise value. Subwavelength particles that go beyond the dipolar approximation offer additional degrees of freedom and are governed by different physical bounds [8-10]. Absorption by an ensemble of particles in a homogeneous medium is yet another related problem with a different upper limit [11].

Plunging the absorber in a complex medium or modifying the illumination offers a myriad of possibilities to further tailor the absorption [6,12,13]. In this work, we consider the general problem of a subwavelength absorber in a complex environment. We focus on the absorption inside the absorber and do not discuss dissipation in the surroundings, if any. To fully exploit the control possibilities offered by the environment, it is crucial to know the relevant figures of merit. The absorption density is proportional to the local electric-field intensity $|\mathbf{E}(\mathbf{r})|^2$, which results from both the environment and the absorber. It is highly desirable to decouple both contributions to provide figures of merit that are intrinsic to the environment. Only then can we properly compare the ability of different structures to modify absorption.

Let us draw a parallel with spontaneous emission, which also depends on the environment. Emission is enhanced by a factor that is proportional to the photonic local density of states (LDOS). For an emitter coupled to a resonant system, the emission enhancement has an upper bound, the Purcell factor, which is intrinsic to the resonator and independent of the emitter. The upper bound is reached if emitter and resonator fulfill a few matching conditions – spectral, spatial and in polarization.

The link between the absorption and the environment properties is more complex than the proportionality relation between emission and LDOS. Within the Born approximation, the absorption is simply proportional to the field enhancement provided by the environment. Hence, hot spots are often thought to lead to large absorption enhancements. But if the presence of the absorber significantly affects the local field, the situation is much more complex. It has been recently shown that both the field enhancement and the LDOS play an intricate role in the absorption [12]. However, no clear upper bound – kind of Purcell factor analogue – has been derived for the general problem of an absorber in a complex environment.
Antenna theory provides a solution in one specific case. For an antenna receiving a signal incident from the direction \((\theta, \phi)\), the maximum absorption cross-section of the load is \(G(\theta, \phi) \lambda^2/(4\pi r^2)\), with \(G\) the antenna gain [14]. The system reaches the upper bound if the load is impedance-matched with the antenna. The gain is defined for an emitting antenna as the fraction of the total power that is radiated in the direction \((\theta, \phi)\) and can be written as \(G(\theta, \phi) = \eta_D(\theta, \phi)\), with \(D\) the directivity and \(\eta\) the radiative efficiency [14]. Unfortunately, the \(G(\theta, \phi) \lambda^2/(4\pi r^2)\) limit only applies to plane-wave illumination and to antennas that can be reduced to a scalar problem. For structures in which the vectorial nature of the electromagnetic field cannot be neglected, the problem remains open. Moreover, the antenna point of view highlights the radiative efficiency and the directivity, whereas other derivations underline the field enhancement and the LDOS [12]. It is thus essential to generalize existing results, while enlightening the link between them.

We have derived a general upper bound for the power dissipated in a subwavelength absorber surrounded by a complex environment. The upper bound is independent of the absorber; it entirely depends on the environment and the illumination. Thus, it provides a relevant figure of merit for comparing the ability of different systems to enhance absorption. This novel figure of merit is a complex vectorial interplay between two fundamental properties of the environment, the field enhancement and the Green tensor. We show under which assumptions the LDOS and the directivity are (or are not) relevant parameters. We also discuss under which conditions the system can reach the upper bound.

We have applied the theory to a few emblematic examples of nanophotonics: a plasmonic dimer nanoresonator, dielectric nanoantennas, and a silicon-on-insulator (SOI) ridge waveguide. In particular, we evidence that a plasmonic system providing extremely large field enhancements is not necessarily an optimal choice to increase absorption.

Abstract

Microfluidic technology allows to operate on liquids within microscale channels as well as to fabricate microfluidic devices for lab-on-a-chip applications. Nowadays a wide range of materials can be used for manufacturing of microfluidic devices which makes possible to design chips with specific features such as optical properties, size/morphology, chemical properties, biological compatibility, etc. Poly(dimethylsiloxane) (PDMS) is one of the most popular materials in microfluidics since it is a cheap polymer with high biocompatibility, optical transparency, ease handle for chip fabrication, etc. Recently we have demonstrated that PDMS-based microfluidic channels can be also used for the fabrication of plasmonic supercrystals through self-assembly of uniform Au octahedrons inside their microchannels through the pervaporation of the solvent (Figure 1A-B). Furthermore, the microfluidic approach enables the fabrication of uniform assemblies of any dimension or morphology. The resulting plasmonic devices could be used for the detection of analytes, even without affinity for gold nanoparticles. Surface-enhanced Raman spectroscopy, SERS, is an advanced analytical technique that can be used for the ultrasensitive detection of analytes since it offers orders of magnitude increases in Raman signals. It occurs at the surface of a plasmon surface mainly due to the presence of strong electromagnetic fields generated after the plasmon excitation. Moreover, this effect could be more intense in the case of hierarchical nanoparticles assemblies due to an antenna effect as demonstrated by recent simulations.²

Figure 1: (A) Schematic illustration of the evaporation-based microfluidic cell used for controlled assembly of Au nanoparticles. (B) SEM images of the hierarchical nanoparticles assembly (C) SERS mapping of the channel in the presence of 100 fM of Malachite Green.

While the plasmonic substrates made by drop-casting show poor uniformity that limits their potential plasmonic applications, the microfluidic approach gives rise to platforms with highly uniform and intense SERS activity (being both key parameter to achieve quantitative analysis and low detection limits (LOD)). Herein we will show the fabrication and characterization of plasmonic platforms fabricated using Au octahedra synthesized through a wet chemical method. Besides, the sensing capabilities of the platforms will be analyzed by investigating the SERS efficiency using different Raman active analytes. For instance, experiment performed with Malachite Green showed a great LOD, lower than 100fM, which is several orders of magnitude lower than those found in the literature.

Abstract

Electromagnetic waves can exert optical forces on microscopic or nanoscopic objects via scattering or absorption due to the momentum transfer. Such responses have opened a new paradigm of confining and trapping small objects and molecules [1] and have been exploited for numerous applications in bioengineering, physical science and chemistry [2]. Recent reports have suggested using surface plasmon polaritons (SPPs), waves that can be confined well beyond the diffraction limit, as promising candidates to enhance the optical forces induced on nanoparticles [3]. Specifically, illuminating a dipolar particle located above a planar plasmonic substrate (such as gold or silver) induces optical forces that compensate the momentum of the directional SPPs excited during the scattering process [4,5]. We note that relation between the induced lateral forces and the wavenumber of the plasmon is not linear, but exponential. As a result, maximum optical forces induced on particles over isotropic surface appears at the intrinsic plasmonic resonance of the material, where the wavenumber of the excited plasmons is larger. In a related context, hyperbolic metasurfaces (HMTSs), structures able to exhibit dielectric or metallic behavior as a function of electric field polarization, have recently been attracted significant attention thanks to their exciting electromagnetic properties [6]. In particular, these surfaces boost the local density of states, support ultra-confined SPPs with ideally infinite momentum (bounded in practice by loss and nonlocal mechanisms), and enable a large set of near-field functionalities.

Here, we merge the photonic spin Hall effect of light with the large local density of states and extremely confined SPPs supported by HMTSs to manipulate Rayleigh particles located nearby with plane waves. By adequately illuminating the particle, it can acquire out-of-plane polarization spin and excite unidirectional surface plasmons over the metasurface during the scattering process. The lateral recoil force experienced by the particle is dramatically enhanced, several orders of magnitude compared to forces on particle over standard surfaces, due to the very large momentum carried out by the hyperbolic modes. To investigate such optical forces, we have developed an anisotropic Green’s function formalism within the dipole approximation, and we have validated our results using full-wave numerical simulations from COMSOL Multiphysics. Our theoretical analysis

Figure 1: Lateral optical forces on a Rayleigh particle, with radius of 15nm and a relative permittivity of 3, located 25 nm above the nanostructured silver surface. Results have been obtained with COMSOL Multiphysics. (a) 3D schematic, showing an incident TM plane wave coming from $\theta_i = 35^\circ$ (elevation angle with respect to z-axis) and $\phi_i = 25^\circ$. Superimposed field plot illustrates the y-component of the magnetic field excited on the structure at 612 THz due to the scattering process. (b) Strength of lateral optical forces induced on the particle versus frequency normalized with respect to the power radiated by the dipole when polarized in the absence of the metasurface. Results are plotted versus frequency assuming that the particle is located over a hyperbolic metasurface based of silver (red line) and over pristine silver (blue line). The metasurface dimensions are $W = 120nm$ $H = 80nm$ and $L = 180nm$. 
reveals that the strength of the induced lateral forces primarily depends on two mechanisms: (i) the helicity of the particle polarizability, which measures the ability of the scattering process to excite unidirectional surface plasmons through the photonic spin-Hall effect; (ii) the confinement of the supported surface plasmons. As an example, we have analyzed a HMTSs composed of a subwavelength periodic silver grating operating in visible frequencies [7]. Such a visible frequency HMTS induces 2-4 orders of magnitude enhanced lateral forces than those found above pristine silver over a large frequency band. Importantly, the broadband nature of these configurations makes them very resilient against fabrication tolerances. The potential applications of such HMTSs are not limited to optical manipulations or force measurement technologies but can also be exploited to trap and characterize particles, biological cells and molecules. For instance, in the presence of a normally incident Gaussian beam, a dipolar particle located above such a plasmonic configuration experiences a set of lateral forces due to the interplay between the incoming wave, dipole’s own retarded field and the surface waves. Such forces exhibit odd symmetric behavior as a function of the dipole’s spatial position around the incoming beam axis, yielding to introducing optical trapping or anti-trapping mechanisms [8]. Our numerical analysis reveal that different sized dipolar particles located above HMTSs experience stable optical trapping over a large frequency band with strong resiliency against the beam focus. Besides, the induced trap stiffness and trap depth are significantly stronger (orders of magnitude) than those found above pristine plasmonic materials near their intrinsic plasmon resonance frequency. We envision that our proposed configuration may pave the way to the next generation nano-optical plasmonic tweezers opening unprecedented applications in physics, chemistry and bioengineering.

Abstract

To demonstrate and understand wave motion in phononic crystals, i.e. acoustic periodic structures, and elastic metamaterials, i.e. structures with local vibrational resonances, we develop an instructive instrument to visualize one-dimensional torsional waves based on a Shive wave machine. Phononic crystals are made by adding extra masses in a spatially periodic fashion, and elastic metamaterials are made by adding blade springs. The frequencies of band gaps agree well with theories based on torsional vibrations, analogous to those based on mass-spring models.

1. Introduction

Techniques for blocking waves in specific frequency ranges are widely applied to filters and isolators. Two main methods for blocking waves by static structures exist. One way is by the use of spatial periodicity, such as in the case of photonic crystals in optics or phononic crystals in acoustics. At the atomic level, crystals exhibit both phononic and electronic band gaps arising from spatial periodicity. Another way of blocking waves is by the use of local oscillators. Examples are electromagnetic, acoustic and elastic metamaterials. At the atomic level, polaritons are one example. To bring out the basic physics of such phenomena in an educational way, recent experiments have demonstrated the properties of elastic metamaterials by the use of mechanical structures of human dimensions [1-3], but their detailed motion is not immediately visually accessible.

The Shive wave machine, as shown in Figs. 1 and 2, was developed 50 years ago [4], and has been widely used to demonstrate wave phenomena [5]. It consists of a periodic one-dimensional array of torsionally-coupled rods suspending on wires, along which passes a torsional wave. Shive wave machines realise a conveniently low wave speed, in the sub-m/s range, with easily visible amplitude. Various wave phenomena such as reflection, transmission, and standing waves etc. can be viewed.

Shive wave machines are characterized by the moment of inertia of each rod $I$ and the torsional spring constant $\kappa = 2Td^2/a$, where $T$ is the tension of the two wires that provide the torsional coupling, $d$ is the distance from the center of the rods to the two wires, and $a$ is the lattice constant. The equation of motion of the $n$-th unit cell in the wave machine is governed by (see Fig. 1)

$$I \frac{d^2 \theta_n}{dt^2} = \kappa (\theta_{n+1} + \theta_{n-1} - 2\theta_n),$$

where $\theta$ is the torsion angle. On the other hand, the equation of motion of the $n$-th unit cell in a conventional one-dimensional mass-spring model is governed by (see Fig. 1)

$$m \frac{d^2 u_n}{dt^2} = K (u_{n+1} + u_{n-1} - 2u_n),$$

where $u$ is the displacement, $m$ is the mass and $K$ is the spring constant. One can appreciate exact correspondence.

By the use of a unit cell with two different moments of inertia, it is possible to mimic the behavior of a phononic crystal. By the use of rods with two blade springs attached to both ends, it is possible to mimic the behavior of an elastic metamaterial. To our knowledge these have not previously been constructed in the form of a Shive wave machine. In this study, we demonstrate the physics of phononic crystals and elastic metamaterials on a Shive wave machine. By tracking the displacements of each rod and taking the spatiotemporal Fourier transform, we demonstrate how one can obtain the dispersion relations governing the wave propagation.

2. Developed instruments

Figure 2 shows a photograph of the wave machine. Approximately 100 acrylic rods of dimension $320 \times 6 \times 6$ mm$^3$ are mounted on an axial central steel wire, and the two...
Fig. 3 A movie frame recorded in a dark room. Fluorescent makers on the rod ends are illuminated. The rectangles show automatic identification by the image tracking system.

polyethylene wires that provide torsional coupling are also arranged to pass through the rods. Pipe-shaped spacers of length 10 mm are used, providing a unit cell of length 16 mm. We arrange for the speed of the travelling wave to be \( \sim 100 \) mm/s, and the wave amplitude to be \( \sim 30 \) mm. Black and fluorescent makers are put on each rod end for enhanced visibility. For systematic measurements, we measure the torsional displacement of each rod by means of a visual tracking system that can capture the displacement of the rod ends in real time.

A phononic crystal can be constructed by incorporating a spatially periodic variation in the moment of inertia of the rods by the addition of extra masses (4.5 g). The moment of inertia with and without the masses are \( I_1 = 1.05 \times 10^{-4} \) kg m\(^2\) and \( I_2 = 3.13 \times 10^{-4} \) kg m\(^2\), respectively as measured by pendulum experiments.

A elastic metamaterial is constructed by adding thin polystyrene blades of dimensions 180 \( \times \) 6.3 \( \times \) 0.5 mm\(^3\) (1.9 g with fixing nuts and screws) and resonance frequency 3.5 Hz.

3. Results

To monitor the frequency response, we record constant-frequency waves generated with a motor-and-crank. Figure 4 shows constant-frequency frames from a movie of the phononic crystal at certain frequencies. In the case when the unit cell consists of four rods as in Fig. 4, four branches exist in the dispersion relation. The measured frequency of every band edge and band gap as well as the wave velocity in the limit of low frequency agree with the dispersion relation calculated from a one-dimensional mass-spring model analogy. Figure 5 shows constant-frequency frames from a movie of the elastic metamaterial at certain frequencies. The torsional wave propagates from a non-metamaterial zone to a metamaterial zone. The measured first resonance frequency of the blade springs attached to the rods is 3.5 Hz, as expected. Waves can propagate in the metamaterial zone at frequencies sufficiently below and above resonance. Damping is evident at frequencies approaching the resonance, and the waves only penetrate to distances of around one or two rods on resonance, as shown as Fig. 5(b). On resonance, the extremities of the rods and blade springs vibrate with opposite phase.

Conclusions

In conclusion, we have demonstrated that it is possible to model the behavior of a torsional phononic crystal and an elastic metamaterial with a Shive wave machine. This gives a dramatic visual demonstration of the physics involved, ideal for educational purposes. In future, we will attempt to realise time-modulated phononic crystals and time-modulated elastic metamaterials on a Shive wave machine.

Abstract

We propose a novel approach to confine light into isolated silicon nanodisk with high-quality (Q) factor electric dipole (ED) or magnetic dipole (MD) states with suppressed scattering inspired by the mechanism of the symmetry-protected bound state in the continuum (BIC). We demonstrate the efficient optical excitation of such states under structured beam illumination, which is not possible for the conventional symmetry-protected BICs in the periodic system. Owing to the strong near-field enhancement, such quasi-BIC state opens a novel opportunity for boosting nonlinear optical processes.

1. Introduction

Control of the light at the nanoscale has been a vibrant field of research for many years due to the various applications including photonic metadevices, high-performance data processing, optical computing, etc. High-index dielectric nanostructures have emerged as a promising tool to enhance light-matter interactions due to its ability to efficiently manipulate light based on the control over both optically induced electric and magnetic Mie-type resonances, offering great potential for applications in nanophotonics and nonlinear optics [1, 2, 3, 4].

BICs, being originally predicted by von Neumann and Wigner in 1929 [5], which represent localised states with energies embedded in the continuous spectrum of radiating waves, has been extensively studied in different fields including acoustics, microwaves and nanophotonics [6]. In a periodic system, when the coupling of particular resonance to the radiation modes is forbidden by symmetry mismatch, a symmetry-protected BIC will form. BICs provide a promising tool for light localisation with high Q and enhancing light-matter interactions.

In this work, inspired by symmetry-protected BIC mechanism in the periodic system, we propose a novel approach to design high Q nonradiating states, i.e., quasi-BIC MD and quasi-BIC ED state in isolated silicon nanodisk by surrounding PEC/PMC-based nanocuboids. These PEC/PMC-based components can be formed through designed metasurfaces, photonic crystal slabs, metals or superconductors, etc. Importantly, such states can be directly excited using structured beam illumination, leading to a robust near-field enhancement which can significantly boost optical processes involving light-matter interactions, such as third-harmonic generation (THG) process in silicon.

2. Results and Discussion

Based on image dipole model, the excited circularly displacement electric currents from MD and the circular displacement magnetic currents from ED in periodic system can be transformed to the corresponding induced electric or magnetic currents from a single resonator surrounded by perfect electric conductor (PEC) or perfect magnetic conductor (PMC) materials [4] (Figure 1a-c). Here, focusing on the fundamental Mie resonance ED and MD, we employ this approach to obtain high Q quasi-BIC ED and MD states in isolated silicon disks by surrounding PEC/PMC-based cuboids at all four sides. We focus the working wavelength \(\lambda_0\) around 1556nm, and the thickness of our silicon disk and PEC/PMC cuboids to be 400nm. The gap between the aSi nanodisk and adjacent PEC/PMC-based structures are 100 nm, which can be easily fabricated experimentally. With the introduction of the PEC-based nanocuboids surrounding aSi nanodisk, a quasi-periodic boundary condition is formed around the nanodisk, leading to the formation of high Q MD state with \(Q \approx 1341\) which can be directly linked to the symmetry-protected BIC with MD nature at \(\Gamma\) point of a TE band structure from a periodic array of Si disk. Importantly, owing to mode matching of this state with the azimuthally-polarised beam, it can be directly excited under AP beam illumination, while the scattering can be well suppressed due to the quasi-periodic boundary condition which limits the outgoing radiation channels (Figure 1d), resulting in a strong near-field enhancement (Figure 2e-f). Similarly, a quasi-BIC ED state (\(Q \approx 2206\)) with suppressed scattering is formed when the Si disk is surrounded by PMC-based nanocuboids at all four sides and can be efficiently excited under a radially-polarised pump illumination (see Figure. 1g). Interestingly, significant field enhancement is obtained inside the Si disk from this ED state, which is different from the conventional ED resonator where the electric field is mainly confined near the edge of the nanoresonators. This feature can further open the way for utilizing ED enhancing light-matter interactions in dielectric nanoparticles.

Such high Q states manifest strong electric energy con-
Figure 1: (a-c) Schematic illustration of the transformation of electric and magnetic currents from periodic system to a single resonator surrounded by PEC or PMC material. (d-f) Calculated multipolar structure and electric near-field distributions for silicon disk surrounde by PEC nanoboid under AP beam illumination. (g-i) Calculated multipolar structure and electric near-field distributions for silicon disk surrounded by PMC nanoboid under RP beam illumination.

...centration inside the Si disk, leading to a giant THG emission as shown in table 1. We further estimate the conversion efficiency using the collected total THG emission power normalized by the pump power incident on the disk area [7]. The predicted conversion efficiency significantly exceeds that from conventional Si MD or ED resonators under structured pump illumination. Specifically, under AP or RP beam illumination with peak pump intensity $I_0 = 1.0$ GW/cm$^2$, we have observed record-high THG efficiency of $6 \times 10^{-3}$ for quasi-BIC MD resonator and 0.8 for quasi-BIC ED resonator, which corresponds to more than 300-fold and $2 \times 10^6$-fold enhancements from conventional Si MD, ED resonators, respectively.

3. Conclusions

In summary, we have demonstrated high-quality nonradiating MD and ED states formed in isolated Si disk with surrounding PEC/PMC nanocuboid at all four sides inspired by the mechanism of symmetry-protected BIC. Such states can be efficiently and directly excited under structured beam illumination due to the mode overlapping and manifest strong near-field enhancement leading to a giant THG emission from Si disks. Our results show the great potential of dielectric nanostructures for nanophotonics applications including strong coupling, quantum photons generation, and the robust structured beam steering at the nanoscale.

A Graphene-Integrated Topological Insulator: Electrical Control of Terahertz Plasmon Polaritons

Chihun In¹, Beom Kim¹, and Hyunyong Choi*¹

Abstract

Collective oscillations of massless particles in two-dimensional (2D) Dirac materials offer an innovative route toward controlling low-energy quasiparticle resonances. Here, we report the experimental realization of electrically tunable 2D Dirac plasma polaritons using a topological insulator (TI) in a proximity contact with gate-controlled graphene. In our integrated TI–graphene devices, the 2D Dirac plasmons in micro-patterned TI generate constant plasmon momenta at terahertz (THz) frequency, while the proximity-integrated graphene controls the TI Dirac plasmon polariton resonances.

1. Introduction

The Coulomb interaction between free carriers and collective charge oscillations is of particular interest in the field of plasmonics. Metal-based surface plasmon polaritons are essentially based on interface charge characteristics between a dielectric and a metal, or a combination of the two. For the active control of the surface plasmon polaritons, either isolated [1], stacked [2], or metamaterial-integrated graphene [3] is a promising for steering the resonances of plasmon toward far-infrared ranges. Coupling graphene plasmons with incident photons, however, is often hampered by inactive electronic states across the physical boundary, which significantly reduces the plasmon polariton lifetime and alters the corresponding dispersion [4]. In turn, the 2D Dirac surfaces of the topological insulator (TI) are protected by time-reversal symmetry, which leads to robust electrical transport against non-magnetic scatterers because of the π Berry phase during the scattering event [5]. Hence, the plasmon momentum on the TI surface is immune to weak disorders on the sample boundary, which contrasts TI plasmons from the metal or graphene cases. In this respect, it is important to exploit the surface plasmon characters of the TI Dirac surface in the light–matter interactions.

2. Experimental results

In this work, we explore the electric control of 2D Dirac plasmon polariton resonances using vertically integrated Bi₂Se₃ TI and graphene heterostructures. The far-field coherent THz radiation excites the 2D surface Dirac plasmons associated with two distinct 2D Dirac layers. We experimentally show that the electrostatic gating on our heterostructure mainly changes the graphene carrier density; hence, we can minimize the effect of bulk carrier excitation.

Figure 1a is the schematic illustration of our experimental scheme, where a single-layer CVD-grown graphene (G) is transferred onto the Bi₂Se₃ TI microribbon structures. The thickness of Bi₂Se₃ TI is 30 quintuple layers (QL) (1 QL = 1 nm). As reported in prior studies, the periodic micro-patterns of Bi₂Se₃ TI produce an in-plane plasmon momentum when coupled to the incident THz radiation [6,7]. A proximity contact of graphene onto the Bi₂Se₃ TI was realized by carefully eliminating any insulating barrier, e.g., natural oxide barrier. A gate voltage \( V \) is applied through ionic double-layer configuration in graphene to electrically control the graphene carrier density. The fabricated TI–graphene heterostructure is shown in Fig. 1b, where the Bi₂Se₃ TI was grown on a series of buffer layers consisting of 8 QL In₃Se₃ and 8 QL (In₀.₅Bi₀.₅)₂Se₃ to reduce the defect sites compared to the nominally grown Bi₂Se₃. The microscopic image shows that the width of Bi₂Se₃ microribbon is \( W = 20 \text{ mm} \) with a periodicity of \( 2W \), which corresponds to the plasmon momentum \( q = \pi / W \sim 1,570 \text{ cm}^{-1} \).

Figures 2 c–f show the experimental confirmation of the electrical control of the surface plasmon polariton. The gate-dependent THz extinction spectra \( E(\nu) \) are shown in Fig. 2c. The plasmon momentum \( q \) is produced when the incident THz electric field is perpendicular to the microribbon (E.). The sharp resonance at ~2 THz indicates the Bi₂Se₃ optical phonon, which weakly interferes with the quasi-continuous plasmons. Such phonon-plasmon interference can be simply understood by a well-established Fano model [7,8], from which we can extract the bare plasmon spectra. The corresponding fit (solid) and plasmon spectra (dashed) are plotted in the same panel of Fig. 2c. Each panel displays data with a relative change in gate voltage, i.e., \( \Delta V = V_\text{CNP} - V_\text{g} \), where \( V_\text{CNP} \) is the gate voltage at the graphene charge-neutral-point (CNP). The spectra at \( \Delta V = 0 \text{ V} \) represent the intrinsic Bi₂Se₃ plasmon polaritons, whereas those at \( |\Delta V| > 0 \text{ V} \) involve the extrinsic contribution from graphene carriers. Note that the Bi₂Se₃ plasmon spectra are clearly blue-shifted with increasing \( |\Delta V| \). On the other hand, the THz electric field parallel to
the microribbon (E_b) yields no gate-dependent shift, showing featureless Drude responses.

In Fig. 2d, we compare the gate-dependent plasmon frequency $\nu_p$ (obtained from the data in Fig. 2c) with the density-dependent 2D Dirac plasmon model. An excellent agreement was seen. From the curve, we obtain the topological surface state (TSS) and two-dimensional electron gas (2DEG) chemical potential of $\mu^{TSS} \sim 200$ meV and $\mu^{2DEG} \sim 50$ meV, respectively, which corresponds to the carrier density of $n^{TSS} = 2 \times 10^{12}$ cm$^{-2}$ and $n^{2DEG} = 3 \times 10^{12}$ cm$^{-2}$. Figure 2e shows the square-root dependence of $\nu_p$ on the graphene carrier density $n^G$. This anomalous density dependence of 2D Dirac plasmons is valid when $n^G$ is sufficiently small compared to $n^{TSS}$ and $n^{2DEG}$ [7,8]. Here, we emphasize that although the change in $n^G$ is small within our $\Delta V$ range, the 2D Dirac plasmon can be modulated up to ~50%. This is primarily due to the anomalous density dependence. In Fig. 2f, we examine the gate-dependent plasmon width $\Gamma$. Because there exists no noticeable dependence of $\Gamma$ on $n^G$, we experimentally exclude the contribution of bulk Bi$_2$Se$_3$ population to the plasmon resonance shifts. The broader plasmon width (E_b) than the Drude width (E_d) indicates additional inhomogeneous broadening from the TSS and 2DEG.

is plotted as a function of $\Delta V$ (solid dots). Inset illustrates the graphene doping with different $\Lambda$. The density-dependent $\nu_p$ model is plotted on the same panel (grey dashed line). (e) $\nu_p$ is plotted as a function of $(n^{TSS}/\nu_p)^{1/2}$. (f) Scattering rates $\Gamma$ for plasmon (E_c, orange dots) and Drude response (E_d, blue dots) are shown, both of which are independent of $\Delta V$. The horizontal dashed lines are a visual guide.

3. Conclusions

In summary, we demonstrated that all 2D Dirac heterostructures consisting of graphene and TI control coherent plasmon polariton oscillations. The 2D Dirac plasmon resonances are modulated through electrically gated graphene, which is in a proximity contact with TI. Our work is different from conventional metallic plasmons or graphene-integrated dipole resonances in that the screening effect on plasmons is weak. The coherent coupling of gate-controlled graphene with TI is manifested by an unconventional blue shift of Bi$_2$Se$_3$ TI plasmon polariton resonances, which otherwise would exhibit a red shift due to strong Coulomb screening. Our integrated device may provide a new opportunity for exploring Dirac quasiparticle physics in low-energy optical modulators with low power consumption in compact heterostructures.

Abstract

Integrated quantum photonics has attracted intensive attention due to the compactness, scalability, and stability. An on-chip photonic quantum source, especially an on-chip entangled photon source, is a basic device for realizing quantum photonic integrated circuits (QPICs) \cite{1}. Here, I will introduce our recent works on on-chip quantum photonic sources based on silicon waveguide.

1. Introduction

Quantum photon pair sources are not only critical to advancing our fundamental understanding of quantum mechanics, but also play a key role in many applications for quantum technologies. Compared with free-space ones, integrated photon pair sources have attracted much attention owing to their compactness, scalability, and stability. For example, path or polarization entangled photon pairs were demonstrated by using the nonlinear processes in a single-mode waveguide or in a micro-ring cavity. Multi-photon quantum sources are critical resources for quantum communication, computation, simulation, and metrology. Great efforts have been made for the realization of high-quality, bright, and scalable multi-photon quantum states to enable a practical and powerful implementation of quantum technologies. Since it is difficult to achieve a nonlinear process directly coupling multiple photons together due to the weak nonlinear susceptibilities of those common optical materials, traditionally multi-photon quantum sources are generated by multiplexing several bi-photon sources and performing post-selections. As the efficiency of the multiplexing process decreases exponentially with the number of entangled photons, it is essential to achieve bright bi-photon sources with high-fidelity and increase the coupling efficiency wherever possible. In comparison with free-space optics, integrated photonics has been recognized as a promising platform for realizing quantum photon-pair sources and compatible with chip-based processes of quantum manipulation and detection. The strong mode-confinement in optical waveguides and field-enhancement in high-Q optical cavities can greatly enhance the nonlinear optical interactions, so that it is possible to achieve on-chip multi-photon quantum sources.

Here, I will introduce three works on on-chip quantum photonic sources based on silicon waveguide: 1. On-chip transverse-mode entangled photon pair source \cite{2}; 2. Generation of multi-photon quantum states on silicon \cite{3}; 3. Frequency-degenerate multi-photon entangled state generation with silicon \cite{4}.

2. On-chip transverse-mode entangled photon pair source

Integrated entangled photon pair source is an essential resource for both fundamental investigations and practical applications of quantum information science. Currently there have been several types of entanglement, among which the transverse-mode entanglement is becoming attractive because of its unique advantages. Here, we report an on-chip transverse-mode entangled photon pair source via the spontaneous four-wave mixing processes in a multimode silicon waveguide. Transverse-mode photon pairs are verified over multiple frequency channels within a bandwidth of ~2THz, and a maximally entangled Bell state is also produced with a net fidelity of 0.96. Our entangled photon pair source is the key element for quantum photonics based on transverse-mode, and also has the possibility to extend to higher-dimensional Hilbert space. Furthermore, the transverse-mode entanglement can be converted coherently to path and polarization entanglement, which paves the way to realizing highly complex quantum photonic circuits with multiple degrees of freedom.
3. Generation of multi-photon quantum states on silicon

Multi-photon quantum states play a critical role in emerging quantum technologies, and greatly improves our fundamental understanding of the quantum world. Integrated photonics is well recognized as an attractive technology offering great promise for the generation of photonic quantum states with high brightness, tunability, stability and scalability. Here, we demonstrate the generation of multi-photon quantum states by using a single silicon nanophotonic waveguide. The detected four-photon rate reaches 0.34 Hz even with a low pump power of 600 μW. This multi-photon quantum state is also qualified with multi-photon quantum interference as well as quantum state tomography. For the generated four-photon states, the quantum interference visibilities are above 95% and the fidelity is 0.78±0.02. Furthermore, such a multi-photon quantum source is fully compatible with on-chip processes of quantum manipulation as well as quantum detection, which is helpful for the realization of large-scale quantum photonic integrated circuits (QPICs) and also shows great potential for the research in the area of multi-photon quantum science.

4. Frequency-degenerate multi-photon entangled state generation with silicon

Integrated photonics is an attractive platform for generating photonic quantum states with high brightness, high stability and scalability. The photonic quantum states generated so far using integrated circuits have shown important practical applications in a range of quantum technologies. However, the schemes used produce photons at different frequencies and therefore the photons are distinguishable, which limits their further use in many quantum information applications. Here, we prepare frequency-degenerate multi-photon quantum states with a silicon nanophotonic waveguide. Two-photon and four-photon polarization entangled states are generated with the help of a Sagnac interferometer. The states are analyzed using quantum interference and state tomography techniques. As an example, we show that the generated quantum states can be used to achieve phase super-resolution. Our work shows the possibility of using integrated waveguides to prepare indistinguishable multi-photon entangled states and realizing quantum algorithms in a compact on-chip setting.

Abstract

Besides its fundamental importance, manipulation of light at the nanoscale is of great interest for the prospect of real-life applications, such as energy harvesting and photovoltaics, wave-guiding and lasing, optoelectronics, biochemistry and medicine. Novel optical designs and architectures that modify the optical power flow through plasmonic nanostructures represent another crucial step towards a nanoscale manipulation of light-matter interactions. In this framework hyperbolic metamaterials (HMMs) have received great attention due to their unusual properties at optical frequencies that are rarely or never observed in nature [1]. Here, we report about unconventional optical properties of metal-dielectric meta-antennas supporting type II hyperbolic dispersion, which enable almost pure and spectrally separated absorption and scattering channels in the visible/near-infrared spectral range [2]. We demonstrate that the physical mechanism responsible for the control of scattering and absorption lies in the different nature of the plasmonic modes excited within the hyperbolic meta-antennas. We also show that scattering is the dominating electromagnetic decay channel, when an electric super-radiant dipolar mode is induced in the system, whereas strong light absorption occurs when a magnetic sub-radiant dipole is excited. Importantly, both modes can be excited directly by coupling with far-field radiation, thereby making the proposed architecture suitable for practical applications. In this framework, we demonstrate also that HMM meta-antennas could find promising applications in photo-thermal therapy. Our findings open the pathway towards novel routes for exploiting light to energy conversion channels beyond what is offered by current plasmon-based architectures, possibly enabling applications including thermal emission manipulation, thermoplasmonics-based theragnostic nano-devices, novel nano-antenna designs and plasmon-enabled enhanced molecular spectroscopy.

Abstract

The hydrogen evolution reaction in the mixed solution of H₂O and D₂O has been investigated on the nano-structured electrodes using the electrochemical mass (EC-mass) spectroscopy system. By the establishment of the EC-mass system, we have successfully discussed about the isotopic selectivity of the hydrogen evolution reaction at the specific nano-structures electrodes. We have demonstrated the specific factor for the precise control of the isotopic selectivity on the hydrogen evolution reactions. The present results prove the importance of in-situ mass spectroscopic measurement for the investigation to establish the arbitrary control of the isotopic hydrogen evolution reactions.

1. Introduction

For the sustainable society, the hydrogen evolution reaction (HER) is one of the most important electrochemical reactions [1]. Although the HER process seems to be a simple two-electron reduction, the actual molecular behavior on the electrode surface is quite complicated. As the well-known process of the HER process, three molecular processes, such as the adsorption, chemical recombination, and electrochemical recombination steps occur simultaneously at the electrode surface [2]. There are various efforts to control the effective HER process, but the arbitrary control of the isotopic selectivity is still a challenging issue in that field. According to the previous reports, it has been reported that the ratio of the generated isotopic molecules, which are generally described as the separation factor (S₀), is sensitively dependent on the HER conditions, such as the mixed ratio of H₂O and D₂O, the solution temperature, over potential or the metal species. From the electrochemical point of view, it can be said that the arbitrary tuning of the reaction selectivity is quite important not only for optimization of HER efficiency but also development of the novel industrial techniques for the D₂O/H₂O condensation.

Up to date, various both experimental and theoretical attempts have been carried out to clarify the specific factor for the control of the selectivity on the isotopic reaction. As the interesting fact, the selectivity of the isotopic reaction is also affected not only by metal species but also the morphology or the configuration of the electrode surface. In this study, we have established the EC-mass system to observe the reaction products originated from the advanced materials of the Ag nano-structured electrodes. In present results, it is interesting that the curious reaction selectivity tuning was observed only in the case for specific Ag nano-structures. Through the in-situ analyses, mechanistic studies of the structure morphological effect on the isotopic reaction selectivity became possible [3]. The present findings would provide important aspects for future methods to control the reaction selectivity of the isotopic HER.

2. Experiment

The electrochemical HER measurements have been carried out using a handmade three-electrode electrochemical cell. The working electrodes were Ag (99.99%), electrochemically roughened Ag, or the well-defined Ag nano-structures supported on the glassy carbon electrode. The Ag nano-structures (Ag-NSL) were prepared by the nano-sphere lithography method as described in the previous report [1]. The counter and reference electrodes were Pt plate and Ag/AgCl, respectively. The supporting electrolyte was 0.5 M Na₂SO₄. The mixed electrolyte solution was prepared by the diluting H₂O (0.991 g, 0.99 mol) to D₂O (9.91 g, 0.91 mol), leading to 90wt% D₂O.

The real-time observations of the reaction product generations were conducted with a quadrupole mass spectrometer, Q-mass (Qulee-HGM, 202, ULVAC Co., Japan) attached to the handmade electrochemical cell. The generated gases are immediately flowed to the mass spectrometer via the capillary immersed into the electrolyte solutions. For avoiding the insertion of the solution into the system, the capillary was coated with the porous Teflon membrane with the pore size of 10 µm. All measurements have been performed under the ambient temperature.

3. Discussion

Figure a shows in-situ mass spectra obtained with the polarization at ~2.0 V to the Ag and roughened Ag electrodes. Basically, the main products of electrochemical isotopic HER from the D₂O rich solution is HD (m = 3) due to the much faster reaction kinetics of H adsorption to the metal surface. However, it is interesting that we have successfully found that the amount of the generated H₂ (m =
2) at roughed Ag was larger than that at smooth while the ion currents of HD and D₂ (m = 4) at roughened Ag were comparable to those at smooth one. This means that the characteristics to the selective improvement of H₂ generation at roughened Ag were observed. It must be strongly emphasized that the effect of AgCl or Cl ions originated from the electrochemical surface roughening process on the isotopic selectivity can be ignored in the present case. This is because that the residual AgCl or adsorbed Cl anions can be completely reduced and removed at more negative region than −0.9 V. From these, improvement of H₂ generation would imply the possibility that selective acceleration of the reaction processes for only H₂ generation process at the structured electrodes. Therefore, we could conclude the acceleration of the electrochemical desorption reaction at the surface of the roughened Ag electrode appeared. This would be due to the surface or the environmental change at the surface during HER or the appearance of the reaction active site by the electrochemical roughening process.

As the next step, we have prepared the well-defined Ag-nano structured on the carbon electrode using the template method. By this method, the well-defined small Ag triangle structures were deposited on the entirely surface of the carbon electrode. With this electrode, the real time observation of the isotopic products was obtained under the same electrochemical condition as the case in Fig. Very surprisingly, the reaction amounts of H₂ drastically improved and exceeded that of HD. And also the S₀ value achieved above 20. To the best of our knowledge, this is the first report about the extremely high S₀ value on the Ag electrode. It should be stressed that this interesting isotopic selectivity only appeared in the case for the specific size of the Ag triangle structure. We think that this size dependence would imply the deeply relationship between the S₀ value and the plasmon energy which is deeply correlated with the size and morphology of the Ag.

Figure: (a) Electrochemical mass spectra obtained with (upper) smooth and (bottom) roughened Ag electrodes in the mixed solution of H₂O and D₂O. The electrode potential was set to −2.0 V. (b) SEM images of (upper) smooth and (bottom) roughened Ag surface [3].

4. Conclusions

The in-situ electrochemical mass spectral measurement system has successfully been established. By using this system, the detail structural morphological effect on the isotopic selectivity has been discussed based on the real time detection of generated reaction products. As the important facts demonstrated in the present investigations, the Ag with the specific nano-structured electrode shows the high selectivity of H₂ generation. This could be originated from the selective acceleration of the H₂ generation at the advanced Ag nano-structures. We now believe that the real time observation of the isotopic reaction products would provide us quite new fact against the various isotopic electrochemical reactions as demonstrated in present paper.

Abstract

We study liquid crystal metasurfaces self-assembling on polymer layers patterned by focused ion beam, which are capable of strong visible light diffraction with millisecond-fast electro-optical control. To improve the efficiency of diffraction into a particular channel, we propose super-periodic metasurface designs generated by a multi-parametric optimization algorithm. While such selective diffraction at small angles is achievable with super-periodic structuring of a single substrate of a liquid crystal cell, obtaining it for larger angles requires consistent structuring of both substrates.

1. Introduction

Metasurfaces – ultrathin two dimensional analogues of metamaterials – allow for precise optimization of their versatile functional optical properties [1]. Hybrid metasurfaces combining planar metal and semiconductor nanostructures with soft matter can be switched by weak electric signals [2] and laser irradiation [3]. Liquid crystal (LC) metasurfaces, proposed recently [4], combine the soft matter flexibility with exceptional optical quality as they self-assemble from transparent nematic LC under appropriate external conditions upon specially patterned polymer layers.

In this contribution, we analyse the performance of LC metasurfaces as diffractive optical elements and focus on their designs optimal for the blazed grating performance. We analyse the experimental data available for metasurfaces assembled on periodical stripe patterns and show that, unlike most colour filters, the metasurfaces possess distinct colouring not related to a selective light absorption but rather to a diffractive light energy redistribution. However, in simple periodic LC metasurfaces, several diffraction channels appear simultaneously. In order to achieve a dominant diffraction into a single particular channel, more complex designs are necessary. We develop a numerical model of LC metasurfaces assembling upon complex aligning patterns and use it for multi-parametric optimization of the diffraction efficiency. We analyse the feasible diffraction efficiency and conclude on limitations imposed by the continuous medium nature of LCs.

Figure 1: Measured (a) and calculated (b) diffraction efficiencies of 5 µm periodic metasurface in 3 µm thick LC-cell. The inset in (b) shows the unit cell of periodic stripe pattern imprinted on one substrate (light grey colour represents FIB-processed area).

2. Periodic LC metasurfaces

As previously [4], glass substrates covered with 10 nm thin rubbed polyimide (PI) layer are patterned with focused ion beam (FIB) in FEI Scios dual-beam electron microscope. Periodic stripes with a 0.5 duty factor and a period from 1 to 8 µm are imprinted on areas of 0.5 × 0.5 mm² each. The LC cells are assembled by stacking the patterned substrates with chromolane coated non-patterned substrates and filling a few micrometer wide gaps with Merck E7 nematic LC.

Efficiencies of light diffraction in transmission geometry are measured using Horiba Jobin–Yvon UVISEL 2 ellipsometer combined with Ocean Optics USB4000 fibre spectrometer. The data confirm that the lacking transmitted energy is redistributed among a few first strong diffraction orders, see Fig. 1(a).

Neglecting certain peculiarities of the LC elastic anisotropy, we develop a model allowing to calculate the diffraction efficiencies for arbitrary periodic boundary values taken by the LC director polar angle on the sub-
Optics Express
Physical Review Applied

Generally, all obtained optimal patterns are similar: they induce a planar adjacent LC alignment on one side of the unit cell and its vertical alignment on the other side, while finer stripes in between provide a gradual transition. Note that the director field in the LC bulk is smoother than at the substrates due to the LC elasticity.

The feasible diffraction efficiency is strongly determined by the metasurface period. For example, optimizing a 10 \( \mu \text{m} \) periodic pattern on one substrate allows achieving a 63\% efficiency of the +1 diffraction order. For a 5 \( \mu \text{m} \) periodic pattern, only a 49\% efficiency is possible, see Fig. 2(a). Note that larger periods yield smaller diffraction angles: the 10 \( \mu \text{m} \) and 5 \( \mu \text{m} \) periodic patterns deflect light by 2.9\(^{\circ}\) and 5.7\(^{\circ}\) respectively. The diffraction can be noticeably enhanced by consistent super-periodic patterning of both LC-cell substrates: as illustrated by Fig. 2(b), such 5 \( \mu \text{m} \) periodic metasurface provides up to 71\% diffraction efficiency with other channels noticeably suppressed.

3. Super-periodic designs

The established connection between the patterns imprinted in PI by FIB and the optical characteristics of LC-metasurfaces enables their multi-parametric numerical optimization. As example, we focus on enhancing the +1 order diffraction at a 500 nm wavelength with the pattern periodicity and LC-cell thickness kept fixed. We employ MATLAB fminsearch routine with the patterned stripe boundaries being varied. For different initial patterns consisting of different number of stripes, the procedure yields same optimal patterns, i.e., the problem has a single global solution. For larger periods, the optimal patterns consist of more stripes, while for smaller periods less stripes are sufficient and excessive ones tend to merge.

Generally, all obtained optimal patterns are similar:

---

**Figure 2:** Diffraction efficiencies of 5 \( \mu \text{m} \) periodic LC metasurfaces self-assembled in 4 \( \mu \text{m} \) thick LC-cells upon one patterned substrate (a) and between two patterned substrates (b) with maximized +1 order diffraction at 500 nm wavelength. The insets show the unit cells of super-periodic patterns: (a) – to be imprinted on one substrate and (b) – to be imprinted on both substrates. Light and dark grey stripes represent FIB-processed areas on different substrates.

---

4. Conclusions

While LC-metasurfaces assembled upon substrates with periodic patterning produce remarkably strong diffraction, the outgoing light energy is evenly distributed between a few first diffraction channels. To concentrate the outgoing light in a particular direction, more sophisticated super-periodic designs are necessary. Further enhancement can be achieved by consistent super-periodic patterning of both LC-cell substrates. The latter design is optimal for LC-metasurface-based tunable blazed gratings and lenses.

Abstract

Noting that emission in organic molecules is from either π-π* or intramolecular charge-transfer (ICT) states, we address here how hyperbolic metamaterial (HMM) modifies ICT emission spectral features by comparing them with a spectral shift dependent on the local polarity of the medium. The 7.0 nm blue shift is observed in ICT emission from 4-dicyanomethylene-2-methyl-6-(p-dimethylaminostyryl)-4H-pyran dispersed into a polymer matrix prepared on HMM multilayered structure, while no spectral shift is observed in π-π* emission from perylene diimide.

1. Introduction

Photophysical properties of ICT emitters in solution are characterized by a strong dependence on the local solvent polarity. In particular, solvatochromism arises from local reorganization of solute and solvent dipoles to minimize the total energy. Similarly, solvatochromic shift can take place in organic thin-films, depending on the local polarity of the light-emitting medium, and the ICT character of the emitter. Here, we demonstrate that ICT dyes doped in polymer thin films deposited on HMM multilayered structure exhibit a blue-shifted emission due to the nonlocal changes in dielectric permittivity and refractive index. In addition, their fluorescence radiative and nonradiative decay rates and their PLQYs are found to undergo significant changes due to HMM. Lippert-Mataga formalism turns out to be very useful to distinguish and describe local and nonlocal effects of the dielectric permittivity and refractive index in evidencing the appearance of spectral changes in ICT emission.

2. Local and nonlocal effects on spectral shift

In order to compare the local effect of the medium polarity and the nonlocal effect of the HMM substrate in giving rise to a spectral shift of the emission, we compare steady-state photophysical properties of two sets of samples, DCM : PMMA films with 2 and 5 wt % on 0p (fused silica) as well as DCM : PMMA films with 2 wt % on 0p and 4p HMM substrates. Figure 1 displays the normalized steady-state photoluminescence (SSPL) spectra of two sets of samples. Figure 1c shows a red shift of 9.4 nm (35 meV) when the concentration of DCM is increased from 2 wt % to 5 wt % in the first set of samples. This is attributed to the increased local medium polarity, resulting from the increased local dielectric permittivity when increasing the concentration of polar DCM dye in the PMMA host. In contrast, the blue shift of 6.0 nm (23 meV) in the emission from 2 wt % DCM : PMMA on 4p HMM structure (Figure 1d) compared to that on 0p in the second set of samples indicates that the HMM structure produces a modulation of the ICT excited state and ground state. This is related to changes of the nonlocal dielectric permittivity and refractive index in the vicinity of ICT emitter when HMM substrate is present.

3. Local and nonlocal effects on fluorescence life-time

Time-resolved photoluminescence (TRPL) was carried out to examine the influence of the Purcell factor on ICT emission. To identify how spectral shift and spontaneous decay rate are related with local medium polarity and nonlocal HMM effects, TRPL spectra of two films of 5 wt % DCM : PMMA on 0p and 2 wt % DCM : PMMA on 4p HMM substrate are then compared with those of 2 wt % DCM : PMMA on 0p.

As shown in Figure 2 a), while there are differences in the weight of monomer and dimer contributions to red-shift in 5 wt % DCM : PMMA on 0p and blue shift in 2 wt % DCM : PMMA on 4p HMM substrate in TRPL spectra, an increased spontaneous emission rate is strikingly pronounced in 2 wt % DCM : PMMA on 4p HMM substrate. Figure 2 b) shows the integrated PL spectra along with time axis. Upon time gating the emission (after about 4.2 ns for 0p and 3.6 ns for 4p), the spectrum of the long-lived species corresponding to dimer can be recorded, which allows to deconvolute the spectrum of short-lived species corresponding to monomer from the SSPL spectrum. SSPL spectrum for 2 wt % DCM : PMMA on 4p (5 wt % DCM : PMMA
FIGURE 1 – Spectral shift of the ICT emission. (a) Steady-state photoluminescence (SSPL) spectra (excited at 470 nm) of DCM :PMMA film with 2 wt % (black curve) and 5 wt % (red curve) on 0p (fused silica) (b) SSPL spectra of DCM :PMMA film with 2 wt % in the absence (0p, black curve) and presence of 4p (blue curve) HMM substrate.

FIGURE 2 – Spectral and temporal behavior of ICT emission from DCM blends. (a) Streak camera images of DCM :PMMA film with 2 and 5 wt % on 0p and 2 wt % on 4p substrates (excited at 470 nm). (b) Integrated photoluminescence spectra for the entire time range (black), the dimer (red) emission integrated from 4.2 ns to the end, and the monomer (blue) emission obtained by the deconvolution of the entire PL spectra with the dimer spectra.

on 0p shows a blue shift (red shift) of 2.4 nm (7.2 nm) for monomer and 3.6 nm (5.4 nm) for dimer compared to those for 2 wt % DCM :PMMA on 0p. This indicates that the spectral shifts of both monomer and dimer result from local medium polarity in 5 wt % DCM :PMMA on 0p and from nonlocal HMM effect in 2 wt % DCM :PMMA on 4p HMM.

4. Conclusions

It is shown that HMM alters both dielectric permittivity and refractive index of environment of ICT emitter, though via very different mechanisms. Image dipole interaction of charge transfer state present in multilayered HMM structure is accounted for by nonlocal dielectric permittivity, while the Purcell factor enhancement from HD of HMM allows to introduce nonlocal refractive index. Elastic Mode Converter based on Supersymmetric Ladders

Choonlae Cho, Sunkyu Yu, and Namkyoo Park

Department of Electrical and Computer Engineering, Seoul National University, Seoul, Korea
*corresponding author, E-mail: nkpark@snu.ac.kr

Abstract

We propose an elastic mode converter for the control of multi-mode and polarization elastic waves. As an elastic analogy of supersymmetric (SUSY) optical transformation, we establish elastic effective potentials and verify quasi-isospectrality in between original and its SUSY partner potentials. Elastic mode filtering is then achieved by using an elastic SUSY ladder, with the concept of the polarization-selective elastic mode filtering.

1. Introduction

The theory of Supersymmetry in particle physics has extended its boundary to quantum mechanics and optics. Using the Helmholtz’s equation of the optical system which resembles the time-independent Schrödinger equation, the optical SUSY transformation has achieved significant progress: in terms of the fundamental interest on finding isospectral potential set [1], as well as practical applications: modal multiplexer [2] with the experimental realization [3] based on the global phase-matching condition, disordered optical potentials with perfect bandgap [4], and random wave switching for binary and fuzzy logics [5].

In this work, we apply the SUSY transformation to polarization-dependent elastic potentials [6], in order to develop the SUSY elastic mode converter which systematically filters the multimode elastic waves. For this, we impose the quantum-classical analogy on elastic systems, to derive the Schrödinger-like elastic Hamiltonian equations.

By adopting SUSY formalism into the elastic Hamiltonian, mode filtering in the elastic SUSY mode converter is demonstrated in the SUSY ladders. The polarization-diversity elastic potentials each for the longitudinal and shear wave mode, which allows the polarization selective elastic wave manipulation, will also be discussed.

2. Results

2.1. Elastic SUSY transformation

SUSY transformation relates original potential and its partner, similar to the creation-annihilation operation in quantum mechanics. In SUSY formalism, the original Hamiltonian operator $H^{(0)}$ is decomposed into Hermitian adjoint pair, by Cholesky decomposition: $H^{(0)} = A^{(0)}A^{(0)*}$, where $A^{(0)} = -d/dx + W$ and $A^{(0)*} = d/dx + W$ are Hermitian adjoint pair operators, $E_0^{(0)}$ is ground state eigenvalue, and $W$ is the superpotential which satisfies the Riccati equation $W^2 - dW/dx = V_0 - E_0^{(0)}$. The SUSY Hamiltonian $H^{(S)}$ and SUSY partner potential $V^{(S)}$ are then defined by $H^{(S)} = A^{(0)}A^{(0)*} + E_0^{(0)}$, $V^{(S)} = V_0 + 2dW/dx$, respectively. A particular solution of the superpotential $W$ is given by logarithmic derivatives of ground-state eigenmode, $W_0 = -d\log \psi_0^{(0)}/dx$, where $\psi_0^{(0)}$ is the ground state eigenvector. It is well known that the SUSY Hamiltonian which is constructed by the above superpotential $W_0$ conserves all the eigenvalues of original one except the ground state: i.e. ground state annihilation. More explicitly, the intertwining relation $A^{(0)}H^{(S)}\psi_0^{(0)} = H^{(S)}(A\psi_0)$ is satisfied; the SUSY partner eigenvalues and corresponding eigenfunctions are given by $E_n^{(S)} = E_n^{(0)}$ and $\psi_n^{(S)} = A\psi_n^{(0)}$, where $n$ is non-negative integer.

To apply the SUSY formalism, we first develop quantum-classical analogy to the elastic wave system. Equations of motion in inhomogeneous elastic media can be written as [6]

$$\rho \frac{\partial^2 \mathbf{u}}{\partial t^2} = (\lambda + \mu) \nabla (\nabla \cdot \mathbf{u}) + \mu \nabla^2 \mathbf{u} + \nabla \lambda (\nabla \times \mathbf{u}) + \nabla \mu \times (\nabla \times \mathbf{u}) + 2(\nabla \mu \cdot \nabla \mathbf{u}),$$

where $\rho$ is medium density, $\lambda$ and $\mu$ are Lamé’s first and second parameters. Focusing on the case of one-dimensional (1D) material variations along $x$-axis, Schrödinger-like formulation of the wave equation can be re-written as the eigenvalue equation $H\psi_n = E_n\psi_n$, where $H = -d^2/dx^2 + V(x)$ is the system Hamiltonian, $V(x)$ is a effective potential, $\psi_n$ and $E_n = -k_n^2$ are the eigenfunction and corresponding eigenvalue, respectively, and $k_n$ is the spatial frequency. In the paraxial approximation, the elastic potential is then described by a set of polarization dependent effective potentials $V_{\perp}(x) = -\omega^2 n \omega^2(x)$, where $\omega$ is the angular frequency and $n_1$ and $n_3$ are refractive indices of longitudinal and shear elastic wave, respectively.

2.2. SUSY ladders for mode selectivity

From the Schrödinger-like formulation of elastic waves, we then establish the concept of elastic SUSY transformations, for the construction of quasi-isospectral potentials. For arbitrary elastic potentials shown in Fig.1, we obtain the ground-state-annihilated SUSY partner potentials which satisfy the quasi-isospectrality. Each polarization-dependent SUSY ladder can then be constructed by assembling SUSY partner potentials. In these SUSY ladders, evanescent mode coupling between adjacent waveguides in the weak coupling regime achieves the perfect power transfer by the global phase matching condition of SUSY partner potentials.
Figure 1: (a) Elastic potentials of the Schrödinger-like elastic wave equations. (b,c) Elastic SUSY partner potentials from original potentials \( V^{(0)} \) for longitudinal (b) and shear (c) waves.

Figure 2: Polarization dependent mode selective elastic wave-mode separation in SUSY ladder. (a) The longitudinal wave-modes are coupled to the left side, and (b) the shear wave-mode are coupled into the right side. Single polarized multimodal waves are then separated, based on SUSY mode filtering.

By arranging two polarization dependent SUSY ladders of which the mode annihilation directions are opposite, an elastic SUSY mode converter can then be constructed, which offers the complete modal filtering; not only for spatial modes but also for polarization modes. Figure 2 shows the operation of SUSY-based polarization-dependent mode-selective filter, for the input of arbitrary spatial- and polarization-mode at the center.

3. Conclusions

In summary, we proposed and achieved an elastic SUSY mode converter, by establishing isospectral elastic potentials via the quantum-classical analogy of the elastic wave equation. With the peculiarity in the elastic wave, i.e., the polarization mixing between longitudinal and transversal waves, polarization diversity SUSY ladders are proposed in order to achieve mode conversion both in spatial- and polarization-domain. Our elastic Hamiltonian and SUSY transformation enables the tailoring of the modal spectra, which differs from conventional dispersion modulation methods, opening up the possibility of constructing polarization and mode number selective devices.

Optomechanical Kerker effect for trembling resonant particles

Alexander Poshakinskiy* and Alexander Poddubny

Ioffe Institute, St. Petersburg, Russia

Abstract

We propose an optomechanical Kerker effect, where the tunable directional inelastic scattering is achieved for a small particle that trembles in space. We show that the motion of the electric dipole leads to appearance of a magnetic dipole. The interference of the electric and magnetic dipole radiation patterns is governed by the frequency dependence of the particle permittivity. For a resonant particle, the light is scattered preferably forward at resonance and backward away from it.

1. Introduction

The control of the scattered light direction is essential for optical circuits. However, small particles usually scatter light symmetrically, in particular, forward and backward scattered waves have equal intensities. The asymmetry can be induced if the scatterer moves. Then, the Doppler effect leads to a difference between the incident and scattered light frequencies, that is maximal for the wave scattered backward and vanishes for that scattered forward [1]. Still, the asymmetry of the emission intensity pattern remains small unless the particle velocity becomes comparable to that of light. Another way to achieve strong scattering directionality was proposed by M. Kerker [2]. It can be realized for scatterers that have both electric dipole (ED) and magnetic dipole (MD) susceptibilities. Since the electric fields corresponding to ED and MD have opposite spatial parity, their interference enables directional forward or backward scattering. The implementation of the Kerker effect requires magnetic response of the same strength as the electric one. At optical frequencies, that is challenging due to the vanishing magnetic susceptibility. A possible solution is to exploit electric and magnetic Mie resonances in high-refractive-index dielectric nanoparticles [3]. However, Kerker effect for the particles smaller than the wavelength in the medium is still unfeasible.

2. Optomechanical multipole conversion

We put forward an optomechanical Kerker effect, where strong tunable directionality is achieved for light scattered by a small particle without any magnetic response that trembles in space. The concept is sketched in Fig. 1(a). The incident wave at frequency $\omega$ excites oscillating electric dipole polarization. Trembling of the electric dipole in space with the amplitude $u$ and frequency $\Omega$ induces the loop electric current $j$ with non-zero magnetic momentum $m$ as well as the electric quadrupole (EQ) momentum at the shifted frequencies $\omega \pm \Omega$. Interference of ED and MD+EQ contributions results in unidirectional scattering as shown in Fig. 1(b).

To describe light scattering by trembling objects, we developed a novel theoretical framework that incorporates the effect of the resonant dispersion of the moving medium [4]. We found that the electric dipole $d$, quadrupole $Q$, and magnetic dipole $m$ induced in the vibrating particle at anti-Stokes frequency $\omega' = \omega + \Omega$ are given by

$$
\begin{align*}
  d &= \alpha(\omega') \frac{\epsilon_0}{c^2} (n_0 \cdot u) E_0, \\
  Q &= \alpha(\omega) \left[3E_0 \otimes u + 3u \otimes E_0 - 2I(u \cdot E_0)\right], \\
  m &= \alpha(\omega) \frac{\epsilon_0}{c^2} [E_0 \times u],
\end{align*}
$$

where $E$ and $n_0$ are the electric field and propagation direction of the incident wave, $\alpha(\omega)$ is frequency-dependent particle polarizability, $I$ is the identity matrix, and we supposed $\Omega \ll \omega$. Note that the induced ED is proportional to the polarizability at the scattered light frequency $\alpha(\omega')$, while EQ and MD are determined by $\alpha(\omega)$. Therefore, the frequency dependence of the polarizability can be exploited to tune $d$, $m$, and $Q$ to the Kerker condition.

Figures 2(a)–(e) show the radiation pattern of the light scattered on the particle trembling along the light propagation direction, $u \parallel n_0$. Panel (a) shows the case when $\alpha(\omega') \gg \alpha(\omega)$ and the radiation pattern is a determined by the ED contribution. Panel (b) shows the con tribu-
There are two origins of the effect. The first is the phase difference between the particle polarizabilities at the initial and scattered light frequencies, that can differ strongly. That leads to the emergence of the optomechanical Kerker and spin Hall effects. They result in the asymmetry of the light scattering pattern, which can be quantified by the directivity $D$, which is the ratio of the scattering intensity in the direction of interest and the total scattering intensity. Figure 1(c) shows by color the forward directivity for the case when particle polarizability has a resonance. In the vicinity of the resonance, the polarizabilities $\alpha(\omega)$ and $\alpha(\omega')$ can differ strongly. That leads to the strong forward directivity that can reach 5.25. The directivity of the optomechanical Kerker effect surpasses the limiting value of 3 for the classical Kerker effect, because the EQ contribution is additionally involved [3]. Away from the resonance, polarizabilities $\alpha(\omega)$ and $\alpha(\omega')$ are close, so forward scattering vanishes while backscattering is enhanced.

### 3. Optomechanical spin Hall effect

Due to the interference of the ED and MD emission patterns, the light with opposite circular polarization can be scattered in different directions, which is termed as an optical spin Hall effect [5]. It results in the emergence of the scattered light circular polarization under linearly polarized excitation. We put forward an optomechanical spin Hall effect, i.e., inelastic polarization-dependent directional scattering on a trembling particle.

There are two origins of the effect. The first is the phase difference between the particle polarizabilities at the initial and scattered light frequencies, that can be achieved in the vicinity of a resonance. For such case, the scattered light circular polarization degree is shown by color on the scattering pattern Fig. 2(e), where $\alpha(\omega)$ and $\alpha(\omega')$ are chosen to have $\pi/2$ phase difference. The other possibility is to consider light scattering on a particle trembling around a circular trajectory. Then, as shown in Figs. 2(f)–(i), the light scattered to the left and to the right with respect to the particle motion plane will have opposite circular polarization. If both mechanisms are present, the scattering intensity pattern and the circular polarization pattern turn to be strongly asymmetric, see Fig. 2(j).

### 4. Conclusions

The optomechanical Kerker and spin Hall effects with trembling-induced magnetic response open a pathway to engineer chiral optomechanical coupling at nanoscale, expanding the chiral quantum optics to the optomechanical domain. Our results can be instructive for the design of non-reciprocal topological circuits, where the disorder-robust propagation of light and sound is ensured by the time modulation of optical and mechanical properties [6]. The proposed effects can be implemented in quantum dots and transitional metal dichalcogenide monolayers featuring exciton resonance, cold atomic gases, atomic nuclei probed by Mössbauer $\gamma$-ray spectroscopy, or superconducting resonators for radio-frequency electromagnetic field.

Deciphering, Characterization and Nanocontrol of Single Quantum Dots for Single Photon Emission and Near-field Imaging

Xuewen Chen

School of Physics, Huazhong University of Science and Technology, Wuhan, 430074, China, *corresponding author, E-mail: xuewen_chen@hust.edu.cn

Abstract

Absorption and emission of matter comprise the majority of optical phenomena in our world. Among various kinds of nanoscopic optical emitters, colloidal quantum dots (QDs) have gained great attention due to intense broad-band absorption, tunable narrow-band emission, solution processibility, and compatibility with photonic structures [1]. The ultimate success of the applications crucially relies on the absorption or/and emission properties of QDs at single-dot level. In comparison to a single-molecular emitter, density of states of a QD is usually very large and a QD in the charged states can be quite stable. Consequently, upon photo- or electrical-excitation, a QD is often found in multi-carrier states. Despite impressive progress in chemical synthesis of non-blinking QDs for the past years, charging, blinking, multiexciton generation and emission still generally occur under relatively intense optical excitation, electric bias or imbalanced current injection. In this presentation, we show in-situ deciphering the charging status, and precisely assessing the absorption cross section, and determining the absolute emission quantum yield of mono-exciton and biexciton states for neutral, positively-charged, and negatively-charged single core/shell CdSe/CdS QD [2]. We uncover very different photon statistics of the three charge states in single QD and unambiguously identify their charge sign together with the information of their photoluminescence decay dynamics. In addition, we report on nano-controlled coupling of one colloidal quantum dot to a dielectric nanotip for single-mode outcoupling of the single photons [3]. We demonstrate three-dimensional manipulation of the QD towards precise integration of nanophotonic structures and near-field imaging.

Key Issues in the Rational Design of Plasmonic Nanoparticles for Second Harmonic Generation

Pierre-François Brevet

1Institut Lumière Matière, UMR CNRS 5306 and University Claude Bernard Lyon 1, University of Lyon, Villeurbanne, France
*corresponding author, E-mail: pfrevt@univ-lyon1.fr

Abstract

Second Harmonic Generation from plasmonic nanoparticles requires a delicate balance between material size, shape or morphology for the best performances according to the laser excitation conditions. We investigate all these issues in a first step using available experimental data and then present further avenues to explore using hybrid dielectric – metallic nanoparticles.

1. Introduction

Second harmonic Generation (SHG) is an ideal method to investigate metallic nanoparticles dispersed as liquid suspensions in the absence of any supporting substrate [1]. SHG is indeed a nonlinear optical phenomenon where the symmetry is critical in determining these properties. This process entails the conversion of two photons at a fundamental frequency into one photon at the sum frequency. Involving three photons simultaneously, it obeys strict symmetry rules, in particular the requirement of a non centrosymmetric material medium to mediate the conversion [2]. Hence, substrates supporting nanoparticles naturally break the inherent symmetry of nanoparticles. The removal of the substrates using liquid suspension fully alleviates the problem. Over the recent years, metallic nanoparticles of different sizes and shapes have been investigated thoroughly, especially those with a centrosymmetric shape like nanospheres, nanorods or nanocubes [3]. Understanding the origin of the response in such system is indeed of utmost importance, as it is not expected at first glance that large SHG intensities can be obtained. Besides, an in-depth understanding of the origin of the response may lead to new paradigms for application, as we have shown for sensing [4]. In this work, we first review the problem of size and shape in the design of plasmonic nanoparticles for SHG before proposing new routes in the second part to engineer efficient nanoparticles.

2. Size effects

In designing metallic nanoparticles for SHG, the most simple route is to start with nanospheres of gold or silver and investigate how the SHG intensity scales with the nanoparticle diameter. This operation is achieved using the standard Second Harmonic Scattering (SHS) technique, also known as Hyper Rayleigh Scattering (HRS) [5], where the nanoparticles are monodispersed in an aqueous suspension as a result from their synthesis. The latter is realized directly in solution by the mere reduction of the corresponding metallic salt with a reducing agent [6].

The SHS intensity I collected from a suspension of metallic nanoparticles is given by:

\[ I = G \left( N_S \beta_S^2 + N_{NP} \beta_{NP}^2 \right) I_0^2 \]  

(1)

where \( I_0 \) is the fundamental intensity, \( N_S \) and \( N_{NP} \) the respective concentrations of the solvent molecules and the nanoparticles and \( \beta_S \) and \( \beta_{NP} \) the respective first hyperpolarizabilities of the solvent molecules and the nanoparticles. In Equation (1), \( G \) is a general constant and the brackets stand for an orientational average due to the liquid suspension isotropy. Interestingly, the solvent contribution that is known by other means serves as a ruler to provide absolute values of the quantity \( <\beta_{NP}^2> \). Using this method, the hyperpolarizability of silver and gold nanosphere particles have been measured and reported [7].

In-depth analysis of these data has been rationalized in terms of an extended version of Mie theory where the frequency conversion is also taken into account. Other methods like finite element method (FEM) and surface integral equation (SIE) have also been used [8, 9]. It appears that the scaling of the hyperpolarizability with the ratio \( a/\lambda \) between the nanoparticle radius \( a \) and the fundamental wavelength \( \lambda \) is a power law with exponent three as soon as the electrostatic approximation breaks down. At small sizes, the SHS signal is sensitive to the exact shape of the nanoparticles and in particular their deviation from that of a perfect sphere. The hyperpolarizability scaling in this domain is quadratic with the ratio \( a/\lambda \) with gold nanospherical particles, the change of scaling exponent appears around 50 nm diameter nanoparticles [7].

Beside the hyperpolarizability absolute value measurement, it is also of interest to understand the nature of the SHS response from metallic nanoparticles in order to use these...
features and properties in potential applications. A polarization analysis of the SHS intensity for vertically polarized output as a function for the input polarization angle has yielded the data reported on Figure 1 for 150 nm diameter gold nanoparticles aqueous suspension.

Figure 1 : Polar plot of the Second Harmonic Scattering intensity polarized perpendicularly to the plane of scattering recorded for an aqueous suspension of 150 nm gold nanospheres.

This feature clearly show that an input polarization angle for the fundamental beam at 45° instead of a vertical or horizontal polarization is much more favorable to yield the largest intensity as the response exhibit a strong quadrupolar nature. This feature has been used in devising a new method for sensing [4].

3. Shape effects

Chemical synthesis of metallic nanoparticles has been developed as well to produce other shapes than just spheres. Hence, metallic nanoparticles with shapes of rods, triangles, cubes, ... have been investigated as well. When designing plasmonic nanostructures, it is well known that introducing roughness induces electromagnetic confinements and enhancements. Hence, nanoparticles with tips like nanocubes with their corners present local regions of enhanced SHG response, as it has been shown with FEM or SIE methods [9].

Investigation has been performed on nanocubes for instance albeit in the regime where the scaling of the hyperpolarizability is that with the third power of the $a/A$ ratio. In this size regime, the hyperpolarizability has been shown to be dominated by retardation and therefore avolume scaling. As a result, the role of the nanocube corners is not prominent despite the localized field enhancements.

4. Conclusions and Perspectives

We have discussed two key parameters for the design of plasmonic nanoparticles with the best performance for SHG. It is interesting to note that other parameters are also important, for instance the nature of the metal used. With the size and the shape of the nanoparticles as well as their environment, this will in particular allow for a precise determination of the resonance location, another way to enhance the electromagnetic fields and therefore the performances.

Nevertheless, we pursue other routes where the introduction of hybrid morphologies and hybrid material structures can provide new benefit. In particular, systems where a non centrosymmetric nanocrystals is inserted in a plasmonic nanoshell opens interesting perspectives in this context.

Optical Slot Yagi-Uda Antennas
Yeonsang Park¹*, Jineun Kim¹, Young-Geun Roh¹, Q-Han Park²

Abstract
We present the design of optical slot Yagi-Uda antennas and demonstrate the directional radiation from optical slot Yagi-Uda antennas. By calculating the phase between a feed slot and an auxiliary groove, we can find out parameters where the groove works as a good reflector and fabricate optical slot Yagi-Uda antennas with a good directivity. Through coupling with the optimized optical slot Yagi-Uda antenna, random light from quantum dot light emitting diodes can be directed towards a specific direction well.

1. Introduction
Since the first report in 2005, an optical antenna has been widely studied because of its various physical properties and functionalities [1-4]. Similar to the radio frequency antenna, the optical antenna can transfer electromagnetic energy from one point to another and pick up energy from propagating EM wave at the wavelength of interest efficiently. In 2014, we presented an optical slot antenna made of a metallic nanoslot [5,6]. We experimentally proved that a metallic nanoslot works as a slot antenna in visible region and it can control the direction of radiation like an optical rod Yagi-Uda antenna by adding the auxiliary element of groove. Compared to the optical rod antenna, an optical slot antenna is easier to be combined with light sources because a precise alignment with antennas and emitters is not necessary in fabrication. This means that radiation from light source devices such as LEDs can be coupled with an optical slot Yagi-Uda antenna easily and its direction can be controlled in micro-scale.

2. Design of optical slot Yagi-Uda antennas
Figure 1(a) shows the schematics of our slot-type Yagi-Uda antennas. It is made of a feed slot and an auxiliary groove. Because the resonance wavelength of a slot is dependent on its length [7], we should investigate an optimal antenna length resonant with 614 nm, the wavelength of our interest. By measuring the transmission spectra of slots with various lengths, we obtained the resonance relation of \( \lambda \ (nm) = 1.66 \ l \ (nm) + 314.14 \) (where \( \lambda \) is a resonance wavelength and \( l \) is an antenna length) and chose 180 nm as a slot length. The phase difference between a feed slot and an auxiliary groove provides us a guide line in designing slot Yagi-Uda antennas. Since it is well-known that an optical slot antenna has linear-polarization perpendicular to its length (x-axis in Fig. 1), the y- and z-components of E-field are very weak [5]. Therefore, we can calculate the phase from the Ex-field in structure. Figure 1(b) shows the calculated phase difference while changing the groove length (L) from 100 nm to 400 nm by 50 nm and the distance between a slot and a groove (D) from 100 nm to 300 nm by 50 nm. At the condition of \( \pi/2 \) phase difference, which is shown as the red line in the contour map, we can see that far-field patterns show a directional radiation well.

3. Experimental results
To make sure the feasibility of our design in use of the phase difference, we have measured far-field patterns with various samples with the groove length (L) changed from 100 nm to 240 nm. Figure 2 shows the measured far-field patterns in each sample. While measuring far-field patterns, we have fixed the distance D between a slot and a groove as 120 nm in order to show the role of a groove clearly. We could see that experimental results are very coincident with the calculated phase map. As L gets increased, the groove
changes from a director, which directs toward where a groove is located, to a good reflector, which reflects radiation from a feed slot. In case of sample with L of 240 nm, we could see that far-field pattern shows a good directivity.

Using the above structure with L of 240 nm and D of 120 nm, we controlled the direction of emission from colloidal quantum dot light emitting diodes (CQD-LEDs) [8,9]. On the electrode of LEDs, we have fabricated an optical slot Yagi-Uda antenna made of a slot and a groove as shown in Fig. 3(a). The LEDs have operated well in supplying voltage and showed electroluminescence as shown in Fig 3(b). When only a slot was fabricated on the electrode of LEDs, we could have obtained bidirectional far-field pattern shown in Fig. 3(c). On the contrary, when a slot and a groove, which is an optical slot Yagi-Uda antenna, were fabricated, directional far-field pattern could be measured as like Fig. 3(d).

4. Conclusions

In conclusion, we presented the design of an optical slot Yagi-Uda antenna and that our design is well-coincident with experimental results by measuring far-field patterns with various samples. Additionally, we showed that random light sources can be well-coupled with optical slot Yagi-Uda antennas and its direction can be controlled. We expect that an optical slot Yagi-Uda antenna will be a promising device in the application of 3D display panel, holography, and nanoscale integrated photonic chips for the future.

Flexible metasurfaces in the visible range for imaging and biophotonic applications

Andrea Di Falco

School of Physics and Astronomy, University of St Andrews, North Haugh, St Andrews, KY16 9SS UK
E-mail: adf10@st-andrews.ac.uk

Abstract

We present our recent results on biophotonic applications of flexible photonic metasurfaces in the visible range, including sensing and imaging in microfluidic environments.

1. Introduction

Flexible metasurfaces retain all the potentials of standard metasurfaces while introducing a variety of unique practical features respect to their rigid counterparts [1-4]. For example their fabrication can be scaled up using techniques typical of printed electronic, like roll to roll manufacturing; they can be conformed to target with irregular shapes [5,6], thus relieving the fabrication requirement and/or to transfer a complex photonic response to otherwise dull materials or objects; they can be easily tuned post-fabrication in different ways, thus offering an additional degree of freedom to design advanced photonic behaviors.

Here, after briefly reviewing a possible fabrication pathway, we present our recent results on holographic imaging and sensing applications, and discuss the potential of flexible metasurface for microfluidic based biophotonic applications.

2. Fabrication

Fig. 1 a)-d) shows the typical fabrication procedure for the flexible metasurface [1]. a) A polymer of choice (blue layer) is spun on rigid carrier precoated with a sacrificial lift off layer (red layer). The specific polymer can be chosen to control the thickness of the membranes (typical values go from few tens of nanometers to a few microns) and other physical parameters, like the elasticity or the biocompatibility. A representative example is SU8, a commercially available (Microchem) epoxy based negative resist. In this case the sacrificial layer is also commercially available. In step b) the shape of the membrane is defined lithographically. The form factor is arbitrary and the total area can go from a few square microns to several square cm. Step c) is the definition of meta-atoms, which can be completed using e-beam lithography of metallic or dielectric materials, either with a lift-off or etch-back technique (see also panel e), which shows a scanning electron microscope picture of a typical sample. Step d) is the definition of handles for the all-optical manipulation of the defined metasurfaces in microfluidic environments. It is an optional feature, which can be completed e.g. using the same polymer used for the membrane, with an additional lithographic step. Panel f) shows a completed membrane released in a microfluidic chip. The individual square

![Figure 1 Fabrication protocol: a) the membrane polymer is spun on a sacrificial layer (red); b) the individual membranes are defined; c) the metallic meta-atoms are defined; d) if required, polymeric handles are added, before lift off; e) Example of meta-atoms patterned on flexible metasurfaces. f) Microscope image of a metasurfaces in a microfluidic chip.](image-url)
handles have side equal to 1µm.

3. Results and Discussion

Following the body of work available in literature in holographic metasurfaces, we designed conformable flexible holographic MSs, using a common three layers configuration [7]. Here we show that the shape of the substrate can be considered as an independent degree of freedom to encode the image information, so that an intelligible image can be obtained only if the substrate has a specific, predesigned topology [8].

As second example, we show that flexible metasurfaces can be used as efficient sensors for Surface Enhanced Raman Scattering (SERS). The key advantage of this approach is that a microscopic solid target of interest can be coated with a conformable SERS substrate, rather than resting unevenly on a rigid and flat surface. Here we discuss how this approach can be used for SERS imaging of extended objects.

Finally, we discuss how flexible holographic metasurfaces and SERS enabled metasurfaces can be scaled to convenient sizes and used in a microfluidic environment, where they can be optically manipulated to interact with specimens of interest. In this context, we will discuss the optomechanical properties of the trapped membranes. This approach has the unique advantage of bringing the full potential and versatility of metasurfaces in terms of light control at the interface with cell and single molecules biology.

4. Conclusions

In this communication we will show our recent achievement in the fields of photonic metasurfaces and discussed critically our preliminary results in their suitability for biophotonic applications.

Abstract

Photonic technologies are at the forefront of the ongoing 4th industrial revolution of digitalization supporting applications such as virtual reality, autonomous vehicles, and electronic warfare. The development of integrated photonics in recent years enabled functional devices and circuits through miniaturization. However, fundamental challenges such as the weak light-matter integration have limited silicon and III-V-based devices to millimeter-scale footprints demanding about a million photons-per-bit. Overcoming these challenges, in the first part of this talk we will show how nanoscale photonics together with heterogeneous integration of emerging materials into foundry-based photonic chips leads to the exciting topic of attojoule optoelectronics.

Here we will discuss our recent devices (Fig. 1) demonstrating 100aJ/bit modulators [1], graphene photodetectors [2], and exotic epsilon-near-zero modes [3] empowering record-efficient phase shifters [4] for applications in data-communication, LiDAR, and photonic neural networks (NN) [5,6].

![Figure 1. Overview of recent opto-electronics devices by the Sorger group towards achieving attojoule-per-bit efficiency. All devices use heterogeneous integration of emerging materials into silicon photonics.](image)

We further show that underlying mathematical function of a multiply-accumulate (MAC) of NN’s can be realized photonically; here the nonlinear activation function (threshold) can be achieved through electro-optic modulators [7]. We will discuss power efficiencies and scaling laws of photonic NN’s and show that just 10aC (or 60 electronic carriers) are required if a MAC/1 efficiency of 10^18 is to be achieved (i.e. the goal of the NSF/SRC E2CDA program) [8] (Fig. 2).

With Moore’s law and Dennard scaling now being limited by fundamental physics, optical information processing has reemerged for special-purpose compute systems such as NNs or RF-signal & image filtering. Here unique opportunities exist, for example, given by signal parallelism (e.g. multiplexing) or avoidance of capacitive wire loading, thus opening prospects for distributed non-van Neumann architectures.

In the second part of this talk, we will share our latest examples of photonic chip-based processors to include a) a feedforward fully-connected NN [6] (Fig. 3), b) a convolutional NN processor where convolutions are expressed as multiplications in the Fourier domain (4f) enabling 1 PMAC/s throughputs at nanosecond-short delays for real-time processing with applications in automated target recognition and ranging, c) mirror symmetry perception via coincidence detection of spiking neurons using the leaky-integrate-and-fire protocol [9], and an all-optical photonic neural network [10].

While the former uses silicon and III-V photonics to realize a two-dimensional mapping of photonic connectivity of neurons, the 4f system is a three-dimensional realization of photonic neurons. Using this system, we show demonstrations in edge-detection. Using the system recurrently, however, one can perform convolutional filtering such as image classification through DeepLearning.
Figure 3. A electro-optic modulator’s transfer function can be used to provide nonlinear activation (thresholding) in photonic neurons (here perceptron model). Training a 2-layer NN with 100 nodes each including noise (shot noise from the photodetector), we find a decent accuracy of 96% in inference for the MNIST data set of handwritten digits [7].

In summary, integrated (nano)photonics connects the worlds of electronics and optics, thus enabling new classes of a) attojoule optoelectronics, and b) neuromorphic circuits by employing the distinctive properties of light for parallel processing and order $O(1)$ operations.

Minimal Designs of Lorentz Non-reciprocal Metasurfaces and “Diatomic” Resonator Arrays

Wenyan Wang, Wang Tat Yau, K. F. Lee, Jin Wang, and Kin Hung Fung*

Department of Applied Physics, The Hong Kong Polytechnic University, Hong Kong, China
*corresponding author, E-mail: kin-hung.fung@polyu.edu.hk

Abstract

Compared to reciprocal systems, the designs of Lorentz non-reciprocal metasurfaces and metamaterials require extra complexity associated with many broken symmetries. We provide minimal designs of Lorentz non-reciprocal metasurface and arrays made of simple dimer unit cells. We find that a coupled dipole-monopole theory (with 2x2 matrix) is enough for describing the one-way metasurface.

1. Introduction

Unconventional phenomena could emerge in metamaterials using the internal structural properties of the artificial unit cells. Recently, designs of complex structures made of Lorentz non-reciprocal materials have introduced many new directions to create unusual photonic devices such as isolators, one-way waveguides, and non-reciprocal antennas. Analytical modeling of these complex systems is not trivial and many designs such as topological photonic crystals are bulky. We aim at reducing the thicknesses and sizes of the non-reciprocal metasurfaces and devices while maintaining the simplicity of the structures.

2. Methodology

We use coupled dipole-monopole theory to design a “diatomic” metamolecules consisting of two cylinders with at least one of the cylinders made of gyromagnetic/gyroelectric materials. The functional performance of the metasurface design is also verified numerically using the commercial software COMSOL. Finally, we have used an effective medium theory to describe the metasurface design.

The analytical results are based on coupled dipole-monopole theory, which expands the fields of each cylinders using multiple expansion up to dipoles. The coupled dipole-monopole equations are written as a 2x2 matrix equation in the form as shown below:

\[
\begin{pmatrix}
-b_{y1} & 0 \\
0 & -b_{z1}
\end{pmatrix}

\begin{pmatrix}
L_0 & L_1 \\
L_2 & L_0
\end{pmatrix}

\begin{pmatrix}
\alpha^{-1} \\
\alpha_0^{-1}
\end{pmatrix}

= \begin{pmatrix}
\alpha^{-1} \\
\alpha_0^{-1}
\end{pmatrix}
\]

where a rotating magnetic dipole (m = -1) is coupled to a monopole (m = 0) through long-range dynamic coupling.

3. Results

The schematic of our design is shown in Figure 1(a). The associated numerical and analytical results for the difference in transmittance (\(\Delta T = T_1 - T_2\)) between forward and backward incident waves are shown in Fig. 1(b). Simulated field patterns at one of the peak-dip pair is shown in Fig. 1(c).

![Figure 1: (a) Schematic of Lorentz non-reciprocal “diatomic” metasurface. (b) Transmission difference between forward and backward incident waves. (c) Simulation field patterns for the same case as in (b).](image)

4. Conclusions

We provide a minimal dimer design of Lorentz non-reciprocal metasurface. Such a simple design supports strong asymmetric transmission properties when the incident wave direction is reversed. The results also show an anomalous anti-resonance-like feature in transmittance,
which is associated with Fano resonance effect. Our 2x2 matrix model accurately predicts such an interesting feature.

Optical Pump – Terahertz Probe Spectroscopy of Semiconductor Nanostructures

Hynek Němec* and Petr Kužel

Institute of Physics, Czech Academy of Sciences, Czech Republic
*corresponding author, E-mail: nemec@fzu.cz

Abstract

Charge transport in semiconductor nanostructures can be studied in non-contact way and with sub-picosecond time resolution using optical pump – terahertz probe spectroscopy. Interpretation of the measurements requires a careful description of photonic effects governing the propagation of the optical excitation beam, modelling of the terahertz conductivity of confined charges and consideration of the depolarization field effects. All these issues will be addressed in this paper.

1. Introduction

High-frequency conductivity carries information about the charge transport at short distances. In particular, terahertz frequencies (10^{11} – 10^{15} Hz) probe the transport on nanometer length scales, while they are insensitive to defects acting on the transport on longer distances. Further benefits of the time-resolved terahertz spectroscopy are the non-contact nature of measurements and the sub-picosecond time resolution.

We will examine in detail the processes which have a fundamental impact on the interaction of the probing terahertz radiation with a nanostructure:

- Absorption of the excitation beam generates an initial inhomogeneous distribution of charge carrier density.
- Terahertz radiation inside nanoparticles is screened by depolarization fields induced due to the inherent heterogeneity of investigated structures.
- Charge confinement strongly influences the conduction response function of charges in individual nanoparticles.

Accounting for all these effects permits determination of the mechanism and parameters of the charge transport in the nanoparticles. Such information is important e.g. for the development of photo-voltaic or opto-electronic devices based on semiconductor nanoparticles.

2. Theory

2.1. Propagation of the optical excitation beam

For nanoparticle sizes much smaller than the excitation wavelength, the nanostructured sample can be regarded as an effective medium. The typically small contrast of optical permittivities of nanoparticles and surrounding environment ensures that common effective-medium models like Maxwell-Garnett or Bruggeman are good approximations for effective absorption.

If the nanoparticle size becomes comparable with the wavelength, photonic effects including wave-guiding and interferences become important (Fig. 1). For example, the effective absorption may be resonantly enhanced in an array of regular nanowires (see the peak at 750 nm in Fig. 1c) [1].

![Figure 1: (a) Array of InP nanowires. (b) Distribution of the initial carrier density (=absorbed optical energy) inside a single nanowire upon excitation at 610 nm. (c) Enhancement factor of the effective absorption α_eff/(α_intrinsic) (effective absorption α_eff compared to the intrinsic absorption α_intrinsic of bulk InP taking into account the filling factor s of InP in the nanostructure).](image)

2.2. Depolarization fields

The macroscopic (measured) response is determined by the conductive response of components as well as by their morphology and spatial distribution. In a vast majority of structures, the effective photo-conductivity Δσ simplifies to

$$\Delta \sigma = V \Delta \sigma_{loc} + \frac{B \Delta \sigma_{loc}}{1 + iD \Delta \sigma_{loc} / (\omega \epsilon_0)} ,$$

(1)

where Δσ_{loc} is the microscopic photo-conductivity of the nanostructure (response to the local field), and V, B, and D are constants determined by the morphology of the nanostructure [2]. In percolated structures, B ≪ V, therefore the macroscopic (effective) conductivity is simply proportional to the microscopic one. However, in non-percolated structures, V is equal to 0 and the B-term dominates. In particular, a plasmonic resonance appears at frequencies where the denominator in (1) is small. Variation of Δσ_{loc} by changing the excitation density allows a clear...
distinguishing between percolated and non-percolated structures.

2.3. Terahertz response of confined charges

For semi-classical systems, the mobility of charges can be efficiently calculated using the Kubo formula

$$\mu(f) = \text{Fourier transform of } \frac{1}{k_B T} \langle v(t) v(0) \rangle,$$

(2)

where the velocity autocorrelation $\langle v(t) v(0) \rangle$ is obtained using Monte-Carlo simulations [3]. The spectra of confined non-degenerate electron gas exhibit a broad resonance (Fig. 2). Its peak frequency follows the reciprocal round-trip time in the nanoparticle $v_{\text{therm}}(2d)$, where $d$ is the size of the nanoparticles and $v_{\text{therm}} = \sqrt{\frac{k_B T}{m}}$ is the mean thermal velocity.

A quantum-mechanical formalism is needed for smaller nanoparticles and/or low temperatures where discrete energy transitions are no longer smeared by thermal fluctuations or by scattering (as e.g. for the 32 nm-size nanoparticles in Fig. 2). Although conceptually based on Kubo-Greenwood formula, quantum mechanical calculations in relaxation time approximation have to consider the restoring diffusion current of scattered charges, which emerges as a consequence of broken translational symmetry [4].

![Figure 2: Comparison of quantum-mechanical calculations (solid lines, [4]) and semi-classical Monte-Carlo calculations (dotted lines, [3]) for GaAs nanocubes with various sizes at room temperature. These calculations match perfectly for the micron-sized nanocubes. Discrete quantum transitions become prominent for nanoparticle sizes below 64 nm.](image)

When combining all the processes discussed in Section 2, we are left with just two adjustable parameters: carrier scattering time $\tau_s$ and quantum yield of generated charges $\xi$. A global fit of all the data in Fig. 3 yields $\tau_s \geq 150$ fs (mobility exceeding 3000 cm$^2$V$^{-1}$s$^{-1}$), and $\xi = 65\%$. The former value shows an excellent quality of the nanowires (the mobility is close to the bulk value of 5400 cm$^2$V$^{-1}$s$^{-1}$), while the yield indicates that a significant part of the excitation photons generates immobile (trapped) carriers.

![Figure 3: Transient effective sheet conductivity of an array of InP nanowires photo-excited at 610 nm. Symbols: measurements, lines: calculations. Closed symbols/solid lines: real part, open symbols/dashed lines: imaginary part (after [1]).](image)

4. Conclusions

Time-resolved terahertz spectroscopy allows non-contact measurement of conductivity with sub-picosecond time resolution. A careful description of processes governing the interaction of the terahertz beam with the photo-excited nanostructure made it possible to determine the charge transport mechanism and its parameters.

Mid IR Dirac-cone dispersion relation
materialized in SOI photonic crystal slabs

Abstract
We materialized the isotropic Dirac-cone dispersion relation in the mid infrared range by electron beam lithography of SOI (silicon-on-insulator) wafers. The dispersion relation was examined by the angle-resolved reflection spectra, which showed a good agreement with numerical calculation and the selection rule derived from the symmetry of Dirac-cone modes.

1. Introduction
The linear dispersion relation on the Γ point of the first Brillouin zone in periodic structures was first materialized in microwave frequencies [1-3], which is known as the CRLH (composite right/left handed) transmission line. Later, the theory was extended to more general cases and higher dimensions by the tight-binding approximation [4,5] and the k-p perturbation theory [6,7]. For highly symmetric periodic structures, we can materialize the isotropic linear dispersion, which is called Dirac cone (Fig. 1). Because the Dirac cone dispersion relation is purely a consequence of the accidental degeneracy of two eigenmodes with certain combinations of their spatial symmetries, we can expect the formation of the Dirac cone dispersion in other wave systems like phonons [6] and electrons [8] as well. Because the effective refractive index is vanishing at the Dirac point frequency, ωD (See Fig. 1), we can expect curious phenomena and their applications like tunneling through sharp bends and cloaking [9].

When the constituent eigenmodes of the Dirac cone have a finite lifetime due to diffraction loss, etc., the linear dispersion is distorted and the group velocity calculated from the slope of the dispersion curve exceeds the speed of light [10,11]. The amount of the distortion is governed by the quality factor of the Dirac-cone mode. To check and examine the linearity of the Dirac cone dispersion relation, we fabricated photonic crystal (PhC) slabs in the mid infrared range by electron beam lithography of SOI wafers. In this presentation, we report on their design, fabrication, characterization, selection rule for angle-resolved reflection, and dispersion relation.

2. Sample fabrication
We fabricated PhC slabs in SOI wafers with a 400 nm-thick top Si layer. Figure 2 shows their photo and SEM images. The PhC slabs consisted of a square array of circular air cylinders with a typical depth of 210 nm. The radius of the air cylinder ranged from 440 to 620 nm. The lattice constant of the PhC was 2.27 µm. These structural parameters were designed by the calculation of the dispersion relation by the finite element method with the perfectly-matched-layer (PML) absorbing boundary condition.

(a)

(b)

(c)

Fig. 2 (a) Photo and (b), (c) SEM images of PhC slabs fabricated in the SOI wafer.
3. Angle-resolved reflection

We examined the dispersion relation by measuring the angle-resolved reflection spectra of the specimens. To obtain a sufficiently high angle resolution, we fabricated a home-made optical system in the sample chamber of a commercial FT-IR spectrometer (Fig. 3). The optical system materialized a non-focused and polarized incident beam onto the specimen at small incident angles. The angle resolution was estimated at 0.3 deg.

Figure 4 shows the spectra measured for a specimen whose dispersion was closest to the Dirac cone dispersion, which have several peculiar features. (1) Two linear dispersions due to the Dirac cone cross each other around 2630 cm⁻¹. (2) In addition to the Dirac cone, there is a flat band (quadratic dispersion surface) as predicted by the k-p perturbation theory. (3) All modes including a nearby A₁-symmetric mode show their own selection rules with respect to the tilt direction and polarization of the incident beam. In addition, A₁-symmetric mode is inactive to an incident beam from the normal direction, so that its reflection peak disappears at an incident angle of 0 deg. These features also agree well with the dispersion relation calculated by the finite element method, which is shown in Fig. 5.

![Image](a) IR Spectrometer (JASCO FT/IR-6800) and (b) the home-made optics fabricated in the sample chamber.

![Image](a) Angle-resolved reflection spectra measured for a specimen tilted to (a) the Γ-to M direction and (b) the Γ-to X direction. The upper and lower panels are for the s and p polarizations, respectively. DC, FB, and A₁ denote the reflection peaks of the Dirac cone, the flat band, and an A₁-symmetric mode. The spectra were measured for the incident angle of -1 to 1 deg.

![Image](b) The dispersion relation of the PhC slab specimen calculated by the finite element method with the PML absorbing boundary condition. M/10 denotes that the horizontal axis is magnified by 10 times.

4. Conclusions

We successfully fabricated PhC slabs by electron beam lithography of SOI wafers that materialized the Dirac cone dispersion relation in the mid infrared range, which was confirmed by the angle-resolved reflection spectra measured by the home-made optics that attained a high angle resolution of 0.3 deg. The observed spectra agreed quite well with the dispersion relation calculated by the finite element method and the selection rules due to the spatial symmetry of eigenmodes. The Dirac cone dispersion thus materialized may find applications such as cloaking and beam shaping.

Abstract

We present and demonstrate the concept of a helical travelling-wave nanoantenna (HTN) consisting of a tiny gold-coated helix end-fired with a rectangular aperture nanoantenna. The resulting non-resonant nano-antenna produces a background-free directional light beam of tunable polarization and intensity by swirling surface plasmons and taking advantage of optical spin-orbit interaction. Taken as individual or coupled nanostructures, HTNs lead to subwavelength polarization optics which provide new degrees of freedom in light polarization control.

1. Introduction

A wide variety of optical applications and techniques demand control of light polarization. Manipulation of light polarization has recently experienced extraordinary advances with the emergence of plasmonics, leading to the concepts of polarization meta-optics [1-4]. However, all the structures developed so far rely on collective optical effects on arrays of nanostructures. They are therefore restricted to areas much larger than the wavelength of light, which limits design strategies in polarization control. Tailoring light with individual subwavelength devices would overcome limits but it remains a challenge [5,6].

On the basis of spin-orbit interaction of light [7], we have generated a helical travelling-wave nanoantenna to produce directional light beam of tunable polarization through a swirling plasmonic effect. Our optical nanoantenna differs from existing helical plasmonic structures [1,8] by its non-resonant nature, thus extending the concept of helical travelling-wave antenna to optics [9]. Four closely packed HTNs are shown to locally convert an incoming light beam into four beams of tunable polarizations and intensities. Moreover, by coupling HTNs of opposite handedness, we demonstrated a subwavelength waveplate-like structure providing a degree of freedom in polarization control that is forbidden with usual polarization optics and metamaterials.

2. Results and discussion

The HTN consists of a narrow gold-coated wire wound up in a screw-like shape forming a tiny helix (Fig. 1a). The gold-coated wire sustains a cutoff-free axially symmetric surface plasmon (SP), known as the TM₀ mode. It is locally excited with the dipolar mode of a rectangular aperture nanoantenna that perforates a 100 nm thick gold layer right at the helix pedestal. An incident wave on the back of the aperture is transmitted as a subdiffraction guided SP, which is non-radiatively converted into the wire mode of the helix. The nanoscale wire mode is non-resonantly converted into the helix-guided mode spreading over the overall structure cross-section and propagating along the helix axis. In the course of propagation, the helix-guided mode acquires OAM oriented along the helix axis (0z).

Figure 1: (a) Schematics of the HTN and its operation principle. (b) Spectra of the ellipticity factor and DOCP of the HTN output beam. They reveal the tunable polarization properties of the nanoantenna. (c) Radiation pattern of the HTN in the polar angle θ measured in two orthogonal
longitudinal planes (x0z) and (y0z) defined in the figure inset.

When circular polarization is generated by a HTN, a vortex guided mode (of charge ±1 depending on the helix handedness) is released as freely propagating waves carrying SAM of ±1 per photon (in h units). A HTN designed to operate as a circular polarizer at \( \lambda = 1.5 \mu m \) has been predicted to radiate light with a polarization ellipticity and a degree of circular polarization peaking at 0.97 and 0.999, respectively (Fig. 1b). The polarization can be tuned either by tuning the operation wavelength or by modifying the geometrical parameters of the helix. The waveguiding properties of the plasmonic helix allows for producing directional beam: our nanoantenna of \( \lambda/3 \) lateral size produces an emission pattern whose full width at half-maximum approaches 55° (Fig. 1c)).

The antennas were fabricated by combining focused-ion-beam-induced deposition, metal coating and focused ion beam milling. Fig. 2(a) shows a scanning electron micrograph of a resulting structure. The HTNs were back-illuminated with polarized light from a tunable laser at telecommunication wavelengths, the nanoantenna output beams were measured and their polarization states were analysed with a rotating linear polarizer. The observed polarization properties (Fig. 2b) agree well with the theoretical model, with an ellipticity factor peaking at 0.97.

![Figure 2](image)

**Figure 2:** (a) Scanning electron micrograph of a fabricated HTN. (b) Experimental polarization diagram of the HTN at \( \lambda = 1.64 \mu m \).

First, we showed that HTNs arranged at will on a surface locally convert an incoming light beam into an arbitrary distribution of directional beams of tunable polarizations and intensities. Different polarization states are here imparted to the output beams in a controllable and tunable way. Second, by near-field coupling four HTNs of opposite handedness, we obtained a subwavelength waveplate-like structure providing a degree of freedom in polarization control that is forbidden with ordinary polarization optics and current metamaterials (i.e., devices utilizing or artificially reproducing birefringence and dichroism).

### 3. Conclusions

Relying on spin-orbit interaction of light, HTNs lead to ultracompact, versatile and robust individual components for manipulating light polarization on the subwavelength scale. They provide functionalities in light polarization control that have never previously been demonstrated. Taken as individual or coupled nanostructures, such nanoantennas may pave the way towards highly integrated polarization-encoded optics, particularly for the generation and control of spin-encoded photon qubits in quantum information and opto-spintronics. More generally, our results lay a solid basis for subwavelength polarization optics, thus opening new perspectives in photonic information processing, polarimetry, miniaturized displays, optomagnetic data storage, microscopy, sensing and communications, etc.

Abstract

Plasmonic nanocones offer strong, highly localized near-fields at the cone apex that can be utilized for applications in microscopy and sensing. However, the tip mode can only be excited by electric field components parallel to the cone axis. To enable the excitation of the tip mode under vertical illumination, tilted cones are fabricated. Their linear optical properties are investigated and simulated, and their nonlinear optical properties are illustrated by second harmonic imaging.

1. Introduction

Near-field enhancement and confinement of the electric field of electromagnetic waves are promising features in plasmonics and nano-photonics. Therefore specially designed optical antennas are needed, which have broad applications, for example in surface-enhanced Raman spectroscopy or single molecule detection [1,2]. Nanocones are well-suited for such applications as they can easily be fabricated and have a very sharp tip with a radius smaller than 10 nm [3]. For an efficient plasmon excitation along the vertical axis the electric field vector of the exciting external electromagnetic wave should have a significant component parallel to the vertical axis [4]. This is only the case for certain laser modes or the illumination of the cones from the side. Therefore the excitation of many cone tips at once under vertical incidence is not possible. If the electric field is oriented perpendicular to the cone axis, no excitation of the tip will take place [3]. But for many potential applications it would be beneficial if the electric field of the light was enhanced at the tips of many cones simultaneously.

It was recently shown that this difficulty can be circumvented by breaking the symmetry of the nanocone. In one case, wing protrusions were added on one side of the cone bases, leading to a conversion of the in-plane excitation of plasmons in the winged base to an excitation of tip plasmons through the asymmetric geometry [5]. This approach was further pursued through the investigation of randomly distributed tilted nanopillars, whose axes were forming defined angles with the substrate plane [6,7].

2. Discussion

In the present work we introduce two strategies for the fabrication of gold nanocones with a pre-defined tilt of the cone axis [8]. In the first process, circular oxide nanodiscs are prepared as hard masks on top of a gold film by electron beam lithography and a lift-off. The masks are subsequently transferred into the gold layer by argon ion milling, where the substrate is tilted relative to the ion beam by the amount of the tilting angle. In the second process, electron beam lithography is performed under an angle, such that the resulting nanoholes in the resist are tilted relative to the substrate. Afterwards, metal is evaporated under the same tilting angle, leading to tilted nanocones remaining on the surface after the lift-off. Examples of a symmetric vertical vs. an asymmetric tilted nanocone are shown in Figure 1.

Figure 1: (left) vertical gold nanocone, tilting angle 0°; (right) tilted gold nanocone.

The asymmetric geometry supports the transformation of a transversal (parallel to the substrate) electric far-field to a longitudinal (perpendicular to the substrate) plasmonic excitation. Extinction spectra obtained by transmission spectroscopy and corresponding simulations will be shown, in which cones with a variety of tilting angles are illuminated under a variety of illumination angles, thus systematically changing the ratio of the electric field components oriented parallel vs. perpendicular to the respective cone axes. Furthermore second harmonic generation microscopy of tilted cones will be shown. The cones are scanned through tightly focused radially or
azimuthally polarized cylindrical vector beams (CVBs), and for each relative position between the cone and focus center the second harmonic intensity generated by the interaction is recorded. The expected simulated results are shown in Figure 2 and will be discussed in comparison with the corresponding experiments [8].

3. Conclusions

Two processes for the nanofabrication of tilted gold nanocones with defined tip displacements are presented. Under vertical illumination, plasmon resonances are excited in the base plane of the nanocones, as is also observed for symmetrical nanocones. In contrast to symmetrical cones, the symmetry breaking leads to a conversion of the base mode into a tip mode, such that an enhanced near-field can be observed at the tip apex even under vertical illumination. These findings are confirmed by the nonlinear optical properties observed in second harmonic imaging of the nanocones gained by scanning through radially and azimuthally polarized focused cylindrical vector beams.

Bismuth-based Metasurfaces for Nanophotonics
from the Ultraviolet to the Far Infrared

Johann Toudert¹, and Rosalia Serna¹

¹Laser Processing Group, Instituto de Óptica, IO-CSIC, Madrid, Spain
*corresponding authors, E-mails: johann.toudert@gmail.com; rosalia.serna@csic.es

Abstract

Bi-based nanostructures show outstanding optical properties making them ideal building blocks for the fabrication of metasurfaces with tunable response over a broad spectral region, from the ultraviolet to the far infrared. We will report the design, fabrication, and relevant optical properties of Bi-based metasurfaces. We will show how their optical absorption, reflection and phase can be tuned using planar optical cavity designs. The impact of the proposed optical structures for applications in several areas of nanophotonics will be discussed.

1. Introduction

Bismuth-based nanostructures (consisting of bismuth, Bi, or one of its chalcogenides, BiₓSbTe, BiₓSbSe or BiₓSbTeₓSeₙ) are promising candidates for applications in nanophotonics in a broad range from the ultraviolet to the far infrared.¹²⁴ The peculiar electronic structure of Bi and its chalcogenides is characterized by giant near-infrared optical transitions that make their dielectric permittivity values turn negative in the ultraviolet-visible, and their refractive index values turn giant in the mid-to-far infrared.¹ These remarkable features make Bi-based nanostructures prone to display epsilon-near-zero and interband plasmonic properties in the ultraviolet-visible range,¹²³ and to enable a markedly-subwavelength dielectric confinement in the mid-to-far infrared range.¹⁴ This opens the way to a broad range of applications in areas such as photocatalysis, color generation, optical data encryption, switchable plasmonics and photonics, thermal photonics.

Getting the best from Bi-based nanostructures for such applications will undoubtedly require using them as the building blocks of metasurfaces in which their individual responses will be coupled or hybridized to enable enhanced optical effects. In this presentation, we will report the design, fabrication, and optical response of different types of Bi-based metasurfaces showing tunable optical properties (absorption, reflection, phase) in the ultraviolet-visible and mid-to-far infrared and discuss their potential for nanophotonic applications.

2. Results

2.1. Optical properties of Bi and its chalcogenides: bulk and nanostructures

Only very recently the bulk optical properties of Bi and its chalcogenides have been characterized accurately.²⁴ Bi presents a negative dielectric permittivity (εᵣ < 0) in the ultraviolet-visible, with an epsilon-near-zero response in the ultraviolet, and a giant refractive index (n ≈ 10) and small extinction coefficient (k ≈ 1) from the mid to the far infrared.¹⁴ The optical properties of Bi chalcogenides, while sharing common features with those of pure Bi, can be additionally tailored by compositional tuning.² In this work we will discuss the role of electronic and optical confinement on the optical properties of nanostructures of Bi and its chalcogenides.

2.2. Bi-based metasurfaces for ultraviolet-visible nanophotonics

Two approaches to achieve Bi-based metasurfaces with tunable optical properties in the ultraviolet-visible will be considered. First, we will focus on metasurface designs combining the interband plasmonic resonances of 3d-confined Bi nanostructures (such as nanospheres or nanospheroids) with the photonic modes of a planar optical cavity. Such hybridization enables tuning in a flexible way the optical absorption in the nanostructures, and to achieve optical darkness and phase singularities.³ Second, we will consider metasurface designs where an ultrathin Bi film is integrated into a planar optical cavity and evaluate their optical absorption properties.⁶

2.3. Bi-based metasurfaces for mid-to-far infrared nanophotonics

We will show how to achieve resonant perfect absorption in Bi-based metasurfaces, at a wavelength tunable in the whole mid-to-far infrared from 3 μm to 20 μm. Perfect absorption can be targeted by harnessing the lossy Mie dielectric resonances of 3d-confined Bi nanostructures, or by integrating a very thin Bi film into a planar optical cavity. We will focus on this second approach, and demonstrate the perfect absorption of infrared light in a sub - λ/100 Bi nanofilm. The absorption wavelength is tunable by simply
varying film thicknesses. The remarkable simplicity, tunability and compactness of the proposed perfect absorber design is enabled by an extraordinary fractal optical interference mechanism that operates thanks to the already mentioned giant infrared refractive index and small extinction coefficient of Bi.⁷

3. Discussion

Bismuth-based metasurfaces in view of their outstanding optical properties are suitable for a wide range of nanophotonic applications. In particular:

- The tunable ultraviolet-visible optical absorption and small thickness of Bi-based metasurfaces is promising for photocatalysis and color generation. Optical darkness and phase singularities are interesting for optical data encryption.

- Achieving a tunable resonant perfect absorption of light in the mid-to-far infrared is appealing for thermal photonics.

- Bi is a phase-change material, with a significant optical contrast between its solid and liquid phase.⁸ This property is appealing for applications in switchable plasmonics and photonics.

4. Conclusions

The outstanding optical properties of Bi and its chalcogenides make Bi-based nanostructures excellent building blocks for metasurfaces with tunable response over a broad spectral range from the ultraviolet to the far infrared. This tunability is enabled by optical phenomena that do not take place in standalone nanostructures but occur when the nanostructures are part of a metasurface, such as hybrid interband plasmonic-photonic modes or fractal optical interference. Such optical phenomena and the tunability they imply are relevant for applications including photocatalysis, color generation and optical data encryption, switchable plasmonics and photonics, and thermal photonics.

Abstract

Determining the molecular orientation at the single molecule level is of key importance for a wide range of applications ranging from molecular electronic devices to biomedical applications. In a first instance, plasmonic nano-gaps formed between a spherical nanoparticles and a metallic film were optimized for single molecule Surface Enhanced Raman Scattering (SERS) spectroscopy. Finite Difference Time Domain (FDTD) simulations were performed to complement the experimental measurements, highlighting the complex interplay between the excitation enhancement and the emission enhancement of the system as a function of particle size.

Using the optimized geometry, single molecule SERS was performed on both a small molecule, rhodamine 6G and single chains of the PF-based conjugated co-polymer, F8-PFB. The anisotropy of the field enhancement in the nano-gap was used in conjunction with Density Functional Theory (DFT) to recover the orientation of the single molecule of each analyte, rhodamine 6G and F8-PFB, within the plasmonic nano-gap.

1. Introduction

Plasmonic technology, referring to the study of specific surface electromagnetic waves resulting from the coupling of photons and collective electron oscillations in metals, has seen a rapidly increasing interest over the past two decades. Combining key advantages directly linked to their nature, such as high field confinement, strong field enhancement, with polarisation and spectral selectivity, plasmonic systems promise many applications encompassing bio- and chemical sensing, signal manipulation and guiding on subwavelength scales. Figure 1: Recovering the molecular orientation in plasmonic nano-gaps. a) Schematics of sample geometry. b) Single molecule SERS spectra showing different peaks with different enhancements. c) 3D molecular structure and orientation of single molecule inside nano-gap [1]
scales, and extend to include photonic devices with enhanced performances, such as photodetectors, solar cells and light emitting diodes.

By bringing metallic nanostructures in close proximity to one another it is possible to generate highly confined regions of electromagnetic field arising from the hybridization of plasmon modes. The so-called nanoparticle on a mirror (NPoM) geometry, formed between a nanoparticle and a metallic film, allows for the simple fabrication of plasmonic nano-gaps giving rise to strong field enhancement and confinement that can be used to enhance light matter interactions. Here we present the use of NPoM systems for single molecule SERS, allowing to recover the molecular orientation.

2. Experimental procedure

Plasmonic nano-gaps were fabricated by coupling an extended silver film with spherical silver nanoparticles with a dielectric spacer containing the analyte molecules. A 100 nm thick silver film was thermally evaporated on top of a glass substrate. In the case of rhodamine 6G, a 5 nm spacer layer was spin coated from a 1 mg mL$^{-1}$ solution of a Zeonex polymer matrix in chloroform doped with the molecular dye rhodamine 6G in concentrations ranging from $5 \times 10^{-5}$ M to $2 \times 10^{-7}$ M.

For the chain of F8:PFB, the polymer itself ($M_\text{w} = 355$ kDa and 0.95:0.05 F8:PFB) was dissolved in toluene at concentrations ranging between $2.8 \times 10^3$ M to $2.8 \times 10^{-10}$ M ([2] and [3]) and deposited via spin coating was spin coated at different concentrations onto the silver film. The conjugated polymer F8-PFB.

3. Discussion

The effect of near-field enhancement and photon scattering efficiency to the far-field on the SERS signal have been investigated theoretically and experimentally as a function of the plasmonic particle size. Concentration dependent SERS measurements highlight the single molecule sensitivity of the optimized nano-gap geometry.

Using the optimized geometry, single molecule SERS is performed on both a small molecule, rhodamine 6G [1] and a single chain of the PF-based conjugated co-polymer, F8-PFB. It was observed that, in the single molecule regime, the same molecular species yielded different SERS spectra from nano-gap to nano-gap. This is linked to the well-defined field enhancement direction in the nano-gaps which preferentially enhances the Raman modes with a tensor component along the field enhancement. In the case of many molecules, this anisotropy is usually averaged out by the random orientation of each molecule. However, in the case of a single molecule, the anisotropy results in a different enhancement of the various Raman modes, leading to a SERS spectrum which is dependent on the molecular orientation.

Using this anisotropy of the field enhancement in the nano-gap, in conjunction with a DFT analysis of the Raman tensor for each Raman mode, it is possible to recover the orientation of the single molecule within the plasmonic nano-gap.

Conclusion

In this work we demonstrated the capability of the simple nanoparticle on a mirror nano-gap geometry to reach single molecule SERS levels. By correlating the single molecule SERS spectra, which reflect the single molecule orientation with respect to the anisotropic field enhancement within plasmonic nano-gaps, with the Raman mode tensors calculated by DFT, we were able to recover the orientation of single molecule inside the nano-gap. We showed this approach to work on both small molecules (rhodamine 6G) and longer polymer chains (F8-PFB). By correlating with Density Functional Theory (DFT) calculations, it was used to determine the orientation of the molecule.

Abstract

Cellulose is the most abundant polymer on Earth and for centuries has had a wide technological impact in areas such as textile, packaging or knowledge storage. It is low cost and biodegradable, and possesses excellent mechanical characteristics that have raised the interest of many engineering fields. The versatility of cellulose has recently opened new venues [1] in advanced materials in electronics, energy and biomedical applications. In this work, we combine hydroxypropyl cellulose (HPC), a water soluble and biodegradable cellulose derivate, with nanoimprinting lithography (NIL), the most promising method for mass-produced inexpensive nanostructures over large areas and with a very low density of defects. Particularly, I will show all-green advanced nanofabrication processes, achievable when using the cellulose derivative as water soluble sacrificial layer [2].

Using HPC as NIL resist we are able to pattern silicon wafers or fabricate metallic nanoparticle arrays in a straight forward process that requires only water as solvent. Furthermore, HPC can be alternatively stacked with traditional resists such as Poly(methyl methacrylate), where one of the two materials can be selectively removed by developing in orthogonal solvents. This capability becomes even more interesting by including nanoimprinted layers in the stack, leading to the encapsulation of arrays of air features in the resist.

HPC solutions in water can be also processed in order to obtain thick free standing membranes that can be used as support layer for transfer printing of nanostructured metal electrodes. The cellulose membranes in fact serves as actual adhesive, allowing us to pick and place thin metallic film from patterned silicon substrate to active devices, obtaining simultaneously the metallic contact and the encapsulation layer.

Furthermore, if necessary, the HPC layer can be eventually dissolved in water, leaving only metallic pattern printed on a target substrate. Interestingly, by simply reiterating this process it is possible to fabricate novel 3D structures made of stacked nanopatterned metallic films that present intense plasmonic resonances and exotic optical properties.

Abstract
We analyse the dynamics of the exciton-polaritons interacting with sound waves propagating in the system. The polaritons are excited by coherent optical pump. The stationary polariton states are found and their stability is examined by solving the corresponding spectral problem and by direct numerical simulations. It is found that the interaction with the acoustic waves can destabilize the polariton condensates. The nonlinear stage of the instability is studied by numerical simulations. A simple theory describing the stationary hybrid acousto-polariton states are developed.

1. Introduction
Complex many-body interactions play an important role in the dynamics of condensed matter systems. One of the very interesting phenomena intensively studied in recent years is Bose-Einstein condensation of the polaritons in semiconductor microcavities [1]. The temperature of the condensate is extraordinary high because of the very low mass and strong mutual interactions of the hybrid light-matter excitations appearing in the strong coupling regime between the excitons and phonons. It was demonstrated that the spectrum of the elementary excitations in such systems is of Bogolubov kind and thus the coherent polariton states demonstrate the effect of superfluidity [2, 3]. The coupling of the polaritons to other quasi particles makes the behaviour of the systems even more complicated. For example, the polariton-electron interaction can lead to polariton lasing [4] and to the transition to a superconducting regime [5]. Another important example is the interaction between polariton and phonons [6]. In has been reported that this interactions give rise to such phenomena as the formation of hybrid exciton-acoustopolaritons [7], polariton Bloch oscillations [8] and the condensation of the polaritons in the periodic potential produced by the standing acoustic waves [9, 10].

The present paper is devoted to the resonant interactions between the polaritons and the phonons in one-dimensional cavity excited by a laser beam. To describe the mutual dynamics of the polaritons and the acoustic waves we adopt the model reported in [7, 11] which in dimensionless units can be written in the form

\[
\partial_t \Psi = \left[i \delta + \frac{i}{2} \partial_x^2 - igU - i\alpha |\Psi|^2 - \gamma \right] \Psi + Pe^{i\kappa x}, \quad (1)
\]
\[
\partial_t^2 U + \Gamma U - \partial_x^2 U = g\partial_x^2 |\Psi|^2. \quad (2)
\]

The complex field \(\Psi\) is the order parameter function describing the polariton condensate, the real field \(U\) describes the acoustic wave, \(\delta\) is the detuning of the pump from the cavity resonance, \(\kappa\) characterises the phase gradient of the pump, \(\gamma\) and \(\Gamma\) account for the losses in the polariton and the phonon systems, \(P\) is the amplitude of the external coherent pump, \(g\) is the parameter describing the strength of polariton-phonon interaction, \(\alpha\) is the coefficient accounting for nonlinear polariton-phonon interaction. Let us remark that the polaritons are described under the assumption that the upper polariton branch does not contribute to the polariton dynamics and the lower polariton branch can be approximated by a parabola. We assume that the geometry is annular and thus the boundary conditions are periodic.

The complex field \(\Psi\) is the order parameter function describing the polariton condensate, the real field \(U\) describes the acoustic wave, \(\delta\) is the detuning of the pump from the cavity resonance, \(\kappa\) characterises the phase gradient of the pump, \(\gamma\) and \(\Gamma\) account for the losses in the polariton and the phonon systems, \(P\) is the amplitude of the external coherent pump, \(g\) is the parameter describing the strength of polariton-phonon interaction, \(\alpha\) is the coefficient accounting for nonlinear polariton-phonon interaction. Let us remark that the polaritons are described under the assumption that the upper polariton branch does not contribute to the polariton dynamics and the lower polariton branch can be approximated by a parabola. We assume that the geometry is annular and thus the boundary conditions are periodic.

2. The results
It is easy to see that the system in question has a solution with zero acoustic component \(U = 0\). The polariton component \(\Psi_0\) is spatially uniform and its amplitude is defined by the amplitude of the pump. For the absolute value of \(\Psi_0\) it is easy to obtain \(|P| = \sqrt{\delta + \alpha |\Psi_0|^2 + \gamma^2 |\Psi_0|^2}\). The polariton state can be bistable, for the repelling polariton-phonon interaction the upper branch of the bifurcation diagram is stable, the intermediate is unstable and the stability of the lower branch depends on the value of the losses in the system. Our goal is to study how the stability is affected by the interaction with phonons. To analyse the problem we will look for a solution in the form \(\Psi = \Psi_0 + \psi\) where \(\psi\) is a small correction. The equations for \(\psi\) and \(U\) are then linear with the coefficients independent on the space and time. Looking for a solution in the form of plane waves we obtain the dispersion relation for the frequency \(\omega\) and the wave vector of the linear excitations

\[
\omega + \sqrt{k^2 - \frac{\Gamma}{4} + \frac{i\Gamma}{2}} = \sqrt{k^2 - \frac{\Gamma}{4} + \frac{i\Gamma}{2}}, \quad (3)
\]

where \(D = \sqrt{(\mu + 3\alpha |\Psi_0|^2 - \frac{k^2}{2})(\mu + \alpha |\Psi_0|^2 - \frac{k^2}{2})}\) and \(\mu = \frac{\delta - \alpha^2}{2}\).

For arbitrary set of parameters the solutions of the dispersive equation (3) can be found only numerically. However assuming that the polariton-phonon interaction constant \(g\) is small the equation can be solved by perturbation
method. The interaction is the strongest in the vicinity of the resonances where the phase matching condition is met. The perturbation analysis shows that some of the resonances lead to the splitting of the dispersion characteristics but the other resonances produce instability.

The instabilities predicted by the spectral analysis have been checked against direct numerical simulations. The comparison has shown that the analytical predictions fit the observed spectra very well, see Fig. 1. The more complex nonlinear regimes were studied by extensive numerical simulations but the lack of space does not allow to discuss them in this summary.

3. Conclusion

It was shown that the interaction between the polaritons and the phonons can result in the instability leading to the emission of the phonons and to the down conversion of the frequency of the polaritons. The process can be cascaded which causes a complex, possibly chaotic behaviour of the hybrid acousto-polariton state. A simpler quasi monochromatics mixed states can be effectively analysed by perturbation theory. The discovered effect can be used for the generation of coherent phonons (phonon laser) and possibly for multi-frequency polariton lasers.

Abstract

In this presentation we show how to achieve an extreme control over the energy deposited in plasmonic systems with femtosecond laser pulses to induce predictable changes in temperature and in turn, in the morphology of gold nanoparticles. We demonstrate that there exists a laser fluence window that combined with the appropriate concentration of the organic surfactant hexadecyltrimethylammonium (CTAB) leads to a gentle multishot modification of the nanorods to a stable situation at which the nanorod aspect ratio is the same for all the nanorods. The result is an ensemble of optically identical nanorods with unprecedented properties.

1. Introduction

The interaction between electromagnetic radiation and the conduction electrons of metals leads to a collective oscillation of these electrons in resonance with the incoming radiation [1]. This effect is known as localized surface plasmon resonance (LSPR) when it is spatially confined in a metal nanostructure (or a nanocavity). The LSPR can concentrate a huge amount of electromagnetic energy in nanometric volumes, offering the maximum possible spatial and temporal control over light [2]. LSPRs decay through re-emission of a photon, creating very energetic electrons and holes (hot carrier emission) and by collisional processes that lead to plasmon decoherence and subsequent carrier thermalization [3]. Equilibration with the atomic lattice takes place by energy transfer through electron-phonon mechanisms, which in addition to balance of the hot carrier emission can lead to a dramatic temperature increase in a nanometric volume within an otherwise cold medium. This released heat is detrimental for most plasmonic devices, but recent studies indicate that it can be used to catalyze chemical reactions [4] or modify structures at the nanometer scale [5-7].

We show in this presentation that irradiation of gold nanorod colloids with a femtosecond laser can be tuned to induce controlled nanorod reshaping, yielding colloids with unprecedentedly narrow localized surface plasmon resonance bands [7]. The process relies on a regime characterized by a gentle multi-shot reduction of the aspect ratio, whereas the rod shape and volume are barely affected. Successful reshaping can only occur within a narrow heat dissipation rate window, i.e. low cooling rates lead to drastic morphological changes and fast cooling has nearly no effect. Hence, a delicate balance must be achieved between irradiation fluence and surface density of the surfactant. This perfection process is appealing because it provides a simple, fast, reproducible and scalable route toward gold nanorods with an optical response of exceptional quality, near the theoretical limit.

2. Methods

We irradiated gold nanorods (Figure 1) with the LSPR at 800 nm with 50 fs laser pulses provided by a Ti:sapphire laser. The repetition rate was 1 kHz and the laser fluence varied from 3.2 to 5.1 J/m². The nanorod dispersion had a concentration of 1 nM and was synthesized by the seeded growth method. The CTAB concentration was varied around the critical micelle concentration (cmc) of CTAB (1 mM). Transmission optical measurements were carried out during the measurements thanks to an in-situ characterization set up (Figure 1).

We carried out sophisticated computational simulations to understand the results. (i) Optical simulation with a FDTD method to determine the energy absorbed per nanorod as a function of the laser fluence and nanorod orientation. (ii) Molecular dynamics (MD) ignoring the CTAB molecules and the surrounding aqueous medium. The temperature in this case was fixed to simulate the energy absorbed by the nanoparticle and the subsequent evolution to the medium was included with a Langevin term using different
characteristic decay times. The MD results helped to understand the morphological modifications of a nanoparticle. (iii) A Monte Carlo code to take into account the fact that the nanorods in dispersion are randomly oriented with the laser polarization. With the Monte Carlo we could understand the effect of the irradiation on the nanorod ensemble, as well as, its optical response.

Figure 1: Schematic representation of the in-situ optical transmission setup to carry out fs-laser irradiation of the colloidal nanorod dispersion and in-situ characterization.

3. Results and discussion

Figure 2, schematically shows the effect of irradiation of a nanorod with a fs-laser pulse. The LSPR leads to a severe energy localization in the nanorod. If the fluence is high enough the temperature can exceed the melting point. Even below this point morphological changes towards a stable sphere take place. If on the other hand a gentle irradiation is carried out in (Figure 3). The fluence is low and heat dissipation is slow (time constant \( \sim 350 \) ps), thus, morphological changes towards the sphere occur. As the aspect ratio changes the LSPR absorption is reduced. Below certain aspect ratio, absorption does not lead to any further change. Since the modification takes place in such a gentle way, all the nanorods change their aspect ratio to the same value, resulting in a dispersion with an absorption spectrum equal to that of a single nanorod. High fluence irradiation leads to direct transformation to sphere. In addition, an important fraction of the absorbed energy can be transformed in electron emission to the surrounding medium (up to 25% in our experiments).

Figure 2. Schematically. Plasmon excitation by means of an intense laser pulse. The nanorod reaches thermal equilibrium and dissipates heat to the medium changing its morphology and becoming a sphere (stable shape) at high irradiation fluences. (Adapted from [7]).

4. Conclusions

It was shown how to modify in a controlled way the aspect ratio of an ensemble of nanorods in water, in such a way that all of them become optically identical. It is remarkable that laser fluences as low as 3 J/m² lead to deposited energies of the order of 0.3 eV/atom. Around 25% of the absorbed energy is lost by hot carrier injection and the nanorod reaches temperatures near the melting point of Au. As a result, the irradiation leads to a fast heating and carrier injection into the surrounding medium.

Figure 3. Optical density of a nanorod dispersion before and after fs-laser irradiation. TEM image of the irradiated nanorods showing with the same aspect ratio.

Pathways for Ultrafast All-optical Magnetic Recording in Garnets

A. Stupakiewicz

Faculty of Physics, University of Bialystok, Poland
*corresponding author, E-mail: and@uwb.edu.pl

Abstract

Nonthermal ultrafast photo-magnetic recording in iron garnet films with femtosecond laser single and multi-pulses was demonstrated. Mechanism of recording is based on a multiple resonant pumping of localized $d$-electron transitions in a garnet. The information transferred from light to spins can be encoded not only in polarization state, but also in the wavelength and the intensity of the recording beams.

1. Introduction

In the recent years finding an electronic transition a subtle excitation of which can launch dramatic changes of electric, optical or magnetic properties of media is one of the long-standing dreams in the field of photo-induced phase transitions [1,2]. Therefore the discovery of the magnetization switching only by a femtosecond laser pulse [3] triggered intense discussions about mechanisms responsible for these laser-induced changes. Research concerning phenomena such as the inverse Faraday effect and ultrafast demagnetization shows exciting possibilities of sub-picosecond optical control over spins and applications in magnetic memory devices [1,4]. In this study we focus on an Co-substituted yttrium-iron garnet (YIG:Co) with nonthermal induced photo-magnetic effect. We demonstrated in such garnet at room temperature a large angle of the magnetization precession through excitation by linearly polarized femtosecond laser pulses via the photo-induced magnetic anisotropy [5]. Recent our discovery revealed a possibility of fastest magnetic recording with a single ultrafast laser pulse in YIG:Co without relying on heat [6]. This result raised question about the optimal wavelength, the polarization and the intensity of light, for such a recording.

Here we report the pathways for spectral and polarization selectivity of ultrafast photo-magnetic recording. The all-optical magnetic recording under both single pulse and multiple-pulse sequences can be achieved at room temperature, in near-infrared spectral ranges with light polarized either along $<110>$ or $<100>$ crystallographic axes of the garnet. The experimental results indicate that the excitations responsible for the coupling of light to spins are $d$-electron transitions in octahedral and tetrahedral Co-sublattices, respectively.

2. Experimental details

Samples of composition $Y_2CaFe_{3.9}Co_{0.1}GeO_{12}$ were grown by liquid phase epitaxy on (001) plane-oriented paramagnetic gadolinium gallium garnet substrate [7]. Saturation magnetization at room temperature was 7 Gs and the Neel temperature was $T_N=445$ K. Dopant Co$^{2+}$ and Co$^{3+}$ ions were located in both tetrahedral and octahedral sites. Fig. 1 shows the crystallographic sublattices in the sample. Photo-induced magnetic anisotropy in such garnets was attributed to transitions between Co ions in nonequivalent sites [7], driven by linear polarization of femtosecond laser pulses [5].

Figure 1: Schematics of the unit cell of the Co-doped garnet crystal structure.

Measurements were performed by means of magneto-optical microscope using Faraday geometry at room temperature without external magnetic field. The magnetic contrast in polarizing microscope comes from the fact that magnetic domains with different out-of-plane magnetization component will result in different angles of the Faraday rotation. The garnet film was excited with one or and multiple pulses. The duration of each pulse was about 50 fs and pulse-to-pulse separation was varied. The wavelength of the pump pulses was tuned within the range between 900 nm and 1600 nm. The images of magnetic domains were taken before and after the pump excitation. Taking the difference between the images we deduced photo-induced effects on the magnetization in the garnet. All
measurements were done in zero applied magnetic field and at room temperature.

3. Results and discussion

The recording was observed for single pump and multiple-pulse excitation with pulse-to-pulse separation time in the range from 1 ms to 20 ms. The spectral tuning of laser-induced magnetization switching by selective pumping of octahedral or tetrahedral Co-sublattices in a garnet was demonstrated. The switching properties are vastly different, related to the crystal site hosting the excited Co ions. Changing the pump wavelength near 1140 nm and 1300 nm and linear polarization of pump pulses along [110] and [100] directions, resonantly excites the single optical transitions in Co ions (see Fig. 2). As these ions are the source of the strong magnetic anisotropy in garnet, this represents a coherent and ultrafast manipulation of the spin-orbit interaction by femtosecond pulses. Moreover, the limited number of absorbed photons in garnet film contributes to the modification of anisotropy, underlining the remarkable efficiency of the photo-magnetic switching.

Figure 2: Pathways for ultrafast all-optical recording.

4. Conclusions

The photo-magnetic effect is a general phenomenon in numerous dielectrics. However, by using ultrashort laser pulses and precisely tuning to optical resonances we vastly enhance the effective light-induced field amplitude. This novel understanding highlights the principles for the engineering of materials for the cold all-optical recording.

Abstract

We describe a light-controlled synthetic procedure to fabricate selected plasmonic oligomers. Directed assembly of gold nanorods using dithiolated molecular linkers allows the controlled tip-to-tip assembly. With the aid of fs laser pulses, this process can be tuned to increase the temperature at the interparticle gaps to either destroy the organic ligands or melt particle tips and weld the particles together, offering a new pathway toward fabrication of novel complex nanoparticles with a plasmonic response not attainable by other methods.

1. Introduction

Gold nanoparticles have unique optical properties, which originate from the interaction of light with free conduction electrons. This phenomenon is known as localized surface plasmon resonance (LSPR) [1], and has a lot of potential for applications in sensing [2], photovoltaics and photocatalysis [3], as well as in waveguides and metamaterials [4], to cite just a few examples. Many of such applications are based on the collective optical properties of nanoparticles in close proximity of each other [5]. When the distance between two particles is sufficiently short, new hybridized plasmon modes appear through LSPR coupling [6], in such a way that the intensity of the resulting interaction is controlled by the interparticle distance [7]. For tip-to-tip NR assemblies of gold nanorods (NRs), the longitudinal mode registers a significant red-shift and an increase of the effective polarizability, with respect to the single rod, as the distance is reduced [8]. Moreover, the near field enhancement at the interparticle gap depends directly on the distance between the nanocrystals, being greater as the gap gets smaller [5]. The strong interaction of light, particularly laser pulses, with plasmonic nanoparticles can result in irreversible morphological changes of the nanocrystals [1]. Ultrashort fs irradiation can induce melting of nanoparticles, whereas ns pulses produce both photothermal melting as well as fragmentation [9]. All these effects have been ascribed to the relaxation dynamics of the localized surface plasmon electron oscillations in resonance with the laser wavelength. In the case of irradiation with a fs laser, a thermal equilibration process takes place after irradiation, whereas for the ns laser the electrons continue absorbing photons when the nanocrystal lattice is still “hot”, ultimately resulting in nanoparticle fragmentation [9]. In this work, we exploit not only the melting capability of fs lasers, but also the possibility of using lower fluence fs laser irradiation to control the assembly of plasmonic nanostructures.

2. Results and discussion

Optimized dithiol concentrations were used to control, both initiation and polymerization rates [10]. Termination of the reaction was achieved by blocking the free thiols of the linker by means of a “click” thiol-maleimide reaction [11]. The redshift of the longitudinal LSPR band resulting from tip-to-tip rod assembly was monitored to follow the polymerization process. Initiation occurs along with a decrease of the LSPR band intensity at 600 nm, and formation of a new intense band centered at ca. 700 nm, likely due to the longitudinal LSPR of dimers. After 8 minutes, the LSPR bands corresponding to single rods and rod dimers showed similar intensities, while after 10 minutes the reaction was stopped, when the LSPR of trimers at ca. 800 nm reached an analogous intensity. Then we performed fs laser irradiation during rod polymerization, acquiring in situ the extinction spectra (Figure 1a-c). The relative concentration of the main species was determined by fitting the experimental spectra with those calculated using FDTD [10]. Possible configurations for the rod oligomers are rather large, far more than can be simulated, which introduces an error in the concentrations predicted by the model. We assume that the nanorods are
preferentially bonded by the tips, according to TEM analysis [10], which considerably reduces the possible number of configurations. The angle between rods does not change the position of the LSPR but only its intensity [12]. Moreover, we considered the spectra for the main species (single rod, dimers and trimers), whereas all larger-chain oligomers were approximated by a Gaussian curve. In spite of its simplicity, the model is able to yield reasonable results for the relative concentrations of the main species.

![Spectra and Concentration](image)

**Figure 5.** Evolution of AuNRs-polymerization for different irradiation conditions. (a-c) Extinction spectra at 20 s intervals for 10 min: (a) without laser irradiation, (b) 130 μJ/cm² per pulse at 1 kHz, and (c) 650 μJ/cm² per pulse at 1 kHz. Arrows point to the spectral region at the LSPR maxima for the monomer (orange), dimer (red) and trimer (black). Concentration of side-by-side (SBS, green lines) dimers yielded by the fit is very close to zero. (d-f) Concentration of single rod, dimers and trimers obtained from the fits for (d) no laser, and pulse fluences of (e) 130 μJ/cm² and (f) 650 μJ/cm².

Concentration of the main species as a function of time are shown in Figure 1d-f for the non-irradiated reaction, as well as those for medium and large fluences. The rate of rod assembly is slightly decreased by laser irradiation with respect to the non-polymerized reaction, which is apparent for a fluence of 130 μJ/cm². This suggests that fs irradiation not only affects trimers but also a small fraction of dimers, due to the natural polydispersity of gold nanorods in aspect ratio, resulting in an increase of monomer concentration at early reaction stages. Our model predicts an inversion of the concentrations of dimers and trimers due to fs irradiation (Figure 1d,e), in good agreement with the proportion of oligomers determined by TEM [10]. We also found a significant increase of the rate at which monomers vanish at the early stages of reaction at the fluence of 650 μJ/cm², suggesting that an alternative reaction pathway based on the activation of chemical reactants by light [13] takes place for larger fluences. When the reactions stops, there is still a significant remaining concentration of monomers (~10¹⁰ particles/cm³) because the reaction rate stagnates from this point onwards. This is probably due to the polydispersity of gold nanorods, from which dimers with large aspect ratios are affected by the laser pulses, increasing the population of non-reactive monomers.

### 3. Conclusions

We have devised a light-controlled synthetic procedure where selective inhibition of the formation of gold nanorod trimers is attained by exciting the longitudinal localized surface plasmon resonance with 800 nm femtosecond laser pulses, allowing efficient trapping of the dimers by hot spot mediated photothermal decomposition of the interparticle molecular linkers. Laser irradiation at higher energies produces near-field enhancement at the interparticle gaps, which is large enough to melt particle tips, offering a new pathway toward tip-to-tip welding of gold nanorod oligomers. Optical and electron microscopy characterization indicates that plasmonic oligomers can be selectively trapped and welded, which has been analyzed in terms of a model that predicts with reasonable accuracy the relative concentrations of the main plasmonic species. Although we have only illustrated the use of laser irradiation for controlling the assembly kinetics of nanorods and spherical particles, this technique can be generalized to a variety of shapes, limited only by the wavelength of available fs lasers.

Phase-change materials (PCMs) provide excellent opportunities to alter electromagnetic response of artificial materials facilitating design of active and reconfigurable meta-surfaces. PCMs possess a high contrast of electromagnetic response between amorphous and crystalline phases accompanied by low optical losses. The phase transition can be triggered using thermal annealing on a hot plate or employing electrical or optical pulses. These allow active altering of both entire meta-surface as well as its individual unit cells enabling an efficient post-production tuning and reconfigurability. Theoretical description and design of PCM based reconfigurable meta-surfaces require a careful analysis of rich multiphysical phenomena associated with the phase transition at nano-scale in inhomogeneous environment. These involves self-consistent treatment of phase-transition, electromagnetic and thermal models. Here some aspects of multiphysics modelling of PCM based meta-surfaces are discussed. Different phase transition models are self-consistently coupled to full wave electromagnetic and heat transfer solvers. Developed methods are used to design active meta-surfaces. An importance of multiphysics modelling is demonstrated.

**Abstract**

Despite the exciting electromagnetic properties metamaterials exhibit, their implementation in nowadays technology is limited by the expensive and low-throughput used procedures. In this communication, we present new low-cost and up-scalable routes for the fabrication of double fishnet metamaterials, based on the combination of colloidal lithography, nanoimprinting lithography and electrodeposition. The proper design of our architectures enables the tuning of the effective refractive index from positive to negative and zero values.

**1. Introduction**

Metamaterials have attracted a great deal of attention over the past years because of the exotic electromagnetic phenomena that they can present, such as negative refraction. A widely studied geometry to achieve such negative refractive index is the fishnet design, which consists of a 2D array of dielectric holes penetrating a multilayered stack of metallic and dielectric films. However, the production of such metamaterials is hampered by the commonly used top-down techniques, which involve rather costly processes [1]. As alternative, we have developed new cost-effective routes for the fabrication of centimeter-sized negative-index metamaterials. Our approaches rely on the combination of low-cost patterning techniques such as colloidal lithography and nanoimprinting lithography with metallic electrodeposition [2].

**2. Results and discussion**

The obtained structures exhibit extinction resonances in the near-infrared that are tunable as a function of the different features of our structures, such the pitch of the array, the size of the dielectric elements or the separation between the gold layers. The good agreement between the optical measurements and FDTD simulations attests the success of our fabrication process.

The effective optical properties, retrieved from the calculations by the homogenization method [3], demonstrate that we are experimentally able to tailor the refractive index from positive to negative and zero values by the proper choice of the geometrical parameters of our structures (Figure 2).

---

**Figure 1:** (a) SEM image and (b) macroscopic view of the fishnet metamaterial.

**Figure 2:** Real part of the effective refractive indices extracted from the calculations.
3. Conclusions

This work presents an effective route for the low-cost and large-scale implementation of fishnet metamaterials. The performed simulations confirm the quality of our structures and demonstrate the feasibility of these new approaches to produce negative-index metamaterials over a broad electromagnetic band.

Abstract

We propose a novel metamaterial-based device inserted in a magnetic resonance imaging (MRI) setup in order to enhance the MRI efficiency. More precisely, we show that a negative magnetic permeability metamaterial, coupled to a standard radio-frequency surface coil, allows to boost the magnetic resonance imaging signal to noise ratio with respect to the standard setup. We prove that, in this configuration, the metamaterial can support magnetic field and a spatial modulation of the electromagnetic field. On the other hand, in this situation, the metamaterial relative permeability is \(\mu_m = -1\) integrated with a standard surface radio-frequency (RF) coil to improve MRI efficiency. In Freire’s configuration, the metamaterial acts as “a poor-man's superlens”\textsuperscript{1} able to suitable refocus the RF magnetic field, such as to enhance both MRI signal and signal-to-noise ratio. It is very surprising that a negative magnetic permeability metamaterial can also support the excitation of magnetic surface plasmons\textsuperscript{2,3} showing relevant characteristics, such as a resonant nature, a strong enhancement and a highly confinement of the local electromagnetic field.

Here, we consider a \(Re(\mu_m) = -1\) metamaterial slab as depicted in Fig.1 where the metamaterial lying between the RF surface coil and the sample. We prove that, in this configuration, the metamaterial can support magnetic surface plasmons and their excitations can boost the MRI signal-to-noise ratio (SNR) with respect to the standard setup. In the case considered by Freire \textit{et al.}, the \(Re(\mu_m) = -1\) slab is located between the coil and the sample and it has the ability to duplicate the electromagnetic field configuration present on the RF coil plane to another plane inside the sample. In our configuration, we exploit the fact that a localized plasmons can be excited near the metamaterial surface. As a consequence, the proposed configuration has the advantages to introduce no limitations to the sample-coil relative position since the metamaterial slab is located in a region usually free in many MRI setups.

2. Numerical simulations

We perform full-wave simulations using the RF COMSOL axis-symmetric package\textsuperscript{4} where we simulate the configuration displayed in Fig.1. We set the radiation frequency \(\nu = 63.866\) MHz, \(l_m = 5.7\) cm, \(l_s = 20\) cm, \(d_m = d_s = 0\) cm, the sample relative permittivity \(\epsilon_s = 90 + i197\) (corresponding to a conductivity of \(\sigma = 0.69\) S/m) and the metamaterial relative permittivity \(\epsilon_m = 1\). The RF surface coil is modeled with negligible thickness along the \(z\)-axis and by a surface current density having only an azimuthal component, viz., \(J_\phi = K_0 \delta(z)\), where \(K_0(\rho) = K_0 \exp\left(-\frac{(\rho - \rho_0)^2}{w^2}\right)\) (\(\rho_0 = 2\) cm, \(w = 2\) mm, \(K_0 = \frac{\text{const}}{}\)) is a constant whose value is fixed to obtain unitary current and \(\delta(z)\) is the Dirac delta function. From simulations, we obtain the RF electric and magnetic fields and the system dissipated power and, applying the principle of reciprocity, the receiving RF coil signal-to-noise ratio (SNR). In Fig.2, we report the spatial distribution of the normalized signal-to-noise ratio \(SNR^{(n)}\) (viz., \(SNR^{(n)} = SNR_m/SNR_s\)), where \(SNR_m\), \(SNR_s\) are the values calculated with and without metamaterial slab, respectively, where the real part of the metamaterial permeability is \(Re(\mu_m) = -1\). In Fig.2(a), we consider the situation where \(Im(\mu_m) = 0.1\) and we get both a significant enhancement of the magnetic field and a spatial modulation of the SNR due to the excitations of a surface plasmon at the metamaterial interface. On the other hand, in this situation, the metamaterial and sample losses are quite high and they reduce the setup performance (\(SNR^{(n)} < 1\)). In Fig.2(b) and (c), we consider the situation very close to the surface plasmon resonance condition \(\mu_m = -1\) \(\{b)Im(\mu_m) = 10^{-3}, \text{c) } Im(\mu_m) = 10^{-2}\}\) and hence we obtain a significant enhancement of RF coil SNR.
In conclusion, we suggest that a negative permeability metamaterial embedded into a MRI setup can increase the performances of a RF coil in an MRI experiment. A $Re(\mu_m) = -1$ metamaterial is able to support magnetic localized surface plasmons around its surface and we exploit this resonance phenomenon to improve the MRI efficiency.

Abstract
Understanding plasmon-driven electron emission and energy transfer on the nanometer length scale is critical to controlling light-matter interactions at nanoscale dimensions. In photoresist and electron-beam resist materials, electron emission and energy transfer lead to chemical transformations. In this work, we use such chemical transformations in two different high-resolution electron-beam lithography resists to map local electron emission and energy transfer with nanometer resolution from plasmonic nanoantennas by exciting both localized surface plasmon resonances and lattice resonances within the antenna arrays.

Results and discussion
Measurement and control of hot carriers produced via surface-plasmon decay may enable routes to guide photochemical reactions,[1]–[4] drive local heating on the nanoscale,[5]–[7] and harvest energy from light.[2] Direct observation of the spatial extent of hot-carrier-mediated chemical processes in materials at the surface of plasmonic nanoparticles will be key to engineering plasmonic nanoantennas for hot-carrier driven reactions. Moreover, identifying and differentiating between different electronic processes within individual plasmonic nanoparticles will allow for greater control of reaction pathways on the surface of these nanoparticles. In this work, we will build on our recent report that took advantage of two common electron-beam lithography resists poly(methyl methacrylate) (PMMA) and hydrogen silsesquioxane (HSQ), to image electron emission from plasmonic gold nanoantennas excited by femtosecond laser pulses at resonant frequencies.[8] Here, we extend this approach to arrays of aluminium nanoantennas excited by continuous-wave (CW) lasers.

We have previously characterized electron emission from plasmonic nanoantennas illuminated by intense femtosecond pulses of near-infrared light. In these recent studies, we have observed signatures of optical-field-dependent emission that are consistent with an emission mechanism based on strong-field tunneling.[9], [10] Moreover, we observed that the distribution of lithographic activity in PMMA thin films on arrays of plasmonic nanoantennas illuminated by intense (~10 GW cm⁻² peak intensity) femtosecond laser pulses, followed the simulated near-field intensity distribution of the nanoantennas. The estimated electron dose received by PMMA in the near-field is comparable to that used in previous reports for low-energy electron-beam lithography using a scanning probe,[11] while also being in agreement with simulated electron emission yields calculated using a model based on strong-field tunneling emission. Investigations using HSQ as an imaging layer showed that HSQ cross-links forming silicon dioxide at the centre of nanorod antennas where resistive losses are strongest. Hot electrons produced at the centre of nanorods were proposed to drive cross-linking of HSQ at the metal surface.

In our most recent work, we have imaged PMMA exposure in the near-field of aluminium nanoantenna arrays illuminated by CW visible lasers (~0.1 MW cm⁻² peak intensity). We have observed localized exposure of PMMA in nanometer-scale hotspots and investigated the effects of nanoantenna geometry as well as lattice resonances controlled by nanoantenna spacing within arrays. The exposed regions of PMMA may provide a route to produce strongly coupled nanoantenna systems for use as single-photon sources as well as plasmon-enhanced photocatalysts by enabling controlled deposition of quantum systems (molecules, quantum dots) within plasmonic hotspots.

Abstract

The first-principles theory of the radiation generated by an electron passing near the system of coupled particles is constructed. Proceeding from microscopic approach and performing the consistent calculations such characteristics as polarizability of the metastructure (the system of many particles) were expressed through the characteristics of a single particle. The obtained results demonstrate essential step towards the further rigorous analysis of the radiation processes in the systems with interaction and collective effects like plasmons, surface plasmon-polaritons, local field effects.

1. Introduction

A charged particle moving near an inhomogeneous target produces different kinds of radiation like diffraction radiation, Cherenkov diffraction radiation, Smith-Purcell radiation. All these are caused not by the scattering of the moving charge in the media, but arise due to the exciting the dynamically changed currents in the material of target [1]. Usually, the calculation of the characteristics of polarization radiation is based on the phenomenological theoretical treatment [2-5], while the microscopic calculations remained undeveloped.

On the other hand, during the last two decades the number of articles dedicated to different processes like radiation, surface waves and localized plasmons generated by moving electrons from metamaterials, local field effects [6-9], including giant enhanced surface phenomena [9, 10], new applications and ways of realization of Smith-Purcell effect from metasurfaces is getting increased.

In such problems it is possible to consider the macroscopically large single particles (nano-, microparticles, etc) as initial objects, and to construct the theory based on the exact description of the systems consisting of such objects [10-12]. This consideration needs taking into account the properties of single elements and effects caused by their interaction [6-9,13].

While all these effects in the case of a single particle as a target could be solve, the finding solution for the system of many interacting particles is not trivial. However, proceeding from microscopic approach and performing the consistent calculations it becomes possible to express the characteristic of the metastructure as a whole (the system of many particles) through the properties of a single particle. The latter is the main goal of this report.

2. Field of radiation from coupled particles

Let us consider the generation of radiation while the electron with the charge $e$ passes uniformly and rectilinearly near a system of two small particles, see Figure 1. The impact-parameter is $h$.

![Figure 1: Passing electron (black) generates radiation from two coupled small particles. The particles may be different, which is marked by their different colours.](image)

The interacting spherical particles are of different sizes $r_\alpha$, $r_\beta$, and polarizabilities $\alpha(\omega)$, $\beta(\omega)$. The form is unimportant in the long-wave approximation $r_{\alpha,\beta} \ll \lambda$, which is supposed to be fulfilled. The positions of the particles are defined by $R_\alpha$ and $R_\beta$, the distance between particles is $R = |R_\alpha - R_\beta|$.

Calculating the field of radiation from two interacting particles and comparing it with the result for one single particle it becomes possible to find the property of the metastructure (for example, polarizability) as a function of characteristics of its elements.

The calculation is performed in terms of local field approach [6, 11-13]. The short schema is given below. Proceeding from Maxwell’s equations we found the field of radiation at far distances through the current density $j'(k,\omega)$ in form:

$$E^{\text{rad}}(r, \omega) = i(\omega)^3 \omega^{-1} (k^2 \delta_{\alpha} - k_k) j'(k, \omega) e^{i\omega} / r,$$  \hspace{1cm} (1)$$

where $k = n \omega / c$, and $j'(k, \omega) = j_\alpha(k, \omega) + j_\beta(k, \omega)$. 

\begin{align*}
\text{Abstract} & \\
\text{Introduction} & \\
\text{Field of radiation from coupled particles} & \\
\text{Figure 1: Passing electron (black) generates radiation from two coupled small particles. The particles may be different, which is marked by their different colours.}
\end{align*}
Within the dipole approximation $\mathbf{j}_{\alpha,\beta} (\mathbf{k}, \omega)$ are defined by the dipole moments:

$$d_\omega (\mathbf{R}_\omega, \omega) = \alpha (\omega) [\mathbf{E}^\omega (\mathbf{R}_\omega, \omega) + \mathbf{E}_b (\mathbf{R}_\omega, \omega)],$$

$$d_b (\mathbf{R}_\omega, \omega) = \beta (\omega) [\mathbf{E}^\omega (\mathbf{R}_\omega, \omega) + \mathbf{E}_b (\mathbf{R}_\omega, \omega)],$$

where $\mathbf{E}^\omega (\mathbf{R}_\omega, \omega)$ is the electron’s Coulomb field acting in points $\mathbf{R}_\omega$ or $\mathbf{R}_b$. The field $\mathbf{E}_{\alpha,\beta} (\mathbf{R}_\omega, \omega)$ is the field produced by one particle and acting on another one, it is the exact solution of Maxwell’s equations. After some calculations one can obtain the field of radiation:

$$E_{\text{rad}}^\omega (\mathbf{r}, \omega) = \frac{\epsilon_0 k}{r} \left( k^2 \delta_n - k \delta_k \right) \times$$

$$\times \left\{ \alpha (\omega) e^{-i R_k} \left[ E_\omega^\omega (\mathbf{R}_\omega, \omega) + E_b (\mathbf{R}_\omega, \omega) \right] + \beta (\omega) e^{-i R_b} \left[ E_\omega^\omega (\mathbf{R}_\omega, \omega) + E_b (\mathbf{R}_\omega, \omega) \right] \right\} + \beta (\omega) e^{-i R_b} \left[ E_\omega^\omega (\mathbf{R}_\omega, \omega) + E_b (\mathbf{R}_\omega, \omega) \right],$$

where notation is entered:

$$E_\omega^\omega (\mathbf{R}_\omega, \omega) = -e^{i R_k} \beta (\omega) V^{-1} \omega^\omega (\mathbf{R}_\omega, \omega) +$$

$$+ \beta (\omega) e^{i R_b} \alpha (\omega) V^{-1} \omega^\omega (\mathbf{R}_\omega, \omega),$$

$$E_b (\mathbf{R}_\omega, \omega) = -e^{i R_k} \alpha (\omega) V^{-1} \omega^\omega (\mathbf{R}_\omega, \omega) +$$

$$+ \alpha (\omega) e^{i R_b} \beta (\omega) V^{-1} \omega^\omega (\mathbf{R}_\omega, \omega),$$

$$L^{\omega (n)} (\omega) = B \delta_n - \left( A + B \right) W^{-1} - A \rho R \frac{R \hat{R}}{WR^2},$$

and also

$$V = 1 - \alpha (\omega) \beta (\omega) e^{i R_b} B^2,$$

$$W = \alpha (\omega) \beta (\omega) e^{i R_b} \left( A + B \right)^2 - 1,$$

$$A = \frac{k^2 R^2 + 3 k R - 3}{R^3}, B = \frac{k^2 R^2 + k R - 1}{R^3}.$$ 

Equation (3) describes the total radiation field from two coupled particles, excited by the field of external sources. Note the solution has been obtained in the most general form without suggestion about any concrete form of the field $\mathbf{E}_b$ (providing the correctness of the dipole approximation).

### 3. Conclusions

We report the theory of radiation for the fundamental problem: the system of two interacting particles excited by the field of passing an electron. The resulting field of radiation differs from the mere sum of the radiation fields from two particles, while the basic equations are linear. The property of the metastructure as a whole was found as a function of characteristics of its elements. Despite the fact that the analytical solution was found for the case of only two interacting particles, the approach demonstrates the possibility of expansion and generalization the result. In addition, even in the most fundamental problems of physics, like the laws of conservation for system consisting of many objects, all the interactions are considered via two-body interactions, between all possible couples. For that reason, the exact theory describing analytically the effects of interaction between two particles can be of primary importance for further rigorous analysis of the radiation processes when it comes to the systems with strong interaction and collective effects, like plasmons, surface plasmon-polaritons, local field effects, including giant surface enhanced phenomena, etc.

Plasmonic nanocavities: New understanding on the correlation of near- and far-field spectra and their impact on strong coupling dynamics

Angela Demetriadou, Kalun Bedingfield, Antonios Kotsampaseris

School of Physics and Astronomy, University of Birmingham, Egbaston, Birmingham, B15 2TT, United Kingdom
*corresponding author, E-mail: a.demetriadou@bham.ac.uk

Abstract

Plasmonic nano-cavities are the ideal photonic environment to realize light-matter strong-coupling at room temperature. However, they support multiple types of modes, each with a large bandwidth, that can interfere both constructively and destructively. We demonstrate that the interference between such modes leads to a very complex photonic system, with different near-field and far-field spectra, which ultimately change our understanding and interpretation of the strong-coupling dynamics measured experimentally in the far-field.

1. Introduction

Plasmonic nanocavities are formed by gaps of just few nanometres between two nano-metallic structures. Such small plasmonic gaps allow the extreme enhancement and confinement of light in mode volumes of only few cubic nanometers. The extreme light confinement has lead to very interesting phenomena, such as single molecule strong coupling at room temperature [1] and the observation of sub single-molecule spectroscopic behaviour [2].

When two metallic structures are brought close together, the plasmons from each structure become tightly coupled to each other, such that higher order modes in nanocavities loose their non-radiative behaviour and acquire a radiative component [3]. This behaviour suppresses the quenching regime for nanoplasmonics [3], which is the main mechanism that allows for strong coupling of a single molecule at room temperatures. We have also shown that other types of dark modes are excited in plasmonic nanocavities, and in fact have a significant impact on the strong coupling dynamics of a quantum emitter with a plasmonic nanocavity [4].

In this paper, we present a theoretical study on how different plasmonic modes in a nanocavity interfere both destructively and constructively to create a photonic system that is not reciprocal any-more. To create a plasmonic nanocavity we consider a spherical nanoparticle assembled on a flat metal surface (Nanoparticle on mirror - NPoM), with the two structures separated by a distance of 1 nm. Spherical nanoparticles though are never perfectly spherical structures, but actually quite faceted. From experimental measurements [5], it has been shown that faceted nanoparticles assemble with their facet parallel to the metal mirror, creating a “waveguide”-like cavity.

2. Near- and Far-field spectra in nanocavities

In figure 1 (left), numerical calculations of the scattering efficiency for faceted NPoM nanocavities is shown. One can observe that for perfectly spherical nanoparticles, the lowest order mode radiates more efficiently than higher order modes. This behaviour correlates well with the near-field spectra (figure 1(right)), where the field enhancement is primarily due to the lowest order mode.

However for very faceted NPoM, (i.e. facets ~ 40 nm), the near-field and far-field spectra are not corelated any more. One can see that the second order mode radiates to the far-field more efficiently than the near-field enhancement due to the same plasmonic mode. For even more faceted NPoM, the third and fourth order modes radiate efficiently to the far-field, while the near-field enhancement takes similar values for each plasmonic mode in the system. This behaviour breaks reciprocity for the nanophotonic system.

3. Discussion

In this paper, we derive an analytical description that decomposes the normal modes in such plasmonic nanocavities. We find that bright modes interference destructively in the near-field, but constructively in the far-field, contributing to some of the discrepancies between the near- and far-field spectra. However, reciprocity breaks primarily due to the dark modes in plasmonic nanocavities that are excited more efficiently for more faceted NPoM. In addition, such dark plasmons spectrally shift as the facet size grows, as previously reported [6]. Also, we break the parity symmetry for the “waveguide”-like nanocavity by considering a facet nanoparticle assembled with its edge on the mirror. Such asymmetric systems have an even more significant impact on the near-field and far-field correlation of plasmonic nanocavities.

Finally, we take the non-reciprocal behaviour of plasmonic nanocavities in the strong coupling regime, by placing a quantum emitter in the nanocavity. The Rabi oscillations of the system reveal that the quantum emitter is coupled to multiple modes simultaneously but with different coupling strengths. However, the far-field spectra show a more simplified picture for the interaction compared to the near-field dynamics.
4. Conclusions

In conclusion, we show that the geometry of a plasmonic nanocavity dominates the reciprocity of the photonic system and as a consequence the spatio-temporal dynamics of a plasmon-exciton.

Abstract

We present a approach aimed at generalizing Parity-Time symmetry to mesoscopic ensembles of coupled oscillators with gain and loss, with inspiration from graph-theoretic tools. We globally minimize the imaginary part of the eigenvalues for small gain/loss and describe how couplings adopt some topologies. We also discuss recent results on distributed-feedback laser diodes operating at 1550 nm and having both real and imaginary index modulation. We notably study their resistance to optical feedback.

1. Introduction

The introduction of Parity-time symmetry concepts in optics has prompted numerous re-examinations of optical devices, notably integrated optics devices: waveguide couplers, lasers, multimode waveguides [1,2], etc. Parity-time symmetry in optics is well-known to be interesting with either “transversal” gain/loss modulation (coupling between adjacent elements), or “longitudinal” gain/loss modulation (e.g. periodic). The first case lends itself to a generalization, e.g. in multimode devices, or in a bunch of coupled fibers. It is the first topic on which we shall report in Sec.2.

We will next report in Sec.3 on our recent results on distributed-feedback laser diodes operating at 1550 nm and having both real and imaginary index modulation, these latter being respectively obtained by (i) ridge shape modulation and (ii) metallic wire elements that periodically modulate the losses. We notably study their resistance to optical feedback, a topic of great importance for high-coherence lasers, and highly desirable in the optical telecommunication realm.

2. Graph PT symmetry for small mesoscopic ensembles

In our main contribution, we will examine a set of “gainy” and “lossy” oscillators connected by a random graph with some constraints such as constant coupling constants for simplicity. The situation could arise for instance in a bunch of a few tens of fibers that couple to each other evanescently, half of them having gain and the other half losses (Fig.1, the drawing in the top is for an example of an ensemble with 5+5 oscillators). The question then arises of making the system “maximally PT-symmetric-like”: we attempt to reduce the imaginary part of the eigenvalue $|\text{Im}(\lambda)|$ as much as possible by reconfiguring the graph edges (the connections). We do this for a small finite gain where we estimate that the exceptional point is almost never already reached.

In the simulation of Fig.1, we obtain for instance the statistical histogram of the dependence of the minimum of $-\langle|\text{Im}(\lambda)|\rangle$ on the number M of edges after optimization from a random start for a fixed number of 16+16 gain+loss units in Fig.1. We show the distribution for 200 random starts and 36,000 iteration steps consisting of single-edge changes towards a minimal $-\langle|\text{Im}(\lambda)|\rangle$. We will discuss the possible implications of such considerations in optics and possibly beyond.

We believe that such systems are also of interest in the broader framework of non-equilibrium thermodynamics, when units must collaborate to channel energy flux (solar, biological,…) by optimizing their organization in a complex system. These are century-old topics, started notably with the...
work of Alfred Lotka in 1922 on the way living systems maximize the use of energy (or not). Recent work by C. Goupil et al. [3] recently outlined how to revisit basic thermodynamic rules such as Carnot efficiency theorem, when dynamic has a finite rate and some kind of "impedance" prevents the attainment of the ideal efficiency, a frame much closer to real life engines. There is some analogy with our coupling that manages energy flow between gain elements and loss elements, and within each category as well. More generally, the issue of how a dynamical association of gain and loss elements behaves can have profound echoes in other areas, at least this is our firm belief that we will partly try to convey.

3. Laser diodes with complex coupling

In this second part of our contribution, we will discuss laser diodes operating with PT-symmetric Bragg gratings, in other words “PT-DFB laser diodes”, which are a sub-class of the more general “complex coupled” laser diodes, whereby the Bragg coupling coefficients have a real and an imaginary part. The real part comes, in our case, from the width modulation of the ridge and the imaginary part from the loss modulation of periodic metal stripes. Gain is continuous and comes from electrical injection, and overall, such diodes compare well with DFB laser diodes with index only or gain only coupling (i.e. periodic modulation). Experimental realizations of such diodes might solve some long-standing issues such as feedback immunity of coherence in DFB laser diodes. To this end, we will start by revisiting the threshold discrimination criteria in the PT-symmetric context, taking into account both the grating phase and the facet phase, using Coupled Mode theory. An example of threshold gain studies for variable facet position is given in Fig.2. We will explain and extend it

Fig. 2: Threshold gth discrimination study for variable facet phases. The gain threshold of all possibly lasing modes are tracked vs. The phase of the front facet, a phase of π bringing, far from the Bragg frequency, one mode to the frequency of the next mode at 0 phase. The situation close and across the stopband can be much more complex.

Abstract
Optical nanoantennas are studied to manipulate light and enhance light matter interactions. Here, we experimentally demonstrate the optical Helmholtz resonance in a metallic slit-box structure, which is predicted to be harmonic and to enhance the electric field intensity by several orders of magnitude. It is fabricated thanks to a two steps electron beam lithography, between which the box was filled with benzocyclobutene (BCB).

1. Introduction
Designing nanoantenna that could strongly and efficiently concentrate incident light into deep subwavelength volumes is a key issue to locally enhance the electric field and thus produce strong light-matter interactions. Many existing designs are inspired by structures widely used in the radiofrequency domain such as bowtie or Yagi-Uda antennas. Here, we rather use an analogy between acoustics and electromagnetism wave equations, in order to adapt the acoustic Helmholtz resonator to optics. This resonator, made of a slit-box structure, behave as a LC circuit. The deep sub-wavelength slit acts as a capacitance, which concentrates the electric field at resonance, leading to huge enhancement in a hot volume. Here, we present a way to fabricate this nanoantenna, and experimentally demonstrate the optical Helmholtz resonance.

2. the Optical Helmholtz Resonator
2.1. Properties
This structure is made of a tiny slit above a larger cavity (see Fig. 1(a)), and exhibits several appealing features: total absorption at resonance, absence of harmonic resonance, giant field intensity enhancement in the whole slit volume, angular independence of the Helmholtz resonance [1, 3].

The key properties of the Helmholtz resonance are:
(i) A giant field enhancement, typically two orders of magnitude higher than expected with gap plasmons resonances.
(ii) A single resonance behavior with no harmonics.
(iii) No influence of the permittivity of the material filling the cavity on the resonance wavelength.
(iv) The resonance wavelength \( \lambda_r \) depends on the square root of all four geometrical parameters according to the following formula:

\[
\lambda_r \propto 2\pi \sqrt{\frac{\varepsilon_s w_x h_x}{w_y}},
\]

where \( \varepsilon_s \) is the permittivity of the material filling the slit.

2.2. Comparison to other resonances
The computed absorption spectrum, for a transverse magnetic (TM) polarized and normally incident light, is plot-
Fabrication steps for a periodic grating of optical Helmholtz resonators with the corresponding top view SEM image: (a) Gold trenches are created by the lift-off of 80 nm of gold after a first e-beam lithography ($d = 3$ μm). (b) A dielectric (BCB) is spin coated on the surface and etched by RIE to reach the gold surface ($d = 3$ μm). (c) A two layer lithography process is performed using PMMA and HSQ ($d = 1.5$ μm). (d) Gold is lifted-off resulting in the fabrication of the optical Helmholtz resonator ($d = 1.5$ μm). The narrow slits in the gold surface above the BCB-filled cavity, which is barely distinguishable.

2.3. Fabrication

Due to its complex architecture and its deeply subwavelength dimensions, the fabrication of the Helmholtz resonator is a rather complex challenge. We have developed a process in two parts, the first consists in fabricating the cavity, which is subsequently filled with benzocyclobutene (BCB), a planarizing dielectric, as shown in Fig. 1(a) to reduce the complexity of fabrication by avoiding freestanding parts. A first step of e-beam lithography is performed to define the cavity on top of the gold layer. 80 nm of gold are evaporated onto the sample and lifted-off (see Fig. 2(a)) to fabricate trenches of height 80 nm and width 400 nm. Benzocyclobutene (BCB) is spin coated on the sample and baked, then a reactive ion etching (RIE) plasma is done so that the surface of the BCB reaches the gold surface while keeping the cavity filled with dielectric (see Fig. 2(b)). On top of these trenches, a bi-layer resist stack (PMMA-HSQ) is used to define the slit with a fine resolution. The second level is aligned on the lower level with alignment markers positioned during the first step of lithography and detected by the e-beam pattern generator. The accuracy of this alignment on the sample size is about 50 nm, and a slight shift of the slit in regard to the cavity can be seen on the SEM images (see Fig. 2(c-d)). Near and mid infrared with a Fourier transform infrared spectrometer confirms the presence of the Helmholtz resonance at $\lambda_r = 2.84$ μm.

3. Conclusion

A process involving a two-steps e-beam lithography was used to fabricate optical Helmholtz resonators. It was used to experimentally demonstrate the optical Helmholtz resonance thanks to measurements in the near and mid-infrared. This resonators produces high field intensity enhancement that can be used to enhance SEIRA.

Metasurface Photodetectors for Directional Image Sensing

Abstract
We report the development of photodetectors integrated with plasmonic metasurfaces that only allow for the detection of light incident along a single, geometrically tunable direction (within a small distribution of angles). These devices are promising for the realization of ultrasmall lensless cameras providing the distinctive imaging capabilities of compound eyes.

1. Introduction
Typical photodetectors measure light intensity isotropically, with only a weak dependence on incident direction dictated by the Fresnel formulas for transmission across the device surface. Here we demonstrate a new family of directional image sensors that only detect light incident along a small, geometrically tunable distribution of angles, whereas light incident along all other directions is reflected. This behavior is produced by coating the photosensitive active layer with a specially designed plasmonic metasurface that acts as a directional filter. The resulting devices are functionally equivalent to the individual elements (ommatidia) of the compound eyes of common invertebrates such as insects and crustaceans, while at the same time featuring a planar lensless architecture. Therefore, they provide a promising new approach to harness the distinct attributes of the compound-eye vision modality (including extreme size miniaturization, wide-angle fields of view, and high acuity to motion [1]), in a flat package that is fully compatible with existing CCD/CMOS image sensor arrays.

In this paper, we will describe the design, fabrication, and characterization of a set of infrared devices providing directional photodetection peaked at different angles, based on simple metal-semiconductor-metal (MSM) Ge photoconductors. Furthermore, we will present the results of computational-imaging simulations showing that high-quality images of relatively complex objects can be reconstructed using flat ultrasmall arrays of these devices.

2. Results and discussion
2.1. Metasurface design
The directional image sensors developed in this work are illustrated schematically in Fig. 1. The device active material (a Ge photoconductor) is coated with a metal film supporting a periodic array of metallic nanoparticles (NPs). The metal film is sufficiently thick (~100 nm) to block any externally incident light from propagating directly into the underlying active layer. Therefore, photodetection in this geometry can only take place through an indirect process where light incident along the desired direction is first diffracted by the NP array into surface plasmon polaritons (SPPs) – i.e., guided optical waves propagating on the top surface of the metal film. A small number of suitably positioned subwavelength slits in the metal film are then used to scatter these SPPs into radiation propagating predominantly into the absorbing active layer [2], and as a result a photocurrent signal is produced. Light incident along any other direction is instead either immediately reflected back by the metasurface, or diffracted into SPPs propagating towards a “reflector region” (shown on the right side of Fig. 1), where the SPPs are then scattered into the air above.

Figure 1: Schematic illustration of the directional photodetectors developed in this work.

The metasurfaces just described were designed via FTDT electromagnetic simulations. Representative results are shown in Fig. 2, where we plot the calculated $p$-polarized power transmission coefficient through the metal film into the absorbing substrate as a function of the polar angle of incidence $\theta$ (on the $x$-$z$ plane of Fig. 1). Each trace corresponds to a different design with different array period. As shown in the figure, these devices can provide tunable directional photodetection with a wide tuning range for the angle of peak detection $\theta_p$ of over ±75° and relatively...
narrow angular resolution. The peak transmission is in the range of 30-45 % for all devices. In contrast, the s-polarized transmission is negligible small for all incident directions. This intrinsic polarization dependence could be exploited to enable polarization vision. Alternatively, polarization independent operation can be obtained with more complex metasurface designs, involving two-dimensional NP arrays and orthogonally oriented slits.

2.2. Experimental results

Several devices were fabricated based on simple MSM Ge photoconductors, with the metasurface patterned in the region in between two metal contacts deposited on the top surface of a Ge substrate. Figure 3 shows a scanning electron microscopy (SEM) image of a representative sample. Angle-resolved photocurrent measurements under near-infrared monochromatic illumination show highly directional response in good agreement with simulations. To illustrate, in Fig. 4 we plot the measured photocurrent of a device designed for peak detection at $\theta_p \approx 30^\circ$, as a function of polar illumination angles. The full 3D response maps of these devices (versus both polar and azimuthal angles of incidence) are also being measured.

2.3. Imaging applications

The angle-sensitive photodetectors just described may be employed for the development of ultrasmall lensless cameras providing the distinctive imaging capabilities of compound eyes, in the form of planar arrays where each pixel selectively detects light incident at a different combination of polar and azimuthal angles. The ability of such arrays to reconstruct relatively complex images is currently being validated with computational imaging simulations. Importantly, these simulations also indicate that the resulting images can have substantially higher resolution compared to the single-pixel angular selectivity, if devices with appropriate overlaps in their angular responses are combined.

2.3. Imaging applications

The angle-sensitive photodetectors just described may be employed for the development of ultrasmall lensless cameras providing the distinctive imaging capabilities of compound eyes, in the form of planar arrays where each pixel selectively detects light incident at a different combination of polar and azimuthal angles. The ability of such arrays to reconstruct relatively complex images is currently being validated with computational imaging simulations. Importantly, these simulations also indicate that the resulting images can have substantially higher resolution compared to the single-pixel angular selectivity, if devices with appropriate overlaps in their angular responses are combined.

3. Conclusions

We have developed a new class of photodetectors that are uniquely sensitive to the direction of propagation of the incident light. The devices presented in this work are based on metallic NP arrays on Ge photoconductors, but can be extended to other materials systems and photodetector technologies. Their key operating principle (i.e., the integration of a photosensitive active layer with a metasurface to selectively control the properties of the detected light) is also quite general and can be applied to other device functionalities, such as polarization vision and direct wavefront sensing.

Abstract

In this work, we describe an active photonic system based on Ge(Si) quantum dots (QDs) embedded into silicon nanodisks. We show experimentally the enhancement of the photoluminescent signal from quantum dots coupled to Mie modes of the nanodisks. Using numerical modeling, we identify the coupling mechanism, which allows for engineering the resonant Mie modes through the interaction of several nanodisks. As the example, we look at linear chains consisting of several silicon nanodisks placed next to each other. We demonstrate the resonance-mediated change of photon spontaneous emission rate in the considered systems (Purcell effect) by investigating emission lifetimes obtained from time-resolved photoluminescence measurements.

1. Introduction

Control of the light at the nanoscale can be achieved in optical nanoantennas through the resonant coupling of the quantum source emission to localized modes. Plasmonic nanostructures allow a strong field enhancement and high spatial localization of the resonant modes. However, metallic systems have high optical losses that can quench spontaneous emission limiting their potential applications. Recently, the resonant all-dielectric photonic nanostructures based on high refractive index materials showed a wide range of applications in nanophotonics and optics [1]. The interaction of quantum emitters with all-dielectric systems have been actively studied theoretically in the recent years. Nevertheless, there were only a few experimental realizations demonstrating the interaction of quantum sources with all-dielectric structures[2, 3]. The incorporation of quantum emitters into silicon nanoresonators would path a way towards applications in active silicon nanophotonics. For that, we propose all-dielectric systems based on silicon nanodisks with self-assembled Ge(Si) QDs, showing a broad emission in the 1200-1600 nm range at room temperature [4]. These Ge(Si) QDs have already demonstrated their suitability for optoelectronic applications in photonic crystal cavities, LEDs, and NIR photodetectors[5].

2. Results and discussion

Mie resonances of small dielectric Mie-resonators can be used to enhance the luminescence of embedded Ge(Si) quantum dot emitters in the telecom range via the Purcell effect. To investigate this experimentally, we fabricated several cylindrical silicon disks with varying diameter in the range of 300-640 nm containing MBE-grown Ge(Si) quantum dots (Figure ??). The emission spectra revealed an enhanced emission intensity at the spectral position of the Mie resonances and a characteristic red shift of the emission maxima with increasing resonator size in the wavelength range 1200-1600 nm (Figure ??). This corresponded very well with finite element simulations determining the resonantly enhanced mode field within the Mie-resonators. To test, if the observed luminescence increase is caused by an increase in radiative emission rate (Purcell factor) or just caused by a redirection of emission in the far field, time-resolved photoluminescence measurements were performed. The observed decrease of emission lifetime at the Mie resonances revealed a clear impact of Purcell-enhancement. However, due to the low Q-factors of the single disk resonances, only moderate Purcell factors up to about 1.4 compared to the unstructured substrate were obtained. This is in agreement with numerical calculations...
Figure 2: PL map of disks with various diameter. Symbols represent simulated spectral positions of Mie-modes.

Figure 3: PL spectrum of an 11-disk chain exhibits several high-Q peaks corresponding to hybridized modes.

considering a dipole source inside the Mie-resonator and integrating the overall radiated intensity. To increase the Purcell factor further, collective Mie-resonances of trimers and periodic chains of dielectric nanoresonators are investigated leading to higher Q-factor resonances. An up to 10-fold intensity enhancement could already be achieved due to a partial cancellation of radiative losses in the far field of the collective Mie-resonators. A systematic investigation of the luminescence response from resonator chains with increasing number of individual resonators confirms the coupling of the emission to the collective resonances. Time-resolved photoluminescence measurements are used to experimentally determine the Purcell factors, and the experimental data are compared with finite element and finite difference time domain simulations.

3. Conclusions
In this work, we demonstrated that Ge(Si) QDs embedded in Si nanodisks can be effectively coupled to the Mie resonances of the nanodisk, which was observed as a strong modification of the PL spectra of QDs. The numerical analysis of the dipole emission resulted in a good correspondence to the experimental results. The emission pattern and intensity can be significantly changed by engineering dipole modes in nanodisk structures consisting of several nanodisks. Here, an up to 10-fold emission enhancement and Q-factors as high as 300 were achieved by exciting hybrid modes inside linear chains with various length (3-11 disks). The suppression of the dipole emission increases the quality factor of the resonant modes and paves a way towards a stronger Purcell effect for emitters inside silicon Mie resonators. The results reported in this paper open a way for efficient nanoscale light sources based on resonant structures supporting Mie modes.

Abstract

Dielectric metamaterials are promising low-loss platform for applications in photonics. In contrast to photonic crystals metamaterials allow a description with effective material parameters. The transition from photonic crystal to metamaterials is found to be accompanied with an abrupt change in electromagnetic field patterns which is typical behavior of phase transitions. Here we review the recent progress in photonic phase transitions between these two classes of artificial structures.

1. Introduction

The advances in adaptation of many concepts borrowed from condensed matter physics to the case of electromagnetic wave propagation have made a great impact on modern photonics. Recently, the concept of photonic phase transitions was introduced to describe how a photonic crystal becomes a metamaterial with a gradual change of the structure parameters [1]. This problem is fascinating by itself as an academic study and has an importance for designing the dielectric metamaterials for applications in optical devices.

Let us remind some aspects of conventional thermodynamic transitions. Among other types of phase transitions we consider those related to an appearance of some property, such as metal-to-dielectric transitions due to the opening of bandgap between the valence and conduction bands. In the dielectric phase there exists a frequency interval (limited by the photon energy below the bandgap width) for the material to be transparent. However, at a certain frequency both phase are opaque, while at other ones they both transparent. Thus, we have to distinguish two terms phase and regime. Regime means the conditions for the effect to be observed, e.g., the frequency range. For example, silicon being a typical semiconductor recently becomes one of the most important dielectric materials for photonics. In other words, for measurements of electric conductivity, silicon is in a semiconductor regime and the same silicon is in a dielectric regime for an interaction with a high frequency electromagnetic field. We use the term phase to emphasis a potential ability to obtain some properties under certain conditions.

Now we turn to the photonic phase transitions related to photonic crystals and metamaterials [1]. The main property of photonic crystals is Bragg resonances owing to a coherent interference of wave scattering on the periodic structure. Thus, at Bragg frequencies the electromagnetic waves propagate though the structure under the condition of strong spatial dispersion. In contrast, a metamaterial operates because of a local resonance supported by each structural element and the effects of spatial dispersion are weak despite the resonant conditions. We notice that the Bragg wavelength obeying the law $\lambda_{\text{Bragg}} \propto \cos \theta$ limits this resonance at the low-frequency edge, however the high-frequency limit is tends to infinity. Thus, above the lowest Bragg frequency the electromagnetic waves propagate under the condition of strong spatial dispersion and in general case the metamaterial regime is not possible. The metamaterial regime occurs when the local resonance of structure elements is lower than the lowest Bragg resonance and a corresponding photonic band diagram contain a polariton-type feature [2]. Therefore, the appearance of the polariton-type feature in the band diagram makes it possible to define the metamaterial phase.

2. Study of photonic phase transitions

The first systematic study of photonic phase transitions was reported in paper [1], which considers high-dielectric index structures of cylindrical rods arranged in a square lattice. A comparison between scattering on a single dielectric rod, a photonic band diagram and a transmission of a 10 layer sample reveals that the structures become a metamaterial with artificial magnetic response when the fundamental dipole Mie resonance in a single rod opens a lowest bandgap in the structure. An analysis of bandgap map as a function of the rod permittivity reveals that the appearance of the polariton-type feature corresponds to the Mie-gap splitting below the Bragg gap.

The way how a periodic structure acquires the metamaterial properties is an important problem of modern photonics. Although the appearance of the polariton-type feature in band diagram is a binary criterion of metamaterial phase, the intuition supposes that a gradual change in structural parameters leads to incremental growth of a metamaterial quality. However, simulations of electromagnetic field pattern in periodic structures uncover the abrupt modifications of the pattern are coincided to the appearance of the polariton-type feature in band diagrams [3]. This result justifies the usage of phase transition terminology when we consider the appearance of metamaterial properties in di-
electric structures.

Since the demonstration of structures with resonant effective magnetic permittivity $\mu$ was a milestone in a study of artificial media, the researches on the dielectric metamaterials were focused to the systems with magnetic response, while the dielectric metamaterials with electric response were not reported. The reason is in a stronger optical mode coupling between the neighbor rods for the case of electric dipoles than their magnetic counterpart. Recently dielectric metamaterials with resonant electric response were presented [4]. These metamaterials have sparse structures, i.e., the lattice spacing is about ten times the rod radius. However it requires the higher values of dielectric index. In particular, the dielectric metamaterials with magnetic response are possible for $\varepsilon > 20$ at $r \approx 0.3a$ [1], while the electric metamaterials exist for $\varepsilon > 28$ at $r \approx 0.1a$ [4].

In order to minimize metamaterial rod permittivity one can consider a hexagonal lattice that has the biggest Brillouin zone, and therefore the condition for the Mie resonance splitting off is weaker. We notice that the structures with a hexagonal lattice possess a near-boundary phase that corresponds to a pair of states per frequency and a strong spatial dispersion condition of wave propagation though the structure. However a hexagonal lattice minimizes the rod permittivity to $\varepsilon \approx 22$ in the case of electric metamaterials [5].

The phase criterion described above is based on the analysis of the second dispersion branch. The metamaterial phase requires high-index materials, which usually have a strong frequency dependence of complex permittivity. However photonic band diagrams do not allow distinguishing the first and the second branches of structures, which constitutes have complex permittivity [6]. The behavior of complex branches in the bandgap range makes it possible to introduce another criterion of metamaterial phase based on a crossing or an anti-crossing dependence [3]. These two criteria were found to give the same results for the lossless structure. Recently, the crossing/anti-crossing criterion makes it possible to build photonic phase diagram of silicon-based metamaterials with magnetic response [3]. The predicted metamaterials consisting of silicon nanorods operate at the visible range since the semiconductor permittivity grows when the wavelength becomes shorter.

The existence of dielectric metamaterials was verified in microwave measurements [1]. The experimental sample was the array of 5 by 10 plastic tubes filled with distilled water ($\varepsilon = 50$ - 80) and fixed by an adjustable frame. Transmission spectra in dependence on the square lattice spacing exhibit that at a certain value the transmission dip related to the dipole Mie mode becomes the lowest gap of the structure in agreement with the numerical simulations.

3. Outlook and perspectives

We have reviewed recent advantages of photonic phase transitions, which is a new topic in metamaterial research. For example, disorder-induced phase transitions in metasurfaces were reported recently [7]. Among a great application potential in designing dielectric metamaterial devices, this topic defines a number of basic problems. In particular, the abrupt change in the photonic subsystem during the phase transition is expected to be accompanied with the peculiarities in energy. We anticipate a study of photonic phase transitions from photonic crystal gratings to flat metasurfaces. The experimental confirmation of a bulk dielectric metamaterial in visible or near infrared range is a challenging but desirable task.

Abstract

The ability to grow plasmonic shells on micro- and nanoparticles by electroless plating leads to the creation of novel and easily deployable heterogeneous materials for detection of biomolecules and medical therapy with high sensitivity and low irradiation needs. The overall quality, optical performances, and stability of the shells are important to address and can be controlled by rational design of the shell structures. Here, Ag and Au nanostructured shells are discussed in the context of magneto-plasmonics and attomolar multiplex protein assays.

1. Introduction

When involving targeted operation with light, multifunctional micro- and nanoparticles can rely on plasmons so that efficient diagnosis and therapy materials can be rationally designed. We explore two practical cases of Ag and Au shells in the context of single particle attomolar sensitive protein assay and magneto-plasmonics for photodynamic therapy.

Current best practices for diagnostics are time consuming and laborious, and plasmonic substrates can revolutionize this industry. Aiming to detect and quantify samples of mixed antigens, we have developed multi-shell microparticles including plasmonic Ag shells enhancing both the Raman and fluorescence in dual multiplex assays. Sandwich immunoassays in this way afford attomolar detection, and are here oriented towards the targeting of a unique panel of antigens for pancreatic cancer.

Because, for plasmonic nanomaterials, incident resonant light results in local heat dissipation \cite{1}, photodynamic therapy is possible. It is hypothesized that when the plasmon shell cores are magnetic, the plasmon absorption can be controlled by magnetic self-assembly and tuned towards near-infrared wavelengths where tissue scattering and absorption are minimum, in the so-called “biological windows” between \(~700 \text{ and } 2000\) nm \cite{2}.

2. Magnetic-tuned Au plasmon in photodynamic therapy

Through magnetic dipole-dipole interactions, superparamagnetic nanoparticles form chain-like structures when an external static magnetic field is applied. Upon removal of the field, the nanoparticles dissociate into a colloidal solution. These superparamagnetic nanoparticles can be used for tunable plasmonic coupling, see Figure 1.

![Figure 1](image1.png) (top panel) Intercellular assembly of magnetic-plasmonic nanoparticles. (bottom panel) Simulations of nano-chain assembly plasmonic activity using COMSOL Multiphysics®. The simulations predict redshift into the NIR and increase of the plasmon absorption.

Iron oxide/gold core/shell nanoparticles were synthesized and were shown to be both magnetically responsive and plasmon active. The synthesis schematic can be followed in Figure 2. To assess the thermo-plasmonic activity, infrared thermography was used after embedding the assembled particles in chitosan hydrogel. A clear increase in laser-induced heating was observed with respect to the control, see Figure 2.

![Figure 2](image2.png) (top panel) Synthesis steps for magnetic-plasmonic nanostructures. Further functionalisation is possible for better tumour targeting (PEGylation/targeting moieties \cite{3}). (bottom panel) IR thermography of magnetic-plasmonic
nanoparticles embedded in chitosan hydrogel, compared to the control (irradiated @ 753nm).

3. Nanoporous silica templated Ag shells

Ag nanoparticle shells were grown from AgNO$_3$ in ethanolic solutions, at the surface of SiO$_2$ nanoporous microspheres/beads via direct electroleess plating, utilizing a novel reducing agent in aminopropyltriethoxy silane (APTES) [4]. The nanoporous silica surface drives the formation of dense nanoparticles films with excellent optical enhancement and excellent reproducibility, with circa 11% variation in signal when measuring 10 individual microparticles. The Ag shells structures can be seen from SEM and TEM micrographs in Figure 3.

APTES also develops inter-particle SiO$_2$ allowing for the direct growth of SiO$_2$ shells by further addition of a silica precursor and pH adjustment, using for example the Stober chemistry [5]. The system further facilitates the formation of immunoassay substrates as SiO$_2$ can be readily functionalized with various surface chemistries.

Figure 3: (a) FE-SEM image of as-grown Ag nanoparticle on nanoporous silica cores. (b) SERS intensity at 1452 cm$^{-1}$ on single beads after self-assembly of amino-thiophenol revealing that equal amount of AgNO$_3$ and APTES supports most optically efficient films. (c) HR-TEM images revealing the embedding of the individual Ag particles within silica. (d) FE-SEM image following SiO$_2$ shell formation. (e) HR-TEM image of the silica covered Ag nanoparticle.

4. Lab-on-a-bead multiplex assay

For assays, the Ag/SiO$_2$ beads were functionalized with unique Raman reporter molecules and the SiO$_2$ shells were grafted with amine surface groups to immobilize monoclonal antibodies. The overall structure allows forming supports for dual sandwich immunoassay at the level of each single beads, whereby the Raman markers afford identification, and secondary fluorescent-tagged antibody offer quantification.

The surface grafted antibodies were chosen to be specific for three novel pancreatic cancer antigens, TSP-2, CEACAM1 and TIMP-1, all were easily detected utilizing Raman spectroscopy. Plotting of the fluorescence intensity against antigen concentration also shows that this system is capable of near attomolar detection from the measurement of single particles.

Figure 4: (a) SERS/fluorescence spectra on a single particle after formation of immunoassay (black: no antigen is present; red antigen present). (c) Fluorescence intensity with respect to antigen concentration, showing attomolar sensitivity.

5. Conclusions

Through the use of direct colloid chemistry, highly controlled Ag nanoparticle films form on silica cores, with excellent reproducibility and spectral enhancement. These are ideal immunoassay substrates and were shown to give excellent SERS as well as fluorescence for attomolar sensitive detection from single particle measurements.

When grown on a magnetic core, Au shells are both superparamagnetic and plasmonic, and form chain like structures in the presence of an external magnetic field. Infrared thermography confirmed the additional heat generation in hydrogels containing magnetoplasmonic nanoparticles in comparison to blank hydrogel, paving the way towards targeted photodynamic therapy.

Abstract
Efficiency of single hybrid plasmonic nanostructures are discussed for SHG and SPDC. After successful fabrication, results show good agreement between experiments and FEM simulations, indicating field enhancement effect as the main factor for increased efficiency. SPDC simulations at the nanoscale predict measurable pair rate for structures already optimized for SHG. Finally, use of entangled photon pairs as a resource for decision-making applications is shown as advantageous over classical photonic states.

1. Introduction
Combining the optical nonlinear efficiency of dielectric media with the electromagnetic field enhancement of double resonant plasmonic nanostructures [1] is a promising way toward nanosized nonlinear photonic devices, with potential applications in integrated and quantum optics. However, previous studies on nanostructure arrays [2] have neither yet shown significant nonlinear efficiency increase, nor if the slight increase comes from the field enhancement inside the dielectric medium or from the plasmonic structures themselves influenced by their dielectric surrounding.

The goal of our work is to obtain single hybrid nanostructures which optimize the efficiency of Second Harmonic Generation (SHG) and/or Spontaneous Parametric Down Conversion (SPDC) inside a nonlinear nanocrystal by using plasmonic nanoantennas.

2. Efficient nonlinear optics at the nanoscale
2.1. Tools and methods
This project requires several kinds of nonlinear optical experiments to be conducted at a single nanoparticle level, while being able to detect weak signals with different wavelengths. To this end, we have realized a versatile setup able to easily switch from one experiment to another while keeping the sample at the same spot, thus reducing experimental variability. The setup is also fully computer controlled, with an autonomous optimization algorithm to run experiments in the most reproducible way.

The numerical simulation part is based on a Finite Element Method to estimate the nonlinear intensity generated by a single nanoparticle in a quantitative way, so as to compare and discriminate between different origins of nonlinear signal [3].

Finally, a rigorous nanofabrication protocol based on electronic lithography and precise realignment has been elaborated. This enables one to optimize each nanostructure according to the crystalline orientation of each nanocrystal experimentally determined beforehand.

2.2. Results
Obtained hybrid nanostructures with gold or aluminum antennas and KTP crystals are pictured on figure 1 with SEM imaging. For each of them, a replica of the bare plasmonic antennas is fabricated nearby to directly compare their efficiency.

After fabrication, SHG measurements let us compare the efficiency between the bare crystal (before), the bare antennas and the hybrid. Efficiency is significantly higher for hybrid structures compared to each isolated component as for the case of figure 1, reaching SHG enhancement of up to 3 orders of magnitude compared with nonlinear nanocrystal, and up to 2 orders of magnitude compared with bare aluminum or gold antennas.

Simulations are in agreement with such enhancement factors, and indicate the main origin of nonlinear efficiency is attributed to the crystal and not the antennas.

2.3. SPDC predictions at the nanoscale
Our team has developed a theoretical model for SPDC at the nanoscale [4], enabling one to quantitatively evaluate the produced photon pair rate for any given configuration. Simulations show that optimizing a hybrid nanostructure in SHG makes it optimized in SPDC as well, confirming the increase of nonlinear efficiency within the nanocrystal thanks to field enhancement effect.

Quantitative evaluations have been made in realistic experimental conditions. Adding plasmonic antennas to a nanocrystal raises nonlinear efficiency by several orders of magnitude, to the point it becomes theoretically measurable. Noise estimate from experimental attempts on
bare KTP is below the theoretical expected optical signal, opening the way to SPDC detection from a single nanostructure for the first time.

3. Entangled photon pairs for decision making

Macroscopic sources of SPDC are commonly used for frequency conversion, as well as entangled photon pair production in quantum optics experiments. The relative simplicity of production, modification and transmission of such quantum photonic states has also attracted interest from the artificial intelligence community to study the potential advantage of quantum information processing over binary information in this respect.

Recent works on single-photon-based decision making [5] have triggered new discussions on the advantages of using entangled photons as a resource for situations like the Competitive Multi-Armed Bandit problem, a typical competitive decision-making situation related to resource allocation between isolated, individual decision makers in an uncertain environment. Such configuration raises new questions with respect to the single decision maker, such as fairness, maximum common income or protection from greedy actions of a player against another.

The 2-arms bandit problem has been experimentally implemented, using a well-known design [6] enabling one to produce either single photons, correlated photon pairs or entangled photon pairs using the polarization of light as a quantum state basis. Higher common benefits and equality for entangled photons, as well as zero conflict of decision, are demonstrated for entangled photons whereas correlated photon pairs only show similar performances for a restricted set of initial conditions. With entangled photons, greedy actions are shown to be counterproductive with respect to both common and individual reward: in this situation, a given player can never get more benefits than the other whatever its decision. On the other hand, both common and individual benefits can be optimized by autonomous polarization alignment schemes, thus providing error correction protocol without any communication between players.

4. Conclusions

Hybrid plasmonic nanostructures have been fabricated and demonstrated as optimized for SHG with both gold and aluminum as plasmonic material. Field enhancement is shown to be the main cause of efficiency increase, in agreement with predictions for SPDC. Finally, entangled photon pairs from a macroscopic source are shown to be of interest for social decision-making situations.

Abstract

We propose beam-shaping and light filtering in reflection based on translational invariant structured mirrors. These meta-mirrors are composed by a thin structured layer with a transverse modulation of the refractive index in the micron scale and positioned in front of a metallic flat mirror. The strong transverse spectrum modification allows spatial filtering and beam-shaping of the reflected beam. The study points toward new possible type of filtering devices without alignment needs due to its translational invariance.

1. Introduction

Angular filtering and beam-shaping are commonly used in many applications to obtain suitable beams from a large variety of radiation sources. The enhancement of the spatial characteristics of the radiation becomes critical for active systems as lasers where the maximal radiation brightness is linked to a single transverse mode emission. Moreover, conventional filtering methods use large sized and external gratings that strongly diminish the robustness of lasers and in particular of micro-lasers. Therefore, the spatial filtering is especially a huge problem in Broad Area Semiconductor (BAS) lasers, Vertical Cavity Surface Emitting Lasers (VCSELs) and microchip lasers, where external filtering arrangements are not convenient.

Beam-shaping and spatial filtering methods based on Photonic Crystals (PhCs) have been proposed as an alternative method for micro-lasers [1]. It has been numerically demonstrated for BAS amplifiers in a single path configuration but also in intracavity arrangement for lasers [2]. Such filters involve simultaneous transverse and longitudinal refractive index periodicities, demanding 2D and 3D spatial photonic structures, an important challenge for current technologies. A satisfactory solution is the replacement of a cavity mirror by a structured meta-surface with filtering and beam-shaping properties.

2. Model

The present paper considers a flat meta-mirror for this purpose. It is based on a thin grating, i.e. a structured layer with a transverse modulation of the refractive index in the micron scale and positioned at a distance of some wavelengths from a metallic mirror. The created transverse structured cavity strongly modifies the transverse spectrum of reflected beams allowing spatial filtering and beam-shaping. The obtained translational invariant meta-mirror would not need supplementary alignments, would neither decrease the micro-laser robustness and becomes more suitable for fabrication purposes. The fabrication of such structures, with wavelength scale size and sufficient index contrast have been experimentally demonstrated by laser writing technologies in organic and nonorganic materials [3].

The analytic approximation considers the meta-mirror as a structured layer composed by equispaced rectangular elements in front of the flat totally reflecting mirror creating a transverse modulated Fabry-Perot cavity, see Fig.1.a. The structured layer is considered as a pair of shifted diffraction gratings and each rectangular element introduces Mie resonances in the system in addition to the ones associated to the cavity.

We consider the incident wave with wavenumber vector \( k_i \) incident angle \( \alpha \) with respect the surface normal direction and corresponding wavevector \( \tilde{k} = (k_x, k_z) = k_i \sin\alpha, \cos\alpha \).

The grating with transverse period \( a \) and wavenumber \( h = 2\pi/\alpha \) diffracts the entering light in components corresponding to the diffraction orders. We consider the field expansion into the zero- and first diffraction orders with transverse wavenumbers \( k_x \pm q_i \) which field amplitudes are written in the vector form \( \tilde{A} = (A_x, A_y, A_z) \).

The reflection matrix of the whole structured mirror as a function of the incident angle is

\[
\hat{R}_{nx}(k_x) = \left[ \hat{R} + \hat{T} \hat{P} \left( \hat{1} + \hat{R} \hat{P} \right)^{-1} \hat{T} \right],
\]

where the complex matrices correspond to reflection \( \hat{R} \) and transmission \( \hat{T} \) of the structured layer and propagation between the structured layer and mirror \( \hat{P} \).

We scan the incident angle of the plane wave to obtain the reflection coefficient profile, arising filtering and beam-shaping properties for certain parameter sets (Fig.1.b). The reflection profiles are associated to diffraction associated to the grating, resonances of the structured cavity and Mie resonances of the structured layer elements.
Fig. 1 (a) Scheme of the structured mirror. (b) Reflection coefficient $R$ as a function of the incident angle and distance between the structured layer and mirror ($D_z$), the rest of the parameters are $g=0.7\mu m$, $a=2\mu m$, $b=1\mu m$, $n_1=1$, $n_2=1.68$, and incident wavelength $\lambda=1\mu m$. (c) Reflection coefficient profile (blue), spectrum of an incident Gaussian beam (red) and reflected spectrum (green) for $D_z=3\mu m$. (d) Incident noisy beam with high $M_2$ and reflected beam with a strongly improved beam quality factor. (e) Far field intensity obtained by FDTD integration with the same parameter set and (f) field intensity distribution between the rectangular elements and mirror for the corresponding spatial mode.

A possible application is the generation of hypergaussian and top-hat beams from Gaussian beams by the simple reflection in selected structures. Filtering and noise reduction in light beams is available from narrow reflection spectra, see Fig.1c, obtaining a decrease of the beam quality factor $M_2$ in a factor 2 due to the reduced angular spectrum in reflection (see Fig.1.d).

The reflection spectra given by the model is in good agreement with the far field intensity obtained from full FDTD simulations with proper beam widths, obtaining similar profiles of first diffraction orders (compare the central part of Fig.1.e. with Fig.1.c).

The reported study uncovers rich possibilities for these new structured mirrors allowing to model beam spectra by simple reflection. We expect the proposed meta-mirrors for applications in micro-lasers and other devices where classical filtering mechanisms are not possible.

Periodic metasurface structures processed with spatially shaped femtosecond laser: Fundamentals and Applications

Xiaowei Li

Beijing Institute of Technology, Beijing, China
*corresponding author, E-mail: lixiaowei@bit.edu.cn

Abstract

We propose a mask-free approach of femtosecond laser nonablative processing to fabricate extremely long-range uniform periodic metasurface structures. A cylindrically focused femtosecond laser efficiently produce large-area periodic modified-stripes, then, the modified-stripes act as fine etch stops to generate desirable structures on sample surfaces during the subsequent chemical-etching process. The diffraction efficiency of the incident light could be flexibly tuned. This morphology-controllable periodic surface structures may facilitate application prospects in broad fields, such as optical communications, optical sensors, etc.

Abstract

We use super-resolution imaging to unravel the coupling of light to a bowtie antenna and investigate single-molecule trapping dynamics.

1. Introduction

Metal nanoparticles (NPs) sustain a collective oscillation of their free electrons, called a localized surface plasmon resonance (LSPR), when excited by an electromagnetic wave. When this incident wave is resonant with the LSPR frequency, the field intensity is strongly increased in the near field of the NP \cite{1}. Plasmonics thus provides a unique tool for the manipulation and confinement of light well beyond the diffraction limit. These plasmonic systems have a broad range of applications, from biology \cite{2} and sensing \cite{3}, to nonlinear optics \cite{4} and as antennas transmitting and receiving light signals at the nanoscale \cite{5}.

Bowtie nano-antennas (BNAs) are small dimers composed of two equilateral triangles with a nano-gap, which have been shown to be very effective for optical manipulation. Indeed, while conventional optical tweezers have the ability to trap and manipulate particles on the micron-scale, the plasmon resonances in BNAs can be used to induce forces on a scale well below the diffraction limit of light. The field enhancement and confinement drastically amplifies optical gradient forces, allowing for trapping and manipulation of these nanoparticles in a sub-diffraction-limited volume \cite{7}.

However, many difficulties remain in experimentally detecting and measuring the trapping dynamics in real and their dependence on shape, size, and enhanced field properties of the localized electromagnetic modes due to the limitations of optical microscopy. Single-molecule fluorescence (SMF) imaging is a powerful technique to optically study structures beyond the diffraction limit by localizing isolated fluorophores and fitting the emission profile to the microscope point-spread function \cite{6}.

In this work, we use SMF in combination with plasmonic...
optical trapping to experimentally investigate the plasmon-fluorophore coupling at the nanoscale.

2. Results and Discussion

SMF measurements of Cy5 in a water solution were made using the random absorption of molecules onto the surface. Dye molecules in a water solution diffuse too fast to be detectable. When one of these molecules adsorbs stochastically to the surface of the sample, it is immobilized long enough to be imaged at which point the intensity distribution of the dye is fit to a 2D Gaussian. The emission location of a single molecule is then determined by the fit, and the localization precision increases with the number of collected photons, thus allowing precisions at the nanometer scale for the brightest points. By observing the adsorption and desorption process over thousands of frames, a map of all single-molecule intensities over the entire sample surface can be made (Figure 1). For the ITO reference sample (no BNAs), a homogenous spatial distribution of dye molecule positions can be seen, with no fluorescence enhancement. However, when the dye molecules couple to BNAs a large fluorescence enhancement can be seen, illustrating the efficiency of these bowties as nano-antennas.

By tracking the molecules over time, we can further probe the dynamics of the system. We define a trapping efficiency function $\eta$, which takes into account the average intensity enhancement, and track length (Figure 2). For the ITO reference values, the average of $\eta$ over all tracks is 1. It reaches a maximum when the dye emission has the best overlap with the BNA LSPR (70 nm side-length BNAs), then monotonically decreases as the detuning between dye and LSPR increases. BNAs thus provide a useful balance between enhancement and losses for single-molecule fluorescence applications. This plasmon-coupled emission has the potential to improve the resolution of single-molecule imaging by increasing the quantum yield and photostability of fluorescent probes, while significant reductions in emission decay times result in high-emission-rates with emitters that can be controllably coupled to the antennas.

3. Conclusions

By using the random motion of single dye molecules in solution to stochastically scan the surface, and by assessing emission intensity, wavelength, and density of emitters as a function of position and time, we gain new insight into the properties of plasmonic systems and observe the plasmonic optical trapping dynamics in real time.

‘Hybrid plasmonic’ to ‘plasmonic only’ transition and ‘photonic only’ mode supported by semiconductor near metal

Ning Liu*

1 Department of Physics and Bernal Institute, University of Limerick, Co. Limerick, Ireland
*corresponding author, E-mail: ning.liu@ul.ie

Abstract

Optical modes supported by dielectric-semiconductor-insulator-metal 4-layered structure have gained increasing popularity in recent years due to their applications in nanoscale waveguides and lasers. In this communication, the author is going to discuss different optical modes that co-exist in this configuration, their physical origins and their applications in nanophotonics.

Among all optical modes that are supported by the dielectric-semiconductor-insulator-metal 4-layered configuration, the author studied in detail the fundamental TM and TE modes. The fundamental TM mode has demonstrated significant advantages over pure photonic modes, which are supported by similar structures without metal, to realize resonant cavities at sub-diffraction limited volumes [1]. It is still under debate in literature, however, how to understand this fundamental TM mode and if the hybridization picture is an accurate description to this mode. Using a model system of insulator-semiconductor-insulator-metal planar structure, the author is able to show analytically and also through variational methods that a transition from ‘hybrid plasmonic’ mode to ‘plasmonic only’ mode exists in this fundamental TM mode at a given configuration as the frequency of the mode increases [2].

The author recently discussed the fundamental TE mode that co-exists in this 4-layered structure [3]. The dispersion relation of this TE mode closely resembles that of the TE photonic mode supported by a dielectric-semiconductor-insulator 3-layered structure. Because no TE mode can exist at a single insulator-metal interface, this TE mode can be called a ‘photonic only’ mode. This TE mode can also be regarded as the superposition of TE photonic mode in the 3 layered structure and its mirror mode due to metal response [2, 3].

Once the semiconductor layer is no longer with infinite lateral span, resonant cavities can be formed (Fig. 1(a)). In most cases, the resonant cavity modes with TE characteristics have poor quality factors due to their lack of mode confinement. Nevertheless, as the length scale of the nanocavity decreases to near the diffraction limit ~ \( \lambda/2 \), only resonant electric dipole and magnetic dipole modes are supported by these semiconductor nano-patches. In this case, when the magnetic dipole mode is perpendicular to the metal substrate, its mirror dipole is in the opposite direction to its original one (Fig. 1(b)) and the total magnetic dipole moment decreases due to the metal response. As a result, the radiation loss of this magnetic dipole mode, even though based on TE ‘photonic only’ mode, is substantially smaller than that of the electric dipole mode, which is based on the TM plasmonic mode [3]. The author therefore calls this magnetic dipole mode near metal as a ‘dark’ magnetic dipole. Low loss photonic cavities at extremely small dimensions (down to 110 nm \( \times \) 210 nm \( \times \) 210 nm) via ‘dark’ magnetic dipole mode is predicted [3]. These subwavelength cavities show great promises to be used in the future high density integrated plasmonic applications.

Figure 1: (a) Diagram of side view of a truncated cylindrical semiconductor disk near metal. (b) diagram showing the metal response creating an opposing electric field, and therefore a magnetic dipole in the opposite direction.

III-V Semiconductor Nanowires for Optoelectronic Applications

Ziyuan Li¹, Hark Hoe Tan¹, Chennupati Jagadish¹, and Lan Fu¹

¹Department of Electronic Materials Engineering, Research School of Physics and Engineering, The Australian National University, Canberra, ACT2601, Australia
*corresponding author, E-mail: ziyuan.li@anu.edu.au, lan.fu@anu.edu.au

Abstract
III-V semiconductor nanowires have been extensively studied for optoelectronic device applications such as lasers, photodetectors, solar cells and light-emitting diodes owing to their small footprint, unique morphology and physical properties, as well as high flexibility to form heterostructures on lattice mismatched substrates such as Si. Here we review our work on the growth and fabrication of III-V semiconductor nanowire materials for solar cell and photodetector applications.

1. Introduction
In the 21st century, there is an increasing demand globally for high performance optoelectronic devices due to their wide range of potential applications. For example, solar cell devices convert the solar energy, a renewable and sustainable resource, into electricity [1]. Photodetectors and cameras working in a broad wavelength range have been applied in manufacturing inspection/measurement systems, scientific instrumentation (e.g. IR spectroscopy), astronomy, search and rescue, surveillance, free space optical communications, missile tracking, and night vision. One-dimensional nanostructures such as III-V semiconductor nanowires (NWs) have tunable absorption and emission properties as optical antennae due to their highly anisotropic morphology and large refractive index [1]. Their development may lead to high-performance, multi-functional, compact but low-cost devices outperforming current planar structure-based optoelectronic technologies. In this talk, we will present our work on binary InP nanowire based solar cells and ternary GaAsSb nanowire based infrared photodetectors.

2. Experimental
In this work, the III-V semiconductor nanowires were synthesized using metalorganic chemical vapor deposition (MOCVD) technique. The axial junction InP nanowires were grown by selective-area epitaxy (SAE) technique on a SiO₂-masked p⁺-doped (111)A InP substrate [2-3], while the GaAsSb nanowires were grown by metal-catalyzed vapor-liquid-solid (VLS) technique on a GaAs (111)B substrate with 40 nm Au colloids as seed particles [4]. To fabricate single horizontal nanowire based optoelectronic devices, the single nanowires were first mechanically transferred to a thermally oxidized p⁺-Si substrate with a 300-nm SiO₂ layer. Ti/Au (10/220 nm) contacts were defined by electron beam lithography (EBL) patterning and deposited on each side of nanowires using electron beam evaporation followed by a lift-off process [1-4].

3. Optoelectronic applications
3.1. Axial junction InP single nanowire solar cells

Figure 1: I-V curves under 1 Sun @ AM1.5G illumination for the p-i-n nanowire solar cells without (blue curve) and with (red curve) SiNₓ coating layer [2]. The inset shows TE mode electric field distribution of the devices simulated by COMSOL under 680 nm light illumination, respectively.

For solar cell applications, in comparison with other III-V nanowires, InP nanowires have the advantages of the most suitable bandgap, low surface recombination velocity and excellent mobility [2,3]. We demonstrated axial p-i-n junction InP single horizontal nanowire solar cells (growth starts with p-segment) whose efficiency could reach up to 6.5% [2]. Furthermore, we changed the bottom up growth sequence of the nanowires with n-segment first and then i- and p-segments, obtaining solar cells with an enhanced efficiency up to 7.73% due to the reduced p-type dopant (Zn) diffusion [3]. By further coating the nanowire devices with a conformal SiNₓ dielectric layer of 100 nm, the solar cell efficiency can be significantly enhanced due to an
optical antenna effect from SiN$_x$ coating [2]. Figure 1 shows the typical $I$-$V$ curves under 1 Sun@AM1.5G illumination from the best single p-i-n nanowire solar cells without and with SiN$_x$ coating layer, respectively. The electric field distribution of the devices under 680 nm light illumination and TE mode simulated by COMSOL are presented in the inset, respectively, indicating the enhanced optical antenna effect and thus doubled light absorption introduced by the dielectric coating, leading to remarkably improved peak efficiency of the solar cells to 10.5% [2].

3.2. GaAsSb single nanowire infrared photodetectors

![Figure 2: Photocurrent spectral response of the single horizontal GaAs$_{0.56}$Sb$_{0.44}$ nanowire photodetector at 0.15 V under the room temperature [4]. The inset shows the schematic of the device.](image)

III-V semiconductor nanowires (NWs) have also been widely used as photodetectors. In particular, ternary GaAs$_{1-x}$Sb$_x$ NWs offer wide tunable bandgaps (from 870 (GaAs) to 1700 nm (GaSb)) with associated flexibility in bandgap engineering for infrared photodetection [4]. We demonstrated a room temperature single horizontal GaAs$_{0.56}$Sb$_{0.44}$ nanowire based photodetector as shown in Figure 2, obtaining high responsivity (2.37 and 1.44 A/W) and detectivity (1.08×10$^8$ and 6.55×10$^7$ cm$^2$/Hz/W) under a very low bias voltage of 0.15 V at the telecommunication wavelengths of 1.3 and 1.55 μm, respectively [4]. The performance could be further improved by in-situ passivation such as adding an InP shell on the GaAsSb core nanowires. The results indicate that the nanowires are promising candidates for applications in future nanoscale integrated optical telecommunication/sensing systems.

4. Future work

To further enhance the nanowire based optoelectronic devices, we propose that plasmonic or metamaterial structures could help enhancing as well as engineering nanowires’ light absorption and thus to realize high-performance and more functionalities. On the other hand, low-dimensional quantum structures such as quantum wells or dots are also potential candidates to be integrated into nanowires to extend the detection wavelength to mid- to long-wavelength infrared range.

5. Conclusions

In conclusion, axial junction InP nanowires were grown by SAE technique and successfully fabricated as solar cells, showing higher efficiency by various approaches, such as changing the bottom up growth sequence of the device structure or coating a SiN$_x$ layer on the nanowires to enable the optical antenna effect. We also demonstrated room temperature GaAs$_{0.56}$Sbx$_{0.44}$ single nanowire infrared photodetectors grown by VLS technique, showing broadband infrared photoreponse and potential in telecommunication applications.

Abstract

Optical excitation of hot carriers in metals can be injected into adjacent semiconductors to collect sub-bandgap photons. In the present work, we experimentally demonstrate that transition metal nitrides and carbides can act as metals and generate hot electrons by optical illumination similar to metals. Since transition metal nitrides and carbides have broad absorption in the visible spectrum with tunable plasmon resonances, they have the potential to be used for photocatalytic, photovoltaic, and photothermal applications to harvest solar energy.

1. Introduction

Photons which go through non-radiative decay processes excite hot carriers and a number of novel applications with photo- or plasmon-induced hot carriers have been studied in the past decade. Recently it has been shown that highly conductive ceramics can be alternative materials of noble metals. In the search for alternative plasmonic materials, transition metal nitrides have been one of the most studied materials in the past few years [1,2]. This is due to their chemical stability, cost effectiveness, and ease of fabrication. Most importantly, transition metal nitrides are one of the few classes of non-metallic materials with plasmon resonances in the visible range.

As transition metal nitrides and transition metal carbides are categorized as cermets, the band structures of both classes of materials are metallic, implying that carbides can also be used in plasmon enhanced photoelectric and photothermal conversions. Owing to their large intrinsic absorption in the visible and NIR range, transition metal carbides have intrinsically high photothermal effects. Among them titanium nitride (TiN), titanium carbide (TiC), tantalum carbide (TaC) are such materials which become plasmonic in the optical range. Previous studies have shown that nitride/carbide seems to be best suited for applications related to photo-absorption and photothermal effects. To further explore the possibility of nitride/carbide for photo-absorption related applications, here we present our recent results on nano-structured of nitride/carbide for photocatalytic, photoelectric, and photothermal applications.

2. Discussion

We synthesized a composite of metal-free carbon nitride–carbon dots (C₃N₄–C dots) and plasmonic TiN NPs to improve the photoelectrochemical water-splitting performance under simulated solar radiation (Fig. 1(a and b)) [3]. Hot-electron injection from plasmonic TiN NPs to C₃N₄ played a role in photocatalysis, whereas C dots acted as catalysts for the decomposition of H₂O₂ to O₂. By incorporating the TiN NPs and C dots, a six-fold improvement in the catalytic performance of C₃N₄ was observed (Fig. 1(c)). This two-step approach overcame the low optical absorption, limited spectral utilization, and charge recombination losses and presented an effective way to improve the photocatalytic activity.

![Figure 1: (a) Schematic structure of TiN-C₃N₄-C dots composite, (b and c) absorbance and visible photosresponse of TiN-C₃N₄-C dots composite. (d) Photocurrent from TiN-oxide-TiN trilayers upon 700 nm light irradiation.](image)

In the photoelectric application, a metal-insulator-metal structure was fabricated using TiN thin films instead of metals. Upon visible light illumination to the sample, photocurrent were observed as shown in Fig. 1(d). The photon energies were smaller than the bandgap of the insulator, hence the photo-excited electrons were generated.
not at the insulator film but at the TiN film [4]. Another example is a TiN/Ge sub-bandgap photodetector shown in Fig. 2(a). The TiN and Ge films were sputtered on Si/SiO$_2$ substrate by DC-magnetron sputtering. The Ge and TiN films show broad absorption in visible-near infrared (Vis-NIR) region. For Ge with top TiN, the generation of photocurrent by NIR light illumination is confirmed up to 2600 nm, well exceeding the absorption limit of Ge (Fig. 2(b)). Figs. 2(c) and 2(d) show the time-dependent photocurrent response of TiN/Ge samples with Ni and Au contacts without bias at different excitation wavelengths. The photocurrent observed for the wavelengths which have smaller photon energies than the bandgap of Ge, the hot carriers were excited at the TiN film. The photocurrent of TiN/Ge with Ni contact is nearly twice than that with Au contact. Thus, fabricating TiN plasmonic nanostructures will inevitably increase hot carrier excitation from TiN by improving the optical absorption and hence performance of TiN/Ge photodetector.

![Figure 2: (a) Schematic structure of TiN/Ge sub-bandgap photodetector, (b) Photocurrent density of Ge and top TiN with Au and Ni contacts at zero bias. Time-dependent photoresponse of Ge and Top TiN with Ni and Au contacts at different excitation wavelengths.](image)

To explore carbide for photovoltaic application, a TiC/ZnO/TiC trilayer was fabricated, and the photoresponse of the sample was observed up to 1000 nm, as shown in Fig. 3(a) [2]. Since the bandgap of ZnO is ~3.2 eV (~390 nm), the measured photoresponse was attributed to the optically excited hot electrons in the TiC layer. However, more investigation on plasmonic properties of TiC needed. Compared to TiC, the tantalum carbide (TaC) can have a strong plasmon resonance in the visible to NIR range. Thus, TaC nanostructures are candidates for use in plasmon enhanced hot carrier generation.

The plasmon enhanced photothermal conversion of transition metal carbides has found applications in chemical reactions. A nanocomposite catalyst (Co@TaC) consisting of cobalt (Co) NPs and TaC NPs has been shown to produce hydrogen and carbon monoxide from carbon dioxide and methane (i.e., carbon dioxide reforming), as shown in Figure 3(b) [5]. The nanocomposite was free from precious metals and was heated by both a heater and a Xe lamp, where the TaC acted as a light-to-heat transducer. This work demonstrates that plasmonic nanomaterials comprising catalytic late-d-metals and early-d-metal carbides and/or nitrides are promising materials toward efficient solar-to-chemical energy conversions.

![Figure 3: a) Time dependent photocurrent measured at a wavelength of 1000 nm for the TiC/ZnO/TiC structure. b) Production of hydrogen over Co@TaC by flowing methane and carbon dioxide gases at 600 °C. The red and blue bars correspond to hydrogen production in light and darkness, respectively.](image)

3. Conclusions

We have demonstrated that transition metal nitrides and carbides can be used for plasmonic photoelectric and photothermal conversions by the excitation of hot carriers. Since those non-metallic materials can be less expensive and can have higher conversion efficiencies than noble metals, research on non-metallic materials for plasmonic photoelectric and photothermal conversions will be an exciting field that will lead to practical applications.

Abstract
Silicon-based nanoplasmonic waveguides are key in integrated chip-scale nanoplasmonic circuitry. In this work, we demonstrate a Si-nanoplasmonic waveguide platform to examine nonlinear light emission processes, such as third harmonic generation, second harmonic generation, white light emission, as well as photogenerated carrier ultrafast streaking and carrier amplification. We envision these structures to be vital components in integrated nanoplasmonic CMOS nanoplasmonic devices.

1. Introduction
As a critical material for electronics, Si has also become the foundation for integrated optical systems, and it merges electronics, photonics, and nanoplasmonics on a single platform. The potential of Si as a functional nonlinear optical material has incited many nonlinear frequency conversion studies. The well-established growth and processing techniques of silicon (Si), along with its transparency at telecommunication wavelengths (1260nm-1675nm) and a high nonlinear refractive index, have made silicon-on-insulator (SOI) nanophotonic waveguides a top contender for chip-scale optical circuitry [1]. However, to date, light emission from silicon is most practically accessible through nonlinear optical wave mixing due to the indirect bandgap of the material. Although silicon is a material that absorbs visible light, third-harmonic generation driven by infrared signals can be used to generate visible light in silicon structures.

In this work, we present the current state-of-the-art physics and applications of Si-based nanoplasmonic waveguides pertaining to strong nonlinear light interaction within the Si core of a Si-loaded nanoplasmonic waveguide. In particular, we present coherent light-emitting mechanisms and incoherent broadband light generation. Furthermore, we also show that the strong light-induced nanoplasmonic field streaks and amplifies the electronic charge within the Si layer. We envisage that the coherent generation in silicon-based nanoplasmonic waveguides could provide a platform for integrated, broadband visible light sources and entangled photons on future hybrid electronic-silicon photonic chips.

2. Results and Discussion
Nanofabrication processes are developed to integrate Si photonic waveguides and Si-based nanoplasmonic waveguides. First, passive propagation and nonlinear interactions are investigated in silicon-on-insulator photonic waveguides to provide a detailed understanding of nonlinear interactions present in silicon at \(\lambda = 1550\)nm and the relevant timescales of the interactions.

Figure 1 illustrates the Si-loaded nanoplasmonic waveguide fabricated on a SOI wafer.

Figure 1: Scanning electron micrograph of Si-loaded nanoplasmonic waveguides integrated onto a deeply-etched characterization beam.

Extensive investigations into third-harmonic and second harmonic generation in silicon nanoplasmonic waveguides are performed. When nonlinear light generation and ultrafast modulation are then applied to sub-wavelength silicon-based nanoplasmonic waveguides, we measure third-harmonic light generation with conversion efficiencies greater than \(7 \times 10^{-5}\) in a nanoplasmonic waveguide having a footprint of only 0.40μm². Furthermore, we demonstrate that the strong nanoplasmonic field at the metal-Si interface can result
in ponderomotive acceleration of the two-photon absorption-generated free-carriers in the Si layer. We show that such electrons can be accelerated to energies exceeding the threshold for impact ionization.

Measurements of the emitted light intensity reveal that the highly confined nanoplasmonic field drives an electron avalanche, and white light emission resulting from the avalanche is observed to scale exponentially with the input power.

3. Conclusions

These results demonstrate the feasibility for conversion of near-IR radiation to visible radiation with technologically significant efficiencies, enabling nanoscale Si-based visible light sources on a chip.

Abstract

Modern information display panels are composed of many optical films with different functions. The trend in the industry has been reducing both the number and thickness of these films. While there have been many proposals so far to replace these films with plasmonic structures or metasurfaces, their optical performance is less than ideal, often below that of current technology. Here, design principles of optical metasurfaces for display applications are investigated and examples with promising optical performances are provided.

1. Introduction

Information displays, from those in smart phones, tablets, and computers to those in television sets and head-up displays, have become integral part of modern society. With ever-increasing demand for mobility or higher aesthetics, the display panels are becoming thinner and lighter at a fast rate: commercial panels from only five years ago already look very thick and bulky by today’s standards. Now even foldable products are in the market and the trend is expected to continue for foreseeable future.

One of the biggest challenges in the field is the number and thickness of required optical films or layers. Both in liquid-crystal displays (LCD) and organic light-emitting diode (OLED) displays, there are many optical layers. Two linear polarizers are typically required for LCD’s due to their working principle (voltage-controlled polarization rotation); a circular polarizer is used in OLED to reduce the reflectance of external light; a set of color filters are used to express colors; a set of compensation films or retardation films are used to improve the contrast and other properties at large viewing angles; a transparent electrode is used to route the electric signals while transmitting the optical signals.

All these optical layers were at least several tens of microns in earlier display panels. Many of the layers have been reduced in their thicknesses: for example, recent resin-type polarizers have thicknesses of a few microns rather than a few tens of microns or even a hundred of a film-type polarizer. However, due to intrinsic limitation of the anisotropy or absorption coefficient of available materials, it is becoming much harder to reduce the thickness further.

2. Metasurfaces for displays

2.1. Opportunities and challenges

The above mentioned problems with current materials are the reason why plasmonic structures or metasurfaces with artificially tailored resonances are providing interesting alternatives. Due to the large density of conduction electrons, a few nanometer or tens of nanometer-thick metallic films can already possess very strong optical response. By tailoring the shape and size of these metallic inclusions or subwavelength holes in metallic films, one can hope to achieve desired optical characteristics required for display panels. In this spirit, there have been numerous proposals to use these plasmonic structures to applications, ranging from color filters to polarizers, over the last decade. However, the optical loss coming from the non-zero imaginary part and finite magnitude of the complex permittivity of metals in the visible wavelengths are providing an enormous challenge to metal-based metasurfaces. It limits the sharpness of the resonances and can also place an upper bound for efficiency. Hence, a very careful design is needed to realize a metasurface-based optical films that possess a comparable optical performance with conventional films but have much smaller thicknesses.

2.2. New designs of metasurfaces for displays

Here we show that a systematic design approach can result in much improved performance for color filters as well as polarizers. Especially, the coupled-mode theory plays an important role in designing the spectral properties of metasurfaces. It is also shown that a multi-functional device is possible in a sub-micron-thick design.

Abstract

The use of all-dielectric materials instead of plasmonic ones to enhance magneto-optical effects allows one to avoid significant energy losses that are present in metals. In this paper, we perform experimental research of the transverse magneto-optical Kerr effect and the inverse Faraday effect in 1D dielectric magnetic structures. Experimental results demonstrate a significant enhancement of magneto-optical effects, as well as high transparency and high Q-factor of the obtained resonances, which opens up broad opportunities for applications.

1. Introduction

The transverse magneto-optical Kerr effect (TMOKE) is promising for light modulation since it allows laser beam intensity control via external magnetic field that could be switched at GHz frequencies. Magnetoplasmmonic crystals were shown to provide resonant enhancement of the TMOKE at the excitation of surface plasmon polaritons, as their propagation constant is sensitive to structure magnetization [1]. However, plasmonic structures have high absorption due to the presence of metal layers. Nowadays there is a growing interest to another type of structures with significantly higher quality factor – hybrid metal-dielectric and all-dielectric structures – which possess lower absorption and could be used for efficient light localization and control. Instead of surface plasmon polaritons, waveguide or Mie modes could be excited to increase the light-matter interaction in these structures. We concentrate our attention on all-dielectric gratings where guided modes with narrow resonances are known to be excited [2]. Excitation of the waveguide modes is responsible for enhancement of the magneto-optical effects with simultaneous increase of the resonance Q-factors demonstrated experimentally in Kretschmann configuration in smooth magnetic films [3]. At the same time, numerical simulations show that the use of all-dielectric magnetic gratings leads to a significant increase of magneto-optical effects [4]. On the other hand, inverse magneto-optical effects can be enhanced as well due to local field concentration.

We present an experimental study of both the TMOKE and the inverse Faraday effect in 1D all-dielectric gratings etched in ferromagnetic iron-garnet film and show that magneto-optical effects experience multifold increase due to the excitation of the waveguide modes.

2. Waveguide modes in all-dielectric iron-garnet gratings

To enhance the magneto-optical effects, we use a 1D all-dielectric grating made of bismuth-substituted iron garnet film perforated with ion beam etching deposited on gadolinium gallium garnet substrate. The width of the air gap of our grating is 200 nm, and the period of the grating is 400 nm. The height of the grating is 225 nm, and the smooth iron-garnet sublayer of 75-nm thickness is left below the grating.

In such a grating, the waveguide modes propagating perpendicular to the slits are excited under the following excitation condition:

\[
\kappa_m \sin \theta + mg = \pm \beta_g,
\]

where \( \kappa_m = \frac{2\pi}{\lambda} \) is the propagation constant of the incident light, \( \lambda \) is the wavelength in free space, \( m \) is the diffraction order (an integer number), \( G \) is the reciprocal lattice vector value, \( \beta_g = \frac{2\pi}{\lambda} n_\text{eff} \) is the propagation constant of the waveguide mode, \( n_\text{eff} \) is the effective refractive index of the mode. Light is incident from the air.

3. The TMOKE in all-dielectric iron-garnet gratings

When a waveguide mode is excited, the propagation constant \( \beta \) acquires a linear on gyration coefficient \( \Delta \beta \), which is dependent on the direction of magnetization [1]:

\[
\beta = \beta_g + \Delta \beta(M).
\]
As a consequence, the TMOKE arises, which is determined by the relative change in the intensity of the reflected or transmitted light at the magnetization reversal. Usually, the TMOKE is observed in absorbing media with oblique incidence of light polarized in the plane of incidence (p-polarization) and is characterized by the parameter $\delta$:

$$\delta = \frac{I(+M) - I(-M)}{I(+M) + I(-M)},$$

where $I(+M)$ and $I(-M)$ is the intensity of the transmitted light in the magnetized in two opposite directions. It is worth noting that the TMOKE is usually measured for reflected light, but in the case of transparent structures, the effect can also be investigated in transmitted light.

### Figure 1: Transmittance (a) and the TMOKE (b) spectra.

Experimental results presented in Fig. 1 show a significant enhancement of the TMOKE in all-dielectric structures up to $\delta=0.5\%$ with simultaneously high transmittance $T=50\%$. For a comparison, the smooth iron-garnet film of the same width provides the TMOKE of about $\delta=0.004\%$. At the same time, the TMOKE resonances in grating structures also have high Q-factor and a width of about 5 nm, which is a significant advantage over plasmonic structures.

### 4. The inverse Faraday effect

The excitation of waveguide modes leads to a significant enhancement of the local field in the iron-garnet layer. This is favorable for the increase of the inverse Faraday effect, as its value is proportional to the local electric field: $\mathbf{H}_{\text{eff}} \propto [\mathbf{E} \times \mathbf{E}']$. The experimental results demonstrate the presence of the resonance in the inverse Faraday effect, related to the waveguide mode excitation (Fig. 2).

### Figure 2: The angular spectrum of the inverse Faraday effect.

### 5. Conclusions

The TMOKE and the inverse Faraday effect in all-dielectric 1D-periodic structures of iron-garnet was investigated. The multifold enhancement of magneto-optical effects in such structures was confirmed experimentally. The optical and magneto-optical resonances in 1D gratings are characterized by the high transmittance and high Q-factors making 1D iron-garnet gratings promising for various applications.

Abstract
Metasurfaces, which are periodic or semi-periodic arrangement of artificially made nanostructures, have attracted enormous attention thanks to its unprecedented ability to control the electromagnetic properties of light. In this invited talk, general introduction of metasurface will be presented with their principles and applications. Furthermore, a full-space control, which indicates simultaneous phase modulation of transmission and reflection space, will be discussed with its theoretical and experimental demonstration.

1. Introduction
Metasurfaces composed of planar distribution of subwavelength-scale structure have been studied by various research groups due to their superb capacity for modulation of light properties, such as optical phase, amplitude, polarization, spectral resonance, etc [1-3]. Especially, phase modulation via metasurface have been considered to show outstanding performance because unwanted diffraction order can be suppressed unlike conventional spatial light modulators. This is also because the application of Pancharatnam-Berry (PB) phase method is intuitive: the phase shifts exactly twice the in-plane rotation angle of each scatterers. This properties are well understood by many research groups and applied in various optic devices such as augmented reality device [4], complex-amplitude modulation [5], achromatic optical lens operating in various frequency ranges [6]. However, most of the metasurface devices handle or design only one space, i.e. transmission or reflection spaces, only to discard the remnant space undesigned.

Recently, thanks to widespread attention of metamaterials in nanophotonics, which are manmade materials for the implementation of desired effects, the scattering radiation pattern including multipolar phase effects are utilized for various optical or physical applications [7]. Kerker effect is a typical example, which is zero backward scattering under the condition that electric permittivity and magnetic permeability are equal to each other. Thanks to the development of nanofabrication, control of magnetic permeability becomes possible in optical frequency regime, and this leads to Huygens’ metasurface by overlapping electric and magnetic dipole mode with equal values [8]. In addition, the control of multipolar coefficients has been studied for various purposes in nanophotonics, such as magnetic mirror [9], diffraction control [10], polarization control devices [11].

In this invited talk, several metasurfaces for unprecedented light manipulation will be presented. Firstly, we will outline the physical instruments and examples of metasurfaces. Particularly, the generalized Kerker effect will be discussed and metasurfaces providing phase modulation will be introduced with their applications. Then, we will introduce bifacial metasurface that can control the phase value of transmission and reflection simultaneously, in visible region [12]. The physical analysis and experimental demonstration will be explained, and this shows the independent phase modulation at both spaces is successfully realized.

2. Results and Discussion

Figure 1: Bifacial metasurface (a) Operational mechanism of the bifacial metasurface. Unit cell is composed of the amorphous silicon, which operates by circularly polarized light. (b) SEM image of the fabricated bifacial metasurface.

Fig. 1 shows the schematic and morphology of the bifacial metasurface. Fig. 1a represents the general concept of the bifacial metasurface. Bifacial metasurface operates on the circularly polarized transmission and reflection, which are cross-polarized components that are influenced by PB phase, at target wavelength of 660 nm. In principle, the geometric size of each meta-atom determines the phase difference between transmission and reflection spaces, and PB phase is exploited to cover the whole phase values of both spaces. As a physical background, the phase difference can be explained by interference of multipolar components. Since
multipolar components has their own phase parity with respect to forward and backward scattering, and by fine-tuning of the nanostructures’ size, it is possible to control the portion of excited multipole modes, which is to modulate phase difference. Fig. 1b shows the SEM image of the fabricated sample, and this shows that the geometric sizes and in-plane rotation angles are spatially varying parameters for desired design method.

![Image of hologram](image)

**Figure 2:** Experimentally captured holographic images from bifacial metasurfaces. Upper four images are captured from transmission space, and lower four images are from reflection space.

Fig. 2 shows the holographic images captured while varying z-plane from 30 μm to 30 μm. Hologram images were measured from optical microscope setup with beam splitter to capture image from reflection space. It is noteworthy that the distinctive hologram images are generated from same image plane, although the focused z-plane is same at both cases. The hologram conversion efficiency is calculated from numerical simulation, which is up to 9.85% and 16.8% for reflection and transmission space, respectively.

![Image of beam deflection](image)

**Figure 3:** Experimentally captured beam deflection sample from bifacial metasurfaces. (a) Schematic illustration of asymmetric beam steering. (b) Upper graph shows image captured from transmission, and lower from reflection space.

Fig. 3 shows the second example of bifacial metasurface: Unlike conventional metasurface beam deflection, presented sample in Fig. 3a can detour light beam with distinctive deflection angles in transmission and reflection beam. When CP light is incident onto this sample, deflection angles are determined as 7.903° and -15.96° for transmission and reflection space, respectively [2]. The images captured by CCD camera is shown in Fig. 3b, showing extinction ratio of 6.33 and 6.81 dB, respectively.

### 3. Conclusion

In this invited talk, several metasurfaces which show hologram and unprecedented manipulation of light properties are discussed. We present physical mechanisms and conceptual illustration of the recent metasurfaces as well. Then we introduced bifacial metasurface, which is a new platform for full-space light control that can be applicable in future optic devices. Finally, we will discuss our perspective on this area.

Engineering the Refractive Index and Phase of Optical Metamaterials

Zi Jing Wong

Department of Aerospace Engineering, Texas A&M University, College Station, USA
E-mail: zijing@tamu.edu

Abstract

Subwavelength structuring of materials can lead to exotic material properties and device functionalities. Using nanostructures, we engineered the real and imaginary part of refractive index and the phase distribution to create optical metamaterials with extraordinary properties and performances.

1. Introduction

For centuries, the extent of light control and optical functionality has been bounded by the limited range of natural materials’ refractive index. This limit is finally broken with the advent of metamaterials which utilize artificially-engineered subwavelength nanostructures to create new material properties. Similarly, the restricted performance of optical materials based on periodic nanostructures has been substantially improved with the use of spatially-varying subwavelength nanostructures. The in-plane symmetry breaking has led to many novel ultrathin optical devices. Here we discuss our experimental efforts in engineering both the real and imaginary part of refractive index as well as the spatial phase distribution to realize new optical phenomena and functionalities.

2. Experiments

2.1. Engineering real part of refractive index

Negative refractive index metamaterials (NIMs) and zero refractive index metamaterials (ZIMs) have shown many extraordinary light behaviors, such as negative refraction, superresolution imaging, electromagnetic tunneling, gigantic optical nonlinearity, photon doping, etc. However, these metamaterials suffer significant optical loss, particularly at visible wavelengths. We showed that by using low beam current focused ion beam patterning through a nanomembrane, low-loss bulk optical metamaterials can be realized in both the near infrared and visible wavelengths [1,2]. More than 40% transmission is achieved even for a 20-layer metal-dielectric metamaterial. We also utilized the low-loss negative phase property at 780 nm to probe the existence of hyper-complex quantum theories in a single-photon quantum optics setup (Figure 1) [2]. The results show that the metamaterial phase commutes with other phases with high precision, placing a new limit on the prediction of hyper-complex quantum theories.

![Figure 1](image1.png)

Figure 1: The use of a NIM in a single-photon optical setup to provide the negative phase to probe the fundamental quaternion quantum theory at 780 nm visible wavelength.

2.2. Engineering imaginary part of refractive index

Material loss is usually undesired in optoelectronics, as it leads to heating and power dissipation. To compensate the loss, material gain is often used, which gives birth to amplifiers and lasers. By judiciously designing both material gain and loss using parity-time (PT) symmetry, a new path for optical mode and emission control can be attained. For instance, a PT-symmetric microring cavity with the unique feature of single-mode lasing can be realized [3]. Here we reveal a novel PT-symmetric structure which supports both lasing and coherent perfect absorption (CPA) modes at the same frequency within a single device (Figures 2 and 3) [4]. This enables strong modulation from coherent amplification to coherent absorption and paves the way for a compact on-chip multifunctional optical device.

![Figure 2](image2.png)

Figure 2: (a) Effective real and imaginary refractive index of the designed PT-symmetric structures and (b) its experimental realization.
2.3. Engineering subwavelength phase distribution

Metamaterial-based optical cloaks have thus far used volumetric distribution of the material properties to gradually bend light and thereby obscure the cloaked region. Hence, they are bulky and hard to scale up to macroscopic sizes. In addition, typical carpet cloaks introduce unnecessary phase shifts in the reflected light, making the cloaks detectable. Here we demonstrate an ultrathin metasurface cloak working at visible wavelengths using the concept of reflection phase manipulation (Figure 4) [5]. The skin cloak comprises a metasurface with distributed phase shifts rerouting light and rendering the object invisible. Our conformal cloak conceals a three-dimensional arbitrarily-shaped object by complete restoration of not only the wavefront, but also the phase of the reflected light. In contrast to bulky cloaks with volumetric index variation, our device is only 80 nanometer (about one-ninth of the wavelength) thick and potentially scalable to hide macroscopic objects. We believe the ultrathin image manipulation capability demonstrated here can lead to practical applications in flexible optoelectronics, 3D display and military technologies.

3. Conclusion

Using subwavelength nanostructures, exotic real and imaginary part of refractive index, and spatially-varying phase distribution can be engineered. These give rise to novel optical properties and many unconventional optical behaviors. Future integration of metamaterials with soft materials and quantum materials will potentially lead to exciting applications in smart optoelectronics, high-speed optical communications and quantum computing.

Index-Tunable Terahertz Metadevices Based on Double-Layered Closed-Ring Resonator Arrays

Tatsunosuke Matsui

Abstract

We demonstrate index-tunable metamaterials and metadevices working in the terahertz (THz) frequency range based on double-layered closed-ring resonator (CRR) arrays. The double-layered CRR arrays have a narrow-band transmission peak which shows negative refractive index even in normal incidence. We show that the effective refractive index can be widely tuned by slightly shifting relative position of the arrays. We also demonstrate that THz beam steering can be realized by utilizing the double-layered CRR arrays arranged in a wedge-shaped prism.

1. Introduction

In recent years, numerous studies have been carried out to develop novel types of metamaterials and metadevices [1]. In typical metamaterials, working frequencies are usually restricted only in a narrow range due to their resonant characteristic. Therefore, numerous attempts have been made to add tunability to develop active metadevices. Slightly shifting relative position of layered metamaterials is one of approaches taken to develop such active metadevices [2–6]. Here we demonstrate our recent results on index-tunable terahertz (THz) metamaterials and devices based on double-layered closed-ring resonator (CRR) arrays [7, 8]. The THz response of double-layered CRR arrays was first reported by Gu et al., in which negative refractive index was demonstrated even in normal incidence [9]. Here we show that the resonant characteristics [7] and the effective refractive indices [8] of double-layered CRR arrays can be tuned by slightly shifting relative position of the arrays. We also show that index-tuning capability can be utilized to make beam steering devices.

2. Numerical simulation

In this study, modeling of the devices and analysis of their THz responses were performed using 3D EM field analysis software, CST Microwave Studio (Computer Simulation Technology Inc.). In Fig. 1, the unit cell of a double-layered CRR arrays is schematically shown. We assume that periodic arrays of CRR made of aluminum are placed on quartz substrate and the periodic boundary conditions are applied in x and y directions. The linearly polarized EM plane wave is incident from normal (z) direction and complex scattering parameters are evaluated. The impedance and the effective refractive indices were retrieved from the analyzed complex scattering coefficients.

We have further simulated negative refraction and beam steering characteristics of EM waves by arranging double-layered CRR arrays in a wedge-shaped prism.

3. Results and discussion

In double-layered CRR arrays, the resonant modes between the two sides of the paired CRRs and the near field coupling between adjacent CRRs on the same substrate can be excited and show negative refractive indices at their resonant frequency. These resonant modes can be approximately modeled by a composite LC-resonance circuit [7, 9]. The effective values of capacitance and inductance of such an LC circuit is quite sensitive to the geometrical parameters of the CRR array. Therefore, slight displacement of relative position of CRR arrays mainly alter effective capacitance and thus our operative principle is possible. Figure 2 summarize real ($n_r$) and imaginary ($n_i$) part of the retrieved effective refractive indices, respectively, for each relative displacement $ \Delta x $. It can be seen that the effective refractive indices can be widely tuned by slightly shifting relative position of the arrays.
At around 0.70 THz, double-layered CRR arrays show relatively low reflection loss and negative refractive index. Therefore, we arranged double-layered CRR arrays in a wedge-shaped prism and simulated negative refraction and beam steering characteristics of EM waves at around this resonant frequency. Figure 3 summarize negative refraction behaviors of THz EM waves from double-layered CRR arrays arranged in a wedge-shaped prism for different relative displacement $\Delta x$. It can be seen that THz EM wave is negatively refracted and the angles of refraction can be changed by slightly shifting relative position of the arrays, which implies that THz beam steering devices can be fabricated by our index-tuning principles.

4. Conclusions

In this study, we have numerically analyzed THz responses of the double-layered CRR arrays and we show that effective refractive indices can be widely tuned by slightly shifting relative position of the arrays. We have also demonstrated THz beam steering devices can be developed by utilizing index-tunable metamaterials.

Abstract
We report integrated nano-opto-electromechanical systems consisting of coupled InP waveguides on a silicon platform. Due to the tight optical confinement, large phase shifts are obtained over short propagation lengths, enabling efficient switching at low voltages in a small footprint. Due to their large response to nanomechanical displacements, they can also be applied as integrated displacement and force sensors.

1. Introduction
The mechanical reconfiguration of a photonic structure can result in strong changes in the propagation constant of a guided mode or in the resonant frequency of a confined mode, which enables optical switching in an integrated circuit and tuning of filters and lasers, among others. This concept, borrowed from micro-opto-electro-mechanical systems, is now being implemented in nanophotonic structures, resulting in nano-opto-electro-mechanical systems (NOEMS) [1], where nm-scale displacements of a moving part produce sizable changes in the device response. A practical challenge however is the implementation of advanced NOEMS within integration platforms where other functionalities such as light amplification and detection can be realized. In this paper we describe NOEMS based on vertically-coupled nanophotonic InP waveguides on a silicon wafer, a platform suitable for the integration of lasers and detectors.

2. Device structure
Figure 1 (a) shows an electron microscope image of an optical switch based on InP NOEMS. It is 2x2 switch based on Mach-Zehnder Interferometer (MZI). Two 50/50 Multi-Mode Interferometers (MMIs) split light into two branches and then recombine it. Electromechanically actuated phase modulators are implemented in both branches (Figure 1 (b)). The InP waveguides are defined by patterning a InP/InGaAsP/InP layer bonded on top of a silicon layer using silicon nitride, BCB and silica. Grating couplers, ridge waveguides and MMIs are defined in the bottom InP layer only, while the phase modulator consists of a double-membrane InP/air/InP waveguide obtained by selective etching of the InGaAsP sacrificial layer. 60µm-long tapers ensure efficient coupling from the mode of the bottom waveguide to the supermode of the double-membrane waveguide. The two InP membranes are oppositely doped to form a p-i-n junction, where the application of a reverse bias results in an electrostatic force on the top suspended membrane. At zero applied bias the vertical gap spacing between the membranes is 200 nm, and light exits through the cross port after interference. When a bias is applied, the distance between the membranes and thereby the effective index of the mode changes, leading to a phase change. The light is switched to the through port when the phase difference reaches π. The total length of the actuated part, including tapers, is 140 µm.

3. Results
Switching from the cross to the through port is obtained with a voltage as low as 4.4V and provides an extinction ratio above 15dB within a 34 nm bandwidth in the C-band. The device also serves as a very efficient optical phase modulator, being able to modify the optical phase by more than 4π with only 6.5V voltage in a 140µm-long waveguide. As compared to other MEMS switch structures, mostly involving switching voltages of tens of V [2], the low switching voltage of our device facilitates the electrical driving. Besides its application as a compact, low-voltage and low-power optical switch, the device can also function as an integrated optical sensor of displacement and force, as a nm-scale displacement of the top membrane results in a measurable transmission change.

4. Conclusions
An integrated optical switch based on nanomechanical InP waveguides on silicon is demonstrated. Strong optical confinement and efficient actuation based on vertical p-i-n junctions enable a small footprint and a low switching voltage. As lasers, detectors and passive circuit elements can be realised in the same InP-on-Si membrane technology [3], this approach can lead to the integration of nanomechanical switches and sensors in photonic integrated circuits.

Quantum control of bosonic modes with superconducting circuits

Liang Jiang\(^1\)

Abstract

Bosonic modes are widely used for quantum communication and information processing. Recent developments in superconducting circuits enable us to control bosonic microwave cavity modes and implement arbitrary operations allowed by quantum mechanics -- in particular, quantum error correction against excitation losses. We investigate universal control of a single bosonic code with superconducting circuits, including unitary control, driven-dissipative control, holonomic dissipative control and quantum feedback control.

1. Introduction

Quantum computation holds the promise of solving certain problems much faster than any known classical computers, such as the larger integer factorization and simulation of quantum many-body problems. To build a real quantum computer, the physical platform should work in the quantum regime with long coherence time, fast quantum operations and good scalability, which are seemingly insurmountable obstacles for current technologies. The promising strategies to overcome such obstacles are quantum error correction (QEC) and fault-tolerant quantum computation, where the coherence time of the quantum memories can be extended and the quantum operations fault-tolerant to some low-probabilistic errors below a certain threshold.

The physical platform we consider is circuit quantum electrodynamics (QED), which is an analog of cavity QED using superconducting circuits. Cavity QED engineers the environment of the atoms by placing them in a cavity that supports only discrete bosonic modes of the electromagnetic field. Circuit QED uses superconducting qubits (such as transmon qubits) as artificial atoms coupled to microwave resonators. A key advantage of circuit QED is that it is trivial to obtain extremely strong coupling between the superconducting qubits and the cavity. For quantum computation using circuit QED, a storage cavity resonator with long coherence time as a harmonic oscillator can encode the quantum information, while the transmon qubits can act as an ancilla and the Josephson junctions coupled to a readout cavity as the reservoir to aid universal control of the storage cavity.

2. Key Results

We investigate the universal control of a harmonic oscillator with the aid of an ancilla qubit dispersively coupled to it. Quantum control of the harmonic oscillator can be achieved in the coupled qubit-oscillator system with qubit as an ancilla. Many theoretical and experimental works were devoted to preparing arbitrary oscillator states assisted by an ancilla qubit with Jaynes-Cummings (JC) coupling. However, it is more challenging to universal control of the oscillator, which usually needs a multi-level ancilla, slow adiabatic evolutions or a large number of control operations. In superconducting circuits, the transmon qubit (as an ancilla) and the cavity resonator (as a harmonic oscillator) can be tuned to be largely off-resonant with the off-resonance much larger than their JC coupling strength, resulting in a strongly dispersive model\(^1\),

$$\hat{H} = \omega_T |e\rangle\langle e| + \omega_C a^\dagger a - \chi a^\dagger a |e\rangle\langle e|$$

where \(\omega_T\) and \(\omega_C\) are the ancilla qubit transition frequency and the oscillator frequency, respectively, \(a\) is the annihilation operator of the oscillator excitation, \(\chi\) is the dispersive coupling strength, and \(|e\rangle\) denotes the excited state of the ancilla.

We may understand the dispersive Hamiltonian in two different ways with different applications [Fig. 1(a) (upper panel)]. On the one hand, the oscillator frequency has a shift dependent on the ancilla state, which leads to changes in the amplitude and phase of photons reflected from or transmitted through the cavity and therefore enables a QND measurement on the ancilla state. On the other hand, the ancilla transition frequency has a shift proportional to the oscillator photon number that is much larger than the cavity line width and atomic line width in the strongly dispersive regime, which splits the qubit spectrum into a series of separately resolved peaks representing the distribution of photon numbers within the driven cavity and hence can be used as a photon number detector. Moreover, for quantum control of the cavity, such a dispersive coupling regime in circuit QED makes it possible to selectively address the ancilla if and only if the cavity state has a specific photon number, hence providing new opportunities for universal control of the oscillator.

Recently, we have theoretically proposed \(^2\) and experimentally demonstrated \(^3,4\) the selective number-dependent arbitrary phase (SNAP) gate of the cavity mode,

$$R[\hat{\phi}] = \sum_{n=0}^{\infty} e^{i\phi_n} |n\rangle\langle n|,$$

where \(\hat{\phi} = \{\phi_n\}_{n=0,1,2,\ldots}\) and the geometric phase \(\phi_n\) is associated with the photon number state \(|n\rangle\). Together with the displacement operation of the cavity mode

$$D[\varepsilon] = e^{-\varepsilon a^\dagger - \varepsilon^* a},$$

SNAP gate enables universal control of the cavity mode. We have proved the existence and constructed the composite
sequences of $D[x]$ and $R[\varphi]$ (e.g., $\cdots D_x R_y D_x R_y \cdots$) to convert the cavity ground state $|0\rangle$ to an arbitrary target state $|\psi\rangle = \sum_{n=0}^{n_{\text{max}}} c_n |n\rangle$. For example, we can now deterministically prepare single microwave photon inside the cavity, which can be used as a deterministic single microwave photon source. Moreover, our protocol can provide a deterministic source that can generate arbitrary microwave photon states. Besides prepare arbitrary photon states, using composite sequences can achieve an arbitrary unitary operation $U = \sum_{i,j=0}^{n_{\text{max}}} U_{i,j} |i\rangle \langle j|$ that acts non-trivially in the subspace spanned by $|0\rangle$, $\cdots$, $|n_{\text{max}}\rangle$. This enables us to universally control a d-level system associated with the lowest d-levels of the cavity mode.

Then we further investigate the extension from the universal unitary control to arbitrary quantum channel construction (CPTP maps) for the oscillator by quantum non-demolition (QND) readout of the ancilla and quantum feedback control [5]. After that, we show that reservoir engineering can be another promising strategy to realize universal quantum computation in some unitarily evolving subspace of the oscillator [6,7]. Finally, we can use the quantum control schemes to entangle different bosonic modes for universal quantum computation [8,9].

3. Conclusions

We have shown that universal control of the oscillator can be achieved with the aid of an ancilla qubit. The SNAP gates of a harmonic oscillator (cavity resonator) can be implemented by indirect control of a dispersively coupled ancilla (transmon qubit), and the SNAP gates combined with displacement operation are sufficient for universal control. We may even construct arbitrary quantum channels for the oscillator by QND readout of the ancilla and quantum feedback control. However, it is still an open problem to find the optimal control of the qubit oscillator system with minimized expenditure of energy and resources.

Large-parameter-space optimization of photonic crystal structures

V. Savona
Institute of Physics, École Polytechnique Fédérale de Lausanne (EPFL), CH-1015 Lausanne, Switzerland
vincenzo.savona@epfl.ch

Recently, considerable progress has been made in the optimization of various figures of merit of photonic crystal (PhC) cavities and waveguides [1–5], leading to record performance in terms of quality factors in various materials [6, 7], broad band slow light [8], second and third harmonic generation [9, 10]. Here, by combining large scale numerical simulations to a hybrid stochastic-global optimization strategy, we demonstrate that there is still considerable room for further improvement of these figures of merit when increasing the size of the parameter space. In particular, we optimize a silicon-on-air L3 PhC cavity to a quality factor $Q > 8 \times 10^6$. While this result may have limited impact on applications, as disorder in the current state of the art in fabrication sets a statistical upper bound of roughly $Q \approx 4 \times 10^6$, we show that the same optimization strategy leads to unprecedented results for buried Si/SiO$_2$ PhC cavities, where we demonstrate a theoretical $Q$-factor in the 10 million range. We also optimize a buried Si/SiO$_2$ nanobeam cavity to an unloaded quality factor $Q \approx 6 \times 10^6$ with a nanobeam length much shorter than existing optimized structures. These results set the new state of the art for the PhC cavities under study. The present optimization approach opens the way to a new class of optimized PhC designs for monolithic structures or for structures made of low-index-contrast materials, such as AlN, GaN or silicon nitride, holding great promise for enhanced optical nonlinearity, sensing, and solid-state quantum optics.

Fig. 1. Scheme of a L3 cavity where the highlighted holes are allowed to vary in position and size. Preserving the two mirror symmetries, only the parameters of the 20 red holes are independently varied, resulting in 53 independent parameters.

Abstract
The recent results on multilayer solar cells and perovskite solar cells may revolve the photovoltaics field, but they still require light control strategies to optimize their performance. Dielectric nanostructures have the ability to efficiently control light at the nanoscale by directing or confining it. This has an enormous interest in several fields, and in particular in solar cells. This contribution pretends to summarize the latest results in this key topic in the fields of nanophotonic and energy harvesting.

1. Introduction
Photovoltaics is currently considered one of the most promising renewable energy sources. For this reason, scientific efforts are nowadays focused on the enhancement and improvement of the solar cells performance. This is a multidisciplinary work involving material engineering, electrical and electronic engineering, as well as photonics.

In the last years, encouraging materials like perovskites [1], or brilliant complex devices as multilayer solar cells are producing great expectations to achieve very high efficient solar cells, even larger than the Shockely-Queisser limit [2]. However, both options require further efforts in order to optimize their optical and electrical performance. On one side, convenient materials for the electron and hole transport layers are required, while on the other side an efficient light management inside the solar cells is critical.

While the use of plasmonic nanoparticles was introduced several years ago for improving the light confinement in solar cells [3,4], the recent advances in the dielectric nanostructures is awakening the interest on them to direct and also confine light into the active layers [5,6].

2. Methodology
The control of light in a solar cell can be achieved in several parts of the device. While some strategies considered the nanostructuration of the front and/or rear electrodes, other works have been considering the insertion of nanostructures in the intermediate or even in the active layers [8, 9]. All these strategies will be considered and analyzed.

3. Discussion
In this contribution, we will discuss about the latest results in the use of the dielectric nanostructures to improve the light management inside solar cells, including our latest results on this topic as well. With this analysis, we want to show the importance and the promising future of these techniques, helping on the improvement of the solar cells performance.

Metasurfaces Enabled by Locally Tailoring Disorder in Phase-Change Materials

Martin Hafermann¹, Philipp Schöppe¹, Jura Rensberg¹, Carsten Ronning¹

¹ Institute of Solid State Physics, University of Jena, 07743 Jena, Germany

Abstract

Active optical metasurfaces with dynamic switchable, tunable, and reconfigurable optical functionalities are an emerging field in photonics and optoelectronics. Especially, chalcogenide-based phase-change materials, such as Ge₂Sb₂Te₅ (GST), can be fast and repeatedly switched by external stimuli between crystalline and amorphous states, typically accompanied by a tremendous difference of the electronic and photonic properties. Here, we demonstrate that focused ion beam-induced disorder in highly confined regions can transform phase-change materials in active optical metasurfaces by locally adjusting the phase [1]. A careful control of the amount of disorder can locally tailor the effective refractive index in GST films on the nanometer scale, which is highly promising for multilevel switching applications. In contrast to direct laser writing, focused ion beam irradiation enables the fabrication of subwavelength-scaled, planar, nonvolatile, and reconfigurable optical metasurfaces, with pattern sizes clearly below the diffraction limit of common laser light sources.

Can optical forces be used to measure the polarization state of light inside a birefringent waveguide?

Abstract

We investigate whether optical forces acting on Mie particles in the vicinity of a birefringent waveguide can be used to reconstruct the polarization state of light inside that waveguide and we identify an interesting parameter regime in which an unambiguous retrieval is possible. This result is utilizing the fact that the lateral Belinfante momentum strongly depends on the helicity of the confined light.

1. Mie resonances and Optical forces

We investigate whether the displacement of a microparticle on top of a waveguide, caused by the near-field optical forces, can be used to retrieve the polarization of light inside that waveguide [1]. We start by evaluating the different forces acting on a particle that is positioned on top of—or at a fixed height above—a waveguide. In general, three optical force components act on a particle, held in the evanescent field of a birefringent waveguide: one acting in each direction ($x$, $y$, $z$). The most important force is the gradient force ($F_z$). This force attracts the particle towards the region of largest intensity [2]. For very small particles, this is the strongest force. The second component ($F_x$) pushes the particle along the direction of propagation of the guided modes [3]. The final component ($F_y$) is proportional to the spin density of the field. In the case of a dipolar, Rayleigh particle, these components can be calculated analytically, for larger particles, one needs to calculate several terms of the Mie series [4, 5, 6, 7]. The complete geometry is visualized in Fig. 1A.

2. A non-invasive measurement of the polarization of light in optical networks

The polarization of light is used to encode information in optical networks [8]. This increases the need for efficient techniques that allow for sensitive probing of the polarization state [9, 10]. An optical probe, with versatility comparable to the microwave probes, would be extremely beneficial to the development of photonic chips. Such a probe would allow for a direct, local measurement of the polarization, thus reducing design iterations and streamlining fabrication.

3. Results

It is known that the lateral force ($F_y$), which ultimately exists because of a transfer of the Belinfante momentum from the evanescent field to the particle, depends on the helicity of light. This suggests that this force can be used as a proxy for light’s helicity. To confirm this idea, we calculate the lateral Belinfante force as a function of the polarization space (Poincaré sphere) and as a function of the electromagnetic properties of the Mie particles (radius, refractive index). In Fig. 1 we visualize the two-dimensional mapping of the Poincaré sphere on a rectangular grid (Fig. 1B-C) and subsequently show the lateral force acting on a Silicon microparticle with radius $a = 300$ nm on this grid (Fig. 1D).

Here, we show that the lateral force acting on microparticles in the evanescent field of a waveguide strongly depends on the size of the particle. Moreover, it is intriguing to see that the maximum and the minimum of the lateral force do not coincide with the north and south poles of the Poincaré sphere. Instead, we find that the maxima are shifted along the great circle of the sphere. This shift depends on the size and refractive index of the particle. The physical origin of this resonant effect relies in the phase difference between scattered TE and TM components of light.

This effect can be used to retrieve the polarization state of light inside waveguides. Indeed, the displacement of a particle on top of a waveguide is found by balancing the lateral force, shown in Fig. 1D with the restoring gradient force that tries to keep the particle at the position of highest intensity. By comparing this displacement of a large Mie particle with the displacement of a smaller one, it is possible to retrieve the polarization state of the light inside the waveguide. This is visualized in Fig. 1F.

4. Conclusions

In addition to the celebrated examples of actuation, sorting, and spectroscopy, our work explores a new application of lateral forces, enabling the development of a local, minimally invasive probe of the polarization state inside waveguide.
Figure 1: (A) Schematic description of the forces acting on a particle in the evanescent field of a waveguide. The guided mode that generates the evanescent wave can have any polarization state represented by the green dot on the Poincaré sphere in (B). (B) and (C) together illustrate the mapping from the Poincaré sphere onto a rectangular grid. (D) and (E) show the helicity-dependent lateral force on a 300 nm radius silicon particle on top of a birefringent waveguide and the corresponding displacements. (F) The overlap of several contour lines of $y_0$ and $\Delta y$. Because of the relative displacement of these contour lines in the $\phi$ direction, we generally find only two intersections per set of two measurements.

Colloidal inorganic perovskite nanocrystals (PNCs) are solution-processable functional materials whose emission can be easily tuned via both size and composition.\textsuperscript{1} Their exciting optical properties such as the large absorption cross-section and high photoluminescence quantum yield (PLQY) make them ideal candidates for a broad range of photonics and optoelectronics applications.\textsuperscript{2} In this work, we present an overview of the exceptionally efficient exciton transport mediated by Förster Resonant Energy Transfer (FRET) in perovskite systems of increasing dimensionality. With a specifically designated optical setup, we directly measure the spatial extent of exciton hopping in a controlled two-dimensional assembly of 0D PNCs, which provides a flat energy landscape with minimal geometric disorder.\textsuperscript{3} Steady-state and time-resolved PL microscopy, together with physical modeling of exciton transport, shows an exciton diffusion length of 200 nm and diffusivity as high as 0.5 cm\textsuperscript{2}/s, which greatly exceed the values reported for FRET-mediated exciton diffusion in chalcogen-based quantum dot solids, and, importantly, matches the optical absorption depth. We further explore the exciton diffusion paradigm in 1D perovskite nanowires and 2D nanosheets, where we image the diffusion across the whole system, with diffusion lengths larger than 1µm. In addition to the exciton diffusion mapping, a significant portion of this work has been dedicated to the optimization of the substrate and the sample passivation. Specifically, we show that with a thermal-based atomic layer deposition process we are able to apply a ~3nm-thick transparent ceramic coating (aluminum oxide) which ensure optical stability over a four month period, thus overcoming the instability issue which often hinders the actual integration of perovskite materials in optoelectronics devices. Our investigation therefore provides the foundation for employing FRET-mediated exciton diffusion in nanostructured perovskites, while also demonstrating practical guidelines to use these bright emitters in optoelectronic devices beyond proof of principle.

Abstract
We study theoretically dielectric-based TiO2/SiO2 Hyperbolic Metamaterial (HMM) at mid-infrared region with high transparency in visible. We report unique resonant properties of a HMM resonator and specific field distribution due to its hyperbolic dispersion relation. We also report an active metasurface which is switchable between HMM and Mic resonator.

1. Introduction
Hyperbolic metamaterial (HMM) is a structure in which substances of positive and negative permittivity are periodically stacked, and novel optical functions are expected by making the equi-frequency surface of hyperboloid in wavenumber(k)-space. HMMs extremely modify the shape of dispersion relation of light because their unconventional open isofrequency surface in k-space permits enlargement of k without limitation [1]. Such isofrequency surface induces the divergence of density of state, resulting in enhancing light-matter interactions. Although similar enlargement of k without limitation can be obtained in negative dielectric (ND) optical waveguide (i.e. plasmonic waveguide), propagation modes are not bulk (3D) waves, but surface (2D) waves [2,3]. Hence, HMMs show a great promise in nanophotonics for the miniaturization of bulk optical components such as optical waveguides or optical cavities.

There are some theoretical proposals in an nano-optical waveguide based on HMMs [4,5]. Anomalous resonant properties are observed experimentally in HMM cavity [6]. However, since conventional HMMs utilize metals, large losses hide interesting properties of HMMs. To solve the problem, HMM utilizing dielectric is promising. Since phonons have Reststrahlen band where the real part of the permittivity is negative with smaller imaginary part than metals, resulting in achieving lower loss HMMs.

In this paper, we report TiO2/SiO2 multilayered HMM and describe the resonant properties of its optical cavity.

2. Dielectric-based HMMs
Figure 1 shows a schematic view of a rectangular HMM optical cavity with the cross section of Wx x Wy, where the length of the cavity is infinite. Optical axis of the HMM is taken in x-direction.

Figure 2(a) shows permittivity spectra of TiO2 and SiO2 in mid-infrared region, where ND is observed at \( \lambda_0 = 8 - 9 \mu m \) and \( \lambda_0 = 12.5 \mu m \). This is caused by Reststrahlen band between TO and LO phonon. Figure 2(b) shows effective permittivity spectra of infinite TiO2/SiO2 multilayered system \( (W_x=W_y=\infty) \). The multilayered system becomes type II HMM at \( \lambda_0 = 8 - 9 \mu m \) (the gray area in Fig. 2(b)).
4. HMM optical cavity

To investigate unique resonant property of HMM cavity, we performed FDTS (Finite-Difference Time Domain) simulation using the above effective permittivity in the configuration as shown in Fig. 1. Linearly polarized pulsed light was irradiated along the x-axis as an incident light and resonant conditions were investigated from an absorption spectral map with respect to the cavity size.

Figure 3 shows the calculated electric field distribution inside a TiO$_2$/SiO$_2$ HMM resonator ($W_x=50\text{nm}$ and $W_y=90\text{nm}$) at the resonance of $\lambda_0=8.58\mu\text{m}$. X-shaped resonant mode is observed clearly thanks to the lower loss permittivity beside the phonon resonance [1,7]. Such mode profile is attributed to the hyperbolic dispersion relation in k-space of HMMs. We will discuss the mechanism of the resonant pattern and the application to nano-optical cavity.

Solution-processed semiconductor nanocrystals have been attracting increasingly greater interest in photonics including spectrally pure color conversion and enrichment in quality lighting and display backlighting [1,2]. These nanocrystals span different types and structures of semiconductors in the forms of colloidal quantum dots and rods to a more recently developing class of colloidal quantum wells. In this talk, we will introduce the emergent field of nanocrystal optoelectronics using solution-processed quantum dots and wells. In particular, we will present a new concept of all-colloidal lasers developed by incorporating nanocrystal emitters as the optical gain media, intimately integrated into fully colloidal cavities [3]. In the talk, we will then focus on our most recent work on the latest rising star of tightly-confined atomically flat nanocrystals, the quasi-2D colloidal quantum wells (CQWs), also popularly nick-named ‘nanoplatelets’. Latterly we have discovered that the CQWs uniquely enable record high optical gain coefficients among all colloids [4]. In addition, we will show the controlled stacking and assemblies of these nanoplatelets, which provides us with the ability to tune and master their excitonic properties, and present the first accounts of doping them for high-flux solar concentration and precise wavefunction-engineered magnetic properties [5]. Given their current accelerating progress, these solution-processed quantum materials hold great promise to challenge their epitaxial thin-film counterparts in semiconductor optoelectronics in the near future.

Abstract

We study the effect of optical forces \cite{1} and torques on a spherical isotropic magneto-optical (MO) nanoparticle \cite{2}. The force on the direction of the applied external magnetic field has two contributions: A first conservative component coming from the “Zeeman” coupling between the light spin density and the external magnetic field through the imaginary part of the MO polarizability, and a second component coming from the direct transfer of the helicity of the electromagnetic field to the particle through the real part of the MO polarizability. The torque also has two contributions: The usual one coming from the spin of the light field and another one depending only on the modulus of the electromagnetic field.

We explicitly show examples where these new contributions lead to: (i) An optical torque on an isotropic, spherical particle using a linearly polarized plane wave, (ii) the formation of a conservative optical lattice with non-interfering incoming fields and (iii) radiation pressure using electromagnetic fields with zero average value of the Poynting vector.

Abstract
We present a monolithic integration technique for the direct integration of single quantum sources into pre-fabricated photonic circuitry. Using a SEM-based nanomanipulator, we preselect, transfer and place epitaxially grown tapered InP nanowires embedded with a single InAs quantum dot on top of or beside pre-fabricated optical waveguides. Because the nanowires are tapered, the optical mode of the nanowire can evanescently couple into the nearby waveguide. The coupling is also bidirectional allowing the optical pumping of the dot to be done by the waveguide as well.

1. Introduction
On-chip demonstrations of photonic integrated circuits for quantum information processing have almost exclusively relied on off-chip sources of quantum light. Our presentation describes a significant technological advance towards overcoming this drawback by integrating a highly-robust, single photon light source with high brightness and near-unity efficiency. We show deterministic integration of single quantum emitters within on-chip photonic circuitry with coupling efficiencies of 74% and single-photon purities of 97%. We demonstrate, for the first time, how the taper geometry of a semiconductor nanowire, with an embedded emitter, can be used to optimize the evanescent coupling between emitter and photonic circuitry. Importantly, the proposed technique allows for the use of pre-fabricated photonic integrated circuitry, as shown in Fig 1a, so that emitters can be added after the integrated optics circuitry is fabricated, facilitating experiments where complex photonic circuits are required, such as boson sampling, optical quantum computing and quantum metrology. The coupling strategy we demonstrate is bidirectional, so that excitation of the emitter can be done through the coupled waveguide itself, removing any need for the free-space optics that is normally used for optical excitation and opening the way for real-world, quantum ‘plug and play’ systems.

2. Numerical Results
We have shown, using numerical simulations, Fig. 1b, that the coupling efficiency using our evanescent coupling technique can approach 100% (Fig 1c). In order for integrated quantum schemes to be practical, on-chip quantum light extraction efficiency is paramount [1]. In this talk, we show a physically demonstrated efficiency of 74%, already beyond the theoretical limit of 36% found for buried nanowire sources.

Figure 1: (a) Cartoon showing placed quantum sources on a pre-fabricated photonic circuit. (b) Numerical simulation of the evanescent coupling between a placed nanowire and a silicon nitride waveguide. (c) Numerical results of coupling efficiency versus taper length. Inset shows a placed nanowire on a silicon nitride waveguide.

3. Scalability
Our technique increases the scalability of solid state quantum sources integrated into photonic circuitry many fold. Removing the need for alignment marks and introducing the capability to use pre-fabricated photonic circuitry reduces the number of fabrication steps needed to realize complex photonic devices for quantum information applications such as in boson sampling and quantum simulation. With companies like IME [2] now providing pre-fabricated chips ready for integrated quantum optics, our technique provides a method to deterministically place large numbers of nanowire sources in strategic locations on such pre-fabricated circuitry. This point has been emphasized in the talk and additional details of the nanomanipulator

transfer process will be shown talk where 2 videos of the transfer process itself will be shown.

4. Experimental Results

Figure 2 shows the resolution-limited spectrum of the ground state emission of the embedded quantum dot collected at the facet of the waveguide at the chip edge.

![Figure 2: Resolution limited peak of ground state emission of embedded quantum dot collected from chip edge.](image)

Figure 3a shows the placed nanowire on a silicon nitride waveguide with the associated power spectrum shown in Figure 3b. Other complexes can be seen as the power is increased. It is important then to filter these energies when the source is operated at saturation. Saturation is required when a high single-photon repetition rate is desired. Figure 3c shows the experimental setup for optical pumping and collection into fiber as well as performing a fiber based Hanbury-Brown Twiss measurement.

![Figure 3: (a) Placed nanowire. (b) Power spectrum of collected emission. (c) Experimental setup of Hanbury-Brown Twiss measurement.](image)

Single photon statistics where demonstrated using CW and pulsed excitation, as shown in figure 4, respectively. When the detector response is deconvolved from the CW data, a multiphoton probability at zero delay was found to be 2%, showing that the single photon emission of sources integrated with waveguides is not effected.

![Figure 4: CW and pulsed excitation of the single-photon measurements.](image)

5. Conclusions

Solid state single photon sources can be monolithically integrated into pre-fabricated photonic circuitry using a SEM-based nanomanipulator, which essentially transforms conventional photonic circuitry into quantum photonic circuitry. The work presented moves the field of integrated quantum sources significantly closer to field-ready quantum technologies.

Abstract:
Hyperbolic metamaterials are playing a key role in the design of integrated deep-subwavelength biochemical sensors, nonlinear nanophotonic devices and magneto-optical applications. Here, we report composite metamaterials, Au-Core/Pd-Shell arrays, over cm² areas using an inexpensive and industrially-friendly self-organization technique. In reflection and transmission typically more than 30% change has been observed with 2% H₂ concentration (2% Vol. Hydrogen mixed with 98% Vol. Nitrogen), these changes are visible to the naked eye with conventional illumination of the sensing substrate.

Introduction:
Hydrogen (H₂) is considered to be one of the most promising clean energy carriers for use in fuel cells and combustion engines. It is extensively used in scientific research and industry, especially in glass and steel manufacturing, refining petroleum products, and in the chemical industry in general. In standard conditions, hydrogen is a highly combustible colourless and odourless gas, extremely flammable in ambient atmospheric conditions at concentrations exceeding 4% in volume. The resonant wavelengths in self-assembled Au nanorod metamaterials modified by interaction between the nanorods, can be tuned throughout the visible and into the infra-red spectral range. These resonances are very sensitive to the surrounding medium. The metamaterials developed here sensitive to the presence of hydrogen, are based on hybrid Au-core/Pd-shell (Fig. 1a) nanorods Palladium is used as the transducer in many hydrogen sensing technologies first because Pd-hydride formation is reversible and thermodynamically stable under ambient conditions and second because it leads to changes of both DC electrical conductivity and optical properties upon exposure to hydrogen due to both electronic and structural modifications.

![Figure 1](image.png)

Figure 1: (a) Schematic of core/shell structures. (b) SEM image Au/Pd-core/shell arrays. (c) Schematic of gas sensing set up. (d, e) Variation in transmission and reflection spectra on exposure to 2% hydrogen in nitrogen. (f) Variation in reflection with different hydrogen concentration.
Variations in the refractive index can therefore be detected optically with very high sensitivity by the incorporation of H\textsubscript{2} in the Pd based plasmonic metamaterial. In most cases carbon monoxide (CO) is produced as byproduct during hydrogenation. Therefore effects of CO on these composite metamaterials are also investigated.

**Experimental Section:**
Metamaterials based on ordered Au-core/Pd-shell, electrochemically grown into perfectly ordered nanoporous alumina membranes, having large domain areas (~square microns) obtained by employing two-step anodization. The pore geometry and spacing can be controlled over a wide range with nanoscale precision by a choice of anodization conditions and chemical post processing. Gold and palladium electrodeposition was performed with a three electrode system.

**Discussion:**
SEM cross-section of the sample is shown in Fig. 1b and schematic of gas sensing set up is shown in Fig. 1c. When the designed metamaterial is exposed to hydrogen, the extinction changes by almost 40% (Fig. 2d) which, although not quantitative, is clearly noticeable to the naked eye as a change in the brightness of light transmitted by the metamaterial. As soon as hydrogen gas is introduced to the flow cell, the transmission of the Au/Pd core/shell metamaterial starts to change at an initial rate of about 0.1% per second. Within the first 60 s, the change in transmission exceeds 5%, then increases substantially with time at a rate of 0.2%/s reaching 38% at saturation. Similarly, the response of the sensor in the reflection geometry (Fig. 1e) demonstrates an almost 40% change in reflection at wavelengths corresponding to a TM-polarized, leaky mode. The high sensitivity of this optical sensor to changes in hydrogen concentration results from a combination of both the change of the plasmonic properties of individual core-shell nanorods and the modification of inter-rod coupling in the metamaterial due to the thickness change of the palladium shell. Both result in the variation of the effective permittivity of the metamaterial. The structural changes result from a chemical reaction between Pd and H\textsubscript{2} forming palladium hydride (Pd-H). Reflectivity dependence on time with time for different concentrations of hydrogen is shown in Fig 1f. Initial investigations showed no interaction between Au/Pd core-shell metamaterials and CO at room temperature.

**Conclusions:**
We have designed a plasmonic metamaterial sensor for the optical detection of hydrogen gas. More than a 30% change in both the reflection and transmission from the metamaterial layer is observed when exposed to 2% hydrogen mixed with nitrogen gas. It provides extremely strong modification of the transmission and reflection of light as a result of the presence of hydrogen gas and can be easily seen by naked eye. Plasmonic nanorod metamaterials present a versatile platform also for development of oxygen and other gas sensors.10

Abstract

The coherent scattering of light by a single quantum emitter is fundamental to quantum optics. Unlike atomic systems, solid-state emitters couple strongly to their host lattice via phonons. Through both theory and experiment we develop an intuitive model of coherent scattering for the case of a solid-state emitter coupled to a nano-cavity. The phonon coupling leads to a sideband that is completely insensitive to excitation conditions, a major deviation from the atomic model of scattering.

1. Introduction

Scattering of light by a single quantum emitter is one of the fundamental building-blocks of quantum optics. First observed in atomic systems, and more recently studied extensively in self-assembled quantum dots (QDs), coherent scattering is attractive as the scattered light retains the coherence of the laser rather than the emitter, giving a means to generate photons whose coherence exceeds the conventional radiative limit whilst still exhibiting anti-bunching on the timescale of the emitter lifetime. Exploiting this behavior by scattering light from a single quantum emitter gives rise to a number of exciting possibilities for quantum technologies such as the generation of single photons with arbitrary waveforms, non-linearities at the single photon level, and the construction of entangled states between photonic or spin degrees of freedom.

Solid-state emitters (SSEs), particularly self-assembled QDs are an attractive system with which to realise such schemes owing to their high brightness, excellent coherence properties and ease of integration with nano-photonic structures. However, in contrast to their atomic counter-parts, working in the solid-state introduces coupling to vibrational modes of the host material, leading to the emergence of a phonon sideband band (PSB) in the emission spectrum [1]. This is attributed to a rapid change in lattice configuration of the host material during an exciton recombination event, leading to the simultaneous emission or absorption of longitudinal acoustic (LA) phonons with the emission of a photon. Therefore, to obtain perfectly indistinguishable photons the PSB must be filtered out, naturally reducing the efficiency of the device, even when using an optical cavity to Purcell enhance emission into the zero phonon line (ZPL) [1].

It is perhaps natural then to presume that phonon coupling may be eliminated by operating in the coherent scattering regime: weak driving leads to vanishing excited state population and therefore no change in charge configuration, suggesting that one may adopt an atom-like picture where the coherent fraction tends towards unity for excitation far below saturation. Recent theoretical work has indicated that this is not the case, predicting that a sideband will persist even for vanishingly weak resonant driving [2]. Here, we experimentally verify this hypothesis and develop a comprehensive model that reproduces experimental results by incorporating cavity effects and off-resonant driving. The results demonstrate that the fraction of light emitted into the PSB is insensitive to the excitation conditions. We interpret this observation using an intuitive picture that attributes the PSB to transitions within the phonon-dressed ground state manifold during a scattering event, implying that any optical spectral features will have an associated PSB.

2. Characterizing the Phonon Coupling

The device studied comprises a single self-assembled InGaAs QD which is coupled (in the weak regime) to a single mode of an H1 photonic crystal cavity, resulting in a large Purcell enhancement of 43 [3]. In order to experimentally resolve the time dynamics of the phonon environment, and consequently characterize the electron-phonon interaction, we make a high time resolution measurement of the first order correlation function ($g^{(1)}(\tau)$) of the emission. The sample is held in a liquid helium bath cryostat at $T = 4.4$ K and resonantly excited below saturation ($S = 0.25$) where coherent scattering is expected to dominate the emission. The result is presented in Fig. 1(a) with the dynamics relating to
Figure 1: (a) First order correlation function \( g^{(1)}(\tau) \) of the QD emission: red circles - experimental measurements; solid red line - polaron ME; dashed line – a simple pure dephasing model that does not capture the phonon dynamics. The phonon parameters \( a \) and \( \nu_c \) are extracted by fitting the short-time data whilst all other parameters are independently experimentally determined. Inset: Spectrum under identical conditions: blue triangles - experimental data; solid line - polaron model with same parameters as the main figure. (b) Evolution of the fractional \( F \) contributions to the resonant scattering spectrum with increasing \( \Omega \): red diamonds – phonon sideband; green circles - coherent scattering and blue triangles - incoherent resonance fluorescence. Dashed lines are the prediction of the polaron ME emission into the PSB occurring in the first few picoseconds. By fitting this region with a Polaron master equation (ME) model we extract an electron-phonon coupling strength \( a = 0.0447 \text{ ps}^2 \) and cut-off frequency \( \nu_c = 1.28 \text{ ps}^{-1} \).

In the second phase of the dynamics starting at around \( \tau = 20 \text{ ps} \), radiative decay associated with incoherent resonance fluorescence occurs on the timescale of the coherence time \( (T_2) \). Noticeably, despite the large Purcell enhancement, this timescale is still an order of magnitude slower than phonon dynamics. In a crude pure dephasing model increasing the Purcell factor suppresses phonon interactions, the separation of timescales observed here shows that this is not the case. Thus, a pure dephasing model (dashed line) cannot accurately describe the phonon coupling. To check the accuracy of the extracted parameters we independently measure the spectrum under identical conditions (inset to Fig. 1(a)), a theoretical spectrum derived by Fourier transforming the model \( g^{(1)}(\tau) \) shows excellent agreement.

3. Phonon Sidebands in Coherent Scattering

To investigate to what extent the PSB persists in the coherent scattering regime, we measure the resonance fluorescence spectrum as a function of saturation (S) by varying the strength of the resonant driving. Fig. 1(b) shows the resulting evolution of the components of the resonant scattering spectrum. The polaron model produces a curve for the coherent fraction (green dashed line) that qualitatively exhibits a similar shape to atomic behaviour. However, when considering additionally the PSB fraction \( F_{PSB} \), a surprising result emerges in agreement with recent theoretical predictions [2]. The fraction of the emission in the PSB (red diamonds in Fig. 1(b)) is constant and independent of \( \Omega \), and thus the fraction of light scattered coherently from the emitter.

This result can be explained by considering that the phonon coupling dresses both the ground and excited states of the transition. Whilst most of the light scatters directly from the “bare” transition as in an atomic system, it is also possible for the scattering event to end in one of the phonon continuum states of the ground state manifold, reducing/increasing the energy of the scattered photon, and leading to the emergence of a phonon sideband. By convention, these inelastic events are classified according to the energy of the scattered photon: Stokes/Anti-Stokes scattering correspond respectively to the emission of a lower/higher energy photon accompanied by the emission/absorption of an LA phonon. At the low bath temperatures here, the probability of phonon emission \( \gg \) absorption, resulting in the characteristic asymmetry of the PSB. The branching ratio between the phonon-mediated inelastic scattering events and elastic (Rayleigh) scattering is determined solely by the square of the Franck-Condon factor \( (B^2) \). As such, whilst coherent scattering is often cited as a means to avoid emitter dephasing, it has no influence on the phonon sideband. Additional experiments with the laser detuned from the emitter show that all optical features have an associated sideband and that phonon interactions strongly influence the coherent/incoherent ratio away from resonance.

4. Conclusions

We have demonstrated that irrespective of excitation conditions, a fixed fraction \( (B^2) \) of the emission of a solid-state emitter is always emitted through a phonon sideband, even in the presence of a large Purcell factor. Our results stress that appropriate modeling of phonon coupling is essential and could be applied to optimize processes such as spin-photon entanglement for solid-state emitters.

Abstract

Bragg filters stand as a key building blocks of the silicon-on-insulator photonics platform. However, achieving narrowband Bragg filters with large rejection is challenging due to fabrication constraints and imperfections. Here, we present our recent results in the development of high-performance Bragg filters based on subwavelength and modal engineering. We experimentally show flexible control over the width and depth of the Bragg resonance. These results pave the way towards high-performance on-chip wavelength filters.

1. Introduction

Driven by the impressive technology development in the recent years, silicon photonics is expanding its frontiers towards new applications beyond Datacom. These include, among others, chemical and biological sensing, radio-over-fiber and quantum cryptography. In this context, nanostructured photonic metamaterials have opened new prospects for controlling and manipulating light in planar waveguide circuits. By periodically patterning silicon with a pitch sufficiently small to suppress diffraction effects, subwavelength engineered structures open new degrees of freedom to control light propagation in silicon photonic circuits with unprecedented flexibility. Since the early demonstrations of a silicon wire waveguide with subwavelength Bragg gratings (SWG) metamaterial core \cite{1}, metamaterial SWG waveguides have garnered a great research interest, enabling the demonstration of various devices with record performance, including fiber-chip couplers, ultra-wideband power splitters and mode converters, to name a few \cite{2}. Here, we present our recent results on the implementation of high-performance wavelength filters in silicon, based on subwavelength engineering.

Bragg filters are a fundamental building block in the silicon photonics technology. However, yielding narrowband Bragg filters with large rejection levels is challenging due to fabrication constraints and imperfections. Here, we present high-performance Bragg filters that harness SWG, modal and symmetry engineering to overcome this bandwidth-rejection trade-off. We experimentally show flexible control over the width and depth of the Bragg resonance, unlocking new tools for the implementation of notch filters with arbitrary bandwidth and rejection level.

2. Silicon Bragg grating filters based on sub-wavelength and modal engineering

A Bragg filter is a periodic structure that rejects light power at a specific wavelength range. From coupled-mode theory \cite{3}, the bandwidth is determined by

$$\Delta \lambda = \frac{\lambda_0}{\pi n_g} \sqrt{\kappa^2 + \frac{\pi^2}{L^2}}$$ \hspace{1cm} (1)

while the rejection level can be calculated as

$$R = \tanh^2(\kappa L)$$ \hspace{1cm} (2)

where $\kappa$ is the coupling coefficient (coupling rate between the forward and the backward propagating modes), $L$ is the filter length, and $n_g$ is the group index. From these equations it follows that for the implementation of high-performance Bragg filters in silicon, based on subwavelength engineering.

Bragg filters are a fundamental building block in the silicon photonics technology. However, yielding narrowband Bragg filters with large rejection levels is challenging due to fabrication constraints and imperfections. Here, we present...
index, this configuration allows weak index modulations with comparatively large corrugations, thereby relaxing constraints in minimum feature size.

As an illustrative example, Fig 2 shows the measured spectra for narrowband Bragg filters based on the conventional corrugation approach, and subwavelength engineering strategy. Note that the conventional Bragg grating requires a 2 nm wide corrugation to yield similar bandwidth as that in subwavelength engineered filters, that have corrugation widths larger than 100 nm.

### 3. Conclusions

In conclusion, we have experimentally demonstrated that subwavelength engineering of modal confinement in Bragg gratings provides a great flexibility for the implementation of high-performance SOI Bragg filters. In this presentation we will show different results illustrating how by proper geometry design we can implement different filter responses ranging from ultra-narrowband, with a few-hundred pm bandwidth, to ultra-deep operation, with rejection levels of ~50 dB. This approach opens a new path for the realization of high-performance, tailorable Bragg filters for the SOI platform.

Abstract
We present the intriguing physical phenomena including generation of quantum vortex and ballistic transport via the optical manipulation of exciton polariton condensate. Exciton polaritons generated in two-dimensional microcavity based on arsenide semiconductor system are exploited for the generation of quantum vortex via directly transferring orbital angular momentum of optical pump to polariton quantum fluid. Nitride semiconductor based one-dimensional exciton polariton shows ballistic transport of exciton polariton condensate at room temperature through the gradient control of exciton reservoir.

1. Introduction
Excitons in low-dimensional semiconductor have attracted a lot of attention due to their rich and unique optical properties and their versatile photonic and quantum photonic applications. Especially, the control of light-matter interaction between photons in microcavity and excitons in low dimensional structure is of great interest for cavity quantum electrodynamics studies and quantum information science. Advanced semiconductor technology can allows entering hybrid nature of exciton cavity polaritons (polaritons), which comply with Bose-Einstein statistics, in the regime of strong light-matter coupling between excitons and cavity photons.1 Photonic components provide the ultrafast velocity of polaritons due to low effective mass, while the excitonic components are responsible for interaction with the environment and polaritons. A crucial benefit of the polariton system is potential energy engineering with real-time controllability via optical manipulation through the excitonic component. Here, we present the intriguing physical phenomena including generation of quantum vortex,3 large Rabi splitting energy,4 and ballistic transport via the optical control of polariton condensate. Exciton polaritons formed in distributed Bragg reflector based on arsenide semiconductor system are used for the creation of quantum vortex through direct transfer of orbital angular momentum (OAM) of non-resonant optical pump to polariton quantum fluid. Toward room temperature application, one-dimensional polaritons based on nitride semiconductor system are exploited for ballistic transport of polariton condensate due to their pure potential properties.

2. Results and Discussion
Starting from two-dimensional polaritons based on arsenide semiconductor system, optical manipulation of quantized OAM can probe characteristics of basic topological object and can be utilized for quantum technology such as information processing and sensing for fundamental physics. In this study, we can directly transfer OAM of optical pump to polariton quantum fluid.3 In experiment, the quantized vortices were generated from polaritonic potential and flow induced by transferred optical OAM in out-of-equilibrium polariton condensate above threshold density. Quantized rotation of this collective polaritons could be maintained robustly without large dependence on size and shape of optical pump in polariton related interactions. For achieving room temperature polariton, nitride semiconductor system is one of suitable candidates due to strong oscillator strength and large exciton binding energy. Nevertheless, fabrication of two-dimensional microcavity for high-quality distributed Bragg reflectors based on nitride semiconductor system is challenging due to low refractive index contrast and large lattice mismatch between AlN and GaN in contrast to arsenide semiconductor system. We present robust one-dimensional, room-temperature polariton system based on nitride semiconductor microcavity structures.4 A hexagonal wire structure can spontaneously generate high-qualified whispering gallery modes without complicated fabrications. High quality excitons are formed because of dislocation bending to bottom part and absence of internal field on m-plane quantum wells for stronger oscillator strength. Therefore, we obtained one-dimensional polaritons from strong coupling between three-dimensional (bulk GaN) or two-dimensional (InGaN quantum well) excitons and crystallographically defined one-dimensional whispering gallery photons. First, we observe unprecedentedly large Rabi splitting in GaN/InGaN core-shell wires. This giant large Rabi splitting result from large spatial overlap between photons and excitons from high quality, non-polar quantum wells. Second, exploiting pure potential property of bulk GaN wire, we demonstrate single mode one-dimensional polariton condensate with ballistic transport. We optically manipulate the ballistic propagation of the condensate along the wire axis by gradient control of polariton potential via exciton reservoir.
3. Conclusions

We optically manipulate the fundamental physical phenomena including quantum vortex and ballistic transport based on the exciton-polariton condensates in semiconductor microcavities. Two-dimensional polaritons systems are exploited for the generation of quantum vortex via directly transferring orbital angular momentum of optical pump to polariton quantum fluid. One-dimensional room temperature polariton shows ballistic transport of exciton polariton condensate through the gradient control of exciton reservoir. These results can suggest versatile potential applications such as all optical control of topological charge in quantum simulator and all optical devices using exciton-polariton quantum fluid system.

Abstract

Probing nano-optical near-fields is a major challenge in plasmonics. Photoemission from metal nanostructures induced by femtosecond laser pulses proved to be highly sensitive tools for plasmonic near-field probing. I will show how this technique can provide sub-nm sensitivity. First applications in the investigation of plasmon-plasmon coupling are also demonstrated. In addition, time-resolved measurements of plasmonic near-field dynamics with unprecedented resolution were also performed, the results of which will be presented.

1. Introduction

Plasmonic enhancement of optical near-fields at nanostructures ensures the nanoscale localization of the energy of light. Although this phenomenon allowed pioneering applications in spectroscopy, photovoltaics and sensors, the measurement of the maximum achievable nanoplasmonic field enhancement for a particular sample is still a challenging problem. Here, we present a method for nanoplasmonic near-field measurement with the help of photoemitted electrons induced by femtosecond laser pulses, and demonstrate its capabilities by studying plasmon-plasmon coupling on nanostructured silver films.

2. Near-field probing with ultrafast photoemission

Our field enhancement measurement method is based on the observation that if photoelectrons are emitted at a favorable phase of the electric field, after roughly a half optical cycle they can return to the metal surface and elastically rescatter there [2], boosting their kinetic energy ($Q_{\text{max}}$) until up to 10 times the ponderomotive energy according to

$Q_{\text{max}} = 10.01 \left( e^2 \tilde{\lambda}^2 E_{\text{loc, max}}^2 / (16 \pi^4 m c^2) \right) + 0.54 W.$  \hspace{1cm} (1)

Here $e$ and $m$ are the electron charge and mass, respectively, $\tilde{\lambda}$ is the laser wavelength, $E_{\text{loc}}$ is the local electromagnetic field, $c$ is the speed of light and $W$ is the work function of the metal. Thus, by measuring the highest electron kinetic energy for a given plasmonic structure, the maximum hot-spot field enhancement can be extracted, since electron spectral cutoff regions are composed of rescattered electrons that are directly sensitive to nanooptical field maxima.

In our experimental scheme, ultrashort laser pulses excite propagating or localized plasmons, of which plasmonic near fields induce photoemission of electrons into vacuum surrounding the sample. Photoelectron spectra are then measured with a time-of-flight spectrometer [1,2], see also in Fig. 1 (a). Since the highest photoelectron energies originate from nanometric rescattering of the electrons from

Fig.1. (a) Scheme of the experimental setup for nanoplasmonic near-field measurement with photoelectrons (black arrows). The femtosecond laser pulse and the entrance to the time-of-flight electron spectrometer are indicated. (b) Field distribution map of the bowtie structure with black arrows indicating the trajectories of rescattered electrons. These electrons gain the highest kinetic energy, therefore they contribute the spectral cutoff. (c) Photoelectron spectrum with the spectral cutoff point indicated from which field enhancement is extracted.
the metal surface [2], nanoscale near-fields can be deduced by analyzing the cutoffs (highest electron energies) of the electron spectra (Fig. 1).

The method is experimentally demonstrated on different model systems involving nanoparticles exhibiting localized plasmons and thin films with controlled surface roughness hosting propagating surface plasmons [1]. We acquired time-of-flight electron spectra for different laser intensities for each sample type by collecting the photoemitted electrons according to the geometry in Fig. 1.(a). For each sample, the validity of equation (1) is clearly shown. Field enhancement factors extracted with the procedure described above are also verified with finite difference time-domain simulations without using fitting parameters [1].

3. Plasmon-plasmon coupling

As a first application of this measurement tool, plasmon-plasmon coupling phenomenon and its effect on field enhancement was studied on nanostructured Ag thin films supporting not only propagating plasmons, but also localized plasmon oscillations in different surface grains [3,4]. In our experimental concept, ultrashort laser pulses excite propagating plasmons in Kretschmann geometry, while localized plasmons are excited on the surface grains via the coupling of propagating and localized surface plasmons [4]. Measurement and analysis of the energy spectra of photoelectrons generated by plasmonic near fields yielded maximum plasmonic field enhancement values ×21, ×23 and ×31 for surfaces exhibiting 0.8, 1.6 and 4.5 nm average roughness values, respectively.

These measurement results showed that there is a non-trivial relationship between the experimental field enhancement values and the surface roughness of the samples. To analyze this relationship, we performed numerical simulation of the plasmon excitation and plasmon-plasmon coupling processes. Simulation results of the individual rough surfaces not only support the measured field enhancement values, but also revealed the contributions from propagating and localized plasmons. By analyzing the field amplitude along the surface normal taken at the hottest spots of each grain, two decay lengths were clearly visible: one sharp component corresponding to localized plasmons with a few nm 1/e decay length and a shallow decay with ~600 nm length corresponding to propagating plasmons [4]. Interestingly, it was also shown, that the propagating plasmon component accounts for some 60 % of the field enhancement.

4. Conclusions

With our method, field enhancement values for different samples (supporting localized and/or propagating plasmons) can be measured within <1 nm distance from the plasmonic surface. The demonstrated method, combined with more sophisticated electron imaging techniques can be extended for full characterization of nanoplasmonic near-fields promising nanometer lateral resolution in the near future. As a first application of this method we probed field enhancement attributed to plasmon-plasmon coupling. Ultrasensitive near-field probing revealed maximum field enhancement factors between 20 and 31 for silver surfaces with controlled roughness. Simulation results corresponded well to measured maximum field enhancement values and this way, the field enhancement contribution provided by the localization of propagating plasmons on surface grains could be clearly identified, amounting to ~50% of the total field enhancement at samples where strong plasmon-plasmon coupling is realized.

These experiments open a pathway not only toward the investigation of plasmon coupling processes, but also toward better exploitation of these phenomena in real-world environments and engineering of plasmonic samples with experimental field enhancement feedback.

Abstract

Recently, Topological photonics has attracted significant attentions from optics community stimulated by discovery of topological phases of matter. One of the interesting photonic systems mimicking SSH model, which is a fundamental system exhibiting topological nature, is a zig-zag chain. In this study, the zig-zag chains composed of split ring resonators (SRRs) were numerically investigated. The photonic topological edge states (PTESs) in the zig-zag chain was observed at the same resonant wavelength as the single SRR. In the PTESs, Electromagnetic fields concentrate at the edge SRR of the zig-zag chain. Introducing SRRs into the zig-zag chain results in polarization and wavelength selective PTESs due to asymmetry of SRRs. Moreover, PTES of the quadrupole mode was also demonstrated. The zig-zag chain is a great platform to demonstrate PTESs with exotic optical properties. By applying various kinds of meta-atoms, new type of topological edge state would be able to realized.

1. Introduction

Recently, Topological photonics has attracted significant attentions form optics community stimulated by discovery of topological phases of matter. One of the interesting photonic systems mimicking SSH model, which is a fundamental system exhibiting topological nature, is a zig-zag chain. In this study, the zig-zag chains composed of split ring resonators (SRRs) were numerically investigated. The photonic topological edge states (PTESs) in the zig-zag chain was observed at the same resonant wavelength as the single SRR. In the PTESs, Electromagnetic fields concentrate at the edge SRR of the zig-zag chain. Introducing SRRs into the zig-zag chain results in polarization and wavelength selective PTESs due to asymmetry of SRRs. Moreover, PTES of the quadrupole mode was also demonstrated. The zig-zag chain is a great platform to demonstrate PTESs with exotic optical properties. By applying various kinds of meta-atoms, new type of topological edge state would be able to realized.

2. Structure and simulated model

Figure 1 shows a zigzag chain composed of SRRs. The SRRs is constituted of gold and thickness is 10 nm. The width and split angle are 20 nm and 30 degree, respectively. The SRRs are aligned along zig-zag line with gap of 10 nm. The zigzag chain is placed periodically with period of 500 nm on a SiO2 substrate. Simulations were carried out using FEM. Input wave is illuminated normal to the surface along z-axis. Polarization is along x- or y-axes. Periodic boundary condition is used. The dielectric constant of gold from Ref. [10] is used and the refractive index of substrate is set to 1.46.

3. Simulated results and discussion

Transmission spectra for x- and y- polarization are presented in Fig. 2(a) and 2(b), respectively. Blue, green, and red line correspond to results for single SRRs, 4-SRRs in a photonic topological edge state (PTES) depending on incident polarization. In this presentation, I will present my recent numerical studies on PTESs in zig-zag chain composed of split-ring-resonators (SRRs). Applying SRRs realizes the PTESs with novel optical properties including wavelength selectivity, PTES of higher order mode at PTESs were achieved.
chain, and 5-SRRs chain, respectively. In the case of x-polarization, single SRR shows dipole resonance at around 1033 nm, as shown in Fig. 3(a). Transmission for 5-SRRs shows two resonant dips at 1033 nm and 1115 nm. The resonance at around 1033 nm, which is the same as resonance of single SRRs, corresponds to PTES (Figs. 3(b) and 3(c)). The resonance at around 1115 nm is dimer mode, which is also observed in the case of 4-SRRs chain (Fig. 2(a)). On the other hand, the lowest mode (dipole mode) is observed at 1993 nm (Fig. 3(d)). Although PTES should be observed for this mode, edge mode and dimer mode are overlapped and mixed due to weak interactions among SRRs and broad resonance band (Figs. 3(e) and 3(f)). The resonance at 830 nm is PTES of a higher mode (quadrupole mode) as shown in Figs. 3(h) and 3(i). The resonant wavelengths of PTESs for x- and y-polarization are different, meaning polarization and wavelength selective PTESs can be achieved in the proposed zig-zag chain.

4. Conclusions

The zig-zag chains mimicking SSH model were numerically investigated. The PTESs in the zig-zag chain was observed at the same resonant wavelength as the case of single elements. Electromagnetic fields concentrate at the edge site of the zig-zag chain. Introducing SRRs into the zig-zag chain results in polarization and wavelength selective PTESs due to asymmetry of SRRs. Moreover, PTES of the quadrupole mode was also demonstrated in addition to the PTESs of the lowest dipole mode. The zig-zag chain is a great platform to demonstrate PTES with exotic optical properties like as demonstrated in this study. By applying various kinds of meta-atoms developed so far, new type of topological edge state would be able to realized.

Figure 2: Transmission spectra of the zig-zag chain composed of SRRs. (a) x-pol. (b) y-pol. Blue, green, and red lines correspond to results for single SRR, 4-SRRs chain, and 5-SRRs chain, respectively.

Figure 4: Electric field distributions for (a-c) 1033 nm (x-pol), (d-f) 1993 nm (y-pol), (g-i) 830 nm (y-pol). Z-component of electric field (a,b,d,e,g,h). Electric field intensity (c,f,i).

Abstract

Dense photonic integration requires miniaturization of materials, devices and subsystems, including passive components (e.g., engineered composite metamaterials, filters, etc.), active components (e.g., modulators and nonlinear wave mixers) and integrated circuits (Fourier transform spectrometer, programmable phase modulator of free space modes, etc.).

1. Introduction

The current optical technology is costly, bulky, fragile in their alignment, and difficult to integrate with electronic systems, both in terms of the fabrication process and in terms of delivery and retrieval of massive volumes of data that the optical elements can process. Our most recent work emphasizes the construction of optical subsystems directly on-chip, with the same lithographic tools as the surrounding electronics. This has been made possible by the advances in lithographic tools, which can now create features significantly smaller than the optical wavelength and is predicted to reach as fine as 11 nm by 2020. Arranged in a regular pattern, subwavelength features act as a metamaterial whose optical properties are controlled by the density and geometry of the pattern and its constituents [1-7]. Such future systems, further require the discovery of new technologies that can operate not only at ultrafast rates (<1 ps), but also at extremely low energies, and with low levels of insertion loss. Additionally, future technologies will need to be highly compact, as well as resilient to temperature change. Moreover, the device designs should provide scalability with respect to the operating wavelength, and the optical carrier should be allowed to range in a broad spectral range to support the necessary aggregate information bandwidth. As specific examples of our most recent work towards these goals, we discuss nonlinear optical devices [9, 10], chip-scale integrated Fourier Transform Spectrometer [11] and programmable phase modulation of free-space modes at GHz rates [12].

2. Second-order nonlinearity in silicon-rich-nitride films

We will present experimental results on second-harmonic generation in non-stoichiometric, silicon-rich nitride films. The as deposited film presents a second-order nonlinear coefficient, or \( \chi^{(2)} \), as high as 8 pm/V. This value can be widely tuned using the electric field induced second harmonic effect, and a maximum value of 22.7 pm/V was achieved with this technique. We further will illustrate that the second-order nonlinear coefficient exhibited by these films can be highly dispersive in nature and require further study and analysis to evaluate their viability for in-wavelength applications at telecommunication wavelengths [9, 10].

3. Fourier transform spectrometers in silicon photonics

Miniaturized integrated spectrometers will have unprecedented impact on applications ranging from unmanned aerial vehicles to mobile phones, and silicon
photonics promises to deliver compact, cost-effective devices. Mirroring its ubiquitous free-space counterpart, a silicon photonics-based Fourier transform spectrometer (Si-FTS) can bring broadband operation and fine resolution to the chip scale. Here we will present the modeling and experimental demonstration of a thermally tuned Si-FTS accounting for dispersion, thermo-optic non-linearity, and thermal expansion. We show how these effects modify the relation between the spectrum and interferogram of a light source and we develop a quantitative correction procedure through calibration with a tunable laser. We retrieve a broadband spectrum (7 THz around 193.4 THz with 0.38-THz resolution consuming 2.5 W per heater) and demonstrate the Si-FTS resilience to fabrication variations—a major advantage for largescale manufacturing. Providing design flexibility and robustness, the Si-FTS is poised to become a fundamental building block for on-chip spectroscopy [11].

4. Programmable phase modulation of free-space wavefronts at gigahertz rates

Space-variant control of optical wavefronts is important for many applications in photonics, such as the generation of structured light beams, and is achieved with spatial light modulators. Commercial devices, at present, are based on liquid-crystal and digital micromirror technologies and are typically limited to kilohertz switching speeds. To realize significantly higher operating speeds, new technologies and approaches are necessary. Here we demonstrate two-dimensional control of free-space optical fields at a wavelength of 1.55 μm at a 1 GHz modulation speed using a programmable plasmonic phase modulator based on near-field interactions between surface plasmons and materials with an electrooptic response. High χ(2) and χ(3) dielectric thin films of either aluminium nitride or silicon-rich silicon nitride are used as an active modulation layer in a surface plasmon resonance configuration to realize programmable space-variant control of optical wavefronts in a 4 × 4 pixel array at high speed [12].

1. Summary

Strong interference in metal-lossy interface could provide the condition to obtain perfect light absorption. This phenomenon offers the opportunity to use planar lithography-free multilayer designs for ultrathin optoelectronic applications. These multilayer resonant absorbers have been realized in different material types including metals, semiconductors, and polar materials. A recent perspective with our group reviews strong light-matter interaction in lithography-free planar perfect absorbers[1]. It was shown, upon choice of proper material and configuration this absorbing behavior can be realized in almost all parts of EM spectrum. Although the common materials for design of multilayer absorber metasurfaces are metals, this strong interference can be also found in semiconductors in the photon energies above their optical band gap. Moreover, phonon and polar materials have been the subject of many absorber designs specifically in mid and far infrared regimes. Figure 1 shows the right choice of materials that can be utilized for light perfect absorption in different portions of EM spectrum. Upon constructing the proper geometry, we could realize perfect light absorption in planar designs.

Initial studies of our group members on this field was mainly focused on realization of perfect absorption in metal based designs. The common cavity design that has been frequently used for perfect absorbers is based on metal-insulator-metal (MIM) design. However, our theoretical findings based on transfer matric method (TMM) revealed substantial potential in the case of metal-insulator-metal-insulator (MIMI) cavity absorbers[1]. Taking these findings into consideration, we applied different modifications to improve light absorption in MIMI cavities while keeping the overall fabrication route lithography. The use of multi-thickness surface texture[2], disordered plasmonic nano holes[3], and the optimum choice of back reflector metal[4] were examples of these ideas. However, the absorption bandwidth of these designs is limited due to inherent permittivity response of metals. The real permittivity part of most of metals becomes negative as we go toward longer wavelengths however the ideal model predict the desired permittivity to be positive. However, Bismuth (Bi) shows an extraordinary response where it is greatly matched into ideal model data. Our recent results demonstrate a near unity absorption from 500 nm to ~3000 nm using simple MIMI cavity which is far beyond any bandwidth reported for MIMI cavities[5]. Further, in another direction to make lithography free ultrabroadband absorber, we utilized densely packed dielectric nanowires as excellent trapping scaffold. We experimentally proved an absorption above 97% in an ultrabroad range using a thin Pt layer[6]. Besides this studies, we also studied the strong light-matter interaction in phononic materials. We showed that far-infrared surface plasmon polaritons of a single-layer graphene can be tailored using plasmon-phonon hybridization in graphene-LiF heterostructures[7]. We also designed a nearly perfect resonant absorption and coherent thermal emission by hexagonal boron nitride (hBN)-based photonic crystals[8].

Long with metal structures, it is possible to design semiconductor based metasurfaces to spectrally control their response. Our recent findings show that the use of metal-insulator-semiconductor (MIS) cavity could tune the absorption response of photodetector design. Employing 3 nm thick Si layer on top of Al-Al_{2}O_{3} cavity leads to strong light absorption in ultraviolet (UV) region and no photo response in visible spectrum. Thus, by his way, visible blind UV photodetector was realized in a couple of nm thick semiconductor layer. The use of titanium dioxide (TiO_{2}) instead of Si could lead to solar blind system which we use it as gas sensor.
Combination of these metal and semiconductor based metamaterials was later found as excellent strategy to obtain color filters in the reflection mode. Generation of red-green-blue (RGB) colors using planar fabry-perot (FP) designs is commonly possible in the transmission mode of a MIM cavity. However, due to inherent loss of metal layers the efficiency of this filtering is below 0.6. We showed that series connection of MIM and MIS cavities which leads to a MIMIS multilayer design can create RGB colors in reflection mode by higher efficiency value[9]. The amplitude of RGB colors were found to be as high as 0.7 in this design. Later, we constructed a MIMSI design to create these RGB colors in efficiencies as large as 0.95.

Finally, in or recent study, we fabricated a colorimetric MS cavity to act as a refractive index sensor. This sensor was made using a innovative technique based on oblique angle deposition. Using this technique, we were able to make Au-Ge nanostructure resonating in visible range. Upon coating this cavity by different materials with different refractive index, the resonance frequency shifts toward longer wavelengths and consequently the color changes. From color change, we can predict the refractive index of the agent. Considering the large scale compatible and polarization insensitive nature of this design, this could be a promising for sensing of bio agents using naked eye.

Abstract

Weyl points, where three-dimensional linearly dispersive bands cross, give rise to many intriguing phenomena including topologically protected surface states and chiral anomaly. The section Chern number defined on two-dimensional momentum space is changed as the normal momentum component pass through a WP. We show that a geometrical dimension can also induce a phase transition in 1D plasmonic-dielectric crystals, where a Dirac point emerges. The surface states can be engineered by such synthetic Weyl point concept and observed in lower dimensional systems. We expect similar results be found in 2D as well.

1. Introduction

In analogy to the two-dimensional (2D) system Dirac Point, three-dimensional (3D) linearly dispersive bands were also discovered, referred to as “Weyl points” (WPs) which also manifest topologically protected phenomena. Apart from the electronic topological insulators, their classical wave counterparts have attracted a lot of attention, such as photonics, acoustic, and plasmonic systems. The characteristic Fermi arc surface states have been theoretically predicted and experimentally observed. Many intriguing phenomena are revealed by the presence of such topologically protected WP which represents a source or sink of the Berry curvature in the momentum space.

Time-reversal symmetry requires a WP at an arbitrary momentum $k$ to have the same charge as its companion point $-k$, while inversion symmetry requires them to have the opposite charge. Then it can be concluded the existence of WPs in a system with both inversion and time-reversal symmetry are prohibited. Such nodal points can exist in various systems with broken PT symmetry. In addition to the geometric dimensions, synthetic dimensions can be combined to form higher dimensional synthetic space \cite{1}. Hence, 1D or 2D structures are easier to explore WP physics with the aid of synthetic dimension.

It has been verified that the existence of interface states are guaranteed by the bulk-edge correspondence, i.e., the difference of the bulk topological invariants across the interface \cite{2}. For the case of 1D inversion symmetric systems, the difference can be featured by the Zak phase below the common gap. Whereas the topological invariants for inversion-symmetry broken systems are no longer the Zak phase, which cannot be quantized as 0 or $\pi$. Recall the aforementioned inversion-symmetry broken property of WP, the concept of WP acts as a powerful tool to explore the topological properties of such 1D crystal with broken inversion symmetry.

2. Synthetic WP in 1D crystals

Multilayered plasmonic-dielectric crystals (PDC) with broken inversion symmetry are taken to illustrate the design and explore the synthetic WP. In addition to the 1D Bloch wave number $q$, two more intrinsic structural parameters fill up the 3D space wherein a synthetic WPs are constructed. The introduction of the synthetic space provides new possibilities for manipulating more internal degrees of freedom, which are of significant importance for potential applications.

Figure 1(a) shows the considered 1D crystal, whose dispersion relation for transverse magnetic modes reads \cite{3}

\[
\frac{4\cos(qA)}{\Xi} = 4 - \frac{1}{4 r_{24}^2} - \frac{1}{4 r_{24}^2} + \frac{1}{r_{24}^2} \tan k_{1} \tan k_{2} + \tan k_{1} \tan k_{2} \cos(k_{1} - k_{2}) - 2 (r_{24} + r_{34}) \tan k_{1} \tan(k_{1} + k_{2}) - 2 (r_{14} + r_{34}) \tan k_{4} \tan(k_{1} + k_{4})
\]

(1)

where $\Xi = \cos k_{1} \cos k_{4} \cos(k_{1} + k_{4})$, $\kappa_{n} = k_{n} d_{n}$, $r_{n} = e_{n} k_{n} / e_{n} k_{n}$, $k_{n} = \sqrt{k_{0}^2 - e_{n}^2}$, $\Lambda = d_{1} + d_{2} + d_{3} + d_{4}$.

Figures 1(b) and 1(c) illustrate the evolution of dispersion relation and two distinct cases of emergence of the linear crossing with fine-tuned parameters for fixed wavelength $\lambda = 1650$ nm. Obviously, the close and re-opening of the band gap are closely related to the geometrical parameter $d_{0}$, and imply the topological feature of the bands. In this case, the topological invariants for inversion-symmetry broken systems are no longer the Zak phase, which cannot be quantized as 0 or $\pi$. 

\[\text{META 2019, LISBON - PORTUGAL, JULY 23 – 26, 2019}\]
In the notion of Weyl points, the topological surface states can be determined by breaking the space inversion symmetry. For the generic configurations in Fig. 1(a), the inversion-symmetry of this crystal is broken with unequal $d_i$ and $d_j$. Then we employ these two spatial parameters to simulate the second and the third dimensions for the 3D synthetic space.

A general Hamiltonian to describe WP dispersions reads $H_{\text{eff}} = E_{\text{0}}\sigma_0 + v_0 \cdot k\sigma_0 + \sum_{i=1}^{3} v_i \cdot k\sigma_i$, where $k = (k_x, k_y, k_z)$ is the wave vector in reciprocal space, and $(\sigma_0, \sigma_i)$ are the identity matrix and Pauli matrices, respectively [2]. Extended to synthetic space of this structure, the new space becomes $k = (\Delta d_x, \Delta d_y, \Delta q)$, with $\Delta d_x = (d_x - d_0)/0.5\Lambda$, $\Delta d_y = (d_y - d_0)/0.5\Lambda$, and $\Delta q = q\Lambda/\pi$. When extended to synthetic space, the surface states are topologically protected. Figures 2(b)-2(d) clearly sketch the key properties of the interface states: (1) its dispersion starts at the bulk bands and terminates at the boundary of parameter space, (2) the connection to bulk band I or II switches as $k_z$ crosses the WP, and (3) the number of interface states is always unity in accord to the bulk-edge correspondence. The interface state dispersion terminates at the first (I) or second (II) bulk bands, depending on the cover medium being air or silver. This represents a hallmark of the topological protected interface states.

Figure 1: (a) Schematic diagram of the multilayered lattices composed of four alternating stacks. (b) and (c), respectively, illustrate the evolution of the band structure ($k_z$ versus $q$) for the inversion-symmetric PDC ($d_1 = d_2 = d_3$) as $d_0$ pass through $55 \text{ nm}$ and $103.8 \text{ nm}$. Here, the wavelength is fixed as $\lambda = 1650 \text{ nm}$ and the insets in (b) are the fields distribution at the center of BZ, i.e., $q = 0$. (d) The trajectory of DPs as a function of $d_0$. Two dashed lines (for wavelength $1650 \text{ nm}$ and $1675 \text{ nm}$) cross the curves with different nodal points, labeled as ‘A’-‘E’.

Figure 2: (a) The schematic structure of the interface formed by a homogeneous medium and the designed 1D PDC. The projected bulk band structure (gray regions, labeled as “I” and “II”) and interface trajectories in the parameter space $d_1$-$d_2$ for (b) $k_z = 1.6k_x$, (c) $k_z = 1.72k_x$, (d) $k_z = 1.8k_x$. The structure for semi-infinite lattices connected with air (silver) is marked as PDC-air (PDC-silver). Then, the red (blue) line corresponds to the trajectory of the interface states for PDC-air (PDC-silver).

3. Conclusions

Synthetic 3D space serves as a promising platform to mimic Weyl point in 1D or 2D plasmonic-dielectric crystals, with the aid of bands linear crossing in inversion-symmetry systems. The use of synthetic space enriches the internal degree of freedom and enables new possibilities for manipulating the topologically protected interface states between bulk crystals and ambient homogenous medium (including plasmonic and dielectric).

Magnon Kerr Effect in a Cavity QED System

Tiefu Li
Tsinghua University, China

Abstract — We experimentally demonstrate magnon Kerr effect in a cavity quantum electrodynamics (QED) system, where magnons in a small yttrium iron garnet (YIG) sphere are strongly but dispersively coupled to the photons in a three-dimensional cavity. The Kerr term comes from the magnetocrystalline anisotropy of the YIG sphere. When the YIG sphere is pumped to generate considerable magnons, the Kerr effect yields a perceptible shift of the cavity central frequency and more appreciable shifts of the magnon modes. We derive an analytical relation between the magnon frequency shift and the drive power for the uniformly magnetized YIG sphere and find that it agrees very well with the experimental results of the Kittel mode. Our study paves the way to explore nonlinear effects in the cavity QED system with magnons. The nonlinear properties may be utilized in the hybrid quantum information processing system.

Abstract

We performed electro-optic sampling of the pulses re-emitted by a heavily-doped germanium antenna resonant in the mid-infrared. This field-resolved measurement allows observing the time domain response of a single plasmonic structure in amplitude and phase.

1. Introduction

Plasmonic nanoantennas receive broad attention in the nanophotonics field owing to the large field enhancement on sub-diffraction limited volumes that allows various applications ranging from nearfield microscopy to sensitive material detection and to the observation of higher order optical nonlinearities. Traditional studies are performed in the visible and near-infrared spectral range generally on metallic (gold) subwavelength structures.

While classic intensity detection allows to study the spectral resonance behavior, the underlying temporal dynamics within the antenna stay hidden. Nonlinear femtosecond spectroscopy in combination of field simulations can be employed to gain insight into these dynamics [1]. With the development of the new material class of heavily doped semiconductors [2], the research expands into the mid-infrared spectral frequency range [3] with new interesting perspectives.

2. Results

We present, for the first time, full time- and field-resolved experimental studies of the response of resonant plasmonic antennas. Our approach relies on femtosecond multi-THz time-domain spectroscopy (TDS) in combination with high-resolution confocal microscopy (Fig. 1(a)).

Figure 1: (a) confocal imaging setup employed to study single germanium nanoantennas. InSb LP is a low pass filter and a white light LED and a CCD camera are employed for alignment of the confocal microscope. The mid-IR pulses transmitted through the sample are characterized by electro-optical sampling (EOS) in presence and in absence of a resonant antenna. (b) Micrograph of a germanium antenna with the sketch of the pulsed illumination and the effect of the resonance on the transmitted mid-IR transient.
Heavily doped germanium antenna structures (see Fig. 1 (b)) with resonance in the mid-IR are fabricated via electron beam lithography from epitaxial films on silicon substrate. The corresponding plasma frequency of 31 THz is located well inside the mid-infrared spectral range [2]. All studied double rod antennas feature a structure thickness and width of 1 µm at a gap width of 300 nm while the arm length and thus the aspect ratio and resonance frequency are varied. Isolated double rod antennas are targeted in a confocal microscope based on two Cassegrain-geometry all-reflective objectives. To probe the antenna response, broadband phase-stable femtosecond pulses in the mid-IR (or multi-THz) frequency range are generated via phase-matched difference frequency generation in GaSe bulk crystals by a system driven by a femtosecond Yb:KGW laser [4]. At a bandwidth of 10.7 THz, the pulse duration equals 58 fs (see Fig. 2 (a,c) blue curves).

Figure 1: Multi-THz TDS on a heavily doped Ge double rod antenna with arm lengths of 5.5 µm: (a) normalized EOS field transient after interaction with the antenna structure (red) in comparison to the unobstructed probe pulse (blue); (b) time-resolved antenna response field amplitude.

The antenna response is detected in transmission geometry via sensitive electro-optic sampling in GaSe (thickness 80 µm). As EOS gating pulses, a broadband white light supercontinuum is generated in bulk YAG crystal and compressed to sub-15 fs durations. To avoid phase fluctuations within the acquisition time, transients are recorded in fast-scan at an acquisition rate of 5 Hz using a piezo delay scanner. Low-noise detection is accomplished by employing a boxcar amplifier on a shot-to-shot basis in combination with optimized ellipsometry balanced detection scheme. The presented data is averaged from 1250 recorded transients each.

Figure 2(a) and 2(c) show the mid-IR field transient and the intensity spectrum of the pulses after propagation through the silicon substrate without the antenna structures (blue curves). In direct comparison, the temporal field trace and intensity spectrum after interaction with a Ge double rod antenna of arm length 5.5 µm in the microscope focal area is plotted as red curves. The difference between the two measurements in the time domain (Fig. 2 (b)) leads to extraction of the antenna response in amplitude and phase (Fig 2 (d)). The time-domain and frequency-domain response of the individual antennas is reproduced by finite-difference time-domain simulations, which analyze their response. A pulse with the same central frequency and bandwidth as in the experimental conditions is injected into the simulation volume and the transmitted pulse after interaction with the antennas is recorded to calculate the differential response both in the time-domain and, by Fourier transformation, in the frequency domain (amplitude and phase).

3. Conclusions

In conclusion, we introduce a new experimental strategy to investigate the resonance of plasmonic nanostructures that is capable of accessing the full temporal structure in amplitude and phase. This capability offers unique opportunities for the study of fundamental aspects in plasmonic excitations and is particularly appealing in a frequency range that is ideally suited for sensing application in the fingerprint region of molecular vibrations.

Control of Emission Photon Statistics from a Single Colloidal Quantum Dot Using Plasmonic Nanostructures

Sadahiro Masuo

Abstract

One of the important emission behavior of semiconductor nanocrystal quantum dots (QDs) is the emission photon statistics, i.e., single-photon and multiphoton emission. Generally, the emission photon statistics of the QDs are governed by the multie exciton dynamics based on the quantum confinement depending on the size, shape, and atomic composition of QDs themselves. In this work, we demonstrated that the emission photon statistics from a single QD could be controlled by the interaction with the plasmonic nanostructures.

1. Introduction

Colloidal nanocrystal quantum dots (QDs) are a unique class of tunable, dispersible fluorophores that are of great interest for applications in a wide range of opto-electronic devices. An important and interesting exciton dynamics is the simultaneous existence of multiple excitons (MX) in a single QD. By utilizing the MX, the efficiency of the optoelectronic devices can be considerably increased. Furthermore, the cascade emission from MX, i.e., multiphoton emission from triexciton (TX) and biexciton (BX) states, is valued for its production of correlated photon pairs (also called entangled photons) to realize quantum information and communication technologies. However, when MX are generated in a single QD, they can decay by nonradiative Auger recombination (AR), i.e., the MX are reduced to a single exciton (SX) by AR and are wastefully consumed. AR also causes the emission blinking behavior that is known as Auger ionization. Therefore, suppression of AR has been extensively studied for efficient use of the excitons. On the other hand, AR facilitates single-photon emission for the single QD, i.e., photon antibunching in the QD emission, because the surviving SX can emit a single photon even when MX are produced in a QD. The single-photon emission is also an important and interesting optical property of the single QD for quantum information and communication technologies. Therefore, it is very important to control the MX dynamics and subsequent emission photon statistics for applications employing QDs.

We previously reported that the emission photon statistics, i.e., multiphoton emission and a single-photon emission from a single QD, can be modified through interactions of the QD with plasmonic nanostructures [1-8]. Recently, a similar enhancement of multiphoton emission was reported using several QDs-plasmonic nanostructures systems. Two possibilities have been discussed to describe the mechanism behind these increases in the BX emission. One mechanism involves the enhancement of the BX emission rate by the plasmonic nanostructure, which is similar to our previous results. Another is the quenching of SX emission by the plasmonic nanostructure, i.e., a decrease in the QY of SX emission rather than an actual increase in the QY of BX emission. Thus, the interplay of QDs and plasmonic nanostructures, particularly the influence of the nanostructures on the MX dynamics of the QDs, is not fully understood. To understand the interaction between single QDs and plasmonic nanostructures, one would have to directly observe changes in the emission behavior of a single QD that accompany the interaction with a plasmonic nanostructure. To achieve this direct observation, we used two atomic force microscopy (AFM) techniques.

2. Results and discussion

2.1. AFM manipulation of a gold nanocube (AuCube)[5]

Monodispersed AuCube of a well-defined size and shape was used in this work. The size of the AuCube was estimated as 87±2.4 nm. The localized surface plasmon resonance (LSPR) band of the AuCube overlaps with both the absorption and emission spectra of the QD. This indicates that both excitation and relaxation processes of the QD can be enhanced with the AuCube by with choice of excitation wavelength. It is well known that the fluorophore-metallic nanostructure interaction strongly depends on the spectral overlap and the distance between a fluorophore and a metallic nanostructure. When the absorption of the fluorophore overlaps with the LSPR band, the excitation rate of the fluorophore can be augmented by the electric field of the LSPR generated by the excitation light. Similarly, when the fluorescence spectrum of the fluorophore overlaps with the LSPR band, this relaxation process can be enhanced. Under our experimental conditions, the LSPR could not be efficiently generated by the excitation laser (405 nm). Therefore, the enhancement of the relaxation process was considered. The advantage of the well-defined AuCube is that there is little variation of the LSPR band in each AuCube; hence, we can simply consider the mechanism of the QD-metallic nanostructure interaction.

The emission behavior of the single QD accompanying the above AFM manipulation of the AuCube is summarized in Fig. 1. Before moving the AuCube near the QD, in the
combining theoretical analysis and the numerical simulation, a decrease and increase in the emission intensity were observed for different wavelengths. Emission from a single quantum dot (QD) on a silver tip (AgTip) was measured using off-resonance multiphoton emission (MPM) with an atomic force microscope (AFM). The emission behavior of the single QD in proximity of the AgTip is shown in Fig. 1b, e, and h. The maximum emission count of the single QD increased in the photon correlation histogram, the contribution of the center peak increased dramatically, and the $g^{(2)}(0)$ values increased to 0.97. This result indicates that the efficiency of the BX emission from the single QD was 6.9 times higher than that of the single QD before approaching the AuCube. The emission behavior of the single QD after the AuCube was pushed away is shown in Fig. 1c, f, and i. It is clear that the emission intensity, photon antibunching behavior, and decay curve were returned to those detected from the QD before the approach of the AuCube. The importance of the above results is that the change in the emission behavior was directly observed by manipulating the distance between an AuCube and a single QD.

2.2. Approach of a silver-coated AFM tip (AgTip) [6]

In this work, the enhancement of multiphoton emission from a QD interacting with a plasmonic nanostructure was investigated using a silver-coated atomic force microscopy tip (AgTip) as the plasmonic nanostructure. Using the AgTip, which exhibited a well-defined localized surface plasmon (LSP) resonance band, we controlled the spectral overlap and the distance between the single QD and the AgTip. The emission behavior of the single QD when approaching the AgTip at the nanometer scale was measured using off-resonance (405 nm) and resonance (465 nm) excitation of the LSP.

We directly observed the conversion of the single-photon emission from a single QD to multiphoton emission with reduction of the emission lifetime at both excitation wavelengths as the QD-AgTip distance decreased, whereas a decrease and increase in the emission intensity were observed at 405 nm and 465 nm excitation, respectively. By combining theoretical analysis and the numerical simulation of the AgTip, we deduced that the enhancement of the multiphoton emission was caused by the quenching of the single-exciton state due to the energy transfer from the QD to the AgTip and that the emission intensity was increased by enhancement of the excitation rate due to the electric field of the LSP on the AgTip. These results provide evidence that the photon statistics and the photon flux from the single QD can be manipulated by the plasmonic nanostructure through control of the spectral overlap and the distance.

The large spacing between the Landau levels (LLs) in graphene is expected to produce a strong optical intensity of the inter-LL transitions [1, 2, 3, 4]. However, so far the reported magneto-infrared spectra revealed only a weak magnetic increase of the absorption [2, 5, 6, 7], in a complete disagreement with theory. A probable origin of the small intensity of the LL transitions is a high concentration of defects in large-area graphene used so far in these experiments.

In order to address this issue, we developed a new magneto-infrared microscopy setup allowing us to obtain circular polarization-resolved magneto-absorption spectra on small exfoliated samples down to the diffraction limit [8]. Through this, we measure magneto-optical circular polarization resolved spectra on high-mobility graphene encapsulated in hexagonal boron nitride (hBN) in magnetic fields up to 4.2 T [8, 9]. We find a series of extremely sharp and intense interband LL transitions in the mid-infrared range. The quality factor of the LL peaks reaches 20-50, which is much higher than what has been previously reported in graphene deposited on other substrates. The maximum electromagnetic absorption in weakly doped graphene of almost 36% is observed, which approaches the fundamental absorption limit of 50% for a thin film illuminated from one side. At the same time the off-resonance absorption can be magnetically tuned below 1%, due to the depletion of the density of states in the quantum Hall regime, which is much lower than the universal absorption of 2.3% [10, 11].

When graphene is doped, we observe intraband LL transitions in the far-infrared/THz range. Interestingly, a strong absorption (> 30%) at about 3 THz is seen already at 1 T, which is a field intensity attainable with a permanent magnet. Another effect of doping is a full magnetic circular dichroism of some inter- and intraband LL transitions due to the polarization dependent Pauli blocking. In this regime we see the absorption of circular polarized light close to 50% on the transition between the zeroth and the first LLs. Additionally, the resonant Faraday rotation of more than 0.15 radian in the mid-IR ranges is seen, which surpasses our previous observation in epitaxial graphene [6].

Overall, our results demonstrate a new potential of magnetic tuning in graphene-based long-wavelength optoelectronics and plasmonics. Using the colossal magneto-optical activity of graphene is also highly promising for constructing new magnetically controlled and non-reciprocal metamaterials.

Abstract

We discovered that irradiation with light possessing orbital angular momentum (OAM) associated from its helical wavefront [1,2] and spin angular momentum (SAM) owing to a helical electric field, has been intensely investigated in a variety of research fields, such as optical manipulations, telecommunications, quantum optics, and micro-fabrications.

In recent years, we discovered that helical light field enables the orbital motion of the irradiated materials, such as metals, polymers, and even liquid-phase resin, to establish chiral structures on a nano- or micro-scale [3-6]. Such chiral structures fabricated by the optical vortex illumination will have a potential to develop chiral metamaterials for highly sensitive detection and reaction of chiral chemical composites.

For instance, surface relief on azo-polymers is formed through mass transport of azo-polymers owing to an optical gradient force, anisotropic photo-fluidity, and trans-cis photoisomerization [7-9], and thus, it mostly reflects a nonuniform intensity profile of the illuminated light. An optical vortex with OAM twists azo-polymers to shape a single-arm chiral surface relief with the aid of the spin angular momentum associated with the circular polarization [10,11]. Also, it is worth noting that chiral surface relief can be created simply by illuminating circularly polarized light via SAM-OAM coupling [12]. Such helical surface reliefs further enable the generation of nearfield OAM light on a sub-wavelength scale, leading to a further nanoscale mass-transport of azo-polymers (Figure 1) [13].

Interestingly, self-focusing of the incident beam occur upon initiating polymerization due to a permanent refractive index change of the resin, resulting in the formation of a laser-induced self-written fiber. The OAM light creates a helical fiber, manifesting helical trajectories of the optical vortex solitons.

In this presentation, we introduce such unique chiral structures formed by illumination of helical light field.

1. Introduction

Abstract

A 2D Lüneburg lens may be formed by patterning a planar slab waveguide with a subwavelength grating structure using a silicon photonics integration platform with the advantage of small footprint. Confocal telescopes employing 15 \textmu m diameter lenses were fabricated using a 300 nm silicon on insulator integration platform. The experimentally measured loss of the fabricated structures was found to be 0.726 dB per lens which is close to the value of 0.517 dB predicted by FDTD simulations.

1. Introduction

3D optical systems and components are regularly bulky and vulnerable to environmental perturbations, sensitive to alignment tolerances, and unsuited to volume manufacture. These issues may be addressed by omitting one dimension and implementing components in a planar slab waveguide of a silicon integration platform with the advantage of a small footprint. The Lüneburg graded index lens may be implemented in a photonic integrated circuit to provide a Fourier transform on a chip for a complex optical interconnection system [1, 2]. It may be built on a planar slab waveguide with solid core, such as silicon, with air as the upper cladding and silica as substrate which together form an asymmetric 1D slab waveguide. The light is confined in the direction normal to the plane but the wave-vector of the fundamental mode can be pointed in any direction in a 2D free-space within the plane [1]. The effective index of the fundamental mode is lower than the refractive index of the core and higher than the substrate for the light to be confined in the core of the waveguide. To construct a structure such as a lens, the effective index of the mode needs to be varied; decreasing radially from the centre of the lens to its rim. The core and cladding materials and their thickness must be selected carefully for a specified operating vacuum wavelength. A major issue arises as the thickness of the slab waveguide must be varied to fulfill the specified graded refractive index profile which requires multiple steps of etching that would add complexity and high cost to the fabrication process.

In this work, the effective refractive index of the Lüneburg lens is engineered by nano-structuring the core layer of an SOI slab waveguide to form a waveguide with a metamaterial core. This offers the simplicity of single etch step in the fabrication process. The process used an SOI wafer with a 300 nm silicon core thickness layer with cylindrical inclusions of air in a silicon slab waveguide. The inclusions may be placed on a regular sub-wavelength lattice and the diameter of cylinders varied according to the local effective index required [2].

2. Simulations

The prediction of the dependence of the local effective index on the hole diameter in a local unit cell was done by a homogenization method [2]. The confocal telescope lens system in which two Lüneburg lenses are placed side-by-side with their rims touching on axis was defined to obtain the insertion loss that may arise from the approximation of a continuous graded index material by a graded metamaterial. In this way, the input to the lens through a single mode access waveguide may be considered as a point source at the rim of the lens. The first lens transforms the point source at its input rim to a plane wave at its output rim and the second lens then transforms the plane wave at its input rim to a point source at its output rim.

In this design, each lens diameter is 15 \textmu m with the effective index varying from 1.925 at the rim to 2.722 in the centre. A single mode ridge waveguide is used to launch the light in and couple light out of the telescope system.

Figure 1 shows the confocal telescope Lüneburg lens system that was built and simulated in FDTD. The predicted insertion loss on each lens was obtained as 0.517 dB with the assumption that the waveguide-lens insertion loss is small.
3. Experimental results

The confocal telescope structure was fabricated and tested. Figure 2 shows an SEM of the fabricated structure on SOI.

The loss per lens without any other considerations of other losses was measured as 0.726 dB per lens which is close to the prediction of the simulation presented in previous section.

The loss of each interface between lens and access waveguide was 3.965 dB. This loss may be reduced by adiabatic lateral taper and/or adiabatic effective index transition between the conventional waveguide and the metamaterial slab waveguide of the lens.

4. Conclusions

The metamaterial structure can offer simplicity in fabrication process in addition to the smaller footprint structures. Metamaterial Lüneburg lens may be built on a slab waveguide with single step etch process. The simulation on a confocal telescope system of two side by side Lüneburg predicted an insertion loss of -0.517 dB on each lens. The experimental result of a fabricated structure was obtained the insertion loss of 0.726 dB per lens which is close to the prediction of the simulation.

Polarization Engineering via in-Plane Rotation of Uniaxial Bilayers

Constantinos Valagiannopoulos

1Department of Physics, Nazarbayev University, Astana, Kazakhstan
*corresponding author, E-mail: konstantinos.valagiannopoulos@nu.edu.kz

Abstract
Engineering the polarization of the transmitted electromagnetic signals within a small fraction of the operational wavelength is an objective with numerous applications. The necessary anisotropy for this objective can be emulated in various ways but the simplest one is with multiple opaque rods stacked on a transparent background. It is shown that the polarization conversion ratio is kept small in the presence of realistic losses; however, we propose a pair of identical multilayers suitably tilted in-plane to overcome that bottleneck.

1. Introduction
Polarization of photonic beams constitutes a continuous variable and thus can be used as a reliable information container; therefore, changing it within a thin volume of space is critical for the operation of various devices based on the diversity of wave polarization [1]. A mandatory requirement to accomplish any polarization conversion is the effective anisotropy of the employed media which admits the coupling between different directions of the electric fields. Such a property is usually realized with use of arrays of small particles such as elliptical posts [2] or chiral resonators [3] with suitable polarizabilities. Alternatively, complete polarization control is achieved as a topologically protected effect [4] or at two-dimensional materials with built-in anisotropy like black phosphorus [5].

In this work, which is based on our prequel study [6], where all the technical details are thoroughly explained, we consider the simplest possible structure suitable for polarization engineering: multilayers of plasmonic rectangular rods stacked in a transparent background. It is shown that if losses are ignored, perfect polarization twist is possible via a single cluster of parallel layers with a specific optically small thickness. Such a flawless outcome is based on the huge asymmetry between the developed modes into the cluster, combined with a 45°-tilted angle. However, the performance gets much poorer when realistic losses are considered being always present in plasmonic media. For this reason, we are introducing a bilayer configuration comprising a pair of these clusters rotated by different angles by keeping the overall thickness small. Therefore, an additional set of waves are excited and that mode interplay “opens” a window for the incident beam to pass with totally different polarization characteristics. By sweeping a large part of the parametric space, we conclude to several optimal designs which have been proven extremely robust with respect to fabrication defects, frequency mismatch and incidence obliqueness. We believe that our study will inspire further theoretical and experimental investigations towards the direction of polarization engineering with help from simple structures.

2. One Slab
The physical configuration of the analyzed structure is depicted in Fig. 1, where two uniaxial layers of identical texture possess thicknesses \( h_1 \) and \( h_2 \); the utilized Cartesian coordinate system \((x, y, z)\) is also defined. Each one is comprised of free-standing multilayers \((d\text{-periodic})\) of opaque medium with relative permittivity \( \varepsilon \) and duty cycle \( 0 < r < 1 \), which are in-plane rotated by angle \( \varphi_1 \) and \( \varphi_2 \) respectively. In a single slab of thickness \( h \) with tilt of optical axis \( \varphi \), two waves are developed with propagation constants:

\[
k_{1,11} = k_0 \sqrt{\frac{(\varepsilon_X + \varepsilon_Y) \pm \sqrt{(\varepsilon_X - \varepsilon_Y)^2}}{2}},
\]

where \( \varepsilon_X = \frac{\varepsilon}{(1-r)\varepsilon+\varepsilon} \) and \( \varepsilon_Y = r\varepsilon+(1-r) \) are the homogenized effective-medium permittivities (for \( d \ll \lambda \)) and \( k_0 = 2\pi/\lambda \) the free-space wavenumber. The matching conditions are those of the Fabry-Perot resonator: \( \sin (k_1 h) = \sin (k_{11} h) = 0 \); however, flawless polarization conversion
is possible only for \( \varphi = 45^\circ \) and, most importantly, for huge contrast between the developed modes: \( k_1 \gg |k_{\text{II}}| \). The later condition is only feasible once the effective permittivity \( \varepsilon_\text{Y} \) blows up, namely for a lossless metal \( \varepsilon = \frac{-\varepsilon_\text{Y}}{1+\varepsilon_\text{Y}} < 0 \). Once the losses (being inevitable to any plasmonic medium) are present, the performance in polarization shift gets severely deteriorated.

![Graph](image)

Figure 2: Maximal polarization conversion as function of the operational wavelength \( \lambda \) and optical thickness \( h/\lambda \) for: (a) a single uniaxial slab by sweeping tilts \( \varphi \) and duty cycles \( r \), (b) the bilayer of Fig. 1 by sweeping \( (\varphi_1, \varphi_2) \) and \( r \) for \( h_1 = h_2 = h/2 \). Free-standing silver rods are employed.

### 3. Pair of Slabs

What if we keep using the same materials having identical level of losses \( \text{Im}[\varepsilon] \) and, by slightly modifying the structure, we achieve a substantial improvement in polarization conversion at the same overall thickness? Indeed, by considering the axes tilts \( (\varphi_1, \varphi_2) \) and plasmonic portion \( r \) (for \( h_1 = h_2 = h/2 \)) as basic design parameters, we report structures, employing actual plasmonic media with realistic losses, with very efficient polarization shifts.

In Figs 2(a), we show the highest degree of polarization conversion that can be achieved at a specific operational wavelength \( \lambda \) with a metasurface of specific thickness \( h \). In Fig. 2(b) we show the response of the best performing device of Fig. 1 by sweeping \( (\varphi_1, \varphi_2) \) and \( r \), under the assumption of \( h_1 = h_2 = h/2 \). As plasmonic material, we use silver with well-known dispersion \( \varepsilon = \varepsilon(\lambda) \) as in [6]. One can clearly notice that for the first configuration (one slab, Fig. 2(a)), the maximal possible polarization shift is less than 35%; however, by simply cutting the same structure in two and properly tilting the formed layers (pair of slabs, Fig. 2(b)), the polarization conversion reaches 90% for a rather extensive range of working \( \lambda \). Further results regarding the operation of the same setup across alternative bands and the immunity of the proposed bilayers with respect to various defects and errors, will be presented.

### 4. Conclusions

Perfect polarization transformation through metasurfaces is a challenging goal with significant scientific and funding interest. We propose a simple configuration which, in spite of the presence of the realistic losses, gives almost flawless polarization twists with huge robustness in its performance.

Abstract

This work aims to study the influence of material growth and laser processing conditions on the plasmonic behavior of various types of layer-patterned thin films, from metal-oxides such as ITO and vanadium dioxide (VO2) to monolayers of hexagonally packed ligand capped gold nano-spheres. Here, direct laser interference patterning or DLIP enables the patterning of these films into plasmonic metasurfaces suitable for flat optics. In addition, the plasmonic assisted ultrafast optically induced nonlinear switching of VO2 patterned structures will also be discussed.

1. Introduction

Ultrathin surfaces that interact strongly with electromagnetic radiation on length scales far below their free-space wavelength are commonly referred to as metasurfaces. These surfaces stand in stark contrast to traditional optical components that require interaction scales comparable to the wavelength of light. While these ultrathin metasurfaces could enable flat optical components and high field concentration, there is an inherent difficulty associated with their fabrication. Optical metasurfaces have traditionally relied upon electron beam lithography to produce the required feature size and spatial gradients. Identifying alternatives to electron beam lithography for the patterning of widely dissimilar types of thin film materials ranging from metal oxides to self-assembled monolayers is very important in order to be able to investigate their plasmonic behavior. This work will discuss one such alternative based on direct laser interference patterning or DLIP, as a way to efficiently generate plasmonic gratings and other types of metasurfaces with potential uses for flat optics applications. DLIP is used to pattern single- or multilayer films containing plasmonic materials such as metal oxides (ITO or VO2) or self-assembled monolayers of gold nanoparticles.

2. Background

Typically, the patterning of metasurfaces is performed by conventional photolithography and subsequent wet/dry etching techniques. These multistep processes can degrade the plasmonic materials being processed and they are not compatible with self-assembled monolayers since they require the application and removal of photoresists. Alternative patterning techniques are required in order to process dissimilar materials such as metal-oxides and monolayers of gold nanoparticles.

2.1. Materials

Conventional metals with high carrier concentrations, such as gold and silver, are typically used in plasmonic and metamaterial devices since their associated plasma frequencies are in the visible and near ultraviolet (UV) ranges. However, these metals exhibit large absorption losses across the near infrared (NIR), which degrade and limit their use for any practical applications in the NIR. For applications in this portion of the spectrum, certain semiconducting metal oxides known as transparent conducting oxides (TCOs), such as Sn-doped In2O3 (ITO) must be considered. Unlike metals, the electrical transport properties of TCOs can be adjusted easily by doping, thus making their optical properties tunable as well [1].

A different class of metal oxides opens the possibility of active tunability and switching of the plasmonic behavior. This class of semiconducting metal oxides which exhibit a temperature dependent metal-insulator transition (MIT) are commonly referred to as phase change materials. Among MIT materials, VO2 is the most studied given that it can be processed into thin films form with a reduced MIT near room temperature, making VO2 films very attractive for active devices such as optical switches, photoconductive emitters, and modulators. To this end, we have shown how VO2 growth conditions can affect not only the transition temperature and switching magnitude but also the switching speed. In particular, the influence of strain and the use of near lattice matched substrates and buffer layers to modify the intrinsic VO2 film properties has been demonstrated [2]. Furthermore, the phase transition dynamics of strained and relaxed VO2 films have been compared together with analysis of the electrical conductivity of VO2. In strained VO2 films, the electrical conductivity can be modulated by a factor of one hundred in less than 500 fs [3]. Based on these properties, we selected ITO and VO2 as the types of metal-oxides for studying their behavior once patterned into metasurfaces.
Large scale plasmonic metasurfaces can be made by directed self-assembly [4]. The molecular control offered by directed self-assembly enables sub-nanometer control of the separation between individual gold nano-spheres. These narrow gaps enable extreme field enhancement and as such are sensitive to the properties of their surrounding environment. In this way, these metasurfaces can serve to probe the refractive index of their environment. Because the direct self-assembly of these plasmonic metasurfaces rely on surface tension during the assembly process, it can be difficult to spatially pattern these films due to the complex wetting behavior of patterned photoresist layers. Fortunately, DLIP provides a clean and efficient means to pattern plasmonic gratings out of these self-assembled monolayers.

2.2. Direct Laser Interference Machining (DLIP)

The DLIP technique is a derivative of laser interference lithography or LIL, both of which rely on the interference of two or more laser beams to form periodic structures on a surface. By using higher intensity laser sources, DLIP is able to use the standing wave pattern existing at the intersection of two or more laser beams to remove material by ablation and generate periodic patterns with a defined long-range order on the scale of typical microstructures given by the interference periodicity [5].

3. Results and Discussion

Thin films ranging of various thickness (25-150 nm for ITO and 25-100 nm for VO$_2$) were deposited via PLD. For the gold self-assembled monolayers, the films were prepared by directed self-assembly [4]. The films were patterned via DLIP into regular gratings with ~300 nm wide film lines spaced ~600 nm from center-to-center, see Figure (1). Similar patterns were achieved with DLIP on the VO$_2$ and the gold nanoparticle films. The optical properties of each of the resulting films was determined via spectroscopic ellipsometry. The effective index of the films after patterning via DLIP into a given metasurface was determined assuming an anisotropic layer of the appropriate thickness for each material.

When illuminated, the DLIP patterned surfaces exhibited classical diffraction along with the spectral dispersion modified by the metasurface as expected. Finally, multilayer test structures were fabricated to characterize the effect of the plasmonic metasurface on the optical switching properties of VO$_2$. The three-layer test structures consisted of a titanium nitride ground plane, a VO$_2$ spacer, and a gold thin film capping layer. In this configuration, the gold thin film served as the metasurface for the entire stack after it was patterned into a periodic grating.

4. Summary

We have shown how DLIP can be used to generate various metasurfaces comprising of different thin film materials including ITO, VO$_2$ and self-assembled gold nanoparticles, without negatively impacting their plasmonic properties. The behavior of each of these plasmonic metasurfaces will be compared and their response will be analyzed under this work.

Abstract

Although it has been claimed that silicon photonic crystal nanocavity devices are compatible with complementary metal-oxide semiconductors, it remains a challenge to make the structure and the fabrication fully compatible. We demonstrate a photolithographically fabricated photonic crystal nanocavity device that has a high quality factor even when clad with silicon dioxide. These characteristics make it possible to integrate this device with other silicon photonic devices.

1. Introduction

Silicon (Si) photonics is considered a promising candidate as a key technology with which to develop optical interconnects due to the mature state of nanofabrication, together with the unique characteristics of Si, namely a high refractive index and a low absorption loss at telecom wavelengths. Today, researchers are working towards accomplishing complementary metal-oxide-semiconductor (CMOS) compatible fabrication. On the other hand, Si photonic crystal (PhC) has been attracting a lot of attention since it enables us to use even smaller devices because it can realize high-$Q$ nanocavities with a small mode volume [1]. The use of high-$Q$ nanocavities will facilitate various functional operations at a very low power [2].

Hence, the integration of a Si PhC with Si photonics will allow us to expand the functionality of Si photonic systems. Although it is often claimed that existing Si PhC devices are compatible with CMOS and Si photonics, several challenges need to be met before complete integration is achieved.

2. CMOS compatible high-$Q$ PhC nanocavity

The key device throughout this study is a CMOS compatible high-$Q$ PhC nanocavity fabricated on a silicon chip [3]. The meaning of CMOS compatibility includes both fabrication and structure. Fabrication is undertaken using a photolithographic process that will allow integration with other silicon photonic devices and also allow future mass producibility. The device structure is clad with SiO$_2$; this is different from previous structures, which required an air-bridge process. Higher stability is achieved thanks to the clad structure.

Now we can use a silicon photonics foundry process, which allows us to conduct a study without having our own expensive nanofabrication facilities.

The fabricated device is shown in Fig. 1(a). The SiO$_2$ cladding is removed simply to facilitate observation with a scanning electron microscope (SEM). A waveguide-width modulated line defect cavity [4] is designed to obtain a high $Q$. The theoretical $Q$ is $8.1 \times 10^5$, where a $Q$ of $2.2 \times 10^5$ is obtained from the transmittance spectrum in Fig 1(b) [3]. We confirmed that the light is indeed localized in the cavity, by observing the light field from the top of the slab as shown in Fig. 1(c).

Fig. 1: (a) SEM image of the PhC nanocavity. (b) Transmission spectrum of the structure. The inset is an enlarged view of the peak transmission. It shows that cavity resonance occurred at a wavelength of 1619.20 nm. $Q$ is $2.2 \times 10^5$. (c) Image of on and off resonance from the IR camera. With on resonance, the light is localized at the cavity.

The use of a standard Si photonics foundry allows us to integrate the photonic components with electrical heaters and $p$-$i$-$n$ junctions, which will enable us to fabricate various active devices.

3. DeMUX filter

Figure 2(a) shows a fabricated eight-channel DeMUX filter [5]. PhC nanocavities are placed along the bus waveguide to drop light at different wavelengths from the input bus waveguide. Since the device is composed of small PhC nanocavities, its footprint is extremely small. The resonance of the cavity can be controlled with integrated heaters.

By carefully optimizing the structure we obtained the transmittance spectra shown in Fig. 2(b), where the power penalty was about -5.5 dB.
Fig. 2: (a) Fabricated PhC nanocavity based DeMUX filter, which is an eight-channel device integrated with heaters. (b) The transmittance spectrum of the device.

4. Electro-optic modulator

When a PhC nanocavity is integrated with a pin junction, it can be used as an electro-optic modulator when carriers are injected into the pin structure [6, 7]. Figure 3 shows the experimental setup that we used to realize electro-optic modulation with a PhC nanocavity. The result is shown in Fig. 3(b) where a 0.5 GHz modulation is demonstrated. Although the speed is not high, it is based on the carrier-plasma dispersion effect, and so it can cover GHz frequencies.

Fig. 3: (a) Block diagram of the experimental setup. A square pulse wave is applied and the output is recorded with an oscilloscope. (b) Modulated optical signal when a 0.5-GHz modulation frequency is applied. The black and red lines represent ON and OFF modulation when the input wavelength is set at the resonance and detuned -0.01 nm away from the resonance, respectively.

5. Photo-receiver

A pin integrated photonic crystal nanocavity can also be used as a photo-receiver [8, 9]. Although Si is transparent at telecom wavelengths, photo-carriers can be generated due to two-photon absorption (TPA) because the light confinement of a PhC nanocavity is very strong. The TPA coefficient is usually too small to allow this phenomenon to be used for photo-receiver operation, but this is not the case when we use a high-\(Q\) PhC nanocavity. The device can outperform others in terms of minimum detectable power, because it has a monolithic silicon structure, which allows us to obtain a small dark current.

Figure 4(a) shows the responsivity of the device, where a sensitivity of 13.4 mA/W is obtained in a linear regime and a minimum detectable power at about the \(\mu\)W level is demonstrated. Figure 4(b) shows the recorded signal when we apply an optical signal modulated with pseudo random bit sequence. Since the PhC operates as an optical WDM filter, we can selectively detect a single wavelength (channel).

Fig. 4: (a) Responsivity of all-Si PhC nanocavity pin receiver at a telecom wavelength. (b) Photoreceiver operation when a random pulse sequence is input into the device.

Abstract

Due to the photothermal property of silver nanowire, the local temperature is increased under the excitation of a control laser beam, which results in the increase or decrease of the intensity of the transmitted surface plasmons on the nanowire generated by a probe laser beam. The amplitude of the photothermal modulation depth is found to be strongly dependent on the focal positions, polarizations, and power of the control beam.

Plasmonic devices have received much attention in recent years due to their ability to confine light beyond the diffraction limit. Manipulating the propagation of surface plasmons (SPs) is of great importance for developing integrated nanophotonic devices. Metal nanowires (NWs) with the size of cross section well below the diffraction limit are highly-compact nanowaveguides for long distance propagation of SPs. The metal NW can be regarded as a Fabry-Pérot resonator with the propagating SPs partly reflected back and forth between the two NW terminals. The fundamental properties of the propagating SPs on metal NWs and some SPs signal processing functionalities in metal NW networks have been studied \cite{Wei2018, Gao2018}. The propagating SPs on metal NWs have also been used to control the photoluminescence of single quantum emitters, due to their nanoscale field confinement and microscale propagation length \cite{Li2009}.

The active control of propagating SPs is a crucial step toward the realization of highly integrated nanophotonic circuits. This talk will present our study on modulating the propagating SPs on a silver NW using the photothermal property of the NW. Due to the Fabry-Pérot resonances of the SPs on the NW, the intensity of the transmitted SPs generated by a probe laser beam can increase or decrease under the excitation of a control laser beam. We systematically investigated the dependence of the modulation depth on the focal positions, polarizations, and power of the control beam. Both numerical simulation and theoretical analysis were performed, which agree well with the experimental results and provide basic understanding about the photothermal response of propagating SPs.

Abstract

Plasmonic and interferometric colors are of great interest for their vibrancy, stability over time and their potential dichroic properties. Here, we present a laser-based technology that allows controlling the colors of plasmonic nanocomposite films and to print multiplexed images observable under white light independently in reflection, transmission or diffraction. Two approaches described here, leads either to hide diffractive images in a homogeneous reflective area or to encode three different images selectively displayed in reflection or polarized transmission on the same area.

1. Introduction

Hiding several images in a single printing, which appear selectively under different angles of observation, is of great interest for applications to security, data storage or design. Several techniques have been developed based on holography [1], moiré methods [2], multiple laser image (MLI) systems [3] or on the use of dichroic plasmonic colors [4-5]. A technology combining plasmonic nanocomposite films and laser scanning is presented here. It provides a simple implementation for printing multiplexed images with high flexibility and a micrometric spatial resolution. It is based on the shaping by ultra-short laser pulses of metallic Ag nanoparticles within thin TiO₂ films and the triggering of self-organization mechanisms that lead to very regular periodic patterns controlled at the sub-wavelength scale. Here, we present the main physic-chemical mechanisms that contribute to the shaping of plasmonic films at the nanometer scale and we show how such a laser technology allows engineering plasmonic colors and reinventing image multiplexing.

2. Experimental section

The initial films in which colors are produced by laser processing are mesoporous films of amorphous TiO₂ synthesized by a sol-gel process and coated on transparent flexible substrates. Their porosity is filled with metallic silver precursors by soaking the film in a silver salt solution. Small Ag nanoparticles are created inside the film volume prior to laser irradiations to create absorbers of visible light. A focused femtosecond (200 fs) laser at 515 nm wavelength scanning the sample surface is used to initiate the growth, reshaping and organization of nanoparticles within the film. The irradiation parameters are far below the damage threshold of the film and substrate. The formed nanostructures and their colors differ depending on the scanning speed, laser power, polarization, focusing, repetition rate or density of the drawn lines [6].

3. Results and Discussion

3.1. Laser-driven plasmonic gratings for multiple images hiding

The laser parameters can be tuned to trigger the formation of self-organized gratings on the film surface, which result from the excitation of transient surface plasmon polaritons during the pulse duration. These self-organized surface gratings have a period very close to the laser wavelength (495 ± 15 nm) and their orientation is perpendicular to the laser polarization, whatever the scanning direction [6]. This control of the grating orientation is used to encode grey-level images that can be observed in diffraction. Such a methodology is used to print three interlaced images, whose 256 grey-levels are converted into 256 grating orientations ranging over 15° and starting for each image at 0°, 60° and 120° respectively. The printed area displays successively the three different pictures shown in Figure 1 when observed in diffraction and, when rotating the sample in its plane with an azimuthal angle varying from 0° to 120°. The negative images are obtained at angles 15°, 75°, and 135°, respectively, and the color of the diffracted images can be changed by varying the angle of observation in the incidence plane. The low grating period actually ensures a high angular dispersion, and well-separated colors. Moreover, all images being printed with the same fluence, scanning speed, spacing between laser lines, and repetition rate (only the polarization angle being tuned), the sample appears fully homogeneous in reflection and transmission, thus
Figure 1: Photographs of a sample recorded in a diffraction configuration for three different azimuthal angles obtained by rotating the sample in its plane. The three different images appear at 0°, 60° and 120°, respectively.

3.2. Laser-driven plasmonic color management for image multiplexing

Such laser process can also result in the generation of micrometer size plasmonic nanostructured areas where the film birefringence and dichroism can be controlled at will, to produce unprecedented color gamuts that satisfy conditions for three-fold image multiplexing in three selected modes of observation under white light: reflection under non-polarized light and transmission between polarizers for two different polarization angles. The conditions that the color gamuts in the three modes must fulfil to produce such color gamuts are explained, followed by how such conditions can be satisfied with laser-controlled plasmonic colors. Three-fold image multiplexing (Figure 2) is shown using different color combinations [4]. Such laser processing is also applied to print dual multiplexed color images, for which more colors can be used. This methodology could be implemented with other technologies like electron beam lithography with a larger freedom on the choice of colors, along with a higher spatial resolution. Laser technologies however hold advantage for being more suitable for rapid and contactless printing on large surfaces.

Figure 2: Photographs of multiplexed images obtained with a single printing on a single layer. Each pixel of the printed encoded image contains three different colors, each of them being displayed in one of the modes. A large number of well-suited nanostructures allows getting all possible combinations of colors in the three modes and displaying three independent images. The first image is observed in reflection, the next two ones in transmission between two polarizers, while the sample is rotated in its plane.

4. Conclusion

Here a scanning laser technique is presented, that allows printing plasmonic colors on large areas. The singular optical properties of these colors and their ability to vary in different manners depending on the mode of observation and illumination in which they are observed allows printing interlaced diffractive images or multiplexed images that can be observed independently in reflection and transmission.

Abstract

We propose the integration of plasmonics concepts into the field of nanophononics using metallic nanoresonators as coherent phonon generators and detectors. Picosecond ultrasonics tools give direct access to the study of phonon propagation both in the time and frequency domains, and to the spatial distribution of strain in nanostructures.

1. Introduction

The development of micro- and nanofabrication techniques enabled the study of nanostructures where it is possible to engineer the acoustic phonon dynamics—aquatic waves with nanometric wavelengths and frequencies in the GHz-THz range). In these structures it is also possible to engineer the plasmonic properties and control both the dynamics and the interactions between the photonic and phononic fields. Picosecond ultrasonics tools gave direct access to the study of phonon propagation both in the time and frequency domains, and to the spatial distribution of strain in nanostructures.[1-2]

2. Acousto-plasmonic engineering

We propose the integration of plasmonics concepts into the field of nanophononics using metallic nanoantennas as coherent phonon generators and detectors. The polarization-dependent optical resonances and the phononic modes of metallic nanostructures are determined by their geometry—size and shape—and material properties—index of refraction and sound velocity, respectively. We show how an array of metallic optical nanoantennas optimized to work at visible wavelengths can be tailored to generate and detect acoustic phonons of variable frequencies in the GHz range, and how the interactions of these modes with plasmons can be put in evidence. We also discuss how the selection of the geometrical parameters of the crosses enables the design and engineering of optimized hypersound sources, with tailored and tunable spectra. We find that the detected phonon spectrum changes significantly when the polarization of the probe light is rotated 90 degrees. This ability to distinguish in the far field the response from local regions of nanostructures is a powerful metrology tool. The presented results expand the toolbox for the design of novel nanophononic systems and the development of opto-acoustically functionalized surfaces.

The possibility to create and manipulate nanostructured materials encouraged the exploration of new strategies to control the electromagnetic properties. Among the most intriguing nanostructures are those that respond in a different way to helical polarization, i.e. exhibit chirality. These structures have been used to boost the signal of an enantiomer over the other to be able to enhance detection. [3-7] Very recently, it has been put forward that planar chiral nanostructure can also present similar extinction properties, but in one enantiomer it would come from absorption, whereas in the other from scattering.[6]

Here we present a simple structure based on crossed bars exhibiting the same property, in a definite spectral range. Due to selective absorption and scattering, the plasmonic modes excited in the bars will depend on light handedness. The coherent generation of acoustic phonons using pulsed lasers strongly relies on how efficiently light is absorbed and scattered by a structure. The proposed structure opens the way to enhanced and selective coherent phonon excitation and detection. [8].

Non-invasive Bio-imager
Based on Frequency-tunable Terahertz Plasmonics

Yukio Kawano1*

1Laboratory for Future Interdisciplinary Research of Science and Technology, Tokyo Institute of Technology, Tokyo, Japan
*corresponding author, E-mail: kawano@pe.titech.ac.jp

Abstract
We report on a frequency-tunable non-circular plasmonic structure for multi-frequency terahertz (THz) analysis on a sub-wavelength scale. In spite of much interest in plasmon-based THz technologies, a main shortcoming of conventional devices is that they exhibit poor frequency-tunability in fixed structures. We here demonstrated that the frequency of THz plasmonic resonance is tunable according to the angle of polarization of the incident THz wave, which enhanced the flexibility in near-field THz applications. Biological and medical applications with this method are presented.

1. Introduction
Recently, applications of plasmon-based technologies have been attracting much attention because of their plasmon-mediated ability to strongly confine an electromagnetic wave [1-4], which enables highly sensitive evanescent-field detection and analysis. Such studies on a scale beyond the diffraction limit have been in strong demand, especially in research fields such as nano-materials characterization, chemical spectroscopy, and biological and medical analysis. Interest in medical applications is growing particularly rapidly, further pushing such demand. However, resonant frequency tuning in plasmonic devices has not been fully established, which limits the availability and flexibility of plasmon-based sub-wavelength applications.

Here we report on a continuously frequency-tunable plasmonic structure in THz region and its application to a non-invasive bio-imager [5,6]. By developing a non-circular shaped structure with a subwavelength aperture surrounded by continuously varied, concentric plasmonic grooves, we demonstrated that the resonant frequency of the plasmon-mediated THz concentration becomes freely tunable, which largely enhances its usefulness for evanescent-field THz sensing and analysis.

2. Results
Figure 1 displays our frequency-tunable plasmonic structure. One of the key features of this device is its non-circular shaped design. Due to its smoothly varied grooves, the...
groove period continuously changes by simply changing the rotation of the non-circular plasmonic structure relative to the diameter direction. This design results in continuously frequency-tunable characteristics in a much convenient manner. The device also increases the electric field intensity at the subwavelength aperture, thus significantly amplifying the transmission.

In order to utilize this device for observations and analysis of biological tissues, we measured THz transmission spectra for several mouse organs (Fig. 2(a)). We successfully observed distinct biological-tissue-dependent THz spectra through the interaction between the frequency-tunable plasmons and bio-samples. We further performed THz mapping of mouse tails (Fig. 2(b)). The obtained image showed that hair (yellow and red), skin (light blue), and bone (dark blue) were clearly distinguished.

3. Conclusions

The above advantages demonstrate that our frequency-tunable non-circular plasmonic metasurface with rotational symmetry breaking can increase the availability of evanescent-field THz detection with much more convenient and simple operation. This is promising for practical applications in future THz medical devices for daily health monitoring and intraoperative mapping. Our structure can be modified to fit most frequency ranges for surface plasmons by changing the diameter and depth of the non-circular shaped grooves, and therefore can be utilized in wide-band, frequency-selective applications including microwave, infrared, and visible light.

Abstract

Superconducting nanowire single-photon detectors (SNSPDs) are typically made from an ultra-thin superconducting film (with thickness of 4 to 10 nm) patterned into a ~50 – 200 nm wide nanowire. An example of such nanowire in a form of a meander is shown on Figure 1(a). The detection mechanism is based on creation of the normal resistive domain across the superconducting current carrying nanowire upon absorption of the photon as shown on Figure 1(b). In turn, normal domain across the nanowire causes the voltage pulse in the readout circuit to appear (Figure 1(c, d)). Sometimes, fluctuations without photon absorption cause the formation of a normal domain; these events are dark counts [1]. SNSPDs are capable of counting photons from ultraviolet (UV) to mid-infrared (mid-IR) and offering unparalleled performance at telecom wavelength but their performance sharply decreases at wavelengths longer than 2 μm. Using thin TiN and MoSi films we have fabricated a range of nanowires with various widths up to 400 nm and tested their low temperature electrical and optical performance.

Here we report on the comprehensive study of superconducting materials and SNSPD devices for mid-IR. We report on thin sputtered films of NbTiN, TiN, NbN, MoSi and on TiN films grown by atomic layer deposition (ALD). We report on electrical transport and superconducting properties such as sheet resistance (Rs), critical temperature (Tc) and critical current (Ic) at low temperatures. Optical properties of the films were tested at room temperature with spectroscopic ellipsometry [11]. The wavelength dependence of refractive index and extinction coefficient of the ALD TiN films is shown on Figure 2. Using thin TiN and MoSi films we have fabricated a range of nanowires with various widths up to 400 nm and tested their low temperature electrical and optical performance.

Figure 1: a) Scanning electron microscopy image of SNSPD device; b) schematic illustration of photon absorption by a current carrying superconducting nanowire; c) bias and readout circuit; d) voltage pulse registered at the output of an amplifier.
For characterization of detectors in mid-IR (wavelength 2 – 4.2 μm) we have built a test setup based on pulsed picosecond optical parametric oscillator (OPO). We have designed, fabricated and tested SNSPD devices for mid-IR using NbTiN films. At wavelength of 2.3 μm these detectors have QE~1.5% and FWHM timing jitter of 280 ps. A pair of NbTiN detectors was used to characterize a photon pair source at 2.08 μm [12] and to demonstrate laser ranging at 2.3 μm [13]. The detection efficiency of our detectors can be further improved by engineering an optical cavity to enhance in-band photon absorption probability [14]. These initial results with TiN, MoSi and NbTiN films show that development of high performance mid-IR SNSPDs for photonic applications is within reach.

Defects of Single Walled Carbon Nanotubes: Photonic and Electronic Integration

Han Htoon

1Center for Integrated Nanotechnologies, Materials Physics and Application Division, Los Alamos National Laboratory, Los Alamos, New Mexico, 87545, United States

Single walled carbon nanotubes with covalently functionalized sp³ defects have been rapidly emerging as a new class of transformational optical materials. Particularly, recent demonstration of room temperature, 1.55 µm single photon generation establish these covalent defects of SWCNTs as promising fundamental building blocks for defect driven quantum information technologies such as quantum key distribution. Defects also provide a significant boost in photoluminescence quantum yield (from <1% to ~28%) and emission stability, making envisioned applications of SWCNTs in optoelectronics, sensing, and imaging technologies more feasible. The key to full exploitation of these technological potential lie in the ability to integrate these SWCNTs with defect into plasmonic/photonic cavities for enhancement of light matter interaction and into nano-electronic devices for electrical stimulation. Here in this talk I will report recent progresses we made together with our collaborators toward achieving this critical photonic and electronic integration. We have successfully integrated the SWCNTs with sp³ defects into 2D slab photonic crystals and metallo-dielectric antenna arrays. In case of coupling with 2D photonic crystal, we were able to demonstrate room temperature single photon generation with 3meV linewidth defined by the cavity quality factor and 50 fold enhancement in emission.1 We achieved narrowest low temperature emission linewidth of 35 µeV by coupling the defects with metallo-dielectric antennas.2 We were also successful in fabricating single SWCNT field effect transistors using dielectrophoresis and attained electroluminescence from the sp³ defects.

Graded metasurface for elastic energy harvesting

Abstract
Metamaterial designs combining graded arrays of resonators and elastic wave excitation allows a precise control of the propagation of mechanical waves in solid media. In this study metamaterial’s broadband control capacities are used to design an innovative piezoelectric energy harvester.

1. Introduction
Recent years have witnessed an increasing popularity of metamaterial concepts, based on the so-called local resonance phenomenon, to control the propagation of electromagnetic, acoustics and elastic waves in artificially engineered media. While the momentum initially focused on the subwavelength bandgaps generated by the resonance, the research has delivered new forms of control, encompassing tailored graded designs to obtain spatially varying refraction index, wide bandgaps and mode conversion \cite{1}. In the field of photonics and acoustic this transition has already taken place and new graded design allows a tailored control of the propagation of light, micro-waves and sound. Elastic waves, are characterized by different compressional and shear wave speeds resulting in mode conversions at the interfaces. On the one hand this makes elastic metamaterials complex to model and the use of computational elastodynamics technique mandatory, on the other hand it offers new control possibilities not achievable in the electromagnetic or acoustic case \cite{2,3}.

2. Results
Starting from the seminal work on the resonant metawedge that supports both conversion and broadband reflection \cite{2}, we have restricted the problem to the case of a plate with graded rod-like resonators. This configuration has the twofold advantage of focusing the energy exactly on one resonator depending on the type of grading used, its slope and spatial extension. Each rod-like resonator has been complemented with a piezoelectric cantilever beam located at the top, also graded, to match the rod resonance strongly amplifying the motion (Fig. 1). This result in a doubly graded pattern that fosters harvesting over a broad spectrum of frequencies and hence a constant energy production when more rods are equipped with tip harvesters. After an introduction of the control capacity of graded elastic metasurface, the talk will present the numerical optimization of the focusing capacity and the results from an experiment with this device in the kHz range.

Figure 1: The elastic metasurface is made of a plate and an array of resonators of increasing height. A piezoelectric beam is inserted at the tip of the rod where the waves are concentrated.

Abstract

We suggest a novel approach to explain the physics of bound photonic states embedded into the radiation continuum. We study dielectric metasurfaces composed of planar periodic arrays of Mie-resonant nanoparticles (“meta-atoms”) which support both symmetry protected and accidental bound states in the continuum, and employ the multipole decomposition approach to reveal the physical mechanism of the formation of such nonradiating states in terms of multipolar modes generated by isolated meta-atoms.

1. Introduction

The quest for compact photonic systems with high quality factor (\(Q\) factor) modes led to the rapid development of optical bound states in the continuum (BICs). BICs are non-radiating states, characterized by the resonant frequencies embedded to the continuum spectrum of radiating modes of the surrounding space [1, 2]. The BICs first appeared as a mathematical curiosity in quantum mechanics [3]. The discovery of BICs in optics immediately attracted broad attention due to high potential in applications in communications, lasing, filtering, and sensing.

Despite the number of existing approaches to understand the nature of BICs, there is still a room for further development of the theory. During the previous few years the electromagnetic multipole theory has been extensively developed as a natural tool of nanophotonics dealing with the lowest (fundamental) resonances of the system. The main advantage of the multipole decomposition method (MDM) is that it provides a representation of an arbitrary field distribution as a superposition of the fields created by a set of multipoles [4].

In this work, we extend the MDM approach for explaining both symmetry protected and accidental BICs. We provide a theory of BICs origin in terms of MDM for a general case of any periodic structure and develop an analytical method, which determines the contribution of the vector spherical harmonics to the far field [5].

2. Results

For the frequencies below the diffraction limit, the far-field of any metasurface (see Fig. 1) can be expressed as

\[
E(\mathbf{r}) = \frac{E_0 V_0}{2\pi k_1} e^{i\mathbf{k}_1 \cdot \mathbf{r}} \sum_{\alpha} \hat{A}_\alpha \mathbf{Y}_\alpha \left( \frac{\mathbf{k}_1}{k_1} \right). \tag{1}
\]

Here \(k_{1z} = \pm \sqrt{k_1^2 - k_{1||}^2}\), \(k_1 = \sqrt{\varepsilon_1 \frac{\omega}{c}}\), \(V_0\) is the volume of the first Brillouin zone. The spherical vector functions \(\mathbf{Y}_\alpha(\mathbf{n})\) depend on the spherical coordinates of a unity vector \(\mathbf{n}\) and \(\alpha\) is a set of indices encoding the multipoles [6]. \(\hat{A}_\alpha\) are the coefficients of the multipolar decomposition.
Equation (1) provides the correspondence between the radiation pattern of a single unit cell and the far-field properties of the whole infinite array allowing for interpreting the BIC in terms of MDM. In strong contrast to a single nanoparticle, where each multipole contributes to the far field, in case of a subdiffractive array there might be direction, where non of the multipole gives any contribution, or alternatively the non-zero contribution of different terms may eventually sum up to zero. The formulated alternative gives a sharp distinction between the symmetry protected and accidental BIC.

The Γ-point BIC corresponds to the absence of the far-field radiation in the direction along the z-axis. Due to the structure of VSH, it appears that a number of multipoles do not radiate in the vertical direction along the z-axis. If the field inside a single unit cell consists of such multipoles, there will be no total radiation in z-direction. This simple fact is illustrated in the upper panel in Fig. 1(b). Noticing that only \( Y_n \) functions with orbital angular momentum \( m = 1 \) are non-zero in parallel to the z-axis direction, we can conclude that at the Γ-point in the subdiffractive array all the modes which do not contain the harmonics with \( m = 1 \) are symmetry-protected BICs. This fundamental conclusion lies in the basis of recent experimental demonstration of lasing with BIC in a 2D subdiffractive array of nanoparticles. The particular operational mode consisted of vertical dipoles oriented along the z-axis, thus, not contributing into the only open channel. There exist an approach that the eigenmodes at the Γ-point can radiate in the normal direction z if their fields are odd under \( C_2^z \) rotations, and do not have any other rotational symmetry of \( C_n^z \)-type. In terms of multipole moments, this follows from the fact that at the Γ-point any radiative mode should contain multipoles with \( m = 1 \). On the other hand, in virtue of the symmetry, the even modes have zero radiation losses, i.e. infinite radiation quality factor, which are known as symmetry-protected BICs.

Let us now turn to the case of accidental BIC description. In general case, coefficients \( \hat{A} \) are complex numbers. They define the amplitudes and phase delay between the multipoles. However, in accordance with [7], if the structure has time reversal and inversion symmetry, the eigenmodes must satisfy the condition \( \mathbf{E}(r) = \mathbf{E}^{\star}(-r) \). It results in a fact that every term of the sum in Eq. (1) is purely real, and all multipoles are in-phase or anti-phase. All coefficients depend on k-vector and structure’s parameters and in a case of the off-Γ BICs this sum turns to zero. In other words, for the particular \( k_1 \) all vector harmonics add up to zero in the direction of \( k_1 \), analogously to the anti-Kerker effect, because they are already in phase and only amplitudes are modulated while k-vector is changed [Fig. 1(b), lower panel].

3. Conclusions

We have demonstrated that symmetry-protected bound states in the continuum in dielectric metasurfaces at the frequencies below the diffraction limit are associated with the multipole moments of the elementary meta-atoms which do not radiate in the transverse direction. Similarly, we have revealed that the accidental bound state in the continuum corresponding to an off-Γ point in the reciprocal space are formed due to destructive interference of the multipole fields in the far-zone. We believe that our results will provide a new way for designing high-quality resonant photonic systems based on the physics of bound states in the continuum.

Direct Imaging of Isofrequency Contours of Strongly Localized Guided Modes in Planar Photonic Structures

Anton Samusev
Department of Nanophotonics and Metamaterials, ITMO University, St. Petersburg, Russia
*corresponding author, E-mail: a.samusev@metalab.ifmo.ru

Abstract
In this work, we investigate all-dielectric metasurfaces and based on the silicon on insulator platform for manipulating strongly localized evanescent waves in the visible and near-infrared spectral ranges. For an anisotropic metasurface, we use the Fourier modal method to demonstrate that it supports both hyperbolic-like and elliptic dispersion regimes. We implement a back focal plane microscope combined with a high refractive index solid immersion lens to directly image the isofrequency contours of the guided modes (surface waves). Reconstruction of 2D dispersion law unambiguously reveals the transition between different regimes of in-plane propagation of the electromagnetic waves.

1. Introduction
Surface waves (SWs) on metasurfaces attract special interest. SWs are propagating electromagnetic states localized perpendicular to the interface and do not radiate into the far-field. These properties make them very promising for applications in modern optoelectronic and all-optical on-chip signal delivery. In straightforward analogy with metamaterials used for the control over bulk waves, metasurfaces form a flexible platform for manipulating surface waves and guided modes.

2. Results and discussion
Modern optoelectronics is based on planar photonic structures, which include periodic ones such as photonic crystal waveguides or metasurfaces. The key characteristic of these structures is the spatial and temporal spectrum of their eigenmodes. Experimental studies of guided and surface modes in planar systems are especially challenging since their dispersion curves reside below the light line. In this work, we implement a back focal plane (BFP) microscope combined with a high refractive index solid immersion lens (ZnSe hemispherical prism) to directly visualize the isofrequency contours of guided modes supported by arbitrary metasurfaces. The numerical aperture of such a setup may reach exceptional values of 2.25 and even higher. The radiation losses, coupling regime and efficiency can be precisely tuned by varying of prism-to-sample air gap [1]. We study an all-dielectric metasurface for manipulating guided modes in the optical spectral range. Using to Fourier modal method we optimize the metasurface design to demonstrate both hyperbolic-like and elliptic dispersion at different frequencies. Reconstruction of the full dispersion surface from experimental data unambiguously reveals the transition between different dispersion regimes [2]. Finally, recent progress of our group in the experimental studies of exciton-polaritons in hybrid 2D systems based on transition metal dichalcogenide (TMD) monolayers coupled to all-dielectric metasurfaces will be highlighted.

3. Conclusions
We have studied dispersion properties of optical SWs supported by a strongly anisotropic all-dielectric metasurface. The nanostructured array composed of closely-packed silicon bars on a silica buffer layer was designed to support hyperbolic-like and elliptic dispersion regimes. In the experiment, the IFCs of SWs were visualized by means of back focal plane microscopy.

The use of a hemispherical solid immersion lens allowed to drastically enhance the numerical aperture of the system and gain access to strongly localized states. Using FDTD simulations, we illustrated multiple dispersion regimes depending on the wavelength and polarization of the incident wave. Finally, joining the whole set of the experimental data we have the full dispersion \( \omega(k_x, k_y) \) of surface waves propagating along the metasurface in all directions.

Abstract

We experimentally demonstrate bilayer metasurfaces for optical antireflection. The metasurfaces consist of a square array of silicon pillars with self-aligned top gold resonators and complementary bottom gold slots, enabling near-zero reflection and simultaneously close-to-unity transmission at designed operational frequencies in the terahertz and mid-infrared spectral regions. We further demonstrate THz bandpass filters based on stacked bilayer metasurfaces, allowing fairly narrow, fast roll-off, and high-transmission bandpass performance, with an extremely clean background outside the passband.

1. Introduction

Optical antireflection has been critical for a wide range of applications from reducing losses to avoiding adverse effects in optical systems and optoelectronic devices. Based on the principle of interference, quarter-wave antireflection coating is the oldest, yet still simplest and widely used, approach to realize narrowband antireflection by introducing a dielectric film with a matched refractive index and a quarter-wave thickness. Broadband antireflection coatings can be accomplished using multilayer dielectric thin films with appropriately arranged refractive index and thickness profiles. However, in the mid- and far-infrared wavelength regions, it becomes a challenge to identify low-loss dielectric materials with the required refractive indices and, at the same time, suitable for cost-effective, high-quality film coating with increasing thicknesses.

The development of metasurfaces [1] – two-dimensional equivalent of metamaterials – has enabled the unprecedented control of the amplitude, phase, and polarization states of reflection and transmission using an array of ultrathin subwavelength metal/dielectric resonators. It has also been shown that few-layer metasurfaces – a stack of metasurfaces separated by dielectric spacers of subwavelength thicknesses – can not only dramatically enhance the performance but also create new functionalities beyond the constituent metasurface layers. Here we demonstrate narrowband, dual- and broadband optical antireflection using simple bilayer metallic metasurfaces in the terahertz (THz) and mid-infrared (mid-IR) spectral ranges. These metasurfaces consist of a square array of silicon pillars with self-aligned top gold resonators and complementary bottom gold slots, enabling near-zero reflection and simultaneously close-to-unity transmission at designed operational frequencies [2]. We further demonstrate narrowband THz bandpass filtering by cascading multiple bilayer antireflection metasurface structures. We show that, by simply stacking multiple identical bilayer metasurfaces, the transmission passband of the resulting filters significantly narrows as compared to that of a single bilayer metasurface, while maintaining 50% peak transmission power intensity in the passband with an extremely clean background (i.e., zero transmission) in the stop band [3].

2. Results

Figure 1 shows the scanning electron microscopy (SEM) images of the antireflection metasurface structures consisting of a square array of silicon pillars directly created on top of a high-resistivity silicon substrate by photolithography/e-beam lithography and reactive ion etching (RIE), where the top and bottom surfaces, but not the sidewall of the silicon pillars, were then coated with thin Ti/Au films (10 nm/200 nm thick for THz and 1 nm/30 nm thick for mid-IR), illustrated by the unit cell false color SEM images in Figure 1(a) and (b).

In Figure 2(a), we plot the experimentally measured reflection and transmission spectra for the THz metasurface structure shown in Figure 1(a) with diameter $d$ varying...
ing from 32 to 64 \( \mu \text{m} \), period \( p = 1.2 \times d \), but height fixed \( h = 8 \mu \text{m} \), demonstrating a dramatic reduction of Fresnel reflection and significant enhancement of transmission at frequencies depending on the cylinder diameter. For the sample with a designed cylinder diameter \( d = 48 \mu \text{m} \), the measured reflectance is \( R = 0.19\% \), and the transmittance reaches \( T = 94.3\% \) at 0.983 THz. For the samples with other cylinder diameters, the measured reflectance is \( R < 2.5\% \) and the transmittance is \( T > 91\% \) at their respective operational frequencies spanning from 0.72 to 1.53 THz.

In Figure 2(b) and (c) we plot the measured reflection and transmission spectra for the dual and broadband THz antireflection metasurface structures shown in Figure 1(b), where \( w = 20 \mu \text{m} \) and \( h = 20 \mu \text{m} \) while \( L \) varies from 64 \( \mu \text{m} \) to 76 \( \mu \text{m} \), and \( p = 1.1 \times L \) for dual band operation, and \( w = 15 \mu \text{m} \) and \( h = 37 \mu \text{m} \) while \( L \) varies from 62 \( \mu \text{m} \) to 78 \( \mu \text{m} \), and \( p = 1.1 \times L \) for broadband operation. For the dual-band THz metasurface with \( L = 76 \mu \text{m} \), we achieve low reflection and high transmission at two frequencies, \( \omega_1/2\pi = 0.587 \) THz with \( R_1 = 2.43\% \), \( T_1 = 91.3\% \) and \( \omega_2/2\pi = 0.932 \) THz with \( R_2 = 0.56\% \), \( T_2 = 89.3\% \). The best broadband antireflection performance occurs when \( L = 62 \mu \text{m} \), achieving small reflectance \( R < 3\% \) in a frequency range between 0.719 and 0.953 THz, a bandwidth of 234 GHz (or a fractional bandwidth of 28%). The corresponding experimental transmittance is \( T > 87\% \) in this frequency range, with the highest transmittance \( T_{max} = 92\% \) at near 0.9 THz. It is worthwhile pointing out that, in the frequency range between 0.748 and 0.932 THz (a fractional bandwidth of 22%), the experimentally measured reflectance is \( R < 1\% \), attractive for many applications where eliminating the undesirable reflection over a broad bandwidth is critical. Similar results were observed for the metasurface structures operating in the mid-IR frequency range, with results not shown here.

Although the quality factor of a single metasurface is relatively low (~2), taking advantage of the high transmission, we have further demonstrated high-performance THz bandpass filters by simply stacking multiple identical bilayer antireflection metasurfaces, achieving a reasonably high transmission in a very narrow passband, and a fast roll-off to an extremely clean background in the stop band. By stacking 4 double-side metasurfaces we narrowed the bandwidth by a factor of 3, with transmittance about 50% (results not shown here). Compared to conventional THz bandpass filters using suspended metal mesh structures or subwavelength metal hole-arrays, the demonstrated narrowband THz bandpass filters are easy to fabricate and mechanically robust and are potentially suitable for a wide variety of applications in the THz frequency region.

3. Conclusions

By using metal/dielectric/metal bilayer metasurfaces we experimentally demonstrate low-loss optical antireflection in the terahertz and mid-infrared spectral regions. We further demonstrate THz bandpass filters based on stacked bilayer metasurfaces, allowing fairly narrow, fast roll-off, and high-transmission bandpass performance, with an extremely clean background outside the passband.

Optimal Design of Rectennas for IR Energy Harvesting

A. Y. Elsharabasy*, M. H. Bakr, and M. Jamal Deen
Department of Electrical and Computer Engineering, McMaster University, ON, Canada
*corresponding author: elsharay@mcmaster.ca

Abstract
In this work, we present a novel approach to design efficient rectennas for the infrared (IR) energy harvesting applications. The rectenna is composed mainly of a rectifying element, i.e. diode, and an antenna. In the IR regime, the ultra-high frequency ac signal captured by the antenna terminals has to be efficiently transformed into a useful dc signal. Owing to the ultra-fast quantum tunneling as a conduction mechanism, metal-insulator-metal (MIM) diode represents the best candidate to operate at these IR ranges. The impedance matching between the antenna and the diode, the diode nonlinearity, and the capacitance effect on the device’s cutoff frequency represent challenges to achieve an efficient rectenna. An optimization algorithm is carried out to improve the rectenna’s performance taking into consideration the aforementioned challenges.

1. Introduction
The infrared (IR) radiations coming from sun or that emitted from earth surface represent untapped energy sources that have been attractive for many research groups [1]. The current photovoltaics technology is still struggling to utilize the full IR portion of solar irradiance. At these terahertz frequencies corresponding to the 1-10 μm wavelength range, silicon and conventional semiconductors are not suitable to support electron conduction with these insufficient photon energies [2].

A direct approach can be used to harvest high frequency ac signal by using rectennas. A rectenna is an antenna where its terminals are connected to a rectifying diode. Since the rectenna concept was proposed in 1972 [3], the idea has been implemented many times in different configurations [4-7]. After the antenna captures the high frequency ac signal forming the surrounding radiations, the diode rectifies this signal and produces a dc current.

The diode at IR frequencies has to possess a short transit time in the range of few femtoseconds. Metal-insulator-metal (MIM) diodes are the best fit to perform at these ultra-high frequencies due to their ultra-fast quantum tunneling mechanism [8]. MIM diode’s performance is controlled by its materials’ properties and geometry. Trade-offs between diode’s resistance and responsivity and resistance and capacitance lead to unexpected degradation of the device performance. Careful considerations should be drawn to select the appropriate materials to improve the efficiency.

The antenna configuration is desired to efficiently match the diode’s impedance. Additionally, polarization-insensitive design will boost the rectenna’s overall performance [9].

Figure 1: Block diagram of rectenna

The selection of the antenna dimensions and correspondingly the resonance frequency can manipulate the unwanted effects exhibited by the diode. In this work, attention is drawn to each element of the rectenna to achieve a considerably acceptable overall performance.

Aggregation Enhanced Two-photon Photoluminescence of Plasmonic Metal Nanoparticles and Their Biomedical Applications

Peiyan Yuan, Zhenping Guan, Cuifeng Jiang, Monalisa Garai, and Qing-Hua Xu

1Department of Chemistry, National University of Singapore, Singapore 117543

Abstract

Noble metal nanoparticles were found to display significantly enhanced two-photon photoluminescence upon aggregate formation, which has been studied in the colloid solutions and on the single particle level. This phenomenon has been utilized to develop various schemes for two-photon excitation based biomedical applications.

1. Introduction

Noble metal nanoparticles (NPs) have found wide range of applications in optoelectronic and biomedical fields owing to their unique optical properties. Resonant interactions of noble metal NPs with light will result in collective oscillation of conduction band electrons, which has been known as localized surface Plasmon resonance (SPR). Plasmon coupling interactions between adjacent NPs in aggregated nanostructures will result in dramatically enhanced local electric-field in the gap region, which have been known to result in giant enhancement in various linear and nonlinear optical responses such as surface-enhanced Raman scattering, fluorescence, second harmonic generation, and two-photon photoluminescence (2PPL) [1].

Two-photon photoluminescence (2PPL) is light emission from materials that are excited by simultaneous absorption of two photons. Due to its nonlinear nature, 2PPL is highly sensitive to the incident light intensity. Very minor change in the local environment can make significant difference in 2PPL responses of metal NPs. 2PPL responses therefore can serve as sensitive probe signals to study local electric-field amplification in plasmonic nanostructures. Furthermore, two-photon excitation possesses unique advantages such as 3-dimensionally confined excitation at the focal volume and deep penetration into biological tissues of near-infrared light, 2PPL has lots of potential biological applications.

Noble metals, such as Au and Ag are generally considered as nonfluorescent due to their low quantum yield. Spherical metal NPs generally display relatively weak 2PPL. Our group recently found that 2PPL of metal NPs became significantly enhanced in the aggregated nanostructures [2-7]. Up to 800 times enhancement in the colloid solution [3] and several orders of magnitude on the single particle level [6] have been achieved. The phenomenon of aggregation enhanced 2PPL of metal NPs has been further utilized to develop various schemes for two-photon excitation based applications such as sensing, imaging and phototherapy [3, 7].

2. Results and Discussion

2.1. Observation of Aggregation Enhanced 2PPL in different systems.

Aggregation enhanced 2PPL of metal NPs were accidentally found when we studied interactions between noble metal NPs and conjugated polymers. Ag and Au NPs were found to exhibit extraordinary quenching effects on the fluorescence of cationic poly(fluorinephenylene). On the other hand, cationic conjugated polymers induce the aggregate formation of metal NPs. 2PPL of Ag and Au NPs were significantly enhanced upon addition of conjugated polymers, by a factor of 51-times and 9-times compared to the isolated nanoparticles for Ag and Au, respectively. [2]

Fig. 1: (A) 2PPL of conjugated polymer induced aggregation of metal NPs (A) and cysteamine induced aggregation of Au@Ag NPs(B)

This aggregation enhanced 2PPL were subsequently demonstrated to be universal for Plasmonic metal NPs. 2PPL enhancement was observed in Au and Ag NPs of different sizes. A maximum 2PPL enhancement factor of up to 840-fold was obtained for Au@Ag core shell NPs with ~3.5 nm Ag nanoshells when a small molecule, cysteamine, was utilized to induced the aggregation of Ag@Ag NPs [3]. Plasmon coupling interactions between metal NPs in the aggregated nanostructures were believed responsible for the observed aggregation enhanced 2PPL. DNA tuned Au NP assemblies with well controlled separation distances from 2.0 to 12.2 nm were further prepared to investigate plasmon coupling strength and particle size effects on 2PPL enhancement [4]. 2PPL intensities of these DNA coupled nano-assemblies were found to increase rapidly as the separation distance decreases. The largest 2PPL enhancement factors of 115 and 265 were achieved at the
shortest available separation distance of 2.0 nm for 21 and 41 nm Au NPs–dsDNA assemblies, respectively [4].

Fig. 2. 2PPL of different single Au nanoparticle clusters.

2.2. Studies of Aggregation Enhanced 2PPL on the single particle Level

2PPL of aggregated metal NPs are expected to be strongly dependent on the morphology of nanostructures. To understand the underlying mechanism and explore the optimum enhancement, 2PPL of coupled metal nanostructures have been studied on the single particle level. Single particle study on the 2PPL enhancement of coupled Au NPs revealed that the 2PPL signal increases from monomer to trimer, and the average enhancement was found to be ~7.8×10^3 and ~7.0×10^4 for a dimer and trimer respectively, as compared to that of individual Au NPs [5]. 2PPL of trimers strongly depends on the coupling angle. The trimer with coupling angle of 180° was found to display the largest 2PPL intensity, which decreases rapidly as the coupling angle decreases. Single particle studies on 2PPL of different dimers also indicate that their 2PPL are strongly dependent on their morphology and relative orientations [6].

2.3. Application of Aggregation Enhanced 2PPL in Sensing, Imaging and Phototherapy.

As many chemically and biologically important species can cause aggregation of metal NPs. This phenomenon can be utilized to develop various schemes for two-photon excitation based biomedical applications. 2PPL-based sensing uses metal NPs themselves as the probe and does not require any probe molecules like Raman tags for SERS. One can monitor 2PPL intensity versus concentration of the analyte for label free quantitative detection.

Fig. 3: Scheme for detection of Thromobin (A) and DNA (B)

Various bio-sensing schemes have been developed. For example, label-free 2PPL-based assay for sensing thrombin in serum have been developed by using Ag NPs and a thrombin binding aptamer (TBA) [7]. TBA adsorbs on the surface of Ag NPs and helps to stabilize them, whereas, the addition of thrombin selectively binds to TBA and leads to formation of aggregates. The detection limit of the method was found to be 3.1 pM in buffer solution, which was two orders of magnitude better than the detection limit obtained from the change in UV-Vis extinction spectra. Similarly, DNA induced coupling of Au NPs and 2PPL enhancement have been further utilized to develop a two-photon sensing scheme for detection of DNA sequences [4]. This 2PPL based method displayed high sensitivity with a limit of detection of 2.9 pM and excellent selectivity against ssDNA with mismatched bases. A single mismatch can be easily differentiated at room temperature. Taking the unique advantages of two-photon excitation, this method could be potentially further extended to DNA detection inside cells or even in vivo.

3. Conclusions

2PPL of metal NPs were found significantly enhanced in the aggregated nanostructures: up to 800-fold enhancement in the colloid solution and several orders of magnitude on the single particle level. This phenomenon have been further utilized to develop various two-photon excitation based applications with high sensitivity and selectivity, with potential for in-vivo biomedical applications.

Abstract

We investigate the quantum electrodynamics of a quantum emitter coupled to a Weyl-point photonic lattice. We find that, despite the smoothness of the density of states near photonic Weyl points, fractional decay is observed when the transition of the quantum emitter is tuned to the frequency of a Weyl point. In addition, we show the emergence in the system of a light-matter bound state exhibiting tunable power-law localization, a feature with no counterpart in any other quantum optical scenario.

1. Introduction

The recent advent of new concepts and experimental techniques in nanophotonics has enabled unprecedented opportunities to tailor the emission properties of quantum emitters (QEs) through modifications of their environment \cite{2, 3}. Of particular interest in this context are periodic structures with band-gaps \cite{4}.

In parallel, last decade has witnessed a spectacular progress in the application to physics of concepts originated in topology \cite{5}. In this context, Weyl physics is playing a prominent role. The recent observation of Weyl excitations in photonic systems \cite{6} has boosted the interest in this class of systems as highly controllable platforms to explore non-trivial topological properties.

In this work, we investigate the quantum electrodynamics of photonic Weyl points. By using a fully non-perturbative approach based on the resolvent operator method, we analyze the decay dynamics of a quantum emitter coupled to a Weyl-like photonic reservoir. We find unique characteristics such as fractional decay in the presence of a smooth density of states and the emergence of a light-matter bound state featuring tunable power-law localization \cite{7}.

2. Analyzed system

Figure 1(a) renders a schematic view of the considered system. It consists of a quantum emitter of transition frequency \( \omega_e \) interacting with a periodic cubic lattice of localized photonic modes. The modes are coupled among them following the first-neighbor hopping pattern displayed in Fig. 1(a), which leads to a two-sublattice structure (A/B sublattice, shown in blue/red in Fig. 1(a)). We also assume that the system features a tunable sublattice frequency offset \( M \), so the frequencies of the bosonic modes in sites A and B are \( \omega_A = \omega_W + M \) and \( \omega_B = \omega_W - M \), respectively. Figure 1(b) shows the corresponding dispersion relation, \( \omega(k) \), as a function of \{\( k_x, k_z \)\}, calculated for \( k_y = 0 \) and \( M = 0 \). As observed, four frequency-isolated single linear degeneracies (Weyl points) emerge at \{\( k_x, k_z \)\} = \{\( \pm \pi/2, \pm \pi/2 \)\}. Figure 1(c) displays the corresponding density of states (DOS), which shows the expected quadratic dependence in the vicinity of the Weyl points frequency.

3. Main results

We first analyze the upper level population of the QE \( \langle |C_e(t)|^2 \rangle \), obtained from the resolvent operator technique \cite{7}. Figure 2(a) summarizes the results for several
Figure 2: (a) Dynamics of the quantum emitter’s excited state population, $|C_e(t)|^2$, calculated for $M=0$ and different values of $\Delta$. Solid lines correspond to a non-perturbative approach (resolvent operator method). Dashed lines display the results of a perturbative approach (Fermi’s Golden rule). In both cases, a light-matter interaction strength of $g = 0.5J$ is assumed. (b) Real space distribution of the photonic probability amplitudes corresponding to the light-matter bound state emerging in the system at long-times for representative values of the detuning, $\Delta$, of the quantum emitter emission frequency with respect to the Weyl frequency (solid lines). For comparison, the predictions from a perturbative approach (Fermi’s Golden rule) are also included (dashed lines). As observed, for all considered values of $\Delta$ the perturbative approach fails to reproduce the corresponding non-perturbative results. This discrepancy is most remarkable for $\Delta = 0$. In that case, the DOS and its first derivative are smooth near $\omega_e$, from which the predictions of Fermi’s Golden rule (no decay of the QE) would be expected to hold. Instead, our results show that after an initial decay, followed by a set of oscillations, $|C_e(t)|^2$ settles down to a value smaller than 1. This fractional decay can be interpreted as the signature of a light-matter bound state [7].

The emergence of this light-matter bound state can be further demonstrated by investigating the real space distribution of the photonic part of the system’s wavefunction for $\Delta = 0$ and long times (i.e., the bound state wavefunction). Figure 2(b) shows a three-dimensional visualization of the corresponding photonic probability amplitude for a $20 \times 20 \times 20$ lattice (the QE emitter is located at the center of the figure). As shown, the probability amplitude is indeed localized around the QE, which fully confirms the presence of a light-matter bound state in the analyzed system.

To quantitatively characterize the real space distribution of the obtained bound state, we analyzed the dependence with the distance from the emitter, $d$, of the above mentioned probability amplitude. For illustration, we discuss here the dependence along the $z$-axis. For the case of no offset between sublattices, $M = 0$, we found that a power-law $1/d^2$ matches well the numerical results. Remarkably, we also found that the variation of the sublattice frequency offset $M$ actually enables tuning the exponent of the observed power-law decay. For $M/J = 2$, we obtained that the bound state decays with a power-law $1/d^3$. For intermediate values in-between $M = 0$ and $M/J = 2$, we observe a broad variety of different decay behaviors. For instance, for the case of $M/J = 1$, we obtained that both $1/d^2$ and $1/d^3$ power-law decays coexist in the same system.

This tunability is enabled by the fact that the sublattice frequency off-set can change the system band-structure without opening a band-gap for $|M| < 2J$, which in turn is because a Weyl point is only annihilated when it meets another one with opposite chirality. To our knowledge, this bound-state power-law tunability has not been reported before in any other structured photonic reservoir.

References

We will demonstrate how to utilize the crystal growth methods for manufacturing of novel composite materials for various applications and especially photonics (metamaterials, plasmonic materials [1-7]), and energy conversion [8-9]. We will focus on two novel bottom-up manufacturing methods: (i) method based on directionally-grown self-organized eutectic structures [1, 5-9]; and (ii) NanoParticles Direct Doping method (NPDD) [2-4] based on directional solidification of dielectric matrices doped with various nanoparticles. In both of these methods we can easily use all available resonant phenomena to develop materials with unusual electromagnetic properties. Eutectic composites are simultaneously monolithic and multiphase materials forming self-organized micro/nanostructures, which enable: (i) the use of various component materials including oxides, semiconductors, metals, (ii) the generation of a gallery of geometrical motifs and (iii) control of the size of the structuring, often from the micro- to nanoregimes. On the other hand, the novel method of NanoParticles Direct Doping enables doping of dielectric matrices with various nanoparticles (varying chemical composition, size and shape) and with the possibility of co-doping with other chemical agents as eg. optically active rare earth ions or quantum dots.

Abstract

Semiconductor quantum dots are one of the best on-demand sources of single and entangled photons to date, simultaneously merging the highest brightness and indistinguishability of the emitted photons. They are, therefore, among the strongest candidates for practical single-qubit quantum photonic devices. However, to exploit the full advantage of quantum physics, multi-qubit photonic devices are absolutely necessary. Here we propose, for the first time, an experimentally feasible multi-qubit photonic device, and a method for individual charging of multiple quantum dots and coherent charge transport between them.

1. Summary

The spin- or location-states of isolated charges in optically-active quantum dots are one of the promising candidates for fundamental building blocks in quantum science and technology. Many practical applications would comprise of multiple coupled quantum dots, each of which must be individually chargeable. However, the most advanced demonstrations are currently limited to devices with only a single dot, and individual charging and charge transport has neither been demonstrated nor proposed for a scalable array of optically active quantum dots.

In this talk I will present a device where we propose and numerically demonstrate a method for controlled charging of multiple quantum dots and coherent charge transport between the dots [1]. We show that charging and charge transport can be implemented in a realistic structure with fidelities greater than 99.9% in a few μs. Our scheme is based on all-optical resonant manipulation of charges in a 1-dimensional array of quantum dots formed by a type-II band alignment. Such structures can be practically realized using, for example, crystal-phase quantum dots in nanowires [2], and are feasible in view of recent advances in controlling the crystal phases in nanowires during growth [3].

Our work opens new practical avenues for realizations of advanced quantum photonic devices such as, for instance, a solid-state quantum register with a photonic interface.

SUMMARY

Plasmonic “V-shaped” nanoantennas and nanorods are building blocks for the rational design of flat metamaterials and optical devices. Yet, the fabrication and structural patterning of such small antennas is not a simple task. E-beam lithography is widely used, but shows limitations when it comes to fabricating very small structures with high crystallinity and purity.

Optical printing of plasmonic particles represents an alternative to standard lithography approaches. In recent years, the use of optical forces has emerged as a straightforward way to pattern spherical gold or silver nanoparticles with a high localization precision and lateral resolution [1]. For nanorods, it has even been shown that not only the patterning, but also the controlled alignment of individual rods can be obtained by using polarized laser light [2].

Optical printing has been achieved for a variety of nanoparticles. Indeed, many particle shapes and compositions are nowadays accessible by synthetic chemistry. The synthesis of V-shaped plasmonic particles, however, remains a challenge. In this presentation, I will demonstrate the possibility of re-shaping and patterning plasmonic nanoantennas with light as an intriguing alternative to conventional nanofabrication.

First, I will discuss how laser manipulation and heating of individual gold nanorods can be applied to controllably re-shape and bend them in solution. Secondly, I will present how the optical force, which emerges during the bending process, can be utilized to simultaneously pattern these bent particles onto an underlying substrate. Finally, I will show that adjusting the laser conditions not only allows to control the bending angle and the alignment of the bent nanoantennas, but also to optically split a single nanorod into two spherical nanoparticles of equal size. Scanning electron microscopy and transmission electron microscopy imaging reveals that the particles are separated at distances of less than ~2 nm with the smallest gaps being in the sub-nanometer regime. Such dimer nanoantennas obtained by optical nanorod splitting thus display a very strong field confinement in the gap region, which is advantageous for sensing and spectroscopy applications such as surface enhanced Raman spectroscopy (SERS).

Abstract

Subwavelength grating metamaterial waveguide structures are becoming established as important building blocks for silicon photonic integrated circuits. The novel optical properties found in these structures and ability to control their optical responses with unprecedented accuracy are opening new prospects for controlling flow of light in nanophotonic waveguides circuits. In this invited talk we will present an overview of our recent advances in this field, including silicon-based subwavelength structures for highly efficient fiber-chip couplers, ultra-broadband waveguide devices, Bragg filters with high spectral sensitivity and nanophotonic waveguides with engineered anisotropy.

1. Introduction

Metamaterial photonics has seen tremendous progress, particularly in nanostructured engineered materials: metamaterials, metallic and dielectric subwavelength structures and subwavelength engineered waveguides. The novel optical properties found in these structures, along with the capability, through advanced fabrication techniques, to control their optical responses with unprecedented accuracy, has opened new prospects for controlling and manipulating light in planar waveguide circuits. Since the early demonstrations of a silicon wire waveguide with a subwavelength grating (SWG) metamaterial core [1-5], metamaterial SWG waveguides have attracted a strong research interest in academia and industry because of their unique potential to control light propagation in planar waveguides [6,7]. The SWG metamaterial waveguides have been adopted by industry for fiber-chip coupling [8] and subwavelength engineered structures in general [6,7] are likely to become key building blocks for the next generation of integrated photonic circuits. In this invited talk we will present a brief overview of our recent advances in this field.

2. Fiber-chip couplers

SWG metamaterial fiber-chip edge couplers, first demonstrated at the NRC Canada [1,5], are becoming the state-of-the-art solution for silicon photonics allowing coupling loss of -0.32 dB and negligible polarization dependence [9]. Barwicz et al. at IBM showed an SWG metamaterial coupler, optimized to interface cleaved SMF-28 fibers, for the O-, S-, and C- communication bands [8].

Surface grating couplers (SGCs) utilize a diffraction grating to couple the light between planar waveguides and optical fibers, allowing wafer-scale testing and relaxed alignment tolerances. We presented the first apodized surface grating couplers hybridized with subwavelength gratings [10], and a record sub-decibel efficiency of -0.7 dB for a single etch process [11]. An alternative way to achieve high-efficiency grating couplers is to increase the intrinsic directionality of the grating by using the blazing effect in an L-shaped geometry. This concept has also been implemented for 193 nm deep-UV lithography, yielding an efficiency of -2.7 dB [12]. A significant practical drawback of grating couplers is their limited spectral bandwidth (~35nm at 1dB). We have proposed a new design concept for highly-efficient and ultra-broadband operation, using the zeroth diffraction order in a prism-assisted configuration, which results in an unprecedented efficiency-bandwidth product: a coupling efficiency of -0.41 dB and a 1 dB bandwidth of 126 nm [13].

3. Dispersion engineered devices

We have leveraged the inherent anisotropy and dispersion of a sub-wavelength structured photonic metamaterial to demonstrate ultra-broadband integrated beam splitting [14-
Spectral filtering is an important functionality in integrated optics. However, the high index contrast of SOI makes it difficult to obtain the weak grating coupling coefficients required for narrow bandwidth Bragg gratings. Recently, SWG corrugated waveguides have been used to yield flexible design of the Bragg rejection and bandwidth [16]. We have demonstrated that integrated Bragg gratings with narrow rejection bandwidths on the order of ~100 pm can be designed using a conventional SWG waveguide core optically loaded with lateral silicon segments [17].

4. Conclusions

These recent advances open exciting prospects for development of a plethora of advanced silicon photonic devices, building upon the fundamental principle of subwavelength grating metamaterial waveguide engineering [7,18].

Abstract
Fiber drawing is used to realize extended and scalable metamaterials. Such metamaterials are used for light guidance and sub-resolution imaging. In this paper, the application of fiber drawn wire array metamaterials for far field imaging is reported. The scalability of the process allows fabrication of structures sized for frequencies between the THz and the IR.

1. Introduction
The ability to co-process different materials at the same time in a thermal process opens up the possibility of realizing metamaterials in large sizes and volumes. In particular, we have exploited the fiber drawing technique combined with the Taylor wire method to realize large volume metal-dielectric structures [1]. The structures produced are invariant in one direction and therefore lead to wire array and slotted cylinders array metamaterials. Such metamaterials are used for guiding radiation in hollow structures [1-3] and to realize hyperlenses for sub-resolution imaging [4-7]. The nature of the fiber drawing process allows us to easily scale the structures with features from hundreds of microns to hundreds of nanometers, allowing operation from the THz to the IR [8]. Moreover, by carefully choosing the dielectric, we are able to fabricate deformable structures allowing tunability of the metamaterial properties [9].

One of the most attractive applications of hyperbolic metamaterials is the ability to support sub-diffraction imaging [10-11]. The use of hyperbolic metamaterials for sub-diffraction imaging has been demonstrated in the microwave [12-14], terahertz [4, 15], infrared [16], and visible spectrum [17].

We present the use of wire array hyperlenses for imaging applications in the far field. Two configurations are used for reconstructing images: reflection and transmission. As imaging devices we use a 8X magnification hyperlens in the THz and show imaging to 1/13th of the wavelength. By cascading hyperlenses we demonstrate that this limit can be pushed further. We also show proof of principle of the scalability of the fabrication process to realize imaging in the Mid-IR with low magnification hyperlenses.

DNA Self-Assembled Plasmonic Nanoantennas

Mauricio Pilo-Pais

1Department of Physics, University of Fribourg, Fribourg, Switzerland
*corresponding author, E-mail: Mauricio.pilopais@unifr.ch

Abstract

DNA can be used as a tool to rationally assemble metallic nanoparticles (NPs) and single photon emitters (e.g. organic fluorophores and quantum dots) with a defined arrangement, nanometer spacing, and tunable plasmon resonance. These structures can be tailored to have unique optical properties. In this talk, I will discuss our assembly strategies to use DNA as a self-assembly tool to fabricate optical antennas that include a variety of hybrid nanocomponents such as a single QD positioned between two metallic NPs.

1. Introduction

DNA is a great tool to position optically active components with both, high accuracy and in a large parallel manner. DNA self-assembly has already been exploited to obtain custom-tuned hot spots for surface enhanced Raman and fluorescence spectroscopies [1], and to produce small mode volumes able to promote strong-coupling between plasmons and molecular excitons [2]. Recently, we have developed a facile approach to assemble plasmonic antennas that consist of two metallic nanoparticles (40 nm) with an individual colloidal quantum dot (e.g. CdSeS/ZnS) positioned at the hot spot.

2. Results

Using DNA complementarity, an individual QD is positioned at exactly the center between two metallic NPs [3]. The design approach of the QD-NP antennas is shown on Figure 1, and it is based on DNA complementarity, stoichiometry, and steric hindrance principles. The structures possess a small gap (~ 5 nm) which is desired to achieve high Purcell factors and plasmonic enhancement, since no intermediate molecules are used other than short DNA strands. The fluorescence emission from antennas assembled with spherical gold particles displays an increased in fluorescence up to ~30-fold, compared to quantum dots without antenna. Fluorescence lifetime measurements on the antennas show the lifetimes of the analyzed traces to be highly suppressed compared to individual QDs. The values obtained, following a deconvolution analysis, exhibit a mean lifetime of 0.065 ns, which are greatly below reported values of similar QDs [4] and as one would expect from Purcell enhancement due to the nearby AuNPs.

Figure 1: Example of DNA self-assembled nanoantenna. Here, an individual QD is positioned exactly between two metallic NPs. The large molar excess of the larger species and their disproportionate size difference prevents more than two NPs to be attached to an individual QD. The antennas display enhanced fluorescence in respect with individual QDs.
3. Conclusions

DNA is a pre-programmable material capable to self-assemble optical antennas. As an example, a simple strategy to build plasmonic antennas with a single QD located at the center of the gap with high yields using DNA-mediated self-assembly is presented. The functionality of these antennas is demonstrated by measuring the fluorescence enhancement of QDs up to ~30-fold as well as increased radiative rate. The fine tuning of this fabrication technique, which is based on steric hindrance and controlled stoichiometry of the species, permits the fulfillment of two important requirements: 1) a small gap combined with 2) a single QE at the center of a plasmonic cavity. This simple self-assembly approach is not only scalable (trillions of QD–antennas are produced in a few simple steps) but can be extended to any other plasmonic material and/or QE functionalized with DNA. Furthermore, these structures can be deposited and measured on different substrates.

Recent advances in phase-change materials for high-speed optoelectronics

Imad Agha\textsuperscript{1,2,*}

Abstract

By doping Ge\textsubscript{2}Sb\textsubscript{2}Te\textsubscript{5} phase change material with different metals, we produce material with improved electrical properties while simultaneously maintaining the optical contrast necessary for light modulation and switching. On the other hand, by nanopatterning the material into nanorod metamaterials, we can change its thermal response by orders of magnitude, paving the way towards ultrahigh-speed materials for reconfigurable photonic applications.

1. Introduction

Spatial light modulation is a critical component of modern free-space optical devices for communications [1] and beam steering, LIDAR [2], and others. Currently, most of the work relies on Liquid Crystal on-Silicon (LCoS) or micromechanical adaptive mirrors (MEMS) for achieving the necessary control of light. These two techniques, while viable, generally rely on non-scalable fabrication techniques and suffer from limited reconfiguration speeds due to the nature of the underlying mechanism of light control. Phase-change materials (PCMs), such as germanium-antimony-tellurium (GST) offer an alternate path for high-speed light modulation [3]. PCMs generally alter their optical constants via an electronic, optical, or thermal stimulus (even though ultimately the change is due to a thermal effect), leading to a phase transition between a low-index amorphous state (index = 4.0) and a high-index crystalline state (index = 5.5). For spatial light modulators, the core idea (Fig. 1) is to implement an electrically actuated device where the refractive index of each individual pixels can be independently addressed as to affect a 0-\(\pi\) phase control on the incoming wavefront. Unfortunately, due to the high-impedance nature of the amorphous state coupled with the high contact resistance with metallic electrodes, electrical actuation a) is relatively slow and b) cannot rely on off-the-shelf radio-frequency (RF) components due to the incompatibility with standard 50\(\Omega\) termination. Moreover, the slow nature of the thermal response requires new techniques for improving the speed of PCMs. In this work, we show a path both towards RF-compatible devides as well as towards high-speed PCM-based components.

2. Doping of GST

It is possible through doping the underlying GST thin film with various metals, to simultaneously improve electrical properties of GST while maintaining the necessary optical contrast for efficient light modulation devices [4]. The idea is similar to the standard doping methods for silicon that reduce its resistivity by orders of magnitude by generating excess holes or electrons in the material. We choose tungsten (W) as the alloy material since a) we expect a transition metal to improve the conductivity and consequently reduce the resistance, b) it can be used as an effective electrode for actuating the pixels, and c) it has a close atomic radius to tellurium and can act as a substitutional active dopant. GST thin films are fabricated via magnetron sputtering with an independent cathode for co-sputtering tungsten into the film allowing for independent control over the percentage of tungsten introduced into the GST alloy. Once the W-doped GST film is deposited with varying doping percentages (2 to 18\% [4], the electrical resistivity is measured using a four point probe technique as a function of temperature/phase (amorphous vs crystalline). Figure 1 shows that for pure GST, phase transition (near 160 \(^\circ\)C) is coupled with a large drop in resistivity, while, as tungsten is introduced, the electrical contrast between the two states is decreased, leading to a relatively low resistance value both in the amorphous and crystalline states of GST, as desired. The inset in Fig. 1 shows that even at the highest tungsten concentration, there is a strong transmission, indicating relatively low losses.

![Fig 1: Resistivity of W-doped GST-based PCM, showing a sharp decrease (reaching a point where both states offer the same resistance). Inset shows the transmission properties of both doped/undoped material.](image-url)
3. Nanopatterning of GST-based PCMs

While doping improves the electronic properties of the material, improving the speed requires a manipulation of the thermal properties of the material itself. This can be done by exploiting the scaling laws that govern thermal heating and dissipation: By employing a metamaterial approach, through which GST is grown into a nanorod geometry (Fig 2), the material can potentially absorb and dissipate heat a lot faster than the bulk thin film, due to the increased surface-to-volume ratio. In our experiments, we produce GST-nanorods via glancing-angle deposition, and employ conformal coating methods to provide both a high-dissipative thermal bath as well as structural stability to the nanorods.

Fig 2: GST-based nanorods grown via self-assembly

4 Single-pulse time dynamics and novel structures

In this set of experiments, we characterize the temporal dynamics and quantity of crystallization of Ge2Sb2Te5 (GST) utilizing a pump-probe technique. The amount of change in the material can be determined by the reflectivity measurement from the probe laser and the temporal dynamics can be gleaned from the resulting graph. In our results we see multiple levels of reflectivity indicating partial change of the GST. After a number of pulses (dictated by the power of each pulse), the reflectivity levels off indicating that the GST is fully changed up to the penetration depth of the laser. From the shape of the graph the cooling times as well as information about the mechanisms of the change can be inferred. This unique, single-pulse setup that operates in the low absorption regime allows us not only to better understand the temporal dynamics of GST-based PCMs, but also to create novel structures for light modulation (e.g. phase plates) with point-by-point phase control, as well as electronic structures (variable resistors) that can be implemented into a circuit post-fabrication (Fig. 3).

Fig 3: Variable resistor created via optical excitation of GST-PCMs between two tungsten electrodes

Abstract

The development of plasmonics has led to significant advancement in sensitive chemical and biological sensing and surface enhanced spectroscopies, which is urgent for real-time electrochemical detection in batteries. Alkali metals featured by ideal free electron gas models, have long been regarded as promising plasmonic materials but seldom been explored due to their high chemical reactivity. Here, we demonstrate our recent progresses in lithium metal plasmonics and in operando monitoring of lithium metal evolution during battery cycling.

1. Introduction

Plasmonics arising from collective oscillations of the free electron gas density, has been widely used for non-destructive, real-time and sensitive chemical and biological detection (1, 2). Alkali metals such as lithium and sodium with free electron gas behavior have long been theoretically predicted as promising plasmonic materials (3) but have seldom been explored, primarily due to their high chemical reactivity (4). The lithium metal battery, which features the highest specific capacity (3860 mAh g\(^{-1}\)) is regarded as the most promising candidate for next-generation energy storage devices (5). However, dendrite formation leads to limited cycle life and safety hazard, which calls for fundamental understanding, real-time monitoring and control of the electrochemical evolution of reactive lithium metals (6).

2. Plasmonic monitoring

Fig. 1 shows the plasmonic monitoring platform of lithium metal evolution by electrochemical reactions. There are two kinds of lithium morphology evolution, including lithium particle and lithium dendrite. We establish the relationship between the lithium metal morphology and optical spectrum by numerical calculations. For the normal lithium morphology (upper panel in Fig. 1B), there are at least two types of optical modes, the localized surface plasmon (LSP) related to the isolated lithium particles as well as Wood’s anomaly (WA) related to the periodic geometry. As depicted in Fig. 1C, the referenced reflectance spectrum of the Ag pattern (black solid line) shows a high intensity with unnoticeable plasmonic modes from 400 nm to 1600 nm. WA modes of Ag pattern is theoretically determined by the formula \(\lambda_{WA} = \frac{2\pi n \mu}{G_{n\mu}} (7)\). Note that the pronounced asymmetric profiles at \(\sim 800\) nm and \(1200\) nm can be ascribed to the hybridizations of the LSP and WA, with amplified LSP observed around \(WA_{1,0} \sim 1230\) nm and \(WA_{1,1} \sim 710\) nm. In contrast, the optical evolution of the abnormal dendrite formation is quite different (lower panel of Fig. 1C). The broadband anti-reflection (flat spectra) can be observed with drastically attenuated reflectance (< 10%), which stems from plasmonic light trapping by light scattering and coupling (8). This distinct difference of optical modes (instead of mere variation of intensity) between periodically controllable normal-lithium particles and random dendrites forms the basis of plasmonic monitoring of the morphological evolution of lithium metal during electrochemical cycling.

![Figure 1](image)

Figure 1: In operando plasmonic monitoring of lithium morphological evolution in battery. (A) Schematic of planar battery device and in operando reflectance spectra measurement. (B) Two pathways of lithium morphological evolution. (C) Simulated reflectance spectra.

To further demonstrate the relationship between the optical spectra and lithium morphology, we measured the reflectance spectra during the lithium deposition process (Fig. 2). Two representative electrical currents (I = 0.03 mA and 1mA) were applied to induce the two different evolution pathways: lithium particle growth and lithium dendrite formation, respectively. For the case I =0.03 mA, the in operando reflection spectra were measured as shown in Fig. 2A. At the initial time of deposition (t = 0 s), the measured spectrum was flat from 400 nm to 1600 nm (relative reflectance ~ 60%). During the process of electrochemical lithium deposition, the overall intensity of reflectance decreases gradually, and a clear dip at \(\sim 800\) nm was developed at t = 8 min. In addition, further deposition resulted in an additional dip at \(\sim 1200\) nm emerging at t = 18 min, which agrees with the tendency of the numerical model. The reflectance at 1225 nm in Fig. 2A was extracted and is plotted versus time after normalization in Fig. 2C, which demonstrates the relatively slow and gentle evolution
process during lithium particle growth. To further identify the ordered morphology of the lithium particles, we removed the current, disassembled the planar cell once the plasmonic modes (800 nm, 1200 nm) were identified, and examined the morphology under SEM, as illustrated in Fig. 2E and G, respectively. It is confirmed that lithium tends to nucleate as discrete nanoparticles on silver triangles and that the average size is ~ 190 nm and 370 nm, as suggested in Fig. 1B. Similar in operando optical measurements of lithium dendrite formation were performed with I = 1 mA. The measured reflectance spectrum remains flat in the range of 400 - 1600 nm. In addition, the reflectance decreased drastically to ~ 10% at t = 5 s and remained stable (~ 5%) after t = 45 s (Fig. 2B). To study the drastic transition, in operando spectra in a narrower wavelength range (1100 - 1300 nm) were measured. Compared with that of ordered particles, the evolution of normalized reflectance at 1225 nm of lithium dendrites over time is plotted in Fig. 2D, which indicates the rapid dendrite growth process and is notably different from Fig. 2B. The SEM images of the evolved dendrites at t = 5 s and 85 s are presented in Fig. 2F and H, respectively, resembling the main features predicted in Fig. 1. To further address the necessity of periodic Ag pattern as electrodes, we performed the same in-situ reflection measurements during lithium deposition with two substrates without periodic Ag pattern (bare W and random Ag/W substrate). Because of the random deposition-sites dominated features, both cases possess almost flat spectra and similar intensity evolution profiles for both normal and abnormal lithium states, making them difficult for fast identification during operando monitoring.

Figure 2: In operando characterization of different pathways of lithium evolution. (A, B) In operando optical reflectance monitoring of the two representative lithium evolution pathways over time during electrochemical lithium deposition: (A) growth of patterned lithium hemispheres and (B) formation of random dendrites. (C, D) Evolution of normalized reflectance at the wavelength of 1225 nm. (E, G) Typical SEM images of lithium morphologies indicating the two essential plasmonic modes λp observed at (E) λp ~ 800 nm and (G) λp ~ 1200 nm. (F, H) SEM images of lithium dendrite morphology at the beginning and end of lithium deposition, respectively.

3. Conclusions

The relationships between the evolving morphologies of lithium metal and in operando optical spectra are established both numerically and experimentally: ordered growth of lithium particles shows clear size-dependent reflective dips due to hybrid surface plasmon resonances, while the formation of undesirable disordered lithium dendrites exhibits a flat spectroscopic profile with pure suppression in reflection intensity. Under the in operando plasmonic monitoring enabled by the microscopic morphology of metal, the differences of lithium evolutionary behaviors with different electrolytes can be conveniently identified without destruction. At the intersection of energy storage and plasmonics, it is expected that the ability to actively control and in operando plasmonically monitor electrochemical evolution of lithium metal can provide a promising platform for investigating lithium metal behavior during electrochemical cycling under various working conditions.

3D Porous Silicon Gradient Refractive Index Micro-Optics and Waveguides

Paul V. Braun¹*

¹University of Illinois at Urbana-Champaign
*corresponding author, E-mail: pbraun@illinois.edu

Abstract

Via electrochemical etching of silicon, various nanophotonic elements, including flat lenses, photonic nanojet generators, Bragg mirrors, polarization sensitive optical splitters and structures with nearly arbitrary refractive index distributions were formed. The conversion from silicon to silica and titania enabled the optics to operate in the visible with minimal loss, something particularly important for visible light applications. A detailed model was developed which enabled tight control over optical properties based only on the electrochemical etch conditions.

1. Introduction

Porous silicon (PSi) exhibits structural birefringence originating from its geometrically anisotropic internal mesostructure.[1–5] Other examples of structurally birefringent optical materials composed of asymmetric subwavelength structures include porous alumina membranes, porous glass fibers, porous glasses, and doped glasses.[6–10] In PSi, it has been shown that the magnitude of the birefringence can be engineered across a broad range by controlling the etching conditions, and is larger than is found in any intrinsically birefringent crystal.[1,3–5] In this work, we use PSi’s tunable optical anisotropy and other patterning approaches to engineer novel birefringent gradient refractive index (GRIN) micro-optics where lensing behavior is governed by the material’s refractive index-dependent birefringence profiles. This builds off our previous work where we reported that square PSi GRIN posts bifurcate an illuminating beam into two focal regions when light is polarized along PSi’s optic axis (TE illumination), and converge an orthogonally polarized illuminating beam (TM illumination) into a single focal region.[10]

2. Results

We suggest that a versatile approach to 3D GRIN elements is to use a defined Si topography to serve as the starting point for the lateral etch required to form a GRIN profile. Now, a time-varying current density generates the GRIN along the PSi etch pathway that initiates at all unmasked Si/electrolyte interfaces (Figure 1a). Our process begins with a p+-type Si wafer doped to form a shallow (~100 nm) n-type surface. Photolithography, followed by deep reactive ion etching, generates an array of microscale elements (e.g., square micro-columns (SMCs)) with less than 10 nm roughness sidewalls across the wafer (Figure 1b). Electrochemical etching (Figure 1a) simultaneously converts all of the elements to PSi in a few minutes. The n-type cap restricts PSi formation to the sidewalls, resulting in an etch path and GRIN profile that runs inward from and perpendicular to each of the SMC sidewalls (Figure 1c). Changes in the current density, whether discrete or continuous, provide nearly arbitrary and highly reproducible control over the refractive index and porosity of PSi (Figure 1d).

Figure 1. Shape-defined electrochemical etching of PSi for GRIN micro-optics. (a) Schematic outlining the process by which p-type Si SMCs with n-type caps undergo shape-defined electrochemical etching to endow them with nanoscale porosity that defines the local refractive index. (b) SEM image of a section of an array of Si SMCs subjected to shape-defined PSi formation. (c) SEM cross-section of an etched feature showing how PSi formation proceeds beneath the n-type cap. (Inset) SEM cross-section of a fully porous ridge, showing that shape-defined etching can proceed through the Si microstructures. (d) Reflection-
mode optical micrograph from the top of an \( \approx 18 \, \mu m \) PSi SMC with an arbitrary GRIN that can be observed through the structure’s n-type Si cap. The GRIN profile along the dashed red line is superimposed on top of the optical image.

3. Discussion

Using PSi as a host, we fabricate a range of optical elements including waveguides, lenses, compound lenses, and polarization sensitive beam splitters. As just one example, starting from shaped silicon features on a wafer, we use the shape-defined electrochemical formation of PSi to form polarization splitters and an element which possesses a linear GRIN that is capable of focusing TM light to a diffraction-limited line, while TE light is directed to two high-intensity regions in roughly the same plane as, but laterally displaced to either side of, the TM focus. The optical physics of these structures is readily predictable, while the flexibility of the fabrication process lends itself to scaling to dimensions on the order of \( 100 – 200 \, \mu m \) if appropriate measures are taken to promote uniformity (e.g., electrolyte stirring and etching breaks) of the electrochemical etch.

4. Conclusions

The optical response of PSi-based GRIN elements is controlled by engineering its refractive index and birefringence profile. PSi’s programmable optical properties were incorporated into the design of polarization independent and dependent optics that perform a range of functions based on the magnitude of the birefringence profile. The results shown in this work point to the possibility of designing novel GRIN optics from PSi.

Local Symmetries in Wave Mechanics: From Fundamentals to First Applications

Peter Schmelcher

Zentrum für Optische Quantentechnologien, Universität Hamburg

Abstract
The concept of local symmetries which hold only in spatially limited domains is developed. Decomposing space into domains where different local symmetries hold a novel layer of complexity is derived. This way the parity and Bloch theorems are generalized to the case of broken global symmetry [1]. Local inversion or translation symmetries are shown to yield invariant currents that characterize wave propagation. These currents map the wave function from an arbitrary spatial domain to any symmetry-related domain. Nonvanishing values of the invariant currents provide a systematic pathway to the breaking of discrete global symmetries [1]. Some examples of applications are provided. A classification of perfectly transmitting resonances in completely locally symmetric scattering setups [2] allows for the design of the scattering behaviour in these non-periodic setups. The emergence and control of flatbands in corresponding discrete quasi 1D setups based on local symmetries are discussed [3]. Local symmetries also allow for the real space design of edge states in aperiodic chains [4]. A generalization to interacting many-body systems is outlined [5].

Abstract

We make use of integrated frequency combs to generate on-chip heralded single photons, cross-polarized photon pairs, as well as two- and multiphoton time-bin entangled states and high-dimensional frequency entangled states.

1. Introduction

Sources of entangled photon-pairs are key building blocks towards applications in quantum information processing [1], quantum communications [2], as well as imaging and sensing with resolutions exceeding the classical limit [3]. The realization of, e.g. polarization, time- and frequency-bin entangled photon-pairs has been demonstrated using spontaneous parametric down-conversion (SPDC) in nonlinear second-order media, as well as spontaneous four-wave mixing (SFWM) in third-order nonlinear media. Specifically, nonlinear (third-order) interactions in on-chip microring resonators have been exploited to achieve classical frequency combs, mode-lock lasers, signal processing, etc [4-6]. Integrated photonics can also find applications for quantum state generation in compact, scalable and efficient devices, required for future optical quantum circuits. In contrast to waveguides, microring resonators with narrow resonances and high Q-factors, offer an improvement in photon-pair generation efficiency, as well as a narrow photon-pair bandwidth, making them compatible with quantum optical devices [7,8]. Most importantly, in contrast to non-resonant waveguides, where individual photon-pairs, featuring one signal/idler frequency pair, are generally created, resonant nonlinear cavities (e.g., microring resonators) enable the generation of correlated photon-pairs on multiple signal/idler frequency channels [9], due to their periodic and equidistant resonance structure.

Here, we investigate different approaches to generate optical quantum states by means of integrated frequency combs. These include the realization of multiplexed heralded single-photons [9] and cross-polarized photon-pairs on a photonic chip [10], as well as the first on-chip generation of two- and multi-photon time-bin entangled states [11], and, finally, the first realization of high-dimensional frequency-entangled photon pairs on-chip and their coherent control [12].

2. Methods and Results

The quantum frequency combs were realized by using a 4-port integrated microring resonator with a 200 GHz free spectral range (FSR), fabricated in a CMOS-compatible high refractive index silica glass [13] and excited with a pulsed mode-locked fiber laser. The high field enhancement and nonlinearity of the resonator allowed generating photon-pairs through SFWM on several frequency channels (corresponding to the ring resonances) symmetrically located with respect to the pump frequency [9]. Depending on the targeted application, different excitation schemes were used. If the pump spectral bandwidth was chosen to be larger than the resonator bandwidth, the laser was spectrally-filtered to excite either a single or multiple resonances. The coupling into the resonator then further spectrally filtered the pump to perfectly match its bandwidth. This configuration enabled the generation of pure single frequency-mode photons [11]. Coincidence detections were used to characterize the photon coincidence statistics as well as their temporal duration. The (heralded) second-order coherence of the emitted photons were measured by using a Hanbury Brown and Twiss setup. In order to create time-bin entangled photons, an unbalanced, fiber-based phase-stabilized Michelson interferometer generating double
pulses was used before the chip. If the pump power was then set to generate no more than one photon-pair per double pulse on average, the photon-pairs were created in a coherent superposition of two discrete time-bins, thus forming an entangled state [11]. To verify entanglement through quantum interference measurement, we added interferometers having a path length difference matched to the first interferometer (see Figure 1). Using coincidence detection, this setup enabled to measure quantum interference and perform full quantum state tomography, which characterize the entangled photon-pairs and multi-photon states. In order to generate high dimensional entangled states, we excited a single resonance of the resonator with a spectrally-filtered mode-locked laser [12]. Due to the broad phase-matching condition, the generated photon pairs cover multiple resonances. Furthermore, the photons are intrinsically created as a high-dimensional superposition of resonance frequency mode states, and are entangled due to SFWM energy conservation. The frequency-entangled photon pairs were coherently controlled via fiber-based electro-optic modulation techniques allowing to perform quantum state tomography and quantum interference measurements [12].

By simultaneously exciting two orthogonal-polarization mode resonances, we introduced a new type of SFWM to the toolbox of integrated photonics [10]. In particular, we demonstrated the first realization of type-II SFWM that allows to directly generate orthogonally-polarized photon-pairs on a chip [10]. We measured photon coincidences, and also drive the system to optical parametric oscillation, generating orthogonally-polarized beams. Using double pulse excitation, we demonstrated time-bin entangled photon-pairs over the entire frequency comb spectrum [11]. We measured the violation of a Bell-like inequality through quantum interference [14] reaching a visibility of 82.4% which is higher than the 71% threshold. Performing quantum state tomography [15], we confirmed qubit entanglement with 94% fidelity, enabling the implementation of quantum information processing protocols. We repeated tomography measurements after 40 km of fiber propagation, and confirmed that the quantum states are well preserved during propagation (a 64% fidelity). This opens up possible implementations in quantum communications applications.

Finally, we achieved the generation of high-dimensional frequency-entangled photon pairs with up to 10 dimension per photon [12]. We validated the dimensionality of the generated states using the Schmidt number, while their entanglement was validated via quantum interference measurements that showed Bell inequalities violation for dimensionality D=2,3, and 4, as well as via quantum state tomography for the same dimensionalities that provided high fidelities (exceeding 80%) [12].

3. Conclusion

We demonstrate the realization of different optical quantum states by means of integrated optical frequency comb sources. Our results indicate the strong potential to use on-chip frequency combs to generate both heralded single photons, two and multi-photon time-bin entangled states, as well as high-dimensional frequency-entangled photon pairs.

Diamond nano-optomechanical devices

Paul Barclay\textsuperscript{1}

\textsuperscript{1}Department of Physics and Astronomy, University of Calgary, Canada
\textsuperscript{*}corresponding author, E-mail: pbarclay@ucalgary.ca

Abstract
Using a novel quasi-isotropic etching process we have created a range of diamond optomechanical devices. These include high-Q microdisk resonators operating in the sideband resolved regime that can be used for optical information processing applications such as pulse storage, wavelength conversion, and multi-colour optical interference.

1. Introduction
Nanoscale cavity optomechanical devices enhance the interaction between co-localized optical cavity modes and nanomechanical resonances. For sufficiently strong optical confinement and field strengths, and appropriate nanophotonic device design, it is possible to realize large optomechanical coupling rates between light and the mechanical motion of the resonator in these devices. When combined with low optical and mechanical loss rates, coherent optical control of mechanical motion can be realized, enabling fundamental studies and new technologies ranging from quantum information processing to sensing.

2. Diamond optomechanics
Realizing optomechanical devices from diamond is of particular interest owing to its exceptional material properties together with its ability to host high quality spin qubits. Diamond optomechanical devices have low optical and mechanical dissipation and can support high optical intensity thanks to the material’s large electronic bandgap, and correspondingly low multi-photon absorption at telecommunication wavelengths. This latter point allows diamond optical cavities to support large numbers of photons before their optical properties degrade, a major benefit for many optomechanics applications.

Until recently, realizing diamond optical devices have been an outstanding challenge. We have invented a new fabrication process that solves this problem and have used it to create a variety of diamond devices, including microdisk cavities [1,2] and nanobeam waveguides [3]. In our most recent work [4], we have harnessed the high optomechanical performance of these devices for several optical information processing applications. In this talk we will show data demonstrating coherent transfer of a pulse of light to the mechanical motion of a diamond microdisk cavity optomechanical device. This pulse storage scheme allows microsecond long optical delays that are optically tunable, as well as wideband wavelength conversion in which the pulse is readout at a wavelength 40 nm detuned from the input pulse. We will also present a novel form of multicolor interferometer, where the optomechanical device mediates interference between widely separated wavelengths of light, allowing construction of a two colour optical switch.

Balancing the photo-budget in far-field optical imaging for enhanced lateral resolution

Wyatt Adams, Chito Kendrick, Christopher T. Middlebrook, and Durdu Ö. Güney*

Department of Electrical and Computer Engineering, Michigan Technological University, Houghton, MI, USA
*corresponding author, E-mail: dguney@mtu.edu

Abstract

Owing to the semiclassical process of photodetection, the resolution of optical imaging systems is often limited by shot noise. Here we present a theory to improve the shot noise limit in incoherent imaging and experimentally show its validity with a low numerical aperture system. The same principles can also improve the performance of near-field sub-diffraction-limited imaging via hyperbolic metamaterials.

1. Introduction

While the diffraction limit is often identified as the barrier to image resolution in the far-field, optical systems can also be limited by the statistics of detecting photons. Since photodetection can be modeled as a Poisson impulse process [1], it is shown in this summary (and independently in other recent works [2, 3]) that the shot noise variance in the Fourier spectrum of an image is given by the total number of expected photons in the image. It follows that decreasing the number of photons decreases the variance, but it will also decrease the signal proportionally.

To achieve an improvement in resolution, we show that the image “photo-budget” can be better balanced by preferentially transferring the high spatial frequency photons to the image, and then deconvolving the resulting image to eliminate the induced low spatial frequency blurring. The result is improved lateral resolution.

2. Theory

The process of incoherent optical imaging is readily modeled by a two-dimensional convolution operation

\[ I(r) = H(r) \ast O(r), \]

where \( I(r), O(r) \in \mathbb{R}_{\geq 0} \) are photon flux densities (photons/s \cdot m^2) and \( H(r) \in \mathbb{R}_{\geq 0} \) is the point spread function (PSF) of the optical system. At the detector, an array of rectangular pixels of size \( \Delta x \) by \( \Delta y \) collect the photons contained in the continuous signal \( I(r) \), giving a discrete output signal at pixel \( p \)

\[ \bar{I}_p = \eta T \int_{A_p} I(r) d^2r \]

\[ = \eta T \int_{y_p-\Delta y/2}^{y_p+\Delta y/2} \int_{x_p-\Delta x/2}^{x_p+\Delta x/2} I(x, y) dx dy, \]  

where \( \eta \) is the pixel efficiency, \( T \) is the exposure time, and \((x_p, y_p) = r_p \) is the center location of pixel \( p \).

Since the pixels absorb light in discrete packets (photons), the signal will have a Poissonian probability mass function. Also, there is noise added by the electronics reading out the signal. Therefore, the observed signal at pixel \( p \) becomes

\[ I_p = \bar{I}_p + N_{p,\gamma} + N_{p,e}, \]  

where \( N_{p,\gamma} \) is the photon (shot) noise and \( N_{p,e} \) is an electronic noise term independent of the input light signal. In many cases, \( \text{Var}(N_{p,\gamma}) \gg \text{Var}(N_{p,e}) \) and we can neglect the third term. We can find the variance of the photon noise in the Fourier domain by

\[ \text{Var}(\tilde{N}_{q,\gamma}) = \text{Var} \left( \sum_p N_{p,\gamma} e^{-i2\pi k_q \cdot r_p} \right) \]

\[ = \sum_p \text{Var}(N_{p,\gamma}) | e^{-i2\pi k_q \cdot r_p} |^2 \]  

\[ = \sum_p \bar{I}_p = n_\gamma, \]

where \( k_q \) is the location of pixel \( q \) in the Fourier space corresponding to \( \{r_p\} \), and \( n_\gamma \) is the total number of expected photons in the entire image. From this simple result, it becomes apparent that reducing the number of photons in the image will reduce the noise level distributed throughout the Fourier space.

Consider a 4f system with a Fourier plane pupil function such as in Figure 1(b) described by

\[ \tilde{P}_q = \begin{cases} 
1 & \text{if } k_- \leq |k_q| \leq k_+ \\
0 & \text{otherwise},
\end{cases} \]

where \( k_0 = 1/\lambda_0 \), \( \lambda_0 \) is the free space center wavelength, \( k = 2NAk_0 \), \( NA \) is the numerical aperture, and \( k_- < k_+ \leq k \). For an incoherent imaging system, the optical transfer function (OTF) \( \tilde{H}_q \) obeys

\[ \tilde{H}_q = \sum_k \tilde{P}_q \tilde{P}^*_q = \tilde{P}_q \star \tilde{P}_q, \]

with \( \star \) denoting the autocorrelation. The spectral SNR for an image formed by the 4f system then becomes

\[ \text{SNR}_q = \frac{|	ilde{I}_q|}{\sqrt{\text{Var}(\tilde{I}_q)}} = \left[ \frac{\tilde{P}_q \star \tilde{P}_q}{\sqrt{\text{Var}(\tilde{I}_q)}} \right]. \]
Figure 1: (a) Open and (b) annular pupil functions. (c) OTFs of the pupils in (a) and (b). The dashed lines show 10% noise levels corresponding to each OTF, and the red circles indicate the corresponding noise resolution limits. The annular pupil resolution limit exceeds that of the open pupil.

From Equation (7), the argument can clearly be made that \( \tilde{P}_q \) gives us control over the SNR by way of both the numerator and denominator. In Figure 1(c), it can be seen that the noise resolution limit for the annular pupil is greater than that of the open pupil.

3. Results

We performed an experiment in which a USAF-1951 resolution target (Thorlabs R1DS1N) is illuminated with an incoherent light source (Thorlabs LIU525B) and imaged by a 4f system consisting of two achromatic-doublet lenses (Space Optics Research Labs) and a custom printed pupil transparency in the Fourier plane. The images were collected with an inexpensive CMOS camera (Thorlabs DCC1645C) and post-processed in MATLAB. Figure 2 shows the collected images with two different pupil transparencies. In (a), the pupil is a 10mm diameter opening, while (b) is the image with annular pupil with obstruction diameter 10mm/\( \sqrt{2} \).

In Figure 2(a), it can be seen that the line visibility in element 4 is poor, and disappears completely in element 5. However, in (b) the lines remain qualitatively visible until element 6. The image quality is further improved by Richardson-Lucy deconvolution in part (d), where the blurring introduced in the lower spatial frequencies are partially corrected.

4. Conclusion

We presented a theory for pushing the lateral resolution of optical imaging systems beyond the shot noise limit. The theory was experimentally implemented using a 4f system with a pupil transparency in the Fourier plane, showing improved resolution when the Fourier plane pupil preferentially transfers spatial frequencies near the diffraction limit, compared to an open pupil of the same numerical aperture. This idea is a far-field extension of our previous works in near-field superresolution imaging with hyperbolic metamaterials [4, 5].

Abstract

We report the generation and characterization of non-classical photon states in the 2-micron spectral region, paving the way to low-loss free-space and guided wave quantum communication in the 2-micron window.

1. Introduction

The spectral region just above 2 µm is attractive for several applications, spanning from sensing to communication. Due to the difficulty in source and detector development, the 2 µm technology lags behind that in the telecom region. Daylight quantum communication has been recently demonstrated at telecom wavelengths [1] and could be further enhanced by moving to a region with a lower solar background. Roughly between 2 and 2.5 µm the atmosphere is transparent, and the solar background is nearly half of that at telecom wavelengths. This makes it extremely relevant for free-space communications and becomes crucial for satellite-to-ground, and satellite-to-satellite quantum-secured communications [1], [2].
The 2 µm region is also relevant for classical guided wave communications, as it may give new breadth to fiber-based links avoiding bandwidth saturation. Efforts to develop low-losses and large bandwidth fibers in this spectral region have already produced remarkable results, e.g., in the form of photonic bandgap fibers [3]. Similarly, from an integrated optics viewpoint, silicon germanium waveguides have recently shown to reach 10 Gb/s [4], [5].

Stimulated by the situation detailed above, we have investigated the generation of non-classical photon states at 2.080 µm and we report the characterization of a correlated photon pair source.

We have characterized the photon pair source quality in terms of the coincidence to accidental ratio (CAR) and also demonstrated the photon pair indistinguishability with a Hong-Ou-Mandel (HOM) measurement.

2. The experiment

We generated photon pairs from spontaneous parametric down-conversion of a 1040 nm pulsed laser radiation delivered by a Chromacity Spark 1040 Ytterbium laser system. The mode-locked laser had a repetition rate of 80 MHz, a pulse duration of 120 fs and a maximum average power of 3 W. The nonlinear process was excited in a periodically poled MgO doped lithium niobate crystal specially designed for the experiment and realized by Covesion Ltd. The chosen crystal had a 31.24 µm poling period and was operated in a Type-0 configuration. The crystal was temperature-controlled with a 0.1°C accuracy and operated at 39.5°C so that the phase matching is optimal for collinear generation of the 2.080 µm photon pairs. Signal and idler photons were separated with a D-shaped mirror in the spatial far-field of the emission and then coupled into single-mode SM2000 fibers by achromatic collimators. The experimental set up is sketched in Fig.1.

To remove the residual pump field, two filters were used. The first is a long-pass filter, with a cut-off at 1450 nm and the second is an antireflection coated 1 mm thick germanium window, which has a high rejection for radiation at a

Figure 1: Experimental setup for the Hong-Ou-Mandel interference measurement. The coincidence measurements were performed connecting the fibers directly to the detector without a fiber beam splitter.
wavelength shorter than 1.850 µm. In addition, bandpass filters centered at the degenerate wavelength with 50 nm or 10 nm bandwidth were employed to select the portion of the generated spectrum relevant to the experiment.

We first characterized the photon pair generation efficiency and the losses of the components in the experiment, observing an efficiency of up to \( \eta = 10^{-10} \) in a regime where ~50 photon pairs were generated each laser pulse. To perform the characterization of properties of photon pairs we employed superconducting nanowire single-photon detectors (SNSPD), with a recorded quantum efficiency of \( \sim 10^{-2} \). The overall losses from generation to the detectors was estimated to approx. 12 dB (excluding detection efficiency). The coincidences were recorded using a time-to-digital converter (HydraHarp 400). An example of a histogram of the coincidences obtained using a 30 minutes long measurement is shown in Fig. 2 (a).

3. Discussion

The coincidence histogram shown in Fig. 2(a) is characterized by a peak in the coincidence counts for zero delay, which means signal and idler photons were created in a time-correlated fashion. Peaks with less counts can be noticed at larger delays, which correspond to coincidences between unrelated laser pulses, and which are therefore defined as accidental. To quantify the photon pair production rate, we determined the coincidence to accidental ratio (CAR). We measured the CAR as a function of increasing pump power (corresponding to increasing single-photon counts per channel) as shown in Fig. 2 (b). The maximum CAR is achieved for a pump power of 6 mW. The CAR could be further increase with better detector quantum efficiencies and lower losses.

Finally, we observed the interference of photon pairs in a HOM scheme, with visibility of \( >72\% \) (without background correction), thus demonstrating the indistinguishability of the two photons.

4. Conclusions

In conclusion, we demonstrated the generation and detection of 2.080 µm photon pairs with a maximum CAR of ~160 in the photon-starved regime. With the improvement of the detector technology at longer wavelengths, down-conversion systems based on MgO:PPLN driven by mW-level Ytterbium lasers can become a practical source of correlated and entangled photon pairs. These sources will be ideal for daylight free-space quantum key distribution in a spectral region with high atmospheric transparency and low solar background. The experimental setup for measuring the photon interference giving rise to the Hong-Ou-Mandel effect is shown in Fig. 1.

Abstract

We discuss the properties of ultrafast nonlinear hybrid devices on a silicon-photonic platform. Nanoscale resonators made of III-V alloys are used as all-optical gates. As an example we have considered this technology for on-chip optical sampling of signals up to 40 GHz. Due to their ultrafast dynamics, high non-linearity and low footprint, these nanoswitches can easily be combined to build complex photonic circuits, e.g. for advanced photonic computing.

1. Introduction

Due to light-matter interaction, light is a mean to perform a variety of measurements and physical characterizations in numerous fields, leading to breakthroughs in domains like sensing, communication and defense over the last decades. In particular it is possible to use the properties of light to perform calculations and signal processing, by using as an example optical correlation [1], or more recently for deep learning via optical neural networks [2].

As it comes to signal processing, photonics is a key component for high-rate operation for it provides low-time-jitter sources [3], overcoming electronic analog-to-digital converters (ADCs) bottleneck [4]. Indeed, a low time jitter improves both the speed and resolution, enabling to implement high performance ADCs. This has first led to photonic-assisted ADCs where e.g. a low-time-jitter optical pulse train (the clock) is modulated by an RF input (signal to be sampled) before being digitized [4]. Some integrated systems in silicon photonics were demonstrated [4,5].

Now, to exploit the properties of light even further, high performance ADC can also be performed through all-optical sampling, with both optical clock and optical input analog signal. These all-optical switches, or all-optical gates (AOGs), would allow to process optical signals without optical-to-electrical (O/E) conversion before sampling, while benefiting from high performance photonic clocks. The main types of AOGs are shown in the graph Fig. 1, where they are compared according to the figure of merit ‘speed vs. energy’. It can be seen that photonic crystals (PhC) are highly suitable to maximize this figure of merit, using for example PhC Fano cavity to maximize the transmission contrast [6].

During my presentation, I will present our nonlinear AOGs using III-V PhC cavities on silicon, and show some possible all-optical signal processing applications such as all-optical sampling and neuromorphic computing.

2. All-optical gate using III-V-on-silicon photonic crystal nanocavities

2.1. All-optical gate based on a resonator

The working principle of an AOG based on a resonator works as illustrated in Fig. 2.

The system consists of a semiconductor optical resonator next to a waveguide, which carries the signal to be sampled as well as the clock. The resonator is designed so that the wavelength of the signal $\lambda_s$ corresponds to a resonant mode of the cavity. The sampling function is obtained as follows: the resonant-enhanced absorption of a clock pulse by the cavity excites free carriers, which induce a spectral shift of the resonances of the cavity towards the blue, leading to an increased transmission of the signal.
2.2. Use of III-V-on-silicon PhC nanocavities

As optical cavity we chose to use III-V PhC nanocavities, whose high quality factor and small modal volume lead to high field enhancement and thus strong nonlinearity. Moreover, using III-V alloys allows to benefit from a wide variety of materials in order to tune the interesting properties such as the absorption, the carriers dynamics, and the nonlinearity [7,8]. III-V materials are also integrable in silicon photonics due to numerous wafer-bonding techniques.

For our work we designed and fabricated InP 1D cavities called nanobeams which are shown in Fig. 3(a), with surface InGaAs quantum wells to accelerate the carriers dynamics. More details will be given about the design and fabrication process during the presentation. The nonlinear dynamics can be characterized by pump-probe measurements from which we determine the spectral shift of the probed resonance, and the recovery time of the nonlinear effect. As shown in Fig. 3(b), this measurement allows to estimate the dynamic contrast of the gate, which is the transmission contrast between 1- and 0-samples, here 10 dB.

3. All-optical processing applications

3.1. All-optical sampling

The AOGs we fabricated (shown in Fig. 3(a)) were designed to perform all-optical sampling, whose general principle is recalled in Fig. 4. We assessed the sampling capacity of the AOG by sampling and reconstructing a known optical analog signal, as it will be explained in more details in the presentation. By comparing the sampled signal and the ideal input signal, we derive the signal-to-noise ratio (SNR) and the corresponding Effective Number of Bits (ENOB). With our InP nanobeams we achieved the all-optical sampling of an optical signal modulated at nearly 40 GHz at a 2 GS/s sampling rate, with a SNR of 15 dB (i.e. 2.4 ENOB), with a power budget of 1mW [9]. These results are preliminary, the performance will be improved with the future integration of the photonic sampling circuit, in particular in order to increase the sampling rate via time interleaving, about which I will show some dedicated photonic circuits, being studied at present.

3.2. Neuromorphic photonic computing

To follow the massive data increase of the recent years, new computing paradigms have to be introduced, such as non-Von-Neumann architectures to overcome the processor-memory bottleneck. Amongst others, optical deep learning circuits mimicking the brain have been implemented using artificial neural networks [2]. Such all-optical implementations need a nonlinear activation function, e.g. the function of the Fano AOG in [6], and we believe that our integrated nonlinear III-V PhC-based AOGs are also completely suitable to fulfill this function, and that they can easily be integrated and inserted in a silicon photonic neuromorphic circuit.

4. Conclusion

We have demonstrated and presented integrable energy-efficient AOGs based on III-V-on-silicon nanophotonics by using small-footprint PhC cavities, through which all-optical sampling was performed. More generally, these optical gates are relevant for scalable integrated architectures combining both linear and nonlinear features, benefiting from their low footprint and femtoJoule operation energy.

Abstract

We report the on-chip generation of hyper-entangled states in the time-frequency domain and their transformation in high-dimensional cluster states via deterministic controlled phase gates. We characterized these states developing a universal technique for deriving “experimentally friendly” entanglement witness operators.

1. Introduction

Polarization-entangled photon pairs have been the workhorse for quantum optical experiments for many years. More recently, however, there has been a growing interest in the generation of more complex quantum states of light. These ranged from states with increased dimensionality, both in the continuous and discrete variable regimes (for e.g. increasing the amount of information carried by a single photon), to the increased number of parties (multipartite states), to a combination of both. Among these complex states, cluster states [1] have gained particular attention as they represent a universal resource for a type of measurement-based quantum computation, i.e. one-way quantum computing [2]. Cluster states are multipartite entangled states characterized by maximal connectedness (any two parties of the system can be projected into a maximally entangled state through measurements on the remaining parties), as well as by the highest persistency of entanglement (compared to other entangled systems, they require a maximal number of projection measurements to fully destroy entanglement in the system). While discrete two-level (i.e. qubit) cluster states have been realized so far, increasing the number of particles to boost the computational resource comes at the price of significantly reduced coherence time and detection rates, as well as increased sensitivity to noise, thus restricting the realization of discrete cluster states to a record of eight qubits [3]. Increasing the dimensionality of the states (from qubit of qudit) by entangling the parties over high-dimensional variables, rather than increasing the number of particles, has the potential to address several limitations of qubit cluster states. First, the quantum resource can be increased without modifying the number of particles; second, d-level quantum states enable the implementation of highly efficient computational protocols; and third, higher dimensions reduce the noise sensitivity of the cluster states. However, so far, the realization of discrete cluster states (i.e. using discrete variables) have been restricted to two-dimensional states. Here we demonstrate the realization of d-level cluster states and we perform d-level one-way quantum processing operations [4].

Similarly to the difficulty of generating discrete d-level quantum states, their characterization also presents some challenges. Indeed, with increasing dimensionality and number of parties the experimental measurements necessary to fully characterize these states increase exponentially. We
therefore developed a compact and universal method for deriving customized entanglement witness operators given different realistic experimental restrictions. By reducing the operator selectivity, it is possible to largely reduce the measurements necessary for identifying a specific entangled state [5].

2. Results

In order to achieve a high-dimensional cluster state without increasing the number of photons we exploit hyperentanglement, i.e. the simultaneous entanglement over independent degrees of freedom. We consider the spontaneous four-wave mixing process occurring in a nonlinear microring resonator pumped by multiple pulses (three in this case) for generating the entangled photons (Fig. 1). The resonance structure of the microcavity allows to achieve frequency-bin entanglement, while the multiple pump pulses generate time-bin entanglement. Provided the pulse repetition rate is much lower than the cavity free spectral range, i.e. the time-frequency product is much larger than 1, time and frequency can be considered as independent despite being non-commuting observables. This allowed us to access the individual state terms and thus transforming a high-dimensional hyper-entangled state (3-dimensional in both time and frequency) in a three-level four-partite cluster state, via a specifically-developed deterministic phase gate. A fiber Bragg grating array, placed in a self-referenced and phase-stable loop configuration, generated a frequency-to-time mapping where the state terms could be individually accessed with a phase modulator (see Figure 1a). By choosing the appropriate phase pattern, the bi-separable hyper-entangled state was transformed into a three-level four-partite cluster state.

In order to characterize the obtained high-dimensional cluster state we exploit the stabilizer formalism [6,7] to derive an experimentally-friendly witness operator for N-partite d-level cluster states that consists of only two measurement settings. Specifically, of the all stabilizers necessary to describe the ideal entanglement witness, we only considered the ones that can be measured with two measurement settings, while we substitute the difficult to measure stabilizers with their maximum eigenvalue. This results in a less selective witness operator, yet easier to measure. Through projection measurements in the time/frequency framework [8,9], we measured a witness expectation value $-0.28\pm 0.04<0$ (Fig. 1b), thus confirming the realization of genuine four-partite cluster state. We furthermore found that the prepared state can tolerate up to 37.5% incoherent noise, in comparison to a qubit cluster state which can only endure 33%.

3. Conclusions

We have shown the generation and processing of high-dimensional cluster states, exploiting integrated photonic chips and optical fiber communication components. We also developed a novel universal technique for deriving experimentally-optimized witness operator for complex entangled states. Our work provides an important step towards achieving powerful and noise-tolerant quantum computation in a scalable and mass-producible platform.

Abstract
We have developed multifunctional plasmon-enhanced nanoscopy for molecular control and analysis. A plasmonic probe tip is utilized not only to enhance Raman scattering from sample molecules but also to apply pressure and voltage to them, enabling us to locally initiate chemical reactions in the vicinity of the plasmonic tip. Combination of plasmon-enhanced nanoscopy with the local external stimuli has now opened up a new way to control molecular properties and functions on a nanometer scale.

Main text
Tip-enhanced Raman scattering (TERS) microscopy has been regarded as a promising application of plasmonics for nano-imaging and nano-analysis with a nanoscale spatial resolution far beyond the diffraction limit of light. A sharp metallic probe tip plays important roles in plasmonically enhancing Raman scattering from sample molecules in the vicinity of tip. However, TERS microscopy has been still limited to passive measurement of intrinsic molecular properties and functions. Recently, we have proposed to utilize the plasmonic tip to locally apply various kinds of external stimuli such as pressure and voltage to sample molecules through the tip apex (Fig. 1), enabling us to actively modulate the intrinsic molecular properties at the nanometer scale. The dynamic change in physicochemical properties can be spectroscopically probed by detecting tip-enhanced Raman scattering in response to the external stimuli.

When the plasmonic tip is controlled by an atomic force microscope in TERS measurement, the tip is utilized to locally apply pressure onto molecules under the tip. The tip-applied pressure has enabled to induce local deformation of molecular structures, which is detected by tip-enhanced Raman spectral changes. In this study, we demonstrated pressure-induced molecular isomerization in-situ observed through TERS spectral change. TERS spectra were measured on self-assembled monolayer (SAM) of cysteamine conformers while applying uniaxial pressure to them through the plasmonic tip with the nanometric apex. As the tip-applied pressure increased, the Raman band of the trans conformers exhibited decreasing of the intensity while Raman intensity of the gauche conformers increased. This result indicates the conformational change from the trans to the gauche conformers in the close vicinity of the tip-apex. We also utilized the plasmonic tip to apply DC voltage to sample molecules under the tip, enabling us to locally induce electrochemical reactions by regulating the tip-applied DC voltage. The details of the experiments will be discussed in our presentation.
Comparison of Plasmonic Response of Semiconductor Nanostructures with Spherical Symmetry and Their Prospect for Terahertz Applications

Abstract

Electric polarization in three types of spherical semiconductor nanoparticles are compared: bare particle, semiconductor core with dielectric shell, and its dual. Physical insight is drawn from the dipole moments and the equivalent circuits. Their possible role as impetus for development of components in terahertz frequency range is explored.

1. Introduction

With a bulk plasma frequency in the terahertz frequency range, extrinsic semiconductors can be expected to find applications in that part of the electromagnetic spectrum [1][2]. Surface plasmon resonance in metallic nanoparticles has led to a variety of applications including sensor, field trapping, filter, polarizer, and waveguides. Spherical nanoparticles are of fundamental interest due to its high symmetry and availability in a large range in size. Much attention has been given to metallic nanoparticles. The semiconductor nanoparticle has been less studied. Although it has weaker polarizability than the metallic nanoparticle, it possesses the provision for varying the charge concentration by doping or otherwise, enabling the plasmon frequency to be adjusted over a substantial range. The presence of an insulating shell on a semiconductor nanoparticle is expected to influence the polarization in terms of the amplitude in the dipole moment and the surface plasmon resonance frequency. Insight can be obtained by comparing the polarization in a bare semiconductor nanoparticle to that of a core-shell structure with a semiconductor core enclaved in a dielectric shell. At the same time, a dielectric core within a semiconductor shell, which is the dual of the core-shell particle mentioned above, can provide a contrast to the comparison, providing additional insight to how plasmonic interactions are mediated in spherical nanostructures. In this paper, the polarization response obtained from electromagnetic simulation on these three nanostructures with spherical symmetry are presented, along their possible role in the realization of devices and circuit elements in the terahertz frequency range.

2. Charge Transport and Polarization

Owing to a lower carrier concentration than that of a metallic nanoparticle, field penetration into a semiconductor nanoparticle is more pronounced so that space charge effect is more significant. To provide a realistic account of charge distribution in the nanoparticle, a transport formulation needs to be employed to describe the dynamics of the charge carriers [3]. By coupling the equation for the electric field to the Boltzmann’s equation, the carrier screening effect is revealed from the interior field within the nanoparticle. Figure 1 shows the real (left) and imaginary (right) parts of the charge density in a semiconductor nanoparticle doped at \(10^{18}\) cm\(^{-3}\) and placed in an electric field close to its bulk plasma frequency. It can be seen that the charge is confined to a layer close to the surface. As a result, the electric field does not penetrate deep into the interior of the nanoparticle.

![Figure 1](image)

Figure 1: Net charge in a semiconductor particle placed in an electric field near the bulk plasma frequency. Results are obtained by electromagnetic simulation. In this particular example, radius of particle \(a = 50\) nm, doping level \(N_c = 10^{18}\) cm\(^{-3}\), relative permittivity \(\varepsilon_r=10\), electron effective mass \(m^* = 0.25m_e\) and momentum relaxation time \(\tau_e = 2 \times 10^{-13}\) s. (a) Real part (C/cm\(^2\)), (b) Imaginary part (C/cm\(^2\)).

From the charge distribution, the induced dipole moment can be obtained. It displays a dispersion in the real part and an absorption peak at the surface plasmon resonance frequency [3]. To gain insight to the process of polarization and to facilitate the analysis of interactions in a cluster of nanoparticles, an equivalent circuit has been developed. The dipole moment calculated from the equivalent circuit give good agreement with the results obtained from electromagnetic simulation [4]. As seen in Figure 2, the circuit has a capacitor \(C\) that dominates the low frequency response, accounting for the screening effect of the space charge. In the high frequency limit, where the electrons cannot respond rapidly to the varying field, the polarization in the particle comes mainly from the lattice, and is represented by the two capacitors series, \(C_i\) and \(C_e\). At
intermediate frequencies, the dynamics of the mobile electrons contribute to the polarization process and the surface plasmon resonance is revealed. The resonance frequency is determined jointly by the inductor, the resistor, and the capacitors. The resistor on the right, $R_r$, is the radiation resistance, which accounts for the energy loss resulting from an oscillating dipole in open space.

Most nanoparticles acquire an oxide layer on their surfaces when exposed to air. At times, an insulating shell is deliberately coated outside to modify its characteristics [5-12], leading to a core-shell structure, as shown in Figure 3.

![Figure 3: A nanoparticle with a core-shell structure.](image3)

The presence of an insulating layer on the surface will lead to a redshift in the surface plasmon frequency while the dipole moment is increased, as a result of the enhancement of the local field while the layer itself is polarized [13].

![Figure 4 (a)](image4a)

![Figure 4 (b)](image4b)

Figure 4 shows the induced dipole moment on core-shell semiconductor nanoparticles with different dopings in the cores. For these calculations the core has a radius of 50 nm. The thickness of the dielectric shell is 5 nm and its relative permittivity is 3.9. Response of the bare nanoparticles with corresponding dopings are included for comparison. They have a smaller amplitude and a plasmon resonance frequency higher than that of the corresponding core-shell nanoparticle. The insulating shell leads to an added capacitor in the equivalent circuit [13], as shown in Figure 5. For simplicity, the radiation resistance is suppressed in the figure.

![Figure 5: Equivalent circuit of a core-shell semiconductor nanoparticle.](image5)

Above the plasmon resonance frequency, the inertia effect of the mobile charges gives rise to a negative contribution to the real part of the dipole moment. When the carrier concentration is sufficiently high, such as the case at doping of $10^{19}$ cm$^{-3}$ in Figure 4, the real part of the dipole moment can become negative immediately above the plasmon frequency. This negative dipole moment can be exploited to provide inductive reactance in circuit elements. However, the negative dipole moment is not of same magnitude as the positive side below the resonance, owing to the polarization of the lattice which makes a positive contribution that offsets the negative value resulting from the dynamics of the mobile charge carriers. In any case, this is a situation for generating inductive reactance without relying on magnetic material.
The nanoparticle in this frequency range may be viewed as a meta-material.

If the roles of the semiconductor and dielectric are interchanged in the above shown core-shell structure, a nanoparticle with a semiconductor shell enclaving a dielectric core is obtained. Under the action of a dynamic electric field, the charge carriers are set to motion in the shell, following a circular path that contributes to the inductive reactance. This effect is readily evidenced by reviewing the dipole moment of the semiconductor nanoparticle shown in Figure 6. Of particular interest is the blue shift in the surface plasmon resonance and a larger polarization response. The negative value in the real part of the dipole moment above the surface plasmon resonance frequency is more pronounced in this case compared to the previous one. Hence this structure is preferred for providing inductive reactance above the surface plasmon resonance frequency.

![Figure 6](image)

**Figure 6.** Induced dipole moment of a nanoparticle with a dielectric core enclaved by a semiconductor shell at $10^{19}$ cm$^{-3}$ nominal carrier concentration (top) real part, (bottom) imaginary part. The radius of the dielectric core is 45 nm. The thickness of the semiconductor shell is 5 nm. Response of the bare semiconductor nanoparticle of similar size as the core is included for comparison.

### 3. Conclusion

Semiconductor nanoparticles exhibit plasmonic resonance in the terahertz frequency range which can be employed for functional applications. Transport-based analysis and simulation for the nanoparticle can account for the space-charge effects in the particles, leading to the construction of equivalent circuits to facilitate the design of nanoparticles and their derivatives. The polarizations in a bare spherical semiconductor nanoparticle and those of core-shell structures are compared. The presence of a dielectric shell on a semiconductor core results in polarization enhancement and a redshift in the surface plasmon frequency. On the other hand, a dielectric core inside a semiconductor shell shows a blueshift in the surface plasmon frequency. The real part of the dipole moment above the surface plasmon resonance of the latter core-shell nanoparticle acquires a negative value that is considerably larger than that of its dual. It can serve as impetus for providing inductive reactance as an entity in sensors and in circuit applications.

Light-Trapping Transparent Electrodes For Photodetection and Photovoltaics

Mengdi Sun and Pieter G. Kik

CREOL, The College of Optics and Photonics, Orlando, FL, USA
*corresponding author: kik@creol.ucf.edu

Abstract

Shadowing losses by electrical contacts remain a pervasive challenge in a wide range of optical devices. Here we demonstrate that light-trapping electrodes consisting of arrays of metallic nanowires in a dielectric cover layer can practically eliminate all shadowing losses at surprisingly high metal coverage. This is achieved through directional reflection by the electrode surfaces toward angles beyond the critical angle. The approach is shown to allow efficient shadowing mitigation using structure sizes smaller than half the optical wavelength. The optical and electrical performance of these electrodes are shown to rival several current approaches in a compact microstructured surface.

Transparent electrodes are widely used in optoelectronic devices, such as solar cells, high speed photodetectors, imaging arrays and displays. In all such devices there is an intrinsic trade-off between optical and electrical performance, with low resistivity typically accompanied by poor optical transmission. In the case of metallic electrodes, transmission loss is predominantly caused by shadowing losses. To mitigate these losses, several approaches have previously been proposed, including encapsulated metal gratings [1-3], high-aspect-ratio metallic contacts [4, 5], periodic structures with plasmon-enhanced transmission [6-8] and patterned electrodes with textured surfaces [9-14]. Recently we proposed light-trapping electrodes using shaped surfaces [10]. In this design, arrays of metal wires with inclined surfaces are embedded in a dielectric cover layer. Under certain conditions a large fraction of light incident on the metallic wires is recovered by total internal reflection (TIR), allowing for transmission approaching 100% with a metal areal coverage well exceeding 25%.

Here we study the optical and electrical performance of silver light-trapping electrodes. Specifically the spectral performance and sheet conductivity of light-trapping electrodes containing triangular and cylindrical silver nanowires are investigated as a function of wire size. Figure 1 shows the angular scattering patterns of triangular and cylindrical silver wires embedded in silicon nitride for wire widths 200nm, 600nm, 1.2 μm and 2 μm. The wires are illuminated at normal incidence at a wavelength of 750nm using TE (top panel, electric field along the metal wire axis) and TM (bottom panel, electric field normal to the wire axis) polarization. The results have been scaled by the total power incident on the metal wire to facilitate comparison between wires with different width. These results show the key features that enable reduction of shadowing losses: any light reflected (scattered) toward angles above 30° can be recovered due to light trapping.

Fig. 1. Angle dependent reflected irradiance of a) triangular silver electrodes under TE illumination and b) TM illumination, c) cylindrical silver electrodes under TE illumination and d) TM illumination.
While small wire sizes are produce undesirable broad angular reflection distributions, larger triangular wires are seen to produce directional reflection with most reflected power directed toward angles above the critical angle of silicon nitride, allowing efficient light recovery. Cylindrical wires show oscillatory directional reflection resulting from the excitation of multipolar surface plasmon polariton distributions on the wires, leading to relatively inefficient light trapping at all sizes.

To evaluate the size-dependent optical performance of real-world high-conductivity light-trapping electrodes, periodic metallic wire arrays with a relatively high areal coverage of 25% were considered. The arrays are embedded in a transparent layer ($n=2$) and covered with an anti-reflection coating with a thickness of 133 nm and index $n=1.41$, producing reduced top surface reflection at the 750 nm illumination wavelength. Figure 2 shows the simulated size-dependent transmitted, reflected, and absorbed power fraction of these interdigitated light-trapping electrodes with triangular (left) and cylindrical (right) electrode lines, at a fixed metal areal coverage of $f=0.25$, averaged over TE and TM polarization. For all electrode widths the transmitted fraction is found to significantly exceed 75%, corresponding to the maximum transmission of traditional flat electrode arrays at this metal coverage (horizontal dashed line) in the ray optics limit. This directly demonstrates the reduction of shadowing losses through recovery of the light incident on the metallic electrode lines. The light trapping efficiency increases from 35% to 80% as the electrode width increases from 200 nm to 2 μm due to the increased directionality of the reflected light. 

Note that even small (200 nm width) triangular electrodes outperform traditional rectangular electrodes. For the largest triangular structures investigated, high optical transmittance (>97%) and low sheet resistance (<0.35 Ω/sq) are achieved simultaneously in a compact light trapping structure.

![Figure 2. Size-dependent optical and electrical performance of light-trapping electrodes consisting of triangular silver wires (left) and cylindrical silver wires (right) at 25% metal areal coverage. The white lines represent a model that ignores plasmonic grating effects.](image)

Abstract

Photonic lattices have provided a powerful platform to emulate Dirac physics while discovering new phenomena that would otherwise be inaccessible in natural 2D materials. In this talk, I will present some of our recent work based on Dirac-like photonic structures, including valley vortex states and degeneracy lifting via photonic higher-band excitation, valley Bloch oscillations and Zener tunneling, and unusual flatband localized states protected by real-space topology. I will then focus on discussing pseudospin-orbit angular momentum conversion and universal momentum-to-real-space mapping of topological singularities arising from the interplay of Berry phase, pseudospin, and orbital angular momentum of light.
Shaping of light in non-Hermitian disordered media

Abstract

In the context of non-Hermitian photonics, we examine a unique method of controlling light inside complex media by engineering the imaginary part of the refractive index appropriately. Using this approach to shape the intensity of light in non-hermitian photonic media with gain and loss, we manage to create waves with constant intensity that make a disordered medium unidirectionally invisible or that produce a strong focus inside the disordered structure.

1. Introduction

The scattering of waves through disordered media is a paradigmatic phenomenon that has captured the interest of various communities for quite some time now [1]. While much work has been invested into understanding the statistical properties of the corresponding wave transport there has recently been a surge of interest in controlling the scattering of waves through systems for specific purposes such as detection, imaging, and efficient transmission across disordered materials [1]. Remarkable progress in these endeavors has recently been made in the optical domain, largely due to the availability of spatial light modulators and new concepts for how to apply them on turbid media. In a first generation of corresponding experiments the focus was laid on shaping the input wave front impinging on an immutable disordered sample such as to achieve a desired output, like a spatial or temporal focus behind the medium. More recent studies focused instead on controlling the medium itself, e.g., through the material fabrication process or through a spatially modulated pumping leading, e.g., to a versatile control of random and micro-cavity lasers.

Largely in parallel to these efforts on disordered media, it was recently realized that materials and devices can get entire new functionalities when adding to them a suitably arranged combination of gain and loss [2, 3]. In particular the field of PT-optics [4] has demonstrated that such an unconventional combination can lead us to counterintuitive phenomena with many novel applications (for a recent review see [4]). One of the celebrated breakthroughs in this field was the insight that PT-symmetric gain-loss gratings are unidirectionally invisible at specific frequencies—a property that has meanwhile also been realized experimentally. Transferring these concepts now to disordered materials, one could ask the question whether also a randomly assembled background medium can be engineered by just adding a tailored gain-loss distribution to it in order to control the multiple scattering. Whereas a successful strategy to answer this question would already be quite remarkable in its own right, we will go here an essential step further by demonstrating that we can generate waves in a disordered medium that are both perfectly transmitted and free of any intensity-variations throughout the entire scattering process. Since interference fringes and the intensity buildup associated with a strongly scattering medium are at the heart of disordered photonics, our new wave states touch on a very central issue in this field with potentially far-reaching consequences for the engineering of light transport.

2. Wave control in non-Hermitian media

2.1. Constant-Intensity Waves

In this framework of non-Hermitian disordered photonics, we have shown that for a general disordered medium, given by a distribution of the real part of the refractive index $n_R(x)$, a corresponding distribution of its imaginary part $n_I(x)$ can be found, such that an incoming wave will feature a constant intensity (CI-waves) throughout the entire non-uniform scattering landscape [5, 6]. In other words, we can show that adding a judiciously chosen distribution of gain and loss to a disordered medium will make waves lose all their interference fringes including perfect transmission through the disorder. Such types of waves have been experimentally realized in the context of acoustics [7], resulting in constant pressure waves in a strongly disordered medium.

2.2. Shaping light in complex disordered media

Regarding the possibility to achieve unidirectional invisibility as well as a complete control of the wave’s intensity inside a complex medium (localized patterns for example), we now explore a solution strategy based on the one-dimensional Helmholtz equation that describes time-independent scattering of a linearly polarized electric field both in forward and in backward direction.

2.2.1. Non-Hermitian Invisibility

We show how one can make any disordered medium, that supports constant-intensity waves, also unidirectionally invisible [8]. In Fig.1(a-c) we can see the real (Fig.1a) and
imaginary part (Fig.1b) of the complex index of refraction and in (Fig.1c) the corresponding scattered field. The intriguing features of such an approach is that only with gain one cannot achieve perfect transmission and also that by adding gain and loss the dependence on wavelength becomes relatively broad, allowing thus in principle to transmit even pulses through such a unidirectionally invisible medium.

2.2.2. Complete control of wave’s intensity

By extending our analysis to the case of a general wave intensity pattern inside the disordered medium, we can derive the gain-loss distribution that is required for such purpose. In Fig.1(d-e) we provide an example of such a localized pattern inside a strongly scattered medium. In other words, we can find a class of non-Hermitian potentials for every form of the profile of the wave’s intensity that we impose. In all cases gain and loss are absolutely necessary for the wave’s intensity control.

3. Discussion

Based on these preliminary results we also apply the same methodology in two-spatial dimensions in order to fully control multiple scattering of waves and to examine the relation of our CI-waves to similar two-dimensional solutions of Bohmian photonics [9]. We start from the two-dimensional Helmholtz equation and reformulate the problem as a non-Hermitian eigenvalue problem with appropriate radiation boundary conditions. The mathematical methods that we apply to study multiple scattering in non-Hermitian environments are the volume integral methods and the recursive Green’s function method.

4. Conclusions

In conclusion, we have presented recent results regarding CI-waves in non-Hermitian media. More specifically, we examined a new way to construct a family of unidirectionally invisible one-dimensional structures. By using a generalized class of non-Hermitian potentials we show how complete wave control can be achieved. Extensions to higher dimensions will also be discussed.

**Abstract**

We demonstrate extreme nonlinear optical properties leveraging epsilon-near-zero (ENZ) effect in plasmonic conductive metal oxide thin films. With the aid of high-mobility indium-doped cadmium oxide (CdO: In) as the gateway plasmonic material, we manage to construct an ultrafast all-optical switch with an absolute change in the p-polarized reflectance from 1.0 to 86.3% within 800 fs. Furthermore, we utilize the ENZ structure to achieve UV high-harmonic generation up to the 9th-order.

**1. Introduction**

Recently, materials that exhibit a vanishing real part of their permittivity in certain spectral ranges, commonly known as epsilon-near-zero (ENZ) materials, have been found to exhibit outstanding nonlinear optical properties[1]. For example, a giant nonlinear refractive index can be expected when the linear permittivity of the material approaches zero[2]. Here, we report on an ENZ meta-film based on an indium-doped cadmium oxide (CdO: In). Benefiting from the low material loss and a perfect absorber cavity design, we are able to modulate the absolute p-polarized reflectance of the cavity from 1% to 86% on a sub-picosecond time scale, at a wavelength of 2.08 μm[3]. We further demonstrate high-harmonic generation (HHG) based on such a platform.

**2. Results and discussion**

2.1. Static optical response

The CdO-based thin film perfect absorber is schematically shown in Fig. 1(a) and consists of a magnesium oxide (MgO) substrate, a 75-nm-thick doped CdO layer, and an optically thick gold capping layer. For the reflectance spectrum measurements, infrared light is incident on the CdO film from the substrate side. The CdO film is deposited on the (100) MgO substrate via sputtering, with the gold layer sequentially deposited by electron-beam evaporation. The carrier density and mobility of the CdO film are retrieved from the ellipsometry measurements to be $2.8 \times 10^{20}$ cm$^{-3}$ and 300 cm$^2$ V$^{-1}$s$^{-1}$, respectively, resulting in a zero-crossing of its permittivity at 2.1 μm. Note that the carrier density is tunable by changing the In flux ratio during the material growth, allowing its corresponding $\omega_p$ to span from near-to mid-infrared frequencies. The exceedingly high electron mobility of the epitaxially grown CdO film, roughly an order of magnitude larger than conventional CMOs such as GZO and ITO, is a result from the sufficiently small substitutional lattice strain induced by In doping[4].

Reflectance spectra of the sample at incident angles ranging from 30° to 70° are obtained using an infrared spectral ellipsometer under free space excitation, and are shown in Fig. 1(b). The minimum measured reflectance of the sample is 1% at an incident angle of 50° and a wavelength of 2.08 μm.

![Fig. 1.(a), schematic of the CdO-based perfect absorber. (b), measured reflectance of the sample for p-polarized light at incident angles ranging from 30° to 70°, and for s-polarized light at an incident angle of 50°.](image)

2.2. Ultrafast all-optical switching

We examine its transient response following optical excitation with pump-probe measurements. We use one beam from the idler output of an optical parametric amplifier (OPA) fed by a Ti: Sapphire amplified laser as the pump. The pump wavelength is tuned to 2.08 μm, and is p-polarized with an incident angle of 30° to allow resonant sample absorption. The probe beam is also p-polarized, but at an incident angle of 50° to achieve minimum reflectance at 2.08 μm, and to spatially separate from the pump beam.
The spectral bandwidth of the probe beam is large because of the ∼50 fs pulse width of the OPA. Therefore, to accurately determine the change of absorption of the sample at different wavelengths after being reflected by the sample, the probe beam is sent through a monochromator prior to being detected by the photodetector. In Fig. 2(b), we present the absolute reflectance of the sample as a function of pump probe delay time, showing a transient bleaching at 2.08 μm and an induced absorption at 2.23 μm. We observe an absolute reflectance change from 1% to 86% at 2.08 μm and an absolute reflectance change from 73% to 11% at 2.23 μm.

Fig. 2 (a) schematic of the pump-probe measurement setup. (b), the measurement absolute reflectance of the sample at 2.08 μm and 2.23 μm at a function of pump-probe delay time. 1.(a), schematic of the CdO-based perfect absorber. (b), measured reflectance of the sample for p-polarized light at incident angles ranging from 30° to 70°, and for s-polarized light at an incident angle of 50°.

2.3. High-harmonic generation

We will also report high-harmonic generation up to the 9th order directly from the ENZ medium.

3. Conclusions

To summarize, by taking advantage of a low loss plasmonic material (CdO) with a stringently designed Berreman mode plasmonic cavity, we manage to construct a high quality factor perfect absorber for the extremely high contrast dynamic tuning of the amplitude and polarization state of infrared light at a sub-picosecond time scale. We envision many more exciting applications, including THz generation and two-photon emission with ENZ meta-films are the platform.

References

We show that optical waves passing through a nanophotonic medium can perform artificial neural computing. Complex information, such as an image, is encoded in the wave front of input light. The medium continuously transforms the wave front to realize highly sophisticated computing tasks such as image recognition. At the output, optical energy is concentrated to well defined locations, which for example can be interpreted as the identity of the object in the image. These computing media can be as small as tens of wavelengths in size and thus offer extremely high computing density. They exploit sub-wavelength linear and nonlinear scatterers to realize sophisticated input-output mapping far beyond traditional nanophotonic devices. To enable these complex neural computing, we draw inspiration from artificial neural network and use stochastic gradient decent to optimize nonlinear nanophotonic structures with structural gradient computed from adjoint state method.
Revealing the Near-Field Dynamics in Chiral Metasurfaces: Interactions of Spatially Displaced Surface Plasmon vortices

Chen-Bin Huang1,*

1Institute of Photonics Technologies, National Tsing Hua University, Hsinchu, Taiwan
*corresponding author, E-mail: robin@ee.nthu.edu.tw

Abstract

The potential to mold user-desired surface plasmon field flow with the existence of two simultaneous surface plasmon vortices with proper spatial offset is studied numerically. In the first case, a squeezed vortex with opposite rotation direction is generated between two co-rotating vortices. In the second case, a linear flow channel is formed in between two counter-rotating vortices.

1. Introduction

Surface plasmons (SPs) are near-field waves that propagate along the metal-dielectric interface as the result of collective electrons induced by external electromagnetic waves. Optical vortices are waves carrying optical angular momentum and exhibit abrupt azimuthal phase discontinuities. Recently, the ability to generate SP vortex in plasmonic chiral structures has attracted immense research attentions [1-3]. Among various nanoscopic chiral structures, Archimedean spiral with a geometric charge of 1 is a representative and noteworthy geometry in two means: (1) Such spiral can be used to convert far-field spin angular momentum of circularly-polarized light having the same sign as the geometric charge into near-field orbital angular momentum, therefore generating SP vortex with a topological charge of 2; (2) On the other hand, exciting the spiral with optical spin angular momentum having the reversed sign would end up with a strong subwavelength SP focusing field. This unique optical selectable SP field characteristic was applied to optofluidics for user-controllable microparticle trapping (using the focusing field) or rotation (using the vortex field) [4]. However, the particle controls were limited in a sense during trapping, only a single spatial trapping potential could be provided by the focusing SP field, and limited to a unidirectional rotation under the vortex field.

Here we propose geometrical design of plasmonic spirals that leads to the potential of controllable SP field directions. By incorporating two plasmonic Archimedean spirals with spatial offsets, two SP vortices are generated simultaneously. We numerically demonstrate unique controllability to the local SP field flows is allowed by changing the relative offsets and the topological charges of the two cortices. Our result could find immediate application in optofluidics and opens up a new path to optical manipulations.

2. Design

Our numerical analyses are performed using the three-dimensional finite-difference time-domain (FDTD) method [5]. The simulation volume is large enough to avoid nonphysical absorption of the near fields by the perfectly matched layers and an uniform mesh step ((10 nm)3) is used such that satisfactory calculation accuracy is obtained with reasonable speed and memory consumption. In our simulations, the plasmonic slits are formed by etching through a silver film of 200 nm thickness on top of a Si substrate. The optical source is a -z-propagating right-hand circularly polarized plane wave with vacuum wavelength of 570 nm, exciting the spiral at the air-Ag interface. The dielectric function of silver is modeled using Drude-Lorentz function to match the experiments [6].

Figure 1. The two designs where two surface plasmon vortices are generated simultaneously with a spacing of 1000 nm: (a) The two vortices are having equal topological charge of 2; (b) the vortex on the left is having a topological charge of -2.

Figure 1(a) shows the geometry of our first design: two right-hand plasmonic Archimedean spirals both with geometric charge of 1 are displaced by 1000 nm in the x-direction. The intersection of the two solid black lines marks the origin in the cylindrical coordinate, while the dotted lines indicate the geometric centers of the two spirals. This design generates two SP vortices with equal topological charge of 2 under right-hand circularly polarized excitation. Figure 1(b) shows the second design: here the spiral offset to the left is replaced with a three-slit structure, equivalent to a left-hand plasmonic Archimedean spiral with a geometric charge of -2.
3. In this case, SP vortex with a topological charge of 2 is generated with an offset of 500 nm, while the second SP vortex with a topological charge of -2 is generated with an offset of -500 nm under right-hand circularly polarized excitation.

3. Result and discussion

Figures 2 and 3 show the time evolution of the SP fields generated by design 1 and design 2, respectively. For each design, four snap-shots are displayed. In Fig. 2, one could observe in addition to the two vortices centered respectively at \( x = -500 \) nm and 500 nm, there is a third vortex with opposite sense of rotation centered at \( x = 0 \) nm.

![Figure 2](image1.png)

Figure 2. (a)-(d) Four snap-shots the resulting SP \( E_z \) field for design 1.

In Fig. 3, a SP field flow channel in the \(-y\)-direction is formed along \( x = 0 \) nm, which is created by the two counter-rotating SP vortices. In the presentation, movies will be used to better illustrate the effects.

![Figure 3](image2.png)

Figure 3. (a)-(d) Four snap-shots the resulting SP \( E_z \) field for design 2.

4. Conclusions

The existence of two simultaneous surface plasmon vortices with spatial offset provides opens up a path to mold user-desired field flow. We anticipate our results to find immediate application in optofluidics.

Integrated single photon sources with colloidal semiconductor nanocrystals

Alberto Bramati

Laboratoire Kastler Brossel, Sorbonne Universités, CNRS, ENS, Collège de France, Paris, France

Core/shell colloidal semiconductor nanocrystals are very efficient room temperature single photon emitters. In particular, in asymmetric core/shell nanoparticles (dots-in rods) with a spherical CdSe core surrounded by a rod-like CdS shell, blinking effects, multi-excitonic emission and polarization of the emitted photons can be independently controlled by tuning the shell dimensions [1]. This allows an unprecedented capability in radiative channels engineering, making dot-in-rods “state of the art” blinking-free sources of polarized single photons on-demand.

In this talk I will discuss our recent results and the different strategies we are pursuing to develop hybrid photonic devices by coupling single nanocrystals with photonic structures such as deep parabolic mirrors [2], liquid crystals [3], semiconductor nanowires [4] and tapered nanofibers. In particular the deposition of a single emitter on a nanofiber and the observation of single photon statistics through the guided mode of the fiber will be reported. Finally I will show how this hybrid system is a very promising playground for novel chiral optics experiments, including a spin-orbit coupling effect for light [5].

Abstract

A metasurface is designed to combine the generation of a focused beam and a vortex beam in the same imaging plane which can be used for super-resolution imaging in stimulated emission depletion (STED) microscopy. It is composed of sub-micron sized nanobar array to modulate the phase of the multi-spectral incident light locally. With this metasurface, the STED imaging system will be greatly simplified, and there is no need to align the two beams with high precision in the same optical path.

1. Introduction

Optical inspection always requires high resolution imaging technology. Stimulated emission depletion (STED) microscopy [1] is one of the technique to achieve super-resolution imaging (~ tens nm). It is a deterministic functional technique exploring the non-linear response of fluorophores to achieve the beyond diffraction limit resolution image. Basically, any object with multi-state energy level can allow for super-resolution imaging with STED microscopy, for example quantum dot [2]. Therefore, the STED microscopy is an enabling technique for semiconductor optical inspection and biological imaging applications. The current STED system is bulky and costly (~1 million US dollars). One of the biggest technical challenges in STED microscopy system is to couple two modified laser beams, one is optical vortex beam and the other is focusing beam, in the same focusing plane to excite and deplete the fluorophore at the same time. Additionally, sophisticated optical system is used to tailor the beams in two different beam shapes and align them precisely at the focal spot in the imaging plane of high NA objective lens. Therefore, a simple solution to alleviate the challenging optical alignment and the complexity of STED system is of great significance.

Metasurface, achieving functionality through nano-structuring, has becoming an enabling technique to control and manipulate light in term of amplitude, phase and polarization state [3]. Thus, the wavefront of light can be arbitrarily shaped for various application, such as beam steering, focusing imaging, and holographic display [4-6]. In this paper, a planar dielectric metasurface is used to shape and focus two beams to suppress the fluorescence for super resolution imaging. With the metasurface, the optical system will be greatly simplified, and there is no need for precise alignment of the focusing beam and the vortex beam in the system. The cost of phase microscope can be dramatically reduced, and it is possible to realize on-chip super-resolution STED imaging with this invention.

2. Experimental results

In this work, the metasurface is designed to combine the generation of a focused beam and a vortex beam in the same imaging plane. It is composed of sub-micron sized nanobar array to modulate the phase of incident light locally [7]. Four nanobars are arranged in a rectangular area and optimized for two different wavelengths. When the two-wavelength light is incident on this metasurface, some of the nanobars respond to one wavelength for light focusing, while the others respond to another wavelength for generation of vortex beam. The efficiency ratio of focused beam and vortex beam can be tuned through the optimization of nanobar parameters.

Figure 1 shows the phase distribution at the multi-spectral metasurface to form optical vortex spot with 633nm (a1) and solid focusing spot with 532nm (a2). (b1) and (b2) are simulated intensity distribution of two beams at imaging plane. Figure 1c shows the normalized cross section of the vortex beam and the focusing beam intensity distribution. The dash line is the cross talk of red beam through the focus cell and green beam through the vortex cells.
Fig. 1 (a1) and (a2) are phase distribution of vortex beam with 633nm and excitation beam with 532nm at metasurface. (b1) and (b2) are the simulation results of intensity distribution of two wavelength at imaging plane. (c) cross section of intensity distribution of two beam. Dash line is the cross talk 633nm through the green cell and 532 through the vortex cell. Green and Red solid line is the cross section of the focusing and vortex beam.

The amorphous Si with 380 nm thickness is growth on a quartz substrate by PECVD. A thin layer of ZEP photoresist is spin coated on the a-Si film. The metalens is patterned on the ZEP photoresist by electron beam lithography. After developing, the sample is dry etched to get the a-Si nano structures. Figure 2 is the scanning electron beam image of the fabricated metasurface. The green boxes indicate supercells composed of four nanobars in each of them. The smaller bar is designed to work at 532 nm, and the bigger one is for 633 nm.

Fig. 2 The SEM photo of part of STED metalens.

Figure 3 shows the characterization of STED metasurface. When the 633nm light is normal incident into the metasurface, an optical vortex sport is generated at the focal plane. When the 532nm light is normal incident, a solid focal spot is generated at the same focal plane. With this metasurface, a simple STED imaging system can be realized on a chip.

Fig. 3 The characterization result of STED lens. (a) the 633nm wavelength light is shaped to a vortex beam in the imaging plane. (b) the 532nm wavelength light is focused in the same imaging plane.

3. Conclusions

Two different sized nano-bars are specially designed to form a supercell metasurface to achieve independent geometric phase modulations for two different wavelength. The supercell metasurface can be utilized to arbitrarily control the wavefront of multi-spectral electromagnetic waves, thus enabling many functionalities. Using this approach, we demonstrate a multispectral metasurface to create a focused optical vortex doughnut-shaped spot at a longer wavelength and a solid light spot at a short wavelength at the same location in the image plane. It is especially useful for stimulation emission depletion (STED) microscope system for minimizing the area of fluorescence emission. This approach alleviates the stringent requirements for precise alignment of two wavelength focus spots in a conventional STED super-resolution imaging systems.

Alternative Plasmonic Materials for SERS and Metasurface Applications: Aluminum and Titanium Nitride

Shangjr Gwo¹²

¹Research Center for Applied Sciences (RCAS), Academia Sinica, Nankang, Taipei 11529, Taiwan
²Department of Physics, National Tsing-Hua University, Hsinchu 30013, Taiwan
*E-mail: gwo@sinica.org.tw

Abstract

Recently, we have developed epitaxial techniques to grow forming smooth, single-crystalline aluminum (Al) and titanium nitride (TiN) films on transparent sapphire substrates using molecular-beam epitaxy (MBE). In comparison to silver and gold, Al- and TiN-based plasmonics have better material stabilities and spectral responses in the ultraviolet (UV) and visible spectral regions, making them particularly suitable for UV surface-enhanced surface Raman spectroscopy (SERS), optical energy harvesting, and metasurface-based linear and nonlinear optics.

1. Introduction

The development of plasmonics and metasurface-based optical structures requires alternative, high-performance plasmonic materials, in replacement of commonly used noble metals. Ideally, plasmonic materials should have the properties of low-cost, low-loss, high chemical, mechanical, and thermal stabilities, biocompatibility, spectral tunability, as well as integrability with existing semiconductor technologies. In comparison to silver and gold, Al- and TiN-based plasmonics have better materials stabilities and spectral responses, making them particularly suitable for UV-SERS and metasurface-based linear and nonlinear optics. Here, recent experimental results from my group related to these application areas are presented.

2. Advantages of Aluminum and Titanium Nitride as Plasmonic Materials

In comparison to gold and silver [1,2], Al is a sustainable and widely applicable plasmonic material owing to its abundance in the Earth’s crust and compatibility with the complementary metal–oxide–semiconductor (CMOS) technology. In particular, Al has a superior performance in the UV region with the lowest material loss and good performance in the full visible spectral range [3,4]. Furthermore, aluminum films remain very stable under ambient conditions due to the formation of surface native oxide (alumina), acting as a passivation layer. On the other hand, TiN [5] is a refractory plasmonic material in the visible and near-infrared (IR) range, exhibiting extraordinary mechanical strength (machine-tool grade), high melting temperature (~3,000°C), high corrosion resistance, and excellent bio- and CMOS compatibilities. Interestingly, TiN is also a superconductor with transition temperature higher than the liquid helium temperature (~6 K in the case of stoichiometric TiN).

3. Experimental

In practice, high-quality Al and TiN films require an ultraclean growth environment because of their propensity to react with residue gases. Especially, titanium is an active absorbing agent or getter material, which is widely used as a sublimation pump material in ultrahigh vacuum systems. Therefore, the achievable material properties of Al and TiN films are so far limited by the growth technique. Recently, we have developed molecular-beam epitaxy (MBE) growth techniques for Al and TiN (N₂-plasma-assisted) epitaxial films, which can be used as alternative plasmonic materials to silver and gold, respectively. Additionally, to make it possible to integrate plasmonic metasurfaces with two-dimensional van der Waals materials, we have also developed the method to grow hexagonal boron nitride (h-BN) epitaxial films using plasma-assisted MBE. In the case of TiN, the stoichiometry and carrier concentration of nonstoichiometric TiN, films (x < 1) can be controlled by the nitrogen plasma flux and sample temperature during MBE growth. The lower carrier concentration in TiN, films further allows for tunability in their plasmonic response using electric gating. Here, MBE-grown Al and TiN epitaxial films are characterized and utilized for plasmonic device applications. Experimental results, in contrast to standard noble-metal-based plasmonics, are presented.

4. Results

Recently, smooth Al and TiN epitaxial films grown on transparent c-plane (0001) sapphire using MBE have been demonstrated by us. The MBE-grown Al and TiN films have small plasmonic losses, enabling us to fabricate and utilize high-quality Al- and TiN-based plasmonic metasurfaces for a variety of applications (i.e., SERS substrates and linear/nonlinear metasurfaces). The surface roughness and crystal structure of MBE-grown Al and TiN films were characterized by atomic force microscopy (AFM) and X-ray diffraction (XRD). Moreover, the formation of single-crystalline close-packed rock-salt TiN structure has been
confirmed by transmission electron microscopy (TEM). We have also measured the optical dielectric function of MBE-grown Al and TiN films by using spectroscopic ellipsometry (SE). These results show that the structural and optical properties of epitaxial Al and TiN films grown by MBE are of high quality, compared to conventional Al and TiN films grown by other deposition methods (e.g., thermal deposition, sputtering, chemical vapor deposition, etc.).

Figure 1: Optical properties of epitaxial aluminum film grown on c-plane sapphire substrate [4]. (a) Optical image of an aluminum epitaxial film grown on a double-side polished c-sapphire wafer. (b) Reflectivity spectrum of the as-grown aluminum film with a native oxide layer (~3.5 nm) shows a high reflectivity (~0.9) in a wide spectral range. The interband transition is at about 800 nm. (c) Real part of the dielectric function ($\varepsilon_1$) extracted from the spectroscopic ellipsometry data as a function of photon energy (black solid curve). (d) Imaginary part of the dielectric constant ($\varepsilon_2$). For comparison, literature data of Al (red dotted curve) and Ag (blue dotted curve) are also shown in the plots.

Figure 2: Epitaxial TiN film grown on c-plane sapphire substrate [5]. (a) Optical image of a TiN epitaxial film grown on a double-side polished c-sapphire wafer. (b) High-resolution TEM image of a TiN epifilm. (c) Surface plasmon polariton (SPP) interference patterns obtained from different double-nanogroove surface plasmon cavities. Corresponding dark-field optical images are shown in the insets.

5. Conclusions

According to these experimental results, epitaxial Al and TiN films represent two versatile plasmonic material platforms in the UV, full visible, and infrared spectral regions, especially for applications related to energy-harvesting and biosensing applications.

Abstract

In this study, we propose selectively reconfigurable terahertz meta-molecules by controlling the micro-patterned ion-gel gate structures to change the conductance of graphene bridges between adjacent meta-atoms. Moreover, we experimentally verify that the proposed structures can change the resonance frequency of metamaterial from 1.40, 1.10, to 0.74 THz, by changing the metamaterial unit cell from the individual atom to dimeric and tetrameric molecules, respectively.

1. Introduction

Recently, active terahertz metamaterials have received numerous attentions in realizing diverse applications by manipulating the incident terahertz waves in real-time [1]. Especially, ion-gel gated graphene terahertz modulators have provided an effective way to change the terahertz properties by applying electrical biases without any complicated optical setups [2, 3]. However, most of the active terahertz metamaterials have exhibited only simple switchable property in resonance frequency, which is hard to be utilized for multi-channel selection of terahertz waves. In this study, by controlling individual micro-patterned ion-gel gating lines on the graphene inter-connected terahertz meta-atoms, we develop a selectively reconfigurable molecularization of meta-atoms for selecting various resonance frequencies in real-time.

2. Results and Discussion

Figure 1 shows the schematic design and optical microscope images of the fabricated active meta-atom molecularization system. The proposed structure consists of metallic meta-atoms and graphene bridges for conductively controllable inter-connection between adjacent meta-atoms [3]. To control resonance frequency of the active meta-atom molecularization system, we designed micro-patterned ion-gel gating system to change the conductance of graphene bridges, individually. The micro-patterned ion-gel lines are formed on the graphene bridges in metamaterial sample by using ion-gel patterning methods as reported in [4]. Because the micro-patterned ion-gel lines were intended to select controllable gating lines, we applied two different gate voltages ($G_1$ and $G_2$) on the individual ion-gel lines to change the molecularization state of meta-atoms as monomeric, dimeric, and tetrameric meta-molecules. Figure 1b shows the electric field distributions of the proposed selective meta-atom molecularization system for the different gate bias configurations. In contrast, when $G_1 = -2.2$ V and $G_2 = 1.0$ V, since only the graphene bridge in the middle of interconnected meta-atoms has low conductivity, the proposed molecularization system can exhibit dimeric meta-atoms.
molecule resonance. Finally, when $G_1 = G_2 = -2.2 \text{ V}$, the tetrameric meta-molecule resonance occurs on the entire metamaterial sample, because four meta-atoms are conductively inter-connected to each other as shown in Figure 1b.

Figure 2a shows the simulated transmission spectra of the proposed selective meta-atom molecularization sample. By changing the gate voltage configuration as discussed above, we can confirm that the resonance frequency of monomeric, dimeric, and tetrameric meta-molecule is successfully modulated from 1.40, 1.10, to 0.74 THz, respectively. As shown in Figure 2b, the measured transmission spectra of the fabricated sample show well defined three different resonance properties, which are very similar with the simulated transmission spectra. These results clearly show that the micro-patterned ion-gel gating structure can selectively control the graphene bridges to achieve three different resonance frequencies. Therefore, we can expect that the multi-channel frequency modulators can be realized by using the proposed electrically controllable selective meta-atom molecularization systems in the terahertz regime.

3. Conclusions

In conclusion, we successfully demonstrated that the electrical reconfiguration of the terahertz meta-molecules by selectively control the conductance of graphene bridges between adjacent meta-atoms with micro-patterned ion-gel gating lines. Moreover, we found that the fabricated sample could actively change its resonance frequency in the spectral range from 0.74 to 1.40 THz with three different gate bias configurations. These intriguing active properties indicate that the proposed metamaterials can customize their resonance properties by changing the numbers of interconnected graphene bridges, which will pave the way for diverse applications including frequency tunable and switchable filters in terahertz and optical regime.

Abstract

Tunable plasmonic modes offered by graphene provide new opportunities to create electro-optically active devices with novel characteristics that have thus far been impossible to be realized by using conventional media. Here we introduce two recent theoretical research results in mid-IR graphene plasmonics: (1) Dynamic complex amplitude modulation in graphene-based metasurfaces and (2) modulated resonant transmission of graphene plasmons across a deep-subwavelength plasmonic waveguide gap.

Electronically Tunable Graphene Metamolecules for Complete Complex Amplitude Modulation

Metasurfaces have been shown to manipulate wavefront of light in subwavelength structures, overcoming the limitations in conventional optical systems. Although many efforts have been made to realize dynamic wavefront reconstruction in nanophotonic elements, current active metasurfaces suffer from inevitable interference between amplitude modulation and phase modulation as well as limited range in tunabilities. Here, we report dynamic complete complex amplitude modulation in metamolecules operating in the mid-infrared. The metamolecule is composed of a pair of metaatoms, and graphene plasmonic nanoresonators are utilized to incorporate electronically tunable functionalities. In the metamolecule, the two metaatoms are independently controlled to secure the two degree of freedoms required for modulating the amplitude and the phase of light, enabling \(2\pi\) phase shift as well as large amplitude modulation including perfect absorption. We develop a generalized graphical model to examine the underlying requirements for complete complex amplitude modulation, offering intuitive design guidelines to maximize the tunabilities in metasurfaces. To illustrate the reconfigurable capability of our designs, we demonstrate dynamic beam steering and holographic wavefront reconstruction in a structurally identical metasurface by simply tuning the metamolecules.

Modulated Resonant Transmission of Graphene Plasmons Across a \(\lambda/50\) Plasmonic Waveguide Gap

We theoretically demonstrate the nontrivial transmission properties of a graphene-insulator-metal waveguide segment of deeply subwavelength scale. We show that, at mid-infrared frequencies, the graphene-covered segment allows for the resonant transmission through the graphene-plasmon modes as well as the nonresonant transmission through background modes, and that these two pathways can lead to a strong Fano interference effect. The Fano interference enables a strong modulation of the overall optical transmission with a very small change in graphene Fermi level. By engineering the waveguide junction, it is possible that the two transmission pathways perfectly cancel each other out, resulting in a zero transmittance. We theoretically demonstrate the transmission modulation from 0% to 25% at 7.5-\(\mu\)m wavelength by shifting the Fermi level of graphene by a mere 15 meV. In addition, the active region of the device is more than 50 times shorter than the free-space wavelength. Thus, the reported phenomenon is of great advantage to the development of on-chip plasmonic devices [1].

Abstract

Vertical cavity metasurface-emitting lasers (VCMEls) have been proposed and designed into back-emitting configuration. We have demonstrated that the integration with metasurface allow the effective control of the lasing emission wavefront.

1. Introduction

Vertical cavity surface emitting laser (VCSEL) technology has been rapidly and consistently developing over the last 30 years, in particular after the demonstration of the first continuous-wave room-temperature device.[1,2] The unique features provided by this type of lasing devices such as low-power consumption, wafer-level testing, circular output beam profile, large-scale two-dimensional (2D) array have made them the most versatile laser sources for various applications including fiber optics optical communications, laser manufacturing, smart-glasses and etc.[3,4] Metasurfaces have emerged as a new class of subwavelength-carved two-dimensional optical components, offering exceptional spectral and spatial controllability over the electromagnetic waves. Their extraordinary capabilities of molding the light in a very compact and efficient ways have been demonstrated from a large variety of novel optical components including frequency selective surface (FSS), polarization converter, wavefront shaping and hologram [5–7]. In comparison with conventional optical components, their unique planar configuration and their CMOS compatible processing techniques hold great potential for monolithic integration into semiconductor optoelectronic devices.

In this work, we propose a wafer-level approach that addresses the problem of wavefront engineering without altering the VCSEL characteristics. Arrays of identical devices with varying beam deflecting properties, called vertical cavity metasurface-emitting lasers (VCMEls), can be fabricated on the same chip. The realization of array of identical emitting beam shaped lasers would find various applications, including image forming and compact laser scanning systems.

2. Discussion

As shown in Fig. 1(a) and (b), our approach consists in integrating wavefront engineering high index dielectric metasurfaces into back-emitting configuration to arbitrary control the phase of lasing beam for directional beam emissions. Centro-symmetric GaAs nanopillars of different diameters are employed as polarization insensitivity meta-atoms. The phase and amplitude of the scattered light can be controlled by adjusting the pillar radius as determined by the finite difference time domain (FDTD Lumerical) simulations, as shown reported in Fig. 1(c).

![Fig.1 The Schematic (a) and photograph (b) of VCMEls, (c) The transmission and the phase of the designed GaAs nanopillars as a function of its radius at λ=980 nm, the inset represents a single nanopillar.](image-url)
emitting beam and their corresponding x-cut intensity profiles, as shown in Fig. 2(b). It can be seen that the beam size of the device with metasurface remains almost the same along the propagation direction. Furthermore, the intensity profile of the emitting beam of the VCMEL can be well fitted into Bessel function. The above facts indicate the generation of Bessel beam from this VCMEL. Moreover, dynamic beam steering can be realized by making advantage of the two dimensional array of VCMELs. As a proof of concept, a chip of 8x8 VCMELs has been fabricated as shown in Fig. 2(c) and (d). Metasurface based beam deflector with different deflection angle has been integrated onto it, respectively. Such configuration allows each VCMEL from the same chip to individually emitting a deflected beam with a given angle to be used for the dynamic beam steering applications.

3. Conclusions

In this work, vertical cavity metasurface-emitting lasers have been proposed and designed into back-emitting configuration for directional beam emissions. We demonstrated that the wavefront of the lasing beam from the VCMELs can be controlled and arbitrarily shaped arbitrarily with properly designed metasurfaces, thus leading to compact, wafer-level collimation and wavefront shaping of laser radiation.

Light sailing to interstellar space and nearby stars

Artur R. Davoyan¹²

Abstract
In this talk we will overview our recent efforts directed at the design of light sails for interstellar missions. We will highlight our ongoing work on both solar and laser sailing with a particular emphasis on photonic materials, sail design criteria, and light-materials interaction.

1. Introduction
Past sixty years of space flight have led to fascinating discoveries within our solar system. Regular missions to inner and outer planets pave the way to new scientific discoveries informing about the solar system formation and the origins of life. Nonetheless, space travel to Neptune and beyond it into the interstellar medium presents a significant technological challenge. Hence, to date only two space probes – Voyager 1 and Voyager 2 – have crossed the boundaries of our heliosphere. It took them over 40 years of flight to reach the interstellar space. Clearly, novel breakthrough advances are needed to enable sustainable and scalable exploration of the outskirts our solar system and for interstellar flight. In this talk we will discuss conceptually new ways of spacecraft propulsion that can revolutionize the future of deep space exploration. In particular, we will show that photon propulsion may be capable of accelerating a lightweight spacecraft to unprecedented velocities beating currently achieved records. We will discuss two means of light driven propulsion, including solar sailing and laser sailing, highlighting challenges and opportunities of both of these technologies.

2. Solar sailing
Solar sails have recently emerged as a robust means of in-space spacecraft propulsion. In particular several technology demonstration missions have been launched within the past decade, with a number of missions scheduled for launch in the next couple of years, including Near Earth Asteroid Scout. Solar sails make use of sunlight radiation pressure and are propelled essentially without using any energy. Whereas sailing in the inner solar system has been demonstrated and regular missions are planned, sailing into the interstellar medium remains of a big technological challenge. It has been shown recently that with the use of solar gravity assist and high solar radiation flux in the vicinity of the sun, sails may be propelled to over 25 AU/year – unprecedented velocities outperforming any the known and demonstrated propulsion means. However, such a propulsion requires a very close approach to the sun, posing a significant problem for materials science, thermal engineering, and trajectory control. We will survey these challenges and highlight our work on identifying suitable designs that can enable future interstellar solar sail missions.

3. Laser sailing
Laser sailing has the potential to advance space travel to even higher velocities and distance. Hence, recently established Breakthrough Starshot Initiative poses an audacious goal of propelling a spacecraft to 20% of the speed of light in order to reach a potentially habitable planet in the Alpha Centauri star system in just 20 years [1]. Achieving this unprecedented speed requires engineering at the limits of current technology. In particular, project assumes that a lightweight sail with a payload will be propelled with the use radiation pressure from a high powered phased array of lasers on Earth (~10 GW/m² of net laser intensity). The lightsail should have an area of ~10m² with a mass of under ~1 gram. Clearly, design of the lightsail will need to push the boundaries of materials science, photonic design and systems engineering to enable performance at these extreme conditions and constraints. We will discuss these challenges in the second part of the talk. Specifically, we will talk about photonic materials, thermal control, and highlight the issues of laser beam riding stability. We will then discuss the possible use of nanophotonics in the design of sustainable and stable Starshot lightsail. We will survey key challenges and discuss potential solutions.

4. Conclusions
We will review our efforts in the design of novel photonic materials for future photon driven in-space propulsion. We show that solar and laser sailing may disrupt the way of space exploration paving the way to conceptually new interstellar missions.

Abstract

Metasurface enables a new paradigm to manipulate electromagnetic wave by tailoring subwavelength artificial structures, which provides a promising method for compact, cascadable, and miniaturization elements in integrated optics. Here, we review some of our works on passive dielectric metasurfaces and Kerr nonlinear tunable metasurfaces enabled by metallic quantum wells. The mentioned metasurface may lead important applications in image processing, sensing, switching, and multifunctional photonics devices.

1. Introduction

Metasurface, two-dimensional equivalent of metamaterial, is composed of discrete subwavelength structures, which possesses the capability of full control of light properties [1, 2]. Here, we present a broadband dielectric spin Hall metasurface achieved by integrating two geometric phase metasurface into one single dynamic phase lens, which is demonstrated to control photonic spin-dependent splitting on transverse and longitudinal directions simultaneously at the whole visible range. Furthermore, we study the tunable Kerr metasurface based on quantum sized metal film with enhanced giant optical nonlinearity. By changing the incident optical power through the designed metasurface, the active functionality of the device could be achieved.

2. Passive and active metasurface

In this section, we will first introduce the broadband dielectric spin Hall metasurface, which attain the spin dependent splitting in multiple directions [3]. Then, the nonlinear tunable Kerr metasurface enabled by metallic quantum well is studied [4].

2.1. Broadband dielectric spin Hall metasurfaces

Figure 1(a) describes the schematic drawing of the spin-dependent splitting in transverse and longitudinal directions. When the photonic spin Hall metasurface (PSHM) is normally illuminated with a linearly polarized (LP) Gaussian light beam, the transmitted beam composing both left-handed circularly polarized (LCP) and right-handed circularly polarized (RCP) components are generated, respectively. The LCP and RCP beams propagate towards different directions and focused at different depths, which corresponds to the desired longitudinal spin-dependent splitting. The microscopy images of the employed PSHM is shown in Figure 1 (b)-(e). Here, the PSHM is fabricated by a laser writing method in a glass substrate, which avoids the typical high-resolution photolithography or e-beam lithography process [5]. As we can see in Figure 1(b) and (c), PSHM is embedded inside of the glass slide. The dark-field optical image (Figure 1(d)) reveals that the laser written layer has a thickness around 80 μm. The SEM image in Figure 1(e) further confirms that the laser exposure formed some self-assembled vertically aligned nanostructures at deep subwavelength scales.

Figure 1. (a) Schematic illustration of transverse and longitudinal splitting by using a photonic spin Hall metasurface (PSHM). (b) Top-view photograph of the PSHM sample. Inset: zoomed-in view shows the center patterned area of the sample. (c) Side-view photograph of
the PSHM sample. Scale bar, 4 mm. (d) The dark field microscopy image for the cross-section of the PSHM sample reveals microscopic laser written patterns. (e) Zoomed-in SEM image of the boxed area in Figure 1(d). Scale bar is 300 nm.

2.2. Kerr metasurface enabled by metallic quantum wells

Active, tunable, and reconfigurable devices are highly desirable in modern electromagnetic and photonic systems, since they create the dynamic manipulations of the incident wave. Optical Kerr effect provides a straightforward solution for such tunable metasurface and devices. However, the Kerr effect of traditional materials is typically too low to fulfill the aforementioned task. Recently, ultrathin metal films with a giant optical Kerr nonlinear response has been demonstrated due to the quantum size effect [6]. Here, we proposed a tunable metasurface design that is employed such quantum-sized gold films. Figure 2(a) shows the basic unit of the nonlinear metasurface, consisting of 6 pairs of Au-SiO$_2$ multilayers (3 nm Au and 2 nm SiO$_2$), 50 nm MgF$_2$ spacer layer, and 80 nm gold layer as a back mirror. One-unit cell length is $L_u$=300 nm, and its width is $L_w$=120 nm. Figure 1(b) shows the linear permittivity $\varepsilon = \varepsilon_r + i \varepsilon_i$ for the 3 nm gold film (red lines, obtained experimentally from an identical Au-SiO$_2$ multilayer) and bulk gold (blue lines, from Johnson and Christy) [7]. Figure 2(c)- (h) shows the performance of designed nonlinear metasurface based on proposed materials at the case of oblique incident light. When the incident light angles are 15°, 30°, and 45°, the linear far field results are shown in Figure 2(c)- (e). As we can see, the metasurface acts as a mirror with most of the energy going into the specular reflection angle at the low intensity. When the incident light intensity becomes large, most reflected energy goes into diffraction orders, as shown in Figure 2(f)- (h).

![Figure 2](image.png)

Figure 2. (a) Schematic of a building block of the nonlinear metasurface. The whole structure sits on a glass substrate, which is made of a top multilayer nanostructure and a bottom bulk gold layer separated by a spacer layer, MgF$_2$. (b) Permittivity (solid and dashed lines for real and imaginary parts, respectively) for 3 nm gold (red) and bulk gold (blue). (c)-(h) Simulated angular distribution of the reflected far field. The linear ($I$=1MW/cm$^2$) cases of the incident angles of 15°, 30°, and 45° are shown in (c), (d) and (e), respectively. The corresponding nonlinear ($I$ = 1GW/cm$^2$) cases are shown in (f), (g) and (h), respectively.

3. Conclusions

In this work, we have introduced two types of metasurfaces, passive dielectric metasurfaces and Kerr metasurfaces enabled by metallic quantum wells. The passive dielectric metasurface have been demonstrated to achieved multiple directions splitting, which could be an integrated metasurface by combining with several single functional metasurface. For the Kerr type metasurface, by varying the optical power of the incident light through quantum sized gold film, the active functionality of the material can be achieved. At low power region, the device acts as a normal reflecting surface. It becomes a phase grating when the incident power is high enough. The mentioned metasurface indicates potential applications in image processing, switching, modulator and multifunctional photonic devices.

Enhancing Chiral Light-Matter Interactions by Metamaterials

Yongmin Liu$^{1,2,*}$

Abstract
In this talk, I will discuss how to design novel metamaterials by symmetry analyses and deep learning to enhance chiral light-matter interactions, which promise important applications in polarimetric imaging and enantioselective sensing.

1. Introduction

Chirality refers to the structural property of an object that cannot be superposed onto its mirror image. The existence of chirality in nature is universal, ranging from molecules at the nanoscale to gastropod shells at the macroscale. Light can be chiral as well. Circularly polarized light with opposite helicity has its electric field vector rotating clockwise or counterclockwise during propagation. Chiral light-matter interactions are widely used in molecule detection, optical communication and quantum information processing. However, the chiroptical response of natural materials is inherently weak. The advent of metamaterials, which are composed of artificial meta-atoms with elaborately engineered optical properties [1], offers an elegant and effective solution to this problem. Over the past decades, a variety of metamaterials with strong intrinsic and extrinsic chiral responses have been demonstrated [2-4].

Here we show how we can design chiral metamaterials based on symmetry analyses and deep learning technique to greatly enhance chiral light-matter interactions. More specifically, we design and demonstrate the so-called chiral metamirror, which can achieve near-perfect reflection of designated circularly polarized light without reversing its handedness, yet complete absorption of the other polarization state [5-8]. It is analytically shown that the building block of such a metamirror needs to simultaneously break the n-fold rotational (n > 2) symmetry and mirror symmetry [7]. Such a metamaterial can be used for polarimetric imaging to extract the polarization information of light [8]. However, the guidelines based on symmetry requirements are insufficient when we want to quantitatively design a metamaterial structure given a desired chiral response or even to simply predict the trend in chiral response as the structure transforms. To overcome this limitation, we have recently applied the deep learning approach to accelerate the design of chiral metamaterials with prescribed chiroptical responses [9]. Our findings would lead to novel metadevices for circular dichroism spectroscopy, enantioselective sensing and sorting.

2. Results

To design a chiral metamirror that can selectively reflect one designed state of circular polarization, we first analyze the necessary symmetry conditions based on Jones calculus. We can readily prove that complete reflection of left circularly polarized (LCP) waves and total absorption of right circularly polarized (RCP) waves require the reflection matrix satisfying

$$ R = \begin{pmatrix} r_{xx} & r_{xy} \\ r_{yx} & r_{yy} \end{pmatrix} = \frac{e^{i\theta}}{2} \begin{pmatrix} 1 & i \\ i & -1 \end{pmatrix} $$

(1)

Then based on symmetry analysis, including rotational and mirror symmetries, we can derive the structural symmetry required for the chiral metamirror. In short, the general yet necessary condition to realize the chiral metamirror is simultaneous breaking of the n-fold rotational (n>2) and mirror symmetries [7].

Figure 1: (a) Comparison of the reflection behavior of a chiral metamirror and a regular mellicet mirror. A chiral metamirror composed of enantiomer A (B) reflects RCP (LCP) incident light and absorbs the entire LCP (RCP) component. (b) Schematic of the fabricated hand pattern. The exterior and interior regions of the hand are formed by enantiomer A and B, respectively. (c) Microscopic images of the metamirror. The sample is illuminated by circularly polarized light, and the reflected light is recorded by a camera after it passes through a circular polarized analyzer.
In collaboration with Prof. Wenshan Cai’s group, we have demonstrated a chiral metamirror consisting of a sandwich system with an asymmetric-hole array perforated film, a thin dielectric layer and an optically thick metallic back plane [8]. In contrast to a metal mirror, there are distinct features associated with the metamirror, that is, the chiral selective absorption and the circular polarization preservation, which are schematically shown in Figure 1a. These features are unambiguously identified through a comprehensive visualization of a fabricated sample, in which a hand pattern consists of the designed enantiomer B while the outside region consists of enantiomer A (Figure 1b). From Figure 1c, one can see that for LCP incident light, a bright hand against a dark surrounding area can be seen with a LCP analyzer, while the entire metamaterial pattern becomes dark when a RCP analyzer is applied. Furthermore, the imaging behavior completely inverts when a RCP wave impinges upon the sample, i.e., a dark hand stands out with a bright background with a RCP analyzer implemented. Note the reflection from the boundary of sample, which is unpatterned metallic film, always shows the opposite contrast compared to the hand pattern, because the spin state reflected from a regular metallic film is always flipped. These results comprehensively visualize the chiral-selective reflection and the circular polarization preservation properties of the chiral metamirror.

Figure 2: (a) Schematic of the designed 3D chiral metamaterial. (b) Illustration of the deep learning model to predict the optical response of chiral metamaterials and inversely design the geometry of chiral metamaterials. (c) Prediction results for the full reflection spectra (top) and circular dichroism spectra (bottom) in comparison with the ground truth.

Although the symmetry requirements provide some useful guidelines for us to design chiral metamaterials, there is no closed-loop solution to efficiently construct the specific metamaterial structures from given requirements, such as the operating wavelength and strength of chirality. This is mainly due to the nonintuitive and highly nonlinear relationship between geometric chirality and chiroptical responses. To solve this problem, we employ the deep-learning technique to automatically model and optimize three dimensional chiral metamaterials [9]. As illustrated in Figure 2a, the unit cell of the metamaterial consists of two stacked gold split ring resonators twisted at a certain angle and separated by two spacing dielectric layers with a continuous gold reflector at bottom. Depending on the geometry, including the size, separation distance and twisting angle of the SRRs, this metamaterial can function as a chiral meta-mirror enabling selective reflection of designated circularly polarized light without reversing its polarization state. We have developed a deep learning model allowing data to flow in both forward path and inverse path as illustrated in Figure 2b. The predicted results from neural networks are in very good agreement with the numerical simulation (Figure 2c), which clearly verifies that neural network can indeed model the complicated nonlinear relationship between meta-atoms and the desired spectral features.

3. Conclusions

The necessary symmetry requirements for a chiral metamirror has been obtained, and its unique optical functionality, that is, selective reflection of one circular polarization without flipping the polarization state, has been experimentally demonstrated. Furthermore, we propose a purpose-designed deep-learning model to accelerate the design of chiral metamaterials. These results open up a new way to design novel metamaterials for circular dichroism spectroscopy, polarimetric imaging, enantioselective sensing, sorting and synthesis.

Microfluidic Sensing and Dynamic Tuning with Huygens Metasurfaces

Adam J. Ollanik, Isaac O. Oguntoye, George Z. Hartfield, Brittany Simone, Yaping Ji, and Matthew D. Escarra

*corresponding author, E-mail: escarra@tulane.edu

Abstract
Huygens metasurfaces have optical performance that is especially sensitive to perturbations in their geometry or constituent material properties. Here we take advantage of this sensitivity for both sensing and dynamic tuning applications. First, we show that silicon metasurfaces embedded in a microfluidic channel provide an affordable, customizable, and highly sensitive platform for refractive index sensing, with experimental transmittance response of 820% T/RIU. Second, we show that by using VO$_2$ for the antenna elements, we can create dynamically tunable metasurfaces.

1. Introduction

Huygens metasurfaces are characterized by spectrally overlapping electric and magnetic dipole resonances. These nanoantenna structures each act as a point emitter for light of resonant wavelengths, and their interactions with incoming light are highly sensitive to geometric parameters, such as antenna width, height, and spacing, and material parameters, such as antenna, substrate, and encapsulant refractive index. For a homogeneous array of these antennas, by tuning any one of these geometric or material properties by ~10%, the optical response of these antennas can be tuned from near unity transmission to near unity reflection of incident light, at a specified wavelength. This level of sensitivity can be useful in a variety of contexts, including liquid or gas-phase sensing, tunable optics, optical computing, communications, and more.

2. Refractive Index Sensing with Silicon-Based Metasurfaces

Dielectric Huygens metasurfaces provide a practical platform for very low-loss manipulation of light, with efficiency of anomalous refraction of at least 78% of incident light expected for ultraviolet, visible, and near-infrared wavelengths [1]. Such structures may also take advantage of overlapping electric and magnetic field resonances to create metasurfaces that either transmit or reflect with near unity (>99%) efficiency, with only minor differences in geometry or material properties. These CMOS compatible structures may be fabricated over large area and may be integrated with microfluidic arrays for liquid or gas-phase sensing. This sensing is accomplished by directly assessing changes in the refractive-index of the medium surrounding the antennas. While most resonance-based sensing techniques employ optical spectroscopy to measure shifts in the resonant wavelength, here we show that with Huygens metasurfaces, such a measurement may be done with a single wavelength method, providing significant cost savings by using a simple light source and photodetector.

We fabricate such a metasurface, integrate it with a microfluidic channel, and experimentally measure sensitivity of 323 nm/RIU (refractive index unit) for 1217 nm light using purified water contrasted with a saline solution ($\Delta n = 0.0062$). This corresponds to a figure of merit of 5.4 (figure of merit defined as sensitivity divided by linewidth of the reflectance peak) and a single wavelength transmittance response of 820% change in transmittance per RIU. We further measure the contrast between purified water and 25*10$^8$ M solution of CaCl$_2$ ($\Delta n = 0.0006$), with a measured response of 880% change in transmittance per RIU. Techno economic analysis predicts a device costing ~$2400 with ability to measure refractive index changes on the order of 2*10$^8$. We are currently fabricating a hand-held, integrated, low-cost sensor prototype based on this single-wavelength metasurface sensing technique [2].

Furthermore, by utilizing off-normal anti-symmetric resonances, we computationally demonstrate a Huygens metasurface with sensitivity of 350 nm/RIU, figure of merit of 219, and single wavelength transmission response of 36,000% per RIU. This FOM exceeds that of any previously reported plasmonic or dielectric nanostructure surface-based refractive index sensor [2].

3. Dynamically Tunable VO$_2$ Metasurfaces

The sensitive nature of Huygens metasurfaces makes them ideal for dynamic tuning applications, where the optical performance of the metasurfaces may be tuned by an external stimulus, such as electric field, optical irradiation, or temperature change. Here we use vanadium dioxide (VO$_2$) as the material for these resonant nanoantennas. VO$_2$ is well-known for its metal-insulator phase transition at
relatively low temperature (~70°C). Our modeling shows that metasurfaces from these materials have strong optical tunability within less than 10% of the phase transition from insulator to metal. We synthesize thin VO₂ films using pulsed laser deposition and pattern these films into nanoantennas using reactive ion etching, via a chlorine-based etch, to achieve desired geometries. Experimental analysis is ongoing, and resonant tunable metasurfaces will be presented.

In order to accurately characterize the properties of dynamically tunable thin films and metasurfaces, one must measure transmission and optical phase shift as a function of external stimuli. We have developed a unique three-beam interferometry technique to perform this characterization. Our approach leads to a >92% decrease in both noise and drift of measured phase shift, achieved through constant measurement referencing with a third beam. We demonstrate this phase shift measurement capability on temperature-tuned VO₂ thin films, and we also show its effectiveness with resonant silicon-based dielectric metasurfaces. An additional method, utilizing Fourier transform processing of measurements with artificially induced periodicity, allows accurate measurement of phase shift with standard deviation of 0.067°, significantly beneath the floor of both noise and drift in our measurements. We demonstrate the effectiveness of this technique by measuring phase shift differences due to monolayer thickness variations in two-dimensional MoS₂ materials.

Finally, in pursuit of passive and active metaholograms from dielectric and phase change Huygens metasurfaces, we report on a design algorithm that takes into account the strong nearest neighbor coupling of these resonant structures. By properly extracting the phase shift of individual antennas despite the coupling to their neighbors, we may build a toolbox of phase-shifting elements that may be used for complex phase front manipulation with resonant Huygens metasurfaces.

4. Conclusions

In summary, we report on highly resonant Huygens metasurfaces from low-loss dielectric and phase change materials. The strong sensitivity of these antenna arrays to changes in material properties enables high performance in a number of important applications. Here we demonstrate their implementation in affordable and highly sensitive microfluidic refractive index measurements. We also show their potential for use in dynamically tunable metasurfaces.

van der Waals Metasurfaces and Transdimensional Photonic Lattices

Viktoriia Babicheva

College of Optical Sciences, University of Arizona, Tucson, AZ, United States
E-mail: vbab.dtu@gmail.com

Abstract

Transdimensional photonics is an emerging field of science and engineering dealing with the optical properties of nanostructures in the translational regime. We consider optical nanoantennas out of hexagonal boron nitride (hBN) which is a natural material with hyperbolic dispersion in the mid-infrared spectral range. The hBN nanoantennas in the lattice support multipole electric and magnetic resonances, and such lattice possesses a 2D/3D translational nature as the optical properties are defined by nanoantenna size and shape as well as in-plane lattice arrangement.

1. Introduction

Nanostructures with excitation of phonon-polaritons have been suggested as an alternative to conventional metals supporting plasmonic resonances. Phonon-polariton excitations in strongly anisotropic van der Waals materials, such as hBN and orthorhombic molybdenum trioxide, enable propagative waves with hyperbolic dispersion and ultra-tight mode field confinement.

Antennas made of hyperbolic (meta)materials along with and dielectric nanostructures can be used for designing optical resonators and scattering elements in metasurfaces [1]-[3]. We propose van der Waals metasurface that includes periodic array of hBN antennas and study different multipole resonances in the lattice (Fig. 1). Nanoantenna resonances and optical properties of the metasurfaces can be controlled by scatterers’ size and shape as well as periodic arrangement of the antennas in the lattice and cross-coupling of the multipole resonances.

2. Model

In the cuboid particle with strongly reflective boundaries and dimensions $a_x$, $a_y$, and $a_z$, resonances occur when

$$k_i a_i = \pi n_i,$$

where $i = x, y, \text{or } z$, and $n_i$ are the integers. In turn, in the hyperbolic medium, the propagation wavenumber ($k_x$, $k_y$, $k_z$) satisfies the dispersion equation

$$\frac{k_x^2 + k_y^2}{\varepsilon_z} + \frac{k_z^2}{\varepsilon_x} = k_0^2,$$

where $\varepsilon_x$, $\varepsilon_y$, and $\varepsilon_z$ are permittivity component of the nanoantenna material, $k_0 = 2\pi/\lambda_0$, and $\lambda_0$ is the free-space wavelength.

Figure 1: The transdimensional lattice of hBN nanoantennas that incorporates 3D design of the resonators, including size and shape, and 2D periodic arrangement of the nanoantennas.

Thus, from Eqs. (1)-(2), in the resonance of hyperbolic nanoantenna, the following condition is satisfied and defines conditions for nanoantenna resonances in case of material with anisotropic permittivity tensor:

$$\frac{1}{\varepsilon_x} \left( \frac{n_x}{2a_x} \right)^2 + \frac{1}{\varepsilon_y} \left( \frac{n_y}{2a_y} \right)^2 + \frac{1}{\varepsilon_z} \left( \frac{n_z}{2a_z} \right)^2 = \frac{1}{k_0^2}.$$

Hexagonal boron nitride nanoparticle supports electric and magnetic multipole resonances in the mid-infrared wavelength range (around 6-7 and 13 \text{\mu m}). Because of the hyperbolic dispersion of the medium, higher-order multipole resonances appear at the longer wavelength with respect to dipole ones. The nanoantennas support excitations of magnetic resonances because of the high-$k$ wave reflection from antenna boundaries, and it brings an additional degree of freedom in designing metasurfaces with subwavelength scatterers.

3. Lattice resonances

The excitations of lattice resonances in the hBN nanoantenna array closely follow Rayleigh anomaly. Upon overlap of the nanoantenna multipole resonances, one can observe a decrease of reflection with resonant scattering.
forward by the antennas in the array, which indicates that generalized Kerker condition of forward scattering is satisfied.

4. Discussion

Material or metamaterial that possesses hyperbolic dispersion supports high-$k$ modes, and consequently, an effective mode index in such hyperbolic medium can be much higher than the one in high-refractive-index dielectric nanostructure or plasmonic one. The thickness of hBN nanoantennas with strong multipole resonances can be further decreased down to several hundreds of nanometers and facilitate ultra-thin optical components and metasurfaces.

Abstract

Chalcogenide glasses (ChGs) are of interest for use in dielectric metastructures for several reasons. They typically possess high linear refractive indices, enabling high index contrast devices; they exhibit exceptionally large optical nonlinearities, making them useful for tunable applications; and they have wide transmission windows extending from the visible through the long-wave infrared. We discuss the potential advantages of these materials in the context of dielectric metasurfaces and present recent results for both passive and active devices.

1. Introduction

ChGs are amorphous semiconductors that contain as a major constituent at least one of the “chalcogen” elements – sulfur, selenium and tellurium – covalently bonded to network formers such as As, Ge, Ga, Sb, etc. They have a number of properties that distinguish them from other glass families. Their refractive indices are typically large. For instance, the linear refractive index, \( n \), of As₂S₃ is approximately 2.4 and that of As₂Se₃ is even higher, with \( n=2.8 \). ChGs can also have exceptionally high values for their nonlinear index of refraction \( n₂ \), with values >1000× that of silica observed [1]. This high nonlinearity makes them good candidates for both tunable metamaterials and nonlinear frequency conversion. Their low phonon energies result in wide transmission windows that, depending on composition, may extend from the visible through beyond 14 \( \mu m \). Thus, they are useful for devices operating in various parts of the optical spectrum, potentially in bands not accessible with traditional glasses.

ChGs have been used for decades in bulk or fiber optic form. More recently, they have been used in thin film form for integrated optic applications [2]. Thin films of ChGs are appealing for several reasons. Many compositions can be deposited simply via thermal evaporation or sputtering, with the composition of the deposited film matching that of the source material. Some ChG materials can act as a photoresist [3], making it straightforward to directly pattern devices. Furthermore, it is possible to locally alter their properties via a photodoping procedure [4], permitting the fabrication of devices with a spatially varying nonlinearity.

Recently, the authors have shown results for nonlinear metasurface devices based on AsS thin films that control the orbital angular momentum (OAM) of a beam [3, 5]. In these devices, the OAM state of the output beam depends on the input beam intensity. In addition, they have demonstrated initial passive devices in AsSe, a material that is of interest for its even higher nonlinear refractive index compared to that of AsS [6]. Here, we summarize ChG properties for a range of compositions, discuss results for their use in metamaterial devices, and consider their prospects for use in future devices.

2. Experiment

Bulk ChG samples were batched from purified precursors in an \( \text{N}_2 \)-purged glovebox. For a given glass composition, a melt was formed by heating the precursors in a sealed quartz ampoule in a rocking furnace. The glass boule was removed, and small pieces were used as deposition materials. Thin films were deposited via thermal evaporation. The resulting films were spatially uniform with low surface roughness (typically, with root mean squared roughness <10 Å) and with compositions similar to those of the deposition materials. Images of an example ChG are shown in Fig. 1 in (a) bulk and (b) thin film form.

Figure 1: A sulfide ChG in (a) bulk and (b) thin film form.
Films were patterned either using traditional photolithography, with a polymer photoresist, or directly, using the ChG as a photoresist.

3. Discussion

A simple metasurface was designed using an As$_2$Se$_3$ glass film on a crystalline Si substrate. The metasurface consists of an array of holes in in the film arranged in a square grid. The metasurface is bordered on the top by air, and the hole is filled with air as well. The lattice constant, $a$, was fixed at 1.32 µm, and the thickness of the film, $t$, was fixed at 200 nm. For modeling purposes, the width of the hole was $a×f$ where $f$ ranged from 0.3 to 0.65, and the free space wavelength, $λ_0$, ranged from 1.0 to 4.0 µm. The thicknesses of the air and Si layers were both 4.0 µm. The metasurfaces were modeled using COMSOL Multiphysics. The sides of the unit cell were treated as a periodic boundary, so modeling an individual unit cell permitted the prediction of the response of an infinite array of holes.

The predicted transmittance, $T$, of this structure is shown in Fig. 2(a) as a function of both $f$ and $λ_0$. Two distinct bands of high $T$, adjacent to bands of low $T$, are evident across all values of $f$, representing resonant modes of the structure. The presence of higher order modes can be observed for shorter wavelengths.

Metasurfaces based on this design were fabricated with $f$=0.56. In order to perform lithography, a laser direct write system was used to pattern a photoresist layer, and the As$_2$Se$_3$ was patterned via the lift-off method. $T$ was measured as a function of $λ_0$ using a spectrophotometer. The results for both a metasurface and a neat film are shown in Fig. 2(b). $T$ is corrected to account for Fresnel reflection from the back surface of the Si substrate. For the metasurface sample, a resonance is clearly visible with a decrease in $T$ at $λ_0$=2.25 µm, with a higher $T$ band on either side. A weaker resonance is evident near $λ_0$=1.3 µm with a less pronounced decrease in $T$. This resonance is partially masked by the roll off in $T$ due to substrate absorption for shorter $λ_0$. While the resonances have a similar form to that predicted by the model, their magnitude and position differ slightly, with the model predicting dips near $λ_0$=1.5 and 2.0 µm. The differences are likely due to imperfections in lithography, which can cause a variation in feature size and rough sidewalls as well. In addition, the dispersion curve of the deposited As$_2$Se$_3$ may differ slightly from the values used for modeling.

4. Conclusions

In this work, we evaluate the potential of various ChG film materials for their use in metamaterials. The high refractive index, optical nonlinearity, and wide transmission windows of these materials make them appealing for metamaterial applications. Simple devices were patterned in an As$_2$Se$_3$ film, showing the presence of resonances similar to those predicted by modeling. Future designs will take advantage of the high nonlinearity of As$_2$Se$_3$ and other ChG to realize tunable devices and nonlinear frequency generation.

Optical elements based on engineered subwavelength dielectric structures

Andrei Faraon
T.J. Watson Laboratory of Applied Physics, California Institute of Technology, Pasadena, CA, USA
*corresponding author: faraon@caltech.edu

Abstract- In this talk I give an overview of our recent work on various optical components and systems based on engineered subwavelength dielectric structures.

Flat optical devices based on lithographically patterned sub-wavelength dielectric nano-structures provide precise control over optical wavefronts, and thus promise to revolutionize the field of free-space optics. I introduce our work on high contrast transmitarrays and reflectarrays composed of high index nano-posts located on top of low index substrates like silica glass or transparent polymers. After presenting their advantages and limitations, I discuss newer concepts based on three dimensional arrangements of sub-wavelength dielectric structures.
Topological protection in spin and valley Hall metasurfaces

Abstract

Topological protection in on-chip optical devices promises strongly improved wave-guiding, insensitive to structural imperfections and environmental fluctuations. Traditional approaches, however, suffer from practicability challenges at optical wavelengths. Periodic dielectric metasurfaces based on optical analogues of the quantum spin and valley Hall effects have recently emerged as a potential remedy, but the nature and strength of topological protection is poorly understood. We here introduce a group theoretical approach to rigorously characterize topological protection for a broad class of designs.

1. Introduction

Since Haldane and Raghu proposed an optical analogue of the integer quantum Hall effect [1] in the advent of topological photonics in 2008, the field has grown substantially. The broad interest in these entirely classical systems is mainly founded in the unique and practically relevant unidirectional edge mode propagation behaviour being insensitive to fluctuations and perturbations. While the original proposal worked as a corner stone with an experimental proof of principle following shortly after at microwave frequencies [2], the need for extremely strong static magnetic fields further up the spectrum towards near-infrared and optical frequencies deems it impractical for real-life solutions in communication and data processing technologies. A number of remedies have been proposed over the years, including emulation of the static magnetic field [3, 4], parity-time-duality symmetric spin emulation [5], and Floquet topological insulators [6].

All these approaches, however, offer limited miniaturization potential, or are expensive and hard to fabricate. Approaches based on purely dielectric platforms, conceivably related to the quantum spin Hall effect (SHE) [7] or the quantum spin valley effect (VHE) [8], have recently been established as an alternative to overcome these difficulties. While these new systems do not require exotic constituent materials or strong magnetic fields, the role and nature of topological protection is ambiguous.

Topological protection has so far been characterized by the spin and valley Chern numbers, respectively. Both these quantities are, however, no topological integers and thus do not yield topological protection in the Hatsugai or Kane Mele sense [9, 10]. Associated surface states are not guaranteed in general, nor are those existent rigorously orthogonal counter-propagating modes. Here we investigate, based on group and perturbation theory [11], in which sense and under which circumstances states are protected in the bandgap, and define a rigorous topological bulk-boundary correspondence for VHE structures. Our analysis focusses on a complete list of perturbed fully $p6mm$ (17) symmetric hexagonal structures, and can be equally applied to square lattices.

2. Methodology

Using group and perturbation theory, the physical vector space of electro-magnetic fields can be reduced to a small 4-dimensional vector space close to $K/K'$-point degeneracies. The 4-dimensional index runs over the irreducible representation (irrep) of the full wallpaper group $p6mm$ with $K/K'$-point Bloch dispersion (outer 2D vector space) and the 2D irrep of the associated little group (inner 2D Rodrigues matrix representation) [12]. The set of group generators $G$ is chosen as a 60 degrees rotation ($C_6$), a $y \mapsto -y$ mirror ($\sigma$), and a translation by the lattice constant $a$ along $x$ direction ($T$). The irrep can thus be defined by the mapping $\Lambda(C_6) = \sigma_1 \otimes R_0^2$, $\Lambda(\sigma) = 1 \otimes \sigma_3$, and $\Lambda(T) = \text{diag}(w^*, w) \otimes 1$, where $\sigma_i$ are Pauli matrices, $R_0 = (1 - \sqrt{3} \sigma_2) / 2$ is the planar Rodrigues matrix of a $C_6$ rotation, $1$ is the identity matrix, and $w := \exp \{2\pi i / 3\}$ (see [12] for details).

Perturbing around an evaluation point where the field
has a dispersion at $K/K'$ ($k = 0$) and the geometry has the full $p6mm$ symmetry ($a_g = 0$) yields the kernel finding problem $\sum_{\alpha \in G}[g - I] W_{\alpha \beta}(a_g, k, \omega) = 0$ that imposes selection rules on the corresponding $4 \times 4$ permutation matrix elements $W_{\alpha \beta}$. The associated frequency shift $\omega$ can be seen as a non-linear eigenvalue which alongside the first order perturbation fields $f_\beta$, expressed as a linear combination of fields at the evaluation point, forms the eigensolution of the problem $W_{\alpha \beta}(a_g, k, \omega_n)^{(n)} = 0$. This allows us to calculate the first Chern number [$13$] of a non-degenerate band $n$ (or a cluster of connected bands) of a closed 2D manifold within the extended parameter space $(a_g, k)$.

### 3. Topological Edge States

We enumerate the possible geometrical perturbations that break the $p6mm$ symmetry by decomposing them into space group representations. Only 3 of all possible representations lead to an opening of a band-gap and thus potentially topological edge states: The first (labeled $\Gamma 2$) opens a gap only if optical reciprocity is broken and is for example found in the Haldane model of graphene [14]. The second ($\Gamma 4$) leads to the documented VHE and two topologically strongly protected edge bands (Fig. 2), predicted by the non-trivial Chern number $C = \text{sgn}(a_g)$ of the corresponding closed manifold in the extended parameter space in two adjacent domains (Fig. 1). Well established extrema at the $K/K'$ points in the bulk bandstructure thus guarantee frequency isolated edge states at moderate arbitrary structural or environmental perturbations. The third representation ($K1$) includes the known SHE with no similar rigorous topological protection to be found, but with ostensibly spin Hall dispersion in the limit of infinitesimally small geometrical perturbations instead. Orthogonality of counter-propagating edge modes is only guaranteed in the limit of infinitesimal perturbations in both the VHE and the SHE cases. In conclusion, the VHE systems seem well suited to provide a simple platform for topologically protected wave-guiding in 2D as long as the associated limitations on backscattering immunity and inclination are not a major concern.

Abstract
We demonstrate that owing to highly-confined surface phonon polaritonic modes, the interfaces between ultra-thin germanium layers and silicon carbide substrate can be used for building diverse mid-IR photonic elements and metamaterials with small on-chip footprints at deeply subwavelength scale. We show that the unique dispersion of the interface phononic modes enables efficient resonant tuning of the optical response by small changes in the layer thickness and composition, as well as in the operation frequency of the device.

1. Introduction
Improvements in device performance and density in photonic circuits can only be achieved with interconnects exploiting highly confined and tunable states of light. Surface phonon polaritons (SPhPs) in high-index nanometric layers on polar substrates bear potential as technology-ready platform for moving forward in this direction. The reported dispersion and scaling of the SPhP modes gives high promise for efficient tuning of the polariton wavelength by small changes in the coating thickness and operation frequency of the phononic device [1,2]. In this work, we demonstrate for the first time highly-confined SPhPs and SPhP-based metamaterials on CMOS-compatible semiconductor platform, consisted of silicon carbide substrate coated with nanometric germanium film of deeply subwavelength thickness.

2. Results
Germanium structures have been fabricated on silicon carbide substrate using electron beam lithography, followed by a few to hundred nm thick Ge layers deposition and lift-off processes. Owing to its excellent adhesion, the Ge film enables low-loss ultra-smooth interfaces, which is critical for achieving high quality factors for SPhPs resonances.

2.1. Real-space nanoimaging of nanometric mid-IR resonators on Ge-SiC interface
Using scattering-type scanning near-field microscopy (s-SNOM) we demonstrate SPhPs in germanium slabs and nano-resonators on silicon carbide, and show first observations of infrared field concentration in sheet and edge modes with optical features more than two orders of magnitude smaller than the wavelength of the free-space light. As an example, s-SNOM optical image of a square Ge resonator (500x500 nm in size), made from several-nm thick film is shown in Figure 1. We experimentally demonstrate that tuning of the resonator modes is possible by a very small adjustment of the excitation frequency, providing efficient spectral control of its optical performance. We also show tuning of the resonator modes by sub-nm oxidation of germanium, which reveals atomic-scale sensitivity of the device to molecular interactions.

Figure 1: Near-field optical image of an ultra-thin nanometric germanium resonator on silicon carbide substrate. Excitation laser line is 924.5 cm⁻¹.

•

2.2. Infrared spectroscopy of Ge-SiC metamaterials
FTIR spectroscopy of metamaterials made of disk arrays and gratings revealed that that the Ge-SiC platform can be used for flexible building of mid-IR devices with small on-
chip footprints consisting of meta-cells with deeply subwavelength dimensions.

Figure 2: (a) SEM image of a metamaterial made of an array of deeply subwavelength size germanium disks on silicon carbide. (b) Dependence of metamaterial mid-IR reflection on the disk diameter.

The reflection spectrums of several disks-based metamaterials (Figure 2) show that it is possible to achieve up to ~50% absorption of far-field mid-IR radiation using a disk thickness as small as ~1% of the radiation wavelength. We note that our fabrication procedure bypasses ion etching – the fabrication step typically used for making phonon-polariton metamaterials. The procedure eliminates the damage of the polar crystal lattice, which is beneficial for achieving high quality (Q) factor resonances. The experimentally demonstrated resonance Q-factors reach ~100 and ~200 for dipole and higher order modes in Ge-SiC gratings and ~40 in disk-array metamaterials.

We further demonstrate via experiments and simulations that the Ge-SiC grating’s resonant wavelength and the field confinement can be well controlled by coupling the localized hybrid mode of the interface with the propagating SPhPs in silicon carbide. Tuning either the propagating mode or the localized hybrid mode affects the coupling, which can be controlled by the grating period or by the germanium ribbon width.

3. Conclusions

Our research would be useful in designing on-chip, low-loss and highly integrated phononic devices in the infrared part of the spectrum. By patterning a thin layer of high-index dielectric on phononic substrate, high-quality surface phonon polaritonic modes can be excited, enabling a new type of metamaterials with small unit cell dimension based on hybrid phononic-dielectric resonance. In particular, we show for the first time that nanometric interfaces between germanium and silicon carbide can support highly-confined mid-IR surface phonon polariton modes at the nanoscale. The demonstrated phononic elements features sub-micron-size footprints, supporting tunable resonances of sheet and edge modes when excited with coherent radiation with a wavelength that is up to hundred times larger than their physical dimensions. Such subwavelength resonant elements could be of interest for highly-integrated optoelectronic applications, filters and optical delay components. The concept can be potentially applied to number of technologically important semiconductor and dielectric compounds.

Abstract

We propose a spin-locking metasurface incorporating a transverse spin of the SP wave to selectively route the nearfield beams. Owing to the combination of the oblique incidence of circularly polarized light with the accurately designed momentum matching of the grating we achieve a precise directional control over the plasmonic distributions. The experimental verification of the directional launching is performed by a time-resolved leakage radiation measurements allowing one to visualize the shape and the dynamics of the excited beam.

1. Introduction

The increasing desire for nanophotonics integrated devices has led to an intensive investigation of surface waves such as surface plasmons (SP) due to their unique optical properties and compatibility with nanoelectronics\textsuperscript{1,2}. Different types of nanopatterned metallic surfaces have been proposed as functional metasurfaces capable of locally modulating the plasmonic wavefront phase and amplitude. Upon these, the metasurfaces providing an externally controlled near-field manipulation seem to be particularly appealing for nanophotonic devices\textsuperscript{3}. Intrinsic polarization selectivity of the plasmonic wave makes it possible to use a plasmonic spin-orbit interaction for spin-based metasurfaces\textsuperscript{4,5}. Such structures exhibit different behavior when excited by right-handed or left-handed circularly polarized light (RCP/LCP). In these systems the space-variant rotation of the structure unit-cell induces a geometric Berry phase of the plasmonic wavefront which results in a spin-dependent near-field distribution\textsuperscript{6,7,8}. This effect has been widely studied and various promising nanophotonic applications have been proposed\textsuperscript{9,10}. Nevertheless, recently it was suggested that the SPs could carry a so-called transverse spin (TS) angular momentum which resulted from the relative quarter period phase lag between the longitudinal and the transverse field components\textsuperscript{11,12}. This TS was shown to be locked to the wave propagation direction and it had already been demonstrated that by illuminating a single slit in a metallic surface it was possible to create a projection of the longitudinal spin (LS, circular polarization handedness) onto the TS of the SP and excite unidirectional plasmonic wave\textsuperscript{13,14}. In this work we present a novel type of a spin-locking metasurface based on the LS-to-TS coupling and enhanced by the accurately designed momentum matching. Our structure collectively excites an SP wavefront in a desired direction depending on the incident circular state. In contrast with other spin-based metasurfaces, here we demonstrate a periodic array of uniform apertures with full mirror symmetry. The spin-locking is achieved through the incident beam inclination combined with apertures periodicity which allows a flexible design and relatively simple realization.

2. Spin-locking metasurface

When the SP wave propagates on a planar metal-air interface in \(x\) direction its TS is given as

\[
\mathbf{s}_\perp \propto \frac{\text{Re} \mathbf{k} \times \text{Im} \mathbf{k}}{(\text{Re} \mathbf{k})^2} \tag{1}
\]

where \(\mathbf{k} = k_{SP} \hat{x} + i k_{SP} \hat{z}\) is the complex valued evanescent wave vector with \(k_{SP} = \sqrt{k_0^2 - k_{SP}^2}\), \(k_0 = 2\pi/\lambda_0\) is the vacuum wavenumber and \(k_{SP}\) is the in-plane plasmonic wavenumber\textsuperscript{15}. As stated previously the transverse spin results from the rotation of the resultant of the vectorial plasmonic field, \(E_{SP} = E_0(x - i y \hat{z})\) in a transverse plane and solely arises from the amplitude ratio between the longitudinal and the transverse field components \(\chi\). Accordingly, \(s_\perp\) is locked to the SPs’ propagation direction and can appear with a single handedness. This has led to suggest a scheme for spin-dependent unidirectional plasmonic excitation\textsuperscript{14,15} where the incidence geometry provides a considerable projection of the LS onto the TS of the plasmonic wavefront. Hereafter we refer to this effect as a “longitudinal to transverse spin (LTS) coupling”\textsuperscript{.} One experimental way to achieve that was by using a single slit as a launching structure illuminated by an inclined Gaussian beam. Then, by choosing the inclination angle an optimal coupling conditions could be obtained. Here we suggest using a periodic structure of short and narrow (100 nm wide) nanoslits as a spin-locking metasurface. The system is designed to perform as follows. We bear in mind that an individual slit illuminated by a plane wave at the incidence angle \(\theta\) produces two plasmonic wings propagating at angle \(\alpha\) with respect to the slit that can be derived via momentum matching condition as, \(\cos \alpha = \frac{\lambda_0}{\lambda_0} \sin \theta\). Instead of the single slit we now consider the array of slits placed roughly along the SP propagation direction at a distance.
Figure 1: The metasurface physical principle. (a) The light is incident at an angle $\theta$ and couples to SPs propagating in the metasurface plane along the angle $\alpha$. The periodicity of the grating is $a$. The inset shows the direct and the reciprocal lattice corresponding to our metasurface. (b) The Fourier imaging leakage radiation microscopy setup. The sample is illuminated by an objective with NA = 0.45 while the leakage radiation is extracted by an oil immersion objective O2 with NA = 1.25 coupled with a 100 mm tube lens. An additional lens is then used to generate a Fourier image in the camera. A movable slit controls the incidence tilt angle.

These leads to a rhombic lattice of slits with a diagonal angle $\alpha$ (see Fig. 1). In a periodic lattice, however, the momentum matching is different from the case of a single slit and should be derived by calculating the $k$-space of the array, i.e. its reciprocal lattice [16]. Inset in Fig. 1 shows the geometry of our rhombic lattice represented by the pair of primitive vectors, $a = a \sin \alpha \hat{y} + a \cos \alpha \hat{x}$, $b = b \hat{x}$. The corresponding primitive vectors in the $k$-space are then $a^* = \frac{2\pi}{a \sin \alpha} \mathbf{k}_y$ and $b^* = \frac{2\pi}{2\alpha} \left( \frac{\mathbf{k}_x}{\cos \alpha} - \frac{\mathbf{k}_y}{\sin \alpha} \right)$. We use these vectors to achieve the momentum matching condition for oblique incidence at angle $\theta$:

$$b^* = \frac{2\pi}{\lambda_0 \sin \theta} \mathbf{k}_x = \frac{2\pi}{\lambda_{SP}}$$

We note that the ± sign choice depends on the desired tilting of the beam with respect to the plasmonic propagation direction. This point will be discussed later in the paper. Clearly, the higher is the illumination tilting angle the larger momentum mismatch should be compensated which requires larger initial grating period. However, the tilt in our system is limited by the NA of the objective (we used NA = 0.45). Therefore we have chosen to work with two structures: ($a = 700$ nm; $\alpha = 45^\circ$ and $a = 1200$ nm; $\alpha = 67^\circ$).

Figure 2: Spin-selective unidirectional plasmonic excitation with the grating parameters - $a = 700$ nm, $\alpha = 45^\circ$. (a) and (b) show the $k$-space for right and left-handed incident polarization respectively and (c) and (d) show the real-space images for these states. The dashes circle guides the eye for the plasmonic wave-vector. Note that the coupling in the $k$-space is clearly seen as a bright narrow line.

These configurations are suitable for excitations with the incident angles of $\theta = -7^\circ$ and $\theta = 7.5^\circ$ respectively, where the negative angles correspond to the case when the tilt of the illumination is in the opposite direction to the SP propagation.

3. Experimental results

The metasurfaces were fabricated using focused ion beam (FIB) milling in a 65 nm-thick gold film that had been evaporated beforehand on top of a thin glass substrate. Our setup, shown in Fig. 1b consisted of the pulsed laser at $\lambda_0 = 785$ nm whose beam was expanded to properly fill the aperture of the microscope objective O1, illuminating the sample. The second, oil immersion objective, O2 was brought into a contact with the back (glass) side of our sample in order to produce leakage radiation which was then collected by the tube lens (100 mm) into the imaging system terminated by a camera (Pixelink, PL-B771U, MONO 27, 1280 x 1024). An additional lens was placed on a flipping mount one focal distance ahead of the camera in order to produce the Fourier image of the light distribution. Our way to manipulate the incidence angle was by moving an iris placed right in front of the illumination objective in $x$ direction as schematically shown in Figure 1b. Additionally our setup included the possibility to make a time-resolved imaging of the plasmonic pulses by means of the heterodyne interference method described in the following sections. Figures 2 and 3 show the measured real and momen-
Figure 3: Spin-selective unidirectional plasmonic excitation with the grating parameters - $a = 1200$ nm, $\alpha = 67^\circ$. (a) and (b) show the k-space for right and left-handed incident polarization respectively and (c) and (d) show the real-space images for these states.

tum space images of the two structures with the tilt chosen above and two circular polarization states. The coupling of light to SP wave is clearly seen in the Fourier images as a bright arc inside the diffraction order spot. We verify the polarization dependence of this coupling by comparing the LCP and the RCP states. Real space images follow the Fourier space and show a unidirectional excitation of the SPs by the metasurface. Moreover, by comparing Fig. 2 and 3 one recognizes that in order to excite SP beam in the positive $x$ direction the tilt should be negative in the case of $a = 700$ nm and positive when $a = 1200$ nm.

As expected from the basic theory of the LTS projection the directionality dependence on the incident spin-state stays the same for the two cases. The projection of the incident spin onto the transverse spin vector of the SP should vary as $\sim \sin \theta \cos \alpha$, so this is clear that the effect can be more enhanced with higher tilt angles. Nevertheless even within the limitations of our simple setup the effect seems to be quite convincing.

Abstract
A platform that combines a one-dimensional photonic crystal with a birefringent surface termination is presented. The platform sustains transverse electric and transverse magnetic surface modes having the same phase velocity, which can be combined to generate chiral surface waves providing homogeneous fields of either handedness over arbitrarily large areas in a wide spectral range. The predicted circular dichroism signals and chiral sorting forces are predicted to be more than two orders of magnitude larger than in any other existing platform.

1. Introduction
Biomolecules typically do not possess reflection symmetry. Therefore, the vast majority of biochemical processes is profoundly influenced by the chiral properties of the involved chemical compounds. For this reason, trapping, separating, or - more generally - discriminating between the two different enantiomers of a chiral chemical compound is of paramount importance for biochemical and pharmaceutical applications. Circularly polarized light is one of the most relevant tools for the discrimination of enantiomers and for the determination of their configuration and conformation thanks to circular dichroism (CD) spectroscopy. Moreover, circularly polarized light can exert enantioselective optical forces on chiral molecules. However, both CD signals and optical chiral sorting forces are extremely weak, making both analysis of small amounts of chiral analytes and enantiomer separation very challenging.

Recently, novel approaches have been proposed to enhance the interaction between light and chiral matter by tailoring the optical chirality \(|C|\) of the former. \(|C|\) is one of the factors that determines the degree of asymmetry in the absorption rate of a chiral molecule between left and right circularly-polarized light in the dipolar approximation and is defined as [1]:

\[
|C| = \frac{\varepsilon_0 c}{2} \left| \text{Im} (\mathbf{E}^\star \cdot \mathbf{B}) \right|
\]  

(1)

Its value for circularly-polarized plane waves of unitary intensity is \(|C_{\text{CPL}}| = \varepsilon_0 \frac{c}{2\pi} [1]. \) \(|C_{\text{CPL}}|\) does not represent a limitation and “superchiral” electromagnetic field solutions can be obtained [1].

In this framework, an ideal platform for the exploitation of chiral light should be able to (i) provide uniform chiral optical fields over large areas, (ii) generate optical chiralities of both handednesses upon reversing the polarization state of the incident field, and (iii) work at wavelengths ranging from the near-UV to the IR depending on the platform design, with a particular attention to the high energy range of the spectrum, below 400 nm, where most electronic molecular transitions occur. Plasmonic nanostructures have been widely proposed and employed as a viable solution for the enhancement of the optical chiral response of biomolecules [2, 3]. However, to date plasmonic platforms do not meet all the above criteria simultaneously. In particular, molecular spectroscopy in the blue and near-UV energy range is not accessible with standard Au plasmonics.

Moreover, superchiral optical fields are spatially confined to the so-called plasmonic “hot spots” and large homogeneous optical chiralities are usually obtained only for chiral plasmonic nanostructures [4, 5, 6], hindering the possibility of switching the local field handedness upon reversal of the incident light polarization state. This last drawback represents a universal limitation to plasmonic chirality [6] and has motivated recent proposals to move to dielectric materials for the realization of superchiral assets [5].

Along this line, we introduce the novel concept of “chiral surface waves” originating from the coherent superposition of the TE and TM surface modes in a one-dimensional photonic crystal (1DPC) with a birefringent termination [7, 8]. The resulting platform provides chiral fields with \(|C| \gg |C_{\text{CPL}}|\) over arbitrarily large areas and wide spectral ranges (down to the UV regime), with CD signals and chiral sorting forces more than 2 orders of magnitude larger than those provided by alternative solutions. These findings pave the way towards on-chip surface-enhanced chiral sensing, spectroscopy, and all-optical manipulation.

2. Discussion
We devise a 1DPC supporting both transverse-electric (TE) and transverse-magnetic (TM) Bloch surface waves (BSWs). The 1DPC is terminated by an additional 1DPC with stacking period much smaller than the light wavelength. Because of the small period, we can describe this termination as a single slab with an anisotropic effective optical constant (see Fig. 1). By tuning the birefringence, we can tailor the relative phase velocities of TE and TM waves and have their dispersion relation overlap. In this
Anisotropic medium

Photonic crystal

Molecular sample

Surface wave

Figure 1: A sketch of the photonic crystal supporting chiral surface waves. The sample consists in chiral molecules exposed to the evanescent fields of the surface waves. The latter are excited by illuminating the photonic crystal with elliptically polarized plane waves impinging from the bottom at the correct incidence angle.

way, TE and TM waves can be simultaneously excited with the desired phase relation to produce BSWs of any polarization state. Thanks to the field confinement at the surface ensured by the 1DPC, this configuration allows generating BSWs that provide intense, homogeneous, and switchable chiral local fields over arbitrarily large surfaces and a wide spectral range [7, 8]. The resulting optical chirality |C| is predicted to be strongly enhanced with respect to |C_{CPL}|, by more that one order of magnitude.

Because of the evanescent nature of SBWs, the chiral properties of our platform can be exploited by placing the sample in close proximity to the free top surface of the 1DPC termination (see Fig. 1). Chiral molecules, either in a solution flowing into a microfluidic channel or embedded into an amorphous film spin-coated on top of the 1DPC termination represent practical realization of this concept.

To evaluate the performances of the platform, we have applied a simple formalism where all the relevant chiroptical quantities are expressed in terms of the Fresnel reflection matrix for the system (1DPC platform + chiral molecules). We obtain the reflection matrix by using the transfer matrix approach together with the constitutive relations for the chiral medium. We find a strong enhancement of the optical chirality provided by the near field of the BSWs supported by our platform, resulting in CD signals [7, 8] and chiral sorting optical forces [9] that exceed by two orders of magnitude the performances of any existing alternative.

3. Conclusions

We have devised a 1DPC supporting chiral surface waves coupled with a uniform and isotropic optically active thin film deposited on its surface, operating over a broad spectral range. This platform provides chiral signal enhancements and chiral-sorting forces of more than two orders of magnitude larger than those obtained with alternative approaches.

Theoretical Design of Two-Dimensional Magnetoelectric Materials

Shuai Dong¹,*

¹School of Physics, Southeast University, Nanjing, China
*corresponding author, E-mail: sdong@seu.edu.cn

Abstract
Achieving two-dimensional magnetoelectric materials should enable numerous functionalities in nanoscale devices. Until now, however, predicted two-dimensional magnetoelectric materials are very few and with coexisting yet only loosely coupled ferroelectricity and magnetism. In this talk, I will introduce several recent works on two-dimensional magnetoelectric materials done in my group.

1. Introduction
Magnetoelectric materials contain both the magnetic and electric degrees of freedom, and thus very important for scientific research as well as functional applications. In the past decades, magnetoelectric materials in the three-dimensional crystals have been extensively studied [1, 2]. Only till very recently, the experimental discoveries of two-dimensional ferromagnets and two-dimensional ferroelectrics bring us attention to the branch of two-dimensional magnetoelectric.

2. Results
In this talk, I will present our recent works on two-dimensional ferroelectric materials and magnetoelectric materials.

2.1. CrI₃δ
CrI₃ monolayer is an experimental verified two-dimensional ferromagnetic material. Our calculation based on density functional theory found that the vacancies of iodine can create (almost) isolated and switchable electric dipoles, making CrI₃ monolayer a magnetoelectric system [3]. Such vacancies can also enhance both the local magnetization as well as the effective Curie temperature.

Figure 1. (a) Structure of monolayer CrI₃ from top and side views where I and Cr atoms are represented by red and blue balls. (b) Schematic diagram of CrI₃ working as an atom-thick two-dimensional material with switchable out-of-plane polarization in which the vacancy is represented by the black dotted circle.

2.2. Hf₂VC₂F₂
The magnetoelectric coupling in most known two-dimensional magnetoelectric materials are loose since the origins of magnetic moments and electric dipoles are independent, which is disadvantage for the cross control. To obtain the strong intrinsic magnetoelectric coupling, we have predict a member of MXene, Hf₂VC₂F₂, to be a type-II multiferroic material, in which the polarization is generated by the noncollinear spin order [4]. The magnetic Neel temperature, i.e. the ferroelectric Curie temperature, can be above room temperature, and more than 98% of polarization comes from the bias of electronic cloud instead of the displacements of ions.

Figure 2. (a) Side views of the Hf₂MC₂T₂. (b) Sketch of the energy splitting of 3d orbitals for M. M: transition metal. T: anion.

2.3. CuInPS
CuInPS is an experimental verified two-dimensional ferroelectric material with out-of-plane polarization, generated by the pair of Cu-In. We found that CuInPS multilayer can show a giant negative piezoelectricity, which is very rare especially in inorganic materials. The loose vdW layer plays an important role.

Figure 3. (a) and (c) Illustrations of negative (a) and positive (c) longitudinal piezoelectric effects, where the lattice contracts or elongates when the electric field is along the direction of the spontaneous polarization. (b) A schematic that outlines the lattice
dimensionalities of three representative ferroelectric materials: 1D PVDF, 2D CuInP$_2$S$_6$ (CIPS) and 3D Pb(Zr$_{0.4}$Ti$_{0.6}$)O$_3$ (PZT). The bottom part shows the energy scales of the inter- and intra-molecular bonds. PVDF is known to possess negative piezoelectric coefficient as schematically shown in (a), while 3D ferroelectrics usually show positive piezoelectric coefficients as illustrated in (e).

3. Conclusions

In summary, several new two-dimensional magnetoelectric materials have been designed, predicted, and synthesized. More effects are needed to push forward the frontiers of this field.

Abstract

It is shown experimentally that the interaction of chiral molecules with a perpendicularly magnetized substrate is enantiospecific. Thus, one enantiomer adsorbs preferentially when the magnetic dipole is pointing up, whereas the other adsorbs faster for the opposite magnetization alignment. The interaction is not controlled by the magnetic field but by the respective electron spin orientations. Magnetization reorientation of magnetic layer can be realized solely by adsorption of chiral molecules on its surface without presence of magnetic or electric fields.

1. Introduction

Enantioselectivity is ubiquitous in nature and many of the molecules in plants and living organisms have their properties depending on the type of enantiomer. Chiral recognition and enantiomeric selectivity, both in nature and in artificial systems, are commonly assumed to be related to a spatial effect, with the recognition process typically described by a “lock and key” type model. Accordingly, chromatography-based enantioseparation requires the chiral substrate to be adjusted so as to interact optimally with a specific enantiomer. Indeed, enantio-separation is an extremely important process in the pharmaceutical and chemical industries. The importance of chirality was only realized by scientists in the sixties of last century after a disaster with Thalidomide drug used by pregnant women which caused birth of children with malformations due to mutagenic effect of one of the enantiomers. Since then chromatography and electromigration techniques have long been the methods of choice in this field. However, despite intensive efforts, obtaining enantiomerically pure synthetic materials remains a challenge, as the cost of separation is relatively high and an extensive effort is required.

2. Results and discussion

In our earlier paper [1] we have demonstrated a new effect of magnetization switching of ferromagnetic thin film without applying a magnetic or electric field but being induced solely by adsorption of chiral molecules. In this case, about 10¹³ electrons per cm² are sufficient to induce magnetization reversal. The direction of the magnetization depends on the handedness of the adsorbed chiral molecules. It is commonly assumed that recognition and discrimination of chirality, both in nature and in artificial systems, depend solely on spatial effects. However, recent studies have suggested that charge redistribution in chiral molecules manifests an enantiospecific preference in electron spin orientation. Therefore it is possible that the induced spin polarization may affect enantio-recognition through exchange interactions. It is shown [2] experimentally that the interaction of chiral molecules with a perpendicularly magnetized substrate is enantiospecific. Thus, one enantiomer adsorbs preferentially when the magnetic dipole is pointing up, whereas the other adsors faster for the opposite alignment of the magnetization. The interaction is not controlled by the magnetic field per se, but rather by the electron spin orientations, and opens prospects for a distinct approach to enantiomeric separations.

The enantioselective interaction of chiral molecules and a magnetic substrate with perpendicular anisotropy provides a potentially generic chromatographic method for enantioseparation, which does not require a specific and costly separating column. As the observed effect depends on the electrical polarizability of the system (that is accompanied by spin polarization) and because this polarization depends on the global structure of the chiral molecule, this new method may also allow the separation of chiral molecules from a mixture of molecules, either chiral or achiral. In addition, this technique could potentially be applied for separating chiral molecules based on their secondary structure and/or for separating two secondary structures of the same chiral molecule. Clearly, the
efficiency of the method depends on the electric and spin polarization properties of the molecules. We hope that this work will motivate further exploration of the detailed mechanisms and ultimate efficiency of this approach.

Fig. 1. Enantiospecific adsorption of a peptide. (A) Adsorption of the PAL oligopeptide [shown in inset of (v)] on FM samples (silicon with a 1.8-nm Co film and a 5-nm Au film), magnetized with the magnetic dipole pointing up (H+) or down (H–) relative to the substrate surface. SiO2 nanoparticles were attached to the adsorbed oligopeptides. Panels (i) and (ii) L-PAL and (iii) and (iv) D-PAL were adsorbed for 2 s on a substrate magnetized up or down. Panel (v) summarizes the nanoparticle adsorption densities shown in (i) to (iv), compared with the adsorption density on Au with an applied external magnetic field (red bars). Double-headed arrows represent error bars. The errors are the standard deviation among 10 measurements conducted on each of the 10 samples, hence a total of 100 measurements. (B) Panel (i) shows the enantiospecific CD spectra of PAL, obtained from exposure of a racemic PAL mixture exhibiting no CD to a substrate with magnetization pointing down (red) or up (blue). CD spectra were obtained postadsorption. After the specific adsorption of one enantiomer, the resulting CD spectra clearly indicate the presence of the opposite enantiomer. The linewidth reflects the uncertainty of the results. Panel (ii) shows the CD spectra of the pure enantiomers, provided for comparison. mdeg, millidegrees.

Fig. 2. Topography and magnetic phase MFM images of molecular induced magnetization orientation. a, b, AFM topography images of SAMs of AHPA-L (a) and AHPA-D (b) adsorbed on FM Co thin layer coated with 5nm Au overlayer and their corresponding MFM magnetic phase images of AHPA-L (c) and AHPA-D (d) magnetization orientation. The change of a contrast in MFM images clearly indicates the magnetization reorientation depending on the type of enantiomer (L or D) adsorbed on magnetic nanosstructure.

3. Conclusions

It was shown for the first time that magnetization reorientation of magnetic layer can be realized solely by adsorption of specific enantiomer of chiral molecules on its surface without any presence of magnetic or electric fields. A new method of enantio-separation is proposed based on the interaction of chiral molecules with a perpendicularly magnetized substrate. one enantiomer adsorbs preferentially when the magnetic dipole is pointing up, whereas the other adsors faster for the opposite magnetization alignment. The interaction is not controlled by the magnetic field but by the respective electron spin orientations of the ferromagnetic layer and chiral molecules.

Abstract

Magnetic nanoparticles with a single-domain crystal structure support a plasmon resonance in the deep UV range with the quality better than gold nanoparticle plasmons. The exchange interaction of electrons splits the energy bands between spin-up electrons and spin-down electrons. These two group of electrons have very different relaxation constants providing high and low plasmon quality for two independent plasmons. The scattering without spin flip is required to keep these two plasmons independent.

1. Introduction

Two largely independent channels of conductivity with a distinct spin-dependent electron scattering rate [1] is the primary origin of giant magnetoresistance [2]. These ideas of two independent channels have been projected onto collective electron oscillations in spin-polarized nanoparticles [3]. Understanding the effect of spin polarization on plasmon oscillations of the free electrons in nanoparticles is, essentially, unexplored and crucial in many envisioned applications at the cross road of magnetism and plasmonics. Particularly, it results in a new type of plasmon, specific for spin-polarized magnetic nanoparticles.

2. Results and discussion

Our results show that Co nanoparticles with a single-domain crystal structure support an excellent plasmon resonance at about 280 nm with the quality comparable to gold nanoparticles. This type of plasmons is unusual in a way that two plasmons coexist in a particle at the same frequency and polarizations of excitation, but for electrons of opposite spin. Inter-nanoparticle interactions completely demolish plasmon quality resonance, which is the probable reason why it was not observed previously and why the results for bulk films [4] cannot be used for single domain nanoparticles

![Figure 1. Absorbance of the Co NPs in hexane solution: experiment (red) and calculated (black) using J&C data [3,4].](image)

Here a concept of two independent plasmons explains the observed behavior, namely sharp plasmon in contrast to J&C based predictions and the vanishing due to mixing of these two channels. Indeed, according to simulations...
performed for GMR a number of s-p electrons in Co is approximately equal for spin-up and spin-down electrons [5]. Terms majority and minority electrons and the bands splitting due to exchange interaction is relevant to d-electrons. This splitting makes difference in the density of empty states in the d-band and thus providing conditions for strongly different mean free path of the s-p electrons. The plasma frequency is related to the conduction electrons. Taking into account that the ratio between spectral width of two plasmons can be up to 20 [5], certainly there is an overlap and the sharp

Briefly, cobalt nanoparticles synthesized by high temperature reduction of cobalt salt show strong plasmon resonance at 280 nm with better quality than that of gold nanoparticles in the visible spectrum, see comparison in Fig. 2. Our experiments with Co nanoparticles clearly show a new type of plasmon excitation, which is specific for spin polarized single domain nanoparticles. Similar features we observe for Fe nanoparticles as well. This type of plasmon has unusual properties due to existence of two independent groups of electrons with opposite spins providing weak interaction so that all electron scattering processes occur without spin flip. Magnetic response of the nanoparticles enables controlled and reversible aggregation accompanied by the tailoring of optical absorption. These statements are supported by the following arguments. An extensive collection of literature on GMR including first principle simulations proof that the materials with spin polarization of d-electrons have two independent channels of the conductivity (note, that the conductivity is mainly caused by the s-p electrons). The values of conductivity are very different for two channels. The two channels are independent only if the electron scattering goes without spin-flip. The scattering with spin flip can be initiated by the domain structure. These points, known from the Mott’s seminal papers, allow explaining our experimental observations, which were possible only by following the described in [3] synthesis recipe. Our observations include correlation of sharp plasmon resonance with magnetic properties, specifically only single-domain superparamagnetic nanoparticles show sharp resonance. Larger nanoparticles with domain structure does not show that. The optical absorption measurements are accompanied by the transmission electron microscopy, dynamic light scattering, and magnetometry to characterize the domain structure in a single nanoparticle, aggregation state, and magnetization. The vanishing of the resonance under aggregation (induced by magnetic field with sonication and reversible) can be explained only by the electron scattering with spin flip in the presence of second magnetic particles, since the spin-flip scattering is the only difference relative to the Ag or Au nanoparticles.

Magnetoelectric structures and magnetoelectric fields

E. O. Kamenetskii

Microwave Magnetic Laboratory, Department of Electrical and Computer Engineering, Ben Gurion University of the Negev, Beer Sheva, Israel. E-mail: kmntsk@bgu.ac.il

Abstract

The question on relationship between magnetoelectricity and electromagnetism is a subject of a strong interest and numerous discussions in microwave and optical wave physics and material sciences. The definition of the energy and momentum of the electromagnetic (EM) field in a magnetoelectric (ME) medium is not a trivial problem. Together with certain constraints on the constitutive parameters of a medium, definite constrains on the field structure should be imposed. Visualization of the ME states require an experimental technique that is based on an effective coupling to the violation of spatial as well as temporal inversion symmetry. There should be a probe with special ME near-field structures.

1. Introduction

In a macroscopic description of the linear magnetoelectric (ME) effect, the magnetoelectric susceptibility tensor is a second rank tensor, which changes sign under space inversion and time reversal and, accordingly, is invariant under simultaneous space and time inversion. Therefore, the ME effect can occur in magnetically ordered systems where spin ordering breaks the spatial inversion symmetry. In crystalline insulators, one observes macroscopic toroidization. Toroidal moment can directly couple with the cross product between the electric field and the magnetic field. So, an energy is in a form: \( W_{\text{ME}} \propto \vec{T} \cdot (\vec{E} \times \vec{H}) \).

Recently, it was showed that an EM angular momentum density directly couple with magnetic moments to provide an energy: \( W_{\text{ME}} \propto \vec{r} \times (\vec{E} \times \vec{H}) \cdot \vec{M} \). Also, ME materials contain a dynamic axion field \( \theta(t, \vec{r}) \). This gives an additional term of the Lagrangian density, \( L_\theta \propto \theta \vec{E} \cdot \vec{B} \), which couples electric and magnetic fields. Pseudoscalar term \( \theta \vec{E} \cdot \vec{B} \) provides ME coupling in topological insulators and antiferromagnet chromia.

2. Magnetoelectric fields

The definition if the energy and momentum of the EM field in a ME medium is not a trivial problem. If a ME material has a certain structure (with the known constitutive tensors), a certain demands on the field structure should be also imposed. We consider propagation of quasimonochromatic EM waves in ME medium. The medium is described by local material parameters: \( \vec{E}_m, \mu, \vec{z}_m, \vec{z} \). The fields are expressed as \( \vec{E}_m = \vec{E}_m e^{i\omega t - k \cdot \vec{x}} \) and \( \vec{H}_m = \vec{H}_m e^{i\omega t - k \cdot \vec{x}} \), where complex amplitudes \( \vec{E}_m \) and \( \vec{H}_m \) are time and space smooth-fluctuation functions. From an analysis of the Poynting theorem in a ME medium, it was shown [1] that the energy balance equation can be reduced to a form of a continuity equation

\[-\nabla \cdot \left\{ \vec{S} \right\} = \frac{\partial \left\{ W \right\}}{\partial t} + \left\{ P \right\} \]

only at certain constraints imposed to slowly time-varying complex amplitudes:

\[ E_m(t) \frac{\partial H_m}{\partial t} = H_m(t) \frac{\partial E_m}{\partial t} \].

In such a case, the average energy density is expressed as

\[ \left\langle W \right\rangle = \frac{1}{4} \left\{ \frac{\partial \left( \omega \vec{E} \cdot \vec{E} \right)}{\partial \omega} + \frac{\partial \left( \omega \vec{H} \cdot \vec{H} \right)}{\partial \omega} - \frac{\partial \left( \omega \left( \vec{z} \cdot \vec{z} \right) \right)}{\partial \omega} \right\} \frac{H_m^a H_m^b}{H_m} \frac{H_m^a H_m^b}{H_m} \]
In EM processes in any lossless dielectric medium, a phase shift between complex amplitudes of the electric and magnetic fields, $E_m \pm iH_m$, can be 0° (180°) or ±90°. In a case of a lossless ME material the angle $E_m \pm iH_m$ can be of different degrees. Because of the presence of non-electromagnetic coupling parameter, in lossless EM structure with ME material we can observe non-Maxwellian field fluctuations – the ME fields.

3. Magnetoelectric near-field structures

When the violation of the invariances under space reflection parity and time inversion are necessary conditions for the emergence of the ME effect, the same symmetry properties should be observed for the near-fields. Visualization of the ME states require an experimental technique that is based on an effective coupling to the violation of spatial as well as temporal inversion symmetry. There should be a probe with special ME near field structures. What kind of the near fields originated from a ME sample one can observe? In the near-fields region of a subwavelength sample, we can only measure the electric $E$ or the magnetic field $H$ with accuracy. There is Heisenberg’s uncertainty principle binding $E$ and $H$ of the EM wave. However, in case of a subwavelength ME sample, the near-field interactions are dominated by two types of the fields: the electric and magnetic fields.

To characterize inherent macroscopic properties of ME materials, a novel near-field microwave sensor had been proposed recently [2]. The sensor is based on a subwavelength ferrite-disk resonator with magnetic-dipolar-mode (MDM) oscillations [3]. Due to a spin-orbit interaction, at MDM resonances in a quasi-2D ferrite disk, one has nonzero product on magnetization: $\tilde{m} \cdot \left( \vec{V} \times \tilde{n} \right)$. The near fields originated from a MDM resonator are characterized by the helicity factor

$$F = \frac{c_0}{4} \left[ \frac{1}{2} E \cdot \left( \nabla \times \vec{E} \right)^* \right] = \frac{\omega c_0 M}{4} \Re \left( \vec{E} \cdot \vec{H}^* \right) \neq 0$$

and power-flow vortices [4, 5]. When the direction of a bias magnetic field is changed, the sign of the helicity factor and the direction of the power-flow vortex are changed as well. The ME near-field sensor based on a MDM resonator is shown in Figs. 1, 2.

![Fig. 1. A microwave probe for near-field measuring of macroscopic properties of ME materials.](image1.png)

![Fig. 2. The power-flow vortex and helicity factor on a butt end of a thin metallic-wire electrode.](image2.png)

Strong energy concentration and unique topological structures of the near fields originated from the MDM resonators allow effective measuring material parameters in microwaves, both for ordinary samples and objects with ME properties.

Abstract
We experimentally demonstrated the significant improvement of the figure of merit (FOM) of the longitudinal magneto-optical Kerr effect and the increase of in-plane magnetic anisotropy in Au/Co/Au multilayered nano rectangular patch array structures. When the local-mode surface plasmons were resonantly excited in the nanostructures, its FOM becomes 3.8 times higher and the in-plane magnetic anisotropy energy density was increased about 24% comparing to those of bare Co nano patch array.

1. Introduction
The magneto-optical (MO) effect such as Kerr effect has attracted much attention owing to its capability of manipulating the polarization state of light, in particular, with the reciprocal optical properties. The angle of polarization rotation by the MO Kerr effect (MOKE) is usually very small, around 1.0 degree, while practical MO devices need a larger polarization angle rotation. Therefore, the enhancement of the MO effect is strongly demanded. Recently, several research groups reported that a large MO effect is observed at the resonant wavelength of local-mode surface plasmons (LSPs). It is well-known that the LSP resonance creates highly localized and high intensity light field. These enhancements by the plasmon resonance are attributed to light/photon accumulation, which is so-called “field-enhancement effect”, at the surface of metals. On the other hand, since the degree of the MO effect is intrinsically independent of the light intensity, the mechanism behind the plasmonic enhancement of the MO effect is different from merely the field enhancement effect.

2. Enhancement of MO Kerr effect
We designed and fabricated an Au/Co/Au multilayered nano rectangular patch array with different short axis lengths ($L_s$) and fixed long axis length ($L_l$) on indium thin oxide (ITO) coated glass substrates as shown in Figure 1 [1]. Since nano rectangular shape is geometrically anisotropic, it enables us to switch the LSP resonance on and off only by changing the polarization direction of the incident light at a certain wavelength.

MO properties of fabricated structures were measured via an L-MOKE measurement system based on a polarization modulation technique. A diode laser with wavelength of 785 nm was used as a light source. Laser light was collimated and introduced at the device surface with a fixed incident angle of 14 degrees and with a fixed power of 28 mW. In the optical setup a half waveplate was introduced and by rotating it, we changed the polarization direction of incident light to switch the surface plasmon resonance on and off. An external magnetic field of 1000 Gauss, which is enough to measure the saturated values of Kerr rotation and ellipticity, was applied parallel to the long axis of the structure.

When the polarization direction of the incident light was set parallel to the short axis, we defined it as “V-pol.”, and that parallels to the long axis is defined as “H-pol.” as shown in Fig. 1. Under the V-pol. condition, absorption peaks were gradually shifted to longer wavelength as $L_s$ becomes long. On the other hand, under the H-pol. illumination, no absorption peaks were observed in the visible region because the resonant wavelength of all structures were in the IR region. From these results, we verified that by changing the lengths of the rectangular patch the wavelength of the SP resonance can be tuned and polarization control enables us to switch the localized SP resonance on and off.
We evaluated the MOKE activities in fabricated Au/Co/Au nanorectangular structures. Figure 2 (a) shows the relationship between absolute value of the complex Kerr rotation (|Φ|) and Ls. As shown in Fig. 2 (a), |Φ| for V-pol. (|ΦV-pol|) is always larger than that for H-pol. (|ΦH-pol|). While |ΦH-pol| shows an almost constant value regardless of Ls, |ΦV-pol| varies according to the Ls and becomes maximum at Ls = 200 nm, in which the LSPs are excited at the laser wavelength. Fig. 2 (b) shows the ratio of |ΦV-pol| to |ΦH-pol| (|ΦV-pol| / |ΦH-pol|) as a function of Ls. It is clear that the ratio becomes maximum at Ls = 200 nm.

Figure 3 show the FOM values with respect to Ls. As shown in this figure, FOM in H-pol. (FOMrpol-pol.) is gradually decreased with increasing Ls. However, as similar to the MO activities, FOM in V-pol. (FOMv-pol.) takes the maximum value at Ls = 200 nm. Moreover, at Ls = 200 nm, FOMv-pol. becomes about 1.8 times larger than FOMH-pol.. This result indicates that the excitation of LSPs on Au layer improves FOM of the device. In Fig. 3, we also plotted FOMs for bare Co nanostructure.

### 3. Plasmonic strengthen of magnetic anisotropy

Magnetic anisotropy is another essential factor for practical applications of magneto-optical devices, because it determines the thermal stability of magnetic devices.
Tunable ferromagnetic resonance in coupled trilayers with crossed perpendicular and in-plane magnetic anisotropies

Thin films with weak perpendicular magnetic anisotropy (PMA) exhibit stripe domains which could be used to control reconfigurable magnonic devices [1, 2]. In amorphous NdCo₈ alloys, the Nd concentration is at the origin of the averaged PMA [3]. To further increase the versatility of PMA-based material systems, the effect of controllably coupling a 64 nm thick, hard magnetic NdCo₈ film with PMA to a 10 nm thick, soft magnetic Ni₈₀Fe₂₀ film with in-plane magnetic anisotropy (IMA) through a non-magnetic Al spacer is investigated. By varying the Co concentration (X = 5, 7, 9) in the NdCo₈ films, the strength of the PMA can be modified. By adjusting the Al spacer thickness T, the type of coupling between the two magnetic layers can be set to either exchange-coupled (T < 1 nm) or stray-field coupled (T ≥ 2.5 nm), respectively. Using transverse magneto-optical Kerr effect and alternating gradient force magnetometry as well as ferromagnetic resonance spectroscopy, the influence of both Co concentration X and Al spacer thickness T on the static and dynamic magnetic properties, respectively, of coupled bi- and trilayers is studied. The two most striking effects of the coupling between the PMA and IMA layers can be observed in their ferromagnetic resonance spectra displayed in Fig. 1, which, compared to a single Py film, show a significant increase of the zero field resonance frequency up to 6.6 GHz and, for low bias fields applied along the hard axis, a frequency hysteresis with a maximum difference between the two field sweep directions as high as 1 GHz. The latter corresponds to a tunability of about 20% at external fields of typically less than 0.1 T. Effectively, only the FMR of the soft Py film is observed, whose magnetic properties are modified by the exchange-coupling to the hard NdCo₈ layer [4], resulting in an induced effective domain pattern as illustrated in Fig. 2. From the top panels (a-c) in Fig. 1, in which the results for samples with fixed Al spacer thickness are shown, it can be seen that an increase of the Co concentration X in the NdCo₈ films leads to a decrease of the resonance frequencies due to the reduced PMA, resulting in a gradual convergence of the frequencies within the hysteretic part of the spectra to the frequencies of the single Py film. Similarly, as depicted in the lower panels (d-f) in Fig. 1, an increase of the Al spacer thickness for a constant Co concentration leads to a decrease of the FMR frequencies and their gradual convergence towards the single Py film frequencies as a result of a weaker coupling between PMA and IMA films.

Complementary 3D micromagnetic simulations have been shown to reproduce the observed features in the FMR spectra both qualitatively and quantitatively with excellent agreement. By combining the data from magnetization reversal curves and FMR spectra with the simulated domain configuration, which is depicted in Fig. 2, an explanation for the occurrence of the frequency hysteresis along the hard axis of the coupled trilayers is given.

References

Figure 1: $f$ vs. $B$ dependency of the coupled trilayers for the magnetic field applied long the hard axis. In the top row (a–c), the FMR spectra of trilayers having the same Al spacer thickness ($T$) are compared, whereas in the bottom row (d–f), the results for trilayers with identical Co concentrations ($X$) are displayed. In both rows, the values for $X$ and $T$ increase from left to right, respectively. Within the hysteretic part of the FMR spectra, the lower frequency branch at negative fields and the higher frequency branch at positive fields can be accessed when increasing the value of the applied field. Conversely, the lower frequency branch at positive fields and the higher frequency branch at negative fields can be accessed when decreasing the value of the applied field. For comparison, the spectrum of a single 10 nm thick Py film has been added to each plot.

Figure 2: (a) Sketch of the domain configuration in the $x$-$z$ plane of a single 64 nm thick NdCo$_5$ film. (b-d) Simulated normalized $x$-, $y$-, and $z$-components of the magnetization at remanence in a coupled trilayer of NdCo$_5$ (64 nm)/Al(2.5 nm)/Py(10 nm) after application of a magnetic field along the $y$ direction. The values of the individual magnetization components are coded according to the color bar on the right. The NdCo film exhibits stripe domains of periodicity $\lambda$ with up/down magnetization, whose stray field generates closure domains in the Py layer.
Chirality and Optical Spin-orbit Coupling in Topological Photonic Crystals

Abstract
We directly observe the states of topological photonic crystals at telecom wavelengths. We show that the unidirectional character of the topological edge states is directly linked to the circular polarization of the states’ far fields. Using this intrinsic radiation, we measure dispersion, loss, pseudospin, and spin-spin scattering. We image spin-selective unidirectional propagation around sharp corners and junctions and characterize topological nanocavities.

1. Introduction
The concept of topology has proven immensely powerful in physics, describing new phases of matter with unique properties. There has been a recent surge in attempts to implement topological protection in the photonic domain \cite{1}, owing to the application potential of robust transport immune to scattering at disorder. A famous class of electronic topological insulators relies on the quantum spin-Hall effect (QSHE) \cite{2}, which uses spin-orbit coupling to cause spin-up and -down electrons to propagate in opposite directions in states that are protected by time-reversal symmetry. Photonic analogues of QSHE were realized using arrayed ring resonators \cite{3, 4}, and recently predicted to occur in photonic crystals with special symmetries \cite{5, 6}. Such states were observed in the microwave domain \cite{7, 8}, and coupled to spin-polarized quantum dots \cite{9}. Interestingly, topological photonic crystals employing QSHE offer the possibility to access their properties via far-field radiation \cite{10}.

2. Results
Here we directly observe topological photonic states at telecom wavelengths in photonic crystals in silicon-on-insulator (SOI) technology. Through angular spectroscopy and polarimetry, we retrieve the properties of the bulk states of crystals with different topological order, as well as the edge states that appear at their interfaces. We reveal that the radiation of the topological states carries a signature of their origin in photonic spin-orbit coupling, linking unidirectional propagation to circular polarization (see Fig. 1a). Through this connection, we selectively excite modes in opposite directions and map their propagation in real space.

Figure 1: a. Schematic representation of spin-orbit coupling in topological photonic crystals: Chirality of the radiation field is connected to propagation direction of states at edges between photonic crystals with different topological bandstructure. b. A scanning electron micrograph of the fabricated sample, with unit cells indicated in blue and red and edge between two topologically different domains by the yellow line. e. Measured reflectometry, showing the edge state dispersion. d. Measured circular polarization intensity (normalized Stokes parameter $S_3$) when the edge is excited with light that is linearly polarized along $y$, showing that the pseudospin is encoded in $S_3$. 
Figure 1b shows the employed photonic crystals, composed of hexagonal unit cells with six sites each, that are either ‘shrunken’ or ‘expanded’ to open bandgaps of different topological order at the $\Gamma$ point [5, 6]. The edge between two domains supports topological edge states of differing pseudospin, protected by the $C_6$ symmetry of the photonic crystal lattice. We analyze these states by dispersing normal-incidence reflected intensity in both frequency and angle, to map the edge state dispersion shown in Fig. 1c. It displays the characteristic linear dispersion of the edge states, with measured group velocity $c/6$ and quality factor $\sim 450$.

We demonstrate that the positive and negative group velocity modes can be selectively excited with opposite circular polarization. Conversely, the states’ pseudospin can be probed directly in the far field through the $S_3$ Stokes parameter obtained from polarimetry (Fig. 1d). Our Fourier spectroscopic measurements moreover reveal a small gap at the edge state crossing that is related to spin-spin scattering. This coupling is inherent to the symmetry breaking at the edge, and differentiates these bosonic topological states from their fermioning QSHE counterparts.

Through the far-field spin-orbit link, we selectively excite edge states in opposite directions, and image their propagation in real-space microscopy. Figure 2 shows examples of the spin-selective excitation with a focused laser beam of circular polarization, and the routing of the edge state at a sharp waveguide junction. Interestingly, we observe an absence of backscattering or forward scattering, demonstrating the topological protection of unidirectional propagation. In fact, the states closely follow the photonic crystal edge — defined by the junction’s chiral structure of sub-unit cell size — even though their transverse extent is significantly larger.

The employed imaging and Fourier spectroscopy techniques establish a straightforward yet versatile path for testing and optimizing novel topological systems for a wide variety of applications in optics, including components for integrated photonic chips, quantum optical interfaces, enantiomeric sensing, and lasing at the nanoscale.

Abstract

Chiral sensing is crucial in probing the fundamental symmetries of the universe, study biomolecular structures, and even develop safe drugs. As chiral signals are inherently weak, different techniques have been proposed to overcome the limitations of traditionally used chiral polarimetry. We propose an angle-resolved chiral surface plasmon resonance scheme that can detect the absolute chirality (handedness and magnitude) of a chiral sample and is sensitive to both the real and imaginary part of a chiral sample’s refractive index.

1. CHISPR

Chirality is a fundamental property of life with far-reaching implications among all disciplines of science. Chiral sensitive techniques have enabled the study of fundamental symmetries of the universe, determination of biomolecular structures, and development of safe and effective drugs, to name few of the most prominent applications of chiral sensing.

The polarimetric techniques of optical rotatory dispersion (ORD) and circular dichroism (CD) are among the most widely used research tools in modern science for chiral sensing. However, polarimetric measurements are typically challenging as the measured signals are small and often suppressed by large backgrounds. To overcome the limitations of traditional polarimetry in chiral sensing, different techniques have been proposed in the recent years. These techniques, which aim to enhance the chiral wave-matter interaction, can in principle be arranged into two main categories, as they rely mainly on either (a) path-length enhancement or (b) chiral-field enhancement. The first type of techniques is primarily cavity-based, for which the ORD and CD signals are enhanced by the number of cavity-passes (typically about $10^3$-$10^4$)\textsuperscript{[1, 2]}. However, cavity-enhanced techniques become inadequate in systems with losses originating from absorption and/or scattering (e.g. chiral molecules within complex matrices, thin films, liquid and/or solid systems), because losses hinder the path-length enhancement. The chiral-field-enhancement techniques rely primarily on generating probing-electromagnetic-fields with chiral densities higher than circularly polarized plane waves (see for example Refs.[3, 4]). Chiral and achiral nanophotonic systems, such as plasmonic/dielectric nanostructures and metamaterials, can generate contorted intense near-fields with high chiral densities around a resonance frequency of the nanosystem, thus amplifying the chiral-chiral interactions between them and a molecule. However, in most demonstrations, elaborate fabrication is required and the employed nanosystems have their own intrinsic chiroptical response that contributes in the total CD signal and, thus, inhibits the absolute and quantitative measurement of chirality. Moreover, to the best of our knowledge, in most nanophotonic-based chiral-sensing protocols only the case of circular dichroism is discussed and, therefore, most results are typically analyzed with respect to the imaginary part of chiral refractive index, while chiral-sensing technologies, which are routinely applied in the pharmaceutical, agricultural, and food industry, require the detection of both real and imaginary parts of the chiral refractive index.

Considering the importance of chiral sensing, it is vital to develop novel schemes that overcome the above-mentioned limitations of path-length enhancement and/or chiral-field enhancement techniques, but most importantly ones that allow for absolute chiral sensing. We propose an angle-resolved chiral surface plasmon resonance (CHISPR) scheme (Fig. 1) that can detect the absolute chirality (handedness and magnitude) of a chiral sample and is sensitive...
to both the real and imaginary part of a chiral sample’s refractive index, contrary to most demonstrations that employ metallic nanostructures and/or metasurfaces. We present analytical results and numerical simulations of CHISPR measurements, predicting signals in the mdeg range for chiral samples of <100 nm thickness at visible wavelengths (as a comparison, optical rotation signals from a transmission measurement of similar chiral samples with realistic chiral parameters would be at least an order of magnitude smaller [5]. We show that CHISPR is particularly suitable for chiral sensing from thin samples which are not easily measurable using alternative techniques, and that our technique has the advantage of being applicable directly on existing SPR instrumentation without the need for additional elaborate fabrication. In addition, with a CHISPR measurement scheme the whole evanescent-wave volume is sensitive to the probed chiral substance (due to the mobility of the propagating surface plasmon polaritons), contrary to schemes based on local surface plasmons, where the sign and magnitude of the chiroptical response possess a complex dependence on sample geometry.

In the outlook, we will also discuss alternative routes towards absolute chiral sensing using nanoplasmonic-based approaches.

Terahertz metamaterials: accessing nonlinear spin and phonon dynamics

Stefano Bonetti¹,²

¹Department of Physics, Stockholm University, Stockholm, Sweden
²IDepartment of Molecular Sciences and Nanosystems, Ca Foscari University of Venice, Italy
*corresponding author, E-mail: stefano.bonetti@fysik.su.se

Abstract

In this talk, I will describe a few metamaterials design that can be used to drive large amplitude, nonlinear dynamics in condensed matter systems, focusing in particular to the spin and lattice degrees of freedom. For this scope, I will discuss different designs aimed at enhancing either the electric or the magnetic field component of terahertz radiation. The metamaterial structures have been investigated thoroughly using three-dimensional finite element simulations in both the frequency and the time domain. Preliminary results of the observation of the large amplitude dynamics induced by such metamaterials will be shown, detected using time-resolved pump-probe microscopy.

1. Introduction

The use of terahertz radiation to investigate different physical systems has been rapidly increasing in recent years. In condensed matter physics, collective excitations of the lattice and spin degrees of freedom are typically found in this frequency range, offering a natural playing field for observing terahertz dynamics. The concomitant development of commercial, intense Ti:sapphire laser systems, as well as of nonlinear crystal able to generate efficient optical rectification, has allowed researchers to have relatively easy access to terahertz electric (magnetic) fields as high as 1 MV/cm (0.3 T). Such large fields are strong enough to initiate nonlinear dynamical effects in both phonon [1] and spin [2] degrees of freedom.

However, it would be desirable to increase such fields by one or two orders of magnitude in order to fully explore the nonlinear regimes in solids. Terahertz metamaterials [3] offer a solution to this demand compatibly with the use of the same commercial laser systems, i.e. without the need of large scale facilities. In metamaterials, typically comprising of periodically arranged gold electrodes deposited on a dielectric substrate, the electric or magnetic field of the impinging radiation are concentrated in localized areas. These areas extend over as much as several square micrometers for the terahertz case, allowing for fabrication using inexpensive and reliable optical lithographic methods.

2. Discussion

In this talk, I will present the design of several metamaterials aimed at enhancing either the electric or the magnetic field of the impinging terahertz radiation. In both cases, I will illustrate finite three-dimensional element simulations detailing the spatial distribution of the electric and magnetic fields, both in the frequency and time-domain. The latter description is key to properly estimate the near-field enhancement when the impinging field is a broadband, single-cycle terahertz pulse, which is the most typical realization.
in table-top systems.

I will also discuss experimental results showing evidence for nonlinear phonon dynamics driven by strong terahertz electric fields, that can be enhanced further in antennas structure such as the one shown in the top panel of Fig. 1. I will also discuss a novel scheme to drive highly nonlinear spin dynamics using lollipop metamaterials (showed in the bottom panel of Fig. 1, that would allow to reach the ballistic magnetization switching regime, so far only observed using terahertz radiation generated in mile-long particle accelerators, on table-top setups [4].

Finally, I will show preliminary spectroscopic measurements demonstrating the accuracy of careful 3-dimensional finite element simulations to reproduce the experimental response of the metamaterials. I will also present the preliminary data of spin dynamics driven in the near-field region of the metamaterial, and recorded using time-resolved magneto-optical microscopy with terahertz pump and near-infrared probing scheme, as shown schematically in Fig. 2.

3. Conclusions

We discussed the design of several metamaterial structures aimed at enhancing either the electric or the magnetic field of terahertz radiation in the near-field. We showed preliminary results demonstrating the optical properties of the metamaterials, as well as time-resolved microscopy data showing large amplitude, terahertz-driven dynamics in solids. We envision that the combination of metamaterials with suitable condensed matter systems will allow for investigating yet unexplored areas of strongly non-equilibrium states in materials of both fundamental and applied interest.

Dynamical chiral metasurfaces: mechanical based modulation and polarimetry

Alessandro Pitanti1,*

1NEST, CNR Istituto Nanoscienze and Scuola Normale Superiore, Piazza San Silvestro 12, 56127 Pisa, Italy

Abstract
We combine the chiral properties of an all-dielectric GaAs metasurfaces operating in the near-infrared range with micro-mechanical motion. We demonstrate polarization modulation and spring-effect based light polarimetry at frequency exceeding 300 kHz.

1. Introduction
Among the amazing properties of metasurfaces, very large circular dichroism has been reported, fairly exceeding the one found in biological molecules or in classical waveplates [1]. An interesting feature would be to enhance the device properties by adding an active response to the original static tunability by-design. To this end, we show how the chiral response of a minimal, all-dielectric metasurface can be dynamically controlled by placing it in a suspended, mechanically actuable membrane. By activating its drum-like mechanical motion, we are able to achieve ~350 kHz polarization modulation; moreover, by using the thermal induced back action of light on the mechanics, we are able to deterministically infer the polarization state of light, paving the way to extremely fast polarimetry.

2. Methods
The metasurfaces consists of a suspended, patterned, 210 nm thick GaAs layer. The pattern used to obtain a chiral response consists of “L-shaped” holes. Fabrication starts from a 220nm/3µm GaAs/Al0.3Ga0.7As heterostructure grown on a GaAs wafer, the pattern has been transferred employing an electronic resist mask (AR-P 6200) and subsequent chlorine based reactive ion etching. Details on sample fabrication and pattern geometrical parameters have been reported elsewhere [2]. The final device configuration is sketched in Fig. 1 (a); it consists of a proper metasurface, whose final pattern is reported in Fig. 1 (b), plus a GaAs substrate showing multiple Fabry-Perot resonances. The membrane vibration modifies the phase of light traveling through the device granting optomechanical coupling. In particular, we investigated the coupling between delocalized electromagnetic modes around 1550nm (see the single cell finite-element-method (FEM) simulations of Fig. 1 (c)) and the fundamental drum-like membrane motion (see the full-membrane FEM simulations of Fig. 1 (d)). The motion is activated by mounting the full chip on top of a piezo-stack.

Figure 1: (a): Sketch of the device under investigation. (b): Scanning Electron Micrograph of the L-shaped pattern which defines the metasurface. (c): Simulation of the electromagnetic mode in a single cell. (d): Simulation of the whole membrane mechanical mode. (e): Sketch of the experimental setup.

The sample holder is then placed in a vacuum chamber and placed in a simple optical line as the one sketched in Fig. 1 (e). The input laser signal is shined onto the sample with an arbitrary polarization; the reflected light is then analyzed using optical waveplates and a lock-in amplifier with the piezo-drive taken as a reference.
3. Results

3.1. Polarization modulation

At first we investigated the effect of the mechanical motion on the system optical response. At atmospheric pressure, where the mechanical resonator is overdamped, a 300 kHz monochromatic bias was fed to the piezo stack and used as a phase reference for the coherent measurements. By acting on the phase of light interacting with the sample, mechanical motion affects the linear and circular dichroism of the system. As an example, the modulation of circular dichroism (defined as the normalized intensity difference of light reflected under left-circular and right-circular polarization) is reported in Fig. 2 (a) along with a simulation based on a hybrid scattering-transfer matrix formalism. A very good agreement between experiment and simulation and the use of polarization filters let us to distinguish between intensity and polarization modulation effects, finding a linear, pure polarization modulation exceeding 0.5 rad on the Poincaré sphere, mainly limited by the linearity of mechanical motion.

3.2. Optomechanical polarimetry

The back-action of light on the mechanical motion was investigated by pumping the sample chamber to a pressure linewidth as small as 0.15 kHz (Q ~ 2000). A residual heating of the membrane (few hundredths of K) which conversely shifted and modified the observed mechanical resonance. A small In vacuum the air damping is greatly reduced and the mechanical mode appears as a narrow peak, with its linewidth.

4. Conclusion

Our device combines together the polarization modulation properties of metasurfaces together with the dynamical tuning and sensitivity of micromechanical resonators. While showing polarization modulation and light polarimetry employing the fundamental mechanical mode oscillating at 350 kHz, we foresee the possibility of producing ultra-fast modulators and polarimeters combining our device with surface acoustic waves which naturally are created on the piezoelectric, GaAs device layer.

Structural chirality combined with optical activity (aka magneto-electricity)

Martin McCall
Department of Physics,
Imperial College London, UK
E-mail: m.mccall@imperial.ac.uk

Abstract
We present a fully analytic solution for axial propagation along a structurally chiral dielectric medium infiltrated by an optically active medium that is chiral at the molecular level.

1. Introduction
On account of the fact that photons are circularly polarized, there is considerable focus nowadays on media that intrinsically engage the photon’s chirality. There are two fundamental types such chiral media: (a) optically active media where chirality occurs at the molecular level, and is due to magneto-electric coupling, and (b) structurally chiral media where chirality occurs due to dielectric inhomogeneity and is formed by the periodic rotation of the principal axes of the dielectric tensor. Our focus here is to examine how these two aspects may be combined into a single medium.

2. Optical Activity
The most frequently used frequency domain constitutive relations for an optically active medium are the so-called Drude-Born-Fedorov (DBF) relations [1],
\[
\begin{align*}
d &= \varepsilon E + i \alpha h, \\
b &= -i \alpha E + \mu h.
\end{align*}
\]
where the usual electromagnetic fields \( \mathbf{D}, \mathbf{B} \) and \( \mathbf{H} \) have been replaced by scaled fields \( h = \eta_0 H, b = (\eta_0/\mu_0)B = cB \) and \( d = \varepsilon_0^{-1}D \), that have the same dimensions as the electric field \( \mathbf{E} \). Here \( \eta_0 = (\mu_0/\varepsilon_0)^{1/2} \) is the free-space impedance and \( \varepsilon, \mu \) and \( \alpha \) are dimensionless. For harmonic fields, the Maxwell curl relations then become
\[
\nabla \times \mathbf{E} = k_0 \alpha \mathbf{E} + i \mu k_0 \mathbf{h},
\]
\[
\nabla \times \mathbf{h} = -i k_0 \varepsilon \mathbf{E} + k_0 \alpha \mathbf{h},
\]
where \( k_0 = \omega/c \). Solving these equations for a plane wave determines that the transverse electric field vector satisfies
\[
\begin{pmatrix}
E_x \\
E_y
\end{pmatrix}
_z = e^{ik_0(z+\mu_0)}
\begin{pmatrix}
\cos \alpha k_0 z & \sin \alpha k_0 z \\
-\sin \alpha k_0 z & \cos \alpha k_0 z
\end{pmatrix}
\begin{pmatrix}
E_x \\
E_y
\end{pmatrix}
_0.
\]
Thus, as it propagates through the medium, a linear polarization is rotated in a left-handed sense at a rate of \( \alpha k_0 \text{ rad m}^{-1} \).

3. Structural Chirality
Structural chirality is characterized by a tensorial \( \varepsilon \) the principal axes of which rotate periodically about the \( z \)-axis (see Fig. 1)
\[
\varepsilon = R^{-1} \varepsilon R, \quad R = \begin{pmatrix} \cos pz & -\sin pz \\ \sin pz & \cos pz \end{pmatrix}.
\]
It turns out that by defining the transverse fields
\[
\mathbf{e} = R\mathbf{E}, \quad \mathbf{h} = R\mathbf{h},
\]
the Maxwell curl relations for a harmonic field propagating along the \( z \)-axis reduce to
\[
\frac{d}{dz} \begin{pmatrix}
\mathbf{e} \\
\mathbf{h}
\end{pmatrix} = \begin{pmatrix}
-pS & i\mu k_0 S \\
-i\mu_0 S \varepsilon & -pS
\end{pmatrix} \begin{pmatrix}
\mathbf{e} \\
\mathbf{h}
\end{pmatrix},
\]
where \( S = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix} \). Since the matrix appearing on the right of Eq. (7) is independent of \( z \), the system admits a straightforward analytic solution that can be written formally as
\[
\begin{pmatrix}
\mathbf{e} \\
\mathbf{h}
\end{pmatrix} = \exp \begin{pmatrix}
-pzS & i\mu k_0 zS \\
-i\mu_0 z \varepsilon & -pzS
\end{pmatrix} \begin{pmatrix}
\mathbf{e} \\
\mathbf{h}
\end{pmatrix}_0.
\]
This solution has been well studied (see, for example Refs. [2] and [3]), and can be used to compute the various reflection/transmission coefficients \( (R_{LL}, T_{LR}, \text{etc.}) \) associated with axial propagation. These can be computed in the presence of interface reflections and with complex principal dielectric coefficients (i.e., gain/absorption).

4. Combining Optical Activity with Structural Chirality

Simply stated, the problem of combining optical activity with structural chirality amounts to replacing the scalar \( \epsilon \) in Eq. (3) with the tensor \( \tilde{\epsilon} \) of Eq. (5). We will show that the combined system is also fully analytic. A key emergent formula is the Bragg wavelength at which co-handed reflection is maximized:

\[
\lambda_0^{(B)} = \left( \left( \left( \epsilon_1 + \epsilon_2 \right) / \epsilon \right)^{1/2} - \alpha \right) \frac{2\pi}{p},
\]

Thus the effect of making the structurally chiral medium optically active is to shift the Bragg resonance from its value \((= 2\pi n / p)\) in the absence of optical activity.

Of experimental interest is the so-called \( g \)-parameter, measuring the chiral dysymmetry:

\[
g_{abs} = 2 \frac{A_L - A_R}{A_L + A_R}
\]

where \( A_{L,R} \) are the absorbed fractions of incident left or right circularly polarized light, computed via

\[
A_L = 1 - T_{LL} - T_{RL} - R_{LL} - R_{RL},
\]

\[
A_R = 1 - T_{LR} - T_{RR} - R_{LR} - R_{RR},
\]

where \((\text{e.g.})\) \( T_{RL} \) is the transmitted fraction of RCP when the incident light is LCP. By way of illustration of the Bragg formula, Eq. (9), in Fig. 2 we compute \( g_{abs} \) both in the absence, and in the presence of optical activity.

5. Conclusions and Prospects

We have successfully combined known analytic solutions for isotropic optical activity with axial propagation along a structurally chiral medium. We will show how practical formulæ emerge for the reflectivities/transmissivities, when the fully analytic solution is replaced by an approximate approach based on coupled wave theory. From the practical viewpoint we will consider the implications of our results on (a) circularly polarized luminescence in chiral dyes [4, 5, 6], (b) chiral lasers [7, 8] and (c) effects occurring when \( \alpha k_0 = p \), i.e., the effects of optical activity are offset by structural chirality.

Controlling the plasmon resonance of an Au/Ni hybrid nanostructures using external magnetic field or temperature

Silvère Schuermans¹, Thomas Maurer¹, Alexander Govorov², and Jérôme Plain¹

¹L2n/ICD, University of technology of Troyes and CNRS, France

*corresponding author, E-mail: jerome.plain@utt.fr

Abstract

We report on the fabrication of plasmonic hybrid Ni-Au nanoantennas. The optical properties of such nanostructure depend on the applied magnetic field and/or the temperature. Thus, we tune under control the plasmon resonance using external stimuli.

1. Introduction

Over the past two decades, metallic nanoparticles have attracted increasing interest because of their varied and complex optical properties. These properties are mainly governed by the collective oscillations of conduction electrons called "plasmons". In particular, the excitation of the latter by optical fields leads to a local exaltation of the electromagnetic field on the surface of the nanoparticle. This very intense nanosource makes it possible to envisage nanometric optical concepts by controlling, manipulating and amplifying light at this scale. In recent years, a new challenge is the control and manipulation of optical properties using an external stimulus [1,2]. In this context, we developed Ni-Au plasmonic nanoantennas which exhibit an optical response that can be modulated either by the application of an external magnetic field or by a change in temperature.

2. Results and discussion

We realized Au/Ni nanorods with different aspect ratio though a top-down approach (e-beam lithography and metal evaporation). Then, the localized surface plasmon resonances of the different nanostructures have been studied using extinction spectroscopy under an applied magnetic field or a local increase of the temperature. In both cases, the LSPR present a clear red shift of about 10 to 20nm for an applied magnetic field (see figure 1) and up to 100nm for a local increase of the substrate temperature (see figure 2). The two process are clearly different. In the case of the magnetic field, one can understand the red-shift as a deviation of the electrons path due to the creation of a Lorentz force.

Figure 1: Relative shift of the plasmon resonance as a function of the applied magnetic field. The LSPR maximum are comprised between 600nm and 700nm.

Figure 2: Relative shift of the plasmon resonance as a function of the substrate temperature for nanorods with an aspect ratio of 2.5. The LSPR is situated around 650nm.
In the case of the temperature, the LSPR-shift is directly correlated with the change of the dielectric functions of the metals.

3. Conclusions

In summary, we demonstrate the possibility to tune under control the plasmon resonance of hybrid Ni/Au nanorods though an applied magnetic field or a local control of the temperature.

Nonlocal effects in piezoelectromagnetic metamaterials

Anatolii Konovalenko, Felipe Pérez-Rodríguez*

Instituto de Física, Benemérita Universidad Autónoma de Puebla, Puebla, Pue., 72570, México

Abstract
A homogenization theory for calculating the nonlocal effective parameters of piezoelectromagnetic crystals with any inclusion form and arbitrary Bravais lattice is proposed. The theory allows to describe the bulk photonic-phononic band structure even beyond the long wavelength limit. Applying the method of expansion into bulk modes, the theory can be used to study the propagation of coupled electromagnetic and sound waves in finite-size piezoelectromagnetic metamaterials.

1. Introduction
Homogenized photonic crystals (PC), i.e. photonic metamaterials have been studied intensively over the last three decades because of their extraordinary optical properties, which can be described by using effective parameters at wavelengths larger than the lattice constant. At present, there exist several homogenization methods, which can be applied to calculate the effective parameters of metamaterials (see, for example, [1, 2, 3] and references therein). Among them, the general homogenization theory [4], which is based on the Fourier formalism, provides explicit formulas for determining all the components of bianisotropic response tensors - the effective permittivity, permeability and crossed magneto-electric tensors for arbitrary Bravais lattice and shape of the inclusions. Besides, such a homogenization theory can also be applied at high frequencies where the bianisotropic response becomes nonlocal, i.e. the effective parameters depend on both frequency $\omega$ and Bloch wave vector $k$. An important characteristic of the nonlocal homogenization approach (NHA) is associated with the fact that the effective parameters describe the photonic band structure even beyond the long wavelength limit. Nevertheless, the application of the homogenization theory [4] still requires the inversion of very large matrices and, consequently, a very long computing time. To make feasible the calculations of the effective bianisotropic-response tensors, an approach based on the form-factor division (FFDA) to get highly accurate results at any filling fraction of the inclusions and arbitrary forms of the inclusion, was proposed in Ref. [6]. As is shown there, the NHA can be complemented with the method of expansion into bulk modes (MEBM) to calculate and interpret optical spectra of finite-size regular structures.

Phononic crystals are periodic structures composed of materials with different mass density and elastic parameters. As in the case of homogenized photonic crystals, at sufficiently long wavelengths, the phononic one can be considered as a homogeneous medium, whose elastic properties are described by employing effective parameters such as the effective mass density and the effective compliance tensor. In the work [5], a very general homogenization theory for describing the propagation of sound waves in three-dimensional solid phononic crystals (SPC) was proposed. The theory is based on the Fourier formalism and provides explicit expressions for the effective mass density and compliance tensors of phononic crystals with arbitrary inclusion form and Bravais lattice. As it was shown in [5], in the quasi-static case, rectangular two-dimensional lattices of water-filled holes in an elastic host matrix behave as metasolids since they exhibit solid-like behavior with strongly anisotropic mass density in the low-frequency limit. The homogenization approach [5] was recently applied [6] to calculate the nonlocal effective parameters, namely mass density and stiffness tensor, for 3D solid phononic crystals, using the FFDA. With the calculated effective elastic parameters, the phononic band structure of the phononic crystal can be described not only in the long wavelength limit, but also beyond it. In addition, it was shown that the anisotropy in the effective dynamic mass-density, appearing at sufficiently large frequencies, is associated with the dependence of the nonlocal metasolid response on the phononic-mode polarization, form of the inclusions, and type of the periodic array.

2. Piezoelectromagnetic metamaterials

Here, we shall introduce a homogenization theory to calculate the effective parameters of periodic structures composed of both piezoelectric and piezomagnetic materials. The theory is based on the Fourier formalism and considers any inclusion shape, arbitrary Bravais lattice, and any linear coupling between electrodynamics and elastic properties of the components. Within the proposed homogenization procedure, we have derived explicit expressions for all the components of the effective response matrix given by the effective bianisotropic ($\varepsilon'$, $\mu'$, $\gamma'$, $\delta'$), mass-density ($\rho'$), compliance ($S'$), piezoelectric ($\varepsilon'$) and piezomagnetic ($d'$)
In the case when there is no coupling between the electromagnetic and elastic responses, the matrix blocks, corresponding to the bianisotropic, mass-density, and compliance tensors go over into the expressions, which were derived in the works [4, 5], respectively. The effective response of the homogenized piezoelectromagnetic crystal (piezoelectromagnetic metamaterial) is nonlocal because the components of the effective matrix depend on both the Bloch wave vector and the frequency. Using the FFDA, we have applied the nonlocal homogenization approach to specific piezoelectromagnetic crystals. In particular, their photonic-phononic band structure is described even beyond the long wavelength limit, where the nonlocal effects are well manifest. Moreover, we show how the proposed NHA for piezoelectromagnetic crystals and the MEBM can be applied to calculate and interpret optical and acoustical spectra of finite-size piezoelectromagnetic metamaterials.

Electromagnetic Sink Based on a Nonreciprocal Metasurface Cavity

Mojtaba Dehmollaian$^1$, Guillaume Lavigne$^2$, and Christophe Caloz$^2$

$^1$School of Electrical and Computer Engineering, University of Tehran, Iran
$^2$Poly-Grames Research Center, Polytechnique Montréal, Montreal, Quebec, Canada

Abstract

This paper proposes a nonreciprocal bianisotropic metasurface cavity to absorb the electromagnetic radiation of a given illumination. Using Generalized Sheet Transition Conditions (GSTCs), it first synthesizes the bianisotropic susceptibility tensors, corresponding to specifications. Next, it employs combined Integral Equations (IEs) and GSTCs to compute the wave scattering by the cylindrical metasurface cavity. Finally, it presents results for a circular cylindrical metasurface cavity illuminated by a plane wave, which reveal that the fields inside the cavity are exactly those of a waveguide mode at its cutoff frequency and that a shadow area appears on the backside of the cavity.

1. Introduction

Metasurfaces represent a vast field of exploration for new electromagnetic concepts and applications. A recent overview of them is presented in [1]. Nonreciprocal ferrite components are costly, heavy, incompatible with integrated circuit technology, and require a cumbersome biasing magnet. Recently, there has been a number of attempts to realize magnetless nonreciprocal components [2]. For instance, Kodera and Caloz introduced in [3] a transistor load ring metamaterial mimicking ferrites at microwaves which exhibits the main properties of ferrites including Faraday rotation. Such a “metaferrite”, enables novel electromagnetic effects and applications.

Confining electromagnetic energy in a small region of space is of significant importance in many areas of science and technology. Such an operation of light trapping has been proposed in [5] and [4] by leveraging nonlinearity. Paper [4] suggests a mechanism to store light in an open core-shell plasmonic structure (‘meta-atom’) with a nonlinear optical response, where the trapped light energy can be pumped with a plane wave excitation [5].

Here, we present the idea of electromagnetic wave trapping using a linear nonreciprocal metasurface cavities based on metaferrite technology. This device operates as an efficient sink for electromagnetic energy.

2. Concept

Figure 1 shows the proposed concept of a nonreciprocal linear bianisotropic metasurface cavity that absorbs and traps electromagnetic radiation from an illuminating plane wave.
For the case in Fig. 1 where the illuminating field is a TE$_z$ plane wave only $\chi_{ee}^{tt}$, $\chi_{em}^{tz}$, $\chi_{me}^{zt}$, and $\chi_{mm}^{zz}$ are excited and the other susceptibilities are hence set to zero. We use two transformations to synthesize these susceptibilities. In the 1$^{st}$ transformation for a fixed incidence angle we enforce full transmission from region $a$ to region $b$, while in the 2$^{nd}$ transformation, we set zero transmission from regions $b$ to $a$. We then synthesize the bianisotropic susceptibilities using the GSTCs. We further assume that the magnetic specular reflection coefficient in the 2$^{nd}$ transformation is -1, then $\chi_{ee}^{tt} = 0$ and $\chi_{em}^{tz} = 0$ while $\chi_{me}^{zt}$ and $\chi_{mm}^{zz}$ are nonzero.

3. Full-Wave Illustration

We compute the scattering of waves by the cylindrical metasurface cavity using the synthesized susceptibilities of the previous section and the combined GSTCs and integral equations method presented in [6].

Corresponding results are shown in Fig. 2 and Fig. 3 for a cylinder of radius $a = X_{31}/k_0$, where $X_{31} = 6.3802$ is the first root of the Bessel function of first kind and 3$^{rd}$ order. Figures. 2(a) and (b) plot $\chi_{mm}^{zz}$ and $\chi_{me}^{zt}$ versus position along the metasurface cavity. Inserting these susceptibilities into the IEs provides the magnetic field shown in Fig. 3 which perfectly exhibits the field distribution of the TE$_{31}$ mode of a circular waveguide at its cutoff frequency inside the cavity and the expected shadow area at the back of the cavity.

4. Conclusions

We presented the concept of electromagnetic wave trapping by a linear nonreciprocal metasurface cavity. The idea is to use a nonreciprocal penetrable metasurface cavity that allows full-transmission from outside to inside while reflecting all energy from inside. This structure leverages metasurface technology to create a device that sinks electromagnetic energy. We illustrated the concept with results for a circular-cylindrical metasurface, which revealed that the fields inside the cavity are exactly those of a circular waveguide mode and that a shadow area appears at the backside of the cavity, as expected.

SIMPLE SPINTRONICS AND SUPERCONDUCTING SPINTRONICS, BASED ON THE CHIRAL INDUCED SPIN SELECTIVITY (CISS) EFFECT

Yossi Paltiel

Applied Physics Department and the Center for Nano science and Nanotechnology, Hebrew University, Jerusalem 91904, Israel

With the increasing demand for miniaturization, nano-structures are likely to become the primary components of future integrated circuits. Different approaches are being pursued towards achieving efficient electronics, among which are spin electronics devices (spintronics). In principle, the application of spintronics should result in reducing the power consumption of electronic devices. A new, promising, effective approach for spintronics has emerged using spin selectivity in electron transport through chiral molecules, termed Chiral-Induced Spin Selectivity (CISS). Studying the CISS effect it was found that chiral molecules, and especially helical ones, can serve as very efficient spin filters.1, 2

Recently, by utilizing this effect we demonstrated a magnet less spin based magnetic memory.3 The presented technology has the potential to overcome the limitations of other magnetic-based memory technologies to allow fabricating inexpensive, high-density universal and embedded memory-on-chip devices.4 We have shown that the memory device can work at ambient temperatures and scaled sown to 30nm.5,6 To further enhance efficiency, we also investigated the interface between superconducting thin films and the magnetic layers improving and simplifying superconducting spintronics devices.7,8

Abstract

I will discuss several topological magnonic materials. The edge spin waves in these magnonic materials are robust against perturbations. Functional magnonic devices such as beamsplitter and interferometer can be made out of domain walls in a strip. It is shown that an incoming spin wave beam along one strip edge splits into two spin wave beams propagating along two opposite directions on the other strip edge after passing through a domain wall.

1. Introduction

Topological matters have attracted enormous attention in recent years because of their interesting and exotic properties. One such property is the existence of unidirectional and topologically protected surface/edge states that are robust against internal and external perturbations. The study was initially exclusive for electron systems and was believed to be a quantum phenomenon. It is now known that the topological states can exist in classical mechanics and photonics. Topological states can also exist in magnetic materials govern both by quantum mechanics at the zero temperature and by classical magnetization dynamics at finite temperatures.

2. Discussion

Magnetic materials are highly correlated spin systems that do not respect the time-reversal symmetry. The low-energy excitations of magnetic materials are spin waves whose quanta are magnons. In the ambient temperature, the magnetization dynamics of real magnetic material shall be govern by the Landau- Landau-Lifshitz-Gilbert (LLG) equation. Like electronic materials that can be topologically nontrivial, magnetic materials govern by the LLG equation can also be topologically nontrivial with topologically protected edge spin waves. Unlike the normal spin waves that are very sensitive to the system changes and geometry, these edge spin waves are robust against internal and external perturbations such as geometry changes and spin wave frequency change. Therefore, the magnetic topological matter is of fundamental interest and technologically useful in magnonics.

3. Conclusions

We will see several examples of magnonic topological materials, including pyrochlore [1] and stacked honeycomb [2] ferromagnets as Weyl magnons, as well as perpendicularly magnetized two-dimensional films with Dzyaloshinskii-Moriya and/or pseudodipolar interactions as generic magnonic insulators [3,4]. The edge spin waves in these magnonic materials are robust against perturbations. Interesting reconfigurable functional magnonic devices called beamsplitter and interferometer can be made out of domain walls in a strip. It is shown that an in-coming spin wave beam along one edge splits into two spin wave beams propagating along two opposite directions on the other edge after passing through a domain wall.

Chirality and Anti-ferromagnetism in Artificial Micro-/Nano-Structures

Kun Huang¹,*

¹Department of Optics and Optical Engineering, University of Science and Technology of China, Hefei, China
*corresponding author, E-mail: huangk17@ustc.edu.cn

Abstract
The light-matter interaction is usually dominated by the coupling between microscopic electromagnetic modes and the geometry of structures. In this talk, the roles of chiral light in enhancing the helical dichroism and exciting antiferromagnetic modes will be introduced. Direct detection of chiral microstructures is implemented by using sign-opposite twisted vortices. High-efficiency polarization conversion in dielectric geometric metasurfaces is also interpreted in terms of microscopic antiferromagnetic modes induced by chiral circular-polarized light.

1. Introduction
Chirality is a common feature in nature and exists in many areas such as human hands, bilateral pictures in arts. In optics, the chirality of light also plays an important role in the light-matter interaction. The optical chirality usually refers to the circularly polarized light and the optical vortex beams with sign-opposite wavefronts. The circularly polarized light has the upward and downward spins, which can be used to detect the chiral objects or artificial structures with birefringence. For example, most molecules are chiral so that their transmission under the illumination of circularly polarized (CP) light depends on the spins of incident light, which induces the so-called circular dichroism (CD). However, the CD interaction is quite weak because the scale of molecules is much smaller than the operating wavelength. Although the optical vortices have been used to detect the chirality of structures[1], it fails due to the scale mismatch between optical vortex modes and electromagnetic multiple modes supported by molecules. It indicates that the supporting modes in nanostructures or nanoobjects play the important roles in the interaction with light[2]. A strong interaction requires the nearly perfect match between microscopic modes and the probe light. It is valid in the entire nanophotonics that focus on the interaction between light and artificial nanostructures. In a dielectric nanorod, the supporting modes could be taken as a coherent superposition of different-order electromagnetic dipoles[3]. When designed properly, the nanorod could work as a nanoscale half-waveplate (HWP) to convert one spin of a CP light beam into the other, which is quite useful in metasurfaces that refer to the subwavelength-pixel diffractive optics[4]. Although it is well-known that the microscopic electromagnetic modes are important during this process, the detailed roles are still not recognized comprehensively. So, the work will focus on these two problems: 1) the strong dichroism of helical objects interacted with vortex beams; 2) the microscopic interpretation of dielectric nano-halfwaveplates by using antiferromagnetic modes.

2. Strong helical dichroism

Figure 1. (a) Illustration of OAM beams with RHW (left panel) and LHW (right panel) illuminating on a chiral structure. (b) Vortical dichroism measurements of chiral microstructures.
helical wavefront and chiral structure. Figure 1b shows our observed results, which show symmetric distribution of vertical dichroism (VD) between two chiral microstructures with opposite handedness. The grey straight line indicates VD=0 for guide-to-the-eye. The solid lines represent the mean values; shading indicates the standard deviation of a set of three measurements with the same sample. One can see that the VD is 120%, which is enhanced by 200 times compared with the previous results.

3. Anti-ferromagnetic modes in dielectric nano-HWP

![Image of cell unit and meta-holograms]

Figure 2. (a) Sketch of a cell unit with the dimension of $p_x=p_y=250$nm. (b-c) Antiferromagnetic mode with even- and odd-numbered anti-parallel magnetic dipoles. (d) Ultra-channel holograms. (e) Vector holographic image.

Geometric dielectric metasurfaces made of spatially rotating nanorods could be used to tune the phase of transmitted light with its polarization cross to the incident one, as sketched in Fig. 2a. A detailed simulation about the induced electromagnetic modes within the nanorod is provided in Figs. 2b and 2c. For the $E_x$ component, its induced electric fields contain four circle displacement currents with the alternative clockwise and anti-clockwise directions, which are relative to four antiparallel magnetic dipoles (AMDs) that are vertically located along the $z$ axis. In such antiferromagnetic modes, the even circle currents orientate both electric vectors of light at the incident (bottom) and output (top) ends of the nanobrick towards the same direction (see Figure 2b). It implies that the $x$-component of the incident CP light is maintained after passing through nanobricks. However, for the $E_y$ component, an antiferromagnetic mode with three AMDs is induced, so that these odd circle displacement currents make the electric vector of the transmitted light inverse to that of incident light (Figure 2b), indicating a phase delay of $\pi$. Differing from the birefringent effects in traditional HWPs and the electric dipole response in plasmonic nano-HWP, the antiferromagnetic modes with the AMDs provide an alternative approach to investigate the dielectric nano-HWP.

Finally, as a proof-of-concept demonstration of ultraviolet vectorial anticounterfeiting, we design and fabricate an ultra-channel meta-hologram that encodes two spin-channel sparse holograms (Fig. 2d) while generates three different images with polarization features (Fig. 2e), which provides a new approach for optical encryption and security.

4. Conclusions

In summary, we have introduced the strong vortical dichroism induced by the micro-structure and optical vortices with an enhancement of around 200 times. The roles of antiferromagnetic modes in dielectric nano-halfwaveplates have also been investigated and shown that it holds the fundamental origin of polarization conversion from one circular polarization to its cross.

Abstract
We study surface-plasmon polaritons (SPPs) for lossy isotropic media, with the plasmon concept applicable both to metals and to double-negative-index media, and apply this framework to generate, propagate and control linear/nonlinear SPPs. We derive SPP propagation conditions along planar and curved interfaces and study controllable propagation of SPP breathers and creation of polaritonic frequency combs at interfaces between an atomic medium and metamaterials. Our results are important for subwavelength photonic-circuit elements such as SPP phase modulators and frequency-comb generators.

1. Introduction
Linear and nonlinear SPPs [1] are valuable in miniaturized photonic circuits [2] with applications to sensing, waveguiding [3], switching and modulating [4]. SPPs arise at dielectric-metal interfaces [2], and effective SPPs arise as well at the interface between a dielectric and a double-negative-index (DNI) metamaterial; metal is a single-negative-index (SNI) medium, and a dielectric is a double-positive-index (DPI) medium. The DNI metamaterial can be regarded as being a doubly plasmonic DNI medium [5], based on interpreting the metamaterial as comprising free-moving electric and magnetic charges (monopoles) [6].

Generating and controlling linear and nonlinear SPPs is challenging due to dependence on material properties at the interfaces, including linear and nonlinear electromagnetic (EM) susceptibilities and surface roughness [7]. We address this design problem by developing a framework that accounts for lossy isotropic media, including materials and metamaterials, and use this framework to design schemes for exciting and propagating linear and nonlinear SPPs. Such capabilities could advance micro-chip detectors, high-speed SPP phase modulators and polaritonic frequency combs.

2. Model
We develop a framework for SPPs that accounts for lossy media. To controllably excite and characterize SPP propagation along these lossy interfaces/waveguides, we employ DPI, SNI and DNI media interfaces with dielectrics. Our results are specialized to the quite general case of linear, homogeneous, isotropic (LHI) media and we assume the interface is subject to a plane-wave driving laser field with uniform intensity distribution via end-fire coupling [3].

We characterize linear SPP propagation along planar and curved interfaces. To this aim, we determine necessary and sufficient conditions for SPP propagation by introducing strict bounds on the real and imaginary parts of the squared propagation coefficient to decide whether a given mode corresponds to propagating SPP or not. These bounds on the squared propagation coefficient at planar interfaces reduce to a set of conditions on the real and imaginary parts of EM susceptibilities, which we refer to as characteristic equations.

We employ these characteristic equations to determine regions for which transverse electric (TE) and transverse magnetic (TM) SPPs propagate along the planar interface between SNI or DNI media with air. Our SPP characterization is valuable for checking application viability; e.g., our method falsifies a prediction that SPPs could propagate through the surface of a DNI medium with any values of permittivity and permeability [8]. Instead, SPP propagation can occur only for certain medium parameters [6]. Thus, SPPs cannot stably propagate in frequency regions corresponding to DNI medium (at interfaces comprising free-moving electric and magnetic charges).

To characterize SPP propagation along circular interfaces between lossy LHI media, we employ conformal transformations [9]. We build on previous techniques for characterizing or guiding SPP propagation at curved interfaces or bent waveguides [10]. Specifically, we employ conformal logarithmic mapping to map circular interfaces between two LHI media to a planar interface between two linear inhomogeneous isotropic (LII) media. We consider circular interfaces due to the simplicity of their solutions; our approach can be extended to other curvatures.

We show that the SPP dispersion equation at the curved interface is analogous to the dispersion equation at the conformally mapped LII media planar interface. To decide whether a given mode at LII media planar interfaces is a propagating SPP or not, we apply bounds on the real and imaginary parts of the complex propagation coefficient. We confirm our SPP solutions by checking the physical intuition through analyzing the field intensity and Poynting-vector properties at the interfaces. Ascertaining the viability of SPP propagation at planar and curved interfaces and checking SPPs sensitivity to materials EM susceptibiliti-
ties through the characteristic equations is advantageous for designing miniaturized photonic circuit elements including waveguides and sensors.

Now we proceed from a simple dielectric medium and linear optics to multi-level atoms that yield nonlinear optics. For active control of nonlinear SPPs, we recommend driving a four-level N-type atomic (4NAs) cloud [11], treated as a cold $^{87}$Rb due to its considerable Kerr nonlinearity and controllable dispersion, at the DNI interface. The atomic cloud is trapped near the interface by a magneto-optical trap [12] with a thickness more than five $|5S_{1/2}, F = 2\rangle \rightarrow |5P_{1/2}, F = 2\rangle$ dipole transition wavelengths. This nonlinear waveguide drive by three co-propagating fields: a pump signal, a coupling signal and a weak probe signal, all injected by end-fire coupling.

Our quantitative description of the system is obtained by solving Maxwell-Bloch equations based on a perturbative, asymptotic, multi-scale position and time expansion [13]. Our third-order truncated solution yields a nonlinear Schrödinger equation. We establish a controllable Kerr nonlinearity by sufficient field concentration and appropriate intensities and detunings for the laser fields. We investigate the Rabi-frequency dynamics for resultant nonlinear SPPs including temporal solitons [14], breathers, solitary localized nonlinear waves with a periodically oscillating amplitude and surface polaritonic rogue waves [15] as functions of field-intensities and detunings.

For spatial control of nonlinear SPPs, we suggest driving 4NAs on the surface of a DNI medium. These components are contained in a stable cavity and serve as a nonlinear planar waveguide. We assume Pr$^{3+}$ dopants, as the atomic medium, in a Y$_2$SiO$_5$ transparent crystal over a thickness of several dipole transition wavelengths. The waveguide is driven by three co-propagating fields: pump, weak probe and standing wave coupling signals, all injected by end-fire coupling.

We show that the laser driving fields excite nonlinear SPPs including Akhmediev breathers, and a frequency comb, as a nonlinear wave that appears briefly at specific positions. We propose generating these nonlinear waves by coupling the probe laser to the dipole moment of the 4NA transition. Stability is arises via a low-loss SPP condition and judiciously modifying SPP nonlinearity and dispersion at the interface.

3. Conclusions
We present a framework for linear and nonlinear SPPs along lossy media interfaces to excite, propagate and control SPPs. We extend the case of SPPs at lossless metallic planar interfaces to define and derive characteristic equations for SPPs at lossy planar and curved interfaces. We then propose controllable propagation of SPP breathers and polaritonic frequency combs at atomic materials interfaces with DNI media.

Abstract
Optical effects induced by the spin-driven chirality and polarity are investigated by using the time-domain terahertz polarimetry. The resonantly enhanced nonreciprocal optical effects are observed on the electromagnon excitation, which is an electrically active collective spin excitation. The observed nonreciprocal directional dichroism, gyrotropic birefringence and natural optical activity can be viewed as the dynamical counterpart of the magnetoelectric coupling.

1. Introduction
Magnetoelectric multiferroics exhibit the strong cross-coupling between the ferroelectricity and magnetism, leading to the novel functionalities of matter. An electromagnon, which is a magnon endowed with the electric activity, is the elementary excitation inherent in magnetoelectric multiferroics. For example, the helical spin orders give rise to the spin-driven ferroelectricity and concomitant electromagnon excitation as reported in many multiferroics. A unique character of the electromagnon is the resonantly enhanced optical magnetoelectric effect; which is induced by the cross-coupling between the electric- and magnetic- transition dipoles. Consequently, the optical response of matter is determined by the sign of the propagation vector of light ($\pm k_z$), resulting in the nonreciprocal optical effect. In fact, the nonreciprocal directional dichroism, which is the $k_z$-dependent absorption of light, has been reported on the electromagnon resonance in the various multiferroics [1].

2. Result and Discussion
We investigated the optical magnetoelectric effects and natural optical activity on the electromagnon resonance of the helimagnets by using the time-domain terahertz spectroscopy and polarimetry. The helical spin orders including proper screw and cycloidal spin structures (Fig. 1) break the space-inversion symmetry. The screw spin structure exhibits the spin-induced chirality and the left- and right-handed screw habits possess different chirality. On the electromagnon resonance, the magnetochiral effect, which leads to the nonreciprocal directional dichroism, has been observed in the magnetic field [2]. In addition, the chiral nature of proper screw order produces the enhanced natural optical activity. On the other hand, the polar nature of the cycloidal spin structure has been attracting increasing attention in recent years since it induces the spin-driven ferroelectricity. The nonreciprocal directional dichroism on the resonance of the electromagnon has been also demonstrated on the cycloidal spin order in the magnetic field [1]. The polarity of this magnetic order gives rise to the different nonreciprocal optical effect, which is referred to as gyrotropic birefringence [3]. These helimagnets induce the versatile optical effects through the dynamical magnetoelectric coupling as well as the multiferroicity.

Abstract: We discuss the electromagnetic wave propagation in a multiferroic, insulating oxide-based metasstructure consisting of alternating coupled layers of ferroelectric (SrTiO3) and ferromagnetic (Y3Fe2(FeO4)3, YIG) layers. The dynamic magnetic and electric polarization responses are explicitly accounted for by self-consistent, discretized, coupled equations for the Maxwell/ferroelectric/ferromagnetic dynamics. We obtain biquadratic relation for the refractive index and work out explicitly the dependence on the ferroelectric/ferromagnetic phase of the constituent layers. Depending on the geometry and the material parameters we find frequency-dependent regimes for ordinary and negative refraction that we analyze analytically. We propagate fully numerically the electromagnetic-waves injected at the edges of the photonic structure and find for particular GHz frequencies that waves with different polarizations are characterized by different signs of the refractive index, implying new phenomena such as a positive-negative birefringent effect, and magnetically controlled light trapping and accelerations.

For materials where both the electric permittivity $\varepsilon$ and the magnetic permeability $\mu$ are negative Veselago’s predicted [1, 2] negative refraction which was later confirmed experimentally [3, 4]. Realization based on metallic heterostructures suffer from losses that can be avoided by using insulating multiferroics that offer also new functionalities. We study synthesized structures that exhibit simultaneously multiple orderings such as ferromagnetic, ferroelectric phases and have thus a coupled electric/magnetic response. The system is sketched in Fig.1. We setup a theory describing adequately the magnetic dynamics as well as the ferroelectric polarization and couple both self-consistently the to the Maxwell-equations [5]. We find negative refraction in ferroelectric (FE)/ferromagnetic(FM) multilayers. Experimentally, the large mismatch between conventional ferroelectric and ferromagnetic resonance frequencies might be an obstacle (e.g., BaTiO3 has a resonance in THz range, while the resonance of the insulating ferromagnet, rhodium-substituted $\varepsilon$-Rh$_x$Fe$_{2-x}$O$_3$ with largest known coercivity is $\approx 200$GHz). However, there is a large class of synthetic materials and other oxides (such as ferroelectric SrTiO3 (STO) and the insulating ferromagnet Y3Fe2(FeO4)3 (called YIG)) with suitable frequencies.

In the pilot numerical simulations shown in Fig.1 the ferroelectric (ferromagnetic) layer is 10 nm (1 $\mu$m) thick.

Figure 1: (a) Schematics for the photonic/ferroelectric/ferromagnetic heterostructure. The electric polarization $P_j$ in the layer $j$ is aligned along $x$ axis. The incident light wave propagating along $z$ axis. $E$ and $H$ denote the electric and magnetic field components. The magnetization $S_i$ in the layer $i$ points also along the $z$ axis. (b) and (c) graphs show real (dashed blue curve) and imaginary (dashed-dotted green curve) parts of the refraction index $n$ versus the mode frequency according to our biquadratic equation. Red solid curve is the $z$ component of the time averaged dimensionless Poynting vector $(W_z)/P_0S_0$. Graphs (b) and (c) correspond to the negatively and positively refracting waves, respectively for the same excitation frequency 30GHz indicated by vertical dotted lines in the insets. Abstract
Multiferroics permit magnetic control of the electric polarization and electric control of the magnetization. These static magnetoelectric effects are of enormous interest: The ability to read and write a magnetic state current-free by an electric voltage would provide great technological advantages. Optical magnetoelectric effects are equally interesting, because they give rise to unidirectional light propagation in multiferroic compounds. We show that static and optical magnetoelectric phenomena can be engineered in crystals on the sub-unit-cell scale, similarly to metamaterials.

1. Introduction
In conventional media light propagation is reciprocal, that is counter-propagating beams experience the same refractive index. However, reciprocity can be violated in multiferroic or more generally in magnetoelectric materials, where the refractive index depends not only on the polarization of light but also on the $\pm k$ direction of the propagation [1]. Such unidirectional transmission is the consequence of the dynamic or magnetoelectric effect emerging in materials with simultaneously broken time reversal and spatial inversion symmetries. This phenomenon, exclusively observed in multiferroic and magnetoelectric materials so far [2-5], may allow the development of optical diodes, transmitting unpolarized light in one, but not in the opposite, direction [5]. Recently, the emergence of such unidirectional light propagation, governed the dynamic magnetoelectric effect, has also been demonstrated in multi-antiferroics [6], i.e. in materials with coexisting purely antiferromagnetic and antiferroelectric (or antipolar) orders.

2. Optical magnetoelectric effect in the GHz-THz frequency range
In the following we show three typical examples when the optical magnetoelectric effect was observed at spin-wave excitations of non-centrosymmetric magnetic crystals.
2.2. Optical magnetoelectric effect in multi-antiferroics

Figure 2: Optical magnetoelectric effect of magnon excitations in the antiferromagnetic state of LiCoPO$_4$ [6]. A strong difference both in the real part ($n$) and the imaginary part ($\kappa$) of the refractive index is found at the magnon resonance near 1.4 THz between the two antiferromagnetic domains. By different combinations of poling electric and magnetic fields either one or the other antiferromagnetic domain can be realized. The spectra obtained for one domain are displayed in orange and red, while spectra characteristic to the other domain are plotted in cyan and blue.

2.3. Optical magnetoelectric effect of skyrmion crystals

Figure 3: Microwave magnetoelectric effect observed at the collective spin modes in the Néel-type skyrmion hosting material GaV$_4$S$_8$ [7]. The red and blue absorption spectra are measured for the transmission of microwaves in opposite directions.

Abstract

Non-reciprocal phenomena of metamaterials are studied in a system containing both chirality and magnetism. Structural chirality and intrinsic magnetism break spatial inversion and time-reversal symmetries, respectively. Such a symmetry breaking gives a magneto-chiral effect, which is a kind of directional birefringence. We experimentally demonstrated and numerically verified that the magneto-chiral effect was enhanced in artificial metamolecules.

1. Introduction

Optical phenomena are often related to symmetry breakings. A simple and familiar example is refraction. Refraction is a change of the wavevector, and is interpreted as a result of a translational symmetry breaking. In a chiral material, a broken space-inversion symmetry splits the degeneracy of refractive indices with respect to polarization states, resulting in polarization rotation, called the natural optical activity. When light is shinned again from the other side of a medium, the rotation angle is reversed. Similar but different phenomena on polarization rotation are the magneto-optical Faraday effects in magnetic materials, in which the time-reversal symmetry is broken. The polarization angle rotates twice if light is again incident from the other side of a medium. It is interesting to ask what happens if a system breaks both spatial inversion and time-reversal symmetry. The answer is polarization-independent directional birefringence dichroism, called the magneto-chiral effect and the optical magneto-electric effect. In Fig. 1, symmetry breakings and resulting optical phenomena are schematically represented. Here we focus on the magneto-chiral effect in a microwave region, realized in artificial media possessing both structural chirality and intrinsic magnetism [1-3].

2. Theoretical background

Fundamental electromagnetic responses of materials are characterized by two parameters: a dielectric constant, ε, and a magnetic permeability, μ. Electromagnetic waves feel these parameters not always independently but as their product and quotient, namely the refractive index, \( n = \sqrt{\varepsilon} \sqrt{\mu} \), and the impedance, \( Z = \sqrt{\mu / \varepsilon} \), respectively. It is interesting that these product and quotient are regarded as fictitious interactions between electric and magnetic responses. If a system has a structural chirality and intrinsic magnetization, these expressions are not the case. Let us consider the following constitutive equations,
\[ \mathbf{D} = \varepsilon_0 \mathbf{\hat{E}} - iY_0 \mathbf{\hat{E}}, \]
\[ \mathbf{H} = (\mu_0 \mathbf{\hat{H}})^{-1}, \]

where \( \varepsilon_0 \), \( \mu_0 \), and \( Y_0 = \sqrt{\varepsilon_0 / \mu_0} \) are the dielectric constant, the magnetic permeability and the admittance of vacuum, respectively. The tensor, \( \mathbf{\hat{P}} \), relates to chirality that causes the optical activity. The magneto-optical is given by the off-diagonal components of \( \mathbf{\hat{P}} \) or \( \mathbf{\hat{m}} \). In this formulation, the chirality and the magnetism do not interact each other. From the constitutive equations and Maxwell equations, we can show that the refractive indices have several terms, representing the optical activity, the magneto-optical effect. Remarkably, we obtained another term, proportional to both chiral parameter and magnetization independent of polarization states. This term represents the magneto-chiral effect caused by a fictitious interaction between the chirality and the magnetism.

3. Experimental and numerical results

To realize the magneto-chiral effect, we prepared a metamolecules as shown in Fig. 2. A helical Cu wire of 4 turns was equipped with a ferrite rod of 15 mm length. This sample was put into a waveguide. Microwave was introduced from Port 1(2), and its amplitude, \( S_{12} \) and \( S_{21} \), were measured at Port 2(1). The external magnetic field was applied to \( \mathbf{z} \)-direction. The magneto-chiral effect is a non-reciprocal phenomenon that is proportional to the difference between \( S_{12} \) and \( S_{21} \). Figure 3 shows the pseudo color plot of \( \log(|\arg S_{12} - S_{21}|) \) as a function of the external magnetic field and frequencies of microwaves. We found three resonances at 10.6, 13.7 and 14.5 GHz due to the chiral structure. These resonances are nothing but magneto-chiral resonances because they are linearly dependent on the ferromagnetic resonance induced by external magnetic field. In the inset of Fig. 3, the intensity of magnetization and the distribution of the surface current density at 14.5 GHz are represented. We observed simultaneous existence of the ferromagnetic and the chiral resonances, resulting in enhanced magneto-chiral responses.

![Figure 2](image2.png)

Figure 2: Magneto-chiral metamolecule composed of a ferrite rod and a helical copper wire, and its configuration in microwave measurements.

![Figure 3](image3.png)

Figure 3: Pseudo color plot of amplitude difference, between \( S_{12} \) and \( S_{21} \), as a function of frequencies and the external magnetic field. Inset: Numerical results of the surface current density (cone) and the intensity of magnetization (pseudo color).

4. Conclusions

We show a new kind of fictitious electromagnetic interactions, a magneto-chiral coupling, realized in magnetic materials together with chiral media. This effect was experimentally demonstrated in microwave regions by using an artificial metamolecule composed of helical metal and a ferrite rod. The results were verified by numerical simulations.

Abstract

Magnetic skyrmions in magnets with broken spatial inversion symmetry have rich device functions and thus have attracted a great deal of research interest. We discuss our recent theoretical studies on dynamical phenomena and functionalities of magnetic skyrmions originating from their peculiar microwave-active spin-wave modes. Excitations of the spin-wave modes under application of a tilted magnetic field give rise to microwave-driven translational motion of skyrmions and skyrmion-based microwave-DC-voltage conversions.

1. Introduction

Magnetic skyrmions have attracted a great deal of interest in the spintronics field [1, 2, 3]. In particular, their microwave-active spin-wave modes and related dynamical phenomena are an important subject [4, 5, 6]. Our theoretical studies recently uncovered intriguing microwave-induced phenomena of magnetic skyrmions in a two-dimensional system under application of a tilted magnetic field [7, 8].

2. Model and Method

A thin-plate magnet with a broken inversion symmetry is described by a classical spin model on the square lattice,

\[
\mathcal{H} = -J \sum_{i, \mu} \mathbf{m}_i \cdot \mathbf{m}_{i+\hat{\mu}} - H_{\text{ex}} \cdot \sum_i \mathbf{m}_i - \sum_{i, \mu} D_\mu \cdot (\mathbf{m}_i \times \mathbf{m}_{i+\hat{\mu}})
\]  

(1)

where $\hat{\mu}=\hat{x}$, $\hat{y}$, and $\mathbf{m}_i$ is the normalized magnetization vector on the $i$th site. The first and the second terms denote the ferromagnetic-exchange interactions and the Zeeman interactions, respectively. The third term depicts the DM interaction where the DM vectors $D_\mu$ determine the skyrmion type, i.e., the Bloch type and the Neel type [Fig. 1(a) and (b)]. To investigate the microwave-driven dynamics, coupling between magnetizations and the microwave electromagnetic fields should be taken into account as well. The skyrmions confined in a two-dimensional system generally have a circular symmetry when the $H_{\text{ex}}$ field is perpendicular to the plane. On the other hand, when the $H_{\text{ex}}$ field is tilted [Fig. 1(c)], their circular symmetry becomes to be broken, and the magnetization distribution has a disproportionate weight slanted from the center [Fig. 1(d)]. The microwave-driven magnetization dynamics are simulated by numerically solving the Landau-Lifshitz-Gilbert equation.

3. Microwave-induced phenomena

It was theoretically revealed that hexagonally packed skyrmions in a skyrmion crystal exhibit peculiar spin-wave modes at microwave frequencies [4, 5], in which the skyrmions uniformly rotate in a counterclockwise (CCW) or clockwise (CW) fashion (the rotation modes) [Fig. 2(a)] or uniformly expand and shrink in an oscillatory manner (the breathing mode) [Fig. 2(b)]. When the $H_{\text{ex}}$ field is perpendicular, both the CCW and CW rotation modes are excited only by an in-plane polarized microwave $H_\omega \parallel x, y$, whereas the breathing mode is excited only by an out-of-plane polarized microwave $H_\omega \parallel z$. In contrast, both the in-plane and out-of-plane polarized microwaves can excite all these spin-wave modes when the $H_{\text{ex}}$ field is tilted as seen in Fig. 2(c) and (d).

It was theoretically demonstrated that continuous excitation of the skyrmion spin-wave modes under a tilted $H_{\text{ex}}$ field induces a translational motion of skyrmion crystal [Fig. 3(a)]. Detailed investigations on the frequency de-
Figure 2: (a), (b) Microwave-active spin-wave modes of skyrmion crystal, i.e., the counterclockwise (CCW) rotation mode (a) and the breathing mode (b). (c), (d) Microwave absorption spectra of skyrmion crystal under perpendicular (θ=0°) and tilted (θ=30°) magnetic fields \( H_{ex} \) for the in-plane microwave polarization \( H^{\omega}\parallel x, y \) (c) and the out-of-plane microwave polarization \( H^{\omega}\parallel z \) (d).

Figure 3: (a) Translational motion of skyrmion crystal driven by the continuous spin-wave excitation through microwave application under a tilted magnetic field. (b), (c) Time profiles of the spin-driven electric voltage induced by the CCW rotation mode excited by the in-plane microwave field \( H^{\omega}\parallel x \) under perpendicular (b) and tilted (θ=30°) (c) magnetic fields. The oscillating electric voltage has a zero average in (b) but has a finite DC component in (c). (d), (e) Those induced by the breathing mode excited by the out-of-plane microwave field \( H^{\omega}\parallel z \).

Continuous excitations of the skyrmion spin-wave modes under application of a tilted magnetic field give rise to intriguing microwave-induced dynamical phenomena. These phenomena are of great interest from the viewpoints of both fundamental science and technical application, which require further studies in the future.

4. Conclusions

Continuous excitations of the skyrmion spin-wave modes under application of a tilted magnetic field have generated large DC components in the microwave-induced electric voltage, which indicates that the resonant excitation of the spin waves drives the fast skyrmion motion. This was also proved that the velocity and direction of this translational motion vary depending on the mode and the microwave polarization.

It was also theoretically demonstrated that temporally oscillating spin motive force and spin voltage with a large DC component are generated by exciting the skyrmion spin-wave modes under a tilted magnetic field [Fig. 3(b)-(e)]. The DC component and the AC amplitude of the oscillating electric voltage show significant enhancement when the frequency of applied microwave is tuned at eigenfrequencies of the skyrmion spin-wave modes. It was also revealed that the sign of the DC voltage varies depending on the microwave polarization and the mode. This finding enables efficient conversion of microwaves to DC electric voltage using skyrmion-hosting magnets.

The influence of the Dzyaloshinskii-Moriya interaction (DMI) on the behavior of spin waves in ultra-thin ferromagnetic films and chiral magnonic crystals is reviewed\,[1]. During the last decade, it has been shown, both theoretically and experimentally, that this anisotropic exchange interaction produces non-reciprocal features on the spin-wave spectrum of a magnetic system, a phenomenon that occurs both for bulk\,[2-3] and interfacial Dzyaloshinskii-Moriya coupling\,[4-6]. More recently, the concept of a chiral magnonic crystal has been introduced\,[7], where the interfacial Dzyaloshinskii-Moriya interaction is periodic. The effect of this periodicity includes additional features such as flat bands, indirect gaps, and an unusual spin-wave evolution, with standing waves showing finite phase velocities in the zones where the DMI is nonzero. These results have been obtained with micromagnetic simulations and using a theoretical approach based on the plane-wave method. These chiral magnonic crystals with periodic DMI, which may be attained for instance by covering a thin ferromagnetic film with an array of heavy-metal wires\,[7], host interesting physical properties, encouraging future experimental studies to prove and evidence these phenomena.

Chiral Metastructures and Bio-Assemblies: Plasmonic, Thermal and Hot-Electron Effects

Alexander Govorov1,2, Larousse Khosravi Khorashad2, Lucas V. Besteiro1,3

1Institute of Fundamental and Frontier Science (IFFS), University of Electronic Science and Technology of China (UESTC), Sichuan, P.R. China
2Department of Physics, Ohio University, Athens, OH, 45701; govorov@ohio.edu

Metamaterials and bio-assembled colloidal complexes incorporating metal and semiconductor nanocrystals exhibit strong optical absorption associated with exciton and plasmon resonances. When a system includes chiral molecules, the Coulomb and electromagnetic interactions between excitons and plasmons are able to alter and enhance natural circular dichroism (CD) of chiral molecular dipoles [1,2]. Especially strong enhancement factors for the molecular CD signals can be achieved using plasmonic hot spots [3,4,5]. Strong CD signals can also appear in purely plasmonic systems with a chiral geometry and a strong particle-particle interaction [6,7,8].

In our theoretical approach, we model electromagnetic interactions between chiral and achiral building blocks using both classical and quantum formalisms. The theory predicts several novel mechanisms to transfer and induce circular dichroism in the visible wavelength region using plasmonic and excitonic nanostructures. The CD mechanisms described in our studies come from: the plasmon-molecule Coulomb interaction [2], plasmonic hot-spot enhancement [3,4,5], a long-range electromagnetic interaction in micron-scale nanostructures with a chiral geometry, plasmonic and excitonic resonances in nanocrystals with chiral shapes [9,10], and strong plasmon-plasmon interactions in helical and other chiral assemblies [6,7,8]. In planar metamaterial absorbers, chiral responses and circular dichroism can be observed using the hot-electron injection mechanism and the photo-thermal effect [11,12,13]. Finally, chiral plasmonic nanocrystals enable a new direction of research at the nanoscale - chiral plasmonic photochemistry [14]. Potential applications of the chiral nanostructures are in bio-sensors, optical materials and asymmetric chemistry.

Tailoring the Chiral Response of Achiral Nanostructures Using Structured Light

Peter Banzer
Max Planck Institute for the Science of Light, Erlangen, Germany
Institute of Optics, Information and Photonics, Friedrich-Alexander-University Erlangen-Nuremberg
*corresponding author, E-mail: peter.banzer@mpl.mpg.de

Abstract

By utilizing engineered highly confined light for excitation, we show that an achiral nanosphere can scatter like a chiral dipole. While the input beam carries neither spin nor orbital angular momentum, we take advantage of the complex polarizabilities of an achiral spherical silicon particle.

1. Introduction

The recent interest in exotic dipole moments such as transversely spinning [1], Huygens [2-6] and Janus dipoles [5,6] has been an important driving force in nanophotonics research, contributing to the understanding of light-matter interaction and opening up new routes towards photon traffic control at the nanoscale [3-5]. In our work, we now investigate an important member of this zoo of electromagnetic dipole moments, i.e. the chiral dipole conceptually known from the interaction of circularly polarized light with chiral molecules or artificial nanostructures. Usually, the chiral dipole is a direct consequence of the twisted path of electrons in helically shaped chiral nano-entities, fixing also their handedness and optical response.

2. Structured Light-Matter Interactions – Exciting Chiral Dipoles in Achiral Nanostructures

In our experiments, we now show that a chiral dipolar mode consisting of parallel electric and magnetic dipole moments phase shifted with respect to each other by $\pi/2$ can also be excited, with full tunability of handedness and strength, in an individual achiral nano-antenna [7]. This dipole represents a fundamental mode in the helicity basis and it exhibits maximum chirality. Here, we excite the mode with a locally linearly polarized beam carrying neither spin nor orbital angular momentum, taking advantage of the complex polarizabilities of an achiral spherical silicon particle. The scattered light, however, carries both, spin and orbital angular momentum, which can be manipulated spectrally. In particular, we can even tune the sign of the helicity/chirality of the mode, by changing the excitation wavelength, a feature which cannot be observed for fundamental modes of chiral plasmonic structures. Our study shows that the excitation and appearance of chiral dipoles is not restricted to chiral nanostructures, but they can also be excited and very flexibly controlled in achiral systems using structured light.

3. Conclusions

In this presentation, we highlight the excitation of chiral dipoles in achiral nanostructures, and survey other interesting related aspects of the interaction of structured light with individual nanoparticles [8].

References

In crystals with helical structure such as tellurium (Te) [1], we propose that a current along the helical axis induces an orbital magnetization [2,3] as well as spin magnetization. In crystals without inversion symmetry, such as chiral crystals, each Bloch eigenstate has an orbital magnetization, but their sum vanishes in equilibrium. We show that in the presence of the current, the electron distribution becomes off-equilibrium, giving rise to nonzero orbital magnetization. We can call this effect an orbital Edelstein effect, because this effect is similar to the Edelstein effect, where the current induces spin polarization in crystals without inversion symmetry.

This effect is analogous to solenoids in classical electrodynamics (Fig. 1(a)). Within this analogy to solenoids, we quantify this effect by introducing a dimensionless parameter $\xi$, which represents a number of turns within the unit cell when regarded as a classical solenoid. Then we found that $\xi$ is largely enhanced when the system is in the Weyl semimetal phase [2,3]. Here the Weyl semimetal phase [4] is allowed by broken inversion symmetry. Moreover, we propose a similar effect for phonons. In crystals, each phonon eigenmode has angular momentum due to rotational motions of the nuclei (Fig. 1(b)), but their sum is zero in equilibrium. Meanwhile a heat current in the Te crystal induces a nonzero total angular momentum [5]. We evaluate this effect for GaN and Te by ab initio calculation, and propose experiments to measure this effect (Fig. 1(c)).

Abstract
We study non-collinear magnetic orders in a transition metal dihalide with competing exchange interactions. We find an unusual defect with the skyrmion topology carrying both magnetic and electric dipole moments, which is stable in uniform and modulated magnetic phases of this material. We study dynamics of these skyrmions induced by spin-orbit torques and by the magnetoelectric coupling to an applied electric field.

1. Introduction
Mott insulators with competing Heisenberg exchange interactions form a new class of materials where topological magnetic defects, such as skyrmions, can exist in absence of inversion symmetry breaking [1-4]. Skyrmions in centrosymmetric materials have more degrees of freedom and show more complex dynamics than skyrmions in chiral magnets. In addition, the electric polarization induced by non-collinear spin textures couples the topological magnetic defects to an applied electric field [5]. This magnetoelectric coupling allows for the electric control of skyrmions in Mott insulators accompanied by low energy losses.

Transition metal halides form an interesting class of multiferroic frustrated magnets that can host skyrmions. These layered van der Waals materials allow for exfoliation down to monolayers and hold promise of new spintronic applications [6]. Competing exchange interactions between transition metal ions result in a variety of magnetic phases, including non-collinear spiral states that induce an electric polarization [7,8]. The interplay between the magnetic orders can be controlled by doping, gating, magnetic and electric fields [9]. We study theoretically stability of skyrmion crystals and isolated skyrmions in Fe-doped NiBr$_2$.

2. Phase diagram
First, we determine the intra- and interlayer exchange constants in NiBr$_2$ using the experimentally measured critical values of the magnetic field applied in the $ab$ plane for the transitions between the spiral, canted antiferromagnetic, antiferro-fan and field-polarized states of this material [10]. We then obtain a magnetic phase diagram of Fe$_x$Ni$_{1-x}$Br$_2$ in the out-of-plane magnetic field for various values of the uniaxial anisotropy, which can be tuned by Fe doping [11]. The phase diagram contains the vertical spiral, conical cycloidal spiral, canted antiferromagnetic and field-polarized states. Importantly, the skyrmion crystal phase is suppressed by the relatively strong antiferromagnetic interlayer exchange interactions. The relative displacement of the skyrmion triangular lattices in neighboring layers found for weak interlayer interactions [12] cannot stabilize the three-dimensional skyrmion crystal in Fe$_x$Ni$_{1-x}$Br$_2$.

3. Topological defects
We found two types of stable topological defects with the skyrmion topology: (i) antiferromagnetic skyrmion tubes with the sign of the in-plane spin component alternating from layer to layer and (ii) skyrmions with topological charge $\pm 1$ localized in a single layer. Although the antiferromagnetic skyrmion tubes are stable in a wider part of the phase diagram than the single-layer skyrmions, the latter topological defects are of more practical interest as they are much easier to create. We found the regions of stability of the single-layer skyrmions in the field-polarized, canted antiferromagnetic and periodically modulated conical spiral phase.

4. Skyrmion dynamics
Dynamics of the single-layer skyrmions is coupled to their helicity dynamics. In the uniform ferro- and antiferromagnetic phases, the helicity angle increases linearly with time and the skyrmion center-of-mass undergoes a circular motion. In the cyloidal conical spiral phase, the skyrmion trajectory is straight: it moves in the direction normal to the spiral wave vector. The skyrmion motion can be excited by the spin-orbit torque in heterostructures of the magnetic insulator with a heavy metal conductor. Alternatively, the electric polarization induced by non-collinear spin textures can be used to move skyrmions in the conical spiral state.

5. Conclusions
Although the antiferromagnetic interlayer interactions in Fe-doped NiBr$_2$ are strong enough to suppress the skyrmion crystal phase, they allow for skyrmion defects with the topological charge localized in a single layer. These single-
layer skyrmions move under applied spin-orbit torques and oscillating electric fields, which makes them potentially useful for magnetic memory and data processing applications.

A major challenge facing nanophotonics is the poor dynamic tunability. A functional adaptive nanophotonic element would feature the real-time large tunability of transmission and/or reflection of light’s intensity and/or polarization, or the light’s propagation direction over a broad range of wavelengths, and would be robust and easy to integrate. Several approaches have been explored so far including mechanical deformation [1-3], thermal [4] or refractive index [5, 6] effects, and all-optical switching [7, 8]. Building on our previous advances in nanofabrication [9, 10] and the combination of the plasmonic and ferromagnetic materials (magnetoplasmonics) [10-15], we devise an ultra-thin chiroptical surface, built on 2D nanoantennas, where the chiral light transmission is controlled by the externally applied magnetic field with tunability exceeding 100%. This is done by the magnetic steering of the chiral near-field of the nanoantennas. We explore this further by building the dynamic chiroptical surfaces with all-dielectric nanoantennas. Combining plasmon and molecular resonances [16], we use a practical combination of the large array of magnetoplasmonic antennas and the thin layers of molecular photoswitches to get insight into the plasmon-molecular strong coupling and the associated polaritonic phototransformation chemistry. Further, we probe the opportunities, provided by the combination of chiral nanoantennas and the enantioselective phototransformations in chiral photoswitches.

Abstract
We predict that rotating nano-rings and solid nanoparticles show different optical circular dichroisms, and when optically trapped by an unpolarized blue-detuned laser above a certain intensity the void particle starts rotating spontaneously.

1. Introduction
The interaction between light and the mechanical motion of nano-objects is fundamentally important, as recognized by the 2018 Nobel Prize awarded for the development of optical tweezer [1]. Light can exert forces and torques on such objects, and for example, a circularly polarized light beam can induce rotation on a nanoparticle due to conservation of angular momentum [2]. The optical response of the rotating particle is fully described by its polarizability $\alpha(\omega)$ when it is much smaller than the light wavelength. However, the polarizabilities of rotating nano-objects have not been rigorously studied in quantum theory, in part because of the complexity of the quantization of the mechanical rotation.

2. Results
We focus on the optical responses of rotating rings [Fig. 1(a) and (b) and disks [Fig. 1(c) and (d)]. Applying quantum mechanics, we find the optical polarizabilities of the particles to depend on the thermal population of their internal electronic states. As shown in Fig. 1(a), the energy spectrum of electrons inside a ring in the rest frame is parabolic (solid curve), but for a rotating ring the thermal population is determined by the electronic energy in the frame rotating with the ring (dashed curve). The thermal population of the electrons in a rotating disk can also be determined similarly [Fig. 1(c)]. We use these considerations to calculate the polarizabilities of the ring and disk using the random-phase approximation. The results are shown in Fig. 1(b) and (d). The rotating ring exhibits a strong CD and the resonance splitting equals the rotation frequency $\Omega$, while the disk almost does not possess CD at small $\Omega$.

Figure 1: (a) Energy spectrum and thermal population of electrons in a rotating ring. (b) Polarizabilities of a ring (radius $R=8$ nm, with 80 electrons) rotating at different frequencies. (c) Energy spectrum in a rotating disk (radius $R=12$ nm, 80 electrons). The black curve shows the Fermi level. (d) Polarizabilities of the ring in (c) rotating at different frequencies.

When illuminating a rotating ring using an unpolarised light beam, the CD leads to an optical torque on the ring [Fig. 2(a)]. When the laser is red-detuned with respect to the resonance frequency $\omega_0$, the optical torque accelerates the rotation of the ring, so the rotational degree of freedom is effectively “heated” [Fig. 2(b)]. Interestingly, the ring at rest is not mechanically stable, as shown by the temporal dynamical evolution in Fig. 1(c), where a small rotation velocity due to any fluctuation is amplified by the “heating” effect until the optical torque is cancelled by a thermal friction torque [3] (red dots). This spontaneous rotation can be regarded as spontaneous chiral symmetry breaking in a nonequilibrium system.
3. Conclusions

In this work, we rigorously derive the polarizabilities of rotating nanoparticles using quantum theory. Our results show that rotating nano-rings and solid nanoparticles (e.g., nanodisks) exhibit different optical circular dichroisms (CDs). From the knowledge of CDs of the particles, we predict that a motionless nano-ring exposed to a red-detuned illumination is not a stable configuration and must rotate spontaneously.

Abstract

We experimentally demonstrate gate-controlled optical properties including an amplitude of anomalously refracted light and group delay of light with graphene integrated metamaterials with different design rules. The graphene based metasurfaces are expected to provide an important applications such as ultrathin lenses, slow light devices and ultrasensitive sensors and switched.

1. Introduction

Metamaterials, which consist of artificially structured building blocks allow us to manipulate optical properties in ways that would not be possible with materials in nature. Unfortunately, however, very feature that makes these devices so useful, structurally dependent optical properties, also limits their potential for dynamically manipulating electromagnetic waves as micro/nano objects are difficult to modify post fabrication. It has been shown that graphene-based optoelectronic devices can be realized and they have superior merit to compare with conventional semiconductor-based ones for application in the terahertz frequency range. For example, graphene-based metamaterial terahertz modulators provide better modulation not only transmission amplitude and phase but also polarization [1,2]. In this talk, I will review our recent work on electrically controllable optical properties by integrating atomically thin, 2D graphene layer onto 2D functional metallic metasurfaces, so called metasurfaces [3,4].

2. Results

2.1. Amplitude modulation of anomalously refracted light

The metasurfaces consisting of U-type aperture antennas is shown in Fig. 1 (a). For the unit-cell structure with optical axis rotated by angle $\theta$, the transmission coefficients can be represented using the Jones matrix in the basis of right-handed and left-handed circular polarization:

$$T_{CL} = \begin{bmatrix} T_{RR} & T_{RL} \\ T_{LR} & T_{LL} \end{bmatrix} = \frac{1}{2} \begin{bmatrix} (T_{xx} + T_{yy}) & (T_{xx} - T_{yy}) e^{i2\theta} \\ (T_{xx} - T_{yy}) e^{-i2\theta} & (T_{xx} + T_{yy}) \end{bmatrix}$$

Here $T_{KL}$ represent the transmission coefficients, where the first subscript indicates the polarization (x or y for linearly polarized and R or L for circularly polarized wave) of transmitted wave and the second subscript indicates the polarization of the incident wave. It is shown that the cross-polarized component $T_{RL}$ possesses a phase discontinuity $e^{i2\theta}$, which is a Pancharatnam-Berry (PB) phase. Therefore, the wave front of the cross-polarized light can be simply manipulated by rotating the U-types of antennas. When the terahertz waves incident normal direction, the refraction angle can be calculated as:

$$\alpha_t = \sin^{-1}((\lambda/2\pi) \frac{d\Phi}{dx})$$

Figure 1: Graphene metasurface for active control of amplitude of anomalously refracted light.
A circularly polarized wave is converted to left circularly polarized wave at refraction angle $\alpha = 20^\circ$ and it is observed that this refracted cross-polarized wave is effectively controlled by the variation of an applied voltage (Fig. 1 (c)). The maximum modulation depth for refracted $T_{RL}$ is measured to be 28%.

### 2.2. Active control of group delay

Electromagnetically induced transparency (EIT) is a well-known quantum phenomenon. A remarkable feature of EIT is the drastic slow-down of the group velocity of light. Recently, EIT-like effect can be observed in classical metasurface system without complex experimental setup including laser stability, strong coupling laser power, and low-temperature. Figure 2 (a) shows graphene EIT metasurface consists of bilayer metallic EIT metamaterial, a single-layer graphene, and an ion-gel gate-dielectric layer. Figure 2 (b) shows the measured and simulated transmission of the graphene EIT metasurface as a function of the gate voltages. More than 51% of transmission of THz wave at 0.75 THz is measured and by increasing gate voltage to graphene layer the transparency peak can be gradually reduced. As a result, the group delay which is characterized as:

$$t_g = -\frac{d\phi}{d\omega}$$

is delayed by 3.1 ps and effectively tuned by changing the gate voltage with tuning range of 3.3 ps. Where $\phi$ is the phase and $\omega$ is the angular frequency of the THz pulse.

Figure 1: Graphene metasurface for active control of light speed.

### 3. Conclusions

In conclusion, we have experimentally demonstrated an electrically tunable optical properties with graphene EIT metamaterial at the THz regime. Benefiting from the electric control of optical properties, the proposed graphene metamaterials may provide opportunities in the design of various applications not only for THz regime but also extended to mid-infrared regime.

Abstract
Spintronic terahertz (THz) emitter has attracted great interest recently\textsuperscript{[1-4]}. Here, we introduce two popular optical concepts, photonic crystal and metamaterials, to improve the performance of the emitter. By utilizing the metal–dielectric photonic crystal structure, the conversion efficiency of spintronic THz emitter is improved due to the enhanced absorption of pumped fs laser. By integrating spintronic THz emitter with metamaterials, the THz emission with tunable polarization is demonstrated in a single device.

1. Introduction
Spintronic THz emitter was firstly demonstrated in 2013, which is based on the spin related effects in ferromagnetic/nonmagnetic (FM/NM) heterostructures\textsuperscript{[1]}; (i) a femtosecond laser pulse impinges on the FM/NM heterostructure, inducing ultrafast spin currents into the NM layer from the FM layer; (ii) transient charge currents are generated by the inverse spin Hall effect, leading to THz emission out of the structure. The new type emitter is broadband (up to 30 THz), compact, low cost, and magnetic field controllable, etc. Since then, efforts have been made in optimizing the material composition and structure geometry, the conversion efficiency has been improved close to that of ZnTe crystal\textsuperscript{[2-4]}.

One of the drawbacks of the current designs is the rather limited laser absorption - more than 50\% energy is wasted and the conversion efficiency is thus limited. Here, we theoretically propose and experimentally demonstrate a novel device, metal-dielectric photonic crystal spintronic THz emitter that fully utilizes the laser intensity and significantly improves the conversion efficiency\textsuperscript{[5]}. One of the unique advantages of the spintronic emitter is that the linear polarization orientation of emitted THz wave can be easily tuned via external magnetic field. We integrate spintronic THz emitter with metamaterials, where metamaterials are designed to act as broadband THz quarter-wave plate\textsuperscript{[6]}, and consequently the polarization state of the emitted THz wave can be switched between linear and circular by rotating the magnetic field in the individual device.

2. Results and Discussions
Figure 1a shows the schematic of metal–dielectric photonic crystal type spintronic THz emitter. It is composed of periodic metal–dielectric films, [dielectric interlayer/NM/FM/NM]\textsubscript{n}, on MgO substrate, where n denotes the number of repeats. Multiple scatterings and interference occurs when laser light propagates along the structure, which can be tailored by adjusting the thickness of the period (d) and the number of repeats (n). In principle, the reflection and transmission could be suppressed simultaneously, thus maximizing the laser absorption in the metal layers, which improves the conversion efficiency. Transfer-matrix method is employed for the theoretical calculations and the structure design. According to the theoretical design, we experimentally fabricate a series of samples with different periods and repeats. In this work, we choose W(1.8 nm)/Fe(1.8 nm)/Pt(1.8 nm) as the single repeat THz emitter, which exhibits the largest THz emission efficiency in our experiments, and SiO\textsubscript{2} for the dielectric interlayer. The measured laser absorbance and the THz amplitude show one-to-one correspondences with the theoretical calculations (Figure 1b). At the optimal conditions, the experimentally obtained conversion efficiency of the photonic crystal structures is about 1.7 times as high as that of the single-repeat spintronic THz emitter (Figure 1c), demonstrating the validity of the proposed method.

Figure 2a shows the schematic of the metamaterial integrated spintronic THz emitter. It is composed of a metal–dielectric photonic crystal spintronic THz emitter and a metamaterials, which are fabricated on the opposite sides of the MgO substrate, respectively. The metamaterials consist of a sandwiched structure, comprising of two layers of metallic wire gratings and three polyimide films, which act as a broadband THz quarter-wave plate. Accordingly, the polarization state of the THz wave generated from the
The spintronic emitter can be tailored depending on the initial orientation of linear polarization. As shown in Figure 2b and Figure 2c, the emitted THz wave varies from linearly polarized light to circularly polarized light as the magnetic field orientation varies from 45° to 0°.

Figure 1: a. Schematic of the metal–dielectric photonic crystal spintronic THz emitter; b. Normalized THz pulse amplitude (red) and femtosecond laser absorbance (blue) as the functions of SiO₂ thickness d for different repeats; c. THz pulse amplitude comparison between conventional and metal-dielectric photonic crystal spintronic emitter.

Figure 2: a. Schematic of the metamaterial integrated spintronic THz emitter; b. The emitted THz wave is linearly polarized when H=45°; c. The emitted THz wave is circularly polarized when H=0°.

3. Conclusions

In conclusion, metal–dielectric photonic crystal structure has been investigated to enhance the laser absorption in the spintronic THz emitter, and thus improve the conversion efficiency. Meanwhile, a polarization-tunable terahertz emitter that integrates spintronic THz emitter and metamaterials has been demonstrated. This work opens a new pathway to improve the performance of spintronic THz emitter from the perspective of optics.

Abstract
Terahertz waves, which are located in the region between radio and light waves, have attracted a great deal of interest in the interdisciplinary field of photonics and electronics. This study presents recent progress on photonic-crystal waveguide devices for advanced applications to the terahertz region.

1. Introduction
Photonic crystals are composed of dielectric materials with periodic refractive index distributions on scales comparable to the wavelengths [1, 2]. They are analogous to solid-state crystals with periodic potential distributions. Appropriate photonic-crystal designs exhibit a photonic bandgap in which no optical modes can exist. Introducing an artificial defect in a photonic crystal by disturbing the periodicity can produce compact and low-loss photonic components. These can be used not only to develop integrated devices [3] but also to manipulate radiation from matter [4]. In particular, two-dimensional photonic-crystal slabs with high refractive index contrasts (semiconductor/air) are promising for practical applications because of their strong optical confinement in simple, thin planar structures [5, 6]. This study presents recent progress on photonic-crystal waveguide devices for the terahertz (THz) region [7–18], which is located between the radio and light-wave frequencies (0.1–10 THz) and has attracted much attention in the interdisciplinary field of photonics and electronics for advanced applications on sensing and communications [19–21].

2. Low-loss THz-integrated platform
Currently, most existing THz application systems are composed of bulky and complex discrete components. Although metallic transmission lines based on conventional electronics are candidates for THz-integrated technology, the propagation loss is high (~10 dB/cm) in the THz region because of high absorption loss in metals. To overcome this critical loss issue, metal-free photonic waveguides can be used for routing THz waves. Photonic-crystal slab waveguides composed of only high-resistivity silicon is promising for this concept [7]. Ultralow-loss (< 0.1 dB/cm) waveguides using a photonic-crystal slab have been successfully demonstrated at the 0.3-THz band [8]. In addition to loss management, very broadband (approximately 10% relative to the center frequency) dispersion control is required for various applications because the absolute frequency of a THz wave is approximately three orders smaller than that of near-infrared light. The dispersion engineering of photonic crystal has yielded simultaneous low-loss and low-dispersion waveguides as well as high-speed communications at 36 Gbit/s [9].

For a practical integrated platform, development of a low-loss interface to connect the waveguide is critical. An adiabatic tapered silicon structure integrated with a photonic-crystal waveguide was applied to efficient couplers for a metallic hollow waveguide [8], which is standard for present THz equipment, and for a THz fiber link [10]. In addition, this type of tapered structure [11] along with a microresonator [12] and gradient index lens using an effective medium [13] integrated with a photonic-crystal waveguide were applied to a free space coupler (i.e., an antenna for wireless communications).

3. Development of THz functionalities
Active functions including THz-signal generation, detection, frequency conversion, and modulation can be integrated with a photonic-crystal platform. Resonant tunneling diodes (RTDs) based on compound semiconductors are promising THz-active devices because of their capabilities of fundamental THz oscillation [22, 23] and sensitive THz-wave detection [23] at room temperature. A major challenge lies in mode and impedance matching between the RTD and photonic-crystal waveguide for efficient coupling because of the large difference in their dimensions. A metallic tapered-slot coupling structure integrated with an RTD chip with an exponential characteristic profile provides an adiabatic impedance change from the RTD to the photonic-crystal waveguide to achieve high coupling efficiency (approximately 50%) with broadband operation (~40 GHz) [14].

Because of the low-loss nature of a photonic crystal, a high-Q THz microcavity (> 10,000) was developed [15]. These cavities were integrated with a waveguide and applied to high-sensitive sensing applications at 0.1-THz [16] and 0.3-THz bands [15]. Strong coupling between the high-Q cavity and RTD manipulates the THz oscillation beyond the performance of the RTD electric circuit [17].
Frequency routing functions can be implemented by a compact diplexer based on a photonic-crystal waveguide directional coupler and a photonic heterostructure [18]. Three-channel operation with a bandwidth greater than 5 GHz were realized in a 0.3-THz band [7]. The number of channels can be increased using a tandem structure of a diplexer.

4. Conclusion

This study reported on the recent progress of silicon photonic-crystal waveguides as a future integrated platform for sub-THz applications. The platform is scalable to higher THz frequencies to take advantage of the larger absolute bandwidth.

Abstract

We describe the development of high quality (Q) factor photonic crystal resonators (PCRs) integrated with microfluidic systems to form the basis of highly sensitive liquid sensing platforms for the terahertz band. The strong confinement of the terahertz field in combination with the high Q-factor provided by the PCR allows the measurement of the dielectric properties of sub-nanoliter liquid volumes. We demonstrate the utility of this approach by measuring the complex permittivity of several bio-liquids at 100 GHz.

1. Introduction

PCRs have a well-established ability to achieve ultra-high quality (Q)-factors while simultaneously confining optical and infrared light to near- or sub-wavelength volumes. This feature makes them ideal sensors for samples with volumes less than $\lambda^3$. In the terahertz band, PCRs are less well developed despite the possibility of offering some of the highest Q-factors at room-temperature. In this paper, we demonstrate the realization of several different types of PCRs operating at 100 and 200 GHz. We show that these resonators when combined with microfluidics allow the extremely sensitive detection of a liquid analyte’s complex permittivity through enhancement of the strength of interaction between the liquid and the PCR’s resonant mode.

2. High-Q terahertz PCRs

We can have experimentally demonstrated both microbeam PCR and slab type PCRs for the low terahertz band and they will now be discussed individually.

2.1. THz Microbeam PCRs

A 1D or microbeam PCR can be fabricated from a rectangular dielectric slab waveguide by exploiting the transverse waveguide (TE) bandgap induced in the waveguide through the introduction of a linear array of cylindrical air holes. Through careful design of the hole radii and positions, a localized defect state can be created which supports a resonant mode with a ultra-high Q-factor [1]. We have experimentally demonstrated microbeam PCRs operating at 100 and 200 GHz [2], recently achieving Q-factors as high as 22,000. Fig. 1(a) shows one of the fabricated microbeam PCRs. The central microbeam is suspending using a series of supporting struts which electromagnetically isolates it from its environment, reducing dielectric losses and maximizing its Q-factor.

![Figure 1: A one-dimensional microbeam PCR with a resonant frequency of 100 GHz.](image)

2.2. THz Slab PCRs

A commonly implemented PCR is the slab PCR, which exploits the 2D TE bandgap created in a dielectric substrate when a periodic array of air holes is introduced. We realized a PCR resonating at W-band by creating a L3 cavity defect (three omitted holes) in a triangular lattice of holes etched in a high resistivity silicon substrate as shown in Fig. 2. The resonant defect was excited using a W1 defect waveguide, created by omitting a line of holes in the lattice. A Q-factor of approximately 11,900±500 was demonstrated, limited by the dielectric loss in the silicon [3].
2.3. PCR Fabrication

Both the microbeam and slab PCRs were fabricated using the Bosch process to perform deep reactive-ion etching (DRIE) of the 525 µm thick silicon wafer (resistivity >10 kΩ cm) to realize the high aspect ratio holes with nearly vertical sidewalls.

3. Liquid Sensing

The PCRs were integrated with microfluidic systems to enable their use as liquid sensing platforms. A microfluidic syringe pump and quartz capillaries with 100-200 µm diameter were used to flow liquid analytes close to or through the high intensity region of the electric field of the PCR’s resonant mode.

The introduction of the liquid analyte modifies the resonant modes properties. Perturbation theory can be used to relate a change in the PCR’s resonant frequency Δf and reciprocal Q-factor Δ(1/Q) to the complex permittivity ϵ_a of a liquid analyte introduced into the field of the PCR. By assuming a quasi-static approximation for the electric field inside the liquid sample, the following analytical expression can be derived [4]

\[
\frac{\Delta f}{f_0} + i \frac{A}{2} \left( \frac{1}{Q} \right) \approx -A \frac{\epsilon_a - B}{\epsilon_a + \epsilon_q}
\]

where ϵ_a and ϵ_q are the liquid sample and quartz capillary permittivities, respectively, and A and B are the coefficients determined through fitting the measured response of binary solutions of water-ethanol solutions of known permittivity.

3.1. Bio-liquid and cell sensing

Once the system is calibrated and the fitting coefficients determined, the PCR can then be used to characterize the permittivity of unknown liquid analytes. As an initial demonstration, we characterize the constituents of human blood at 100 GHz using the slab PCR. We prepared cell suspensions of white (0.5% vol.) and red (50% vol.) blood cells and measured relative complex permittivities of 8.6±0.4+i(14.2±2) and 8.2±0.4+i(11.4±2), respectively. The blood plasma was measured to have a permittivity of 8.7±0.4+i(13.6±2).

3.2. Toward single biological cell sensing

The sensitivity provided by the use of a high-Q PCRs can be leveraged for the detection of sub-wavelength particles in a liquid. An important application of this is the dielectric measurement of single biological cells in a culture medium. To achieve this, we have designed improved PCRs which confine the field to smaller modal volumes and improved the microfluidics to allow smaller diameter capillary tubes to reduce the liquid interaction volume. Initial measurements have shown this approach to be capable of detecting individual cells. The potential advantage of this approach is that it allows non-invasive, label-free and contactless cell analysis to be made in real-time.

4. Conclusions

We have demonstrated microbeam and slab type PCRs for the terahertz band, realizing Q-factors as high as 22,000 and limited by dielectric loss in the silicon. By combining these resonators with microfluidic systems, we have created sensing platforms for the measurement of the dielectric properties of nanoliter and sub-nanoliter quantities of liquids. This result represents a step towards a lab-on-a-chip device for the analysis of bio-liquids at terahertz frequencies.

Singular graphene metasurfaces for broadband absorption

Paloma A. Huidobro*, E. Galiffi, J.B. Pendry

Imperial College London

*corresponding author, E-mail: p.arroyo-huidobro@imperial.ac.uk

Abstract

Metasurfaces can be formed by structuring a plasmonic surface at the subwavelength scale (see Fig. 1) and yield to richer interactions with external electromagnetic radiation than conventional gratings.

1. Introduction

In this talk conformal transformations will be discussed to design plasmonic metasurfaces, focusing in the case where these transformations have singular points. This gives rise to singular metasurfaces which have continuous spectra rather than the discrete set of peaks characteristic of conventional gratings [1].

2. Singular graphene metasurfaces

2.1 Designing singular metasurfaces

Figure 1(a) shows a plasmonic grating designed from a translationally invariant slab through the conformal transformation given by,

\[ z' = \frac{d'}{2\pi} \log \left( \frac{1}{e^{2\pi z_x/d} - i\omega_0} + i\eta_0 \right) \]

This equation maps a length d of a translationally invariant slab placed at \( x_0 \) in frame z into a grating of period \( d' \) in frame \( z' \). This is done by successively mapping the slab into an annulus, then to an off-centered annulus and finally to the grating [2]. A singular grating can be designed by taking the inversion center \( i\omega_0 \) very close to the inner annulus, and at the same time renormalizing the whole grating by \( d' \rightarrow \infty \). This results in a grating schematically depicted in Fig. 1b. Such plasmonic grating can represent graphene if the grating thickness is mapped to the conductivity, which varies periodically and is vanishingly small at the grating valleys, see Fig. 2.

Figure 1: (a) A plasmonic surface structured at the subwavelength scale. (b) Surface with touching points which forms a singular metasurface. (c) In the limit of infinitesimal thickness, the singular plasmonic metasurface in (b) represents graphene with modulated conductivity. The conductivity is suppressed in the singular points.

Figure 2: p-polarized light incident on a modulated graphene sheet with vanishing conductivity at the grating valleys.
2.2 Broadband absorption

Non-singular metasurfaces [2] support the excitation of a discrete set of surface plasmon modes, appearing as absorption peaks in their spectrum. As the valley-point conductivity is reduced, more and more peaks can be excited, and the resonances get closer together. Each of this excitations consists of surface plasmon modes featuring extreme confinements close to the singular point. When the metasurface approaches the singular limit, many resonances merge into a broad peak. In this limit, a wealth of surface plasmon resonances merge into a continuum of modes, which can strongly couple to external radiation over a broad range of frequencies, as shown in Fig. 3. These atom-thick metasurfaces then act as broadband absorbers, able to efficiently harvest THz radiation over fractional bandwidths approaching 200% [3,4].

3. Conclusions

This talk will discuss how singular metasurfaces can be designed using analytical tools provided by transformation optics. Broadband absorbers based on singular graphene metasurfaces will be presented.

Figure 3: Absorption spectrum of singular graphene metasurfaces. The resonance peaks merge into a continuum once the resistive broadening reaches the spacing between the modes.

Terahertz Spoof Surface Plasmon Polaritons: Modelling, Design, and Experimental Characterization

Mehmet Unlu

1Department of Electrical and Electronics Engineering, TOBB University of Economics and Technology, Ankara, Turkey

*corresponding author, E-mail: munlu@etu.edu.tr

Abstract

In this paper, we report the latest progress on the modelling, design, and characterization of the spoof surface plasmon polariton (sSPP) waveguides (WG) for the terahertz band. We will summarize our approach on the empirical modelling of the effective dielectric constant, extraction of the lumped-element circuit model, and realization of fixed-length delay lines using sSPP WGs. To the best of our knowledge, this is first extensive characterization that can be used for advanced sSPP circuit design for the terahertz band.

1. Introduction

Surface plasmon polaritons (SPP) are surface waves that propagate at the boundary of a dielectric and metal. Starting from the date that they have been discovered in 1950s [1], these extraordinary waves have attracted a lot of interest due to their ability to confine and guide the incoming light, which could make it possible to develop miniaturized photonic circuits [2, 3]. It is also possible to structure the metal surface so that the electric field is strongly enhanced around these structures, and a huge signal enhancement can be achieved, which is vital for sensing applications [4].

Surface plasmon polaritons do not exist at the microwave, millimeter-wave, and terahertz bands due to the perfect electric conductor (PEC)-like behavior of the metals at these bands. However, it was shown by Pendry et al. [5] that surface waves showing SPP-like behavior can exist at the dielectric-metal boundaries. Structuring the metal surface can allow the designer to control the propagation properties of these surface waves, which are mostly called as the “spoof” surface plasmon polaritons (sSPP). There have been a significant number of studies presented on sSPP engineering for the microwave band in the last few years including modelling [14], filters [6], metasurfaces [7], couplers [8], power dividers [9], antennas [10], switches, mode splitters, and sensors [11].

sSPP structures can also be used for promising applications in the terahertz band [12]. sSPP waveguides can be utilized for the miniaturized terahertz integrated circuits with improved signal integrity, thanks to their high confinement. In addition to that, sSPP waves can be employed for localized signal enhancement, which will significantly improve sensitivity for terahertz sensing applications.

Despite these unprecedented possibilities, a limited number of studies have been reported so far that deeply investigate the properties of the sSPP waves for the terahertz band, few of which include experimental verification [13]. However, a detailed investigation and modelling of the sSPP waves is required for the development of the terahertz integrated systems.

In this talk, we will present our latest progress on the development of the sSPP waveguides for the terahertz band. We will first introduce our approach on modelling the most design critical parameter for the design of the sSPP waveguides, namely the effective dielectric constant. Then, we will present some sSPP delay lines examples for the terahertz sSPP phase shifters and reconfigurable circuits. We will also present a lumped-element circuit model for the terahertz sSPP waveguides. Finally, we will give some examples of the reconfigurable sSPP circuits for the terahertz band.

THz Metasurfaces for Spatial Beam Modulation and Chemical Identification

Polina Stefanova, Rhiannon Lees, Andreas K. Klein, Michael D. Cooke, Andrew J. Gallant, and Claudio Balocco*

Department of Engineering, Durham University, Durham, United Kingdom
*corresponding author, E-mail: claudio.balocco@durham.ac.uk

Abstract

The wavelength of THz radiation enables the use of metasurfaces which are both compact and easy to manufacture using conventional photolithography. This contribution addresses two specific applications: the optical control of an amplitude and phase THz modulator, and the fabrication of large-area disposable split-ring resonators on plastic and paper for chemical identification. All experiments were carried out using a vector network analyser with THz extenders operating in the frequency range 0.75-1.1 THz.

1. Introduction

Metamaterials operating in the THz region can take advantage of the relatively short wavelength to produce compact structures, and of the fabrication methods typical of the semiconductor and micro electro-mechanical system (MEMs) industry. The minimum features are of the order of a few microns, which can be easily achieved by the photolithographic processes often available in research institutions.

This contribution addresses two specific applications which have been explored at the THz laboratory in Durham in recent months: the optical control of the properties of metasurfaces for THz amplitude and phase modulation, and the manufacturing of disposable metasurfaces on flexible substrates, plastic and paper, for chemical analysis.

Optically controlled THz modulators are desirable for their fast switching speeds, which find application in real-time THz imaging and in future high data rate communication devices. Nevertheless, their use is limited by the poor modulation depth, which requires high optical powers in the order of several W/cm² [1]. Optically controlled THz modulators may exploit the photoconductive nature of a near-intrinsic semiconductor, which reduces the THz transmissivity when is illuminated by light with a photon energy above its bandgap [2]. The measured average change in transmission due to photo illumination for high-resistivity floating-zone (HR-FZ) silicon in the range between 0.75 and 1.1 THz was measured to be approximately 0.72 dB (equivalent to a modulation depth of 7.8%), with a normal illumination of 200 mW/cm² of unpolarised white light. This is too small for any realistic application; however an increase in optical power would require large sources and bulky heat sinks. Nevertheless, resonating metasurfaces can be incorporated on the semiconductor substrate to improve the modulation efficiency. The response of the material to electromagnetic excitation can be tuned by changing the geometry of the cells. The resonance in this type of metasurfaces can be designed to exhibit exotic properties, such as a negative refractive index, invisibility and zero-thickness [3]. As resonant metamaterials are highly susceptible to changes in the substrate, an increase in modulation depth at their resonance is expected.

The sensitivity of resonant metasurfaces to the substrate can also be exploited for chemical detection and analysis. In this case the aim is to use cost-effective materials, such as paper and plastic, and fabrication techniques which can be easily scaled up. As an example, tumor markers are necessary for a correct cancer diagnosis. The speed and accuracy of these tests can potentially be improved using metasurfaces which resonate at the specific frequencies of these markers. Due to the need to keep samples sterile, it is also highly desirable to make the substrates easy to be dispose of. While paper-based sensor technology has been driven forwards in recent years, the paper fibres result in an uneven surface, which causes the small resonant features to lay on the substrate in an unideal way. In addition to this, paper does not lend itself well to conventional fabrication techniques. Nevertheless, photolithography on paper has been demonstrated with micrometre feature sizes [4]. Other methods such as printing, screen printing [5] and stencil and spray [6] are also potentially viable.

2. Results and Discussion

The reported experimental results were taken using a Keysight vector network analyser (VNA) with Virginia Diodes extenders operating in the 0.75-1.1 THz frequency range. All the designs of the resonant metasurfaces were optimised by 3D finite-difference time-domain (FDTD)
simulations, using both a commercial package, Lumerical, and our own code, Lucifer [7].

2.1. Optically controlled THz modulators

Figure 1 shows two common types of resonant structures fabricated on HRFZ silicon: the first type (Fig. 1a) is the classic split-ring resonator (SRR); the second type (Fig. 1b) is a conductively coupled joint supercell (JSRR), consisting of two connected square split rings.

![Figure 1: SSR (a) and JSRR (b) fabricated on HRFZ silicon.](image)

Figure 1: SSR (a) and JSRR (b) fabricated on HRFZ silicon.

Figure 2 shows the measured amplitude modulation as the metasurface in Fig. 1b was intermittently illuminated by white light, with a measured maximum modulation depth of over 400% at resonance.

![Figure 2: Measured amplitude modulation of JSRR.](image)

Figure 2: Measured amplitude modulation of JSRR.

A phase modulation of over 130° was also observed, which opens interesting applications if this modulator were used in the Fourier plane of a THz system.

2.2. Metasurfaces on plastic and paper

Figure 3 shows two different metasurfaces on plastic and paper. The structure in Fig. 3a, on paper, was optimised as a broadband stopband filter, with a centre frequency of approximately 0.9 THz. The structure in Fig. 3b is a more conventional single SRR on a plastic (PEN) substrate.

![Figure 3: A broadband bandstop filter (a) and single SSR (b) on paper.](image)

Figure 3: A broadband bandstop filter (a) and single SSR (b) on paper.

The advantage of using paper is that the chemical to be analysed can be absorbed in the paper fibres. Moreover, functionalisation of paper can increase sensitivity to specific elements. We have also successfully coupled the resonant structures on a plastic substrate to a sheet of paper containing the analyte, combining the benefit of the flat plastic, resulting in sharper features, and the availability of an absorbing materials.

3. Conclusions

To summarise, we have reported on the use of THz metasurfaces for enhancing the modulation depth of THz modulators (above 400%) and for chemical detection using disposable paper and plastic substrates.

Abstract

We review the results of extensive R&D activity focused on elaborating high-performance quasi-optical components of THz instrumentation using plasmonic metamaterials. Practical solutions for frequency filters of different types, non-profiled focusing devices, phase/polarization transformers, ultra-thin metasurface absorbers and metasurface-based radiation detectors, thin-film and SEIRA sensors are presented. The issues of design optimization, technological fabrication, and spectral characterization of the developed devices alongside with their practical applications are considered.

1. Introduction

Overlapping the frequencies from 0.1 to 10 THz, the terahertz band of the electromagnetic spectrum has been experiencing a rapid progress in the last decade stimulated by advancement in methods of THz generation and detection [1, 2]. Weakly developed in the past due to technological limitations, this spectral range attracts much interest both in fundamental and applied research owing to unique potentials of THz waves unachievable for adjoining infrared (IR) and microwave (MW) domains. A relatively large penetration depth into various optically opaque materials, absence of ionizing effects, attainability of mm/submm spatial resolution acceptable for imagining of concealed targets, high sensitivity to metallic and water-containing media, existence of rotational and vibrational “fingerprints” in organic molecules, and high information capacity make THz radiation promising for security, non-destructive testing, environmental monitoring, communications, biomedical diagnostics, etc.

It is noteworthy that plasmonic metamaterials enables noticeably extending functional properties of THz devices breaking the limits of classical optics. In particular, subwavelength plasmonic structures allows implementing very thin and high-performance quasi-optical components, which fabrication can be easily realized using well-proven photolithographic or other micromachining techniques of micrometer accuracy. Elaborated for the THz band and highly demanded in the market of THz instrumentation, such cost-effective solutions facilitate the more rapid development of optical, IR, and MW technologies.

In this contribution we consider practical examples of various metamaterial-inspired quasi-optical devices and components operating at frequencies from 100 GHz to several THz and providing amplitude, phase, and polarization manipulation of radiation beams in different applications. We discuss frequency filters, quarter- and half-wave plates, planar focusing structures, absorbers and absorber-based detectors, sensors of thin-film analytes. Both novel instrumental solutions and the improved conventional ones are presented.

2. Developed THz components and devices

All the metamaterial-inspired THz components and devices discussed in this work are implemented as single- or multilayer plasmonic structures based on frequency selective surfaces (FSSs) or metasurfaces (MSs). The complete development cycle includes: a) electromagnetic modeling using ANSYS EM Suite, methods of moments, and equivalent circuit methods; b) structure fabrication using UV-, X-ray, or E-beam lithography; c) spectral characterization with BWO-, TDS, or FT-spectrometers. The detailed description of the employed methods and techniques is given in [3-5].

2.1. Frequency filters

Stimulated by experiments with quasi-optical frequency demultiplexing and spectral measurements of broadband THz radiation from electron-beam plasmas [6], we mastered technological routes to fabricate high-performance FSS/MS-filters of the following types:

2.1.1. Band-pass filters (BPFs)

Assembled from free-standing patterned copper foils produced by electroplating [5], these multilayer structures have a multiplex (non-interference) configuration. The entire device set includes 25 BPFs with shifted spectral...
bands overlapping the range of 0.1–5 THz. Each BPF exhibits a high peak transmittance in the passband (~90%) at the fractional bandwidth (FWHM) of 12–20%. It is worth highlighting that due to a proper design of the FSS/MS pattern, the BPF of out-of-band transmission is maintained at the level of ~30–50 dB up to IR frequencies with no spurious transmission peaks.

2.1.2. Low-pass filters (LPFs)

The LPFs are represented by interference structures with 6-10 layers of capacitive patch-like FSSs/MSs patterned on polypropylene (PP) substrates and stacked together by means of a hot-pressing technique. The LPFs provide ~30–40 dB attenuation above their cut-on frequencies positioned between 0.25 and 2 THz. Originally, the LPFs were developed to suppress spurious absorption bands in MS absorbers integrated with our spectrometric pyrodetectors. We also successfully applied the LPFs to TDS measurements in the low-frequency regime to show a noticeable improvement of a S/N ratio and shortening the data acquisition time.

2.1.3. High-pass filters (HPFs)

The HPFs are implemented as thick single-layer structures of a wavelength-comparable thickness ranging from 0.3 to 1 mm. The HPFs strongly attenuate frequencies below the cut-off, which in our case can be selected within 0.2–1 THz. The topology of hexagon-shaped through holes separated by narrow crosspieces is utilized in the HPF design [7]. The HPFs are produced with one of 2 methods: a) via through-thickness lithographic patterning of a PMMA wafer with hard X-rays followed by its entire surface metallization (so-called “pseudometallic” structures [7, 8]); b) via reactive ion etching of low-resistivity silicon.

2.2. Planar focusing devices

The planar focusing devices are realized in 2 variants: a) as high-aspect-ratio “pseudometallic” structures with through holes of spatially-dependent dimensions operating in transmission [8]; b) as low-aspect-ratio grounded PP-backed MSs operating in reflection [9]. Due to electromagnetic optimization and holographic technique used in phase synthesis, we reach the diffraction efficiency of 75-90% when focusing 0.3–1 THz waves to focal areas of desired shapes.

2.3. Phase/polarization transformers

The phase and polarization transformers investigated in this work are implemented in single and bilayer configurations using anisotropic PP-based MSs operating in the range of 0.1–0.6 THz and exhibiting low absorption losses. Herein, we present a design of an efficient frequency filter with polarization discrimination using a MS of the half-wave plate type, and also consider a THz ellipsometer operating at 0.14 THz which exploits original quarter-wave plate elements based on self-complementary MSs.

2.4. Resonant absorbers and absorber-based detectors

We undertook extensive investigations of high-performance ultra-thin MS absorbers designed for narrow-band operation at frequencies from 0.1 to 1 THz and applicable to wavelength-selective (at 3-6% bandwidth) spectrometric detectors of a thermal type [5, 10]. In addition, we demonstrate a cost-effective industry-oriented technology of MS-absorber-based pyroelectric sensors and pyro-sensor arrays with tailored spectral and polarization responsivities.

All-dielectric metasurfaces for terahertz science and technology

Willie J. Padilla¹, and Kebin Fan¹

¹ Department of Electrical and Computer Engineering, Duke University, Durham, NC 27708, United States of America
*corresponding author, E-mail: willie.padilla@duke.edu

Abstract
All-dielectric metasurfaces are useful for investigation of new devices for terahertz science and technology. Scattering effects ranging from high absorption and Huygens' reflect arrays bound-states-in-the-continuum (BIC) suggest their use for applications. We experimentally demonstrate several all-dielectric metasurfaces which realize high transmission Huygens' structures, high absorptive devices for imaging, and dynamic surfaces with optical control. The all-dielectric metasurfaces we explore consists of arrays of high dielectric geometrical shapes, and may support a number of eigenmodes of either odd or even symmetry.

1. Introduction
Electromagnetic all-dielectric metasurfaces (DMSs) consist of one functional layer of dielectric resonator arrays, and are a versatile platform for exploration of a myriad of unconventional physical scattering responses ranging from high absorption and Huygens' arrays bound-states-in-the-continuum (BIC) and zero rank absorbers (ZRAs). Dielectric metasurfaces realize several advantages over their metal-based counterparts, i.e. zero Ohmic loss, high temperature operation, and low thermal conductivity. Notably, like metal-based metasurfaces, DMSs support two dipole like modes – one a magnetic mode and the other electric – both of which are tunable with geometry. Therefore, dielectric metasurfaces possess much of the salient features generally attributable to metal-based metamaterials, without the disadvantages listed above.
We developed a few technology demonstration systems using DMS operating at THz frequencies. We also demonstrate dynamic control of a DMS through photodoping, suggesting applications ranging from high speed filtering to frequency diverse imaging.

2. Simulation and Experimentation
The metasurface is simulated using full-wave 3D electromagnetic software, with a frequency domain solver (finite element method). We also use two-port S-parameter simulations, where the two ports were set symmetrically with respect to the mid-plane of the unit cell, and periodic boundaries were used on all sides. Eigenvalue simulations are also performed permitting extraction of the modes complex frequency. Metasurfaces may be simulated with and without material loss, which permits us to determine the individual pieces of scattering and dissipative loss in the structures. We use silicon or zirconium dioxide (also called zirconia) as the base materials for all-dielectric metasurfaces, and – in some studies – use a slight silicon boron doping. The metasurfaces were fabricated by deep reactive ion etching and we use polydimethylsiloxane (pdms) or extruded polystyrene as support substrates, or use silicon interconnects between unit-cells to make the metasurface free-standing. The all-dielectric metasurfaces are characterized by various methods including a vector network analyzer, terahertz time-domain spectrometer, or a Fourier transform spectrometer.

Two examples of metasurfaces are shown in Fig. 1, a zirconia zero-rank absorber [1] and a silicon metasurface which supports high Q-factor bound-states-in-the-continuum modes [2].

Figure 1: Two examples of fabricated all-dielectric metasurfaces. The left is an optical photo of a zero-rank absorber fashioned from zirconia, and the right is a free-standing silicon metasurface which realized high Q-factor BIC modes.

We demonstrate dynamic control of the amplitude and phase of transmitted light. Two different optical sources are used – a 980nm LED [3] and an ultra-fast titanium sapphire laser producing radiation at a wavelength of 800nm. We obtain a transmitted phase of 120 degrees with transmission modulation of over 99.9%. Theoretical analysis and numerical simulations coupled with temporal coupled mode theory indicate that the tuning is due to a substantial increase in the material dissipation rate of the odd eigenmode of the structure. [4] This serve to lift the degeneracy of the odd and even eigenmodes, while simultaneously destroying the critical coupled state.
In Figure 2 we present simulations of the BIC metasurface (top) and the ZRA (bottom). The high-Q BIC mode can only be coupled to by breaking the symmetry of the system. We thus use off-normal THz light which allows us to realize a high-Q mode in transmission at 1.2 THz (blue curve top left of Fig. 2). However, normally incident light (grey curve) does not couple to the mode and there signature of the BIC in transmission. The top right panel in Fig. 2 shows a dispersion diagram which uncovers the origin of the BIC mode. We find that the metasurface supports a surface leaky mode, which gets band-folded at the Brillioun zone and returns to the zone center at 1.2 THz. The leaky mode cannot be driven at normal incidence, and thus oblique incident light is needed to drive the mode and thus the BIC.

The bottom panel of Fig. 2 shows a color map showing high absorption (red colors) as a color map vs height of the metasurface absorbers and frequency in THz. There are two main modes – an even hybrid mode termed CPA-Even and an odd hybrid mode termed CPA odd – here CPA stands for coherent perfect absorber. Each one of these modes may act as a coherent perfect absorber for even (CPA-even) and odd (CPA-odd) symmetric light incident on the absorber. However, when these two modes are degenerate, then the coherency of incident light is not relevant as an absorber fashioned at this height (1.1mm) and operating at this frequency can absorb both even and odd symmetric incident light – this is what we term a zero-rank absorber. Temporal coupled mode theory shows that the scattering matrix of the ZRA is nullity, whereas the scattering matrix of the coherent perfect absorbers (CPAs) is not zero. Thus the ZRA may absorb even, odd, or incoherent light, whereas the CPA may only absorb either odd or even symmetric light.

3. Discussion

Coupled mode theory and S-parameter simulations are used to elucidate the mechanism underlying physics and dynamics of the metasurfaces shown here. Similar to metal-based metamaterials, both systems may be scaled in size to operate in nearly any band of the electromagnetic spectrum. The dynamic terahertz photonic systems studied here show wide tunability and versatility which are not limited to the spectral range demonstrated, offering a new path for reconfigurable metasurface applications.

4. Conclusions

Our all-dielectric metasurface is an ideal platform to investigate unconventional physics in electromagnetic wave absorbing systems. The demonstration of a dynamic all-dielectric structure highlights a new strategy for controlling metasurfaces, and highlights a potential path to achieve reconfigurability for future applications.

Abstract
Quantum-dot semiconductor structures have been used mostly in laser development. However, the unique properties of QD have allowed us to exploit it in the development of THz light source. Here we review our recent progress in generation of CW and pulsed THz radiation from QD based photoconductive antennae. The development of an ultra-compact, efficient, room temperature THz source based on QD structures is possible.

1. Introduction
Novel materials, notably quantum-dot (QD) semiconductor structures, offer the unique possibility of combining exploitable spectral broadening of both gain and absorption with ultrafast carrier dynamic properties [1]. Thanks to these characteristics, QD-based devices have enhanced the properties of CW devices as well as the development of compact ultrashort pulse lasers and provided a fertile ground for ultrafast science and technology.

2. Discussions
In this paper we review recent progress in generation of CW and pulsed THz radiation from QD based photocative antennae (PCA) pumped by ultrafast and dual wavelength semiconductor lasers. QD-PCA substrate incorporates InAs QDs in a GaAs matrix, thus keeping semiconductor carrier mobility at higher levels than is typical for SI GaAs, while QDs themselves serve as lifetime shortening centres, allowing to achieve sub-picosecond operation similar to LT-GaAs. Thus, such substrates combine the advantages and lack the disadvantages of GaAs and LT-GaAs, which are the most popular materials so far, and thus can be used for both CW and pulsed THz generation. Moreover, by engineering the design of the QD structure, effective pump wavelengths can be tuned in the range between 0.9-1.3 μm, which is well beyond the GaAs energies, hence compact and relatively cheap ultrafast and narrow line double-wavelength semiconductor and fibre pump lasers can be used for pumping such antennae for both pulsed and CW THz generation [2], [3].

However, antennae possess a low coefficient of optical-to-terahertz conversion due to the carrier screening effect and low quantum efficiency. To overcome these limitations, an optical nano-antennae technique can be employed. Optical nano-antennae are resonant nanostructures capable of transforming incident optical waves in a strong near-field. Such nano-antennae can be used to enhance the electric field and increase the absorption cross section in the active layers of the photoconductive antenna. We present our recent results on enhancement of THz generation in QD based log-periodic PCA with silver nano-antennae embedded in the antenna gap. Our first results demonstrated that using silver spheroid nano-antennae fabricated by a relatively simple method, can increase the coefficient of optical-to-terahertz conversion up to 4 times [4]. We also performed numerically investigation of THz photoconductive antennas based on optimized plasmonic nanostructures and studied the absorption enhancement of silver and transparent-conducting oxides (TCO) nanocylinders with different diameters by means of effective medium approximation. This study reports on the stronger enhancement in case of TCO nanocylinders. The results show that resonant absorption amplitude and wavelength are dramatically affected by the thickness of the nanostructure as well as by the distances between nanocylinders [5]. In case of TCO nanocylinders, absorption enhancement for NIR wavelengths, being relevant for present THz generation setup, reaches up to 5-fold leading to 25-fold increase in THz radiation.

3. Conclusions
In conclusion the development of an ultra-compact, efficient, room temperature THz source is possible. The inclusion of multiple bandgap-engineered semiconductor materials and quantum-confined structures enables additional pump absorption energy ranges and ultrafast charge carrier dynamics, crucial in the efficient generation of THz radiation.

Abstract

Certain materials exhibit dynamically controllable transitions from the plasmonic state to the dielectric state, traversing through intermediate states. Components made of such materials disappear electromagnetically in the vacuum state, except for ohmic loss. We have demonstrated the use of two materials, InSb and graphene-dielectric metamaterial in reflection gratings, transmission gratings, and metasurfaces for on-off switching operations that rely on the vacuum state or somehow deviate from it.

1. Introduction

Electric, magnetic, and thermal control of electromagnetic constitutive parameters of materials such as InSb, VO2, graphene, and ITO are often investigated for the realization of tunable and switchable devices operating in diverse spectral regimes. Materials with the capability of transition from the plasmonic state \( \text{Re}(\varepsilon_i) < 0 \) to the dielectric state \( \text{Re}(\varepsilon_i) > 0 \) have attracted particular attention, with focus on achieving the maximum contrast between \( \min(\text{Re}(\varepsilon_i)) = \varepsilon_0 < 0 \) and \( \max(\text{Re}(\varepsilon_i)) = \varepsilon_\infty > 0 \). Such a wide range encompasses the zero-permittivity state \( \text{Re}(\varepsilon_i) = 0 \) and the vacuum state \( \text{Re}(\varepsilon_i) = 1 \). Whereas the zero-permittivity state has been extensively investigated this century, the vacuum state was only recently identified [1] despite it being the more distinguishable of the two intermediate states.

Ideally, the device components made of a material in the vacuum state disappear for electromagnetic purposes, so that an efficient on-off switching scenario can be achieved [1]. In this talk, our main objective is to demonstrate the capability of two selected materials for on-off switching of deflection in reflection and transmission modes in the THz spectral regime. The two materials are InSb [1,2] and a graphene-dielectric multilayer metamaterial [3], with thermal control applicable to the first one and electric control to the second.

2. Results and Discussion

We first revisited the effect of ohmic loss in the chosen materials by comparing the realistic case and the hypothetical cases of larger and smaller (including zero) losses. The goal was to assess the possibility of using these materials in (i) reflection gratings, (ii) transmission gratings, and (iii) as resonators in uniform and gradual metasurfaces. Ohmic loss is a critical issue for both transmission gratings and resonators. Based on computed data, we determined which ranges of values of \( \text{Im}(\varepsilon_i) \) are still acceptable for reflection gratings, transmission gratings and metasurfaces, and thus assessed the usefulness of both chosen materials.

The potentially realizable on-off switching scenarios may include but are not restricted to those based on vacuum-plasmonic-state transition, vacuum-to-high-\( \varepsilon_\infty \)-dielectric transition, and vacuum-to-zero-permittivity state transition.

2.1. Indium Antimonide (InSb)

The reflection grating shown in the inset of Fig. 1 enables nearly perfect deflection. The device comprises InSb microrods of square cross-section on a SiO2 buffer layer (\( \varepsilon_{\text{SiO2}} = 2.25 \)) backed by a metallic reflector. The relative permittivity \( \varepsilon_{\text{InSb}} \) of InSb can be varied at THz frequencies in a wide range, due to strong sensitivity to the temperature \( T \). The grating period is \( L = 80.22 \) \( \mu \)m. At 3.135 THz frequency and \( T = 315 \) K, the grating disappears in an electromagnetic sense because \( \varepsilon_{\text{InSb}} = 1.015 + i0.234 \) then, and only specular reflection occurs. When the temperature is lowered to 275 K, \( \varepsilon_{\text{InSb}} = 9.72 + i0.095 \) and the 1st-order nonspecular reflection is very strong. Temperature-controlled on-off switching of deflection is thus possible in the reflection mode.

Next, the SiO2 substrate was replaced by InSb, the metallic reflector was removed, the period was changed to 62.66 \( \mu \)m, and the remaining geometrical parameters were also adjusted. At 4.58 THz frequency, \( \varepsilon_{\text{InSb}} = 12.88 + i0.0305 \) at \( T = 275 \) K but \( \varepsilon_{\text{InSb}} = 1.577 + i0.154 \) at \( T = 355 \) K. The 1st-order nonspecular transmission is very strong at 275 K but very weak at 355 K. Temperature-controlled on-off switching of deflection is thus possible in the transmission mode. Ohmic loss in InSb may not permit the 1st-order transmittance to be higher when \( \text{Re}(\varepsilon_{\text{InSb}}) = 1 \).
The grating period \( L = 80.22 \) \( \mu \text{m} \) and \( k \) is the free-space wavenumber.

Changes in temperature on the order of 10 K or 20 K can be sufficient to achieve a dramatic change of the diffraction characteristics, provided that the geometric parameters are properly chosen [1]. The role of the vacuum state in the tunability of a gradient meta-array composed of microrods similar to the ones in Figs. 1 and 2 has also been investigated.

### 2.2. Graphene-Dielectric Multilayer Metamaterial

Next, we consider two different devices comprising a graphene-dielectric multilayer metamaterial, with constitutive and geometric parameters given by Khromova et al. [3]. In the first device, the metamaterial is used as a substrate for a uniform two-dimensional array of dielectric resonators (microrods), as shown in the left panel of Fig. 3. By varying the Fermi energy level from 80 meV to 20 meV, the metamaterial’s relative permittivity can be changed from \( \varepsilon_{\text{F}} \approx -2.5 \) to \( \varepsilon_{\text{F}} \approx 2.2 \), according to the model given in Ref. 3. The resonances of the individual microrods and, thus, the transmission and reflection characteristics of the whole device are affected. Using the results obtained for the uniform (non-gradual) arrays, we estimated the potential of the graphene-dielectric multilayer substrates in tunable deflection of THz waves by nonuniform (gradual) metasurfaces composed of such resonators. Finally, the case when the resonators are embedded in a tunable metamaterial substrate was considered; see the right panel of Fig. 3. A comparison of these two devices is being carried out.

![Graphene-Dielectric Metamaterial](image)

**Figure 3:** Schematic views of (left) a nonperiodic array of Si microrods with a graphene-dielectric metamaterial as the substrate and (right) a periodic array of Si microrods embedded in a slab of the graphene-dielectric metamaterial.

### 3. Conclusion

To summarize, materials with plasmonic-to-dielectric state transition and vacuum state as one of the intermediate states allow us to make some components of a whole device on/off switchable. The presented examples show how the intermediate vacuum state is connected with the switch-off regime, when gratings and metasurfaces may disappear electromagnetically. In reflection mode, the tunable components of the studied structures may be weakly sensitive to the ohmic loss which acquires greater importance for transmission-mode devices. Both InSb and the graphene-dielectric multilayer metamaterial are suitable materials in the THz regime.

Abstract

Advances in terahertz (THz) research and technology, has bridged the gap between radio-frequency electronics and optics. More efficient control of THz waves would highly benefit noninvasive, high-resolution imaging and ultra-fast wireless communications. However, lack of active materials in THz spectrum, hinders the realization of these technologies. Graphene, 2d-crystal of carbon atoms, is a promising candidate for reconfigurable THz optoelectronics due to its unique electronic band structure which yields gate-tunable broad-band optical response. In this talk I will present our experimental work on graphene based devices for controlling intensity, phase and polarization of terahertz waves. These new modulation mechanisms could pave the way for developing active THz optoelectronic systems.

Surface waves of ferromagnetic films and spheres propagate only in one direction, with a handedness governed by the vector product of magnetization and surface normal [1,2]. This chirality gives rise to for example the spin conveyor belt effect [3].

I report our theoretical efforts to understand, control, and find applications for chiral spin waves [4,5] and chirally excited conventional spin waves [4-6] in yttrium iron garnet, an insulating ferrimagnet with exceptionally high magnetic quality. We compare our results with available experiments [6,7].

Spin waves and electromagnetic waves in photonic-magnonic crystals

Abstract

In the periodic structures combining the ferromagnetic and dielectric elements, both the spin waves and electromagnetic waves can propagate characterized by the dispersion relations with magnonic and photonic band gaps (MBGs and PBGs), respectively. These hybrid structures called photonic-magnonic crystals (PMCs) can be used to enhance the magneto-optical interactions. We calculated the MBG and PBG structures in 1D PMC and discussed the enhancement of Faraday rotation and cross-polarized contribution to Goos-Hänchen shift resulting from the periodicity in the structure under consideration.

1. Introduction

In this paper, we are considering a new type of 1D structure of similar type in which the periodically arranged magnetic layers (constituting a magnonic crystal (MC)) are spaced by dielectric multilayers (finite-size dielectric photonic crystal (PC)). Thus, the whole system has a double periodicity, which generates complex PBGs and MBGs. Its multifunctional properties manifest themselves by the possibility of simultaneous propagation of both electromagnetic waves (EMWs) and spin waves (SWs) [1-3]. In the considered structures the EMWs can be highly localized in magnetic layers when their frequencies correspond to the frequencies from the stop band of the finite-size PC. For such modes we can observe enhancement of magneto-optical (MO) interaction (resulting e.g. in the increase of Faraday rotation) and we expect to find the noticeable interaction between the SWs and the EMWs.

2. Photonic-magnonic crystal

The exemplary structure of 1D PMC is presented in Fig.1. We considered the structure where the dielectric ferrimagnetic layers (made of yttrium iron garnet (YIG)) are separated by nonmagnetic SiO₂/TiO₂ multilayers. The dielectric multilayers SiO₂/TiO₂ are thin enough to couple dipolar SWs in YIG layers. We investigated the case when the magnetization is saturated and oriented in the plane of the YIG layers which are, on the other hand, transparent for EMWs.

Figure 1: (a) The considered 1D PMC acting as magnonic and photonic crystal. The parameters d_m, d_s, and D=d_m+d_s denote the thicknesses of the magnetic, or complex non-magnetic layers, and the period of the whole structure, respectively. (b) The transmittivity spectra log|T| as a function of the incidence angle and frequency of the EMW. The dotted lines denote the PBG edges for the infinite dielectric PC with the unit cell (TiO₂/SiO₂) for the details see [1, 2]). (c) The SW dispersion and profiles in YIG layer.
For the structure presented in Fig.1 we found the dispersion relations of dipolar SWs in simple 1D layered MC and the dispersion relations of the EMWs for complex PMC where the double periodicity is manifested in the splitting of the bands of SiO₂/TiO₂ PC into minibands and in the presence of weakly dispersive bands of the modes in the PBG of SiO₂/TiO₂ PC [1]. We call these modes as inside-PBG modes. The similar problem was investigated for a PMC with complex unit cell which contains two magnetic layers with different thicknesses [4].

3. Faraday rotation and Goose-Hänchen effects in photonic-magnonic crystal

We analyzed theoretically the Faraday rotation (FR) and the Goose-Hänchen (GH) effect (lateral shift of the transmitted Gaussian wave packet) for the near-infrared electromagnetic beams in PMC. These effects can be enhanced for inside-PBG modes which are confined in the magnetic layers. The presence of the linear magneto-electric coupling in the magnetic layers can result in a significant increase of the FR (see Fig.2c) and in a vanishing of the positive maxima of the cross-polarized contribution to the GH shift (see Fig.3b).

Figure 2: The evolution of the FR angles of (a) p-polarized and (b) s-polarized incident light, respectively, with frequency \( \omega \) and incidence angle \( \theta \) for the photonic structure \([M(AB)^4A]^3M\) (where M is YIG layer and A,B are SiO₂, TiO₂ layers.) The white dots depict the positions of the PBG edges and the inside-PBG modes. (c) Fine structure of the FR angles in dependence on frequency for selected inside-PBG modes at the incidence light angle \( \theta = 30 \) deg. Blue lines (pink lines) correspond to p-(s-) polarized light. We considered the magneto-electric constant \( \alpha = 0 \) (solid lines) and \( \alpha = 30 \text{ ps}\cdot\text{m}^{-1} \) (dotted lines) [4].

Figure 3: The GH shift vs frequency for (a) s-s, p-p transmission and for (b) p-s (s-p) transmission for selected inside-PBG modes at the incidence light angle \( \theta = 30 \) deg. We considered the same structure as in Fig.1 and Fig.2 for the cases when the magneto-electric constant \( \alpha = 0 \) (solid lines) and \( \alpha = 30 \text{ ps}\cdot\text{m}^{-1} \) (dotted lines) [5].

Abstract

We demonstrate the excitation of multipolar resonances in kirigami metamaterial and the switching of electromagnetic properties among various chiral states. Single-band, dual-band, and broadband circular polarizers with reconfigurable performance are realized by steering the electric, magnetic and toroidal dipolar response. The underlying mechanism is explained and calculated via detailed analysis of the excited multipoles. With the ongoing development of micromanufacturing techniques, our findings may offer an alternate approach to lightweight, reconfigurable, and deployable metadevices.

1. Introduction

Metamaterials and metasurfaces are artificial materials engineered at the subwavelength scale to achieve electromagnetic functionalities[1, 2]. To date, one of the remaining difficulty is the large shape modification of the artificial structures, rendering them nonreconfigurable in various electromagnetic functionalities. Several methods have been utilized to dynamically control the optical properties of metamaterials, such as capacitors[3], semiconductors[4], phase change materials[5] and ferromagnetic/ferroelectric materials[6]. However, compared with the surrounding media and metamaterial constituents, most of these methods suffer from a limited tuning range because the variation is usually very small. Recently, origami provides an alternative approach to construct strong, lightweight, and tunable three-dimensional (3D) blocks from flat sheets[7, 8]. By applying prescribed sequences of folds to flat surfaces, researchers demonstrated flexible and efficient control over mechanical[7], electronic[9], acoustic[10], and electromagnetic functionalities[11]. Although the design capacity of origami is remarkable, achieving complex target shapes with only folds is mathematically challenging. Therefore, combining cut and fold together, namely, the technique of kirigami, would be a promising platform to design multifunctional metamaterials with less structural complexity.

In this talk, we will review our recent results on kirigami metamaterials[12], whose chiral responses can be flexibly controlled by the arrangement of meta-atoms and properly design kirigami. Three types of kirigami-based chiral metamaterial will be presented and the underlying multipolar responses with be discussed. We will also envision the future applications of the kirigami technique, as well as the origami one, in reconfigurable electromagnetic devices.

2. Results

The schematic illustration of the kirigami metamaterials is presented in Fig. 1. We start with an achiral two-dimensional (2D) metasurface consisting of periodically arranged meta-atoms. Only electric dipolar responses exist in the transverse plane, indicating no macroscopic chiral effect. Subsequently, the 2D metasurface is transformed into 3D geometries by introducing cuts at the boundary between neighboring meta-atoms. Through kirigami, parallel and anti-parallel electric and magnetic dipoles can be constructed, as well as the excitation of toroidal dipoles. As a result, various chiral polarizers can be realized (Fig. 2). Type-I kirigami metamaterial reaches high circular dichroism (CD) in a single band. Type-II kirigami metamaterial has two resonant frequencies where the handedness of the chirality is opposite. More intriguingly, the bandwidth of the chiroptical response can be improved by exciting a toroidal dipolar resonance, so as the Type-III kirigami metamaterial shows. Furthermore, the chirality of all three devices can be flexibly reversed by changing the folding direction of the kirigami process. The reconfigurable circular dichroism generated by toroidal dipoles offers an alternative approach to broadband chiroptical responses beyond the widely adopted methods based on parallel electric and magnetic dipoles. Circular dichroisms of 0.88, 0.94 and 0.92 have been experimentally observed for single-band, dual-band and broadband configurations, respectively. Due to the scaling properties of Maxwell’s equations, the proposed strategy for reconfigurable electromagnetic performance can be extended to other frequencies, from
millimeter-scale architectures in microwave regimes to tunable metasurfaces in terahertz regimes. If it is combined with advanced micro technologies, such as electromagnetic-systems (MEMS), we expect the kirigami metamaterials could find promising applications in terahertz sensors and detectors.

Figure 1. Kirigami metamaterials as a platform to steer the multipolar manipulation and reconfigurable chiroptical responses.

Figure 2. Electromagnetic performance of three types of kirigami-based chiral metamaterials. (a, d, g) Type-I device for single-band chiral resonances. (b, e, h) Type-II device for dual-band behaviors. (c, f, i) Type-II device for broadband behaviors.

3. Conclusions

We have proposed and demonstrated a general class of kirigami-based chiral metamaterials whose electromagnetic functionalities can be switched between nonchiral and chiral states. By introducing cuts and selecting the connection points between neighboring meta-atoms, 2D achiral metasurfaces can be deformed to 3D shapes with enhanced chiroptical responses. Highly efficient single-band, dual-band and broadband circular polarizers have been experimentally demonstrated. The underlying mechanism has been confirmed by detailed analyses of the excited electrical, magnetic and toroidal dipoles. Compared with the technique of origami, kirigami allows for the practitioner to exploit cuts in addition to folds to achieve large deformations and create complex 3D objects.

Cavity optomagnonics with magnetic quasi-vortices

Alto Osada\textsuperscript{1*}

\textsuperscript{1}Komaba Institute for Science, The University of Tokyo, Tokyo, Japan

Abstract

We investigate Brillouin scattering of whispering gallery modes, or optical vortices, by various magnetostatic modes, or magnetic quasi-vortices, both being supported inside a ferromagnetic sphere. As a consequence of conservation of angular momenta, Brillouin scattering becomes reciprocal or nonreciprocal, depending on the orbital angular momentum of the magnetic quasi-vortex. Observed experimental results are reasonably explained by the conservation of angular momenta, and the possible enhancement of Brillouin scattering by the use of optical cavity is inferred.

1. Introduction

Cavity optomagnonics has emerged recently as an activity to pursue the possibility of enhancing spin-light coupling \cite{1, 2, 3, 4, 5, 6, 7, 8, 9}, which is inherently weak due to unavoidable mediation of spin-orbit coupling of an electron, by the use of an optical cavity. A ferromagnetic sphere, in this perspective, is an excellent venue for the investigation since it supports optical whispering gallery modes (WGMs) and magnetostatic Walker modes inside the sphere itself [see Fig. 1(a)], equipping them with high quality factors \cite{1, 2, 3, 4, 8}.

Moreover, these optical and magnetostatic modes can be regarded respectively as optical vortex and magnetic quasi-vortex, which are typical topological excitations characterized by topological charges or orbital angular momenta. Thus, the system of cavity optomagnonics using a ferromagnetic sphere also provides a suitable platform for exploring the novel physics emerged from the interaction between topological excitations. It is expected that in the interaction between optical vortex and magnetic quasi-vortices, spin and orbital angular momenta are passed from one to the other. This, combined with the broken time-reversal symmetry of the material, can result in the nonreciprocal phenomena \cite{7, 9}. Hence, the cavity optomagnonics may serve as a new approach to opto-spintronics, chiral quantum optics and topological photonics.

2. Nonreciprocal and reciprocal Brillouin scatterings

Experiments are conducted with the setup schematically shown in Fig. 1(b). Laser light with the wavelength of 1550 nm is evanescently coupled to WGMs via a prism, and then Brillouin-scattered by Walker modes. Walker modes possess their frequencies around 7 GHz and are excited by microwaves from a loop coil, in the presence of magnetic field $\sim 0.25$ T applied perpendicular to the sheet. The incident and scattered light, which are coupled out of the WGM in the same path, possess different polarization state, so that a half-wave plate and a polarization beam splitter make them interfere to generate beat signal. This beat signal manifests itself as the signal of the Brillouin scattering under investigation. The signal is detected by a high-speed photodetec-

![Figure 1: (a) Schematic illustration of the cavity optomagnonics involving whispering gallery modes and Walker modes. (b) Schematics of the experimental setup for the observation of Brillouin scattering. HWP: half-wave plate, PBS: polarization beam splitter, Amp.: microwave amplifier.](image)

![Figure 2: Normalized microwave reflection spectrum with the mode indices assigned to the Walker modes of our interest. Along the horizontal axis, the relative frequency to the Kittel-mode frequency $\omega_{Kittel}/2\pi$ is used. The transverse-magnetization distributions of the assigned modes are also shown. Note that the spectra below (green, left axis) and above (black, right axis) 100 MHz are separately scaled.](image)
tor, which gives us information about the strengths of the Brillouin scatterings by various Walker modes.

The microwave reflection spectrum is displayed in Fig. 2. Along the horizontal axis, the relative frequency to the Kittel-mode frequency $\omega_{\text{Kittel}} / 2\pi$ is used. The transverse-magnetization distributions of the assigned (1, 1, 0), (3, 1, 1), (3, 1, 1) and (4, 0, 1) modes are also shown. Note that the spectra below (green, left axis) and above (black, right axis) 100 MHz are separately scaled.

Corresponding to the observed Walker modes, signals of Brillouin scattering by them are observed, as presented in Fig. 3. Red (bottom) and Blue (top) plots are the signals obtained when counterclockwise (CCW) and clockwise (CW) WGMs are used in the experiment. It can be seen that the signal of the Brillouin scattering is larger for CW WGM with (1, 1, 0) and (3, 1, 1) modes with vanishing OAM, whereas it is larger for CCW WGM when (3, 1, 1) mode is involved, where the OAM reads 2. Furthermore, (4, 0, 1) mode, whose OAM is 1, results in the absence of the noticeable difference whichever WGM is used. These peculiar behavior can be clearly explained by taking conservation of spin and orbital angular momenta into account, by which together with the experimental results deepens the understandings of the system of cavity optomagnonics.

3. Cavity-enhanced Brillouin scattering

According to the theoretical consideration, the Brillouin scattering of the CW WGM by (1, 1, 0) (Kittel) mode is resonantly enhanced by WGM. This cavity enhancement can be achieved when a suitable pair of WGMs of the same orbital angular momentum possess the frequency difference equal to the Kittel-mode frequency. Figure 4 shows the plot of Brillouin-scattering signal versus the Kittel-mode frequency tuned by magnetic field. The data and fitting endorse the presence of resonant peak when above condition is satisfied, in agreement with the theory.

4. Conclusions

Cavity optomagnonics using a ferromagnetic sphere has been proven to be an interesting platform to investigate Brillouin scattering of optical vortices by magnetic quasi-vortices, which could be enhanced by the presence of optical cavity. In accordance with the theory, conservation of angular momenta resulted in the pronounced or absence of nonreciprocity depending on the orbital angular momentum of magnetic quasi-vortex. This work may provide novel approaches to fields such as opto-spintronics and chiral photonics.

Abstract
We theoretically demonstrate an unnoticed role of the three-dimensional (3D) superchiral structure in the near-field circular dichroism (NF-CD), and propose a scheme of 3D NF-CD measurement near plasmonic chiral field by using the optical force exerted on a tip of the atomic force microscope (AFM), which cannot be performed by aperture-type scanning near-field optical microscope (SNOM) because of its 2D character of the field measurement.

1. Introduction
The interplay between the optical chirality and matter systems is essential for the analysis of matter chiral properties. Circular dichroism (CD), which is the difference in absorption of left- and right-circularly polarized light for substances, is a standard measure of matter chirality. In order to overcome the weakness of the intrinsic absorption cross section of molecules, recently, the superchiral fields near metallic structures is paid great attention\cite{1, 2}. Near the metallic structure, a chiral asymmetry is greatly enhanced, and clear CD of a few molecules can be obtained\cite{3, 4}. Actually, the various nanostructures have been reported to generate superchiral fields and huge optical activity\cite{5, 6, 7, 8}. However, these studies measure the extinction of the propagating light through the target, i.e., measure the far-field component of the CD (FF-CD) signal. In order to extract the full potential of nanoscale superchiral fields and elucidate microscopic chiral properties of single molecules, direct measuring of NF-CD is crucial. To this end, we propose an approach utilizing optical force exerted on a metallic scanning probe. Importantly, the proposed method is sensitive to the longitudinal component (z-component) of polarization in the chiral near-fields through the optical force on the nano-probe tip.

2. Model and method
We assume that the probe tip is fixed to open end of the cantilever, and the optical force is evaluated. Indeed, the similar methods have succeed in obtaining the super-resolution imaging of the sample surface\cite{9}. We calculate the map of the optical force exerted on the scanning probe with left- or right-handed circularly polarized incident light. The time-averaged optical force acting on the metallic probe is calculated\cite{10}. We scan the probe on the gap area of the four gammadions (see Fig. 1(a)). Under top of the tip is set at $z = 5 \text{ nm}$. We set the incident light intensity to be $1 \text{kW/cm}^2$.

3. Results
We should note that the optical force is approximately proportional to the gradient of the field intensity. (In the present case, the scattering and absorbing forces are much smaller than the gradient force.) In the present analyses, we compare the maps of field gradient and optical forces. Figure 1(b) shows the map of the optical-force difference between illuminated by the LCP and RCP light. In Fig. 1 (c) and (d), we show the field gradients along z-direction for the field with xy-polarization and z-polarization, respectively. Here, we can see that the map in Fig. 4 (b) well reproduces Fig. 4 (c) inside the gap area because the longitudinal component is weak in this region. However, on the edges of the metallic structures, the gradient of the longitudinal component becomes remarkably large as seen in Fig.4 (d). This situation is well reflected in the corner regions in Fig.4 (b). (Note that the color in the corner regions in Fig. 4(b) is strikingly different from that in Fig. 4 (c) with adjusted color bar scale.) Thus, we see that force map well provides information of the contribution from the longitudinal component.

4. Discussion
Here, we should note that the position dependence of the electric fields and the field intensity in itself are affected by the probe tip and generally different from those in the absence of the tip. However, the obtained information provides significant insight into the spatial structures of NF-CD indicated in Fig. 1. This result encourages the study for more detailed analyses of the force map to obtain the 3D NF-CD information including the case in the presence of the targeted molecules on the metallic structures in the next step.

5. Conclusions
We have proposed a scheme for 3D NF-CD measurement by utilizing the optical force exerted on the probe tip. Our demonstration shows that the superchiral fields near the
metallic nanostructures include rich longitudinal component that makes a great difference between NF-CD and FF-CD spectra, and the obtained force map well reproduces the 3D NF-CD map including z-component polarization. The understanding of NF-CD stereoscopically will advance the plasmonic chiral sensing and optical chiral manipulation to the next stage.

Chirality Generation in Discrete Silicon Nanostructures

Xin Zhao\(^1\) and Björn M. Reinhard\(^1,\ast\)

\(^1\)Department of Chemistry and The Photonics Center, Boston University, Boston, United States
\(\ast\)corresponding author, E-mail: bmr@bu.edu

Abstract

Silicon nanostructures provide morphology-dependent resonances that can be tuned across a wide wavelength range, which makes them versatile building blocks for higher order photonic molecules. Electromagnetic interactions between individual building blocks in silicon-based photonic molecules provide additional degrees of freedom for enhancing and controlling light-matter interactions. In this presentation we will review recent studies from our laboratory aimed at generating enhanced optical chirality densities in achiral structures.

1. Introduction

Depending on their precise morphology silicon nanostructures sustain a wide range of optical modes in the visible range of the electromagnetic spectrum. For instance, high refractive index silicon nanoparticles provide both magnetic and electric Mie resonances, and silicon nanorods can sustain additional guided modes.\(^{1,2}\) If the diameter of the silicon nanowires is small, these modes can have a significant mode volume outside of the nanowire. Due to this field penetration of the ambient medium, higher functionality can be achieved by incorporating the individual silicon building blocks into higher order structures with sufficiently short spacing between the building blocks to allow for strong electromagnetic interactions. We will describe in this presentation recent progress from our laboratory to utilize silicon nanostructures (see for example Figure 1) to generate same sign near-field chirality enhancement and to boost chiral light-matter interactions.

2. Generating Near-Field Chirality in Silicon Nanowire Dimers

The spectra of silicon nanowires are dominated by weakly confined hybrid HE modes, described the nomenclature HE\(_{m,n}\) with 2\(l\) intensity maxima around the circumference of the nanowire and \(m\) maxima along the radial direction.\(^3\) The fundamental HE\(_{1,1}\) mode is two-fold degenerate with \(E\)-field components pointing either into \(x\)- or \(y\)- direction: HE\(_{1,1,x}\) and HE\(_{1,1,y}\). Importantly, this degeneracy is removed if the two nanowires are localized in close vicinity to each other, and the leaky \(E\)-fields of the wires show different interactions along different directions.\(^3\) If we assume the two nanorods to be arranged along the \(x\)-axis then the \(x\)-component of the \(E\)-field associated with a mode show a much richer interaction than along the \(y\)-axis. As the \(E\)-field along the \(x\)-axis penetrates the neighboring silicon nanowire, the refractive index of the \(Ex\) component is effectively higher than that of the \(Ey\) component due the the presence of the second high refractive index silicon nanorod. One important consequence of this birefringence that leads to differences in the refractive index between \(Ex\) and \(Ey\) components of the propagating modes is that the associated modes build up a phase difference as they travel along the nanowire. Importantly this phase difference will increase with increasing propagation length of the nanowire. In other words, the length of the fabricated nanowires provides opportunities to control the accumulated phase difference.

The ability of an electromagnetic field to enhance chiral light-matter interactions depends on the chirality density, \(C\):\(^{4,5}\)

\[
C = -\frac{1}{2} \varepsilon_0 \text{Im}(\mathbf{E} \cdot \mathbf{B})
\]  

Figure 1. SEM images of silicon nanowire dimers generated by reactive ion etching. The images show an array with increasing wire radius from 55 nm (bottom) to 90 nm (top) in steps of 5 nm. Insets show magnified views of marked dimers. Scale bar = 1 micron in the array image and 200 nm in the insets. Reproduced with permission from X. Zhao and B.M. Reinhard, ACS Photonics 4, 2265 (2017). Copyright American Chemical Society.
where $E$ and $B$ are electric and magnetic field, respectively. According to this relationship, it is clear that the near-field chirality depends on the alignment of electric and magnetic fields and the phase shift between electric and magnetic field. In dimers of silicon nanowires the presence of orthogonal HE$_{1,1}$ and HE$_{1,3}$ modes from two adjacent nanowires whose electric and magnetic compounds accumulate a relative phase shift, $\gamma$, as they propagate along the nanowire provides opportunities for achieving the correct alignment of $E$ and $B$ fields of the propagating modes to enhance the near-field chirality. We will demonstrate in this presentation that silicon nanowires and other silicon nanostructures can generate robust same sign chirality near-fields under illumination with linearly polarized light.

Figure 2 shows a finite difference time domain (FDTD) simulation of $C$ in the plane between two 2 micron long silicon nanowires (140 nm diameter) with a spacing of 40 nm. The incident light polarization is $\pi/4$ (relative to the nanowire-nanowire axis). The simulations clearly confirm a strong near-field chirality in the gap between the two silicon nanowires.

We will discuss and characterize the fundamental working principles underlying optical chirality generation in dimers of silicon nanowires and other silicon-based photonic molecules.

3. Discussion

Silicon nanostructures provide tunable resonances over a broad spectral range as well as a high degree of mechanical and thermal stability. Their physical properties together with the availability of accurate top-down fabrication strategies for integrating them into higher order structures makes silicon nanostructures ideal building blocks for nanoscale optical antennas in the visible range of the electromagnetic spectrum. In this presentation we will discuss recent examples from our laboratory of how discrete silicon nanoantennas can be generated that provide exquisite control over the optical near-field chirality. Our fabrication strategies will be discussed and the underlying electromagnetic working principles will be characterized through combination of optical spectroscopy and electromagnetic simulations.

4. Conclusions

Silicon nanostructures that can provide both electric and magnetic field enhancements are versatile building blocks for generating chiral field enhancements in achiral antennas. The ability to enhance optical chirality in achiral structures with linear light polarization provides unique opportunities for enhancing chiral light-matter interactions and, thus, paves the way to detecting molecular chirality with higher sensitivity than is currently possible.

Generalization of the Optical Chirality to Arbitrary Media

Abstract
Motivated by recent theoretical results concerning energy, momentum, angular momentum, and optical helicity of electromagnetic waves in dispersive and lossless media, here we address a parallel derivation for the optical chirality, extending it so as to include dissipative effects as well. Looking into the mathematical structure of the continuity equation, we find a new general expression for the optical chirality density in lossless and lossy dispersive media, which may be applied to any medium, including dielectrics, plasmonic nanostructures, and metamaterials.

1. Introduction
Chirality is a geometrical property that allows us to describe objects that cannot be superimposed with their mirror image. This property is ubiquitous in nature at many different scales, with a special role at the molecular level, since enantiomers may behave very differently. Besides physical objects, chirality can also be exhibited by electromagnetic (EM) waves. In this context, as originally introduced by Tang and Cohen [1], optical chirality is a fundamental property of light that determines the degree of the handedness of optical fields in free space:

\[ C_{\text{vacuum}} \equiv \left[ \varepsilon_0 \mathbf{E} \cdot (\nabla \times \mathbf{E}) + \mu_0 \mathbf{H} \cdot (\nabla \times \mathbf{H}) \right] / 2, \]

where \( \varepsilon_0 \) and \( \mu_0 \) are the permittivity and permeability of vacuum, respectively, and \( \mathbf{E}(r,t) \) and \( \mathbf{H}(r,t) \) are the local, time-dependent electric and magnetic fields. This formula has been successfully used in circular-dichroism measurements for the experimental detection and characterization of chiral biomolecules by superchiral fields (i.e., fields with optical chirality larger than that due to circularly polarized light) [2, 3], thus confirming its physical significance and the feasibility for practical applications. Nonetheless, mainly due to the mismatch between the scales of the illuminating wavelength and the typical size of chiral molecules, the chiroptical responses are generally very weak [1].

Recent advances in nanofabrication have led to nanostructured metamaterials and plasmonic systems that tremendously boost chiral light-matter interactions. Indeed, the occurrence of strong optical chirality relies on the complexity of the EM-field distribution, and thus metallic nanostructures have been considered as the best-suited platforms for investigating chiroptical effects [4]. Still, it is certainly surprising that contributions of material dispersion as well as dissipation have mostly been ignored.

2. Continuity equation for optical chirality
Aiming to get the optical chirality density in dispersive media, we will first address the most complete form of its conservation law. In the presence of charges and/or currents, conservation laws are to be expressed through the continuity equations. Therefore, just as for the energy conservation (derived from the Poynting vector), for the optical chirality one must start by defining its flux density:

\[ \mathbf{F} \equiv [\mathbf{E} \times (\nabla \times \mathbf{H})] - [\mathbf{H} \times (\nabla \times \mathbf{E})] / 2. \]  

Here it is worth remarking that, so far the literature concerning optical chirality has been mostly dealing with EM fields in free space [1, 5]. Then, we can often find several expressions for the chirality flux density where the fields \( \mathbf{B} \) and \( \mathbf{H} \) are used interchangeably yielding the same results. However, this does not occur in dispersive media, and special care should be taken in dealing with EM fields either in free-space (\( \mathbf{E} \) and \( \mathbf{H} \)), or within a medium (\( \mathbf{D} \) and \( \mathbf{B} \)). Be that as it may, the chirality flux density as defined in Eq. (2) is in fact used in Ref. [6], and coincides with that originally introduced by Tang and Cohen [1] for EM fields in free space. Then, taking the divergence it follows that

\[ \nabla \cdot \mathbf{F} = -\mathbf{J} \cdot \partial_t (\nabla \times \mathbf{D}) + \mathbf{D} \cdot \partial_t (\nabla \times \mathbf{J}) + S_{\mathcal{J}} / 2, \]

where \( S_{\mathcal{J}} = \mathbf{E} \cdot (\nabla \times \mathbf{F}) \) is the current-related source-like contribution. Taking into account the mathematical structure of the continuity equation, Eq. (3) can be recast as

\[ \nabla \cdot \mathbf{F} + \partial_t \mathcal{C} = \mathcal{S}, \]

where the optical chirality density and the source-like terms have been defined as

\[ \mathcal{C} \equiv [\mathbf{E} \cdot (\nabla \times \mathbf{D}) + \mathbf{H} \cdot (\nabla \times \mathbf{B})] / 2, \]

\[ \mathcal{S} \equiv [\partial_t \mathbf{E} \cdot (\nabla \times \mathbf{D}) + \partial_t \mathbf{H} \cdot (\nabla \times \mathbf{B}) - S_{\mathcal{J}}] / 2. \]

The above expressions represent the most general result for the conservation law of optical chirality without restrictions on the nature of the medium [7]. Still, on account of the dispersion-related terms, they differ considerably from those ones previously established [1, 5, 6].

3. Optical chirality density in dispersive media
For monochromatic EM fields, \( \mathbf{E} = \text{Re}[\mathbf{E}(r)e^{-i\omega t}] \) and \( \mathbf{H} = \text{Re}[\mathbf{H}(r)e^{-i\omega t}] \), the time-averaged optical chirality density is usually given by [1, 2, 3, 4, 5]:

\[ C_{\text{vacuum}} = \frac{\omega}{2c^2} \text{Im} [\mathbf{E} \cdot \mathbf{H}^*], \]

where \( \omega \) is the angular frequency, \( c \) is the speed of light in vacuum, and \( \text{Im} \) is the imaginary part.
where bold letters stand for complex field amplitudes and the asterisk denotes complex conjugation. However, this expression is only valid for optical fields in free space. Inspired by recent works examining dispersive features of several dynamical properties such as energy, momentum, angular momentum and helicity [8, 9], here we report on the optical chirality in lossless and lossy dispersive media [7]. Specifically, building on previous treatments addressing the electromagnetic energy density in a lossless dispersive medium (giving rise to the so-called Brillouin’s formula), we are able to find a similar expression accounting for the optical chirality density in lossless dispersive media:

\[ C_{\text{lossless}} = \text{Re}[n(\omega)\tilde{n}(\omega)]C_{\text{vacuum}} = \frac{\omega}{2} \frac{\text{Im}[\mathbf{E} \cdot \mathbf{H}^*]}{v_p(\omega)v_g(\omega)}, \]  

(8)

where \( v_p \) and \( v_g \) are the phase and group velocities, respectively, which can be given in terms of the refractive index \( n(\omega) \) and the corresponding dispersion-modified group index \( \tilde{n}(\omega) \equiv n(\omega) + \omega \partial n(\omega) / \partial \omega \).

According to the Kramers-Kronig relations, a more realistic description of dispersive media requires careful considerations of dissipative effects as well. However, in a lossy dispersive medium, there are certain frequency ranges where the physical meaning of the group velocity turns out to be somewhat unclear. Hence, in order to avoid misleading outcomes, the analysis of the optical chirality has to be carefully carried out from a material standpoint. Assuming a medium whose material parameters can be fitted by Lorentzian line shapes, and looking into the underlying mathematical structure of the continuity equation [Eq. (4)], it can be demonstrated that the optical chirality density in a lossy dispersive medium reads as [7]

\[ C_{\text{lossy}} = \frac{\omega}{4c^2} \text{Im}[\varepsilon(\omega)\mu_{\text{eff}}(\omega) + \varepsilon_{\text{eff}}(\omega)\mu(\omega)]\mathbf{E} \cdot \mathbf{H}^*], \]  

(9)

where \( \varepsilon_{\text{eff}} \) and \( \mu_{\text{eff}} \) are the real-valued effective parameters:

\[
\left\{ \begin{array}{l}
\varepsilon_{\text{eff}}(\omega) \\
\mu_{\text{eff}}(\omega)
\end{array} \right\} = 1 + \sum_n \left( \chi'_n + 2\omega\chi''_n / \gamma_n \right),
\]

(10)

with \( \chi = \chi' + i\chi'' \) being either the electric or magnetic susceptibilities. As shown in Fig. 1, both lossless and lossy approaches yield similar results, but they significantly differ in spectral regions with high absorption and anomalous dispersion. This fact should be accounted for and examined in experiments considering chiroptical interaction between light and metamaterials or plasmonic nanostructures.

4. Conclusions

We have provided insights into the theoretical derivation of the optical chirality in lossless and lossy dispersive media. Our results are perfectly consistent with that originally introduced for EM fields in free space, and should be enormously relevant for the development of advanced chiroptical applications, mainly in the context of lossy media such as plasmonic systems and metamaterials, whose chiral properties are currently receiving strong attention.

Figure 1: Optical chirality density for (a) silver, and (b) silicon. For comparison we represent the results for lossless (red dashed lines) [Eq. (8)] and lossy (blue solid lines) [Eq. (9)] dispersive media in terms of \( C_{\text{vacuum}} \) [Eq. (7)].

Abstract

We discover strong coherent terahertz emission from the Weyl semimetal TaAs and demonstrate unprecedented manipulation over its polarization and chirality on femtosecond timescale. Such controllability is achieved via polarization-dependent, colossal ultrafast photocurrents in TaAs generated using the circular and/or linear photogalvanic effect.

1. Introduction

Ultrafast currents can cause terahertz emission in the terahertz (THz) frequency regime, where it is difficult to control the ellipticity and chirality over a broad spectral range [1-4]. A promising way to achieve these tasks is to generate the chiral photocurrents using the novel topology of band structures where electrons demonstrate unique spin-momentum locking [5-7]. It has been shown experimentally that both the circular photogalvanic effect (CPGE) [8] and linear photogalvanic effect (LPGE) [9] can lead to the colossal DC photocurrents exist in the Weyl semimetal (WSM) TaAs. Here, we investigate THz emission process due to the ultrafast photocurrents in TaAs, and reveal a new route to realize the generation and control of the broadband elliptically polarized THz waves.

2. Results and discussions

We mainly focus on the results obtained from the TaAs (112) single crystal. Figure 1(a) illustrates the THz emission spectroscopy. \( \hat{x} \) is along the [-110] direction. The sample was excited by the laser pulses (duration ~80 fs, center wavelength 800 nm) from a Ti:sapphire amplifier (repetition rate 1 KHz) under ~ 3° angle of incidence with a beam diameter of 1.5 mm (full-width at half intensity maximum). A typical pump power of 25 mW was used. The THz electric field was detected by electro-optic sampling, with probe pulses from the same laser co-propagating with the terahertz field through an electro-optic crystal, which is the ZnTe(110) with a thickness of 0.4 mm. All measurements were performed at room temperature in a dry-air environment with relative humidity < 5%. Within our pump power range, the THz peak field strength can reach up to ~1 kV/cm.

The excitation given by pump pulse on the surface of TaAs initiates a transient photocurrent. According to the Maxwell equations, an ultrafast change in the current density \( \bar{J}(z,t) \) on the picosecond (ps) timescale will result in electromagnetic radiation in the THz spectral range (1 THz = 1 ps⁻¹) [10]. The transient THz electric field \( \tilde{E}(t) \) is generated with a polarization parallel to the direction of the current. Therefore, one can directly detect the time-domain spectra \( \tilde{E}(t) \) of the THz radiation as a probe for the ultrafast sheet current density given by \( \tilde{J}(t) = \int dz \hat{z}(z,t) \).

The THz electric field \( \tilde{E}(t) = [ E_x(t) \hat{s} + E_y(t) \hat{p} ] \) consists of two components along two perpendicular directions. Measurement of \( E_x(t) \) and \( E_y(t) \) by the EO sampling provides access to the sheet current density \( \tilde{J}(t) \) owing inside the sample.

Figure 1(b) and (c) show time-domain THz far-field EO signal component \( S(t) \) along the \( \hat{s} \) direction, detected for various settings of pump polarization via rotating the \( \lambda/4 \) or \( \lambda/2 \) waveplate, characterized by the angle \( \theta \) or \( \phi \). Here, \( \leftrightarrow (\theta = 0°), \uparrow (\theta = 45°), \text{and} \downarrow (\theta = 135°) \) represent the spin, right-handed, and left-handed circularly polarized light, respectively. Clearly, both the magnitude and temporal shape of the THz waveform \( S(t) \) depend strongly on the
light polarization. The key observation is that signals $S_i(t)$ taken with right- ($\Uparrow$) and left-handed ($\Downarrow$) circularly polarized light are completely out of phase. A similar observation was found for the 45° and 135° linearly polarized light in Figure 1(c). The helicity-dependent signals arise from the CPGE, while the signals depending on the linear polarization originates from the LPGE.

Figure 1(d) shows EO signal component $S_{\hat{p}}(t)$ along the $\hat{p}$ direction. Both the magnitude and temporal shape of the THz waveform $S_{\hat{p}}(t)$ remain the same nearly as the pump polarization changes. $S_{\hat{p}}(t)$ is almost polarization-independent and differs substantially from $S_x(t)$. $S_x$ has a thermal origin. Such distinct $S_x$ and $S_{\hat{p}}$ components lead to a elliptically polarized transient THz field $\hat{S}(t)$. Clearly, the chirality of $\hat{S}(t)$ can be manipulated by changing the polarization state of the pump light.

![Figure 1: (a). Schematic of the THz emission spectroscopy. Excitation of a fs laser pulse with an incident angle $\Theta=3^\circ$ onto a TaAs single crystal initiates a photocurrent burst and, consequently, emission of a THz pulse. (b). Typical THz EO signal component $S_x(t)$ along the $\hat{s}$ direction was measured at various settings for pump polarization via rotating the $\lambda/4$ waveplate. (c). Typical THz EO signal component $S_s(t)$ along the $\hat{s}$ direction was measured at various settings for pump polarization via rotating the $\lambda/2$ waveplate. (d). Typical THz EO signal component $S_{\hat{p}}(t)$ along the $\hat{p}$ direction was measured at various settings for pump polarization via rotating the $\pm\lambda/4$ or $\lambda/2$ waveplate.](image)

3. Conclusions

Strong THz emission due to the colossal ultrafast photocurrent response generated following excitation by near-infrared light was observed in WSM TaAs. Changing the circular or linear polarization of pump light can switch the polarization state of the broadband THz waves including the chirality.

Photonic Orbital Angular Momentum Transfer and Magnetic Skyrmion Rotation

Wenrui Yang, Huanhuan Yang, Yunshan Cao, and Peng Yan

1School of Electronic Science and Engineering and State Key Laboratory of Electronic Thin Films and Integrated Devices, University of Electronic Science and Technology of China, Chengdu 610054, China

Abstract

We predict a photonic orbital angular momentum transfer effect, by studying the dynamics of magnetic skyrmions subject to Laguerre-Gaussian optical vortices, which manifests a rotational motion of the skyrmionic quasiparticle around the beam axis. The topological charge of the optical vortex determines both the magnitude and the handedness of the rotation velocity of skyrmions. The twisted light beam acts as an optical tweezer to displace skyrmion motions.

1. Introduction

A skyrmion is a swirling noncoplanar texture originally introduced by Skyrme a half century ago, as a hypothetical particle in the baryon theory [1], and later was observed in many condensed matter systems, such as liquid crystals, superfluids, and chiral magnets. The magnetic skyrmion, a topologically protected spin texture with a quantized topological charge, has been a prominent topic of spintronics since the first experimental observations of skyrmion lattices in bulk noncentrosymmetric magnets [2, 3] and thin films [4]. Depending on the magnetization rotation, three distinct types of skyrmions have been observed experimentally, referred to as Néel skyrmion, Bloch skyrmion and antiskyrmion. The manipulation of skyrmions is of great importance and interest: skyrmions can be driven by spin-polarized current, magnetic field or electric-field gradients, temperature gradients, and spin waves. However, the genuine skyrmion Hall effects tend to result in skyrmion accumulations at the edge of devices, although strongly coupled bilayer-skyrmions were proposed hopefully to overcome the problem. Crystal imperfections on the other hand may capture or stop skyrmions. These difficulties hinder the precise manipulation of the skyrmion motion by the mentioned control methods. Thus, it should be very interesting and important if one can find other effective control methods and principles to manipulate skyrmions in magnetic thin films.

Since the theoretical work of Poynting and the experiments by Beth, it has been known that light can carry angular momentum and arises from the spin of individual photons and is termed spin angular momentum. Following the pioneering work by Allen et al., it was realized that light can also carry orbital angular momentum (OAM) with helical phase fronts characterized by an $\exp(i\ell\phi)$ azimuthal phase dependence. Such twisted lights have a phase dislocation on the axis that is sometimes referred to as an optical vortex. A number of demonstrations and applications of twisted lights have been brought forward. They range from optical data storages to quantum communications, and black holes, among others. Optical vortices with high OAM have been achieved using spiral phase plates, computer-generated holograms, mode conversions, spatial light modulators, etc.

In this work, we let skyrmions enter the field of OAM. We theoretically propose to use Laguerre-Gaussian (LG) optical vortices to manipulate the skyrmion dynamics via the OAM transfer [5]. A rotational motion of an isolated skyrmion is found. We show that the topological charge $\ell$ of the optical vortex plays a key role in driving the skyrmion motion: a positive $\ell$ brings about an anticlockwise rotation of skyrmions around the beam axis, while a negative $\ell$ results in a clockwise one. Finally, we demonstrate that optical vortices like tweezers can grip a skyrmion to overfly large-scale defects in magnetic films to avoid being captured.

2. Model and results

We consider an isolated Néel skyrmion whose magnetization dynamics generally is modeled by the Landau-Lifshitz-Gilbert (LLG) equation. The total effective field consists of isotropic exchange coupling, uniaxial anisotropy, the interfacial Dzyaloshinskii-Moriya interaction favoring Néel skyrmions, and the optical vortex field. Finite temperature effects can be taken into account by including a Gaussian stochastic magnetic field satisfying fluctuation-dissipation theorem. We focus on skyrmion dynamics at zero temperature, if not stated otherwise.

To demonstrate the time evolution of the skyrmion motion, we solved numerically the full LLG equation using the micromagnetic simulation codes MuMax3. We used magnetic parameters for Pt/Co/AI Ox system. In Figs. 1(a1)-(a9), we observe an anticlockwise rotation of the skyrmion about the beam center due to an application of an optical...
vortex with OAM quantum number \( l = +5 \). To prove that the rotational motion is indeed due to the OAM transfer from optical vortices to the skyrmion, we provide two more numerical evidences: (i) we reverse the helicity of the optical vortex from \( l = +5 \) to \( l = -5 \) without changing the rest parameters. Figures 1(b1)-(b9) demonstrate a striking reversal of the rotation direction of skyrmions, as expected.

Fig. 1: Time evolution of an isolated Néel skyrmion under optical vortices with OAM quantum number \( l = +5 \) (a1)-(a9) and \( l = -5 \) (b1)-(b9). The time intervals between successive snapshots in two cases are 0.8 ns and 0.5 ns, respectively. A positive (negative) topological charge induces an anticlockwise (clockwise) rotation of a skyrmion around the beam axis.

The rotation velocity of skyrmions as a function of the driving frequency is shown in Fig. 2(a). The velocity linearly increases with the frequency below 1.5 GHz and sharply decreases then. The peak is due to the resonance between the skyrmion circular frequency and the vortex frequency. Higher frequency indicates more diluted photon number density, thus reducing the OAM transfer and lowering the skyrmion velocity drastically. Figure 2(b) shows the OAM dependence of the skyrmion velocity which is shown to be sensitive to \( l \).

Fig. 2: Skyrmion velocity as a function of the driving frequency (a) and the topological charge (b) of optical vortices. The red cross stamps a skyrmion annihilation. The minus sign of the velocity is dropped.

3. Conclusions

In summary, we proposed an all-photonic orbital angular momentum transfer mechanism to manipulate magnetic skyrmions. This OAM transfer can effectively drive the skyrmion rotation around the beam axis. The mechanism applies not only to ferromagnetic skyrmions but also to antiferromagnetic ones. Our proposal opens the door for all-optical manipulations of magnetic skyrmions by harvesting the OAM of twisted lights and raises the challenge to generate micron-/submicron-focused optical vortices. Other types of vortex beams such as electron vortices and their acoustic counterparts without breaking the diffraction limit are also promising candidates to drive skyrmion rotations via magnetoelectric and magnetoelastic couplings, respectively. These should be interesting subjects for future research.

Chiral quantum photonics

Rotenberg, Nir¹,*

Abstract
We report on recent advances in the field of chiral quantum optics, focusing on experimental implementations using solid-state quantum emitters such as quantum dots. In particular, we discuss how chiral quantum light-matter interactions can form the basis for deterministic spin-photon interfaces and enable non-reciprocal photonic devices.

1. Introduction
One of the recent consequences of our ability to finely structure the photonic landscape using advanced nanofabrication techniques is the emergence of the field of chiral quantum optics [1]. At the heart of chiral light-matter interactions lies our ability to structure the local electric field polarization of waveguides such that, at certain points, it is circular, but with opposite handedness for the counter-propagating modes. A circular dipole – that is, one that can be thought of as being composed of two orthogonal linear dipoles oscillating 90 degrees out of phase – placed at such a location, will therefore couple well to light propagating in one of these modes, leading to directional radiation [2]. Amazingly, this chiral interaction is a purely electronic phenomenon that occurs in symmetric structures. This stands in stark contrast to light-matter interactions with chiral structure and metamaterials, where the directionality derives from the combined electric and magnetic response of the system.

2. Chiral quantum photonics
The transition dipoles of solid-state quantum emitters such as quantum dots can be circularly oriented, for example in the case of the neutral exciton in an external magnetic field or the spin-states of a charged exciton. The ensuing chiral-light matter interactions with these emitters, when embedded at the correct positions within waveguides, can therefore be used to control and initialize their spins [3] and for the basis for non-reciprocal photonic circuits [4] such as optical circulators, isolators or even quantum networks that operate at the single photon- and single emitter-level [1].

Abstract
Chiral magnetic systems gain more and more relevance for future information technology. Aside from the now famous proposal of skyrmionic information bits, recent publications suggest possible applications in the field of neuromorphic computing in the form of skyrmionic reservoirs, which rely on the non-linear magnetoresistance. Despite its practical importance, a general physical understanding of the electrical transport through chiral magnets is yet to be reached. Experimental studies of the Hall conductivity in chiral magnets commonly face the challenge of how to decompose the measured signal into several parts with a clear physical interpretation. Theoretical investigations on the other hand struggle with the complex electronic structure, especially in the case of isolated topological solitons. Inspired by our recent work on the orbital magnetism of chiral magnets [1, 2, 3], we demonstrate how semiclassical gradient expansion in combination with tight-binding modelling of the electronic structure can shed some light on the classification of Hall effects in chiral magnets. These results may open up new perspectives for the all-electrical detection of non-collinear magnetic structures such as skyrmions, hopfions and chiral bobbers [4].

Abstract

Complex conducting oxide ferromagnets, \( \text{La}_0.07\text{Sr}_{0.8}\text{MnO}_3 \) and \( \text{SrRuO}_3 \), are shown to form a Ru exchange spring at their coherent interface when grown on \( \text{SrTiO}_3(001) \) substrates. In low magnetic fields, non-coplanar, topologically non-trivial spin textures arise and can be switched, as is demonstrated based on magnetization and x-ray magnetic circular dichroism data.

1. Introduction

Engineering interfacial magnetism opens pathways to topologically non-trivial spin textures, an approach often utilized in metallic heterostructures. Interfaces of magnetic oxides, due to their complexity, are much less understood regarding the characteristics and physical origins of spin textures. They offer strong potential for novel types of spin structures as well as alternative tools for tuning them. For example, intimate links between lattice and electronic degrees of freedom can enable efficient control of interfacial magnetic anisotropy [1], exchange coupling [2] and Dzyaloshinskii-Moriya (DM) interaction [3] which are together responsible for the formation of spin textures.

In this work, the spin textures are formed at interfaces between two well-studied conducting oxide ferromagnets, \( \text{La}_0.07\text{Sr}_{0.8}\text{MnO}_3 \) and \( \text{SrRuO}_3 \). Such interfaces are chemically abrupt and show immense strength of antiferromagnetic Ru-O-Mn exchange coupling [4]. Magnetization depth profiling using polarized neutron reflectivity suggested a non-collinear spin configuration [5]. Different growth sequences of the ferromagnets have been shown to lead to crucially different interfacial spin orders [2]. Here, we introduce an interface with topologically non-trivial spin textures switchable in small magnetic fields.

2. Results and Discussion

\( \text{La}_0.07\text{Sr}_{0.8}\text{MnO}_3 \) (LSMO) and \( \text{SrRuO}_3 \) (SRO) layers of thicknesses between 4 and 20 unit cells (uc) have been grown on TiO\(_2\)-terminated SrTiO\(_3\)(001) (STO) substrates by pulsed laser deposition. Structural characterization by x-ray diffraction and scanning transmission electron microscopy revealed coherently strained films with sharp LSMO-SRO interfaces chemically terminated by MnO\(_2\) for the growth sequence of SRO/LSMO/STO(001). Magnetization vs temperature and magnetic field has been measured in a superconducting quantum interference device magnetometer. X-ray magnetic circular dichroism (XMCD) was measured at the BL29 BOREAS beamline at the ALBA synchrotron, providing element-specific magnetization loops. The impact of chemical interface termination on interfacial Mn-O-Ru exchange coupling was calculated using density functional theory (DFT) [2].

Fig.1 summarizes field-dependent low-temperature magnetization \( M(H) \) data of a sample series with varied SRO thickness. Note the magnetic transition near \( \mu_0 H_{\text{c}} = 2 \) T for thicker SRO layers \( (d_{\text{SRO}} \geq 14 \text{ uc}) \) which vanishes for \( d_{\text{SRO}} \leq 10 \text{ uc} \). In contrast to earlier interpretations, our thickness-dependent data reveal rigid antiferromagnetic exchange coupling of Mn and Ru across the interface. A reversible rotation of interfacial Ru spins occurs driven by the in-plane magnetic field (Fig.2). Hence, a so-called exchange spring of \( \sim 10 \text{ uc} \) thickness is formed in the SRO layer. The transition at \( H_{\text{c}} \) originates from field-induced reversal of the interface-far top part of the SRO layer.

Further support for the spin texture sketched in Fig.2 is derived from element-specific XMCD magnetization loops (Fig.3, recorded at 60 K). Complete XMCD data of Ru and Mn for bilayers, including both growth sequences, were published in [2]. While (interface-far) SRO coherently strained to STO(001) has large magnetic anisotropy with an easy axis canted out-of-plane [6], the interfacial Ru spins lie mostly in the film plane. This is derived from the fact that Mn spins coupled at 180° to Ru spins have very weak out-of-plane remanence (Fig.3). Domains have been excluded as cause of that since Ru keeps a large remanence caused by the top part of the layer.) The reversed Mn loop sense with negative remanence is a consequence of the antiferromagnetic coupling to SRO. The very low switching field notable in Fig.3a results from relaxing the Ru exchange spring which twists or relaxes depending on the balance between SRO magnetic anisotropy plus exchange energies and field-dependent Zeeman energies dominated by LSMO.
Spin textures like that in Fig.2 resemble a Bloch wall parallel to the film plane with a gradual out-of-plane spin canting. They are non-coplanar in magnetic fields which twist the exchange spring and, thus, fulfill the criterion of Nagaosa [7] for being topologically non-trivial. If there is a sufficiently strong DM interaction in SRO, one expects a dominating chirality of the exchange spring. Additionally, the interfacial exchange spring is associated with (local) electric polarization like that of type II multiferroics [8] which is, however, screened in the conducting SRO. Thus, coherent interfaces between magnetic oxides bare potential for engineering topologically non-trivial and multiferroic spin textures. I will also discuss our current insights into the preconditions for forming such spin textures.

3. Conclusions

A coherent interface between complex oxide ferromagnets, La_{0.7}Sr_{0.3}MnO_3 and SrRuO_3, is shown to form an exchange spring which enables low-magnetic-field switching of topologically non-trivial and electrically polar spin textures. Thus, interface engineering of magnetic oxides with strong electron correlation offers unexplored terrain for topology-based or magnetoelectric functionalities of electronic devices.

Abstract
The electric-field-induced nucleation of magnetic inhomogeneities is discussed. This magnetoelectric effect can develop in accordance to both chirality-dependent and chirality-insensitive scenarios related to two different mechanisms of magnetoelectricity.

1. Introduction
Chiral magnetic structures such as a spin cycloids [1], [2], homochiral domain walls [3],[4] skyrmions [5–8] and magnetic bubble domains [9], [10] are the subject of extensive research during the last decade. They demonstrate chirality-dependent behavior like spin-current-driven motion due to the spin-transfer torque effect [4], [7]. In this report we will focus on another property of these magnetic structures: the magnetoelectricity. The magnetoelectric behavior was observed as the electric-field-driven motion of domain walls [11], and Bloch lines [12], as a nucleation of the bubble domains by electrically charged tip electrode [13], [14], and as the voltage control of skyrmion bubbles nucleation and annihilation [9], [10]. The mechanisms of these effects are disputable [15], [16] and they can be divided in two groups: chirality-sensitive electric tuning of Dzyaloshinskii-Moriya interaction [10], [17] and chirality-independent magnetic anisotropy modulation by electric field [9], [15]. Based on the experimental data obtained in iron garnet films we will illustrate the characteristic features of both type of the mechanisms.

2. Experimental methods
The 11-micron-thick iron garnet film with chemical composition (BiLu)₃(FeGa)₃O₁₂ grown on (210) GdGa₃O₇ substrate was used. The saturation magnetization was 4πMS=44G. Uniaxial, orthorhombic and cubic anisotropy constants were respectively: Ku=1054 erg/cm³, Ko-rh=erg/cm³, Kc=1016 erg/cm³. The atomic force microscope cantilever tip was used as a source of the high gradient electric field: applying 100V to it results in electric field of 1MV/cm in micron-sized region near the tip.

Figure 1: The electric field control of magnetic domain structure with atomic force microscope cantilever tip [18]: a) the initial domain structure b) bubble domain nucleation from the single domain state [14].

3. Experimental results and discussion
In analogy to the electric-field induced bubble domain nucleation (fig.1) observed in [13,14] the tip electrode also nucleates magnetic inhomogeneities in this sample (Fig.2). They have specific gray color different from yellow/green contrast of domains. However there are striking differences compared to the magnetoelectric effects observed in [13,14]:

• The nucleation of the magnetic inhomogeneity is observed in spontaneous magnetic state, in contrast to the bubble domain nucleation (fig.1 b) no special magnetic bias is needed (fig.2a);

• In contrast to the electric-field-nucleated bubble domains observed in [13,14] this magnetic inhomogeneity always attracts to the tip: no chirality dependent motion is observed;

• The application of the voltage to the tip electrode leads also to the domain wall image widening and coalescence of the “island” with the wall (fig.2 b).
4. Conclusions

The electric-field induced domain structure transformation described above manifests itself as a nucleation of the island of new phase with the easy-axis anisotropy. In contrast to the effect of bubble nucleation [13,14] it is not chirality dependent and corresponds to the mechanisms described in [15]. The chirality dependent domain wall attraction or repulsion is observed only upon applying in-plane magnetic field that imposes the certain direction of magnetization direction: opposite for the opposite sides of the domain.

Abstract
Laser science and technology have been rapidly developed in the last decades. The application of laser to solids is being one of the hottest topics in condensed-matter physics. Particularly, the significant development of intense terahertz (THz) laser science has accelerated the study of controlling magnetism with THz laser because the photon energy in THz regime is comparable to the energy of magnetic excitations. The control of magnetism with laser [1] has also attracted much attention as a large branch of spintronics [2].

Interestingly, theoretical methods for nonequilibrium systems have also been developed in recent years, and they have a high potential to capture laser-driven nonequilibrium dynamics. Applying such methods, we have theoretically explored/proposed several ways of controlling magnetism with electromagnetic waves. For instance, based on the concept of Floquet engineering [3], we have proposed some methods of controlling spin currents, spin spiral orders, and magnetizations with circularly polarized THz lasers [4]. We have also showed the ultrafast ways of generating a class of topological spin textures (such as skyrmions) in (chiral) magnets with topological light waves (such as vortex beams) [5]. Furthermore, we show that a DC spin current can be generated if we apply AC electromagnetic fields to noncentro-symmetric magnetic insulators (This phenomenon may be viewed as a spin-current version of solar cell) [6]. In the conference, I would like to report some of the above results, especially, focusing on the generation of spin current and spin textures.

Chiral Optomagnonics with Polarized Light in Magnetic Insulators

Abstract

Several questions related to the interaction of magnetic excitations with polarized electromagnetic fields will be considered. We are going to discuss how chirality of spin waves can be introduced in analogy to the optical zilch, how chiral electromagnetic fields can be used to generate magnon spin currents, and couple to the collective degrees of freedom via the magneto-optical interactions.

1. Spin wave chirality in antiferromagnetic insulators

After Lipkin’s original discovery of a new conservation law for the electromagnetic field in vacuum [1], it was realized that similar to geometric objects, dynamical fields can be characterized by chirality. In particular, free electromagnetic field can be described by locally conserving pseudoscalar that is even under the time reversal and odd under the spatial inversion transformations. Recently, this quantity, which is known in the literature as optical chirality or Lipkin’s “zilch”, attracted attention in chiral optics and plasmonics after Tang and Cohen demonstrated its relation to the asymmetry in light-matter interactions [2].

Based on the formal analogy between the electrodynamics and the low-energy magnetization dynamics in antiferromagnets, we demonstrate that the concept of optical chirality can be generalized on antiferromagnetic spin waves, which, similar to light, are doubly degenerated with respect to two polarization directions. This fact allows us to use the method of nongeometric symmetries originally developed for the Maxwell’s equations and to find the conservation law for spin-wave chirality [3].

Similar to the case of light interacting with chiral medium [2], we show the relation between spin-wave chirality and asymmetry in the magnetic excitation energy absorption rate in an antiferromagnet, which host a pure spin current. The latter plays a role of the symmetry breaking mechanism and lifts the degeneracy between left- and right-polarized spin waves [3]. We find that injection of the spin current inside an antiferromagnetic insulator, creates the difference in population numbers of thermally excited left- and right-polarized magnons thus generating nonzero chirality inside the material.

2. Optical excitation of spin photocurrents

Antiferromagnetic insulators are promising candidates with which to address the problem of creating and transmitting spin currents. Spin currents in these materials, carried by magnons, can be generated in several different ways, e. g. thermally excited using spin Seebeck/Nernst effects or pumped from the neighboring ferromagnetic insulator. Ultrafast optical excitation of coherent magnon dynamics is another prominent area, which lies in the basis of optospintronics – a direction targeting optical control of spin states in magnetic materials [4].

We propose a new mechanism for generating spin currents in antiferromagnetic insulators by optical excitation of spin dynamics [5]. The mechanism involves polarized light and is motivated by the photogalvanic effect in metals, where circularly polarized light can produce a direct electron photocurrent, which direction depends on the polarization. We suggest that an analogous nonlinear effect exists for antiferromagnetic insulators wherein the total spin of light and spin waves is conserved. In consequence, a spin angular momentum is expected to be transferred from photons to magnons so that a circularly polarized electromagnetic field will generate a direct magnon spin current, as shown in Fig. 1. We also discuss geometric contributions to the magnon photocurrents, which appear for materials with complex lattice structures and Dzyaloshinskii-Moriya interactions, where it is possible to use linearly polarized
Figure 2: Chiral soliton lattice with the pinning potential at the center inside the cavity resonator and the corresponding effective mechanical model of a particle in the potential energy profile of magnetic pinning.

light to produce magnon spin currents.

3. Optomechanics of collective excitations in topological spin textures

Cavity optomechanics is an established field that studies mutual effects between the electromagnetic radiation pressure and mechanical degrees of freedom. It covers an impressive variety of phenomena such as optical damping/antidamping, laser cooling, parametric instability and chaotic dynamics, optomechanical entanglements, and quantum information protocols for numerous mechanical systems ranging from moving mirrors to cold atoms [6]. Finding new potential areas for application of cavity optomechanics is a relevant problem from both technological and fundamental viewpoints.

Here, we would like to discuss how topological spin textures in magnetic insulators may serve as an effective mechanical subsystems for optomechanical experiments. It is known that low-energy collective dynamics of such magnetic structures as domain walls in ferromagnets or soliton lattices in chiral helimagnets can be described in terms of several effective mechanical degrees of freedom known as collective variables thus making them behave analogously to massive mechanical particles. By adding a pinning potential to defects and magnetic impurities, we obtain a magnetic analogue of a mechanical oscillator, which frequency is determined by the pinning strength. We demonstrate [7] that such oscillator can feel the electromagnetic radiation pressure via magneto-optical interactions (such as inverse Faraday and Cotton-Mutton effects) effectively leading to the same effective Hamiltonian that is used in cavity optomechanics[8]. Moreover, using the inverse Faraday effect, it is possible to make the effective optomechanical coupling sensitive to the helicity of light, which makes the magnetic texture analogous to the chiral oscillator interacting with polarized cavity electromagnetic field (see Fig. 2).

Low damping of some magnetic insulators together with GHz range of oscillator frequencies make it possible to address quantum regime of oscillator dynamics, challenging in pure mechanical systems, which maybe useful for application quantum information processing.

Abstract

Light-matter interactions can exhibit a strong dissymmetry in chiral structure specifically, the phase and amplitude can be strongly affected by altering the chirality strength. The Kramers-Kronig relation between the imaginary and the real part of the index prescribes the connection between the two measurable effects of the optical activity, namely the optical rotation dispersion (ORD) and the circular dichroism (CD). Our results establish a basis for the development of the metasurface that incorporates structural local chirality for phase modulation.

1. Introduction

Structures with subwavelength dimensions exhibit unusual behavior when they interact with electromagnetic (EM) waves and can be utilized for a variety of novel applications. In particular such behavior arises when the interaction between the metal surface irregularities and the incident light results in the excitation of a surface confined evanescent waves called surface plasmon polaritons (SPPs) [1]. Chiral nanostructures that support SPPs play a crucial role in improving the sensitivity of spectroscopic properties [2],[3]. Thus, the understanding of the underlying physical concepts is important to realize the desired tuning. Recently, it has been shown that chiral metamaterials exhibit extraordinary capabilities in controlling and manipulating the polarization states of light. For example, 2D arrays of planar chiral structures of gammadion-shaped metal nanoparticles produced by broken front-back symmetry exhibit a large CD and a giant optical activity [2] exceeding significantly those of conventional three dimensional materials. Particularly, gold nanostructures are widely used in the photonics and plasmonic integrated circuits aiming to manipulate the light at the nanoscale. Leakage radiation microscopy (LRM) is a surface sensitive optical technique that is especially useful for imaging of the SPP propagation with small changes of light polarization. The interaction of metallic nanostructures may depend on the design parameters of the structure such as length, width, periodicity and film thickness. In addition, one can tune the transmitted light polarization by changing the period of the structure and design.

In this study we use the LRM technique to collect and analyze the transmission through the structure of the right and left circularly polarized light as a function of the structure chirality and periodicity. This shall be the basis for the future analysis of the SPP excitation and propagation dependence on the chiral structure parameters. We have fabricated gold chiral rectangular planar structure by using FIB method and have demonstrated optical rotation [3] and circular dichroism [4] in direct transmission that strongly depends on the structure period. We also verified the existence of the Krammers-Kronig’s connection between the measured spatial ORD and the CD in our structure.

2. Experimental part

The samples were fabricated by using focused ion beam (FIB) on a 100 nm thick Au film deposited on glass cover slips. Each array consisted of two rectangular apertures (250 nm length by 100 nm) that were shifted with respect to each other exactly by one length. The sample was illuminated by a 780 nm laser beam pre-focused by a 10X objective (NA =
0.4 and the leakage radiation was then collected through objective with NA = 1.25 (50X). The incident light’s polarization was set to 45 degrees with respect to the array main axes and the emerging beam was then analyzed by a similar polarizer. We rotated the second polarizer to find the angle at which the maximum intensity at the exit was obtained. This polarization rotation angle was plotted as a function of the structure period to form the ORD of the structure. We note a characteristic bi-resonance behavior expected from optically active materials.

In the additional experiment we illuminated the structure with a circularly polarized light. For each handedness of the illumination we measured the transmitted intensity, $I_R$ and $I_L$ for right and left handed light respectively, and plotted the normalized value of the differential absorption, $\Delta = I_R - I_L$. This provided us the spatial CD spectrum of the structure. In Fig.1 we demonstrate the two measurements together as a function of the spatial period of the grating, $\Lambda$. Despite some noise, due to the depolarizing effects and fabrication imperfections, one can clearly recognize the resonance peak at 750 nm period. This period corresponds to the plasmonic wavelength and apparently leads to a resonant coupling of the chiral unit cells producing the enhancement of the optical activity.

Finally we use the spatial ORD data obtained in the first experiment to calculate the expected CD values by Krammer’s-Kronig relations and obtain a perfect matching between observed and the measured results. We then conclude that our chiral metasurface behaves as an artificial chiral medium with the resonant chiral response obtained due to a collective plasmonic effect. Moreover, the rotation and the CD achieved in these experiments are unusually strong which leads to an additional conclusion, that our structures can be utilized to alter the light’s polarization. This leads us to future research in the improvement of the chiral symmetry structure.

Electromagnetic responses, dynamics, and superconductivity emerging from multipole order

Hikaru Watanabe, Atsuo Shitade, Akito Daido, Jun Ishizuka, and *Youichi Yanase

1Department of Physics, Kyoto University, Kyoto, Japan
2RIKEN, Center for Emergent Matter Science, Wako, Japan

Abstract
We will discuss electromagnetic responses, dynamics, and superconductivity arising from odd-parity multipole order. Combining group theoretical analysis, numerical calculation of microscopic models, local thermodynamics, we reveal intriguing properties of electromagnetic multipole states with spontaneous inversion symmetry breaking. Candidate materials are proposed by analyzing the existing experimental data.

1. Introduction
A concept of multipole moment has been established in the classical electrodynamics. In solid state electron systems, entanglement of spin, orbital, and sublattice degrees of freedom is described by the multipole moment, and spontaneous multipole order is a ubiquitous phenomenon in strongly correlated electron systems.

First, we present a group theoretical classification of multipole order in solids. Intriguing duality between the real space and momentum space multipole order parameters is revealed for odd-parity multipole order which spontaneously breaks space inversion symmetry. More than 110 odd-parity magnetic multipole materials are identified by the magnetic representation theory.

Second, emergent cross-correlated responses of elasticity, electricity, and magnetism are clarified by using real-space and k-space representations of multipole moment. In addition to the group theoretical classification, we provide a fully quantum mechanical formula for the odd-parity magnetic monopole, quadrupole and toroidal dipole moment, from which magnetoelectric (ME) effect can be quantitatively estimated.

Third, application to the antiferromagnetic spintronics is studied. Using the magnetic representation theory and magnetic space group analysis, antiferromagnetic domain switching by electric current is proposed.

Finally, exotic superconducting phases induced by the odd-parity multipole fluctuation are explored. Near the quantum critical point, spin-triplet superconductivity is stabilized by the effective interaction mediated by the magnetic multipole fluctuations. Then, a $Z_2$ topological superconducting state is identified. Multipole quantum criticality may be a route to the topological superconductivity.

2. Classification theory of multipole order
We carried out group-theoretical classification of the even-parity/odd-parity multipole order [1,2]. Multipole order parameter in cubic, tetragonal, and hexagonal systems has been classified by point-group symmetry. Classification in other crystal groups is straightforwardly obtained by compatibility relations. Even though real compounds are sometimes too complicated to see the relevant multipole moment characterizing the ordered state, we can identify the multipole order parameter by group-theoretical analysis.

3. Cross-correlated responses
Compounds with ferroic odd-parity magnetic multipole order are also called magnetoelectric materials since the electromagnetic crossed correlation appears. The magnetoelectricity has been extensively studied in the research field of multiferroic materials, and then the candidates should be insulating to hold well-defined electric polarization reversible by external electric fields. On the other hand, the odd-parity multipole order also leads to nontrivial electronic structures such as spontaneous emergence of spin-momentum locking and asymmetric band distortions in itinerant systems. Accordingly, characteristic electromagnetic responses may occur in metallic states. To explore intriguing phenomena in both metallic and insulating odd-parity multipole states we show the group theoretical classification of various electromagnetic response tensors and reveal their close relationship with multipole moment [2].

4. Quantum mechanical formula
We derive a quantum-mechanical formula of the spin and orbital magnetic monopole, toroidal, and quadrupole moments in periodic crystals by using the gauge-covariant gradient expansion [3,4]. We also prove a direct relation between the multipole moment and ME susceptibility for insulators at zero temperature. It indicates that the multipole moment is a microscopic origin of the ME effect. Using the formula, we quantitatively estimate these quantities for room-temperature antiferromagnetic semiconductors BaMn$_2$As$_2$ and CeMn$_2$Ge$_{2-x}$Si$_x$. We find that the orbital contribution to the ME susceptibility is comparable with or
even dominant over the spin contribution. We also formulate what we call gravitomagnetoelectric (gravito-ME) effect, in which the magnetization is induced by a temperature gradient. Although the Kubo formula for the gravito-ME effect provides an unphysical divergence at zero temperature, we prove that the correct susceptibility is obtained by subtracting the spin magnetic multipole moment from the Kubo formula. It vanishes at zero temperature and is related to the ME susceptibility by the Mott relation. We explicitly calculate the gravito-ME susceptibility in a Rashba ferromagnet and show its experimental feasibility.

5. Antiferromagnetic spintronics

Antiferromagnets are robust to external electric and magnetic fields, and hence are seemingly uncontrollable. Recent studies, however, realized the electrical manipulations of antiferromagnets by virtue of the antiferromagnetic Edelstein effect. We present a general symmetry analysis of electrically switchable antiferromagnets based on group-theoretical approaches [5]. Furthermore, we identify a direct relation between switchable antiferromagnets and the ferrotoroidic order. The concept of ferrotoroidic order clarifies the unidirectional nature of switchable antiferromagnets and provides a criterion for the controllability of antiferromagnets. The scheme may pave a way for perfect writing and reading of switchable antiferromagnets.

6. Superconductivity

Using a microscopic calculation and symmetry argument we reveal superconductivity in the vicinity of parity-violating magnetic order [6]. We show unconventional superconductivity induced by an odd-parity magnetic multipole fluctuation in a two-dimensional two-sublattice Hubbard model motivated by Sr$_2$IrO$_4$. We find that even-parity superconductivity is more significantly suppressed by spin-orbit coupling than that in a globally noncentrosymmetric system. Consequently, two odd-parity superconducting states are stabilized by magnetic multipole fluctuations in a large spin-orbit coupling region. Both of them are identified as $Z_2$ topological superconducting states. Our finding implies a new family of odd-parity topological superconductors. Candidate materials are proposed.

Biomacromolecular Charge Chirality Detected Using Chiral Plasmonic Nanostructures

Marion Rodier, Maryam Hajji and Malcolm Kadowala*

1School of Chemistry, University of Glasgow, Joseph Black Building, Glasgow, G12 8QQ, UK, *corresponding author, E-mail: malcolm.kadodwala@glasgow.ac.uk

Abstract

The spatial distribution of charge at the solvent exposed surfaces of complex biomacromolecules such as proteins, define electrostatic properties that control intermolecular interactions, which govern function. To date there is no known phenomenon that allows the surface charge distributions to be directly characterised. Information is restricted to that provided by modelling of proteins with both known structures and sequences. We show this essential but currently “invisible” property, can be detected by monitoring the chiroptical response of protein-plasmonic nanostructure complexes. To illustrate the unique capabilities of the phenomenon it has been used to discriminate between two forms of the same enzyme, type II dehydroquinase (DHA), which have the identical structures, but differing primary sequences. The different sequences results in the two forms having dramatically different surface charge distributions. The two form are indistinguishable with conventional chiroptical spectroscopy (i.e. circular dichroism) which are sensitive to secondary structure. However the DHQ-chiral plasmonic complexes of the two forms display different chiroptical properties. The phenomenon is rationalised with a simple model, validated by numerical simulations, whereby the surface charge of a protein induces an asymmetric mirror charge distribution within the surface region of a gold chiral plasmonic nanostructure. This causes a differentially change in the chiroptical response of left and right handed structures, which is dependent on the properties of distribution. The reported phenomenon affords a route by which changes in surface charge can be detected without prior knowledge of protein structure and sequence. Thus providing a new tool for understanding interactions between biomolecular materials.

Abstract

Chiral magnets are an emerging class of topological matter harbouring localized and topologically protected vortex-like magnetic textures called skyrmions, which are currently under intense scrutiny as a new entity for information storage and processing. Chirality in magnetism is introduced through the chiral symmetry breaking Dzyaloshinskii-Moriya interaction, which arises through the spin-orbit interaction in magnets with structural bulk and interface inversion asymmetry. We have shown that chiral magnets cannot only host skyrmions but also antiskyrmions and chiral bobbers as localized magnetization particles. We present a multiscale approach relating the electronic structure to an atomistic spin-lattice model and further to micromagnetic models by means of density-functional calculations, derive practical criteria for their occurrence and coexistence with skyrmions and minimizing the energy on a mesoscopic scale applying varying spin-relaxation methods. We conjecture on possible materials for antiskyrmions and give experimental evidence for bobbers. The technology potential of having two distinctly different stable particles will be discussed.

1. Introduction

After the discovery of skyrmions – nanoscale localized and topologically protected vortex-like magnetic textures – in bulk magnets [1] and at surfaces [2] – the research field of chiral magnetism developed to one of the most active fields of magnetism and spintronics as skyrmions promise to be the new information-carrying particle in future low-power information and communication technology. Skyrmions in chiral magnets may appear as isolated solitons or condensed in regular lattices. Their stability results from the Dzyaloshinskii-Moriya interaction (DMI), which breaks the chiral symmetry of the magnetic structure. The energy and size is determined by the competition between the Heisenberg, Dzyaloshinskii-Moriya (DMI), and Zeeman interaction together with the magnetic anisotropy energy (MAE) here expressed in terms of the spin-lattice model applied to an interface geometry:

\[ H = - \sum_{ij} J_{ij} (S_i \cdot S_j) - \sum_{ij} D_{ij} \cdot (S_i \times S_j) - \sum_i B \cdot S_i + \sum_i K_{z} (S_i \cdot \hat{e}_z)^2 \]  

(1)

with classical spin \( S \) of length one at atomic sites \( i,j \) and the corresponding microscopic pair \( J_{ij}, D_{ij} \) and on-site \( K_{z} \) interactions. The DMI results from the spin-orbit interaction and is only non-zero for solids lacking bulk \( (r \rightarrow -r) \) or structure inversion symmetry \( (z \rightarrow -z) \). With respect to future applications, interfaces offer a great variety of options for optimizing and controlling magnetic the parameters \( J, D, K \): Variation of the interface composition [3, 4], of the interface crystal symmetry [5], as well as the fabrication of interlayers [6] and multilayers [7, 8] such as to obtain skyrmions with sizes and temperature stability suitable for technology, e.g. in the context of the race track memory.

2. Methodology

To understand the stabilization mechanism of skyrmions, to predict and design their properties in setups for technological use by theoretical models, \textit{ab initio} spin-lattice models (1) proved to be a very powerful approach to realistically describe non-collinear magnets, single skyrmions and skyrmions lattices in experimentally realized systems. In such a model the parameters for an \textit{ab initio} spin-lattice model are obtained directly from the total energy of the electronic structure by density functional theory, e.g. applying the \textsc{FLEUR} code [9], and the magnetic ground state as well as metastable states are found for example by spin-dynamics or Monte-Carlo methods using the recently developed \textsc{SPIRIT} code [10]. The long-wave length limit leads to micromagnetic energy functional whose mathematical analysis allows a rigorous examination the micromagnetic energy landscape.
3. Results

We employed this approach and developed the Skyrmion à la carte concept [7], predicting the properties (size, stability, Curie temperatures) of skyrmions in thin films at surfaces [2, 3, 7], interfaces [4], multilayer [7, 8], exchange bias-systems [6] to optimize the properties of skyrmions.

In chiral magnets the presence of the DMI commonly prevents the stability and coexistence of topological excitations of different types. In a recent work [5] we extended the scope of skyrmions to antiskyrmions and introduced a classification scheme partitioning chiral magnets into isotropic rank-three DM bulk and rank-two DM film magnets, described by an isotropic DM interaction expressed by a single DMI constant in the micromagnetic theory, for which antiskyrmions are stable only for bulk crystals with certain point group symmetries. Newly introduced are the anisotropic rank-two DMI film magnets, where skyrmions and antiskyrmions can coexist, while the sign of the determinant of the micromagnetic DM matrix determines which of the two has the lower energy. Finally, zero determinant indicates a rank-one DMI material, for which skyrmions and antiskyrmions have the same energy. Employing the methodology introduced above we conjecture that a Fe double on W(110) provides a possible system that hosts antiskyrmions.

Recently, we were able to extend the scope of skyrmions to a second class of particles, the chiral magnetic bobber (CB), first through theoretical analysis [11, 12] and then verified experimentally by the direct observation in thin films of B20-type FeGe by means of quantitative off-axis electron holography [13]. The CB is a localized three-dimensional hybrid particle on the nanoscale composed of both the smooth magnetization texture of skyrmions an a Bloch point, singularity in the micromagnetic theory of smooth magnetizations textures playing the role of a monopole. The interaction of electrons with such hybrid-objects. e.g. to understand how to move CB by spin currents is subject to ongoing investigations.

Abstract

We report on the first demonstration of THz-driven ultrafast magnetization switching of a magnetically ordered material using intense, single-cycle THz pulses. The magnetization switching process evolves on a few picoseconds timescale as probed by time-resolved magneto-optics in visible spectral range. Our findings reveal a fully deterministic switching event occurring upon each single-shot THz excitation of the ferrimagnetic GdFe alloy.

Using light to control the magnetic order parameter on ultimate time and length scales is a core research activity of modern magnetism [1, 2]. Of particular interest for both fundamental and applied science is the use of femtosecond (fs) laser pulses to fully switch the magnetization orientation of a spin ensemble on ultrashort time scales [3, 4].

A novel yet less explored approach towards controlling the magnetization and spin dynamics is the use of intense THz pulses (photon energies in the meV range) as an ultrafast external stimulus.

Here, we report on the first demonstration of ultrafast magnetization switching of a spin-ordered material using single-cycle, intense THz pulses at a central frequency of 2 THz. In particular, by employing intense THz radiation from a table-top THz source [5] to photo-excite a ferrimagnetic GdFe alloy and magneto-optics in visible spectral range to probe the subsequent magnetization changes, we reveal:

(i) a single-shot magnetization switching process driven by linearly polarized THz pulses i.e. the so-called toggle magnetization reversal, as shown in Figure 1

(ii) an ultrafast magnetization switching event investigated in time domain using a THz pump-MOKE probe approach.

Our findings indicate a highly efficient non-equilibrium energy transfer from the driving THz pulse to the spin system that leads to a magnetization switching event occurring on a few picoseconds timescale. Our results demonstrate a fully deterministic control of magnetization using single THz pulses, paving the way for an entire class of new experiments employing light-spin interactions at THz frequencies.

Spatio-Temporal Conductivity Modulation: A Pathway Towards CMOS Compatible, Low Loss, Magnetic-Free Non-Reciprocity

Abstract

Magnetic-free non-reciprocity using spatio-temporal modulation has gained a lot of attention in the recent years. Some approaches use permittivity modulation, but feature a large form-factor or high loss due to small modulation contrasts of permittivity. More recent approaches leverage much larger conductivity modulation contrasts available in CMOS to achieve drastically smaller form-factors and low-loss non-reciprocity across wide range of operating frequencies. Here we review recent progress on spatio-temporal conductivity-modulation, which enabled non-reciprocal components operating from radio frequencies to millimeter-waves in a CMOS platform.

1. Introduction

A medium with symmetric transmission of electromagnetic waves between two spatially separated points is referred as a reciprocal medium. Various theorems of reciprocity have been formulated over the years, including the work of Green (electrostatics), Rayleigh (dynamic systems), Helmholtz (optics, acoustics) and Lorentz (electromagnetics). Non-reciprocal components, such as circulators, isolators, gyrators and non-reciprocal phase-shifters, are critical for various applications ranging from radio frequencies (RF) to optical frequencies, including communications, radar, imaging and sensing. Traditionally, non-reciprocity has been achieved by using magnetic materials such as ferrites, which lose their reciprocity under the application of an external biasing magnetic field. Unfortunately, such materials are not compatible with existing semiconductor manufacturing processes and, therefore, lead to large form-factors and high implementation costs. In recent years, there has been progress on breaking reciprocity through time-variance. At RF, initial approaches have focused on permittivity modulation using modulated varactors (variable capacitors)[1, 2]. However, varactors have a weak modulation ratio ranging between 2-4, a weak modulation index directly translates to a large device size over which modulation must be performed or narrow transmission bandwidths if resonances are employed for miniaturization. Consequently, these approaches resulted in designs that exhibit a trade-off between loss, size and bandwidth.

Recently, we found that high conductivity modulation ratios \(10^3 \sim 10^5\) of transistors acting as electronic switches can be leveraged to realize a rich set of unique non-reciprocal properties, including wide-band gyration, isolation and circulation [3, 4, 5, 6]. In this abstract, we will cover our recent research on using commutated circuits to break reciprocity and build high-performance passive circulators operating from RF to mm-wave frequencies in CMOS. We will describe the fundamental physical principles, as well as the designs of our four generations CMOS circulators [3, 4, 5, 6].

2. Spatio-Temporal Conductivity Modulation

2.1. Non-Reciprocity Using Commutated Multipath Networks

Fig. 1(a) consists a 2-port commutated multipath network realized using \(N\) identical branches containing a shunt capacitance in each branch. The set of switches left and on the right are modulated using non-overlapping pulses each having the period \(T_s\) and the width of \(T_s/N\). When the time constant \(\tau = Z_0C >> T_s/N\) (where \(Z_0\) is the input/output port impedance), the structure behaves as a high-Q filter (commonly known as N-path filter) and is commonly used to realize a compact on-chip bandpass filter. In Ref. [3], we have shown that applying a relative phase shift to the non-overlapping clocks driving the left and right switch sets imparts a non-reciprocal phase-shift to the signals traveling in the forward and reverse directions since they see a different ordering of the phase-shifted switches. Essentially, the two-port N-path filter with a clock phase shift of \(\pi/2\) realizes an electrically-infinitesimal gyrator with transmission response \(\pm \pi/2\). Later a 3-port circulator is realized by embedding the gyrator transmission line loop within a length of \(3\lambda/4\) and by placing 3 ports with a relative circumferential distance of \(\lambda/4\) (see Fig. 1(a)). The combination of the non-reciprocal phase shift of the N-path filter with the reciprocal phase shift of the transmission line results in constructive interference in clockwise direction and destructive interference in counter-clockwise direction.

2.2. 25 GHz Switched-Transmission-Line Based Non-Reciprocal Circulator

Inspired by the N-path-filter-based RF circulator, we proposed a generalized conductivity modulation concept using switched transmission lines [4]. The concept, shown in Fig. 1(b), consists of two sets of differential mixer-quad switches on either end of a differential transmission-line delay. The switches are modulated using square wave clocks with a frequency \(\omega_m\), and the relative phase shift between the clocks is \(T_m/4\), which is also equal to the delay pro-
provided by the transmission line. For this structure, waves traveling from left to right experience the transmission-line delay with no sign flips in both halves of the clock period. On the other hand, waves traveling from right to left experience the transmission-line delay along with one sign flip. This additional sign flip produces an infinitely broadband 180° non-reciprocal phase difference, i.e., an infinitely broadband gyrator.

The infinite bandwidth of the gyrator implies that the signal frequency and the modulation frequency are completely decoupled. This feature was exploited to realize a mm-wave (25GHz) fully-integrated passive circulator in 45nm SOI CMOS, shown in Fig. 1(b) [4], by modulating the switches at 1/3rd of the operating frequency (8.33GHz). The lowering of the modulation frequency, as well as the need for 50% duty-cycle clocks made this high frequency implementation feasible.

2.3. Highly Linear 1 GHz Non-Reciprocal Circulator with Loss-Free, Inductor-Free Isolation Tuning

Fig. 1(c) shows the architecture of a highly-linear RF circulator, which uses the feature of lowering the modulation frequency to enhance the power handling and linearity of the circulator at 1GHz operating frequency. The switches were modulated at 333MHz for 1GHz operation, and such a low modulation frequency enables the usage of the thick-oxide devices in 180nm SOI CMOS technology to boost power handling. This implementation notably improves linearity and power handling of the CMOS circulator by 10-100× when compared with our prior implementations [5]. The TX-RX isolation of all shared-antenna interfaces, even circulators, is limited by the matching of the antenna port, which necessitates an antenna tuning mechanism. Traditionally, magnetic circulators are followed by antenna tuners. In this work, inbuilt isolation tuning is achieved by implementing digitally programmable differential feed capacitor banks between TX-RX and ANT-RX ports. The ability to compensate a VSWR of up to 1.85 (and beyond) was demonstrated in this work.

2.4. 60 GHz Circulator Based On Switched-Bandpass-Filter

Theoretically, the switched-transmission-line structure has no loss and infinite bandwidth. In practice, however, they are limited by the switch ON resistance \( R_{ON} \) and parasitic capacitance \( C_{OFF} \) and the product \( R_{ON}C_{OFF} \) is constant for a given semiconductor technology. Hence during the design process, there exists an trade-off between the losses from \( R_{ON} \) and \( C_{OFF} \). In this work, we break this unfavorable trade-off between \( R_{ON} \) and \( C_{OFF} \) by recognizing that the mixing products are centered around the input frequency \( f_{in} \), and therefore, a bandpass filter (BPF) with quarter-wave group delay is sufficient to preserve them. The bandpass filter exploited here includes shunt-LC resonators at the input and output of an 8-section LC ladder (Fig. 1(d)). The shunt LC resonators allow for the absorption of larger switch capacitance, allowing for a lower \( R_{ON} \), while still allowing enough bandwidth in the BPF to sustain the dominant mixing products, thus allowing low \( R_{ON} \) loss as well as low filtering losses due to parasitic capacitance (Bragg loss). In our 60GHz circulator, the loss and power handling are improved by 1.3 dB and 9 dB respectively by using the switched-bandpass-filter approach.

Topological valley transport on the surface of biaxial hyperbolic metamaterials

Ruo-Yang Zhang, C. T. Chan*

Department of Physics, Hong Kong University of Science and Technology, Hong Kong, China
* Corresponding author, E-mail: phchan@ust.hk

Abstract
On the iso-frequency surfaces of a homogeneous biaxial hyperbolic metamaterial, there exist four doubly degenerate diabolic points, which are protected by PT and mirror symmetries and can be utilized as valley degrees of freedom. By introducing chiral or gyroelectric material perturbations, we can lift the degeneracy at the diabolic points, and control the existence and chirality of the gapless Fermi arc at each valley. In particular, we can achieve topological valley-dependent helical transport for surface-arc waves.

1. Introduction
The concept of “valley”, originating from semiconductor physics, refers to the local extrema in the band structures, and has been used as a new degree of freedom to manipulate the transport of electromagnetic waves [1,2]. It is also known that in Weyl and other nodal semimetal systems, the nonzero charges of the topological nodes ensures the existence of Fermi-arc surface states. It has been shown that fascinating surface wave transport effects can be achieved by manipulating the Fermi-arc dispersion, such as surface wave negative refraction [3], and helical transport using spin-polarized Fermi arcs [4]. In this work, we introduce valley degrees of freedom (VDF) to control the chirality of Fermi arcs, and achieve novel transport effects.

2. Results
An ideal platform for valley topological effect is biaxial hyperbolic metamaterials (BHMs)[5,6]. Similar to ordinary biaxial dielectric crystals, a BHM with the permittivity $\varepsilon_\alpha = \text{diag}(\varepsilon_x, \varepsilon_y, \varepsilon_z)$ ($\varepsilon_x < 0 < \varepsilon_y < \varepsilon_z$) possesses four doubly degenerate diabolic points on the iso-frequency surface, which are stabilized by the quantized Berry phase $\gamma = \int \sum_{\alpha} \langle \psi | V_\alpha | \psi \rangle \cdot d\mathbf{k} = \pi$ encircling the degenerate point (see Fig. 1) and are protected by both the combined parity time-reversal (PT) symmetry and the mirror symmetry ($M_y$) about the plane of $y = \text{const}$. By breaking both PT and $M_y$ symmetries, the diabolic points will be gapped, and the hyperbolicity of the media ensures the appearance of complete momentum-gaps. The spatial dispersion near a diabolic point, $\mathbf{k}^d = (k^d_x, 0, k^d_y)$, can be described by the eigen-equation $H\psi = \delta \mathbf{k} \cdot \psi$ with a 2D Dirac Hamiltonian:

$$H = s_s s_y v_f (\delta k_x \sigma_y - \delta k_y \sigma_x - \delta k_z \sigma_y) + m(s_s, s_y) \sigma_x,$$

where $\delta \mathbf{k} = \delta k_x \mathbf{e}_x + \delta k_y \mathbf{e}_y + \delta k_z \mathbf{e}_z$ denotes the displacement from the diabolic point ($\mathbf{e}_i$ is along the direction of $k^d_i$); $s_x = \text{sgn}(k^d_x)$, $s_y = \text{sgn}(k^d_y)$ label the quadrants of the four valleys; $v_f = \frac{\pi}{4} [(1 - \varepsilon_y/\varepsilon_x) (\varepsilon_x/\varepsilon_y - 1)]^{1/2}$ is the Fermi velocity; and $m(s_s, s_y)$ is the valley-dependent mass. The integration of Berry curvature over a semi-infinite Dirac cone is

Figure 1: Iso-frequency surface of a BHM (a) with and (c) without PT and $M_y$ symmetries. (b,d) Enlarged view around a diabolic point and a gapped valley respectively. The red arrows in (b) denote the eigen-polarization of electric field around the diabolic point. The polarization changes a $\pi$ phase after winding around the diabolic point, which corresponds precisely to the Berry phase of the circle. The color on the surface in (d) represents the Berry curvature distribution.
tends to a half-integer topological invariant, the valley Chern number, determined by the sign of the effective mass: \( C_v = \text{sign}(m) / 2 \). For two hyperbolic media facing at the interface of \( y = 0 \), the difference between valley Chern numbers of two sides, \( n = s_x s_y [C_v (y > 0) - C_v (y > 0)] \), predicts the existence and chirality of a gapless Fermi arc in the \( k_y \)-gap at each valley.

The effective mass \( m(s_x, s_y) \) depends on the mechanism of symmetry breaking. We have investigated different mechanisms: (1) bianisotropic chiral coupling with either a diagonal chiral term \( \tilde{\gamma} = \text{diag}(\gamma_x, \gamma_y, \gamma_z) \) or an antisymmetric chiral term \( \tilde{\gamma} = g_x \times \tilde{I} \); (2) gyroelectric effect induced by magnetic field either along \( x \)-or \( z \)-direction \( \tilde{e} = \tilde{e}_0 + i \tilde{b}_i \times \tilde{I} \) (\( i = x, z \)), which shows different valley Chern number distributions in Fig.2(a). Letting two hyperbolic media with different perturbations join at an interface, a full control of topological multi-valley transport, namely manipulating the existence and chirality of Fermi arcs at any specific valleys, can be achieved. In particular, for the interface of two BHMs with opposite antisymmetric chiral coupling, the Fermi arcs associated with left and right valleys in the same \( k_z \) bulk gap have opposite chirality as shown in Fig.2(b). Even if the interface is parallel to \( y \) axis, the crossover of the two Fermi arcs only induces an extremely tiny gap (see Fig.2(c)). This enables us to realize valley Hall effect using the Fermi-arc states. The full-wave simulations in Fig.2(d,e) manifest that the Fermi-arc surface waves possess valley-dependent helical transport feature and are immune from sharp-corner scattering.

### 3. Conclusions

We demonstrated that valley-dependent gapless Fermi arcs can emerge at the interface of two BHMs without PT and \( M \), symmetries, and valley Hall effect are realized using the Fermi-arc surface waves. Furthermore, the chirality of the Fermi arc at each valley can be individually controlled via introducing different kinds of material perturbations, hence this platform can be utilized to achieve multiple-valley topological transport.

As one of the most fundamental topological excitations in nature, vortices are widely known in hair whorls as the winding of hair strings, in fluid dynamics as the winding of velocities, in superconductors and superfluid as the winding of order parameters. However, vortices have hardly been observed other than those in the real space. Using a home-made polarization-resolved momentum-space imaging spectroscopy, we experimentally observed vortices in momentum space, as the winding of far-field polarization vectors in the first Brillouin zone of periodic plasmonic structures. We completely mapped out the band structure, lifetime and polarization states of all radiative states. The momentum space vortices were experimentally identified by their winding patterns in the polarization-resolved iso-frequency contours and their diverging radiative quality factors. Such polarization vortices, leading to high Q factor modes so called bound states in the continuum (BIC), can exist robustly on any periodic systems of vector fields, while they are not captured by the existing topological band theory developed for scaler fields. Our results also inspire that the non-trivial topological effects could be also found in photonic crystals assumed to be topologically trivial in the past.

Abstract

We study theoretically and numerically the electromagnetic response of a dipole near an Epsilon-near-zero (ENZ) surface. Explicit analytical expressions are given for the LDOS near a plane surface. A criterion for evaluating the threshold height above (below) which radiative (non-radiative) processes dominate is established. We found results elucidating the origin of LDOS cancellation. By the determination of an optimal spacer thickness between the ENZ substrate and a dipole emitter, the obtained results can be used to strongly augment the lifetime of the emitter.

1. Introduction

The development of near-field optics has led to an important number of applications involving the control of light emission. In this context, considering the electromagnetic environment is crucial for an accurate description of the physical mechanisms involved. In particular, when light sources are in the vicinity of a complex electromagnetic background, the emission properties of the source are modified. Therefore, considering the advances in nanofabrication of the last decades and microscopy techniques with sub-wavelength resolution, it is possible to study near-field interactions in the visible and infrared region of the spectrum. The case of a half-space system is of particular importance, as it can be considered the simplest structured electromagnetic background.

The electromagnetic Green function plays an important role in absorption and emission processes. Indeed, the Green function gives the local density of optical states (LDOS). The LDOS provides spectroscopic information and is independent of the illumination modes. In the case of the ‘half-space’ system, a rigorous solution for the Green function exists in reciprocal space [1]. As the rigorous solution requires some care in its evaluation, approximate solutions based on the method of images [2] are frequently used, the so-called Image-Dipole model (IDM).

We study the contribution of the substrate to the modification of the local density of optical states (LDOS) using a short-distance expansion (SDE) of the Green function. General trends for radiative and non-radiative contributions to the LDOS are discussed and examples of application of the formalism are given for ε-near-zero (ENZ) materials.

2. Green function formalism for a particle in a half-space background

In a half-space geometry, a plane interface separates a medium with refractive index $n_1 (z > 0)$ from another with refractive index $n_2 (z < 0)$. For the sake of simplicity, we will consider the case in which the emitter is located in the upper medium with refractive index $n_1$.

Figure 1: Schematic representation of a small particle above a plane interface. The particle interacts directly with an incident plane wave and with the field reflected at the interface. The dashed circle in the substrate represents the main idea of the image dipole moment (IDM), in which the surface is replaced by an ‘image’ charge on the substrate side.

The Green function associated to the half-space geometry, in the region $z > 0$, has two contributions: the dipole fields of a homogeneous medium (direct contribution) and those coming from the reflection at the interface (reflected contribution). A rigorous solution for the field scattered by a point dipole in the presence of the plane interface was obtained by Sommerfeld [1] in the context of radiowave propagation. The general procedure for obtaining such a solution relies on transforming the Green function from direct to reciprocal space. For our purposes, we write the half-space Green function as

$$G^{HS}(\mathbf{r}, \mathbf{r}') = G^0(\mathbf{r}, \mathbf{r}') + G^R(\mathbf{r}, \mathbf{r}'),$$

(1)
with
\[ G^R(r, r') = \int_0^\infty \int_0^{2\pi} \frac{q \, dq \, d\phi(q)}{2\pi K(q)} \mathbf{D}(q) e^{iq\phi(q)} \] (2)
and
\[ \Phi(q) = q R \cos \phi(q) + ik(q)\\. \] (3)

Here \( G^0 \) is the Green function of a homogeneous medium with refractive index \( n_1 \) and \( \lambda \) the free-space wavelength. The tensor \( \mathbf{D}(q) \) is related to the dielectric properties of each medium. An analytic solution for the so-called Sommerfeld integral in equation (2) is not known and it is necessary to evaluate it numerically. The integral, however, can be approximated as [4]
\[ G^R(r, r) \approx \frac{1}{32\pi k_1^2 z^3} \sum_{l=1}^N (2k_1z)^l \mathbf{K}^{(l)}. \] (4)

for small \( k_1z \). We have used the fact that \( R = 0 \) and \( Z = 2z \). The dyadic \( \mathbf{K}^{(l)} \) contains the coefficients of the \( l \)-th order term.

2.1. Local density of optical states near a plane interface

The local electromagnetic density of states (LDOS) \( \rho(r) \) is proportional to the imaginary part of the Green tensor, they are related through the expression [3]
\[ \rho^{HS}(r) = \frac{6\omega}{\pi c^2} \text{Tr} \{ G^{HS}(r, r) \} \] (5)
and represents the density of electromagnetic modes at frequencies \( \omega \pm \delta\omega \) and position \( r \). If the dipole has a preferential orientation, one may define a projected LDOS \( \rho^{HS}_u(r) \) as
\[ \rho^{HS}_u(r) = \frac{6\omega}{\pi c^2} \text{Tr} \{ \mathbf{u} \cdot G^{HS}(r, r) \cdot \mathbf{u} \}, \] (6)
where \( \mathbf{u} \) is a vector containing the dipole’s orientation. Using equation (1), the LDOS modification can be expressed as
\[ \tilde{\rho}(r) = 1 + \frac{6\pi}{k_1} \text{Tr} \{ G^R(r, r) \}. \] (7)

In this expression we defined \( k_1 = n_1(\omega/e) \) and the corresponding LDOS as \( \rho_1 = 6n_1\omega^3/(\pi c^2) \). A similar normalization is used for \( \rho_u \).

3. Discussion

Using the formalism described above, the \( zz \) component of \( \mathbf{G}^R \) and the normalized projected LDOS \( \tilde{\rho}_z \) are studied for \( e \)-near-zero substrates. In particular, the SDE is used to identify radiative and non-radiative contributions to the LDOS. These contributions are separated by their dependence, in each case, with the distance \( z \) of the dipole to the substrate. In this context, the SDE provides extremely useful information regarding the dependence of the LDOS with the macroscopic dielectric properties of the substrate and upper medium, on the wavelength of emission and on the position of the emitter above the substrate.

4. Conclusions

Considering a dipole above an ENZ substrate, we found that if non-radiative effects are weak compared to the radiative ones, significant suppression of the LDOS can occur for the projected LDOS, i.e. \( \tilde{\rho}_z \) < 1 (see fig. 2). We analysed these suppression effects using the SDE of the reflected Green function. We find the necessary conditions to considerably suppress the LDOS and identify the particular term in the SDE that is responsible for the cancellation. Exact calculations have been performed in order to validate the SDE. We also found that a third-order approximation accounts for the LDOS cancellation, with the order \( O(x^3) \) being responsible for the suppression. For sufficiently weak absorbing substrates, we find that the seventh-order approximation can describe accurately the cancellation process up to \( z \approx \lambda/7 \). Minimum values for the normalized LDOS \( \tilde{\rho} \) on the order of a few percent were found for realistic materials.

Abstract
We demonstrate several inverse-designed ultracompact and highly functional silicon devices based on digital subwavelength structures for on-chip optical interconnects, including mode multiplexer, dual mode power splitter, multimode waveguide crossing and multimode bent waveguide. An improved direct-binary-search-based inverse design method is utilized to optimize digital nanophotonic devices. Besides, an efficient inverse design approach based on digitized adjoint method is also discussed. The footprint of the devices we demonstrate is about two order of magnitude smaller than that of conventional ones, which has great potential for application in high-density integrated on-chip optical interconnects.

1. Introduction
Mode-division multiplexing (MDM) has provided an effective approach to further increase the transmission capacity of on-chip optical interconnect [1]. A variety of key building blocks based on conventional waveguides have been extensively reported typically including mode multiplexer, multimode waveguide crossing and multimode bent waveguide. The conventional waveguide based devices exhibited high performance and large fabrication tolerance. However, due to the limit of adiabatic evolution or weak-coupling strength, the conventional schemes suffer from relatively large scale, which may not be suitable for high-density integrated MDM systems. Recently, inverse design method potentially offers a new route to optimize refractive index distributions at the nanoscale and provide a promising platform for designing ultracompact and highly functional nanophotonic devices simultaneously [2,3]. However, the present inverse-designed silicon structures usually have random and complex etching patterns and may suffer from fabrication errors significantly.

In this work, we propose lag effect-insensitive digital subwavelength (SW) structure and utilize an improved direct-binary-search-based inverse design method to realize several ultracompact digital nanophotonic devices. The footprint of these devices is about two order of magnitude smaller than that of conventional ones.

2. Ultracompact multimode silicon devices
As a proof of concept, ultracompact multiplexer and multimode waveguide crossing are demonstrated by improved inverse design method [4,5]. In addition, a digitized adjoint method is also discussed.

2.1. Multimode multiplexer
On-chip mode (de)multiplexer (([DE] MUX) is one of the most essential elements in MDM systems. Various mode multiplexer schemes based on conventional silicon waveguides have been proposed typically including asymmetric directional couplers (ADCs), multimode interferometers (MMIs), or asymmetric Y-junction. Although these schemes have proved to be promising, they usually suffer from a relatively large footprint of tens or hundreds of µm² for two mode MUX due to adiabatic evolution or weak-coupling strength. As shown in Figs. 1(a) and (b), small branching angle (<9°) is required for satisfying adiabatic evolution in conventional asymmetric Y-junction scheme, which leads to a large scale. As a result, we theoretically discuss the feasibility of realizing a SW asymmetric Y-junction with a large divergence angle for mode conversion. A mode conversion factor (MCF) is used to evaluate the effect of mode conversion, and mode conversion occurs when the MCF is greater than approximately 0.43. By engineering material index and manipulating phase profiles of light at the nanoscale using the digital SW structures, we realize SW asymmetric Y-junctions with large divergence angles to reduce the device footprint greatly.

Fig. 1. (a) and (b) Working principles for two-mode (De) MUX and N-mode (De) MUX based on conventional waveguides asymmetric Y-junctions, respectively. (c) Mode conversion factor (MCF) as a function of the refractive index of the material.

An improved direct-binary-search-based (DBS) inverse design method is utilized to optimize digital SW structure MUX. Our simulation results indicate that a better device performance can be achieved by manually presetting an initial pattern like a conventional waveguide Y-junction rather than a random initial pattern in the DBS optimization algorithm. And we also find that the optimum pattern will automatically converge to a pattern equivalent to a SW asymmetric Y-junction with high performance. In this way, we demonstrate a three-mode SW MUX occupied 3.6 × 4.8 µm² as preset in Fig. 2.
In this way, an ultra-compact and highly functional dual-mode waveguide crossings was demonstrated using inverse design method.

Similarly, the improved DBS-based inverse design method is also utilized to optimize the device. The manually set initial and optimized patterns are shown in Figs. 4(a) and 4(b), respectively. In this way, an ultra-compact and highly functional dual-mode waveguide crossings was demonstrated using inverse design method.

2.3. Digitized Adjoint Method

To improve the efficiency of inverse design for large scale and high-performance “digital” subwavelength nanophotonic devices, We also present a digitized adjoint method. We design a single-mode 3-dB power divider and a dual-mode demultiplexer to demonstrate the digitized adjoint method for single-object and dual-object optimizations, respectively. The optimization comprises three stages, a first stage of continuous variation for an “analog” pattern, a second stage of forced permittivity biasing for a “quasi-digital” pattern, and a third stage for a multi-level digital pattern. Compared with conventional DBS method, the proposed digitized adjoint method can improve the design efficiency by about 5 times, and the performance optimization can reach approximately the same level using the ternary pattern. The digitized adjoint method takes the advantages of adjoint sensitivity analysis and digital subwavelength structure and provides a new route for efficient and high-performance design of compact digital subwavelength nanophotonic devices, which may be attractive for inverse design of large-scale digital nanophotonic devices.

3. Conclusions

In summary, we exploit an improved DBS-based inverse design method to realize several ultracompact digital nanophotonic devices. The digitized adjoint method is also discussed to improve the efficiency of inverse design. By flexibly engineering index at the nanoscale and exhibiting robustness, digital SW structures offers a route to design ultracompact and highly functional nanophotonic devices, which has great potential for application in high-density integrated-on-chip optical interconnects.

Abstract
We provide a novel photonic topological insulator design (PTI) exhibiting the quantum-spin-Hall effect, which, as opposed to previous designs, is conceived using numerical optimization of the transmission through PTI edge states. Specifically, we use topology optimization to maximize the transmission of light through a carefully configured model domain composed of two photonic crystal phases. This leads to a numerically generated PTI, which features larger bandgaps than previously predicted for planar PTIs and excellent suppression of backscattering from sharp bends.

1. Introduction
Time-reversal-invariant photonic topological insulators (PTIs) support pseudo-spin-dependent edge states with bi-directional propagation and robustness against certain classes of disorder [1, 2]. Such properties are obviously desirable in many applications in chip-scale photonics where controlled propagation and low losses are essential. However, designing a PTI is highly non-trivial as it requires inversion of band symmetries around a band gap and thus the designs for dielectric planar PTIs available in the literature have so far been obtained using clever ideas and painstaking trial and error [3, 4, 5]. We present a completely different approach to the design of PTIs where the problem is formulated as an inverse problem which we solve using density-based topology optimization [6]. In the design process, the material configuration constituting the PCs is changed iteratively in order to simultaneously maximize the transmission of energy from P1 to P2 and P4 and minimize the transmission to P3 while ensuring that both PC phases exhibit bandgaps at the targeted frequencies by enforcing a set of inequality constraints. By achieving negligible transmission from P1 to P3 and high transmission from P1 to P2 and P4, a behaviour identical to that of a PTI, configured as shown in figure 1, is obtained.

2. The Method
A classical electromagnetic model is assumed for the light,
\[ \nabla \times (\nabla \times \mathbf{E}(\mathbf{r})) - k_0^2 \varepsilon_r(\mathbf{r}) \mathbf{E}(\mathbf{r}) = \mathbf{S}(\mathbf{r}), \quad \mathbf{r} \in \Omega \subset \mathbb{R}^2, \]
with \( \mathbf{E} \) denoting the electric field, \( k_0 = \frac{2\pi\nu}{c} \) the free-space wave number with \( \nu \) being the frequency and \( c \) the speed of light in vacuum, \( \varepsilon_r \) the relative permittivity and \( \mathbf{S} \), a source. The two-dimensional model domain \( \Omega \subset \mathbb{R}^2 \) is truncated using a perfectly matched layer [9].

Figure 1: Conceptual sketch of the design-model domain, \( \Omega \). The edge (bulk) of the PC phases constituting the PTI are colored orange (yellow) and black (grey). The input/output ports are denoted P1-P4 and the arrows indicate power flow.

The PTI structure consists of two periodic hexagonal photonic crystals (PCs) with a zig-zag interface. In the design problem, the two PCs are placed in \( \Omega \) as sketched conceptually in figure 1. The problem of designing the PTI is formulated as an inverse problem and solved for a set of frequencies using density-based topology optimization [6]. In the design process, the material configuration constituting the PCs is changed iteratively in order to simultaneously maximize the transmission of energy from P1 to P2 and P4 and minimize the transmission to P3 while ensuring that both PC phases exhibit bandgaps at the targeted frequencies by enforcing a set of inequality constraints. By achieving negligible transmission from P1 to P3 and high transmission from P1 to P2 and P4, a behaviour identical to that of a PTI, configured as shown in figure 1, is obtained.

3. Discussion
A PTI consisting of a silicon membrane \( (\varepsilon_{\text{Si, reduced}} = 9.61) \) with air holes \( (\varepsilon_{\text{air}} = 1) \) is designed using the proposed
approach. Both PC phases are initiated from the structure shown in figure 2A. $C_{6v}$-symmetry is imposed on the PC unit cells, and the frequencies $\nu \in \{184 \text{ THz, } 187 \text{ Thz}\}$ are targeted in the design process. The two PC phases constituting the final PTI design are shown in figure 2B-2C.

In order to demonstrate the directional pseudo-spin dependent energy transport supported by the PTI, a chiral TE-polarized dipole source is placed at the interface between the two PC phases while varying the chirality from clockwise to counter-clockwise. The $H_z$-component of the resulting field (shown for $|H_z| > 0.05$) is plotted in figure 3(A) and 3(B), respectively. It is clearly seen that the right-handed (left-handed) chirality excites the edge state with positive (negative) pseudo-spin travelling to the left (right).

A numerical demonstration of the back-scattering robustness offered by the PTI is shown in figures 3C and 3D. The former showing a field propagating along the PTI interface (C) past four 120° bends and (D) along a straight channel. The $H_z$-field component is shown for $\nu = 184 \text{ THz}$, overlaid on the PTI-structure.

A novel PTI is proposed and analysed along with the topology-optimization-based approach used in its design. The resulting structure features large bulk bandgaps, very low bending losses, and a very high degree of direction emission. The proposed design approach may be used to devise novel PTIs and/or to tailor them to maximize different figures of merit, such as operational bandwidth and/or energy transmission.

Optically Tunable Epsilon-Near-Zero Metamaterials

Surya Ayyagari, Alireza R. Rashed, Humeyra Caglayan *
Photonics Laboratory, Tampere University, 33720, Tampere, Finland
*Humeyra Caglayan, E-mail: humeyra.caglayan@tuni.fi

Abstract

In this study, we obtained epsilon-near-zero metamaterial at visible range by designing and fabricating a metal–dielectric multilayer anisotropic hyperbolic metamaterial. To do this, we experimentally characterize and extract the permittivity from the TMM (transfer matrix method). Later, we show by optically pumping with fs pulses at a proper wavelength the ENZ point of the structure alters, in comparison to the linear case. The change in the effective permittivity happens in the order of unity, leading to ultrafast light induced refractive index change.

1. Introduction

Optical metamaterials such as hyperbolic metamaterials (HMMs) have a unique property that exhibits high-k modes due to hyperbolic dispersion and the existence of epsilon-near-zero (ENZ) point in their electromagnetic spectral range. Beside the existence of ENZ point, HMMs can enhance the radiative recombination rate (spontaneous emission) of quantum emitters. Recently, people have investigated deeply the linear properties of ENZ metamaterials. Such investigations lead to achieve a broad range of applications such as novel waveguiding regimes and controlling the radiation pattern of electromagnetic sources [1-2]. In addition, the experimental evidences are presented for the role of ENZ metamaterials to affect the optical nonlinearity. Such affect demonstrates the efficient third harmonic generation and nonlinear Kerr index n2 for TCO (transparent conductive oxides) materials and HMMs [3-5]. Our approach relies on modification of complex effective refractive index of the designed HMM in the visible spectral range which leads to the generation of the higher order nonlinear refractive index (Δn). Consequently, such modification in the effective refractive index changes the reflectance and transmittance properties.

2. Results

The HMM structure was fabricated on 0.5 mm (500 µm) thick substrate of fused silica (FS). The metal-dielectric stack (4 pairs of 16 nm thick Au and 32 nm thick TiO2) was deposited by using electron-beam deposition technique (see Figure 1). Deposition rate was kept below 0.2nm/sec for Au and below 0.16 nm/sec for TiO2 in order to achieve a homogenous surface of the layers.

Linear characterization

We have extracted the reflection and transmission properties of the designed HMM by using Transfer matrix method (TMM) as well as Numerical FDTD software. Later, the linear optical properties of the fabricated HMM experimentally are investigated. The reflection and transmission measurements are done under a white lamp illumination and by using CCD spectrometer (Figure 2).

Nonlinear characterization

In order to see the nonlinear response of the HMM, we have measured the change in reflectivity ΔR/Rlin (Figure 3) and transmissivity ΔT/Tlin (data not shown here) of the structure by optically inducing a pump signal. This characterization is done in a pump-probe spectroscopy system, in such a way that pump signal is fixed at a single wavelength with varied powers, while the broad band probe beam is varied temporally with respect to the pump beam.

Figure 1: The SEM image of the fabricated sample showing the alternative layers of Au (16 nm) and TiO2 (32 nm).

Figure 2: Comparison of reflectance and transmittance of HMM experiment (green), TMM (blue) and FDTD simulation (red).
Figure 3: Nonlinear reflectivity (after pumping) as function of probe wavelength at 350µw and 1100µw with a fixed pump wavelength.

The pump-induced nonlinear refractive index change is given by \( \Delta n = (n_{\text{pump}} - n_{\text{lin}}) \approx n_2 I \) [6], where \( I \) is the intensity of the optical pump and \( n_2 \) is the Kerr nonlinear refractive index. \( n_{\text{pump}} \) and \( n_{\text{lin}} \) stand for refractive index values after and before pumping, respectively, which are retrieved from the experimental data.

Figure 4: Change in the real part of nonlinear refractive index (red), imaginary part of nonlinear refractive index (green), real part of change in permittivity (red) and imaginary part of change in permittivity with respect to the linear case (non pumped).

3. Discussion

Figure 3 and 4 show evidently the modification of the reflectance and transmittance properties of the pumped structure, as a result of the effective refractive index change. Such change of the index refraction in turn is responsible for the modification of ENZ wavelength of the excited structure.

4. Conclusions

In this work, we have shown the ability to exploit the ENZ regime, for effectively tuning the optical properties of a metamaterial with simple design, operating in the visible range. The applied nonlinear change in the index of refraction leads to an ultrafast light induced metal to dielectric phase change at the ENZ region. The ability to access ultrafast light induced refractive index changes represents a new paradigm for the nonlinear optics.

Experimental demonstration of topological photonic states based on composite left/right-handed coupled ring resonators

Zhiwei Guo, Yong Sun*, Haitao Jiang, and Hong Chen

MOE Key Laboratory of Advanced Micro-Structured Materials, School of Physics Science and Engineering, Tongji University, Shanghai, 200092, China
*corresponding author, E-mail: yongsun@tongji.edu.cn

Abstract

The array of two-dimensional coupled ring resonators is a typical system to realize the photonic and acoustic topological insulators with robust one-way transportation against defects and impurities. In this work, we theoretically propose and experimentally demonstrate the photonic analogue of quantum spin Hall effect in an improved broadband anomalous Floquet topological insulator in microwave regime, taking advantage of efficient and backward coupling between composite left/right-handed metamaterial rings resonators.

1. Introduction

Diversified coupled ring resonators (CRRs) arrays as suitable platforms for the study of topological photonic have been paid much attention. In these platforms, the roles of pseudo-spins with opposite directions are played by the clockwise and anti-clockwise propagations of the light [1]. Based on CRR arrays, the optimized topological optical devices with high-performance, such as delay lines, optical isolators, lase, have been proposed as the key components in optical communication systems. In particular, in 2013, Liang and Chong theoretically revealed that a lattice of optical ring resonators can exhibit a topological insulator phase even if all bands have zero Chern number [2]. Instead of delicately tuning the aperiodic couplings of the inter-resonators, this simplified structure is periodic because of the identical coupled ring resonators [2]. Inspired by this anomalous Floquet topological insulator, the topological edge states with T-symmetry have been experimentally measured by using a surface plasmon structure [3]. Furthermore, this novel topological edge mode also has been theoretically proposed [4] and experimentally demonstrated [5] in acoustic system. Nevertheless, it should be pointed out that the coupling between site rings in CRR array need be strong for the anomalous Floquet topological insulator. The widely used solution is to insert a coupler ring between two site rings. However, the strong coupling achieved in this way will rely on the resonance of the coupler ring, which severely limits the band width of the strong-coupling regime.

In this work, we propose a broadband anomalous Floquet topological insulator in microwave regime using a square array of metamaterial rings, and experimentally demonstrate the photonic analogue of QSHE. Different from the narrowband strong coupling relying on the resonance of the additional coupler ring, the broadband high efficient coupling is realized by utilizing a directional coupler made of the composite right/left-handed (CRLH) transmission line (TL) metamaterials. We construct a square array of CRRs with CRLH TL metamaterials, and measure the photonic topological edge states. In each individual ring resonator, the roles of opposite pseudo-spins are played by the clockwise and anti-clockwise propagations of the electromagnetic waves. It should be noted that the directional coupler inserted into the site rings supports the backward wave coupling. Therefore, the direction of energy flow in each ring is same for a given pseudo-spin state. We also investigate the robustness of edge states against a variety of perturbations. Our finding not only pave a new way to realize the broadband topological photonic device.

2. Band structure and the gapless edge modes in the topological structure

The scheme of our designed array of CRLH ring resonators is shown in Fig. 1. The size of our fabricated sample is $4 \times 5$ unit cells. Different from the previous schemes, every ring resonator in Fig. 1 belongs to the site ring except that two U-
shape waveguides play the roles of input and output ports, respectively. As an improved platform with backward coupling between the unit cells, the mediated coupler ring is not needed in the structure, as is shown in Fig. 1. In our proposed periodic rings array, there are two-fold degenerate modes in each resonator ring that correspond to a twofold pseudo-spin degree of freedom. By setting the position of input port, clockwise and anti-clockwise circulating photonic modes (e.g., two kinds of pseudo-spins) can be selectively excited along the opposite directions. In this work, we construct CRLH ring resonators based on TLs. TLs, as a good experimental platform, have been used to realize the effective medium with arbitrary parameters, quantum-optics-like systems and even the topological photonic structures. At first we use distributed composite CRLH TLs to design left-hand metamaterial with the negative refraction and backward wave-vector coupling. Next, the strong coupled ring resonators can be constructed by connecting left- and right-hand TLs in sequence. At last, the square array of CRLH coupled ring resonators can be established, as is schematically shown in Fig. 1.

In the next we experimentally demonstrate the selectively excited pseudo-spin one-way edge states. We can find that the pseudo-spin-up edge state will propagate along the upper edge while the pseudo-spin-down edge state will propagate along the lower edge, as are shown in Fig. 2(a) and Fig. 2(b), respectively. The decay phenomenon of the topological edge states mainly comes from the absorption of the CRLH TLs.

### 3. Discussion

Our results pave a new way to realize the broadband topological photonic device with topological protection. Moreover, by using the mechanisms of multiple scattering in single negative metamaterials and effective negative coupling coefficient, our design also can be extended to higher frequencies and acoustics systems.

### 4. Conclusions

In conclusion, based on TLs, we propose an improved platform of photonic analogue of QSHE by using a square array of CRLH ring resonators, in which the mediated coupler ring is not needed and the topological edge state has a broadband property. Our experimental demonstration of the selectively excited one-way edge states will further enrich the design of anomalous Floquet topological insulator and may pave the way to design novel photonic topological devices.

Abstract
Photic topological insulators are promising as a new photonic platform due to the unidirectional edge states insensitive to bendings and fabrication imperfections. A recently prososed all-dielectric perturbed honeycomb photonic crystal, however, intrinsically suffers from backreflection due to the symmetry breaking at the interface. Here, we propose an all-dielectric photonic topological insulator based on the kagome lattice geometry in which the topological edge modes do not undergo back reflection for termination along the $\Gamma$-K direction.

1. Introduction
Topological insulators (TI) enables a variety of exotic properties due to their correspondence between global, bulk properties of a material and their local properties at the edges. This is known as the bulk-edge correspondence and it guarantees topologically protected edge modes at the interface between two topologically distinct materials with interesting features such as unidirectional propagation and robustness against bendings and fabrication imperfections. The photonic counterpart, known as photonic topological insulator (PTI) [1], is even more promising for real-life applications because it is easier to study and design.

Many different topologically non-trivial photonic designs have been proposed using non-reciprocal systems [2], complex metamaterials [3], etc. However, most of the PTIs are either complicated to fabricate or require strong magnetic fields. Recently, a deformed honeycomb-based topological photonic crystal (PhC) [4] that emulates the quantum spin Hall effect (QSH) has gained interest due to its simplicity of fabrication compared to other PTIs. However the time-reversal anti-unitary operator $T^2 = -1$, which is required for well-defined orthogonal spin up/down channels, is constructed on the basis of the six-fold rotation ($C_6$) operator of the crystal. Therefore the edge modes intrinsically suffer from back reflection due to the crystallographic symmetry breaking at the interface which leads to the coupling of the two spin channels showing an anti-crossing behaviour in their dispersion.

In this paper, we propose an all-dielectric PTI which is a deformed kagome-based [5] photonic crystal composed of dielectric rods. The proposed design emulates the so-called quantum valley Hall effect (QVHE) [6] and exhibits edge modes which do not intrinsically suffer from backscattering at the interface but instead are sensitive to its termination.

2. Results
Figure 1(a) shows the proposed kagome-like photonic crystal with the rod on the middle of the edges of the hexagons. Due to the hexagonal symmetry, its corresponding photonic band structure has a linear degeneracy at the K and K’ points (Fig. 1(c)). We consider transverse magnetic (TM) polarization which has the magnetic field components in the 2D plane. The unit cell is composed of three rods and the geometric perturbation to lift the degeneracy is such that the rods get closer (negative perturbation $\delta < 0$) or away (positive perturbation $\delta > 0$) starting from their shared corner of the hexagons (see Fig. 1(b)): $\mathbf{r}' = (1 \pm \delta) \mathbf{r}$ where $\mathbf{r}$ is a vector taken from the corner of hexagon to the adjacent rod. Applying the methodology detailed in [7] to the hexagonal space group, i.e. the plane group p6mm (17), one gets the corresponding effective Hamiltonian:

$$H_{\text{kagome}} = \begin{pmatrix} \mathcal{W}_K & 0 \\ 0 & \mathcal{W}_{K'} \end{pmatrix}$$  \hspace{1cm} (1)

where $\mathcal{W}_{K/K'} = \pm \hbar \cdot \sigma$ are the Weyl Hamiltonians close to the K/K’ point ($\delta k_x, \delta k_y$) with $\hbar = (-\delta k_y, \delta k_x)$ and $\sigma = (\sigma_1, \sigma_2, \sigma_3)$ the Pauli matrix vector. The conservation of translation symmetry with the geometric perturbation,
i.e. the lattice constant remains the same, leads to distinct and well-defined K and K’ point which was not the case for the perturbed honeycomb case [4]. More importantly, it gives an effective Hamiltonian which is necessarily block-diagonalized in two Weyl Hamiltonians (see Eq. (1)) in the same way as in the Kane-Mele Hamiltonian. One can therefore infer that the K (K’) point plays the role of some pseudo-spin up (down) channels, known as the valley degree of freedom.

As a consequence, at the interface, where the C6v is broken, as long as the K and K' points remain distinct, there is no coupling between the two pseudo-spin channels. From the expression of the kagome Hamiltonian \( H_{kagome} \), it becomes evident that a non-trivial Weyl charge is located at the K and K’ points and will be opposite because \( \mathcal{W}_K = -\mathcal{W}_{K’} \). Additionally the Weyl charge at the K (or K’) will be opposite for opposite perturbations. This gives opposite valley Chern number for opposite perturbation. As a consequence of the bulk-boundary correspondence, edge modes are guaranteed at the interface between two joined kagome photonic crystals with opposite perturbations. Figure 2(a) shows the supercell band structure for a termination along the \( -K \) direction. Because K and K’ are not projected on the same point along the \( k_{\parallel} \) line, there is no inter-valley coupling, leading to a crossing for the edge mode dispersion. Furthermore, for the case of a \( \Gamma\-K \) termination, edge modes lie close to or below the light line, thus improving mode confinement to the fabricated surface substantially without the need of sub- and superstrate mirrors.

Figure 2(b) shows the power profile propagation along the interface of the type denoted by red lines in Fig. 2(a) with two bendings. Since the termination keeps \( \Gamma\-K \) direction, the light propagates without back reflection for a finite wavelength range where the edge modes exist.

3. Conclusions

In summary, we have introduced a new kagome-like photonic topological insulator which does not suffer from backscattering at the interface but instead depends on its termination. We showed the crossing behaviour of the edge modes using the band calculations for \( \Gamma\-K \) termination directions, and have demonstrated the possibility of achieving vertical confinement due to edge modes below the light line.

Approaching the fundamental limits of heat transfer at the nanoscale: the surprisingly limited role of inverse design

Prashanth Venkataram, Sean Molesky, Weiliang Jin, and Alejandro W. Rodriguez
Department of Electrical Engineering, Princeton University

Radiative heat exchanged between bodies at the nanoscale can surpass blackbody limits on thermal radiation by orders of magnitude due to contributions from evanescent electromagnetic fields, which carry no energy to the far-field. Such super-Planckian emission is known to depend strongly on both material and geometric properties. However, the relative importance and interplay of these two facets and their fundamental limitations remain open questions. While guiding principles have thus far assumed utility in the possibility of improvements (beyond planar media) through nanoscale texturing, thus far trial-and-error explorations and large-scale optimization procedures have failed to surpass the performance of ideal (unstructured) metals [1–3]. In this talk, I will present fundamental limits to near-field radiative heat transfer in resonant media [4]. We will show that at any given wavelength, multiple scattering between proximate bodies severely limits the marginal utility of nanoscale texturing for the purpose of enhancing near-field heat transfer, beyond shifting the resonant response of bulk materials to selective wavelengths. While compact bodies can benefit from stronger material response (larger indices of refraction and smaller losses) up to a size-dependent threshold, leaving room for applications of inverse design to discover optimal geometries, the near-field heat transfer between extended structures is shown to scale very weakly (logarithmically) with increased material response, and to be practically reached by planar materials at the surface polariton condition. The existence of tight bounds for heat transfer has ramifications for the performance of thermophotovoltaics, nanoscale cooling, and other thermal devices operating in the near field [5].

Topology Optimization of Photonic Crystals and Large-area Metasurfaces

Summary
Recent developments in computational freeform inverse design \cite{Molesky2018} have provided a fertile landscape of structures and topologies for nanophotonics. However, simply dumping millions of parameters into a simulation can easily lead to intractable computational problems. Fortunately, a given engineering problem often admits many different mathematical formulations, and by carefully matching the formulation to the available electromagnetic solvers and optimization algorithms one can set the stage for extraordinarily flexible automated design. In this talk, we will show that, with careful consideration and reformulation of the design problem, powerful inverse design techniques can be successfully applied to a multitude of interesting problems ranging from designing exotic spectral features in photonic crystals \cite{Lin2016a,Lin2018} to beam-forming and manipulation through multi-layered metasurfaces \cite{Lin2018a,Lin2019}.

Optimal metasurfaces: Theory and inverse design

Owen D. Miller

Department of Applied Physics and Energy Sciences Institute, Yale University, New Haven, Connecticut 06511, USA

ABSTRACT

We use two approaches to design best-in-class metasurfaces: large-scale computational optimization, i.e. “inverse design,” to find optimal configurations of thousands of geometrical degrees of freedom, and analytical bounds, to discover fundamental limits that cannot be exceeded. The two ideas work in tandem: analytical bounds suggest areas ripe for orders-of-magnitude improvement, while computational design can identify structures exhibiting such improvements. In the area of optical superresolution, where one wants to created sub-diffraction-limited optical beams with maximal intensity, we develop a quadratic-programming framework and analytical expressions for the maximum intensity of any sub-diffraction-limited optical beam, and we use inverse design to discover metasurface structures operating close to these limits. Conversely, in the realm of broadband metasurface lenses, where no such bounds are known, we use inverse design to discover high-numerical-aperture, high-efficiency, broad-bandwidth metalenses.

1. SUPERRESOLUTION

Free-space optical beams with large focal-point intensities and arbitrarily small spot sizes are a long-sought goal\textsuperscript{1–3} for applications from imaging\textsuperscript{4–8} to 3D printing,\textsuperscript{9,10} for which nanostructured lenses have enabled recent experimental breakthroughs.\textsuperscript{11,12} Here, we derive fundamental limits to free-space optical-beam concentration, revealing the maximum possible focal-point intensity (related to the well-known “Strehl ratio”\textsuperscript{13,14}) for any desired spot size. For waves incident from any region of space—generated by scattering structures, spatial light modulators, or light sources of arbitrary complexity—we show that the non-convex beam-concentration problem can be transformed to a quadratic program\textsuperscript{15} with easily computable global optima. By honing in on the two essential degrees of freedom—the field intensity at the focal point, and its average over a ring at the desired spot size—optimal beam concentration can be further simplified to a rank-two optimization, resulting in analytical upper bounds in the far zone. For very small spot sizes $G$, which are most desirable for transformative applications, we show that the focal-point intensity must decrease proportional to $G^4$, a scaling within the exact bounds that cannot be overcome through any form of wavefront engineering. The bounds have an intuitive interpretation: the ideal field profile at the exit surface of an optical beam-shaping device must have maximum overlap with the fields radiating from a dipole at the origin yet be orthogonal to the fields emanating from a current loop at the spot size radius. We compare theoretical proposals and experimental demonstrations to our bounds, and we find that there is significant opportunity for order-of-magnitude intensity enhancements at those small spot sizes. We use “inverse design”,\textsuperscript{16–19} a large-scale computational-optimization technique, to design metasurfaces that generate nearly optimal wavefronts and closely approach our general bounds.

Consider a beam generated by almost any means. The physics underlying the extent to which such a beam is concentrated spatially in free space is distilled to its essence by the electromagnetic equivalence principle:\textsuperscript{20} the (arbitrarily complex) interactions in the beam-generation process can be replaced by appropriate effective currents on a closed surface in free space. By this principle, the beam-generation problem is equivalent to asking: what is the maximum spatial concentration of a beam generated by electric and magnetic surface currents radiating in free space? We consider fields and currents at a single temporal frequency $\omega$ ($e^{-i\omega t}$ time evolution), and simplify

Figure 1. Inverse design of metasurfaces operating near the fundamental limits to sub-diffraction-limited optical beams.

the expressions to follow by encapsulating the electric and magnetic fields \((\mathbf{E}, \mathbf{H})\) and currents \((\mathbf{K}_{\text{eff}}, \mathbf{N}_{\text{eff}})\) in 6-vectors \(\psi\) and \(\xi\), respectively:

\[
\psi = \begin{pmatrix} \mathbf{E} \\ \mathbf{H} \end{pmatrix}, \quad \xi = \begin{pmatrix} \mathbf{K}_{\text{eff}} \\ \mathbf{N}_{\text{eff}} \end{pmatrix}.
\] (1)

The fields \(\psi\) emanating from the effective currents \(\xi\) distributed across the “exit” surface \(A\) are given by the convolution of the currents with \(\mathbf{\Gamma}\), the \(6 \times 6\) free-space dyadic Green’s function:

\[
\psi(x) = \int_A \mathbf{\Gamma}(x,x')\xi(x').
\]

Thus, the currents comprise the degrees of freedom determining the beam shape, and finding the maximum focal intensity at a single point for any desired focal spot size now reduces to determining the optimal effective currents. We will assume the underlying equations can be solved by any standard electromagnetic discretization scheme, and we will write the matrix versions with the same symbols but without position arguments. For example, \(\psi = \mathbf{\Gamma} \xi\) is the matrix equivalent of the Green’s-function convolution, with \(\psi\) and \(\xi\) vectors and \(\mathbf{\Gamma}\) a matrix. The total intensity at any point in free space, summing electric and magnetic contributions, is given by the squared norm of \(\psi\):

\[
I(x) = |\psi(x)|^2 = \int_A \int_A \xi'(x'')^\dagger \mathbf{\Gamma}^\dagger(x,x'') \mathbf{\Gamma}(x,x')\xi(x')
\]

\[
= \xi^\dagger \mathbf{\Gamma}^\dagger \mathbf{\Gamma} \xi.
\] (2)

We now formulate the maximal-concentration question as a constrained optimization problem. The ideal optical beam has maximum focal intensity at a point (set at \(x = 0\)), zero field along some spot-size contour \(C\), and a total propagating power \(P\) not exceeding an input value of \(P_0\). Thus, the maximum focal intensity, and the ideal effective currents generating it, solve the optimization problem:

\[
\max_{\xi} \quad I(x = 0) = \xi^\dagger \Gamma_0^\dagger \Gamma_0 \xi
\]

subject to \(\psi(x)|_C = \Gamma_c \xi = 0\) and \(P \leq P_0\),

\[
\text{(3)}
\]

where the “0” and \(C\) subscripts indicate whether \(\mathbf{\Gamma}\) and \(\psi\) are evaluated (in the appropriate basis) at the origin or at the spot-size contour, respectively. Attempting to directly solve Eq. (3) is infeasible: the \(\Gamma_0^\dagger \Gamma_0\) matrix is positive semidefinite (which is nonconvex under maximization), the equality constraint prevents the use of Rayleigh-quotient-based approaches, and the power constraint is difficult to write in a simple linear or quadratic form.

We will not work through the detailed derivation of the following results, but we will note that the nonconvexity of the problem can be bypassed through multiple transformations. The results of those transformations are the following bounds. The general bound, which actual applies in any medium, in the near-field/near-zone/far-zone/etc., is:

\[
I \leq \mu^\dagger \left[ \Gamma_0 \Gamma_0^\dagger - \Gamma_0 \Gamma_c^\dagger \left( \Gamma_c \Gamma_c^\dagger \right)^{-1} \Gamma_c \Gamma_0^\dagger \right] \mu,
\] (4)
where $\mathbf{G}_0$ is the Green’s function from the exit surface to the focal point, $\mathbf{G}_C$ is the Green’s function evaluated over the contour in space where the field should be zero, and $\mu$ is the polarization vector of the optimal field at the focal point. Equation (4) represents a key theoretical result of our work. Although it may have an abstract appearance, it is a decisive global bound to the optimization problem, requiring only evaluation of the known free-space dyadic Green’s function at the maximum-intensity point, the zero-field contour, and the effective-current exit surface. The matrix in the square brackets is a $6 \times 6$ matrix, whose largest eigenvector represents the optimal polarization. And the structure of Eq. (4) has simple physical intuition: the maximum intensity of an unconstrained beam would simply focus as much of the effective-current radiation to the origin, as dictated by $\mathbf{G}_0 \mathbf{G}_0^*$, but the constraint required zero field on $C$ necessarily reduces the intensity by an amount proportional to the projection of the spot-size field ($\mathbf{G}_C$) on the field at the origin ($\mathbf{G}_0$).

Figure 1 depicts the results of many design optimizations. Figure 1(a) compares unique optimal designs at spot sizes ranging from 1 down to 0.21 to the bounds described above; strikingly, the designed metalenses closely approach the bound for all spot sizes, with the best designs achieving 90% of the maximum possible intensity. In Fig. 1(b) three specific designs are shown alongside the resulting field profiles in their focal planes. The intensity does not perfectly reach zero but is forced to be significantly smaller than the peak intensity through a penalty constant. It is difficult to explain exactly how the computationally designed metasurface patterns achieve nearly optimal focusing; for spot sizes close to 1, the variations in material density suggest an effective gradient-index-like profile that offers lens-like phase variations across the device width, though the scattering effects of the front and rear surfaces render such explanations necessarily incomplete. The depicted design with $G = 0.21$ exhibits to our knowledge the smallest spot size of any theoretical proposal to date.

Abstract

A data-driven design approach based on deep-learning is introduced in nanophotonics to reduce time-consuming iterative simulations. We report the first use of conditional deep convolutional generative adversarial network to design nanophotonic antennae that are not constrained to a predefined shape. For given input reflection spectra, the network provides desirable designs in the form of images. Numerical simulation results obtained from the generated designs agree well with the input reflection spectrum. The results provide a noteworthy contribution in nanophotonics.

1. Introduction

Recently, data-driven design approaches have been proposed to replace a time-consuming iterative optimization method on designing nanophotonic structures [1, 2]. These approaches use artificial neural networks (NNs) to design nanophotonic structures. Previous studies first set the shape, such as multilayers [1] or H-antenna [2] of structures to be predicted, then trained NNs to provide output structural parameters that achieve desired optical properties. Once the NNs are trained, they provide the corresponding design parameters without additional iterative simulations. Such attempts have greatly reduced the effort and computational costs of designing nanophotonic structures. So far, these approaches have only been applied to conditions in which basic structures are predefined where only structural parameters are predictable [3].

Here, we provide the first use of conditional deep convolutional generative adversarial network (cDCGAN) [4] to design nanophotonic structures [5]. cDCGAN is recently developed algorithm to solve the instability problem of GAN, which provides much stable Nash equilibrium solution. The generated designs are presented as images, so they provide essentially arbitrary possible design for desired optical properties which are not limited to specific structures. Our research provides designs of a 64 × 64 – pixels probability distribution function (PDF) in a domain size of 500 nm × 500 nm, which allows $2^{64 \times 64}$ degrees of freedom of design.

2. Results and Discussion

2.1. Deep-learning procedure

Figure 1: Schematic of the cDCGAN architecture to suggest designs of structures. GN is composed of a transposed CNN to generate structural images, and DN consists of conventional CNN to distinguish real designs from generated designs. Each layer introduces nonlinear activation functions (ReLU, Tanh, Leaky ReLU and Sigmoid) according to the guideline of Radford et al. [4].

We implement cDCGAN algorithm using Pytorch framework. The cDCGAN architecture to design nanophotonic structures is presented in Figure 1. A generator network (GN) is composed of four transposed convolutional neural networks (CNNs) layers that consist of 1024, 512, 256, 128, and 1 channel, respectively; a discriminator network (DN) is a convolutional neural network with four hidden layers. GN takes inputs both the 100 × 1 size random noise (z) which generates appropriate design images, and the 200 × 1 size input spectrum which directs to generate a design that satisfies the condition. GN generates a design on a 64 × 64 – pixels probability distribution function (PDF) in a 500 nm × 500 nm physical domain. The gener-
ated design is again fed into DN to be discriminated from ground-truth designs. GN is trained to generate a superficial authentic design to deceive DN, and DN is trained to distinguish ground-truth designs from the design generated by GN.

2.2. Network Evaluation

Figure 2: 12 examples of cDCGAN suggested images and their simulation results. Each panel is composed of reflection spectra and their corresponding structural cross-sectional images. The upper-right structural images are ground-truth designs (black) and the lower-right images are suggested images by cDCGAN (red). The left spectra show desired input spectra (black solid lines) that we fed into the network and predicted responses obtained from the suggested designs (red dotted lines).

The trained cDCGAN is evaluated on test data that were not used in previous training or validation steps. The randomly chosen test results are shown in Figure 2. Ground-truth designs of various nanophotonic antennae (upper-right panel in Figure 2 and corresponding suggested PDFs (lower-right panel in Figure 2) show good qualitative agreement. For the quantitative evaluation of the suggested PDFs, FDTD simulation based on those suggested designs are conducted. The PDFs were converted to binary designs to be imported into the simulations. Reflection spectra of the suggested images agree well with given input spectra. We introduce a mean absolute error (MAE) criterion,

$$\text{MAE} = \frac{1}{n} \sum_{i=1}^{n} |Y_i - \hat{Y}_i|$$

(1)

to quantitatively measure the accuracy of the model by comparing the predicted response with ground truth of input spectrum. The average MAE error of 12 test samples is 0.0322, which supports that the trained network can essentially provide appropriate structural design that has desired reflection spectrum.

3. Conclusion

This study demonstrates the first use of a cDCGAN to design nanophotonic structures. The two networks of GN and DN in cDCGAN competitively learn to suggest appropriate designs of nanophotonic structures that have desired optical properties of reflection. Our cDCGAN is not limited to suggesting predefined structures, but can also generate new designs. It has numerous design possibility with $2^{64 \times 64} = 2^{4096}$ degrees of freedom. Although our examples set the thickness of each layers and the material type of antenna, they can also be added as output parameters to be suggested. This modification would allow artificial intelligence to be used to design nanophotonic devices completely independently, and would thereby greatly reduce the time and computational cost of designing them manually. We believe that our research findings will lead to rapid development of nanophotonic by solving the main problem of designing structures.

Abstract

We derive a coupled electric and magnetic dipole (iCEMD) theoretical formulation to describe the optical properties of a periodic array consisting of one/several electric/magnetic dipoles per unit cell. In the case of high refractive index cylinders described by their lowest-order Mie resonances, this formulation yields analytical expressions for the reflectance and transmittance. In this regard, we show that although a zero back-scattering condition can never be achieved for individual cylinders, when they are arranged in a periodic array their mutual interaction leads to a generalized Brewster effect in such a nanorod-based metasurface. We also exploit this formulation to investigate symmetry-protected bound states in the continuum in arrays of dimers consisting of detuned resonant dipoles. Indeed, we demonstrate analytically that robust BICs emerge from Fano resonances when dipole detuning vanishes, as a universal behavior occurring regardless of dipole position within the unit cell. We also propose a scheme to engineer angularly-selective BICs with single magnetic-dipole resonance meta-atoms, called Brewster-like quasi BICs.

1. Introduction

In recent years, high-refractive index (HRI) nanophotonic structures are attracting a widespread interest [1], mostly due to the strong magnetic dipole resonances found in the visible and telecomm spectral ranges for HRI nanoparticles, which make them especially appealing to tailor light at the nanoscale, as an alternative to plasmonic nanostructures. HRI nanostructures are being used as building blocks of metasurfaces [2] which can be seen as ultrathin gratings whose thickness and periodicity are small compared to a wavelength in the surrounding media. Metasurfaces have been shown to be relevant in a variety of applications. As an example of particular interest, properly designed all-dielectric metasurfaces, based on HRI spheres or disks, exhibit zero reflectivity, a generalized Brewster effect, potentially for any angle, wavelength and polarization of choice [3, 4]. At normal incidence, the effect is related to the absence of backscattering from small dielectric spheres or disks at the, so-called, first Kerker condition. In contrast, homogeneous HRI cylinders do not fulfill the first Kerker condition due to the mismatch between the local electric and magnetic density of states.

In addition, bound states in the continuum (BICs) have attracted much interest lately in photonics for their (theoretically) infinite Q factor. These states are leaky modes that in a certain limit of some parameter space cannot couple to any radiation channel [5]. In order to trap light in such nearly-zero-linewidth electromagnetic modes, a common approach is to exploit metasurfaces [6, 7]: outgoing specular channels can be suppressed by tuning the parameters of the system in various manners, leading to symmetry-protected BICs.

2. Coupled electric/magnetic dipole theory for metasurfaces

In order to explore all this fascinating phenomenology in metasurfaces, we have theoretically investigated the reflection from and transmission through a periodic array of electric and magnetic dipoles. To this aim, a coupled electric (ED) and magnetic dipole (MD) formulation for infinite planar arrays (iCEMD) has been developed where the electric and magnetic polarizabilities are given by the meta-atom response. In particular, if the meta-atoms consist of HRI cylinders (see Fig. 1) described by the two lowest-order Mie resonances in both polarizations, general analytical expressions are explicitly derived for reflection and transmission, the optical theorem, and the Kerker conditions of the cylinder array [8]. The formulation can be applied to any array of HRI subwavelength wires across the electromagnetic spectrum, as long as the wire response can be reasonably described by the lowest order longitudinal/transverse electric/magnetic polarizabilities. Moreover, we have also extended the iCEMD formulation to account for actual 3D metasurfaces with arbitrary ED/MD meta-atoms upon numerically solving the required lattice sums.

3. Generalized Brewster effect in HRI cylinder metasurfaces

First, we will show that, although a zero back-scattering condition can never be achieved for individual cylinders (as mentioned above), when they are arranged in a periodic array their mutual interaction leads to a generalized Brewster effect in a nanorod-based metasurface. This is done through our iCEMD analytical approach, which describes the reflection/transmission of a periodic array of HRI nanorods in full
4. BICs in coupled dipole metasurfaces

We will also show that simple metasurface configurations support robust, symmetry-protected BICs. On the basis of the iCEMD mentioned above [8], a variety of scenarios is investigated where single/double meta-atoms can be simply described by a combination of various EDs and/or MDs. First, an ED-dimer array is shown to yield a BIC at normal incidence as the dipole detuning parameter vanishes; this has been experimentally verified through Au-rod dimer metasurface in the THz domain [9].

Second, an array of single perpendicular MDs exhibits a so-called Brewster BIC at normal incidence, which evolves into a quasi-BIC at oblique incidence with a rich phenomenology as the (non-degenerate) MD is tilted. We will show that a high-refractive-index disk metasurface in the GHz domain in turn provides clear experimental evidence of such Brewster quasi-BICs [10].

Abstract

In this contribution, we use two different efficient global optimization techniques in order to optimize 3D real life gradient metasurface based on GaN semiconductor. Our results show that we can achieve more than 87\% of diffraction efficiency at the visible regime using only 150 solver calls for optimizing 12 parameters. Our methods seem to be more efficient than other optimization techniques that require costly simulations, especially for 3D structures. The optimized structure will be fabricated and characterized experimentally.

1. Introduction

The field of metasurface has drawn a lot of attention in the last few years, because of the offered degrees of freedom that provide nearly a full control of the light properties in a very short propagation distance with high resolution [1, 2, 3]. The complexity of the problem, the wide parameter space, and the new fabrication capabilities, make the direct modelling problem insufficient and the use of inverse design is mandatory to achieve the maximum desired performance [4]. Several optimization methodologies have been used in the field of metasurfaces, including local and global search methods. The former, require fewer iterations, however, they can be stuck in local maxima/minima, the later is more general and is suitable for optimizing large parameter space. Nevertheless, most of the global techniques used in the metasurface designs require large number of solver calls, which make them inapplicable for modelling 3D real-life designs that require 3D solvers. The main target of this contribution is to find an optimal geometry for 3D gradient metasurface made of GaN nano-ridges (see the inset in Fig. 1) in order to achieve a maximum light deflection (in the same plane of incidence) with a specific angle at \( \lambda = 600 \text{ nm} \). We choose GaN semiconductor due to its negligible losses and due to its high refractive index in the visible regime, which make it ideal nanoresonator (phase-shifters) for metasurface designs [1, 3].

Here, we use two different efficient global optimization techniques based respectively on advanced evolution strategies and statistical learning. The first one is the covariance matrix adaptation evolution strategy (CMA-ES) [5]. The CMA-ES has been gaining a lot of attention since it requires fewer cost function evaluations compared to the other evolutionary algorithms like genetic algorithms (GA) [4, 6] especially for 3D designs that require expensive simulations. The second method is the Efficient Global Optimization (EGO) algorithm [7]. The EGO algorithm is based on the surrogate modelling, that is to say, replacing the complex or costly evaluation process by a simpler and cheaper model [7] to reduce dramatically the computational cost (number of calls for the electromagnetic solver).

We use our rigorous Discontinuous Galerkin Time Domain (DGTND) solver from the DIOGENES software suite dedicated to computational nanophotonics [8] together with the optimization algorithms, in order to achieve a maximum diffraction efficiency \( \eta(n, m) \), where \( n, m \) are the mode indices) at \( \lambda = 600 \text{ nm} \). We consider a normal incident plane-wave with electric field polarized in the y-direction, and we aim to maximize the diffraction efficiency of the first order mode \( \eta(0, -1) \) (deflect light in the same plane of incidence y-z plane). Thus, we consider a sub-wavelength period in the x-direction (300 nm), and we consider a period of 1500 nm in the y-direction, as it can be seen in the inset shown in Fig. 1. We restrict ourselves to rectangular shapes made of GaN semiconductor, in which the position and x and y thicknesses together with the height of the ridges need to be optimized. The 12 optimized parameters

![Figure 1: Optimization process using the EGO (red curve) and the CMA-ES (dark blue curve) methods as a function of the solver calls. The dark red points represent the DOE for the EGO. The inset shows the geometry under consideration, green region for the substrate (Al\textsubscript{2}O\textsubscript{3}), GaN ridges are shown in red. The 12 red circles represent the optimization parameters.](image)
are represented by the red circles in the inset of Fig. 1.

In Fig. 1, we show the results obtained using our optimization techniques. First, for the EGO model, the dark red points represent the design of experiment (DOE) obtained before the optimization process in the EGO model. Based on these points, a surrogate model is constructed and will be used during the optimization process to find a global minimum below the best point found in the DOE process. More precisely, after only 150 iterations (solver calls), we optimized 12 parameters and obtained a diffraction efficiency around 87% at λ = 600 nm, which is sufficient for us at least at this moment, since we need to make a compromise between the number of iterations and the maximum diffraction efficiency obtained. The diffraction efficiency of the main modes, and total transmission as a function of the wavelength can be obtained in Fig. 2(a). As it can be seen, at λ = 600 nm, nearly all the light is concentrated at the first order mode which is inferred in Fig. 2(b). Second, in Fig. 1, we show the results obtained from CMA-ES (dark blue curve). We have found that after 200 iterations, we obtain a point in which the diffraction efficiency is above 85%, but still the EGO provides a better point than the CMA-ES, at least below 200 iterations.

In conclusion, we used our global optimization techniques to optimize 3D gradient metasurface. Our results reveal that we can get up to 87% of diffraction efficiency by optimizing 12 different parameters using only 150 iterations. Our techniques seem to be more efficient than the usual global optimization methods available in the literature in which numerous simulations are required for achieving optimized geometries. Based on the above results, the optimized geometry will be fabricated and characterized experimentally using our modern and efficient fabrication techniques.

Abstract

We propose a novel numerical method to efficiently and accurately model the optical response of disordered metasurfaces, consisting of large ensembles of non-spherical nanoparticles in a stratified medium, including in cases where the nanoparticles are in the near field of a surface or of each other.

1. Introduction

Disordered metasurfaces, consisting of resonant colloidal nanoparticles – or meta-atoms – deposited onto or incorporated into layered media (Fig. 1a), provide a very rich panel of optical features, such as frequency-selective wide-angle light absorption [1], controlled light coupling between free-space modes and guided modes in an optical stack [2] and strong light localization [3], which may be exploited for a wide range of photonic applications, from thin-film photovoltaics to lighting, to environmental sensing. This richness of optical properties comes from the nanoparticles themselves, their interaction with one or several interfaces and their mutual interaction with neighboring nanoparticles.

Theoretically or numerically predicting the optical properties of disordered metasurfaces has however remained a challenge so far due to the difficulty to simulate coherent phenomena occurring both at the scale of an individual nanoparticle and at the scale of the nanoparticle ensemble. Nanoscale phenomena are typically investigated using brute-force Maxwell’s equations solvers (FDTD, finite-elements, ...), however these approaches can hardly deal with large ensembles of nanoparticles distributed in a large volume. This problem may instead be solved efficiently with a T-matrix formalism, where the incident and scattered fields are decomposed on a basis of vector spherical harmonics, however this method becomes very limited as soon as strong near-field interactions (between nanoparticles or between a nanoparticle and an interface) take place. Efforts are currently undergoing to overcome this limitation [4].

2. Results

The numerical method that we propose relies on finding a small set of fictitious electric and magnetic dipoles, described by a complex polarizability tensor, that can reproduce the near field scattered by an arbitrary nanoparticle for any excitation (planewave, point dipole source) at a given wavelength [5]. The polarizability tensor is obtained by solving a numerical inverse problem. Contrary to generalized multipole methods and alike [6], in which the inverse problem is solved by imposing specific boundary conditions on the surface of the scattering element, our method relies on a series of electromagnetic simulations, which can be performed with an arbitrary Maxwell equations solver, to find the polarizability tensor that reproduces the scattered field on any surface around the nanoparticle. It is therefore very general and versatile. Once this is done, the multiple scattering problem where nanoparticles are in the near-field of each other or of a surface can be solved via a classical Green tensor formalism [7].

The validity of our method is illustrated here with the example of a long silicon cylinder. The polarizability tensor of a set of 10 numerical dipoles regularly arranged along the cylinder principal axis was obtained from a data set of finite-element simulations (COMSOL Multiphysics) performed for an individual cylinder embedded in a uniform medium with refractive index 1.5 (glass). Figure 1b shows a comparison of the field scattered by the cylinder when placed in the near field of a gold substrate, as predicted by our method (left) and by the finite-element method (right), for an incident planewave. An excellent agreement is observed. In Ref. [5], we also demonstrate our capability to simulate large disordered ensembles of such cylinders incorporated into a metal-dielectric optical stack.

Figure 1: (a) Example of a disordered metasurface, consisting of metallic nanocubes deposited on a metallo-dielectric stack, that may be modelled with our numerical method. (b) Validity of the method (adapted from Ref. ??). A long silicon cylinder (L = 500 nm, d = 100 nm) embedded in glass is placed 20 nm above a gold layer and illuminated by a TM planewave at $\lambda = 580$ nm and 20 degree incidence. 10 numerical dipoles are equally distributed along the cylinder principal axis. The scattered field predicted by our numerical method (left) outside the cylinder is in excellent agreement with the one obtained with the COMSOL Multiphysics (right).

Designer hyperbolic nanostructures for thermo-plasmonic biomedical applications using finite element and finite difference time domain methods

Abstract

Novel optical designs and architectures that modify the optical power flow through plasmonic nanostructures represent a crucial step towards a nanoscale manipulation of light-matter interactions. One of the main drawbacks of plasmonic nanostructures is the superposition of scattering and absorption processes and, more in general, the difficulties of controlling scattering and absorption separately. For guiding light, for instance, it is essential that the photonic or plasmonic circuit does not have a high absorption, while for other kind of applications, such as photo-acoustic imaging, it is essential that the light is absorbed rather than scattered. To this aim sophisticated approaches have been developed often based on antenna’s design enabled by modern commercial CADs. The ideal solution would be an architecture and/or material which allows to control individually the absorption and scattering band through a clear physical concept, and possibly to tune the relative spectral position and modes strength. Here, we show how hyperbolic meta-antennas overcome these limitations [2]. We present a detailed numerical study where, by means of finite element and finite difference time domain methodologies, we design nanostructured meta-antennas which enable a full control of absorption and scattering of light. Furthermore, the proposed hyperbolic meta-antennas are directional and show both polarization and angular independence, which is an important property if the meta-antennas are dispersed in solvents or grown on different kind of surfaces. The powerful numerical approaches used in this work allow the design of novel nanostructured metamaterials suitable for practical applications spanning, for instance, from thermal emission manipulation, theragnostic nanodevices, optical trapping and nano-manipulation, non-linear optical properties, plasmon-enhanced molecular spectroscopy, photovoltaics and solar-water treatments.

Abstract

This paper combines Integral Equations (IEs) and Generalized Sheet Transition Conditions (GSTCs) with bianisotropic susceptibility tensors, to compute the wave scattering by cylindrical metasurfaces of arbitrary cross sections. It applies this technique to a newly introduced form of cloaking, penetrable cloaking, which is more realistic than transformation-electromagnetics cloaking. It shows that for a given object, properly synthesized gain-less and loss-less susceptibilities can perfectly cloak the object.

1. Introduction

Metasurface technology has been increasingly developed in recent years. A recent overview of the concept, design and applications of metasurfaces may be found for instance in [1].

Practical applications involve a variety of curved objects (e.g., [2]), requiring proper analysis tools. For example, [3] presents wave scattering by multilayered spherical shells using the method of moments (MoM) combined with tensor boundary conditions (TBCs). Generalized Sheet Transition Conditions (GSTCs) have been recently applied to the numerical study of circular-cylindrical [4], spherical [5], and arbitrarily-curved metasurfaces [6] using different analysis techniques [7].

This paper presents a generalization of the GSTC-IE/MoM technique for cylindrical metasurfaces of arbitrary cross section, and illustrates it with the example of the perfect bianisotropic penetrable cloaking of an elliptical object.

2. Computational Formulation

Fig. 1 shows the two-dimensional problem of interest, the analysis of wave scattering by a metasurface cavity of arbitrary cross section illuminated by an arbitrary source. The exterior and interior media, respectively labeled 1 and 2, have permittivities and permeabilities \((\varepsilon_1, \mu_1)\) and \((\varepsilon_2, \mu_2)\).

2.1. Generalized Sheet Transition Conditions (GSTCs)

Let us assume that the metasurface has only transverse electric and magnetic surface polarization densities, \(\vec{P}_1\) and \(\vec{M}_1\). In this case, the harmonic \((e^{-i\omega t})\) GSTCs reduce to [1]

\[
\hat{n} \times \Delta \vec{E} = i\omega \mu_0 \vec{M}_1, \quad \hat{n} \times \Delta \vec{H} = -i\omega \vec{P}_1, \tag{1}
\]

where \(\Delta\) denotes the difference of the fields at both sides of the metasurface, and

\[
\vec{M}_1 = [M_x, M_z]' = \bar{\chi}_{me} || \vec{E}_i, av \times \vec{n} + \bar{\chi}_{mn} || \vec{H}_i, av, \tag{2a}
\]

\[
\vec{P}_1 = [P_t, P_z]' = \varepsilon_0 \bar{\chi}_{em} || \vec{E}_i, av + \bar{\chi}_{em} || \vec{H}_i, av / c, \tag{2b}
\]

where \(\bar{\chi}_{mn} || \bar{\chi}_{me} \), \(\bar{\chi}_{em} \) and \(\bar{\chi}_{ee} \) are the surface susceptibility tensors, and “av” denotes the average of the fields at both sides of the metasurface [1]. Eqs. (1) with (2) form two vector equations in terms of the four unknown vectors \(\vec{E}_1\), \(\vec{H}_1\), \(\vec{E}_2\) and \(\vec{H}_2\) in the local coordinate system \((n, t, z)\).

2.2. Integral Equations (IEs)

According to the Huygens principle, the fields scattered by the metasurface outside/inside the metasurface enclosure are the convolution of the equivalent electric and magnetic polarization currents \(\vec{J}_{e,m}(\rho)\) with the dyadic Green function of the corresponding medium \(\bar{F}_{1,2}(\rho, \rho')\) as [8]

\[
\bar{F}_l(\rho) = \oint \left( ik_l \eta_l \bar{G}_l(\rho') \cdot \vec{J}_e(\rho') - \vec{J}_l(\rho') \cdot \vec{J}_m(\rho') \right) d\ell', \tag{3}
\]

where \(l = 1, 2\) is the medium number and \(\bar{F}_l(\rho, \rho') = \nabla \times \bar{G}_l\). If the source is in region 1, then \(\bar{F}_1^e = \bar{F}_1 - \bar{F}_2\) and \(\bar{F}_2^e = \bar{F}_2\), where \(\bar{F}_1^e\) and \(\bar{F}_2^e\) are the total electric fields in regions 1 and 2, respectively, and \(\bar{F}_1\) is the incident field, all in the global coordinate system \((x, y, z)\). Using duality, similar IEs exist for the total magnetic fields, \(\bar{H}_1^e\) and \(\bar{H}_2^e\).

We want to express global coordinate system electric and magnetic polarization currents \(\vec{J}_{e,m}(\rho)\) in terms of the four unknown vectors \(\vec{E}_1, \vec{H}_1, \vec{E}_2\) and \(\vec{H}_2\), expressed...
in the local coordinate system. First, we express the global-
system electric current densities \( \mathbf{j}_{\text{el}}(\mathbf{p}) \) in terms of local-system electric currents \( \mathbf{j}_{\text{el}} \) as \( \mathbf{j}_{\text{el}}(\mathbf{p}) = \mathbf{T}(\mathbf{p}) \cdot \mathbf{j}_{\text{el}} \) with

\[
\mathbf{T}(\mathbf{p}) = \begin{pmatrix}
\hat{x} \cdot \hat{t} & \hat{y} \cdot \hat{t} & 0 \\
0 & 0 & 1
\end{pmatrix}.
\]

Second, we express the local-system current densities in terms of local-system magnetic tangential fields as \( \mathbf{j}_{\text{el}} = \hat{n} \times \mathbf{H}_{\text{el}} = \mathbf{H}_{\text{el}} = \mathbf{N} \cdot \mathbf{H}_{\text{el}} \), where \( \mathbf{N} \) is the 2 by 2 matrix \([0, -1; 1, 0]\). As a result, we have \( \mathbf{j}_{\text{el}}(\mathbf{p}) = \pm \mathbf{T}(\mathbf{p}) \cdot \mathbf{N} \cdot \mathbf{H}_{\text{el}} \). Similarly, \( \mathbf{j}_{\text{el}}(\mathbf{p}) = \pm \mathbf{T}(\mathbf{p}) \cdot \mathbf{N} \cdot \mathbf{E}_{\text{el}} \).
