Now, upon multiplying both sides of (3) by \( \mathbf{T}^\dagger \), we obtain the electric fields in the local coordinate systems [e.g., \( \mathbf{E}_{\text{el}} = \mathbf{T}^\dagger (\mathbf{p}) \cdot \mathbf{E}_{\text{el}}(\mathbf{p}) \)]. This way, Eqs. (3) and their counterparts for the magnetic fields are all given in terms of the tangential fields \( \mathbf{H}_{\text{el}}, \mathbf{E}_{\text{el}}, \mathbf{H}_{\text{el}} \), and \( \mathbf{E}_{\text{el}} \). We find \( E_{x1} - E_{x2} \) and \( E_{x2} \) and \( H_{x1} - H_{x2} \) and \( H_{x2} \) from Eqs. (3) and their counterparts for the magnetic fields, as the four solutions of the four scalar (or two vector) integral equations.

### 2.3. Combined GSTCs-IEs/MoM

Combining the two pairs of vector equations given by the GSTCs (1) and IEs (3) forms a system of four equations in four unknowns, the tangential fields [8]. Once they are determined, the IEs provide the fields everywhere in space.

### 3. Application: Penetrable Cloaking

#### 3.1. Bianisotropic Loss/Gain Less Metasurface

Let us assume that a TE\(_2\) plane wave (i.e., \( \mathbf{H}_{\text{el}} = e^{i k z} / \eta_1 \)) is illuminating the object. The reciprocal, passive, and lossless metasurface [9] has nonzero purely real \( \chi^{\text{ee}} \) and \( \chi^{\text{mm}} \), and purely imaginary \( \chi^{\text{zm}} \), given by

\[
\chi^{\text{ee}} = A t_2^2 \sin \alpha, \quad \chi^{\text{tt}} = B \sin \alpha, \quad \chi^{\text{zm}} = \frac{iz t_2}{\chi^{\text{mm}}},
\]

where \( \alpha = (k_1 - k_2) x, A = 2 T / (k_0 D \eta_1), B = A R^{2} / \eta_1 \eta_2, T = \sqrt{\eta_2 / \eta_1}, D = t_y / (1 + (\eta_1 \eta_2) / (2 \sqrt{\eta_1 \eta_2}) \cos \alpha), \) and \( t_y \) is the y-component of the tangential unit vector \( \hat{t} \).

#### 3.2. Numerical Results

We illustrate a metasurface-coated elliptical cylinder with major and minor axes \( 2a / \lambda_2 = 4 \) and \( 2b / \lambda_2 = 2 \), and non-magnetic media with \( \varepsilon_1 = 1 \) and \( \varepsilon_2 = 4 \). Figs. 2(a)-(c) show the synthesized susceptibilities \( \chi^{\text{ee}}, \chi^{\text{zm}}, \) and \( \chi^{\text{zm}} \). Inserting these susceptibilities into the IEs provides the magnetic fields shown in Fig. 2(d), exhibiting the expected perfectly unperturbed phase fronts.

Abstract

We study the scattering of waves by a single row of resonant inclusions, of the Mie type. An effective model based on matched asymptotic analyzed is used to account for the small thickness of the array. Hence, instead of the effective bulk parameters (permittivity and permeabiltiy), we end up with interface parameters entering in jump conditions for the electromagnetic fields; among these parameters, one is frequency dependent and encapsulates the resonant behavior of the inclusions. Our effective model is validated by comparison with results of full wave calculations.

1. Introduction

Starting in the 1990’s with the pioneering work of [1] in the context of elasticity, resonant structures with subwavelength unit cells have been proposed in the context of electromagnetism [2], and in a unified mathematical context [3]. In this case, the resonances are attributable to an inclusion placed in the unit cell and presenting a high contrast in its material properties with respect to the surrounding matrix. These resonances often referred to as Mie resonances occur at frequencies producing a wavelength in the inclusion comparable to the inclusion size (and this size is much smaller than the incident wavelength). The ability of these so-called locally resonant structures to forbid the wave propagation has been exhibited and the forbidden band gaps have been interpreted in terms of an effective negative parameter being the mass density in elasticity and the permeability in electromagnetism. Since then, locally resonant materials have been intensively studied for applications including the design of efficient wave shields, see e.g. [3] or absorbers of small thicknesses, see e.g. [4].

Motivated by the design of compact metamaterial devices and following the intuitive argument that each local resonator vibrates almost like an independent unit, structures involving a single row of resonators or few rows have been thought, see e.g. [5]. In this case, interrogating the bulk response of the device becomes questionable. Indeed, when the number of cells is too small, the metamaterial device is dominated by boundary layer effects and the response of its bulk, in terms of effective parameters, is not pertinent anymore; the failure of the effective medium theories for thick structures has been illustrated in [6]. Here, we extend these works to the case of an array composed of a single row of locally resonant inclusions (Fig. 1).

2. The actual and the effective problems

We consider transverse electric polarized waves propagating in the air and interacting with a row of inclusions with relative permittivity $\varepsilon_i$ and permeability $\mu_i$ (and we set for the air $\varepsilon = \mu = 1$). In the case where $\varepsilon_i \mu_i \gg 1$, the wavelength inside the inclusions is much smaller than in the air, and resonances of the Mie type are possible. In this case, asymptotic analysis can be conducted which result in an effective interface model, see [7], where the array of resonant inclusions are replaced by jump conditions of the form

$$\begin{align*}
[\varepsilon \mathbf{E}]_e &= hB \overline{\partial_y \mathbf{E}}, \\
[\partial_y \mathbf{E}]_e &= hS \overline{\partial_y \mathbf{E}} + hC \partial_{xx} \mathbf{E} - hD(k) k^2 \mathbf{E},
\end{align*}$$

(1)

where we defined, for any field $f$, $[f]_e \equiv f^+ - f^-$ and $\overline{f} \equiv (f^+ + f^-)/2$, with $f^\pm \equiv f(x, \pm e/2)$. The effective parameters $(B, C, S)$ depend only on the geometry of the inclusions while $D(k)$ has an additional dependence on the frequency and it is the parameter which encapsulates the possible resonances of the Mie type. For instance, for rectangular shape of inclusion, as we shall consider in the numerical example, we have $S = \frac{\varepsilon}{\varepsilon_i} \left(1 - \varphi\right)$, $B = \frac{\varepsilon_i}{\varepsilon} \left[\frac{2}{\pi} \log \left(\cot \left(\frac{\pi \varphi}{2}\right)\right)\right]$, $C \approx \frac{\pi}{8} \left(1 - \varphi^2\right)^2 \left(1 - e^{-\frac{\pi \varphi}{\pi \varphi + \varphi}}\right)$ and

$$D(k) = \frac{\varepsilon_i}{\varepsilon} \left[\frac{1 - \sum_n a_n^2 k_n^2}{k^2 - k_{in}^2}\right],$$

(2)

with for $n = (n_1, n_2)$, $k_n^2 = \left(\frac{n_1 \pi}{h}\right)^2 + \left(\frac{n_2 \pi}{h}\right)^2$ the wavenumbers at the resonances and $a_n = \frac{\varepsilon_i}{\pi^2 n_1 n_2}$.
3. Fano resonances

In our homogenized problem, the region $|y| < e/2$ is disregarded and the wavefield satisfies (1) for $|y| > e/2$; a solution of this problem for an incident plane wave at oblique incidence $\theta$ reads

$$E = \begin{cases} e^{ik(y+e/2)\cos\theta} + Re^{-ik(y+e/2)\cos\theta} e^{ikx\sin\theta}, \\ T e^{ik(y-e/2)\cos\theta} e^{ikx\sin\theta}, \end{cases}$$

for $y < -1/2$ and $y > e/2$ respectively. Next, applying the jump conditions (1) yields the scattering coefficient

$$R = -\frac{1}{2} \left( \frac{z_1}{z_1^2} - \frac{z_2}{z_2^2} \right), \quad T = \frac{1}{2} \left( \frac{z_1}{z_1^2} + \frac{z_2}{z_2^2} \right),$$

where $z^*$ denotes the complex conjugate of $z$.

We report in Fig. 2 the variations of the reflection coefficients against the dimensionless frequency $kh$, $R^{\text{num}}$ being computed numerically and $R$ from (4) (the incidence is $\theta = 45^\circ$). In the range $kh \in [0, 1]$, the first monopolar resonance for $n = (1, 1)$ in (2) is visible (it occurs for $kh = 8.9$ whence $kh \approx 0.9$, resulting in a wavelength within the inclusions being about half the inclusion length). The agreement between $R^{\text{num}}$ and its homogenized counterpart $R$ is good, about 2% and this accuracy is the same for any incidence $\theta$ up the grazing incidence (results not reported). The resonance of the inclusions produces sharp variations of the reflection with a typical Fano resonance curve characterized by a perfect transmission followed by a perfect reflection. Results including the attenuation due to losses in the dielectric will be presented, with the same accuracy of the effective model to reproduce the scattering properties in the actual problem.

4. Concluding remarks

There are at least two natural extensions of the present study that we shall discuss. We have considered waves in a binary structures but the present work can be extended to ternary structure, as proposed in [8]. This extension may be of particular interest when locally resonant materials are considered in the acoustic case; as previously said, this is obtained in practice considering binary or ternary structures mixing fluids and elastic materials, thus for which the conversions between shear and longitudinal waves have to be accounted for. We believe that this is the key point to properly describe the negative index material reported in this context [9].

The second extension is technically much demanding. Our result has a serious limitation, already mentioned in [2]. The analysis holds for resonances with non zero mean value (namely, $n_1$ and $n_2$ odd in (2)). Although these resonances have a higher quality factor and thus are much more sensitive to losses, the accuracy of the homogenized solution would be enhanced if one is able to account for them. This requires to develop the model up to higher order and this is not incremental.

Abstract

We combine gold grating with vertical cavity surface emitting lasers (VCSELs) to realize a prototype of miniaturized chemical/biosensor. The advantage of such chips include compact size, low cost and low power consumption, long life time, stable performance, easy to make array and mult-flux test, and label-free sensing. The finite difference time domain method is employed to model the transmission signal from the chips. It is believed that the biosensor chip has potential applications in health care, clinical diagnostics, and environmental monitoring.

1. Introduction

Vertical cavity surface emitting lasers (VCSELs) are key devices in optical fiber communication systems and 3D sensing in iPhone due to their important characteristics such as high modulation bandwidth, circular beam shape, small divergence angles, low power consumption, easy to integrate and make arrays, as well as high reproducibility in fabrication. To obtain a new type high sensitivity and high stability biochemical sensors, the gold grating have been integrated on the top surface of the VCSEL to realize the integration of the sensing material and the light source and then the sensors have both the advantages of the VCSEL and gold grating. Three-dimensional finite difference time domain (FDTD) algorithm simulations are utilized to explore their transmission spectra and steady-state field intensity distributions of the sensors to calculate the sensitivity. The design sensitivity of the sensors has been reached 10⁶ nW/RIU and the VCSELs have been produced by using normal semiconductor processes. After that, the gold grating was fabricated on the top surface of the VCSELs by using the focus ion beam (FIB). The sensing performances of the sensor were characterized via transmission light output power with different refractive index samples. The exosome interaction experiment was also adopted to verify the sensitivity of the surface binding reaction. Through four steps modification, the exosome specificity detection has been achieved and the exosome has been found very well combined on the gold nanoslit array. It is believed that the biosensor chip has potential applications in health care, clinical diagnostics, environmental monitoring, especially, cancer biomarker testing.

2. Design and fabrication

We first describe the fabrication of biosensor chips shows in Figure 1. A VCSEL epitaxial structure with 850 nm emission wavelength has been grown on an n-GaAs substrate. It contains 22.5-pairs of p-type top DBRs and 34.5-pairs of n-type bottom DBRs. Both DBRs consist of Al₀.₉Ga₀.₁As/Al₀.₁₂Ga₀.₈₈As except for a 30-nm Al₀.₉₈Ga₀.₀₂As oxidation layer inserted in the bottom of top DBRs. The mesas were formed by SiCl₄/Ar/Cl₂ inductively coupled plasma reaction ion etching (ICP-RIE) down to the active region, using SiO₂ as the etching mask. Then the Al₀.₉₈Ga₀.₀₂As layer was selectively oxidized to form the needed shape oxide aperture. After that, top ohmic (Ti/Au) ring contacts were patterned and bottom ohmic (Au/Ge/Ni/Au) contacts were formed. The devices were then annealed using rapid thermal annealing at 430 °C for 35 sec. After that, a chip with 8×8 VCSEL array has been produced and the size of the chip is 1cm×1cm. And then a 50 nm-thick gold film was deposited on the output window of the VCSEL. To isolate the chip and the metal film, a 500nm thick SiO₂ was inserted between the chip and the metal film. We employed focused ion-beam milling to fabricate gold grating structures on the metal film and the period and width of the gratings are shown in the table1, respectively. To test the property of the sensing chip and inject the medium, a microchannel was fabricated by using micro-replication technology. After that the PDMS...
layers with microchannel and VCSEL with Au nanoslit array are bonded together and the SPR biosensor chip has been successful fabricated.

![Diagram](image2.png)

Figure 3. Gold grating transmission spectra for different medium refractive index. The Grating period is 570 nm, both the thickness and the slit width of the grating are 50nm.

![Diagram](image3.png)

Figure 4. The sensitivity curve with different refractive index samples as air.

3. Results and discussion

In current biosensor architecture, the wavelength of the incident beam is fixed at 850 nm, and the beam is incident on the plasmonic aperture approximately normal to the surface. Consequently, we employ the intensity modulation principle to measure the strength of the coupling between the incident light wave and an SP mode at a single wavelength and a fixed narrow range of incident angles [19]. The intensity of transmitted light wave serves as the sensor output. Here we employ liquids with different refractive indices to demonstrate the sensitivity of the plasmonic VCSEL structure. The refractive index was varied from 1 to 1.5, as shown in Figure 2 and 3. There one signal channel to observe the surface property changes is transmission signal channel. When the output window is covered by a metal grating, the transmission properties can be tuned through the change of the refractive index on top of the nanostructures. the output beam will be monitored by the photodiode. When the signal changes because of the refractive index change at the window surface, we observe a change in signal from the photodiode. In this case, a chemical/biosensor function could be achieved by observing the transmission light signal. The sensing performances of the sensor were characterized via transmission light output power in four kinds of refractive index samples shows in Figure 4. The highest sensitivity reaches $4 \times 10^6$ nW/RIU.

![Diagram](image4.png)

Figure 5. The four steps Biomolecule binding light output power of the biosensor chip, and the insert image is the SEM of the exosome.

4. Conclusions

A intensity detection sensor chip based on VCSEL was proposed. In the sensing chip VCSELs and gold grating are integrated together. Three-dimensional finite difference time domain algorithm simulations are utilized to explore their transmission spectra to calculate the sensitivity of Au grating. The simulation results are in agreement with the experiment. The highest sensitivity of the VCSEL based SPR sensor reaches $4 \times 10^6$ nW/. The exosome specificity detection has been achieved and the exosome has been found very well combined on the gold grating. The biosensor chip has the merits of VCSELs and may have potential applications in health care, clinical diagnostics, environmental monitoring, and cancer biomarker testing.

Abstract

Beam steering devices have wide applications in both military and civil fields. The ultimate goal for such devices is to reduce their size, weight, and power consumption. A novel electrically controlled micro beam-steering chip based on coherently coupled VCSEL array integrated with liquid crystal optical phased array was achieved. One-dimensional beam steering was successfully realized. Such a highly integrated beam steering system has high compactness, small size, simple packaging, which could be transformative for various sensing and imaging applications.

1. Introduction

Beam steering devices are essential for a variety of applications in both military and civil fields such as LiDAR, communication, sensing and imaging. The ultimate goal for such devices is to reduce their size, weight, and power consumption, so that they can be mounted on, e.g. drones and autonomous cars [1]. However, most of the reported beam steering devices have the problem that the laser source in the device is spatially separate from the phase shifter [2-5], e.g. optical phased array (OPA), with optics, waveguide, or optical fiber in between, resulting in difficult miniaturization, large size, complex packaging, and low coupling efficiency.

In this paper, we propose a novel electrically controlled integrated beam steering chip based on in-phase coherently coupled VCSEL array (CCVA) and liquid crystal OPA. First, we use the simple and low-cost proton implantation technology to fabricate large-area in-phase CCVAs with uniform near-field to act as the coherent laser source for the chip. Then, taking advantage of the planar structure of the CCVA, the liquid crystal OPA is directly integrated on the CCVA by conventional process. The coherent light generated by the in-phase CCVA is uniformly and normally incident into the OPA without going through any optical elements, fibers, or waveguides, leading to high compactness, small size, simple packaging, and high coupling efficiency. One dimensional beam steering with a field of view of 2.19° has been realized. Larger deflection angle and two dimensional beam steering can be achieved by proper design and optimization of the chip’s structure. Such a highly integrated beam steering chip has high compactness, small size, simple packaging, and high coupling efficiency, which could be transformative for various LiDAR, communication, sensing and imaging, and many other applications.

2. Device design and fabrication

A schematic structure of the beam steering chip based on a 4×4 square CCVA is shown in Fig. 1. Fig. 1 (a) is the three-dimensional schematic sketch of the chip, and Fig. 1 (b) is the cross-section view of the chip along the A-A’ direction in Fig. 1 (a).

![Figure 1: (a) Schematic structure of the beam steering chip based on a 4×4 square CCVA. (b) The cross-section view of the chip along the A-A’ direction.](image-url)

The chip consist of a 4×4 VCSEL array and a 1×4 LCOPA. The element dimension of the VCSEL array is 6 μm×6 μm and the inter-element spacing is chosen as 8 μm to achieve phase-locking among elements [6]. Proton implantation was performed to define the VCSEL array elements. An 800 nm-thick SiO2 layer was deposited on the surface of the VCSEL array to realize electrical isolation between the VCSEL array and the LCOPA. Then, four ITO
By proper design and optimization of the chip’s structure, the LCOPA is proposed, which has successfully realized one-dimensional beam steering. The laser source is directly integrated with the LCOPA, leading to high coupling efficiency, high compactness, and simple packaging. Thus, the chip can meet the trend of integration and miniaturization of photoelectric systems.

Modelling of Nonlinear Metasurfaces: Second-Harmonic Generation and Kerr Effect

Karim Achouri$^1$, and Olivier J. F. Martin$^1$

Abstract

We present a nonlinear metasurface modelling framework based on the generalized sheet transition conditions (GSTC). It may be used to synthesize or analyse the scattering behavior of second- and third-order metasurfaces. We specifically study second-harmonic generation (SHG) and the Kerr effect. This framework is formulated in the frequency-domain and provides the relationships between the metasurface linear and nonlinear susceptibilities and the fields interacting with it.

1. Introduction

The emergence of (linear) metasurfaces along with the progress of nanofabrication technologies have paved the way for ever more elaborate wave-manipulation operations and hence complex metamaterial structures. Following these advances, nonlinear metasurfaces have naturally appeared as a logical outgrowth of conventional linear metasurfaces. However, the tremendous increase in degrees of freedom provided by nonlinear responses compared to linear ones, requires an adequate set of theoretical tools to efficiently model these structures. The purpose of this work is hence to develop a general modelling framework for second- and third-order nonlinear metasurfaces, which takes into account all possible fields interactions.

2. Modelling of Nonlinear Metasurfaces

A metasurface, whether it is linear or nonlinear, may generally be modelled as a zero-thickness homogeneous sheet consisting of electric and magnetic polarizations. Such a sheet may produce discontinuities in the electromagnetic field, which are effectively modelled by the generalized sheet transition conditions (GSTC) [1–5] for a metasurface lying in the $xy$-plane at $z = 0$, the GSTC are given by

$$z \times \Delta \mathbf{H} = \frac{\partial}{\partial t} \mathbf{P} - z \times \nabla M_z,$$  

(1a)

$$z \times \Delta \mathbf{E} = -\mu_0 \frac{\partial}{\partial t} \mathbf{M} - \frac{1}{\epsilon_0} z \times \nabla P_z,$$  

(1b)

where $\mathbf{P}$ and $\mathbf{M}$ are electric and magnetic polarization densities, respectively, and the operator $\Delta$ refers to the difference of the fields on both sides of the metasurface.

For the past few years, the GSTC have been extensively used to model linear biaxial isotropic metasurfaces [3–5] but they are also perfectly suited for nonlinear operations, as demonstrated in [6–9]. In this work, we present how the frequency-domain GSTC may be applied to model second-harmonic generation (SHG) and the third-order nonlinear Kerr effect.

2.1. Second-Harmonic Generation

Second-harmonic generation is a second-order nonlinear process, where the nonlinear medium scatters light with a frequency that is twice that of the exciting pump [10]. In the case of nonlinear metasurfaces, this effect is typically modelled by assuming that the pump is not depleted [6–9]. Accordingly, we may treat the pump as a constant source of power, which excites nonlinear responses on the metasurface. The frequency-domain GSTC, which thus apply to SHG read

$$z \times \Delta \mathbf{H}_{2\omega} = j2\omega \mathbf{P}_{2\omega} - z \times \nabla M_{2\omega},$$  

(2a)

$$z \times \Delta \mathbf{E}_{2\omega} = -j2\omega \mu_0 \mathbf{M}_{2\omega} - \frac{1}{\epsilon_0} z \times \nabla P_{2\omega},$$  

(2b)

where the superscripts $2\omega$ refers to second-harmonic light with $\omega$ being the frequency of the pump. The polarization densities may be expressed as

$$\mathbf{P}_{2\omega} = \mathbf{P}_{2\omega}^{\text{lin}} + \mathbf{P}_{2\omega}^{\text{nl}},$$  

(3a)

$$\mathbf{M}_{2\omega} = \mathbf{M}_{2\omega}^{\text{lin}} + \mathbf{M}_{2\omega}^{\text{nl}},$$  

(3b)

where the linear components (“lin”), which read

$$\mathbf{P}_{2\omega}^{\text{lin}} = \epsilon_0 \bar{\chi}_{ee} \mathbf{E}_{2\omega} + \epsilon_0 \nu_0 \bar{\chi}_{em} \mathbf{H}_{2\omega},$$  

(4a)

$$\mathbf{M}_{2\omega}^{\text{lin}} = \bar{\chi}_{mmm} \mathbf{H}_{2\omega} + \frac{1}{\nu_0} \bar{\chi}_{me} \mathbf{E}_{2\omega},$$  

(4b)

correspond to the interactions of the light at $2\omega$ with the metasurface, while the nonlinear components (“nl”), which are given by

$$\mathbf{P}_{2\omega}^{\text{nl}} = \frac{1}{2} \epsilon_0 \nu_0 \bar{\chi}_{ee} \mathbf{E}_{2\omega} \mathbf{E}_{2\omega} + \nu_0 \bar{\chi}_{em} \mathbf{E}_{2\omega} \mathbf{H}_{2\omega},$$  

(5a)

$$\mathbf{M}_{2\omega}^{\text{nl}} = \frac{1}{2} \nu_0 \bar{\chi}_{mmm} \mathbf{H}_{2\omega} \mathbf{H}_{2\omega} + \bar{\chi}_{mem} \mathbf{E}_{2\omega} \mathbf{H}_{2\omega} + \frac{1}{\nu_0} \bar{\chi}_{me} \mathbf{E}_{2\omega} \mathbf{E}_{2\omega},$$  

(5b)
represent the nonlinear sources excited by the pump. In these expressions, the subscript “av” refers to the average of the fields on both sides of the metasurface and $\eta_0$ is the vacuum impedance. In (4), the tensors $\bar{\chi}$ represent linear susceptibilities evaluated at $2\omega$, while in (5) they represent nonlinear susceptibilities evaluated at $\omega$. To be very general, these expressions take into account all possible combinations of electric/magnetic excitations and responses.

Combining (3) to (5) into (1), specifying the fields to be that of normally propagating plane waves, and solving for the forward (+$z$) and backward (−$z$) second-harmonic waves scattered by the metasurface yields

$$E_{bw}^{2\omega} = \frac{1}{\epsilon_0} \bar{C}_1 \cdot \bar{P}_{nl}^{2\omega} + \eta_0 \bar{C}_2 \cdot \bar{P}_{nl}^{2\omega}, \quad (6a)$$
$$E_{fw}^{2\omega} = \frac{1}{\epsilon_0} \bar{C}_3 \cdot \bar{P}_{nl}^{2\omega} - \eta_0 \bar{C}_4 \cdot \bar{P}_{nl}^{2\omega}, \quad (6b)$$

where the tensors $\bar{C}$ contain the linear susceptibilities and are provided in [9]. Relations (6) may either be used to homogenize and thus retrieve the nonlinear susceptibilities of a metasurface, or to predict the second-harmonic light scatter by a nonlinear metasurface with known susceptibilities.

2.2. Kerr Effect

The Kerr effect is a third-order nonlinear process, which typically occurs in centrosymmetric structures and where the response of the medium is modulated proportionally to the field intensity [10]. Here, we restrict our attention to the case of the AC Kerr effect, where the modulation of the medium is due to the light beam itself and not an external DC field. We also ignore the generation of third-harmonic light and thus consider only the interactions between the metasurface and the light at frequency $\omega$. This transforms (1) into

$$z \times \Delta H = j\omega \mu_0 P - z \times \nabla M_z, \quad (7a)$$
$$z \times \Delta E = -j\omega \mu_0 M - \frac{1}{\epsilon_0} z \times \nabla P_z, \quad (7b)$$

where the polarizations may be expressed in a similar fashion as in (3) except that all terms are evaluated at the frequency $\omega$. From a general perspective, the nonlinear polarizations are now given by

$$P_{nl}^{\omega} = \frac{3}{4} \epsilon_0 \bar{\chi}_{eeem} : E_{av}^{\omega} E_{av}^{\omega} H_{av}^{\omega} + \eta_0 \bar{\chi}_{eeem} : E_{av}^{\omega} E_{av}^{\omega} H_{av}^{\omega} + \eta_0 \bar{\chi}_{eeem} : E_{av}^{\omega} E_{av}^{\omega} H_{av}^{\omega} + \bar{\chi}_{eeem} : E_{av}^{\omega} E_{av}^{\omega} H_{av}^{\omega}, \quad (8a)$$

$$M_{nl}^{\omega} = \frac{3}{4} \eta_0 \bar{\chi}_{mmmm} : H_{av}^{\omega} H_{av}^{\omega} H_{av}^{\omega} + \epsilon_0 \bar{\chi}_{mmmm} : H_{av}^{\omega} H_{av}^{\omega} H_{av}^{\omega} + \frac{1}{\epsilon_0} \bar{\chi}_{mmmm} : E_{av}^{\omega} E_{av}^{\omega} E_{av}^{\omega} \quad (8b)$$

where the superscripts $-\omega$ indicate that we consider a negative frequency to satisfy the condition that the nonlinear polarizations be at frequency $\omega$. Since the fields must be real, we have that $E(-\omega) = E^*(\omega)$ [10]. This implies that the polarizations (8), of a metasurface exhibiting low loss and low reflection, may essentially be expressed in terms of the incident light intensity. For instance, an isotropic nonlinear metasurface illuminated with a normally incident x-polarized plane wave would exhibit the nonlinear polarizations

$$P_{x,av}^{\omega} = \frac{3}{2} \eta_0 \epsilon_0 \left( \chi_{eeem} + \chi_{eeem} + \chi_{mmmm} + \chi_{mmmm} \right) E_{x,av}^{\omega}, \quad (9a)$$
$$M_{y,av}^{\omega} = \frac{3}{2} \eta_0 \left( \chi_{mmmm} + \chi_{mmmm} + \chi_{meem} + \chi_{meem} \right) H_{y,av}^{\omega}, \quad (9b)$$

where we have used $E_{x,av} = \eta_0 H_{y,av}$ and $E_{x,av} H_{y,av} = 2I$. From these expressions, one may easily obtain the transmitted field in terms of the susceptibilities following similar procedures as those described in [5, 9].

Different Photonic Structures via Inverse-Design Algorithm

Döne Yılmaz, Mediya Tutgun, Ahmet M. Alpkılıç, Yusuf A. Yılmaz and Hamza Kurt

Department of Electrical and Electronics Engineering,
TOBB University of Economics and Technology, Ankara, Turkey

Abstract
In this work, we present various photonic structures generated by the inverse design algorithm. The computational method is used to obtain various photonic phenomena such as negative refraction, optical filtering and wavelength selectivity. The high performances of the designed structures reveal that the objective-first inverse-design algorithm is an effective and successful computational design approach for the realization of the photonic devices.

Keywords: Objective-first, inverse-design algorithm, optical notch filters, negative refraction, wavelength demultiplexer.

1. Introduction
In the design of photonic medium, the algorithms have recently attracted a lot of interest [1,2]. Inverse design algorithms enable the formation of the spatially varied structure in an easier way without much depending on intuition. Considering many parameters such as efficiency and functionality in device performances, a more comprehensive and controlled design method rather than intuitive method has been needed. Therefore, the inverse design method, also known as objective-first method, has emerged in the literature [3]. The objective-first inverse design algorithm is an effective optimization method that has been successfully applied to many linear and nonlinear photonic devices. In this design methodology, performance metrics of desired electromagnetic fields that can be revealed by targeted nanophotonic devices are first defined as the objective parameters in the cost function, then the dielectric distribution of the structure is iteratively obtained.

2. The Applications of Algorithm
The negative index medium, optical notch filter and wavelength demultiplexer (WDM) are achieved by the nonconventional design manner. The design details and results are presented in the following sections.

2.1. Negative Refraction
Anomalous light behaviors in photonic mediums such as bending, confining, and backward propagation provide different novel applications. The negative refraction as one of the peculiar properties of light propagation is practical to design effective super lens, prism and high-pass filters [4]. In contrast to conventional mediums, the incident and refracted electromagnetic wave are on the same side of the interface normal in the negative index mediums which means the reversion of the Snell’s law. In literature, the negative refraction has been achieved by using metamaterials and photonic crystals [4-5]. In this part of the study, this extraordinary refraction effect is revealed by designing disarranged medium with the computational method.

![Figure 1](image)

Figure 1: (a) The dielectric constant distribution of the design. (b) The electromagnetic response of the structure at the wavelength of $\lambda=750$ nm and incident angle of $\theta_{inc}=60^\circ$.

The photonic medium with dimensions of $1.33 \, \mu m \times 3.55 \, \mu m$ given in Fig. 1(a) has been designed at the wavelength of $\lambda=750$ nm for the transverse-electric (TE) polarization owing to additional constraints in the inverse-design algorithm. The performance of the structure has been evaluated through the finite-difference time-domain (FDTD) method. When the properly adjusted oblique Gaussian beam is incident to the interface, the negative refraction phenomenon has arisen in the dielectric structure. Figure 1(b) shows the magnetic field distribution of the propagating wave in the inhomogeneous photonic medium. While the structure routes the wave in the oblique direction, the light conserves its wavefronts. In addition, the output light direction at the structure termination is the same as the route of the incidence in accordance with the Snell’s law. As a result, the negative refraction phenomenon is realized at the visible range by using the objective-first algorithm.
2.2. Notch Filter Design

The photonic notch filters are used in many applications like broadband wireless communications and satellite systems [6]. For the first time in the literature, on-chip photonic notch filter design is performed by effective manipulation of the objective-first algorithm. The Notch filter is designed in the visible range to drop frequencies around 545.077 THz. The dielectric constant distribution of the Notch filter is shown as Fig. 2(a) with dimensions of 2.32 µm x 1.40 µm. As shown in the figure, the frequency range that is intended to be blocked is transferred to the defined discharge port below the design area. The normalized transmission graph of the design is presented in Fig. 2(b). As can be seen in the figure, at the targeted point the attenuation of almost -20 dB is provided. The frequency at which the 50% attenuation is achieved (-3 dB) is measured as 32.4 GHz. The proposed optical Notch filter with great performance is a good candidate to be utilized in integrated photonic circuits.

2.3. Wavelength Demultiplexer (WDM)

WDM designs with a channel configuration of 1×4 are presented in Fig. 3. The designs are elongated along the propagation direction of the added channels, resulting in a footprint of 2.80 µm × 4.60 µm. A continuous distribution of 1×4 T-junction WDM is shown in Fig. 3(a). Figure 3(b) shows transmissions in the range [1.20—1.70] µm, where the design possesses ultimately yields high transmission efficiencies at the specified wavelengths: -0.57 dB at 1.31 µm, -0.71 dB at 1.39 µm (E-band), -1.25 dB at 1.47 µm (S-band), and -2.11 dB at 1.55 µm. The dielectric distribution of the binary structure resulting from the level-set method for the structure in Fig. 3(a) is shown in Fig. 3(c), and the normalized transmission efficiencies are given in Fig. 3(d). The transmission efficiencies of the level-set binary structure presented in Fig. 3(d) are -0.92 dB at 1.31 µm, -1.65 dB at 1.39 µm, -2.07 dB at 1.47 µm, and -2.23 dB at 1.55 µm. The resulting devices exhibited ultra-high transmission, small footprint, low crosstalk, and relatively narrow channel spacing, all of which are very important for a variety of applications in integrated photonics.

3. Conclusions

We have demonstrated that it is possible to obtain the photonic device applications in the complex media via the objective-first inverse algorithm. Besides being compact, the proposed devices work with high performance at the design spectrum. Since the algorithm provides unconventional design capability with an acceptable simulation time, it has great potential to be used in new generation designs in the future.

Inverse Design and Optimization along Machine Learning for Metasurfaces

Samad Jafar-Zanjani¹, and Hossein Mosallaei¹*,

¹ Metamaterials Lab, Department of ECE, Northeastern University, Boston, Massachusetts 02115, USA
*corresponding author, E-mail: hosseinnm@ece.neu.edu

Abstract

Despite many advantages, performance of the conventional optical metasurfaces is not yet satisfactory, in terms of their functionality, frequency and angular response, and efficiency, due to the limitations imposed by their constituent units of canonical shape. In this summary we propose more sophisticated geometries, such as binary-pattern unit-cells, along with adaptive genetic algorithmmulti-objective optimization, to overcome the limitations of the conventional metasurfaces and pave the way for efficient inverse design by machine learning algorithms.

1. Introduction

As optical metasurfaces become increasingly pervasive the expectations from them are becoming progressively complex[1, 2]. Metasurface building blocks (BBs) have been mostly limited thus far to nano-scatterers with canonical shapes. The limited number of structural parameters in conventional BBs do not support the growth rate of metasurfaces and limits them to mostly a single functionality with narrow frequency and angular response.

To overcome the mentioned limitations, one needs to choose more sophisticated BBs with increased structural degrees of freedom, such as binary pattern BBs. Here, we propose a powerful evolutionary optimization method, adaptive genetic algorithm (AGA)[4], to handle the inherent difficulties that arise in designing the binary-pattern metasurfaces. We also demonstrate that surplus data generated by the AGA technique can be employed by machine learning algorithms to facilitate efficient inverse design of metasurfaces.

2. Adaptive Genetic Algorithm

In the most general case, a multi-objective optimization problem can be expressed as an attempt to maximize a fitness function

$$\max_{\mathbf{p} \in \mathbb{R}} F(\mathbf{p})$$

(1)

where \(\mathbf{p} = (p_1, p_2, ..., p_n)\) is a vector representing the parameter space and the fitness function, \(F(\mathbf{p})\), can be represented as a weighted sum of the sub-objective functions:

$$F(\mathbf{p}) = W_1 \times f_1(\mathbf{p}) + W_2 \times f_2(\mathbf{p}) + ... + W_n \times f_n(\mathbf{p}).$$

(2)

In the AGA method we start with an initial set of weights \((W_i)'s\) in eq. 2, and employ the conventional genetic algorithm (GA)[3] to maximize the corresponding \(F(\mathbf{p})\). During the course of the optimization, if an objective update criterion is met, the fitness function is updated and the optimization proceeds until the stop criteria is satisfied.

3. Binary-Pattern Plasmonic Metasurface

As an example of the application of the AGA method, in this section we present the results of the optimization of a binary-pattern plasmonic metasurface, working at 120 THz. We have taken advantage of an in-house developed GPU-enabled FDTD solver for electromagnetic characterization of the metasurface. Unit-cell of the inverse-designed metasurface is illustrated in Fig. 1. Here, we optimize one quarter of the binary pattern with 10×10 pixels. The fitness function is considered as

$$F(\mathbf{p}) = W_2 \times \exp[-6.0 \times (\varphi(\mathbf{p}) - \varphi_{\text{target}})^2] + W_a \times \exp[-4.0 \times (1.0 - A(\mathbf{p}))^2]$$

(3)

In this application, the reflection phase is of extreme importance for achieving different functionalities, such as beam-steering and lensing. Therefore, in the AGA optimization, we first optimize the unit-cells to achieve sample phase levels from 0 to 2\(\pi\). In other words, initial weighting coefficients in eq. 3 are considered as \(W_2 = 1.0\) and \(W_a = 0.0\). Once an acceptable value for the initial fitness function has been achieved by GA optimization, we update the fitness function to include a small weight for the amplitude of the reflection, which is of lower priority compared to the reflec-

[Figure 1: Unit-cell of the optimized plasmonic metasurface. (a) Perspective, and (b) side views of the unit-cell. Parameters: \(h_1=100\ \text{nm}\), \(h_2=30\ \text{nm}\), \(h_3=30\ \text{nm}\), \(\Delta_p = 25\ \text{nm}\), \(b=25\ \text{nm}\), \(\Lambda = 550\ \text{nm}\) [4].]
tion phase, but, is crucial for improving the efficiency of the metasurface. More specifically, the weighting coefficients have been updated to \(W_\phi = 0.7\) and \(W_\alpha = 0.3\).

We further design a reflect-array consisting of the optimized BBs to bend a normally incident beam to an arbitrary direction at 120 THz. Figure 2 (a) depicts the 8×8 super-cell of the reflect-array. Reflection pattern of the reflect-array is also presented in Fig. 2, showing a beam very close to the targeted direction.

(a)  
(b)

![Reflection pattern of the designed metasurface](image)

Figure 2: (a) Designed super-cell of the metasurface to reflect a normally incident beam to \((\theta_0, \varphi_0) = (30^\circ, 45^\circ)\). Reflection pattern of the designed metasurface, showing a main-lobe very close to the targeted direction at \((\theta, \varphi) = (28.6^\circ, 45^\circ)\) [4].

In addition to presented application, AGA method has been successfully employed to tackle other complicated applications including: A dual-beam aperiodic leaky-wave antenna, which diffract TE and TM excitation waveguide modes to arbitrary directions, and A dual-band visible-transparent IR-emitting metasurface. These applications will be elaborated during the presentation.

4. GA Surplus Data and Neural Network Based Inverse Design

Evolutionary optimization methods provide a valuable dataset that can be employed to conceive an image of the solution domain. As an example, surplus GA data corresponding to the binary-pattern plasmonic metasurface in the previous section is illustrated in Fig. 3. A uniform amplitude of around 0.4 is achievable with reflection phase samples from 0 to \(2\pi\). Alternatively, one can choose to work with highest amplitude at each sample phase, for achieving highest possible reflection efficiency, at the price of some spurious side-lobes.

GA data can also be used to facilitate neural network based inverse design of metasurfaces. To demonstrate this concept, authors have recently proposed machine learning for efficient inverse design of an all-dielectric diffractive metagrating with parameterized units of arbitrary shape, defined by 16 radii values. A high-performance in-house developed RCWA solver is used to map the radii to the diffraction efficiencies (DEs) of the metagrating. 90,000 sample units in 8 categories have been solved to generate a diverse training dataset. A 3-layer artificial neural network (ANN) has been trained to yield a network function, which can mimic the response of the metagrating in much faster fashion than direct solution of the Maxwell’s equations. Taking advantage of the obtained network function, we have been able to inverse design the metagrating orders of magnitude faster than brute-force optimization.

5. Conclusions

We have demonstrated the AGA technique as a powerful multi-objective evolutionary optimization method for designing binary-pattern metasurfaces. Inverse design of a binary-pattern plasmonic reflect-array with high tolerance to fabrication imperfections have been presented as an application of the AGA technique. We have explored more applications that will be presented in the conference. Finally, we have shown that the surplus GA data, can give an intuitive image of the solutions domain, and be used in new-age algorithms, such as, machine learning.

Abstract

We present a numerical method allowing to solve efficiently the Maxwell system in the presence of many obstacles. Each obstacle is characterized by a scattering matrix written in an adapted basis. The scattered field is then represented by fictitious sources. This approach is mixed with a fast multiple algorithm in order to deal with several different obstacles.

1. Introduction

The recent advances in the field of metasurfaces [1], have led to an increasing interest in the numerical methods that can deal with a large number of different resonators arranged along periodic or aperiodic patterns. Several methods can be used to obtain the scattered field. Two main categories can be singled out: on one hand, those who use a modal expansion, such as multiple scattering methods or the Fourier Modal Method or on another hand, those who use a discretization in direct space (such as the FDTD or the FEM).

We propose here a mixed approach where the field scattered by one obstacle is obtained through any available method (boundary integral equation, finite volume, DDA...). Then, a modal basis adapted to the scatterer is obtained by solving for the eigenfunctions of the Laplace-Beltrami operator on the boundary of the scatterer. This allows to express the exterior Calderon operator and to represent the scattering matrix. The scattered field outside the obstacle has then an integral expression in terms of fictitious sources and can be used in a multiple scattering scheme.

2. Description of the method

The method used here to compute the field scattered by one obstacle is the DDA

2.1. Numerical computation of the scattering matrix

Let us consider an obstacle $\Omega$ that is connected and has a smooth boundary. It is characterized by its relative permittivity $\varepsilon$ (it needs not be constant inside $\Omega$).

Given an incident harmonic field $(E^i, H^i)$ with pulsation $\omega$, the field $(E^s, H^s)$ scattered by the obstacle can be computed by using the Discrete Dipole Approximation.
admits an integral representation involving \( m^s \) only by use of the exterior Calderón operator. In order to obtain an efficient representation of the scattering matrix, we need to be able to decompose the functions defined on the boundary of the obstacle as well as the Calderón operators. In the case of a sphere, a natural basis is that of the spherical harmonics \( Y^{lm}(\theta, \phi) \). These functions are eigenfunctions of the angular part of the Laplacian in spherical coordinates, which is nothing else than the Laplace-Beltrami operator on the sphere \([5]\). These functions can be generalized to any sufficiently obstacle with regular boundary precisely as eigenfunctions of the Laplace-Beltrami operator \(-\Delta_{\partial\Omega} Y_n = \lambda_n Y_n\). There are efficient numerical methods to compute these functions \([6]\). Given this basis, it is possible to obtain a basis for tangent fields to \( \Omega \). This is a generalization of the so-called vector harmonics

\[
Y_{1n} = (\lambda_n)^{-1/2} \text{curl}_{\partial\Omega} Y_n, \quad Y_{2n} = (\lambda_n)^{-1/2} \nabla_{\partial\Omega} Y_n.
\]

The set \( \{Y_{ln}, l = 1, 2, n = 1, \ldots\} \) form a (hilbertian) basis. This can be used to represent the tangential trace of the field in the form

\[
m^s = \sum_{ln} m^s_{ln} Y_{ln}, \quad m^i = \sum_{ln} m^i_{ln} Y_{ln}
\]

and the scattering matrix relates \((m^s_{ln})\) to \((m^i_{ln})\).

### 2.2. Several obstacles from a point of view of the multiple scattering

Now that we know how to characterize each object \( n \) by a scattering matrix \( S \), we put our interest in how we can solve a problem with several objects.

Dealing with the interaction between all the \( N \) objects directly represents an algorithm scaling as \( N^2 \). An algorithm \([7]\) called Multi-Level Fast Multipole Method (MLFMM) was developed to reduce the computational complexity.

This algorithm divides the entire domain that contains all of the scatterers into nested subdomains of cubic shape, until there is only one scatterer by subdomain. The interactions are then represented via a tree. In the lower branch of the tree, the scatterers interact directly with the other scatterers in the immediate neighborhood, whereas in the higher branches, the interactions are treated by means of multipoles.

Our approach is particularly suited to this algorithm since the field are represented by means of fictitious sources. The field scattered by a cluster of obstacles can be easily represented by fictitious sources situated on the boundary \( \Gamma \) of a domain comprising the cluster, once the field radiated by each obstacle is known. More precisely, given the tangential traces \( m^s_k \) for a collection of obstacle \( k = 1, \ldots, N \), there is a transfer operator \( T \) relating this traces to that on \( \Gamma \). The numerical representation of \( T \) involves the evaluation of the free space Green function on predetermined points, a calculation that can be easily pre-computed.

### 3. Conclusion

The proposed method allows to compute the field scattered by many, possibly different, scatterers in an efficient way since the electromagnetic behavior of each different scatterer can be pre-computed before solving the multiple scattering problem. This leads to efficient optimisation codes that usually require many iterations. It is to be noted that the present method does not assume any specific position for the scatterers. For instance, scatterers deposited on a surface or a plane can be considered.

Global Topology Optimization Networks (GLOnets) for Metasurface Design

Jonathan A Fan¹

¹Department of Electrical Engineering, Stanford University, Stanford, CA USA
E-mail: jonfan@stanford.edu

Abstract
I will introduce a new method for designing ultra-high efficiency metamaterials using global topology optimization networks (GLOnets). These networks combine deep generative neural networks with adjoint-based topology optimization to perform a global search and topology optimization within the design space. Importantly, these concepts utilize a population-based approach to optimize a distribution of device instances, which ensures that the full design space is properly sampled and vetted during network training. These hybrid algorithms that combine machine learning with physical calculations will set the stage for big data approaches to assist in defining the next generation of nano-based optical devices.

Fig. 1 GLOnets for metasurface design. (a) Architecture of GLOnets. A conditional generative neural network combines with adjoint-based optimization algorithms to perform device design. (b) Histogram plot of the efficiencies of a distribution of devices over the course of optimization. As the optimization iteration number increases, the device efficiency distribution narrows and converges towards high efficiency values.
Metasurface-based Light Sources, Modulators, and Detectors
Miniaturization is a main stream in modern technology, but reduction of conventional optical components accompanies performance degradation that limits the minimum feature size of optical devices. Metasurfaces that consist of ultrathin subwavelength antenna arrays can be a promising solution because metasurfaces provide an effective way to control phase and amplitude without constraints on the device size. Metahologram is one of the most promising applications of phase-control metasurfaces because fundamental limitations of conventional holograms such as twin images can be removed by metaholograms due to their sub-wavelength pixel size. Early metahologram research has achieved high efficiency by tailoring electric and magnetic dipole resonances through adjusting unit structure shapes [1] or materials [2]. As a result, silicon becomes main material for metaholograms due to high refractive index in the visible as well as CMOS compatibility. Metaholograms have enabled further applications such as a polarization independent broadband beam splitter [3] and random point-cloud generator for 3D detection [4]. On the other hand, amplitude-control metasurfaces realize sub-wavelength color printing. These are based on absorptive resonance determined by structure shapes, thus, it is possible to make a metasurface have different colors by incident polarization enabling cryptographic applications [5]. In this case, silicon still shows higher efficiency than typical plasmonic metasurfaces [6]. Comprehensive metasurfaces that enable to control both phase and amplitude have also been realized by adjusting unit structure configurations. The hologram resolution can be drastically improved by controlling complex amplitude using X-shaped nanostructures [7]. It is also possible to achieve both functions of holography and color printing in a single metasurface [8]. In the future, metasurface research will be expanded to a practical region by large-scale fabrication and tunability incorporating with active materials such as 2D and organic materials [9].

Abstract

A new technique to achieve image tuning in a reversible fashion by dielectric metasurfaces, composed of subwavelength silicon resonators, is demonstrated. We show that by controlling the temperature of a metasurface we can tune the encoded transmission pattern. To this end, we have designed and fabricated two sets of nanoresonators composed of non-concentric silicon disks with a hole that exhibit spectrally close sharp Fano resonances and forming a Yin-Yang pattern, with a full control on the contrast.

1. Introduction

Today, increasing the resolution of miniaturized displays is an important technological challenge for small gadgets. The further need for improving the resolution in images and displays, together with higher compactness, has motivated scientists to exploit novel alternatives, such as metasurfaces, allowing substantial improvements to the current technologies. Recently, many techniques have been proposed for tuning metasurfaces. Changing phase state of structured materials by laser illumination \cite{1} offers reversible tuning in metasurface functions, but suffers from the challenges to achieve intermediate states in the output. Hydrogenation/dehydrogenation of metasurfaces is another novel tuning technique \cite{2}, however this process is relatively slow. Doping materials \cite{3} can be used for changing the behavior of the metasurface, however it is not reversible. Utilizing free carrier plasma effect \cite{4-6} can be achieved in plasmonic and semiconductor nanostructures in designs, however, it introduces high optical loss which limits the tunability. Tuning the metasurface response can also be achieved by covering the metasurface with liquid crystal \cite{7} however this method revokes the access to the surface of nanostructures that forbids some applications, such as sensing.

Nevertheless, none of the aforementioned approaches have been used for image tuning. Recently, some research works have presented manipulating and decoding the output waveforms of the metasurface to construct an image \cite{8, 9}. However, with the proposed imaging techniques, the dynamic tuning on the spatial of distribution of light in images has remained a challenge. Here, we propose a novel tuning technique that is compatible for image tuning. It is known that the thermo-optical effect of dielectrics can be used to alter the refractive index and subsequently optical responses of bulk materials \cite{10, 11}. Such a rarely used degree of freedom provides a great platform for tuning the optical properties of nanostructures. Moreover, temperature control has never been used, as a versatile tool, to tune the contrast of the constructed image.

Here, we exploit heating and cooling for controlling the contrast of an image constructed by metasurfaces. For obtaining a tunable image with high switching contrast image, we employ Fano Resonance (FR) concept \cite{12, 13} to exhibit a narrow-band resonance that is ideal for achieving very high transmission contrast \cite{14}. This contrast is formed by transmission through the metasurface that is designed to filter the light at certain wavelengths. Our technique does not require external stimulator such as altering the polarization or angle of the illumination, or refractive index of environment. Silicon is chosen because of its high refractive index and pronounced thermo-optical properties. \cite{10, 11}. For demonstration of the concept, we have chosen an Yin-Yang image that contains a binary region: bright and dark \cite{14}.

2. Results and Discussions

For building blocks of the Yin-Yang pattern, non-concentric disk and hole nanostructures are proposed (Fig. 1a). These building blocks exhibit sharp Fano resonances, therefore being opaque at a certain wavelength. Thus, the image construction is determined by type and arrangement of building blocks and the image contrast is determined by the resonance features of them. The experimentally measured transmission spectra of building blocks type A and B at temperatures 22\textdegree C, 75\textdegree C and 125\textdegree C are plotted in the Fig. 1b. As can be seen, the increment of the temperature, can lead to the optical transparency of one building block and opaqueness in the other at $\lambda = 784$ nm. When the metasurface is at room temperature, Types A and B transmit 25\% and 75\% of the light, respectively. But when the metasurfaces temperature reaches 125\textdegree C, Types A and B transmit 75\% and 40\% of the light, respectively. This reversible transmission behavior effectively leads to a reversible contrast of the image.
The images of the Yin-Yang pattern at target illumination $\lambda = 784$ nm, in different temperatures, can be seen in Fig. 4c. As expected, by changing the temperature from 22°C to 125°C, a dynamic reversible image can be observed, sweeping itself from one state to another, with exhibiting no contrast in the intermediate state. Point (i) is recorded image at 22°C, where building block type A is opaque, while building block type B transmits the light, therefore the contrast is very clear. Point (ii) represents the temperature, at which the contrast is negligible. Experimentally this point is at 75°C. And finally, Point (iii), shows the case, where one can see an opposite contrast, when building block type A is transparent and building block type B is opaque. In the proposed image tuning method, more shades and image states can be achieved by simply including different resonator building blocks in the image. Alongside this, it is worth noting that by employing the localized heating technology such as the one developed for anti-fog windows, this technique can find various applications in functional transparent displays, tunable tinting windows, tunable optical filters and optical switches.

![Image](https://example.com/image.png)

Figure 1: (a) The SEM images of the fabricated Yin-Yang pattern. The location of building blocks types A ($r_{A, \text{small}} = 60$ nm, $r_{A, \text{large}} = 190$ nm) and B ($r_{B, \text{small}} = 56$ nm, $r_{B, \text{large}} = 183$ nm) are identified in the inset, accompanied by magnified SEM images. (b) Experimentally measured transmission of the building blocks type A and B at wavelength 784 nm in different temperatures. (c) The images obtained at 784 nm in temperatures of (i) 22°C, (ii) 75°C and (iii) 125°C, respectively.

3. Conclusions

In summary, a Yin-Yang pattern, consisting of two building blocks possessing different resonant wavelengths, has been used to demonstrate the contrast control. Due to high quality factor of the FR, a slight modification in the metasurfaces temperature, results in a large transmission contrast. Sweeping temperature from 22°C to 125°C, was used as a versatile tool to completely control the contrast of the image, where binary building blocks of the image become transparent or opaque, separately and reversibly. This type of thermally tunable metasurfaces can be fabricated in larger dimensions and encompasses more integrated building blocks with different resonances, which leads to the formation of an image with more shades (dynamic range) and details. The proposed mechanism for designing tunable metasurfaces paves the road for applications such as real time displays, optical switches, passive temperature sensors and selective illumination systems.

Abstract
Like amplitude and phase, polarization is a fundamental property of light, whose spatial distribution can be used to record, process and store information. Optical metasurfaces have shown unprecedented capabilities in the manipulation of the light’s polarization profile, providing an unusual approach for image encryption. A novel metasurface platform has been demonstrated to hide an image into the polarization profile of a light beam.

1. Introduction
A laser beam usually has a homogeneous polarization after passing through a polarizer, while a vector beam has an inhomogeneous distribution of polarization in the transverse plane perpendicular to propagation. Vector beams have been recognized as a promising future technology in quantum memories, particle trapping, and high-resolution lithography. However, despite tremendous advances in the fundamental principles of vector beams (e.g., Mobius strip, Poincare sphere beams), the real-life applications remain limited, mainly because of complexity of the experimental system and the inability to arbitrarily manipulate polarization state of light at subwavelength scale. Thus far, metasurfaces have been demonstrated to generate vector beams, such as radially or azimuthally polarized cylindrical beams, and arbitrary spatial polarization profiles. However, none of the metasurfaces demonstrated previously can be used to encode images in the polarization profiles. In order to overcome the present technical limitation of resolution and fundamental challenge of arbitrary polarization manipulation, we propose and experimentally demonstrate that, by precisely manipulating the spatially variant polarization states of a laser beam with an ultrathin metasurface, we can hide a high-resolution image within a laser beam. In this talk, we are going to introduce a metasurface platform for the arbitrary polarization manipulation for encoding various types of images, including a high-resolution grayscale image [1], a quick response (QR) code [2] and a color image [3].

2. Results
The structured beam that used to hide an image is created by a metasurface illuminated by the laser light at normal incidence. A linear polarizer is used to seek the hidden image in the generated structured beam. According to Malus’ Law, when completely plane polarized light is incident on the analyzer, the intensity of the light transmitted by the analyzer is directly proportional to the square of the cosine of angle between the transmission axes of the analyzer and the polarizer.

To hide the portrait of James Clark Maxwell, a single reflective metasurface is used to continuously manipulate the superposition of two beams with opposite circular polarization states. The reflective metasurface consists of a gold ground layer, a silicon dioxide (SiO2) spacer layer, and a top layer of gold nanorods. The generated structured light has a very specific polarization in the light beam, thus the electromagnetic field oscillates differently for different parts of the beam. In order to visualize the hidden image in the polarization topology of the laser beam, we reveal the grayscale of the image by using an analyzer (linear polarizer). In doing so, we do not directly observe the spatially-variant polarization profile of the laser beam but rather indirectly confirm its existence through the intensity profile (grayscale image) behind the analyzer. Figure 1 shows the simulation and experiment results. Because the theoretical amplitude of the two beams are exactly the same, no image is observed in the beam without the aid of the analyzer. The experimental result indicates that the image-hiden functionality is unambiguously realized. Similarly, a QR code can also be hidden in the polarization profile of a light beam.

We also demonstrate a metasurface platform for simultaneously encoding color and intensity information into the wavelength-dependent polarization profile of a light beam. Unlike typical metasurface devices in which images are encoded by phase or amplitude modulation, the color image here is multiplexed into several sets of polarization profiles, each corresponding to a distinct color, which further allow polarization-modulation induced additive color mixing. This unique approach features the combination of wavelength selectivity and arbitrary polarization control down to a single subwavelength pixel level. Upon the illumination of a linearly polarized light beam with multiple wavelengths, a color image is revealed after the light beam passes through a dielectric metasurface and a linear optical polarizer. The dielectric metasurface consists of silicon nanoblocks “meta-atoms” with different in-plane orientations and sizes on a fused silica substrate, which can be used to generate the desired polarization profile for two
different colors, with locally controlled intensity profile. We design two wavelength-selective polarization profiles for producing the polarization-encoded color images based on additive color mixing. Each supercell responds to a specific wavelength upon the illumination of a light beam containing red and green colors. The supercell represents a pixel of a mixed-color image with brightness of each color being individually controlled. Figure 2 shows the simulation and experimental results upon the illumination of linearly polarized red and green light.

Figure 1: The simulated and experiment results with and without the analyzer.

![Simulation and Experiment Results](image1.png)

Figure 2: Simulated and experimental results of the full-color-like image.

3. Discussion

The obtained image shows how the electric field is oriented in the beam profile of the laser beam. These hidden images demonstrate the rich polarization structure that a light beam can possess at subwavelength scales. The precise control over the polarization state of light is faithfully mapped onto the intensity profile for each color, according to the famous Malus Law. The encoding approach for polarization and color may open a new avenue for novel, effective color display elements with fine control over both brightness and contrast, and may have significant impact for high-density data storage, information security, and anti-counterfeiting.

4. Conclusions

Our approach provides a novel route to hide a high-resolution grayscale image in the polarization topology of a laser beam. The dielectric metasurface having the ability to encode a spatially-varying and wavelength-selective polarization profile may provide a viable route for generating structured beams that unveil high-resolution color images with well-defined brightness and contrast.

Dielectric Metasurfaces for Ultrathin Half Waveplates

Yuttana Intaravanne, Xianzhong Chen*

School of Engineering and Physical Sciences, Heriot-Watt University, Edinburgh, UK
*corresponding author, E-mail: x.chen@hw.ac.uk

Abstract

Traditional half waveplates are not suitable for device miniaturization and system integration due to their large volume. The unprecedented capability of metasurfaces in the manipulation of light’s polarization at subwavelength scale has provided an approach to develop ultrathin half waveplates. We developed an ultrathin half waveplate and evaluated its performance in term of conversion efficiency, phase retardation, and polarization rotation. Although our samples cannot be a perfect half waveplate, they can function as a quarter waveplate at some wavelengths.

1. Introduction

A half waveplate (HWP) is commonly used to control or rotate the polarization state of the linearly polarized light into two times of the angle of incident with respect to the fast axis (2α), where the refractive index along this direction is lower than that along the other. Traditional HWPs are made of birefringent materials (e.g., quartz, calcite, mica, magnesium fluoride, or sapphire), which can cover the optical range from ultraviolet to mid-infrared regions. However, these types of waveplate are very bulky so that there are not good for device miniaturization and system integration. Optical metasurfaces have provided an unusual approach to develop ultrathin HWPs in the optical range. Recently, Zang et al. have experimentally demonstrated a dielectric metasurface approach to hide an image into the polarization profile of a light beam [1]. Each nanopillar in the ultrathin device acts as a HWP. The performance of the HWPs influence the desired performance of the designed devices, so how to design, evaluate and improve their performance is a key step.

2. Results

The key idea for design and optimizing the dimension of nanopillars is shown in Figure 1(a). Each nanopillar was designed to generate a phase retardation (Δφ) of 180° as a function of HWP with a high efficiency at wavelength (λ) of 550 nm. Each nanopillar was designed to have a pixel size (p) of 360 nm along two orthogonal directions. The nanopillars are 310 nm high (h), 100 nm long (l), and 75 nm wide (w) oriented in a horizontal axis. To develop the sample as shown in Figure 1(b), amorphous silicon nanopillars sitting on a quartz substrate were fabricated. The fabricated sample was characterized by using the experimental setup diagram shown in Figure 1(c) in order to evaluate the performance in terms of conversion efficiency, phase retardation, and polarization rotation.

Conversion efficiency is a very important parameter, which is defined as the ratio between the optical power with desired polarization rotation and the transmitted power [1]. The obtained conversion efficiency of the sample is shown in Figure 2(a). The experimental result shows that the operating wavelength is at 580 nm, which is shifted by 30 nm when compared to the designed wavelength. At this wavelength, the conversion efficiency is 89.60%. As shown in Figure 2(b), the sample was designed to generate the phase retardation of 180° whereas the real sample provides the phase retardation of 142.40° at wavelength of 580 nm. Similar to a perfect HWP (phase retardation 180°) that can generate a polarization rotation of 2α, but there is a slight difference in the polarization rotation for the fabricated samples due to the difference of the phase retardation (142.40°), Figure 2(c). All collected data from optical measurement was also plotted and compared with the simulation results as shown in Figure 2(d).

Although our samples cannot be a perfect HWP, it can function as a quarter waveplate at some wavelengths. Therefore, the Figure 2(b) was recalled and considered at the wavelengths that can generate the phase retardation of 90°. The corresponding wavelengths are around 562 nm and 602 nm for this sample.

Figure 1: (a) The dependence of phase retardation on the wavelengths; (b) SEM image of the sample used in this work; (c) The experimental setup diagram for characterization of the sample.
3. Discussion

The slight difference in the phase retardation between the simulation and experiment is due to the imperfection of the fabricated sample. The phase retardation can be increased by increasing the height of the amorphous silicon layer with the current geometry of the nanopillars unchanged or optimizing the feature size of the nanopillars with the current height unchanged. Furthermore, the shifting of the operating wavelength can be tuned by controlling the length and width of the nanopillars as reported by Zang et al. [1]. Ultrathin HWP with spatially variant fast axes (orientation of nanopillars) at subwavelength scale are very attractive for the generation of arbitrary polarization profile for image encryption, including high resolution grayscale image [1], color image [2], and a quick response (QR) code [3].

4. Conclusions

In summary, we designed and developed an ultrathin HWP based on a dielectric metasurface. The performance of the ultrathin HWP was evaluated in the terms of conversion efficiency, phase retardation and polarization rotation. Good agreement between measurement and simulation was found. Solutions on how to improve the device quality were given and future applications of nanopillars in polarization manipulation were also discussed.

Abstract

High-index dielectric Huygens’ metasurfaces offer a means to create compact, high-performance infrared optical devices such as lenses, filters, beam-deflectors, waveplates and so on for applications where quality components are difficult to come by. The functionality of such devices could be vastly expanded by creating reconfigurable designs that enable switching and dynamic behavior. We detail how to design reconfigurable Huygens’ surfaces, demonstrate some devices operating in the mid-IR, and discuss technical challenges and possible future developments.

1. Introduction

In the infrared range, there are numerous applications (astronomy, biomedical imaging, security, night-vision, missile-detection, etc.), which suffer from expensive, unwieldy, or low-quality bulk optical devices. Phase-gradient metasurfaces, or Huygens’ surfaces [1], have strong potential to overcome these limitations, and can be used to create ultra-thin optical components with a high degree of precision for manipulation of electromagnetic (EM) wavefronts [2]. Huygens’ surfaces can be constructed as a 2D array of subwavelength dielectric structures, which have been manufactured from a high refractive index material. The high index of refraction allows the structures (i.e. meta-atoms) to support magnetic and electric multipoles [3], that when excited, cause a temporal delay for incoming EM waves. The responses of these multipoles change with the geometry of a meta-atom, which provides a means of tuning the phase of an EM wave. A set of meta-atoms that adequately covers the full $2\pi$ phase range can be arranged along a surface in an appropriate pattern to produce meta-optical devices, such as lenses, filters, waveplates, polarizers, beam deflectors, and so on. Although the control of EM waves enabled by metasurfaces is considerable, applications often call for multiple device functionality or dynamic behavior (such as zooming) that would ordinarily be unattainable by a single metasurface (or often any other type of optical component). Reconfigurable optical components are capable of such performance, but current devices depend on mechanical adjustment, which is slow, or make use of liquid crystals, which can be unstable when the device is in motion. As a solution to this challenge, we introduce building meta-atoms from a material, such as Ge$_2$Sb$_2$Se$_4$Te (GSST), whose index of refraction can be controlled via a reversible thermally induced phase change between amorphous and crystalline states [4]. The heat necessary to induce the phase change can be supplied electrically to individual meta-structures, allowing the creation of the first electrically tunable solid-state infrared devices.

![Image](image_url)

Figure 1: Example of reconfigurable meta-atoms for a 2-bit design. Atoms 1-4 have approximately the same phase in the amorphous (A) state but exhibit a roughly 90 degree phase progression in the crystalline (C) state. Atoms 5-8 behave similarly but are offset by 90 degrees from atoms 1-4 in the amorphous state. The remaining atoms continue in this manner so that full $2\pi$ coverage is available in both A and C states.
2. Reconfigurable Huygens’ Surface Design

Complete control of the phase of an incoming EM wave requires many more meta-atoms for a reconfigurable Huygens’ surface than for an ordinary one. The case of a phase increment of 90 degrees between meta-atoms would only modest wave manipulation. 16 meta-atoms are needed for this so-called 2-bit design (Fig. 1), as compared to only 4 that would be needed for an ordinary non-tunable Huygens’s surface. A 3-bit design, which is more efficient and allows for better wavefront control by reducing the phase increment to 45 degrees, would require 64 structures (as compared to 8), and so on.

With a suitable set of reconfigurable meta-atoms, many devices can be constructed from appropriate arrangements such as determined by the Generalized Snell’s Law of Refraction [5] (Equation (1)) or applying Fermat’s Principle. Equation (2) is the metasurface phase distribution, \( \phi(r) \), required for lenses [6], which we have used to construct a meta-lens with a focal spot that changes from 0.5 mm in the amorphous phase to 1.0 mm in the crystalline phase (Fig. 2 and Fig. 3).

\[
\begin{align*}
\frac{\sin \theta_i - \sin \theta_e}{\frac{d\phi}{dx}} &= \frac{1}{n_i n_e} \\
\phi(r) &= k \left( \sqrt{r^2 + f^2} - f \right)
\end{align*}
\]

3. Discussion

While there is great potential to create a wide variety of reconfigurable optical devices that would be superior to the current state of the art, there are some technical challenges to be overcome. For example, 3-bit and higher designs require a large number of suitable structures to be found, for which it can be increasingly challenging to obtain the proper performance for both states of matter. This challenge can be even more formidable for designs requiring broadband response. Additionally, fully electrical control over each structure becomes more difficult as the size of the surface is increased. We will demonstrate our approaches to overcome these challenges.

4. Conclusions

Huygens’ surfaces have the potential to be used for high-quality, thin, and reconfigurable infrared flat optical devices. We will demonstrate how a reconfigurable Huygens’ surface can be obtained and present some devices we have developed, such as lenses, polarizers, waveplates, and beam deflectors with tunable/reconfigurable responses. We also discuss more complex devices under development such as reconfigurable filters and dynamic zoom lenses.

Abstract

Information and image multiplexing based on the polarization states of the light is a powerful tool that can be easily realized with optical metasurfaces. Here, we have demonstrated a novel method for achieving high-dimensional vectorial holography based on birefringent all-dielectric metasurfaces to explore the full capacity of polarization. By considering the anisotropy property and extra design freedom of rotation matrix, together with smart multiplexing algorithms for establishing quantified related phase profiles, high-dimensional multichannel polarization multiplexed holograms have been successfully achieved using the simplest nanofin as the building block. Compared to previously demonstrated metasurface multiplexed holograms that can only be switched between two states by two orthogonal polarization for the light, here all combinations within twelve polarization channels in total can be obtained.

1. Introduction

The practical realization of metasurface holograms relies on the encoding of holographic profiles on ultrathin meta-atoms which can possess strong light-matter interaction within ultrashort distance. Many efforts by incorporating novel holographic related functionalities such as beam shaping and ghost imaging into metasurfaces have been done. Meanwhile, for the purpose of optimizing the tremendous information capability of metasurface holograms, multiplexing techniques are highly desired including color holograms, polarization multiplexing and hybrid multiplexing. Among the mentioned multiplexing techniques, polarization multiplexing is an attractive method due to the polarization sensitive ability of such artificially tailored meta-atoms. However, the full capacity of all polarization channels (input/output polarizations) has not been explored yet. This limits the improvement of the information capacity stored in metasurface holograms and restricts the versatile functionality of holographic-based optical devices.

Here, we demonstrate a novel method for achieving multichannel vectorial holography and show its potential for obtaining dynamic displays and high-security applications. We explore birefringent metasurfaces for the complete control of polarization channels with the freedom of designing both the polarization dependent phase shift and polarization rotation matrix. We show that although the target holographic phase profiles have quantified phase relations they can process very different information within different polarization manipulation channels. The reconstructed vectorial images can be switched with negligible cross-talk by selecting the desired combination of input/output polarization states. The set of the reconstructed images can conceive absolutely different meanings and therefore hosts unique merits for encryption. Our demonstrated multiplexing method may lead to a new frontier for applications related to dynamic holographic displays, switchable optical devices, data storage and optical encryption/anti-counterfeiting, to be compatible with most optical systems that operate in transmission. Furthermore, our proposed method can also be adapted to arbitrary spin to orbital angular momentum conversion or other types of polarization/phase modulation and enhance the information capacity.

2. Result

We comparatively study two schemes of multiple polarization channels (from orthogonal two channels to twelve channels) by using birefringent dielectric metasurfaces, as shown in Figure 1. We show that polarization and angle multiplexed holograms can be achieved by utilizing nanofins of different cross-sections but without rotation (Fig. 1a). Two sets of off-axis holographic images can be generated with two orthogonal states. However, by considering the flexibility of designing the entire Jones matrix, we can achieve more multiplexed functionalities with complete control of polarization and
phase (Fig. 1b). Three independent images (we choose the words “holography”, “meta”, and “surface” as the reconstructed images) can be reconstructed successfully with high resolution and high fidelity for different combinations of the input and output polarization channels. All combinations of these three images in a total of twelve different polarization channels can be observed (“meta” + “holography”, “meta” + “surface”, “surface” + “holography” and “meta” + “surface” + “holography”) with satisfactory efficiencies. In addition, the reconstructed images exhibit vectorial feature for the polarization state of the different words in analogy to optical vector beams.

Figure 1: Schematic illustrations of polarization multiplexed holograms based on dielectric metasurfaces. The red and blue arrows indicate the polarization of incident light and the transmission axis of polarizer placed behind the metasurfaces sample.

We demonstrate such method also allows encrypting different original images that can be superimposed at the same spatial location. Such superposition has the ability to convey an absolutely different meaning in the reconstructed image and can be used to provide an alterable information content of the image, that is, encryption, as shown in Figure 2. We choose a dice as our original image. The dice has six faces that are represented by the number of pips on the surface. Interestingly, by using a suitable selection of different combinations of the input/output polarization states, a different number of pips (from one to six) can be observed. This kind of illusion of viewing different sides of the dice results from the increased multiplexing capability of our method that can encode of up to six different images for the various combinations of polarization states.

Figure 2: Simulated and experimental results for the reconstruction of a dice with different faces up.

3. Conclusion

In summary, such high-dimensional vectorial metasurface hologram can be applied in holographic display and encryption. Only by using the correct polarization keys the receiver will get the exact information delivered (as for the dice case). An even higher flexibility can be obtained by further increasing the complexity of the images together with a detailed analysis of the reconstructed vectorial image properties. Further application of arbitrary spin to angular momentum conversion and various phase modulation/beam shaping can be achieved accordingly.

Terahertz Photonic Devices Employing Graphene-based Hybrid Metasurfaces

Peter Q. Liu

Department of Electrical Engineering, University at Buffalo, the State University of New York, Buffalo, USA
E-mail: pqliu@buffalo.edu

Abstract

Graphene has emerged in recent years as a versatile material for photonic devices operating in the infrared to terahertz (THz) spectral region. In particular, the large tunability of carrier density and the high carrier mobility of graphene allow this two-dimensional material to support tunable THz surface plasmon polaritons with exceedingly high field localization and enhancement as well as relatively long lifetime. The compatibility of graphene with a wide range of materials and various micro- and nano-fabrication processes also makes integrating graphene-based structures with other structures/devices relatively straightforward. In this invited talk, we will present several types of THz photonic devices we developed in recent years, including modulators and detectors, which employ graphene-based hybrid structures (e.g. metasurfaces) to achieve enhanced light-matter interactions and hence improved device performances.

Abstract

We present a concept for rapidly evaluating different nanostructures for enhanced out-coupling of light from light emitting diodes in the deep ultra violet wavelength region. The scattering matrix for a given nanostructured interface is calculated by means of rigorous simulations combined with a Brillouin zone sampling technique to minimize the number of required simulations. We then use the scattering matrix to evaluate the out-coupling for a source with an arbitrary angular distribution.

1. Introduction

Light emitting diodes (LEDs) based on AlN and operating in the deep ultra violet (DUV) wavelength regime (200-360 nm) represent a promising technology for a multitude of applications. These include air and water purification, optical data storage, sterilization, sensing and spectroscopy [1, 2]. Compared to established mercury lamps, LEDs have the advantages of miniaturization, they can be produced with different operating wavelengths and they can provide a lower energy consumption [3].

In order to make this a reality, the optical extraction of light emitted inside the LED must be as high as possible. For a simple planar AlN on sapphire substrate system, the expected light extraction to air is around 7%. We will present concepts for increasing this extraction efficiency. In order to increase this efficiency, the Al/sapphire interface may be nanostructured as shown in fig. 1(a).

Nanostructuring can increase the transmission from the AlN semiconductor into the sapphire substrate via wave optical effects such as diffraction. In order to optimize efficiently, a method of quickly evaluating the effectiveness of a given structure is needed. To this end, we present a method by which the total transmission at the AlN/sapphire interface can be obtained with a minimum number of simulations. This allows for an optimization of the transmission with minimal computational cost.

2. Method

In order to obtain the transmission through the AlN/sapphire interface for a source with an arbitrary angular distribution inside the AlN semiconductor, the transmission for each incident angle and polarization is required. For nanostructures with 2D periodicity in plane of the interface, the transmission taking into account all wave optical effects can be determined using the finite element method (FEM). In this case we use the commercial software package JCMsuite [4].

However, solving for each incident angle is a costly process. In order to accelerate the speed of simulations we exploit two factors based on the k space considerations. Simulating for all incident angles is equivalent to simulating for sources with k vectors with transverse components lying within the Fermi circle $k_{\perp} < nk_0$. Where $k_0$ is the vacuum wave-number and n is the refractive index of the incident material. Figure 1 shows points sampled within the first Brillouin zone (BZ) for a geometry with hexagonal periodicity in the transversal plane. If the structure presents a symmetry in the transverse plane, then the BZ can be further reduced to the irreducible Brillouin zone (IBZ). This means that all points lying within the first BZ but outside of the IBZ can be reached by applying the symmetry operators of the respective point group to points within the IBZ.

The second property used in order to reduce the number of simulations is the Bloch periodicity of the k space inside the Fermi circle. Figure 2(a) shows a sampling of points inside the Fermi circle (note the symmetry operations previously considered have already been applied, restricting the points to the wedge shown). Also shown are the 1st and higher order BZs which are represented by the lattice pattern of hexagons. In fig. 2(c) the points are colored by subset. For each subset, the position of each point in k space is related by translation of a reciprocal lattice vector. This means that the points share a common Bloch periodicity. When performing calculations using the FEM, multiple sources with the same Bloch periodicity may be evaluated using the same system matrix. In the case presented here, only four families are present. This means only four matrix inversions need to be performed to sample all the k points shown. Since the matrix inversion is the most costly part of a given FEM simulation, this reduces the computational cost significantly.

3. Discussion

Circular structures in a hexagonal arrangement, such as for a photonic crystal, are commonly used for nanostructuring in LEDs. This geometry presents a C6 symmetry, mean-
Figure 1: (a) The basic structure of a DUV LED. Light is emitted in the AlN layer and travels through the sapphire substrate to be transmitted at the lower interface to air. A schematic of a nanostructure at the AlN/sapphire interface is shown. (b) An arbitrary sampling (points) of the first Brillouin zone (blue hexagon) for a geometry with in-plane hexagonal symmetry. The irreducible Brillouin zone (green triangle) allows the number of sampling points to be reduced to those highlighted in red.

Figure 2: (a) A sampling (points) of the symmetry cone within the Fermi circle for a geometry with in-plane hexagonal symmetry. (b) The sampling from (a) recolored by Bloch family. There are four families present (blue,green,red,orange).

Using that the number of required simulations is reduced by a factor of 12 (fig. 1(b)).

Exploitation of the Bloch families depends heavily on the relationship between the pitch of the periodic structure and the wavelength of light. For DUV LEDs, the pitch is generally much larger than the wavelength due to experimental constraints on the nanostructuring processes. For the case of a 265 nm free space wavelength and 1000 nm pitch, the speedup of simulation time is \( \sim 20 \). This is especially useful since FEM simulations become more costly when the pitch of the simulated device is larger than the wavelength.

Using these two factors, obtaining a scattering matrix to use for evaluating the performance of a nanostructured AlN/sapphire interface can be sped up by a factor of \( \sim 240 \). Thereby considerably accelerating the speed at which different structures can be evaluated. We will further discuss how an estimate for the light extraction can be obtained via a simple matrix scheme and the physical mechanisms which contribute to the enhanced light extraction.

4. Conclusions

We have presented a method of evaluating different nanostructures for enhanced out-coupling of light from light emitting diodes in the deep ultra violet wavelength region. This entails calculating the scattering matrix via finite element simulations. Due to the large size of the structures compared to the wavelength of light, these simulations are costly. We were able to reduce the amount of simulations required by a factor of \( \sim 240 \) by sampling \( k \) space at regular intervals defined by the reciprocal lattice vectors.

Using the scattering matrix allows the for a rapid optimization of the light extraction from an DUV LED for a source with an arbitrary angular distribution.

Abstract

Here, we report giant tunability of EFISH signal from a subwavelength thick polymer film sandwiched by a transparent electrode and a metallic mirror. By exploiting band-edge enhanced third-order nonlinear susceptibility from the organic conjugated polymer, we successfully demonstrate a gigantic EFISH effect with modulation ratio up to 422% per volt at pumping wavelength of 840 nm. The band-edge enhanced EFISH opens new avenues for modulating the intensity of SHG signals, and for controlling nonlinear electro-optic interaction in nanophotonic devices.

1. Introduction

Dynamic control of nonlinear optical signal may have important applications in optical modulation and switching. Various switching technologies based on Kerr or free carrier nonlinearities in semiconductor materials have been developed using the all-optical control scheme. Alternatively, the control of nonlinear optical signal can be realized by using electro-optic interactions. For example, the electric-field-induced SHG (EFISH), which was proposed in early 1960s, provides an alternative route for designing nonlinear optical modulators. [1] In EFISH process, an external static electric field can be mixed with the fundamental wave (FW) to produce SHG in nonlinear optical materials with large third-order susceptibilities. Because the symmetry of the nonlinear optical materials has less restrictions on third-order processes as compared to second-order processes, EFISH process has been extensively exploited in various media such as optical crystals, [1][2] electrolytic solutions, [3] metal-oxide-semiconductors, [4] organic devices, [5] silicon waveguides, [6] and photonic metamaterials. [7][9] It was demonstrated that the efficiency of EFISH signal could be greatly improved by utilizing the backward phase matching technique in plasmonic metamaterials [9] and quasi-phase matching in silicon waveguides [6]. EFISH was recently realized by electrostatic doping in two-dimensional (2D) materials. Specifically, electrically tuneable SHG was theoretically studied using plasmonic resonances in doped graphene nanoislands [10] and experimentally realized based on strong exciton charging effects in monolayers of WS2. [11] The electric field controlled SHG in 2D materials also have many limitations. For example, SHG predicted from graphene nano islands strongly relies on the heavy doping of charge carriers, and thus imposes critical requirements on the fabrication of graphene monolayers. In addition, the electric field enabled modulation depth of SHG from the WS2 transistor is less than 3% per volt, which limits its potential applications as nonlinear optical modulators.

2. Results and Discussions

![Figure 1. Nonlinear optical properties of ITO/PFO/Aluminium with applied voltages.](image)

(a) Configuration of SHG measurement, The TM-polarized FW (the) is obliquely incident onto the ITO/PFO/Aluminium device at angle of 45°. L1 and L2 are lenses; LP1 and LP2 are polarizers. (b) Characterization of the spectral response of H-polarized SHG from ITO/PFO/Aluminium with and without applied voltages. (c) The SHG intensity as a function of the applied voltages is plotted for SHG wavelength at 420 nm. (d) The SHG intensity as a function of the applied voltages is plotted for SHG wavelength at 405 nm. In the case of positive and negative voltages, ITO layer serves as anode and cathode, respectively.

We study the electric field induced SHG from the ITO/PFO/Aluminium device by applying a DC voltage (U) to the ITO and aluminium electrodes. As shown in Fig. 1a, ITO layer can be used as either an anode (U > 0) or a cathode (U < 0). To avoid the damage of the EFISH device, the spectral measurement of EFISH signal for DC voltage only up to U = 6 volt is carried out (red dot line with circles in Fig. 1b) for TM-polarized FW at incident angle of 45°.
Compared to the case of U = 0 (black dot line with triangles in Fig. 1b), one can see that the applied electric field can greatly boost the efficiency of SHG. To better understand the mechanism and the efficiency of the EFISH process, we plot the electric field induced SHG intensity versus the applied voltage $U$ at the fundamental wavelength of 840 nm and 810 nm in Figs. 1c and 1d, respectively. At the resonant wavelength of 840 nm, the SHG always has the highest efficiency for EFISH device regardless of the applied DC electric field. When $U$ is swept from zero to 6 Volts, the intensity of SHG initially drops to a minimum value of $I_{2\omega} = 0.489$ (a.u.) at $U = 1.5$ Volt and then grows quickly to $I_{2\omega} = 9.29$ (a.u.) at $U = 6$ Volts. This corresponds to a SHG modulation depth $I_{2\omega}(U = 6)/[\Delta U \cdot I_{2\omega}(U = 1.5)] \sim 422\%$/Volt, with $\Delta U = 4.5$ Volt in this case. This modulation depth is much higher than that in the conventional EFISH devices or the electric controlled SHG from WSe$_2$.[10] Also, the modulation depth of electric field controlled SHG from plasmonic metamaterials[7][8] and WSe$_2$[10] is less than 0.9%/Volt and 3%/Volt, respectively. If a reversed voltage is applied to the device, the trend of EFISH shows a very different behavior; the intensity SHG keeps increasing when $U$ is swept from zero to -6 Volt, and the measured modulation depth of SHG has a negative value of $\sim -335\%$/Volt. In comparison, the electric field controlled modulation depth of SHG in WSe$_2$ devices is negative for both positive and negative biases. A very similar optical response was observed from the EFISH measurement at a non-resonant wavelength of 810 nm Fig. 1d. The measured EFISHG dependence over the applied electric field can be perfectly explained by the theory, and the relative values of effective $\chi^{(2)}$ and $\chi^{(3)}$ of the EFISH device can be retrieved by fitting the measured EFISH curves using Eq. 1, as shown in Figs. 1c and 1d. The ratio between the effective $\chi^{(2)}$ and $\chi^{(3)}$ is found to be 1.6271 V/m and 1.4451 V/m for fundamental wave at 840 nm and 810 nm, respectively.

3. Conclusions

This work opens new avenues for designing organic conjugated polymer based electric field controlled SHG with giant modulation depth. It is expected that through the integration of plasmonic metamaterials, metasurfaces into the current EFISH device, the performance such as modulation depth and efficiency of SHG will be further enhanced, indicating the great potentials in applications such as electro-optic modulators.

Abstract

In this work, we successfully demonstrated flat optical concentrators operating in mid-wavelength infrared (MWIR) spectral range.¹ The optical concentrators are solid immersion polarization-independent transmissive metasurface lens designed to operate in the 3-5µm band. These 30µm diameter lenses were tested using a JPL-developed MWIR camera showing very good optical characteristics with a small focal spot size and focal length of about 150µm. This demonstration is the first step in the realization of infrared detectors monolithically integrated with flat lenses.

1. Introduction

High operating temperature of mid- and long-wavelength infrared imagers can be achieved by integrating detectors with optical concentrators that increase optical collection area while keeping detectors volume constant. The most common way to realize optical concentrators is by integrating spherical microlens with detectors but this technology is not well developed in mid- and long-infrared. Recently, a new class of optical components dubbed metasurfaces has been invented.²³ These components are based on inhomogeneous arrays of optical resonators with subwavelength separation. These metasurfaces offer novel approach for realization of optical concentrators that can be monolithically integrated with infrared detectors as well as small pixels of infrared focal plane arrays (FPAs).

These metalenses need to feature specific characteristics to enable their integration with FPAs. The lens needs to be transmissive and of the immersion type to focus light in the detector materials. The lens also needs to be fabricated on the backside of the detector so it is made of the same material as the detector wafer substrate (GaSb, InSb or CdTe). Hence, the fabrication process needs to be compatible with the detector manufacturing. Furthermore, it has to be scalable to the size of microlens arrays and robust to avoid issues with FPA uniformity and operability. Finally, similar to many other applications, the lens should have a high focusing efficiency, work for all incident polarizations and be broadband (e. g. 3 – 5 µm or 8 – 12 µm).

2. Design and fabrication

Here we developed a transmissive metalens focusing light from air into the substrate material. The metalens consists of circularly shaped posts etched directly into a GaSb substrate (Fig. 1). The circular shape of the posts ensures that the designs work for all incident light polarizations. The phase change in the dielectric resonators relies on the control of the scattering properties of ultrathin subwavelength scale optical resonators. By varying the diameter of the posts, a phase coverage of 2π and a relatively high and uniform transmission amplitude response can be achieved. The phase profiles of the metalenses were realized by placing these subwavelength posts with varying post diameter at fixed edge-to-edge separation.

Figure 1: SEM image of a single metalens. Individual posts are clearly visible.

We fabricated a 10 × 10 metalens arrays with each metalens having a 30 µm in diameter and a focal spot size of 10 µm. For fabrication of the metalenses, the substrates were first prepared by solvent clean (IPA and acetone), oxygen plasma ash, and buffered oxide etch. Then a hard mask made of SiNx was deposited on the wafer. The metalenses were patterned by electron-beam lithography using a ZEP520A resist with a film thickness of around 500 nm. After the resist development, the hard mask was etched with CF₄ and O₂ using an inductively-coupled plasma (ICP) system (Plasma-Therm ICP etching system). Prior to the metalens...
etching, samples were mounted on substrate carriers with a thermal conductive-cooled adhesive medium. The GaSb was etched with a mixture of Cl₂, BCl₃, and Ar in an ICP etching system. The hard mask was then removed.

Figure 2: IR camera images of a 3x3 subsection of metalenses array. (Left) Camera was focused on the metalenses. The center-to-center distance of the neighboring metalenses is 30 µm. (Right) Camera image at the focal plane showing the intensity enhancement

3. Measurement results

The blackbody at 1273K was used as the infrared source and metalenses were placed after the bandpass filter with the posts facing the bandpass filter. Imaging was performed with a 36x reflective microscope objective and an MWIR infrared camera. The infrared camera with the attached microscope objective was mounted on a translational stage and moved along the optical axis (z).

Figure 2 shows acquired IR images of the metalenses array taken at different z values after subtracting the background intensity taken when the objective was blocked. z = 0 µm was set when the camera was focused on the metalens [Fig. 2 left]. The metalens shapes are clearly visible. The camera assembly was then moved away from the metalens in 1 µm steps. Figure 2 (right) is the camera image taken at the focal plane of the metalens array.

We analyzed the measured normalized intensity and found the measured full beam waist is 16.4 µm for spectral range of 3–5 µm. This value is greater than the diffraction-limited spot size which is possibly caused by the incident light not being single wavelength and normal incidence and also fabrication imperfections. The measured focal length of the metalens, f = 153 µm, was constant for in the spectral band of 2.95–4 µm. The designed value is f = 153 µm. As the wavelength increases further, the focal length decreases to f = 130 µm. However, the percentage change is relatively small Δf/f<14.6% for λ>4µm.

Metalenses act as optical concentrators to collect incident light and focus it onto the active area (pixel size) of the FPA pixel unit cell (pixel pitch size) after propagating through the substrate material; hence, the device responsivity is increased. To quantify the focusing power of the metalenses, we measured the focusing efficiency and the intensity enhancement of the metalens as an optical concentrator. The focusing efficiency was defined as the optical power over the pixel size of 10 µm at the focus divided by the incident power over the pixel pitch size of 30 µm. The maximum focusing efficiency measured is 52% with the bandpass filter BP-3390-345 nm. In the simulation, the average focusing efficiency is 70% over a wavelength range of 3–5 µm and the maximum focusing efficiency is 80%. The loss in the simulation mainly comes from the reflection at the GaSb/air interface. The focusing efficiency can be improved by matching the optical impedance of the planar device with that of free space and/or depositing a layer of anti-reflection coating.

4. Conclusions

In summary, we demonstrated a type of metalens that operates as a solid-immersion lens, i.e., incident light is focused into the substrate material. The metalenses comprising GaSb posts were fabricated directly on the backside of GaSb substrates, making it compatible with backside illuminated IR FPAs. To keep the detector volume small, our metalenses are 30 µm in diameter corresponding to the FPA pixel pitch size and only 2 µm thick which are much smaller than the typical size of microlenses and microspheres for FPAs. The metalens has a constant focal length in 3–4 µm spectral range and has a small focal length variation over the incident wavelength range (3–5 µm).

Metalens shows intensity enhancement of around three times at the focus indicating a potential to improve responsivity of the FPAs. In particular, the demonstrated 10 ×10 metalens array proves the scalability of this approach for FPAs. Our demonstration opens a path to the realization of high operating temperature IR detectors and FPAs monolithically integrated with flat and lightweight

Abstract

I will present our recent efforts of achieving an assortment of low-loss all-dielectric metasurfaces operating down to a record-short deep-UV wavelength of 266 nm, with efficiencies up to 72%.

In this talk, I will show how low-loss, all-dielectric metasurfaces operating at UV wavelengths down to the deep-ultraviolet range can be implemented using Hafnium Oxide (HfO\textsubscript{2}), an amorphous dielectric material most commonly exploited as a high static dielectric constant (high-k) material in integrated circuit fabrication, that is characterized by a wide-bandgap. We develop a unique Damascene fabrication process, involving both low-temperature atomic layer deposition (ALD) of HfO\textsubscript{2} onto patterned resist and back etching with Argon ion milling, to achieve high-aspect-ratio HfO\textsubscript{2} nanostructures with straight and smooth sidewall profiles. We first demonstrate a variety of polarization-independent UV metasurface devices having distinct functionalities, namely diffraction-limited focusing lenses (metalenses), hologram projectors (metaholograms) and self-accelerating beam generators, operating at two near-UV wavelengths (364 and 325 nm) with efficiencies as high as 72%. Scaling down metasurface critical dimensions, we achieve metaholograms operating with high efficiencies at a record-short, deep-UV wavelength of 266 nm. Finally, we demonstrate 266-nm, spin-multiplexed metasholograms of greater degree of geometric complexities, with efficiencies up to 61%. Our work paves the way towards low form factor and multifunctional UV flat optical systems.
Gate-tunable Conducting Oxide Epsilon-near-zero Metasurfaces with Active Nonlinear and Quantum Responses

Abstract

The optical response of epsilon-near-zero (ENZ) materials has been a topic of significant interest in the last few years as the electromagnetic field inside media with near-zero permittivity has been shown to exhibit unique optical properties, including strong electromagnetic wave confinement, non-reciprocal magneto-optical effects, and abnormal nonlinearity. These ultrathin ENZ materials are promising for the enhancement of quantum emission for optical sensing and enhanced absorption/emittance for energy harvesting.

This talk will review our recent development on a gate-tunable conducting oxide epsilon-near-zero metasurfaces [1-5]. I will present our recent development on the use of gate-tunable materials, transparent conducting oxides, to demonstrate an electrically tunable ultrathin ENZ perfect absorber enabled by the excitation of ENZ modes. In addition, I will present the active control of emissive properties of quantum emitters and enhanced optical nonlinearity in hybrid ENZ-plasmonic heterostructures.

Abstract
The first Kerker condition states that spectrally overlapped, and equal strength, electric and magnetic dipole modes will result in cancellation of the backscattered field. In this talk, I will outline how this effect, and related Kerker effects, can be harnessed in all-dielectric modulators and light sources. In the case of modulators this allows for high on-state transmission and large modulation depth. In absorbing metasurfaces this effect can be used to realize near-unity absorption leading to efficient thermal emitters.

1. Introduction
In 1983 Kerker et. al. published a paper in which scattering of a sphere with \( \mu \neq 1 \) was studied [1]. One of the observations of this study was that spectrally overlapped and in-phase electric and magnetic dipole modes result in cancelation of the backscattered field. This is known as the first Kerker condition. In the absence of absorption, this results in unity transmission with each scatterer corresponding to a “Huygens’ source” allowing for tailoring of the wavefront [2].

In this talk, I will outline how this effect can be used to realize optical modulators with high on-state transmission [3]. Modulation of such surfaces can come in the form of carrier injection or through the use of phase change media such as vanadium dioxide (VO₂). In both cases, large modulation depth can be achieved by working close to the epsilon near-zero (ENZ) point of the medium. I will also discuss Kerker’s first condition when employing highly absorbing media, such as silicon carbide (SiC). In this case, the presence of two resonances allows for critical coupling and unity absorption without the use of a reflecting backplane, as is commonly employed in metamaterial perfect absorbers.

2. Metasurface Modulators
In Fig. 1a we provide a schematic of a metasurface unit cell comprising a cylindrical resonator made from silicon with a thin bus bar connecting the resonators. These resonators
are designed to operate near the first Kerker condition such that backscattered light is cancelled. Active modulation of the metasurface is achieved by placing a thin film of indium tin oxide (ITO) on top of the resonator. By tuning the coupling between the resonators and the ENZ point of the ITO thin film, active control over the transmission amplitude is achieved. This results in near-unity transmission in the on-state. Upon moving the ITO film through its ENZ point, absorption is increased reducing transmission, as shown in Fig. 1b. Spatially patterning the modulated area allows one to create beam steering devices such as diffraction gratings as shown in Fig. 1c. While we will focus on transmission modulation, use of lower loss ENZ films may allow this approach to be translated into phase modulators in the future.

I will also discuss implementing these surfaces with VO$_2$ to achieve dynamic modulation. In this case, the larger absorption of the VO$_2$ results in larger modulation depth. One interesting application of such metasurfaces are optical limiters as such films have high, and spectrally flat, transmission in the on-state. When the metasurfaces are heated, for instance by an incident laser, a narrow stop band emerges with a modulation depth greater than 30dB. While working at the ENZ point of VO$_2$ results in the largest modulation depth the film can be designed at other frequencies with only a slight decrease in modulation depth.

3. Metasurface Absorbers and Thermal Emitters

While most Mie resonance-based metasurfaces employ low-loss constituents there are certain applications that could take advantage of absorption loss, such as thermal emitters and photodetectors. In the second half of the talk I will discuss spectrally overlapped electric and magnetic resonances in the presence of strong dispersion and absorption. While the first Kerker condition results in unity forward scattering in the absence of loss, we show that in a material of high dispersion, permittivity, and loss this condition can result in a uniquely strong and narrow absorption peak.

We accomplish such metasurfaces experimentally by employing 3C-SiC nanopillar arrays. The electric and magnetic dipole resonances are overlapped in the high index, and high absorption, region around the transverse optic (TO) phonon. We demonstrate an absorptance of 78% with a quality factor of 170. This design has one of the highest quality factors of any thermal emitter at this wavelength range while also still possessing near-unity absorptivity. In addition, the resonators have a deep sub-wavelength size due to the high refractive index near the TO phonon which results in a relatively angle insensitive response, unlike past work on SiC gratings.

Freely controlling the surface plasmon polaritons (SPPs) is always an issue of photonic researches. While traditional approaches to excite and reshaping SPPs are widely utilized for a long time, they still suffer from some inherent challenges, e.g., low-efficiency, limited functionalities and huge size. While gradient metasurfaces exhibit strong abilities to control electromagnetic waves, most of previous works are devoted to modulate far-field EM waves [1-3]. Meanwhile, some metasurfaces are proposed to either couple the SPPs [4-6] or control the wavefronts of SPPs [7, 8] with very high efficiency. However, the metadevice with these two distinct functionalities merged together are rarely reported. Here, we propose a new scheme to simultaneously excite and reshape the SPPs with a single meta-device. Moreover, the chirality of input propagating waves can be utilized as a flexible freedom to modulate the wavefronts of the excited SPPs [9, 10]. Moreover, the wavefronts of the excited SPPs can be flexibly modulated to the totally independent forms, e.g., surface plasmon focusing and deflection, by simply changing the polarizations of impinging light. Our idea is successfully demonstrated by full wave simulations and near-field experiments. Our work may stimulate many near-field related applications, e.g., SPP holograms, complex SPP beam generations, super resolution imaging, enhanced non-linear effect, and so on.

Abstract
An electrically tunable filter based on a nanoimprinted plasmonic phase retarder and liquid crystal cell is reported. A plasmon resonance and its abrupt phase jump yield structural colors between crossed polarizers. A range of 8V is enough to access to more than half of the area covered by standard RGB filters in CIE color coordinates with a single filter. Such approach is foreseen in particular to increase the spatial resolution of display devices.

1. Introduction
Surface plasmon resonances in metallic nano-structures enable the confinement and manipulation of the electromagnetic field well below the diffraction limit, thus opening new paradigms for phase and polarization control of light. An electrically tunable filter covering a large area in CIE coordinates is reported here. This effect is achieved by design and fabrication of plasmonic nanostructures showing a strong and spectrally narrow birefringence effect. The color transmitted through the device can be actively controlled by liquid crystals.

2. Discussion
The basic working principle of the device is shown in Fig. 1. A plasmonic phase retarder can generate different colors in transmission when placed between crossed polarizers and the output polarization is rotated [1]. The plasmonic phase retarder consists of a periodic array of deep-subwavelength metallic nanowires (50nm width), in order to have a stable optical response as a function of the incidence angle. The light polarized across the nanowires (TM) excites a plasmon resonance, while the other polarization (TE) does not induce a resonance. Here, a first entrance polarizer prepares the incident light in a polarization state oriented at 45° from the nanowires orientation. A phase retardation between TM and TE polarization yields an elliptically polarized light in transmission. A polarization analyzer based on liquid crystal cells allows to project the transmitted light onto a polarization state whose orientation depends on the applied voltage. Interferences between the different birefringent contributions lead to a color effect. As a result, the transmitted light has different colors depending on the applied voltage.

Figure 1: (a) Plasmonic retarder between in a polarizer and a liquid crystal based polarization analyzer, allowing to generate a variety of colors as a function of the voltage applied to the liquid crystal cell. (b) Plasmonic phase retarder made of a deep subwavelength array of silver nanowires. (c) Measured phase retardance between polarization along and across the wires.

In order to ensure the applicability to large area production, UV nanoimprint lithography (UV-NIL) and thin film coatings have been used to fabricate the plasmonic phase retarder, which are both wafer-scale and roll-to-roll compatible methods. The nanoimprint master consists in a periodic grating over an area of 30x30 mm\textsuperscript{2} fabricated with electron beam lithography (EBL). A 100 nm Si wafer was initially covered with 20 nm of Cr in a blanket deposition by electron beam evaporation. A thin ~100 nm PMMA layer was subsequently spin-coated onto the Cr layer and exposed by EBL. The wafer was developed and the pattern
transferred from the PMMA layer onto the Cr layer by plasma etching. The PMMA layer was subsequently stripped and the grating pattern transferred into the Si wafer by inductively coupled plasma reactive ion etching (ICP-RIE), resulting in a well-controlled and anisotropic etch [2]. Finally the Cr mask was removed by CI-based plasma etching, generating the UV-NIL master. A plasmonic phase retarder has been fabricated by UV-NIL of the grating master and evaporation of a silver thin film, followed by an encapsulation. The evaporation is performed with an angle, so that a self-shadowing effects prevents full coverage of the surface. The resulting structure is sketched in Fig. 1b and consists in a periodic array of silver nanowires with a cross section forming an inverted U-shape. This particular shape shows a high degree of tunability of the plasmon resonance position given the constraints of a sub-wavelength periodicity, and also enables a higher degree of transmission. Multiple interfering resonances are observed so that the peak transmission can reach >70%. Measurements of the phase retardation between the transmitted TM and TE fields (Fig. 1c) show a strong phase variation at the plasmon resonance at 750nm. Placed between a polarizer oriented at 45° from the nanowires orientation and a liquid crystal cell, the transmission spectrum of the plasmonic phase retarder can be tuned with the voltage applied to the liquid crystal cells. For a low voltage, the polarization transmitted through the liquid crystal cell is oriented along the gratings lines. For higher voltage, the light transmitted through the liquid crystal cell is oriented across the gratings lines and the resulting spectrum has a dip in transmission, which is the signature of a plasmon resonance at 725nm. At a voltage of 8V, a full rotation of the polarization by 180° has been spanned. The corresponding colors are shown in the CIE plot of Fig. 2a. A large range of colors can be spanned using this approach. Compared to a system where the analyzing polarization is rotated mechanically, the colors are similar for a low voltage up to 5.5V and diverge for higher voltages. The different originates from the appearing of Michel-Lévy colors in the birefringent liquid crystal cells. Therefore, only a voltage of 8V is enough to obtain a large number of different colors. In Fig. 2b, different colors have been selected at particular voltages, showing in particular that orange, magenta, purple, blue, turquoise, green and yellow can be obtained. Further colors ranging from orange to more saturated purple and blue can be obtained for higher voltages (from 9V to 20V), corresponding to a larger contribution of the Michel-Lévy interference colors. However, these colors require more time to be generated which reduces their applicability to a display device with high frequency.

Figure 2: (a) CIE plot of color range spanned by the system. White: colors obtained by mechanical rotation of an analyzing polarizer. Black: colors obtained by increasing the voltage applied to the liquid crystal cell from 0V to 20V. (b) Colors at particular voltages.

3. Conclusions

We performed the design, fabrication and characterization of plasmonic phase retarders with spectrally narrow phase variations. Starting with the fabrication of a high resolution master using electron beam lithography, an upscalable nanoimprint and thin film coating process flow has been used to fabricate the plasmonic retarders. We have shown the tunability of their transmitted colors using liquid crystal cells, which paves the way towards their implementation in displays [3]. In particular, a range of 8V is enough to access to more than 50% of the area covered by standard RGB filters in CIE color coordinates with a single filter. Such approach is foreseen in particular to increase the spatial resolution of display devices.

I will here present our recent results on reflective displays, with focus on developing and understanding hybrid plasmonic and electrochromic systems for electronic paper in color.

Electrochromic systems have potential to enable highly important applications for society, such as smart windows and various types of energy-efficient displays and labels for use in, for example, internet-of-things devices, electronic readers, and advertisement boards.

In part of our research, we study organic electrochromic conducting polymers. These materials are popular for electrochromics due to advantages such as low-cost and compatibility with high throughput and low-temperature processing. Furthermore, they can provide superior switching speeds and optical memory compared with common inorganic alternatives. Our recent studies demonstrate that they can be used in various types of devices, including free-standing electrochromic paper, infrared electrochromic systems, and greyscale picture-to-picture displays.¹²³

Conducting polymers, however, cannot provide good control of the reflected color, but are typically limited to black and white functionality (or blue and white). By contrast, plasmonic metasurfaces are capable of providing highly reflective surfaces with vibrant colors, which is ideal for reflective displays in color. We studied such plasmonic metasurfaces based on the abundant metals aluminum and copper, instead of the more commonly used gold and silver.⁴ The metasurfaces were capable of providing high-quality colors in reflection, covering all the primary RGB colors and enabling accurate reproduction of color photographs. Combining these metasurfaces with electrochromic polymers then enabled the development of switchable plasmonic devices.⁵ In brief, we utilized the variable transparency of electrochromic polymers to control the reflection from underlying colorful plasmonic metasurfaces. Besides these works, I would also like to present our yet unpublished research addressing the need for solution-processable fabrication methods not only of the conducting polymer layers, but also of the plasmonic metasurfaces.

Abstract

The combination of plasmonic nanostructures and electrochromic materials for dynamic color generation has been of interest in recent years due to the possibility to make reflective displays in full color with extremely low power consumption compared to emissive displays. We show a comparison between two electrochromic materials, tungsten trioxide (inorganic) and PProDOT-Me₂ (organic), for electrical modulation of the resonantly reflected light from plasmonic nanostructures. The comparison focuses on achievable contrast, switching speed, coloration memory and power consumption.

1. Introduction

Plasmonic metasurfaces with conjugated polymers have been used to generate dynamic color control in reflection mode [1][2]. The metasurfaces consist of three solid films made by evaporation: 150 nm silver film, for high reflection, an alumina spacer layer which tunes the reflective color (via Fabry-Pérot interference) and a 20 nm gold film where short-range ordered 150 nm nanoholes are prepared by colloidal lithography. These structures can generate vibrant red, green and blue colors which may be used as pixels in a reflective display. To switch the colors on and off, conjugated polymers with tunable optical absorption have been used [1]. However, there is room for improvements regarding the contrast, the switching speed, the coloration stability and power consumption.

Among materials which have electrochromic properties, we chose to compare the best inorganic and organic ones for full transparent/black switching across the visible. The first is tungsten trioxide (WO₃), an inorganic electrochromic material that has been used in smart windows applications for many years [3]. It shows high contrast over the whole visible spectrum up to >50% [4] and long lifetime [5]. The second is PProDOT-Me₂, reported to show highest contrast among all polymers (close to 78%) [6] and fast switching speed [7].

2. Results and discussion

Fig.1 shows a schematic of the structure used for the comparison. Bleached and colored state correspond to a voltage of 1 V and -1 V respectively vs Ag/AgCl. A Pt wire is used as counter electrode. WO₃ is switched using 1 M LiClO₄/Propylene Carbonate as electrolyte while PProDOT-Me₂ using 0.1 M Tetrabutylammonium perchlorate/ Acetonitrile.

In Fig.2, transmission spectra of 285 nm WO₃, approximately 200 nm PProDOT-Me₂ and the bare gold substrate before deposition (sputtering of WO₃ and electropolymerization of PProDOT-Me₂) are reported. WO₃ shows a contrast of 22% in the red region (660 nm), 32% in the green region (520 nm) and 25% in the blue region (490 nm). PProDOT-Me₂ shows a contrast of 7% in the red region, 15% in the green region and 11% in the blue region. Although the contrast does not seem to reach values comparable with, for example, black and white paper (around 50%) [8], both are reported to have potential to reach higher contrast [3][6] and data is here presented for transmission mode. Results will improve after optimization of the electrochemical polymerization of PProDOT-Me₂ and thickness of the films. The ideal thickness is around 200 nm for PProDOT-Me₂ and 300 nm for WO₃ in transmission, which are a good compromise between high contrast and transparent bleached state. In
reflection, they will differ by approximately a factor of 2 as the light passes through the film twice. The switching speed of PProDOT-Me₂ is on the order of hundreds of ms, while for WO₃ in the order of a few seconds which is acceptable for devices displaying stationary images. Coloration memory of WO₃ and PProDOT-Me₂ is on the order of a few minutes. It is defined as the time required for the contrast to drop by 10% while no voltage is applied. The maximum contrast can then be restored with a short voltage pulse. The power consumption per switch is, on average, 4 mJ/cm² per full switch for PProDOT-Me₂ and 30 mJ/cm² per full switch for WO₃.

The coloration memory of both WO₃ and PProDOT-Me₂ is on the order of a few minutes and the full contrast can be restored with a short voltage pulse. The power consumption for full switch is 30 mJ/cm² for WO₃ and 4 mJ/cm² for PProDOT-Me₂. More accurate evaluation of the power consumption will consider the short voltage pulse needed to restore the full contrast.

Abstract

Optical structures based on nano-structured ultrathin materials offer unprecedented flexibility in molding light propagation for a variety of applications from the visible to the infrared range. In this talk we will discuss our recent work on optical surfaces that combine large-area graphene and/or ultra-thin (<10 nm) metal films with scalable nano-patterning techniques (dewetting, nano-imprint). Their applications include transparent electrodes, glass functional nano-structures for displays, and plasmonic metasurfaces for surface-enhanced sensing.
Tunable All-dielectric Metasurface for Color Printing

Abstract
Color printing has drawn tremendous attention as a promising candidate in display and security technology. Plasmonic nanostructures has been intensively investigated and opened up a way to achieve color printing at deep-subwavelength scales. However, plasmonics suffers from intrinsic loss and heating effect. Dielectric materials with low loss and strong mie resonance become a promising candidate to fabricate metasurface for color printing. Here, we demonstrate all-dielectric Si nano-rings (SRMs) for generating high saturation colors by tuning structure parameters.

Introduction
Colors are everywhere in our daily lives and play important roles in art works, signal indicators and decoration industry due to their abilities for information transfer and aesthetic expression. Among various mechanisms to generate colors, structure color, which directly generates colors by manipulation of light absorption and scattering utilizing nanostructures, has shown great promise in next generation imaging, display and security technology. Metallic nanostructures that possess the property of surface plasmon resonance open up a way to generate structural colors at deep-subwavelength scales. Recent studies show that array of small isolated metal nanoparticles can produce different colors. Such plasmonic colors have extremely high spatial resolution and are robust under ambient effect [1]. Plasmonic colors can therefore be used in security engineering and high-density data storage. However, plasmonics has intrinsic drawbacks such as high optical losses, heating effect, and incompatibility with semiconductor nano-fabrication processes, which reduces color quality and impedes its spread and applications. Dielectric and semiconductor materials with high refractive indices can be promising alternatives for structure color generation due to low loss and strong mie resonance [2]. Qinghai Song et al. demonstrate TiO2 metasurfaces for full color printing utilizing the electric and magnetic resonances [3].

Here, we demonstrate all-dielectric Si nanoring metasurfaces (SRMs) for full-color printing. Because of the strong local field enhancement due to Mie resonance, high reflection peaks have been obtained within the entire visible region. By carefully tuning the outer diameter, inner diameter of nanoring, and the distance between nanorings, the recorded colors were widely distributed in the a standard CIE 1931 chromaticity diagram map and match the R, G, B colors very well. Our approaches will be important in applications of imaging and data storage.

Discussion

Figure 1: Illustration of the metasurface for color printing. The parameters D, d and g denote the outer diameter, inner diameter and the spacing between the adjacent ring.

As depicted in Fig 1, the metasurface is composed of Si nanoring on PDMS substrate in square lattice. We invetigate the individual influence of the outer diameter, inner diameter and the spacing between the adjacent ring on the reflection spectra, which determine the reflected color. As depicted in Fig 2, with the increasing of the outer diameter, the spectra show red shift. With the increasing of the inner diameter, the spectra show blue shift. With the increasing of the spacing, the spectra split to two evident peaks. These are related to the interaction between the Si resonators.
Figure 2: (a) The effect of the outer diameter on the reflection. (b) The effect of the inner diameter on the reflection. (c) The effect of the spacing on the reflection.

Conclusions

In summary, we demonstrate all-dielectric Si nanoring metasurfaces (SRMs) for color printing. By varying the parameters, the reflection spectra can be tuned, which is suitable for color printing.

Abstract
The plasmonic color metapixels have attracted increasing interest in the area of sensing and information technologies, including high-density data storage. We experimentally demonstrate plasmonic nanostructures that significantly expand the number of degrees of freedom for tuning the output colors and encoding more information states in a single metapixel. Departing from the Morse-style sequential reading, a set of the plasmonic antennas orientation angles inside each metapixel is simultaneously mapped onto a unique color code and then translated into a corresponding state. Such information-multiplexing holds a great promise for high-density data storage, already exceeding the capacity of conventional optical disks.

1. Overview and Discussion
Accounting for the Global Datasphere that is predicted to exponentially explode from its 33 ZB (1 ZB = $10^{21}$ Byte) level in 2018 to 175 ZB by 2025 puts forward challenging technological tasks [1]. These challenges concern all branches of the modern information technologies. In the optical data storage, the storage density is fast approaching its theoretical limit, and the cost-per-bit is struggling to improve with increasing storage capacity [2]. In this talk, we offer designs and experimental demonstrations of optical metapixels that enable advanced optical data storage, based on structured color generation. Excitation of resonant modes encodes discrete topological states of metapixel designs into highly diverse colors, broadly increasing the information capacity that can be stored in an individual pixel. The combination of high color diversity with high spatial resolution enables robust, highly discernible color codes generated with metapixels. We also discuss an advanced parallel read-out system for rapid data acquisition unattainable with conventional optical data storage techniques. This is a important advancement beyond the approaches inherited from the Morse times (in 1837, Samuel Morse developed an early version of the Morse code) in the modern data storage – DVD and Blue-Ray disks – where dots and dashes are still translated from a reflected binary dash-dot sequence into meaningful content. So instead of using either dots or dashes, topologically-different nanostructures are employed in individual pixels. In the talk, we also review the structured colors that have attracted increasing interest to applications pertinent to optical displays, sensors, and cryptography due to their high spatial resolution and mechanical/chemical stability. Recently, such structured colors and especially plasmonic colors applications have generated much attention due to the increasing demand in optical steganography and cryptography techniques [4].

2. Conclusions
Thus, advancing from the Morse-style sequential reading, we associate the prime objective of the plasmonic color metapixels with the paradigm of storing and reproducing meaningful information with colors, where a set of the topological states inside each pixel area is mapped onto a unique set of colors and then decoded. Application of Artificial Intelligence techniques for optimizing the metapixels discernible with minimalistic hyperspectral filtering are also discussed. We conclude that the information-multiplexing metapixels hold a great promise for high-density data storage, advanced imaging steganography, and optical cryptography.

Light manipulation by natural photonic structures in diatom microalgae

Johannes Goessler and Martin Lopez-García

Abstract

In this work, we communicate an experimental investigation of the photonic properties of nano-porous silicate exoskeletons of diatom microalgae. We demonstrate that such natural structures can function as a wavelength selective light coupler and waveguide. The brilliant colors produced under certain illumination conditions could be the visual side-effects of an important underlying biological principle, i.e., manipulation of the photonic environment inside the cell to optimize light capture and photosynthesis.

1. Introduction

Recent research demonstrated that some plants evolved photonic structures that can modulate their photosynthetic efficiency [1]. However, this phenomena has not been yet described in algae. Interestingly, structural coloration is widespread in algae, but has been scarcely studied from a photonics perspective [2][3]. On this study, we unveil the effect of photonic structures in diatom microalgae light harvesting.

Diatoms are a class of unicellular microalgae encompassing more than 10,000 species. They are responsible for a quarter of carbon fixation by photosynthesis, and thereby of global importance as basal species in aquatic food webs. One outstanding feature of diatoms is a silicate exoskeleton named the frustule, perforated by periodic nanostructures like pores, honeycomb chambers or grids. The frustule has photonic properties and might facilitate photosynthesis in aquatic environments [4].

We studied the optical properties of a large centric diatom species (*Coscinodiscus granii*, Fig. 1a/b) by Fourier image spectroscopy in of reflected/transmitted configuration, which facilitate wavelength and angular dependent characterization at microscale. The frustule of this species has a well-defined hexagonal photonic crystal 2D lattice on a cylindrical symmetry (Fig. 1c/d).

2. Discussion

The highly ordered nano-porous structure of the silicate diatom frustule has been suggested to have a photonic behaviour. However, it is still debated how and why such structures are formed by diatoms. Possible biological functions of the periodic frustule lattice are discussed in the literature, e.g., mechanical strengths as a defence against predation, filtering of harmful agents such as virus and bacteria, or light manipulation for optimized photosynthesis.

Figure 1. a) Single cell specimen of the diatom *Coscinodiscus granii* under epifluorescence white light microscopy. b) SEM image of the frustule (silica extracellular structure). b) Detail of the hexagonal lattice showing cylinder shaped holes on the silica exoskeleton. d) Internal 3D structure of the frustule in conceptual illustration.

We present an advanced morphological characterization of live diatoms and oxidized frustules using Environmental-SEM and Focus Ion Beam (FIB), respectively. We observed two hexagonal lattices at the external (cribrum) and internal (foramen) side of the frustule. These two lattices seem to cause various photonic effects related to their different lattice structure. The detailed morphological 3D characterization of the frustule also revealed a honeycomb chamber inside the frustule wall. On the base of this advanced 3D morphological reconstruction, we developed a numerical model that can explain the experimental data on frustule photonic properties. In fact, our optical model suggests that light confinement could take place at the frustule providing a wave guiding channel for a more
efficient light distribution to other parts of the cell. Moreover, our microscatterometry measurements suggest a blue-shift in the photonic response of the frustule (Fig. 2), which could be related to wave-guiding that could facilitate redistribution of more energetic light within the cell. However, the coupling effects to single modes described by the optical model have not yet been observed in experimental measurements (Fig. 2). This might in future be solved by increased spectral and/or angular resolution of the setup in this natural photonic crystal slab.

![Reflectance of a frustule in air as shown in Fig 1b. The measurement was performed by Fourier image spectroscopy with white light and a circular spot of ~40 µm diameter.](image)

**Figure 2.** Reflectance of a frustule in air as shown in Fig 1b. The measurement was performed by Fourier image spectroscopy with white light and a circular spot of ~40 µm diameter.

### 3. Conclusions

Our work explain the major features in the photonic response of a diatom frustule. Moreover, our data are supported by theoretical models which allows us to infer non-trivial photonic and biological properties of the microalgae such as wave guiding of the incoming light. In conclusion, our results suggest that the frustule may be understood as a photonic environment in which a highly efficient natural photocatalytic process, i.e., photosynthesis, takes place. Also, the photonic properties of the frustules could be a source of inspiration in light harvesting technologies such as new designs for more effective photocatalytic reactors.

Dual-color plasmonic filters

E. Heydari,¹ J. Sperling,¹ S. Neale¹ and A.W. Clark¹*

¹School of Engineering, University of Glasgow, UK
*corresponding author: Alasdair.clark@glasgow.ac.uk

Abstract- We demonstrate a plasmonic approach to high-density optical data storage. We employ dual-color plasmonic nano-pixels to encode two information sets into a single arrays of metal nano-apertures.

The ability to effectively separate discrete colors from white-light lies at the heart of how we record and view optical information; whether that be the arrangement of colored inks in painting and printing applications, or the spectral filters that enable many modern image display and recording technologies. Structural color systems based on engineered nanophotonic materials have emerged as an appealing alternative to absorptive dyes [1]. Among these examples are color filters based on plasmonic resonances. Filters such as these are promising candidates for applications in sub-wavelength color printing [1], image recording [2], anti-counterfeiting [3], and data storage [4].

Using asymmetric cross-shaped nano-apertures in a thin film of aluminum, we demonstrate a method for patterning full-color images and codes, at subwavelength resolutions, that exhibit dual, polarization-dependent information states. Each aperture is engineered to exhibit 2 plasmonic colors that can be individually tuned across the sRGB spectrum. This enables us to encode 2 arbitrary information sets using a single nano-aperture array. We show that using a standard optical microscope, color separation can be controlled down to 2x2 nano-pixels while retaining polarization selectivity. The maximum data density we can achieve using this technique is approximately 1.46 Gb/cm², with the added ability to further encode each of those pixels using the full visible-color spectrum.

Tunable spherical colloidal photonic pigments with non-iridescent structural color

Laurinda Areias¹, José Paulo S. Farinha¹

¹CQE & CQFM-IN, Instituto Superior Técnico, Universidade de Lisboa, Lisboa, Portugal
*presenting author: laurinda.areias@tecnico.ulisboa.pt

Abstract

Colloidal photonic crystals exhibit shining structural coloration that arises from the modulation of electromagnetic waves by means of Bragg reflection from photonic stop bands, originated from the periodical arrangement of nanoparticles. We develop uniformly sized spherical colloidal photonic pigments that exhibit structural coloration throughout the visible spectrum light range, from differently sized colloidal building blocks synthesized by emulsion polymerization. Spherical photonic pigments were obtained upon self-assembly of colloidal nanoparticles inside monodispersed emulsion droplets generated by soft-lithography microfluidics.

1. Introduction

Structural colors¹ are based on diffraction, scattering, and dispersion of light as a result of its interaction with structured materials². Materials with structural color shows no photobleaching and can generate a wide range of colors in non-toxic and environmentally friendly ways. Depending on their behavior with respect to the angle of observation, structural color can be iridescent and non-iridescent. The former offers color generated from structures that contain periodically arranged nano- or microparticles and depend on the observation angle. These are called photonic crystals³. By contrast, the latter possesses a quasi-ordered arrangement of colloids (photonic glass) and offers the opposite: angle-independent color, where the arrangement of the colloidal particles show a glassy structure with a short-range order⁴. these find a wide range of potential applications including reflective displays, colorimetric sensors, textiles, etc. In this study, non-iridescent spherical colloidal photonic crystals were fabricated by means of microfluidic droplet technology from soft-lithographic techniques. Differently sized highly monodispersed polymeric nanoparticles were synthesized by emulsion polymerization. Self-assembly of polymeric nanoparticles in the spherical confinement of emulsion droplets is induced by controlled temperature and stirring conditions. In order to break long range order, we added small amounts of black polydopamine nanoparticles to the emulsion droplets, that also act as incoherent light scattering absorbers, originating highly bright and non-iridescent photonic pigments.

2. Methodology and Results

Spherical photonic pigments were obtained from W/O emulsion droplets, generated in PDMS microfluidic devices. Dispersed aqueous phase is composed of a suspension of polymeric nanoparticles at 16% wt; continuous oil phase is composed of hexadecane with 3% SPAN 80 surfactant. Upon water evaporation, droplets shrunk, and polymeric nanoparticles self-assemble into ordered structures. Highly monodispersed spherical photonic pigments with sizes between 40-60 µm in diameter were obtained (figure 1A), from nanoparticles that self-assemble in face centered cubic structures (figure 1B, shows the hexagonal arrangement of nanoparticles on the surface of the microsphere). Polymeric nanoparticles with sizes from 173 to 333 nm in diameter, originated photonic pigments that spans the entire visible spectrum light range (figure 1C).

Figure 1: A) Spherical photonic pigments of 55 µm in diameter; B) Hexagonal close packed arrangement of polymeric nanoparticles (290 nm diameter) in photonic pigment surface; C) Reflectance spectra obtained for the 111 plane of structurally colored spherical photonic pigments, composed of differently sized polymeric nanoparticles.
2.1. Prediction of photonic stop band

The theoretical maximum reflectance wavelength of the photonic pigments can be calculated based on Bragg’s law of diffraction modified with Snell’s law:

\[ \lambda_{max} = 2d_{util} n_{eff} \left( 1 - \frac{s n^2 \theta}{n_{eff}^2} \right) \]  

(1)

\[ n_{eff}^2 = f_1 n_1^2 + f_2 n_2^2 \]  

(2)

\[ d_{111} = \frac{2}{\sqrt{3}} D \]  

(3)

where \( n_{eff}^2 \) is the average refractive index of the photonic structures. For polymeric air in air we calculate the average refractive index from the volume fractions occupied by nanoparticles and air (\( f_1 \) and \( f_2 \); generally 74% and 26%, respectively, for close-packed fcc structures) and their respective refractive index (\( n_1 \) and \( n_2 \)). The lattice spacing for the 111 plane is given by equation 3, where \( D \) corresponds to polymeric nanoparticles diameter.

The calculated maximum reflectance wavelength \( \lambda_{max} \) (eq. 1), are comparable to those obtained experimentally (table 1).

2.2. Non-iridescent colored photonic pigments

Upon addition of small amounts of polydopamine nanoparticles (93 nm diameter), a quasi-ordered structure is developed in contrast with the long-range order of photonic crystals. By applying Fast Fourier Transform (FFT) to the SEM images, a frequency domain is obtained, where the appearance of sharp spots at certain frequencies indicate the existence of structural periodicity. Comparing the pattern before and after addition of polydopamine nanoparticles, we confirm that the as-prepared structures have only short-range order. Figure 2 compare the FFT pattern of a photonic crystal pigments (A) and the corresponding photonic glass (B), upon addition of PD nanoparticles (highlighted in yellow circles).

The absence of long-range order is also noticed in angle resolved reflectance measurements, were light hits the sample at 45° and reflected signal is collected from 0 to 75°. From 0° to 75° viewing angles, only a slightly shift towards the blue, around 45 nm, is observed for the maximum reflected wavelength, as expected for non-iridescent structurally colored photonic pigments.

![Figure 2: Periodic (A) vs random arrangement (B) of colloidal polymeric nanoparticles in photonic pigments.](image)

3. Conclusions

Spherical non-iridescent photonic pigments were successfully obtained by combining microfluidics soft-lithography and temperature induced colloidal self-assembly of highly monodispersed polymeric nanoparticles. The obtained pigments provide a platform for future color and displays applications.

Enhancing the purity of reflective structural colors with bilayer hybrid absorbers and investigation of solution process via electrodeposition of thin-films

L. Jay Guo, Saurabh Acharya, Zhengmei Yang, Chengang Ji

Department of Electrical Engineering and Computer Science
The University of Michigan, Ann Arbor, MI, 48109, USA

Abstract:
In recent years, structural colors based on optical interference effects of layered structures and resonance of nanostructures have received increasing interest due to their various advantages over traditional colorant-based pigmentionation [1]. However, these structures typically involve sub-wavelength patterns that require complicated and time-intensive fabrication techniques such as e-beam lithography and focused ion beam milling, which significantly limit their large-scale feasibility. In comparison, planar thin-filmm structures based on Fabry-Pérot (F-P) cavity resonances can create wide-range colors by simply varying the spacer layer thickness. Their fabrication procedures only require physical vapor deposition tools (e.g., evaporation or sputtering systems), which have advantages of low cost and high scalability.

In many applications, structural colors of high purity and brightness are desired. Here we present a general strategy of selecting the appropriate material and thickness of each layer to create high-purity reflective colors in a classic asymmetric Fabry-Pérot cavity structure based on a dielectric-absorber-dielectric-metal multilayered configuration. Guided by the derived complex refractive index of the ideal absorber layer, an effective absorbing bilayer medium consisting of two ultrathin lossy films is used to improve the color purity of reflective colors by suppressing the reflection in the undesired color range with the enhanced optical absorption. Highly-purity red, green, and blue reflective colors are designed and experimentally demonstrated employing different effective bilayer absorbers. Due to the high refractive index of the dielectric material, the colored structures exhibit great angle-robust appearance up to ±60°. The generalized design principles and the proposed method of using effective bilayer absorbers open up new avenues for realizing high-purity thin-film structural colors with more materials selections.

Such multilayered structural colors could be fabricated using roll-to-roll deposition techniques [2]. Although they have been successfully adapted into pigment flakes for decorative paints, these special paints exhibiting a metallic appearance with high color purity are still too costly for wide-scale applications [3]. To address this issue, we developed a simple, inexpensive, and non-toxic bench-top electrodeposition process for the fabrication of structural color based on multilayer films at ambient conditions. This process avoids the need for expensive vacuum-based equipment and is compatible with highly non-planar substrates of arbitrary shape, size and roughness. Asymmetric metal-dielectric-metal structures were achieved by sequential electrodeposition of smooth gold, thin cuprous oxide, and finally thin Au on conductive substrates, forming an effective asymmetric Fabry-Pérot cavity. Different colors of high brightness were achieved by simply tuning the thickness of the electrodeposited middle cavity layer. Due to the high refractive index of the cuprous oxide dielectric layer, the vividness of the generated colors was invariant to viewing angle. This work is the first demonstration of solution-processed, electrodeposited metal-dielectric-metal
film stacks and highlights the clear advantages of this approach over traditional deposition or assembly methods for preparing colored films, and can be applied directly to curved surfaces.

Skin-like Full-Color Angle Independent Plasmonic Reflective

Pablo Manuel Cencillo Abad, Debashis Chanda
NanoScience Technology Center, Dept. of Physics, CREOL, College of Optics and Photonics, University of Central Florida, Florida, USA

Abstract
Tuning plasmonic light absorption with liquid crystal (LC), the color reflected from a nanostructured surface can be changed as a function of voltage. The engineered plasmonic surface allows complete LC reorientation and maximum overlap between plasmonic fields and LC, enabling large tunability across the entire visible spectrum.
Acoustic Metamaterials in the audible frequency range
Using mean flow to make a broadband acoustic diode

Vassos Achilleos, Yves Aurégan* and Vincent Pagneux

Laboratoire d’Acoustique de l’Université du Mans, CNRS, Le Mans Université, Avenue Olivier Messiaen, 72085 Le Mans Cedex 9, France
*corresponding author, E-mail: yves.auregan@univ-lemans.fr

Abstract

A mean flow in a waveguide can cause significant changes in wave propagation. Among the effects of flow (possibility of creating an acoustic gain [1], changes in the characteristics of the metamaterials located in the waveguide [2], etc.), the flow can be used as a vectorial field that break reciprocity in order to make a broadband acoustic diode. In this context, we demonstrate theoretically and experimentally that an acoustic diode can be manufactured in a flow duct by slowing down the acoustic wave. In the slow sound region, the effective sound velocity can be so low that no waves can propagate against the flow while propagation is still possible in the direction of flow. Sound is slowed down by putting locally reacting tubes in the duct wall. This phenomenon can occur over a wide range of frequencies that can be extended to very low frequencies.

1. Introduction

An acoustic diode is a device that allows acoustic waves to travel in one direction but not in the opposite direction. This type of device is quite difficult to achieve because the reciprocity is difficult to break in a conventional acoustic system. To obtain this reciprocity break, non-linearity, temporal invariance break or polarization of the system with a vector field can be used. The use of a mean flow in an acoustic system adds a vector field that breaks reciprocity. In this article we show that the use of a compliant wall material emphasizes this effect over a wide frequency range.

2. Model

When considering the propagation of sound in a 2D waveguide with a uniform flow, the 2D convected wave equation and boundary conditions are written [3]:

$$\begin{cases}
D_t^2 \phi - \nabla^2 \phi & \text{for } 0 < y < 1 \\
\partial_y \phi = 0 & \text{for } y = 1 \\
\partial_y \phi = D_t(\partial_y \phi) & \text{for } y = 0
\end{cases}$$

(1)

where $\phi(x, y, t)$ is the normalized acoustic velocity potential in the duct, $D_t = \partial_t + M \partial_x$ is convective derivative, M is the Mach number and $C = \tan(b\omega)/\omega$ is the normalized compliance of a wall composed of reactive tubes (see Fig. 1). The parameter $b$ is the ratio between the height of the tubes and the height of the duct.

Looking for solutions propagating in the $x$ direction in the form $\exp(i(-\omega t + kx))$, leads to the dispersion equation expressed as a function of the frequency in the moving frame $\Omega = \omega - Mk$:

$$D(\omega, k) = \alpha \tanh(\alpha) - \frac{\tan(b\omega)}{\omega} \Omega^2 = 0,$$

(2)

where $\alpha = k^2 - \Omega^2$.

3. Dispersion relation

The real solutions of the dispersion equation (2) are given in Fig. 2. Without flow, there are two solutions for each frequency and the liner introduces a dispersion relation with a quarter-wavelength resonance ($\omega_R = \pi/2b$). For low frequencies, the dispersion relation can be approximated by $\omega = k/\sqrt{1+b}$, leading to a phase velocity $c_b = 1 \sqrt{1+b}$ which is always smaller than the free space normalized velocity $c_0 = 1$. Thus the presence of the liner on the wall of a wave guide produces slow sound.

When a mean flow flow is present (blue curves in Fig. 2) the solutions of the dispersion relation (2) have a richer structure (see also [3]). Starting from the low frequency regime (for instance $\omega_1$ in Fig. 2), the Eq. (2) has four real solutions corresponding to four propagating modes. Two of them, which we call acoustic, approach $k = 0$ as $\omega \rightarrow 0$, and they propagate in both directions with the slow sound velocity $c_b$ corrected by the convective effects. The other two modes do not exist without flow and we further on refer to them as dispersive modes. In this low frequency regime both the dispersive modes travel in the direction of the mean flow (positive slope). Beyond a critical frequency $\omega_c$, two of the solutions collide and disappear and for higher frequencies ($\omega > \omega_c$) for instance $\omega_2$ in Fig. 2, the system

Figure 1: Sketch of a waveguide with a liner of height $b$. 
supports only two modes that are traveling in the flow direction.

In summary, in the presence of flow above a liner, for frequencies below \( \omega_c \), acoustic propagation is possible in both directions while for frequencies above \( \omega_c \), acoustic propagation is only possible in the direction of flow. This principle can be used to build a broadband diode because \( \omega_c \) can be set to zero when \( M > 1/\sqrt{1+b} \).

### 4. Experimental results

To experimentally perform a diode, a compliant wall composed of thin tubes with a honeycomb structure is used (see Fig. 3-a). The thickness of the honeycomb structure is such that the ratio between the height of the tubes and the height of the duct is \( b = 10/3 \). The diode is flush mounted in a rigid rectangular channel between two measuring sections (upstream and downstream) which allows the determination of the incoming and outgoing waves on both sides of the diode. Two acoustic sources, on both sides of the system, provide two different acoustic states of the system to evaluate the four elements of the scattering matrix for plane waves (transmission and reflection coefficient in both directions). The measured transmission coefficients are shown in Fig. 3-b in the case without flow and in the case of grazing flow with a mean Mach number equal to \( M = 0.3 \).

Without flow, the transmission coefficient displays some oscillations at low frequencies that are due to standing waves along the length \( L \) of the material. Due to the decreasing of the effective sound velocity when the frequency approaches the quarter-wavelength resonance \( (f_r = c_0/4H = 1715 \text{ Hz}) \), the transmission coefficient is supposed to oscillate increasingly rapidly until it reaches the bandgap. This effect is partially masked in this experiment by the dissipative effect in the material. With flow, the diode effect can be clearly see by considering the difference in the transmission coefficients according to the direction of the wave propagation. In the flow direction, the transmission is slightly larger than without flow but against the flow the transmission is substantially reduced. For frequencies higher than 850 Hz, no significant transmission against the flow can be measured showing a blockage of the transmission against the flow as predicted by the model for super-critical conditions.

### 5. Conclusions

The diode effect in audible acoustics has been theoretically demonstrated and experimentally confirmed. The next steps will be to take better account of the dissipative effect and the boundary layer effect in order to extend this unilateral propagation to very low frequencies.

Abstract

We inspect the influence of the spacing on the resonance of a periodic arrangement of Helmholtz resonators for which an effective model is derived. It is shown that the strength of the resonance is enhanced when the array becomes sparser, which provides a degree of freedom to control the radiative damping of the array. This is of particular interest since it does not affect the resonance frequency nor the damping due to losses within each resonator; besides, it does not affect the total thickness of the array. We show that it can be used for the design of a perfect absorbing walls.

1. Introduction

Originally studied for their musical properties [1], the Helmholtz resonators are the most classical resonators for the acoustic waves. When organized in two or three dimensional arrays, they are known to have a collective behavior which has been used for several applications, including the improvement of edifice sonority [2]. With the development of metamaterials, it has been promoted to a key piece in devices as perfect absorbers efficient in the low frequency regime [3]. Here, we use an effective model derived in [4] to study the influence of the array spacing, from compact to sparse arrays. This model provides the reflection coefficient of the array in a close form, and a comprehensive picture of the wave pattern inside the resonators (in particular the pressure amplitude is correctly predicted). We shall use that the strength of the resonance can be tuned by the spacing $h$. The idea is intuitive: for a sparse array the resonance is close to that of a single resonator and it turns out that the collective effect of closer resonators weakens their resonance. This provides a degree of freedom to tune the radiative damping without affecting the damping due to the losses, this latter being related to the geometry of a single resonator, not to the array spacing. Thus, when the losses are accounted for, the two dampings can be tuned independently to reach the so-called critical coupling condition realizing perfect absorption.

2. The effective model

The two-scale homogenization of the array of Helmholtz (see Fig. 1) resonators has been presented in [4]. It provides an equivalent anisotropic medium replacing the region of the cavity where the wave equation reads as

$$\frac{\partial^2 p}{\partial y^2} + k_r^2 p = 0, \quad (1)$$

where $k_r$ is the wavenumber in the cavities, being possibly complex when the losses are accounted for (and $k_r = k$ in the lossless case). The acoustic velocity $u = (u, v)$ reads as $u = 0, v = \varphi, \partial_k p$. Eventually, the effect of the necks is encapsulated in non intuitive jump conditions, namely

$$[p] = hB \varpi, \quad [v] = -hC \frac{\partial^2 p}{\partial x^2} - e\varphi k_r^2 p. \quad (2)$$

In the above expressions, we have defined the jump of $f$

\begin{align*}
\text{being } [f] &\equiv f|_{y=0} - f|_{y=-e}, \text{ and its mean value } \overline{f} \equiv \frac{1}{2} \left( f|_{y=0} + f|_{y=-e} \right) . \text{ Then, } k_r \text{ refers to the wavenumber in the neck, being possibly complex valued in the lossy case (and } k_r = k \text{ otherwise). In principle, the interface parameters } (B, C) \text{ are deduced from elementary problems that have to be solved numerically, but good estimates of } (B, C) \text{ are given by}

\begin{align*}
B \simeq \frac{e}{h\varphi_e} - \frac{1}{\pi} \log \left( \frac{\pi \varphi_e}{2} \right) &\quad \sin \left( \frac{\varphi_e}{2} \right) \sin \left( \frac{\varphi_e}{2} \right) , \\
C \simeq \frac{\pi}{16} \varphi_e^2.
\end{align*} \quad (3)
\end{align*}

Eventually, the boundary condition to be applied at the bottom of the cavities at $y = -D$ with $D = e + d$ remains the condition of rigid wall (zero normal velocity) which holds all along the anisotropic equivalent medium, namely

$$\frac{\partial p}{\partial y}(x, -D) = 0. \quad (4)$$

Figure 1: Array of Helmholtz resonators, with the aspect ratios $\varphi_e = h_e/h$ and $\varphi = h_e/h$. A compact array corresponds to $h_e \sim h$, a sparse array to $h_e \ll h$.\n
\textsuperscript{3} META 2019, LISBON - PORTUGAL, JULY 23 – 26, 2019
3. Realization of a perfect absorbing wall

For an incident wave \( p^i(x, y) = e^{-i\omega y + i\beta x} (\alpha = k \cos \theta, \beta = k \sin \theta) \), the solution \( p(x, y) \) of the effective problem (1)-(4) reads \( p(x, y) = A \cos(k_y(y + D))e^{i\beta x} \) for \(-D < y < -e\), and \( p(x, y) = (e^{-i\omega y + Re^{i\theta}y}) e^{i\beta x} \), for \( y > 0 \). The amplitude \( A \) in the cavity and the reflection coefficient \( R \) are given in [4], and the approximate expressions

\[
R \approx \frac{k_x t_r - \frac{1}{h_c} - (i - \delta_u) \alpha_{rd} + i \alpha_{vd}}{k_x t_r - \frac{1}{h_c} + (i - \delta_v) \alpha_{rd} + i \alpha_{vd}},
\]

\[
A \approx \frac{2}{h_c \cos k_x d} \frac{k_x t_r - \frac{1}{h_c} + (i - \delta_v) \alpha_{rd} + i \alpha_{vd}}{k_x t_r - \frac{1}{h_c} - (i - \delta_u) \alpha_{rd}},
\]

allow to exhibit the balance between the radiative damping \( \alpha_{rd} = \frac{kh}{c^2} \) and the viscous losses \( \alpha_{vd} = \frac{\nu}{d} \), where we have defined \( k_x = k_x + ik_i \), \( \tan(k_i d) = t_r + it_i \), and \( \delta_u = (k_i/k_e + t_i/t_e) \). The losses are due to viscous thermal effects and following e.g. [5], they are written

\[
k_x = k \left( 1 + \frac{1}{\sqrt{\nu}} \alpha_{cs} \right),
\]

with \( \alpha_{cs} \) defined by \( \alpha_{cs} = \frac{\sqrt{\nu}}{\sqrt{\alpha_{vd}}} \left( 1 + \frac{\alpha_{cs}}{\sqrt{\nu}} \right) \frac{1}{h_x \cos k_x d} \), with in the air \( \nu = 1.5 \times 10^{-5} \text{ m}^2 \text{s}^{-1} \) the kinematic viscosity, \( c = 340 \text{ m} \text{s}^{-1} \) the sound speed and \( \gamma = 1.4 \) the heat capacity of air, hence \( \alpha_{cs} = 3.10^{-4}/h_{na} \text{ m}^{-1/2} \). Perfect absorption is obtained at the critical coupling, when the losses balance the leakage \( \alpha_{vd} = \alpha_{rd} \) and when this condition is compatible with that of the slightly shifted resonance \( k_x t_r = \frac{1}{h_c} - \delta_u \alpha_{rd} \). In order to fulfill these two conditions, we need two degrees of freedom which are provided by \((k, h)\), although it is not guaranteed that a solution can be found for any geometry of the resonators. We report the absorption \((1 - |R|)\) computed numerically against \((k, h)\) in Fig. 2 for \( e = 0.6 \text{ cm} \) and for \( e = 2.4 \text{ cm} \). In both cases, the perfect absorption is obtained for relatively low \( kh \) value: \( k = 0.191 \text{ cm}^{-1}, h = 9.165 \text{ cm} \) for \( e = 0.6 \text{ cm} \) and \( k = 0.126 \text{ cm}^{-1}, h = 5.65 \text{ cm} \) for \( e = 2.4 \text{ cm} \), well predicted by the effective model (white plain circles).

Finally, the sensitivity of the perfect absorption on \( h \) is illustrated in Fig. 3 where we report the wavefields for the same Helmholtz resonators arranged on an array with spacing \( h = 9.2 \text{ cm} \) (realizing perfect absorption) and with a spacing \( h = 3 \text{ cm} \). To get a perfect absorption for a spacing \( h = 3 \text{ cm} \), we should use \( e = 7 \text{ cm} \) (and for a spacing \( h = 1 \text{ cm} \), \( e \approx 15 \text{ cm} \)).

Figure 2: Absorption \((1 - |R|)\) for an array of resonators \((h_e = 1 \text{ cm}, d = 5 \text{ cm}, h_i = 1/3 \text{ cm})\) (a) \( e = 0.6 \text{ cm} \) revealing a perfect absorption \(|R| = 0\) for \( h = 9.165 \text{ cm} \) and \( k = 0.191 \text{ cm}^{-1} \). (b) \( e = 2.4 \text{ cm} \); \(|R| = 0\) for \( h = 5.65 \text{ cm}, k = 0.126 \text{ cm}^{-1} \).

Figure 3: Acoustic pressure fields for an incident wave \((kh_i = 0.19, \theta = 40^\circ)\) on an array of Helmholtz resonators \((d/h_e = 5, e/h_e = 0.6, h_i/h_e = 0.3)\); each panel contains the homogenized solution (right half panel) and the solution given by direct numerics (left half panel). (a) \( h/h_e = 9.2 \) realizing perfect absorption, (b) \( h/h_e = 3 \) for comparison.

Abstract

We study the propagation of acoustic waves through a thin bubbly screen. The analysis is conducted in the time domain and preserves the non linear response of the bubbles; it provides an effective model involving a jump of the normal velocity coupled to an equation of the Rayleigh-Plesset’s type for the bubble radius. Numerical implementation of the effective model allows us to discuss the influence of the distance between bubbles within the screen and that of the non linearities.

1. Introduction

In 1985, Caflisch and co-workers analyzed the wave propagation in bubbly liquids \cite{Caflisch85} offering a rigorous mathematical framework to the former analysis developed by \cite{KellerSamoilov68}. Using asymptotic analysis, they derived an effective wave equation involving a continuous version of the bubble radius satisfying an equation of the Rayleigh-Plesset’s type.

In some practical situations, the reduction of bubbles is reduced to one or a few layers (Fig. 1). The most famous example are the anechoic tiles, codenamed Alberich, developed during the Second World War by the german marine; these tiles are the building blocks of a rubber net containing bubbles used to block the signals of sonars. It is also the case of bubble nets used to protect underwater structures from damage by underwater explosions or those created by some of the marine mammals to catch fish. Recently, these metascreens with subwavelength thickness have been revisited in the context of metamaterials. Resonant bubbles are the equivalent of split rings in electromagnetism and by designing judiciously their structuration, it is possible to obtain exotic properties as those obtained for their electromagnetic counterparts, see e.g. \cite{Chiappe04}.

To describe such a thin screen, we conduct an asymptotic analysis which results in effective transmission conditions (instead of an effective wave equation); while the pressure is continuous across the screen, the normal velocity satisfies a non intuitive transmission condition involving a continuous version of the bubble radius satisfying an equation of the Rayleigh-Plesset’s type. The calculations are performed in the time domain and preserving the non linear behavior of the bubble oscillations. We present numerical results which exemplify the influence of the spacing between bubbles and of the non-linearities on the propagation of an acoustic wave train.

Figure 1: The actual problem of a bubbly screen in the \(x_1=0\) plane with spacing \(h\).

2. The actual and the effective problems

We start with the Euler equations which apply both in the air bubbles and in the surrounding fluid, namely

\[
\begin{align*}
\frac{\partial \rho}{\partial t} + \text{div} (\rho \mathbf{u}) &= 0, \\
\rho \left( \frac{\partial \mathbf{u}}{\partial t} + (\mathbf{u} \cdot \nabla) \mathbf{u} \right) &= -\nabla p, \\
\nabla \cdot \mathbf{u} &= 0.
\end{align*}
\]

For a nearly incompressible liquid and a perfect gas under adiabatic transformations, the equations of state are written in the form \(p_w = P_w + p = P_w + c_w^2 (\rho - \rho_t)\gamma\), in the liquid and \(p_w/P_w = (\rho/\rho_t)^\gamma\) in the gas, with \(c_w^2 = \gamma P_w/\rho_t\), where \(\rho_t\) and \(c_t\) are the mass density and the sound speed in the fluid and in the gas at the equilibrium with pressure \(P_w\), and with \(\gamma\) the adiabatic index. Eventually, the waves hitting the bubble \(i\) produces its oscillation, hence a time variation of its radius \(R_i(t)\) around \(R_{eq}\), its value at equilibrium. At the interface with the liquid, the radius of the bubble \(i\) is dictated by the condition \(\mathbf{u}(x, t) \cdot \mathbf{n} = R_i(t)\), where the dot denotes the time derivative. The homogenization procedure relies on a multiple scale analysis which leaves us with an effective problem in which the bubbly screen has disappeared, the derivation is detailed in \cite{Pham07}. In the liquid, for a low Mach number, \((p, \mathbf{u})\) satisfy

\[
\frac{\partial p}{\partial t} + \rho_t c_t^2 \text{div} \mathbf{u} = 0, \quad \rho_t \frac{\partial \mathbf{u}}{\partial t} = -\nabla p, \quad \nabla \cdot \mathbf{u} = 0,
\]
with the initial and radiation conditions being the same as in the actual problem. The effect of the bubbly screen is reduced to effective transmission conditions which read as

\[
\begin{align*}
[p] = 0, & \quad [u_1] = \frac{4\pi R^2}{h^2} \dot{R}, \\
\rho \left( \frac{R \ddot{R}}{h^2} + \frac{3}{2} \dot{R}^2 \right) + \frac{\rho c_\ell^2}{\gamma} \left( 1 - \left( \frac{R_{eq}}{R} \right)^3 \right) = -p|_{x_1=0},
\end{align*}
\]

where \([p] = p(0^+, \mathbf{x}', t) - p(0^-, \mathbf{x}', t)\) (with \(\mathbf{x}' = (x_2, x_3)\)), the same for \([u_1]\]. The discontinuity of the normal velocity is thus related to the bubble oscillation whose effective radius is dictated by an equation of the Rayleigh-Plesset’s type.

### 3. Numerical results

To inspect the characteristics of the effective model, we set the physical constants to: \(\rho_1 = 10^3 \text{ Kg.m}^{-3}, \ c_\ell = 1500 \text{ m.s}^{-1}, \ \gamma = 1.4, \ R_{eq} = 10^{-5} \text{ m} \) and \(P_{eq} = 0.225\ \text{atm},\) and we consider an initial Gaussian pulse of the form

\[
P_a(x_1, t_{\text{ini}}) = \Delta P e^{-\left( x_1 - x_{\text{ini}} \right)^2 / \sigma^2}.
\]

With a wavelength at the resonance \(\lambda_\ell = 10^{-2} \text{ m}\) (and \(T = \lambda_\ell / c_\ell \approx 6.10^{-6} \text{ s}\)), we use \(\sigma = \lambda_\ell / 10 = 10^{-3} \text{ m}\) and \(T_\sigma = T / 10 \text{ s}\). Making use of the above numerical values, the parameter \(\kappa\) measuring the strength of the interaction is given by \(\kappa \approx 10^4 \left( \frac{R_{eq}/h}{\Delta P/P_{eq}} \right)^2\), and we illustrate below the effects of the array spacing \(h\) and of the non-linearities on the propagation.

![Figure 2](image-url)

**Figure 2:** Propagation of an initial Gaussian pulse for \(\Delta P/P_{eq} = 1\) and 20. The pulse reaches the bubbly screen at \(x_1 = 0, t = 0\).

To begin with, we report in Fig. 2 time series of the acoustic wave trains during propagation for \(h/R_{eq} = 20\) and increasing \(\Delta P/P_{eq} = 1\) (in the linear regime) and 20 (in the non linear regime). For larger \(\Delta P\), we observe that the reflected signal is smaller in amplitude, while the transmitted signal resembles more and more to the initial pulse. This is attributable to the fact that pressure pulses with increasing amplitude produce more important bubble compression hence an apparent smaller scattering cross section. As a result the screen becomes invisible for large pressure amplitudes, as illustrated in Fig. 3(a). Varying now the distance \(h\) between the bubble, we observe that the screen becomes transparent for increasing \(h\), see Fig. 3(b). In both cases, the weakening of the scattering strength of the bubbly screen occurs while the bubble oscillations are (i) of higher amplitude and (ii) less and less damped, see [4].

![Figure 3](image-url)

**Figure 3:** Normalized reflected and transmitted energies (a) against \(\Delta P/P_{eq}\) for \(h/R_{eq} = 20\), and (b) against \(h/R_{eq}\) for \(\Delta P/P_{eq} = 10^{-5}\).

### 4. Conclusions

The interaction of acoustic waves with a screen made of a thin layer of bubbles can be described by an effective model which reduces the effect of the bubbly screen to transmission conditions on the acoustic pressure and normal velocity. The numerical implementation of this effective model shows that the effect of the screen is weakened when the bubbles oscillate in a non linear regime or when their relative distance is large. Straightforward extensions of the present study would account for the surface tension and for the viscosity. A more demanding extension is to conduct the analysis to higher orders to account for the arrangement of the bubbles within the screen.

Abstract

Used as building biomaterials for centuries, cereal straws are known for their remarkable acoustic performances in sound absorption. Yet, their use as fibrous media disregards their internal structure made of nodes partitioning stems. Here, we show that such nodes can impart negative acoustic bulk modulus to straw balls when straws are cut on either side of a node. Large spectral bandgaps and slow sound regimes are theoretically predicted and experimental results from impedance tube measurements on an idealised 3D-printed sample layer perfectly capture these physical behaviours. Perfect absorption is achieved at wavelengths 13 times larger than the thickness of the metafluid layer, and slow sound entails an increased density of states causing a cascade of high absorption peaks.

1. Introduction

Particularly interesting in acoustic and thermal insulation are cereal straws such as wheat, reed or rattan. Attention was mainly paid to the effects of the length, concentration, and relative orientations of the straws on sound absorption. While arrays of straws were usually idealised as classical visco-thermal fluids made of either solid or completely hollow straws, closer examination of cereal straws reveals that nodes within the stem partition the straw into tubular segments. Therefore, when cutting straws on either side of a node, the resulting pieces are neither solid obstacles in the path of the acoustic wave, nor open hollow straws channeling the flow, but rather double quarter-wavelength resonators (QWRs) separated by the node. Based on this observation, we designed a metafluid inspired by the cereal straws (MCS) made of the periodic repetition of double QWR, see Fig. 1.

2. Critical coupling and perfect absorption

The slow sound effect induced by the fundamental resonance of the double QWR and the inherent losses of the MCS can be used to design finite size perfect absorber samples. For the sake of comparison, the absorption of the equivalent anisotropic fluid inspired by cereal straws (FCS) in the absence of the QWR [1], that is when \( r_j = 0 \) and hence \( \phi_j = 0 \) for \( j \in \{1, 2\} \), is also plotted. On the one hand, the frequencies of the Fabry-Perot resonances drastically decrease due to the slow sound regime of the MCS.

Figure 1: Schematic of the idealised Metafluid inspired by cereal straws. (a) Representation of the \( \Omega \)-periodic arrangement of the double Quarter-Wavelength Resonators (QWRs) elements. (b) Details of the unit cell. (c) Details of the QWR opening. (d) Zoom at the corrugation of the walls.

As a consequence, these resonances occur for wavelengths much larger than the structure thickness, i.e., the MCS becomes deeply sub-wavelength. On the other hand, the MCS layer behaves as an open lossy and resonant system, characterised at the resonant frequencies, by both the leakage rate of energy (i.e., the coupling of the resonant elements with the propagating medium) and the inherent losses. In the reflection problem, the balance between the leakage and the losses activates the condition of critical coupling, enabling a perfect impedance matching to the background medium, and therefore generating a perfect energy absorption [2]. The layer sample analysed here has been designed so that the layer of thickness \( L = 13\ell_3 = 109.2 \) mm is critically coupled to air under plane wave excitation at normal incidence with \( \lambda_e = 13L \) in the principal direction \( e_3 \). Figure 2(a) shows the complex frequency plane for the FCS sample. The pairs of pole/zero represent the different Fabry-
3. Conclusions

The metafluid inspired by cereal straws has been theoretically and experimentally reported for sub-wavelength perfect sound absorption. A straw bale constituted of straws cut on either side of a node is idealised by a three-dimensional periodic repetition of tightly packed double QWR. This idealised straw bale is homogenised, exhibiting slow sound regime enabling to increase of the density of state in the subwavelength regime together with viscous and thermal diffusion through the arrangement of stems. The designed MCS possess a 99.6% absorption peak at 258 Hz, which corresponds to a wavelength 13 times larger than that of the slab thickness. The design of the present MSC offers both a comprehensive explanation of the acoustic properties of bio-sourced materials, such as wheat, reed, or rattan and large perspectives for the design of bio-inspired metafluid, notably through its anisotropy.

Abstract

We study the interaction of acoustic waves with arrays of cavities open at both ends. This is done owing to an effective model which provides explicit expressions of the reflection and transmission coefficients. Here, this is used to provide the relations required to produce zero reflection situation which are known to be surrounded by rapid variations of the scattering coefficients. The influence of the symmetry or asymmetry of the array is discussed.

1. Introduction

In electromagnetism, mushroom structures on a ground plane have attracted a lot of attention due to their capacity to produce high impedance boundaries [1]; in acoustic, similar structures are arrays of Helmholtz resonators. More recently, mushroom metamaterials open at both ends (with no ground plane) have been shown to enable interesting properties [2]. Here, we consider similar structures in acoustics consisting in arrays of cavities open at both ends (Fig. 1). For small openings, the backscattering is in general large but large variations of scattering can be observed in the vicinity of zero reflection configurations of practical interest, including Fano resonances. Such arrays have many free geometrical parameters, in particular for asymmetric configuration; thus it is meaningful to use approximate models to help in their designs. In [3], we have derived an effective model which accurately reproduces the scattering properties of such arrays. In the effective model, the wave in the region of the cavities satisfies \( \frac{\partial^2 p}{\partial x^2} + k^2 p = 0 \) with \( p \) the acoustic pressure, while across the regions of the necks, jump conditions apply. At the entrance of the array, we have

\[
[p] = hB_1 \pi, \quad [u] = -hC_1 \frac{\partial^2 p}{\partial x^2} - e_1 \varphi_1 k^2 p, \quad (1)
\]

where \([p] = f^+ - f^-\), \( f^+ = \frac{1}{2}(f^+ - f^-) \) with \( f^- = f(x, 0) \) and \( f^+ = f(x, e_1) \) and where \((B_1, C_1)\) are parameters well approximated by

\[
B_1 = \frac{e_1}{h \varphi_1} - \frac{1}{\pi} \log \left( \frac{\sin \frac{\pi \varphi_1}{2}}{\sin \frac{\pi \varphi_1}{2}} \right), \quad C_1 = \frac{\pi \varphi_1^2}{16}, \quad (2)
\]

The same condition holds at the exit of the array \( 1 \to 2 \) and \( f^- = f(x, e_1 + d) \) and \( f^+ = f(x, \ell) \), with \( \ell = e_1 + e_2 + d \).

2. Scattering properties

For an incident plane wave, the solution of the effective model reads as

\[
p(x, y) = e^{ik_x x} \begin{cases} e^{ik_y y} + R e^{-ik_y y}, & y < 0, \\ A e^{ik_y y} + B e^{-ik_y y}, & e_1 < y < \ell - e_2, \\ T e^{ik_y (y - \ell)}, & y > \ell, \end{cases} (3)
\]

![Figure 1: Scattering of an array of open ended resonators.](Image)

![Figure 2: Perfect transmission for a symmetric array of resonators. Top panels: transmission spectrum and homogenized prediction (7). Bottom panels: velocity fields at the two first perfect transmissions for \( \theta = 45^\circ \).](Image)
with \( k_y = k \cos \theta \), \( k_x = k \sin \theta \). Applying the 4 jump conditions (1) gives \((R, A, B, T)\) as solution of the system

\[
\begin{pmatrix}
-\alpha_1^* & \gamma_1^* & \gamma_1 & 0 \\
\beta_1 & \delta_1 & -\delta_1 & 0 \\
0 & \gamma_2 e^{ikd} & \gamma_2^* e^{-ikd} & -\alpha_2^* \\
0 & -\delta_2 e^{ikd} & -\delta_2 e^{-ikd} & -\beta_2
\end{pmatrix}
\begin{pmatrix} R \\ A \\ B \\ T \end{pmatrix} =
\begin{pmatrix} \alpha_1 \\ \beta_1^* \\ 0 \\ 0 \end{pmatrix}
\]

(4)

where \(^*\) means complex conjugate and where

\[
\begin{align*}
\alpha_1 &= 1 + \frac{i}{2} \hbar B_1 k_y, \\
\beta_1 &= k_y + \frac{i}{2} \left( \hbar C_1 k_x^2 - e_1 \varphi_1 k^2 \right), \\
\gamma_1 &= 1 + \frac{i}{2} \hbar \varphi B_1 k, \\
\delta_1 &= \varphi k + \frac{i}{2} \left( \hbar C_1 k_x^2 - e_1 \varphi_1 k^2 \right),
\end{align*}
\]

(5)

(the same for index 2). It is easy to see that the condition \( R = 0 \) is possible if the following condition is satisfied

\[
Z_1 = Z_2^*, \quad \text{with } Z_1 = e^{ikd} \frac{\alpha_1 \delta_1^* + \beta_1^* \gamma_1^*}{\alpha_1 \delta_1 - \beta_1^* \gamma_1^*},
\]

(6)

the same for \( Z_2 \). This condition is not easy to satisfy since \( Z \) is complex. To begin with, we consider symmetric arrays, for which it is sufficient that \( Z_1 = Z_2 \) is real. In this case, we find the condition that \( g(k, \theta) = 0 \) with

\[
g(k, \theta) = \mathcal{D}(\theta) k \tan kd \left( 1 - \cos^2 \theta \left( \frac{1}{\varphi^2} - B_1^2 (kh)^2 \right) \right),
\]

(7)

with \( \mathcal{D}(\theta) = 2 \varphi \left( B_1 \cos^2 \theta + C_1 \sin^2 \theta - e_1 \varphi \right) \). Hence, for any \( \theta \), a set of \( k\)-values produce zero reflection. This is illustrated in Fig. 2 where we reported \(|T|\) against \( \theta \) and \( kh \) for a symmetric array \((\varphi = 0.7, d/h = 5, \text{and } \varphi = 0.1, e/h = 0.3); \) the accuracy of the condition (7) is better than 5% in the reported range.

We now move to asymmetric arrays; by simple inspection of (6), zero reflections appears to be possible if \( B_1 \simeq B_2 \). Hence, for a given geometry of the first necks \((\varphi_1, e_1)\), a relation between \( e_2 \) and \( \varphi_2 \) is obtained, with

\[
e_2 \simeq e_2^0 = \hbar \varphi_2 \left( B_1 + \log \left( \frac{\sin \frac{\pi \varphi_2}{2} \sin \frac{\pi \varphi_2}{2}}{\frac{\varphi}{2}} \right) \right).
\]

(8)

The accuracy of the above expression is exemplified in Fig. 3 where we report \(|R|\) computed numerically against \( kh \) and \( e_2/e_2^0 \) for \( \varphi_2 = 0.05 \) (otherwise \( \varphi = 0.7, d/h = 5 \) and \( \varphi_1 = 0.2, e_1/h = 0.6 \)).

![Figure 3: Perfect transmission for asymmetric arrays. With \( e_2 \) as free parameter, \(|R| = 0 \) is obtained for \( e_2 \sim e_2^0 \) according to (8).](image)

Eventually, we report in Fig. 4 the reflection curves for asymmetric arrays (i) realizing zero reflection in green \((e_2 = 0.09 \text{ from Fig. 3, and } e_2^0 = 0.1)\), (ii) in blue unable to produce zero reflection for \( e_2 = 0.35 \) and (iii) for a symmetric array by setting \( e_2 = e_1 \) and \( \varphi_2 = \varphi_1 \).

![Figure 4: Perfect transmission for a symmetric array. Top panels : \(|R|\) against \( k \) for a symmetric array and for 2 asymmetric ones \((e_2 = 0.09 \text{ close to } e_2^0 \text{ in (7)}, \text{and } e_2 = 0.35)\); numerics (plain black lines) and from the effective model (dotted lines). Bottom panels: same representation as in Fig. 2 for \( e_2/h = 0.09 \).](image)

### 3. Conclusion

We have exemplified the interest of effective models to predict the acoustic properties of arrays with specific symmetries. When a symmetry is lost, a new degree of freedom is available. This may be of interest to design an array with specific properties; however, this make the actual problem more cumberson to analyze. We shall discuss (i) the acoustic properties of a mushroom type array, with disconnected cavities in three dimensions and (ii) other properties of such arrays, notably the possible appearance of Fano resonances already observed in [2].

Abstract

This work reports the experimental validation of a deep-subwavelength material for sound diffusion named metadiffuser. Metadiffusers are rigidly backed slotted panels, each slit being loaded by an array of Helmholtz resonators (HRs) introducing strong dispersion in the slits and slow sound conditions. Therefore, the effective thickness of the panel is dramatically reduced down-shifting its quarter wavelength resonance in the deep-subwavelength regime. By tuning the geometry of the metamaterial, the reflection coefficient profile can be tailored to obtain a custom reflection phase. In this work we validate a metadiffuser based on a quadratic residue sequence, producing a uniform scattering function, so that the reflecting waves are dispersed in many different directions by the subwavelength metadiffuser of thickness $\lambda_0/34$ (where $\lambda_0$ is the wavelength of the design frequency).

1. Introduction

Sound diffusers are locally-reacting reflecting surfaces with spatially dependent reflection coefficient designed to produce uniform scattering, i.e., the reflected waves by these surfaces are scattered in many different directions [1]. Therefore, diffusers present a uniform far field magnitude, i.e. a uniform magnitude Fourier transform of its spatially dependent reflection coefficient distribution. The generation of spatially dependent reflecting surfaces is commonly achieved by using phase grating diffusers, also known as Schröeder’s diffusers [2], that are rigidly-backed slotted panels where each slit acts as a quarter wavelength resonator. However, Schröeder diffusers are limited by their depths, which becomes large at low design frequencies. This results in thick and heavy panels, limiting the use of phase grating diffusers at low-frequencies where the wavelength of sound in air is of the order of several meters.

In this work, we present the experimental validation of the concept of metadiffusers which are deep-subwavelength thickness diffusers based on slow sound acoustic metamaterials [3, 4, 5] to dramatically reduce the thickness of Schröeder diffusers. By tuning the geometry of the HRs and the thickness of the slits, the phase of the reflection coefficients can be tailored to those of usual diffusers but with extremely deep subwavelength structures. We present the validation of a metadiffuser based on the one presented in a previous work of some of the authors of the current abstract [1].

\begin{figure}[h]
\centering
\includegraphics[width=0.5\textwidth]{figure1.png}
\caption{(a) Phase and (b) magnitude of the spatially-dependent reflection coefficient of a QRD (black line) and the QR-metadiffuser (red doted). Picture the analyzed metadiffuser (b).}
\end{figure}

2. Design of metadiffusers

A quadratic residue diffuser (QRD) is made from a numerical sequence given by $s_n = n^2 \text{mod} N$, where mod is the
least non-negative remainder of the prime number $N$. If the phase grating diffuser is based on quarter wavelength resonators (wells), the depths of the wells are given by $L_n = s_n \lambda_0 / 2N$, where $\lambda_0$ is the design wavelength. A classical QRD with $N = 5$ and total thickness of $L = 27.4$ cm with side $Nd = 35$ cm could be designed for a frequency of 500 Hz. The resulting reflection coefficient could be mimicked by a metadiffuser structure as shown in Figs. 1(a,b). Perfect agreement is found between the reflection coefficients of the meta-QRD and the target phase. The picture of the designed metadiffuser is shown in Fig. 1(c), with a deep sub-wavelength thickness of $L = 2$ cm.

3. Experimental set-up

The metadiffuser is experimentally tested in the anechoic chamber of the Laboratoire d’Acoustique de l’Université du Mans (LAUM). The metadiffuser is excited by a maximum length sequence (MLS) radiated by a source placed at 2 m from it at 90° of incidence. The metadiffuser is placed on a turning table covering all the azimutal angles. The scattering pressure field, $p_s$, is evaluated in the polar angles, along a semi-circumference of 1 m radius centered in the center of the metadiffuser. Therefore all the scattering directions can be captured by the experimental set-up. The scattering field is obtained by Fourier transforming the impulse response of the system after windowing it in the corresponding time period in order to remove the direct sound from the source.

4. Results

We evaluated a single repetition of the meta-QRD and an equivalent rigid panel of the same dimensions. Figure 2 shows the experimental results for the evaluated meta-QRD (in red lines) and for the rigid panel (in blue lines). In both cases the experimental scattered field, $p_s(\theta)$ is plotted. Two different frequencies are evaluated. The first one at 700 Hz, where the meta-QRD behaves as a rigid panel. The second frequency, at 1500 Hz, shows the spreading of the acoustic energy in all the directions produced by the meta-QRD.

5. Conclusion

The concept of metadiffuser as a design of deep subwavelength locally reacting surfaces with tailored acoustic scattering was experimentally validated, demonstrating the potential of the metadiffusers to be used in critical listening environments. Due to their deep-subwavelength nature, the thickness of the panels can be strongly reduced. In the context of smart building design and sustainability, metadiffusers can be used to save space and to produce lightweight materials, improving the performance of the acoustic solutions using less resources. Moreover, the proposed designs have the potential to meet the aesthetic requirements that are mandatory for modern auditoria design.

Abstract

We report a material that suppresses the acoustic scattering for a given set of incident wave vectors. This stealth acoustic material consists of multiple scatterers, rigid diaphragms, located in an air-filled acoustic waveguide. The experimental results are in good agreement with the theory. The robustness and the generality of the results motivate potential applications in wave physics.

1. Introduction

The control of the scattering of waves represents a major topic of interest in acoustics, photonics, and electromagnetism, due to the vast possibilities in fundamental physics with potential applications. In particular complex media [1, 2] and recently metamaterials [3], have been shown as potential candidates to control the scattering of different types of waves.

Recently, stealth distributions of scatterers [4] that are counterintuitively disordered, hyperuniform, and highly degenerate have been exploited to show novel thermodynamic and physical properties as for example broadband and omnidirectional band gaps for electromagnetic [5] or elastic waves [6]. These materials are designed by using the structure factor, which is a physical parameter proportional to the scattered energy. This structure factor can be controlled by the position of the scatterers in the stealth distribution.

In this work we construct disordered stealth configurations by engineering the material properties in a controlled manner in such a way that the system prevents scattering only at prescribed wavelengths with no restrictions on any other wavelengths. In particular we focus on the suppression of the Bragg scattering of the corresponding periodic case and make the structured system transparent for a broad-band range of frequencies. The inverse problem to generate the configuration of multiple scatterers with a specific scattering properties is non-trivial, as multiple solutions are conceivable. The approach is based on the optimization of the structure factor which, in the Born approximation, can be used as the outcome of a scattering experiment. The configuration of multiple scatterers is used to construct an one dimensional (1D) stealth structure made of rigid diaphragms embedded in an air-filled wave-guide (as shown in Fig. 1). The system is analytically analyzed by using the Transfer Matrix Method (TMM). Full wave numerical simulations have been done by using Finite Element Method (FEM). The system is analyzed considering the intrinsic viscothermal losses of the system. Experiments are performed to validate the theoretical results.

2. Main results

In Fig. 2(a) we represent the scattering coefficients of the periodic distribution of scatterers. The Bragg scattering of the finite structure is shown. Figure 2(b) shows the scattering coefficients of the designed stealth material (Fig. 1(e)) in the lossless case. The reflection coefficient is dramatically reduced and the transmission is almost one for the target range of frequencies (yellow area). We notice that in this lossless case, the reflection coefficients from both sides of the sample must be equal, \( R^+ = R^- \). We analyze now the lossy case. Numerical, theoretical and experimental results are compared in Figs. 2(c) and 2(d). In this case, as
the stealth material is not symmetric, \( R^+ \neq R^- \), but being reciprocal \( T^+ = T^- = T \). We start by analyzing the results for the system excited from the right side (forward direction, Fig. 2(c)). In the optimized frequency band, the values of the reflection coefficient are nearly zero while the transmission coefficient has been reduced with respect to the lossless case. However, the coefficients keep the flat behavior also shown in the lossless case. In order to check the transparency of the stealth material, we compare its transmission coefficients with the corresponding empty waveguide. In the optimized range of frequencies the transmission of the stealth material matches the transmission of the empty tube in very good agreement between numerics, analytics and experiments. As in the lossless case, out of the optimization range, the system is not transparent. One of the properties of the structure factor is that the scattered intensity should be the same in opposite directions even if the configuration of multiple scatterers conforming the stealth material is not symmetric, i.e., the reflection coefficient from both sides of the structure should be equal. Figure 2(d) analyzes the same coefficients as Fig. 2(c) but evaluated for the backward incidence direction, having a similar behavior as the opposite direction. Figure 2(e) shows that the difference between the amplitudes of the reflection coefficients evaluated from each side of the stealth material is less than 3% in the whole frequency range.

3. Conclusions

These preliminary results provide new insights into the nature of wave control by amorphous structures being the basis for future applications in acoustics and more generally in wave physics. It is worth noting here that the methodology is general and can be applied for any type of wave.

Abstract

Acoustic metamaterials and phononic crystals are often presented as improved materials for vibration and acoustic isolation. Calculating the dispersion relation, typically done using the assumption of periodic boundary conditions on a single unit cell, leads to accurate knowledge of frequency bands with high wave attenuation inside the structure. However, structural band gaps in a metamaterial plate do not necessarily lead to high sound transmission losses, since acoustic transmission is not only governed by wave processes. In the low frequency range, isolation is governed by the wall’s mass, above the coincidence frequency out-of-plane wave attenuation is responsible for the sound transmission loss. In this paper, the case of a sandwich panel with a core consisting of periodic stiffeners is considered. A suitable geometry is defined based on structural band gap analysis. Consequently, the sound transmission loss under diffuse excitation is predicted, and compared to values measured on a realistic sample in an accredited testing facility.

1. Introduction

Metastructures are an established way to achieve elastic wave attenuation in plates. Two common approaches are: adding an array of resonators onto the plate, or altering the material in a regular pattern. The first path leads to narrow band gaps around the eigenfrequency of the resonators, which are to be placed less than a wavelength away from each other [1]. The latter method results in Bragg scattering of elastic waves, leading to destructive interference under certain propagation directions in broad frequency bands [2]. However, the band gaps only occur at wavelengths comparable to or larger than the structural period, hence it is hard to achieve low frequency attenuation. Moreover, since the forbidden frequencies are direction dependent, the existence of omnidirectional band gaps is not ensured.

In this paper, we present a phononic crystal plate with increased acoustic isolation properties compared to a plate with equal mass but without periodicity. The isolation is quantified by the sound transmission loss (STL), which is the sound power reduction as a function of frequency when the panel is excited by a diffuse sound field. Bending waves in the considered sandwich plate are scattered by a periodic arrangement of stiffeners in the core. The band gap frequencies are calculated using unit cell analysis. Subsequently, the STL is predicted by a hybrid Wave Based - Finite Element Unit Cell method. The results are validated by a standardized measurement on a representatively large sample.

2. Sandwich panel geometry and materials

Beams with periodically varying bending stiffness exhibit a series of band gaps with high flexural wave attenuation coefficients [3, 4]. Similarly, a plate with a rectangular pattern of stiffeners is expected to attenuate out-of-plane waves in certain frequency bands.

In order to achieve efficient wave scattering, the bending stiffness contrast between soft and hard parts should be as large as possible. We therefore propose a sandwich structure with outer shells made out of 3 mm PMMA plates ($E = 1.8$ GPa, $\rho = 1280$ kg/m$^3$). The shells are spaced by octagonal blocks made out of an aluminium sandwich material (face thickness 1 mm, $E = 40$ GPa) with an aluminium honeycomb core (15 mm). The difference in Young’s moduli between PMMA and aluminium ensures a...
large enough bending stiffness contrast. The core blocks are arranged in a square pattern with a unit cell size of 120 mm. Their dimensions are given in Fig. 1.

3. Modelling

3.1. Dispersion relation calculation

The wave dispersion is calculated according to the method proposed by Mace and Manconi [5]. A finite element model of a single unit cell is set up in ANSYS 18.2. The degrees of freedom of the right (top) edge are related to those of the left (bottom) edge according to the Bloch theorem:

\[ q_R = \exp(ik_{Bx}d_x)q_L, q_T = \exp(ik_{By}d_y)q_B. \]

Using these relations, the degrees of freedom in the slave nodes at the right and top edges can be eliminated from the equations, resulting in reduced mass and stiffness matrices \( M_r \) and \( K_r \). The reduced matrices are a function of the Bloch wave vector \( k_B = (k_{Bx}, k_{By}) \). The corresponding eigenfrequencies \( \omega \) can be found as the eigenvalues of the homogeneous system

\[ K_r - \omega^2 M_r = 0. \]

3.2. Sound transmission loss

The STL of the infinite periodic structure is predicted using the hybrid Wave Based - Finite Element (WB-FE) UC method [6] coupling the structural FE UC model to two semi-unbounded periodic acoustic WB domains, above and below the structure. The upper acoustic domain is excited by an impinging acoustic plane wave. The pressure field in the acoustic domains is described using an expansion of wave functions that fulfill the governing Helmholtz equation, the Sommerfeld radiation condition and the Bloch-Floquet boundary conditions. Using a direct hybrid WB-FE coupling strategy, a system of equations is obtained, which is solved for the nodal degrees of freedom in the FE domain and the wave function contributions in the WB domain. The latter are used to calculate transmission coefficients \( \tau \) and thus the STL = \(-10\log(\tau)\) of the infinite periodic structure.

4. STL measurement

The sound transmission loss was measured according to European Standard EN-ISO-10140-1 [7]. The separation wall is placed between two reverberant rooms, thereby ensuring a diffuse field excitation. The STL value can be measured as the difference in sound pressure levels between both rooms \( L_1 \) and \( L_2 \), corrected by a term involving the size of the window \( S \) and the absorption surface of the rooms \( A \) as \( \text{STL} = L_1 - L_2 + 10 \log(S/A) \).

5. Conclusions

The use of phononic crystal plates to achieve a higher STL is not trivial for several reasons. Firstly, wave attenuation in the plate is not the only mechanism for the total acoustic isolation. Moreover, the elastic wave band gaps are not omnidirectional, and their contribution to the acoustic radiation has to be investigated more closely. In this work, calculations of the dispersion relations and sound transmission loss in a diffuse field are compared to STL measurements. This approach gives insight in the interaction between structural and acoustic properties.

Abstract

Acoustic metamaterials composed of a periodic arrangement of plates or membranes in the air are of growing practical interest because of their peculiar properties such as the possibility to obtain zero dynamic mass density. The aim of this work is to experimentally, numerically and theoretically report and characterize the anomalous propagation of sound waves in a one-dimensional periodic system of thin elastic clamped plates emphasizing a hiding zone due to the near zero density regime.

1. Introduction

Density Near Zero (DNZ) acoustic metamaterials have drawn lots of attention in the last decades. One way to achieve the DNZ condition is to arrange periodically thin clamped elastic plates in the air [1]. Due to the strong dispersion around the band gap produced in such a system, zero mass density occurs. The phase velocity tends to infinity in the lossless case, leading to an effective quasistatic field distribution in the metamaterial. Interesting applications are then exhibited such as energy super-squeezing and tunneling in narrow duct [2] or non delayed propagation. Independently of the channel length or the twisting of the guide, a wave impinging the structure can propagate along the metamaterial without being delayed and with a high transmission. DNZ metamaterials can also lead to efficient cloaking effect as it has been studied numerically in a 2 dimensional lossless case in [3]. At the zero phase delay frequency, in the DNZ region, a propagating wave is not impacted by the presence of the scatterer. However, losses, not avoidable in reality, can be dramatically important in such systems and therefore drastically modify the metamaterial behavior. We thus propose an experimental evidence of this hiding zone in a one dimensional Density-Near-Zero material and an investigation on the inherent limits to these losses.

2. Experimental evidence of anomalous propagation

2.1. Set-up

The proposed system is composed of a periodic arrangement of 6 thin plastic plates clamped in a circular waveguide of inner radius $R_a = 1.5$ cm. The unit cell is built of a clamped plate of thickness $h = 102 \, \mu m$ surrounded by two air cavities of length $L_{gap}/2 = 0.5$ cm. The transmission and reflection coefficients measured in a 4 microphones impedance tube allow to retrieve the metamaterial effective properties [4, 5]. Two different extraordinary features are explored here: the non-delayed propagation and the scatterer hiding efficiency.

2.2. Non-delayed propagation

Transfer matrix, Full-wave simulations (FEM), and measurements show that the 6 plates metamaterial exhibits a zero effective dynamic mass density. Furthermore, in this vanishing frequency region, the structure presents a zero phase of the transmission coefficient resulting from propagation without phase change. The non-delayed propagation is thus robust to losses (mostly from the plates), which are solely responsible for a decrease of the transmission (one in the lossless case), an increase of the reflection (zero in the lossless case), and a shift of both the zero density and the zero phase frequencies.

A circular diaphragm, playing the role of scatterer is then embedded into the plate metamaterial. The diaphragm alone induces a phase delay to the incident wave. The phase of the diaphragm transmission coefficient varies from $-0.05\pi$ to $-0.4\pi$ rad in [10 500] Hz. Adding the 6 plates metamaterial allows the phase to vanish in the DNZ region. The zero phase (non-delayed propagation) frequency depends on the aperture radius $R_d$ of the diaphragm as shown by Fig. 1.

2.3. Hiding zone

Moreover, the DNZ metamaterial allows to hide the scatterer. At the zero phase frequency, the transmission and
Figure 1: 6 plates metamaterial behavior with an embedded $L_d = 2$ mm thick annular diaphragm; a) phase of the transmission coefficient (light blue) and real part of the effective dynamic mass density (green color) of the total system (metamaterial alone with an embedded diaphragm of aperture $R_d = 4$ mm). Circle markers, dashed line and solid line correspond respectively to the measurements, the Full-wave simulations and the TMM. b) relative frequency shift (ratio of the zero phase frequency of the total system to the one of the metamaterial alone) versus the diaphragm to waveguide radii ratio, from TMM. d) Transmission (blue color), reflection (red color) coefficients modulus at the zero phase frequency, and e) zero phase frequency values (green) of the total system for several diaphragm positions $x_d$ inside and outside the metamaterial. The dots correspond to the TMM results and the circles to measurements. Dotted red and blue horizontal lines show respectively the measured reflection and transmission values of the 6 plates metamaterial alone at $f_{\Phi t,0}$.

loss, wherever the diaphragm along the material is placed, it remains hidden and does not impact neither the transmission nor the reflection. The plate arrangement with an embedded scatterer behaves as an homogeneous and symmetric material in the lossless case. Losses inherent to such a system modify this anomalous hiding behavior. Reflection slightly increases when the diaphragm position is moved away from the metamaterial entrance as illustrated by Fig. 1d-e). The metamaterial also becomes asymmetric in reflection ($R^+ \neq R^-$ whereas $T^+ = T^- = T$).

The DNZ metamaterial has also an effect outside the metamaterial. The diaphragm can be placed in a unit cell distance from the metamaterial appendicular zones, in the transition layer, without impacting the transmission.

3. Conclusions

This work investigates experimentally, numerically, and theoretically the impact of losses, not avoidable in reality, on the DNZ behavior of a plate-type metamaterials. Even if losses results in a decrease of the transmission through the metamaterial, the non-delayed propagation is robust and has been measured. An hiding zone has also been experimentally shown in the DNZ region.

Abstract

In an effective medium description of acoustic metamaterials, the Willis coupling plays the same role as the bianisotropy in electromagnetism. Willis coupling have not only emerged to obtain physically meaningful effective parameters, but also to describe media presenting asymmetry in reflection. Asymmetries in reflection have also been made possible by considering the Parity-Time symmetry. In this work, we theoretically, in accordance with experimental results, show that a passive Willis media can be mapped onto Parity-Time symmetric systems [1].

1. Introduction

Waves irradiating onto a passive reciprocal medium usually display symmetric transparency in that the transmittance does not depend on the side at which the waves are launched. In contrast, if the elementary building units of the medium involved lack intrinsic inversion symmetry, then the reflectance depends on the side of the slab from which the waves are irradiated. Commonly, for electromagnetic waves, such asymmetric responses are known to occur in bianisotropic media, which are important in applications comprising unidirectional radiation, single-sided light detection, and emission. An analog picture for the case of sound is provided through the cross coupling between strain and velocity in so-called Willis media.

2. Acoustic effective Willis medium

In an one-dimensional, along the z-axis, cylindrical acoustic waveguide, the effective constitutive matrix $M_{\text{eff}}$ of a reciprocal Willis media with the time convention $e^{-i\omega t}$ has the following form [2]

$$\frac{\partial}{\partial z} \Pi \begin{pmatrix} P \\ U \end{pmatrix} = i\omega \begin{pmatrix} S\rho_0 c_0 / K_{\text{eff}} & \chi \\ -\chi & \rho_{\text{eff}}/(S\rho_0 c_0) \end{pmatrix} \begin{pmatrix} P \\ U \end{pmatrix} ,$$

where the Poynting operator is defined by

$$\Pi = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix} .$$

3. Exceptional point in passive Willis media

Taking the case of acoustic waveguide side-loaded by two quarter-wavelength resonators with two distinct resonance frequencies, the eigenvalues $\zeta_{1,2}$ of the constitutive matrix $M_{\text{eff}}$ coalesce at approximately 860 Hz, as can be seen in Fig. 1, demonstrating the formation of an exceptional point.

At this exceptional point, the constitutive matrix $M_{\text{eff}}$ can be mapped onto a conventional $2 \times 2$ $\mathcal{PT}$-symmetric system matrix of the form

$$\Upsilon_{\mathcal{PT}} = \begin{pmatrix} a + i\Delta \gamma & i\kappa \\ -i\kappa & a - i\Delta \gamma \end{pmatrix} ,$$

where $a$, $\Delta \gamma$ and $\kappa$ are real numbers. The mapping is performed through a gauge transformation comprising a shift.
Figure 2: Gauge transformation of Eq. (4) comprising the elements of the constitutive matrix $\mathbf{M}_{\text{eff}}$ at the EP. The gauge transformation maps the constitutive matrix onto a $\mathcal{PT}$-symmetric matrix $\Upsilon_{\mathcal{PT}} + i\gamma_0 \mathbf{I}$, where $\text{Re}(\chi) = 0$, marked with vertical gray dotted lines in the gray areas in the $\mathcal{P}$ operation associated an average loss bias, and has the form [3]

$$\mathbf{M}_{\text{eff}} = U_u \left( \begin{array}{cc} a + i\Delta \gamma + i\gamma_0 & i\kappa \\ -i\kappa & a - i\Delta \gamma + i\gamma_0 \end{array} \right) U_u^{-1},$$

$$= U_u (\Upsilon_{\mathcal{PT}} + i\gamma_0 \mathbf{I}) U_u^{-1}, \quad (4)$$

where $\gamma_0$ is a gauge biasing the system with an average level of losses, $\mathbf{I}$ is the identity matrix, and $U_u$ is the propagator matrix

$$U_u = \left( \begin{array}{cc} \cos(k\delta) & i \sin(k\delta) \\ i \sin(k\delta) & \cos(k\delta) \end{array} \right). \quad (5)$$

The propagator matrix is an unitary gauge transformation, which maps ideal $\mathcal{PT}$-symmetric systems such as $\gamma_{\mathcal{PT}}$ of symmetric $\mathcal{P}$ operation, that is, $z \rightarrow -z$, which is a mirror operation at the center of the cell onto shifted $\mathcal{PT}$-symmetric systems accommodating the generalized $\mathcal{P}$ operation $z \rightarrow 2\delta - z$, where $\delta$ is the distance to center of the cell. This gauge transformation is exposed in Fig. 2.

4. Discussion

This exceptional point translates into an unidirectional reflectionless propagation, which is of primary importance for sound absorption because, if combined with coherent perfect absorption, it results in an unidirectional perfect absorber. Further, our present findings can lead to a deeper insight into the unidirectional invisibility phenomena, altogether showing how the Willis coupling broadens the possibilities of embracing both worlds of acoustic metamaterials and $\mathcal{PT}$ symmetry physics at once to achieve unprecedented control of sound and vibrations.

Abstract
Acoustic cloaking for backscattering reduction is proposed inside ducts in the audible range where plane waves are bended around the object using liner surface modes. It is shown that a slowly varying resonant liner forms a dumb zone in which an object of any shape can be rendered acoustically invisible for a wide range of frequencies. The cloaking band is a function of the impedance and height of the obstacle relative to the duct. For smooth shaped obstacles, there is an ability of the object to help hide itself, which increases the cloaking frequency band (self-cloaking).

1. Introduction
Rendering an obstacle hidden from the scattering of electromagnetic, acoustic or elastic waves has recently been a subject of particular interest because of its promising applications [1]. However, its manufacturing and broadband performance is still a challenging task. Recently, cloaking an obstacle located inside a waveguide was shown in the case of microwaves [2] and it has also be widely applied in spoof plasmon waveguide [3]. In this work, we first show that, by using a smooth axial variation of the wall impedance, it is possible to create a zone of silence in a duct. The purely reactive impedance gradually transforms a plane acoustic wave in the duct into an acoustic surface wave. This results in a bending of the acoustic wave towards the liner with a slower effective propagation velocity. In addition, we show that an obstacle with a smooth cross section variation can be cloaked even if it is outside the silence zone. This effect is called self-cloaking [4].

2. Cloaking in ducts
We consider the sound propagation in a two dimensional channel, see Fig. 1. The lower wall is rigid while the upper wall is described by a varying admittance \( Y(x) \). When the distances are non-dimensionalized by the height of the channel \( H \), the Helmholtz equation, governing the propagation of the acoustic pressure \( p \), is:

\[
\Delta p + k^2 p = 0
\]

(1)

where \( \omega \) is the frequency and \( c_0 \) is the sound velocity and \( k = \omega H/c_0 \) is the Helmholtz number. The boundary conditions are \( \partial_y p = 0 \) for \( y = 0 \) and \( \partial_y p = Y p \) for \( y = 1 \). For a uniform admittance \( Y \), the solution is searched under the form \( p = A \cosh(\alpha y) \exp(i(-\omega t + \beta x)) \) where \( \alpha^2 = \beta^2 - k^2 \) which leads to the dispersion relation \( Y' = \alpha \tanh(\alpha) \). For a rigid wall, \( Y = 0 \), at low frequencies, only the plane wave can propagate thus \( \alpha = 0 \) when \( k < \pi \) (Fig. 2(a)). If the admittance is positive and, is slowly varying compared to the sound wavelength, the local value of \( \alpha \) increases as \( Y \) increases. It means that the wave is more and more concentrated against the wall, see Fig. 2(b). A silence zone is then created near the wall opposite to the admittance. In order to verify the cloaking efficiency with a smooth scatterer, Fig. 2(d) depicts the reflection coefficient \( |R| \) for a smooth elliptical obstacle. The cloaking band in this case is from \( \pi/4 \leq k \leq \pi/2 \). The admittance only (green) curve corresponds to a lined duct and the cloaked (red) corresponds to lined duct with an obstacle.

One way to realize a liner is by using small closed tubes whose lossless admittance can be written as \( Y(x,k) = k \tan[kb(x)] \). When \( kb \ll 1 \), the admittance can be approximated by \( Y = k^2 b \) and the phase velocity of the wave is given by \( c_{\phi} = (1 + b)^{-1/2} \) implying that the wave velocity is reduced compared to sound velocity. When the frequency \( k \) approaches the first resonant frequency of the tubes given by \( k_r = \pi/2 \), the admittance and \( \alpha \) goes to \( \infty \). Thus, for frequencies slightly less than \( k_r \), the wave decreases exponentially from the wall being transformed into a surface.
wave. Near $k_c$, the phase velocity and the effective wavelength of the wave goes linearly to zero. The propagation is then highly dispersive. The admittance profile is taken under the form $b(x) = \frac{b_0}{2} \left[ \tanh \left( \frac{x}{d} \right) - \tanh \left( \frac{x}{d} - \frac{L}{k} \right) \right]$, where the maximum tube height has been arbitrarily fixed to $b_0 = 1$ and the two parameters $l$ and $d$ allow to tune separately the length of the admittance zone and maximal slope of the axial change in admittance.

3. Self-Cloaking in ducts

The parameter $\alpha$ gives the exponential decay of the pressure from the wall. The bending of the wave towards the liner is controlled by this parameter. The height of the channel $H_0$ between the obstacle and the liner, decreases with increasing height of the obstacle. This region follows a local dispersion relation of the form $k \tan(kb) = \alpha \tanh(\alpha H_0)$. The decrease in $H_0$, increases the $\alpha$ and therefore the presence of the obstacle helps to concentrate (push) the wave towards the compliant wall. This effect is called self-cloaking and it improves the efficiency of the cloaking for smoothly varying obstacle. The shape of the obstacle in this case is chosen to be: $h(x) = \frac{h_0}{2} \left( 1 + \cos \left( \frac{\pi x}{L} \right) \right)$. The results are shown in Fig. 3(a). An almost complete reflection is obtained in the uncloaked case at low frequencies ($k \approx 0.25$) as seen in Fig. 3(a). For such a low frequency, the admittance variation alone is unable to generate a significant dumb/shadow zone. But when a smooth obstacle is added to the admittance (Fig. 3(b)), the reflected energy $|R|^2$ decreases drastically for the entire frequency band $0.25 < k < \pi/2$ demonstrating the self-cloaking effect. The cloaking band is then considerably increased compared to sharp obstacles where this self-cloaking effect cannot be seen due to the reflection induced by any sudden change in the geometry.

4. Conclusion

In this work, we report a broadband acoustic cloak to suppress backscattering inside ducts using liner surface modes. By using a smooth variation in wall admittance of a duct which does not produce reflection, it is possible to create a silent zone in which acoustic waves can not penetrate. For an object which is half the height of the duct and with a liner made of tubes of the same height as the duct, this effect occurs at frequencies between the resonance frequency $f_r$ of the liner and $2f_r/3$, which is a wide frequency band compared to other conventional cloaking techniques. When the object is smooth enough, the presence of the object broadens the cloaking bandwidth which is termed self-cloaking. The novelty of this cloaking, made simply from a resonant wall, contrasts with other cloaking techniques that are more complex to perform and lack broadband performance.

Abstract

In this work, we propose an acoustic realization of two-dimensional Su-Schrieffer-Heeger model by constructing a network structure for sound wave, and we observe experimentally the existence of topological edge waves. A tight-binding model is used to describe the acoustic wave dynamics in the network, and topological edge waves are predicted on the boundary of the network. Moreover, we experimentally confirm the existence of topological edge wave. And a good agreement is found between the experiment and simulation results. The observation of topological edge waves in the acoustic network provides a flexible platform for the study of topological properties of sound waves.

1. Introduction

Recently, the study of novel topological phase with a zero Berry curvature has been attracted a lot of attention in different two-dimensional (2D) systems [1, 2, 3]. In such systems, a 2D Su-Schrieffer-Heeger (SSH) model is proposed by extending the one-dimensional SSH chain of identical atoms with alternating strengths of bonds in both $x-$ and $y-$directions. Different from most topologically nontrivial systems, which require a non-vanishing Berry curvature, the existence of topological phase of a 2D SSH model exhibits a fractional wave polarization characterized by the 2D Zak phase [1]. In this work, we propose an acoustic realization of the 2D SSH model, and experimental investigate the topological edge waves.

2. Results

The tight-binding model of a two-dimensional (2D) Su–Schrieffer–Heeger (SSH) model is depicted in Fig. 1(a), where identical mass points are arranged in a square lattice (lattice constant $2L$) with alternating coupling terms $s$ and $t$ in both $x-$ and $y-$directions. The unit cell of the 2D SSH model containing four mass points (marked as $\alpha$, $\beta$, $\gamma$ and $\delta$) is labelled by the black-dashed box in Fig. 1(a).

2.1. Model

To realize the 2D SSH model in experiment, two kinds of rigid square blocks of width $L_1 = 0.01$ m, $L_2 = 0.013$ m, and height $H_2 = 0.03$ m are fabricated as shown in Fig. 1(b). A plate of thickness $H_1 = 0.02$ m is applied as the substrate to hold the blocks in a square lattice. By placing a same size of glass plate (thickness $H_1 = 0.02$ m) on the top of the blocks, i. e., Fig. 1(c), a 2D experimental sample for sound wave is constructed. A close view of the unit cell of the experimental structure (lattice constant $2L = 0.025$ m) is illustrated in Fig. 1(d) by the white-dashed box. It can be seen that the block of size $L_2$ placed in the center of the unit cell is surrounded by 8 blocks of size $L_1$. This leads to two kinds of air channels of the width $S_1$ (orange bonds) and $S_2$ (blue bonds) between blocks, and four junctions connecting the channels as marked by $\alpha$, $\beta$, $\gamma$ and $\delta$ in Fig. 1(d). By extending the unit cell into a $xy$ plan, e. g., $4 \times 2$ m in experiment, a 2D acoustic network structure for sound wave is completed. This network is an acoustic realization of the 2D SSH model due to the fact that the acoustic pressure on the junctions interact with those on its neighboring junctions by alternating widths of channels in the $x-$ and $y-$directions. Therefore, the couplings of pressures between neighboring junctions can be tuned by the widths of air channels $S_1$ and $S_2$, which also determine the existence of nontrivial topological phase of the network.

2.2. Dispersion curves

For the experimental network, the values of $S_1$ and $S_2$ are fixed to be $S_1 = 0.025$ m, and $S_2 = 0.01$ m. Figure 2(a) shows the dispersion relation of the same parameters. Four propagating branches (blue curves) and two full gaps around $550$ Hz and $900$ Hz can be found. For comparison, we implement the COMSOL calculation by considering the same unit cell of the network, and the corresponding band structure (red curves) is shown in Fig. 2(b). A good agreement can be achieved between the two cases.

As had been reported in previous 2D SSH model, in the acoustic network, when $S_1 > S_2$, the network exhibits nontrivial topological phase and support topological edge states on the boundaries. To see the existence of edge waves, we investigate a super cell containing 8 unit cells along the $y$ axis, and the edges of the super cell are set to be open, namely the pressure at the opened channels is zero. The dispersion curves from theory for the super cell is shown in Figs. 2(c). Two edge branches marked as black curves
2.3. Experiment

The schematic illustration of the experimental sample and set-up are shown in Fig. 3(a). First of all, we experimentally observe the band gap by putting the source at position $A$ as marked in Fig. 3(a), and a sweep signal from 300 Hz to 800 Hz is generated from the source. We focus on the line $x = 24$ (red line), and measure the pressures of all the junctions on the line. The measured amplitude of the signal (in dB) is plotted in Fig. 3(c). The results of COMSOL by simulating the same experimental process is shown in Fig. 3(d). It can be see that in both cases that there is a bulk gap around the frequency range $\sim 540 - 620$ Hz. However, sound waves are observed to be localized near the edge $y < 2$, suggesting the the existence of bulk gap and the localization of sound pressure on the edges.

To further confirm the existence of edge waves, we put the source at position $B$ as marked in Fig. 3(a), and a harmonic signal of 570 Hz is sent from the source. We focus on three lines $x = 8$, $x = 18$, and $x = 24$, noted by green, blue and red lines, respectively. And he pressures of all the junctions on those lines are measured. Figure 3(b) shows the pressure field distributions (absolute value) of each line. It can be seen sound energy is localized on the edges but vanished fast in the bulk, exhibiting the edge wave property. Figure 3(e) shows the edge wave profile a into the bulk obtained by measurement. It has a excellent agreement with Fig. 3(f) which is obtained by COMSOL calculation.

3. Conclusions

In this work, a 2D SSH model is realized by an acoustic network structure, and the existence of topological edge waves is experimentally observed. The study of this work can pave the way for the study of the experimental observation of higher-order topological modes [4] in acoustic systems.

Abstract

Realizing directional acoustic signal transmittance and reception robust against surrounding noise and competing signals is crucial in many areas such as communication and detection for medical and industrial purposes. Here we show how topological acoustic valley transport can be designed to enable a unique beamforming mechanism that renders a super-directive needle-like sound radiation and reception pattern, which offers new ways to control sound with improved performance and functionalities that are highly desirable for versatile applications.

1. Introduction

For many animals, like dolphins, can produce directional acoustic wave beams of about 16° in width for detecting and tracking prey with high resolution in a blind and noisy environment [1-3]. Unlike dolphins, the function of human’s acoustic communication system is given by the conventional outer ear and mouth structures, which are based on the acoustic horn concept rather than an acoustic lens, thus bringing forth sound emission/reception of poor directivity to/from almost every direction. In addition, duplex-devices both with the ability of emitting and receiving signals remain a great challenge in both physics and engineering. Therefore, there is a great need to develop a novel scheme and functional devices for super-directional duplex acoustic communication that can overcome the limitations of current acoustic technologies.

On the other hand, “topological acoustics” has attracted considerable attention over the past two years due to the fascinating quantum-like effects in acoustic systems [4-13], which originates from studies of condensed-matter states [14,15]. Here we extend the concept of topological order to acoustic communication, and report a super-directional topological acoustic antenna (TAA) for audible sound based on VHTIs.

2. Results

The valley-polarized edge states observed above originate inherently from valley-projection, which guarantees reflection-free out-coupling from the topological interface into the free-space [16]. We begin by demonstrating the directional emission into free-space of out-coupled edge states along both positive- and negative-type interfaces in TAAs. As shown in Fig. 4, the direction of the outgoing beam into air depends on the type of valley (K or K’) from which the edge state is projected. Hence, sound waves that are launched from left to right along the negative-type interface are projected from the K valley (Fig. 4A), and conversely along the positive-type interface are projected from the K’ valley (Fig. 4D). To illustrate the refraction of the radiated beam, we draw the equifrequency curves in free-space (black dashed circle in Fig. 4A/4D) and the BZ (black solid regular hexagon in Fig. 4A/4D) on a scale that represents the relative magnitudes of the wavevectors of the incident and refracted waves. By matching the parallel component of the incident wavevector K on to the equifrequency curve of free-space, one is able to find the propagation direction of the radiated beam. The theoretical refraction angle θ_{theory}^− (for the negative-type interface) can be quantitatively determined by the phase-matching condition $\mathbf{k}_{term} = \mathbf{K}_{term}$, ultimately giving rise to a refraction angle. Likewise, at the same frequency, analytically we calculate the refraction angle for the positive-type interface TAA shown in Fig. 4D to be $\theta_{theory}^+ = 7.47^\circ$. In order to verify this analysis, we scanned the far-field radiation pattern within an angular range as shown in Fig. 4, both by means of numerical simulations and measurements. We obtain, for the TAA having the negative-type interface, refraction angles as predicted $\theta_{sm}^- = 67.86^\circ$ and measured $\theta_{exp}^- = 69^\circ$ shown as seen in Fig. 4B. With the positive-type interface we obtain: $\theta_{sm}^+ = 7.74^\circ$ and $\theta_{exp}^+ = 6^\circ$, shown in Fig. 4E. Additionally, as shown in the insets of these figures, we measure the pressure signals in the time-domain, in each case, both refraction angles $\theta_{exp}^+/−$ are considered, -69° and 6°. These results show that the super-directional out-coupled edge states indeed obey the valley-projected selection rule with time, such that the TAA with the negative (positive)-type interface suppresses sound refraction with positive (negative) angles. Lastly, as illustrated in Fig. 4C and Fig. 4F through the experimentally observed far-field energy spectra, we emphasize that the proposed acoustic antenna functions in the entire topological band gap spanning between 8.30 – 9.31 kHz.
3. Conclusions

To sum up, theoretically and experimentally we proposed valley-Hall topological insulators acting efficiently as sound transmitting and receiving antennas, of which the structure is based on a Kagome lattice made of epoxy resin rods. Based on such platform, we have experimentally put forward a prototype topological acoustic antenna that is capable of out-coupling and sustaining valley-polarized edge states permitting energy efficient communication. The proposed duplex antenna not only supports super-directive needle-like sound radiation with less than a 10° beamwidth, but also achieves anti-interference sound reception in various acoustic environments while being immune to white noise. This topological acoustic antenna provides the unique possibility to advance communication technologies such as hands-free smartphones and noise-immune hearing aids, but also to improve sonar applications with highly directional collimated beams and underwater communications at efficient energy levels.

Abstract
The decay coefficient of sound propagating through a phononic crystal of solid rods in a viscous fluid is calculated in the low-frequency limit for arbitrary Bravais lattice and arbitrary cross-section of the rods. The decay coefficient exhibits anisotropy and anomalous frequency dependence. Strong enhancement of losses in a phononic crystal is due to viscous boundary layers formed near each solid scatterer.

1. Introduction
Exponential dissipative decay of sound amplitude (∼e−γx) in pure water is weak. For a plane wave the decay coefficient γ0 = ω2(4η/3+ξ)2ρ0c0 3 grows with frequency as ω2 and is linear over the viscosity coefficients η and ξ. Even for frequencies, in the region around 100 kHz, the propagation length 1/γ0 is about several kilometers. Such low dissipative losses can be safely neglected. However, near a solid boundary a viscous layer of thickness δ = 2ηω/3ρ0 3 is formed. Within this layer the acoustic energy dissipates much faster than in a free fluid. Each reflection from solid-fluid interface is accompanied by energy losses that scale as 1/3ω3. Multiple reflections strongly increase the energy losses. Thus, a phononic crystal is a dissipative metamaterial. Since the viscous losses in many cases is the main factor that limits the efficiency of acoustic device, it is of principal interest to develop a feasible method for calculation of the decay coefficient γ or the effective viscosity of phononic crystals.

In solid-solid phononic crystal dissipation can be described phenomenologically by introducing imaginary part of elastic moduli of the constituents. This approach was developed in Ref. 2. A microscopic approach based on Navier-Stokes equation was proposed in Ref. 3. Scattering of sound by a homogenized cluster of solid circular cylinders arranged in a square lattice was calculated and the effect of viscosity on scattering cross-section was analyzed 3.

Here we propose a method of calculation of the decay coefficient γ = 1/2(ceffE) in solid-fluid phononic crystal assuming that the dissipation occurs only in the viscous fluid. Here ceff is the effective speed of sound in homogenized phononic crystal. In the low-frequency limit the dispersion of sound is linear, ω = cffkf, with cff = cff(n) being independent of ω but in lattices with low rotational symmetry it depends on the direction of propagation n. Acoustic energy E is obtained by integration of ρV2/2 over the area of the unit cell A = A0+Aa, containing viscous fluid (ρ = ρ0) and solid rod (ρ = ρa)

\[ E = \frac{\rho_0}{2} \int_{A_0} V^2(r)dr + \frac{\rho_a}{2} \int_{A_a} V^2(r)dr. \] (1)

The power dissipated at a given point in fluid is defined by the gradients of velocity. If the viscous layer is well localized near the solid rod, i.e. δ ≪ d, where d is the lattice period, the following approximation is valid for the energy ˙Q dissipated per unit length within the unit cell

\[ \dot{Q} = \frac{1}{2\sqrt{2}} \sqrt{\rho_0 \eta \omega} \int_{\Omega} V^2(r)dl. \] (2)

Here the integration runs over the contour L which is the circumference of the solid rod. The dissipated energy in Eq. (1) is calculated in the lowest approximation over low viscosity η, therefore the velocity V(r) in Eqs. (1) and (2) is obtained from the dynamical equation for inviscid fluid. The latter is the Euler equation for pressure p(r). The velocity is expressed through the scalar quantity p(r) as V(r) = -np(r). The pressure is expanded over the plane waves and in the low-frequency limit the coefficients of this expansion can be calculated 4. Calculating the integrals in Eqs. (1) and (2) in the limit ω ≪ cff/d (i.e. below the band gap) the following result was obtained for the decay coefficient:

\[ \gamma(n) = \frac{L_0}{2\pi c\rho c_{eff}(n)} \frac{M(n)}{N(n)}. \] (3)

Here L0 is the length of the contour L, p = fρa+(1−f)ρ0, and f is the filling fraction of the rods. The quantities M(n) and N(n) are represented by series over the reciprocal lattice vectors G

\[ M(n) = \rho_{ij}^{-1} \rho_{ij}^{-1} n_i n_j + 2\rho_{ij}^{-1} n_i n_j \sum_{G≥0} L^*(G)[v(G)\delta_{ij} - a_{ij}(G)] + n_i n_j \sum_{G≥0} L^*(G + G')[v(G)\delta_{ij} - a_{ij}(G')]. \] (4)
Nonlinear Transmission of $G$$G$, Nonreciprocal $L$$L$, and $G$$G^+$,$G$$G^-$, calculated neglecting $\delta$$\delta$, that the effective mass is also $\nu$$\nu$, -Coefficient is different from that in pure viscous fluid. The phononic crystal shown in the inset was used in Ref. [6] for demonstration of nonreciprocity in a system with broken PT-symmetry. The decay coefficient calculated in the lowest approximation is reciprocal, $\gamma(n) = \gamma(-n)$ since the distribution of velocities $V(r)$ is calculated neglecting viscosity, i.e. the T-symmetry is not broken.

\end{align*}

Here $\rho_i^{-1}$ is the tensor of the inverse effective mass $\rho_i^{-1} = \bar{\nu} \delta_{ij} - \sum_{G,G \neq 0} G_i G_j \nu(-G') (G \cdot G' \nu(G') (G' \cdot G'' \nu(G''))^{-1}$.

The lattice form factors, $L(G)$ and $F(G)$ are related to integration over the contour $L$, $F(G) = \frac{1}{4\pi} \oint_L e^{-iG \cdot r} dr$

Figure 1: Angular dependence of the normalized decay coefficient for a phononic crystal of asymmetric Al rods embedded in water. The inset shows the unit cell with period of 5.5 mm, and the radius of the 120° circle sector is 2.2 mm. The angle $\theta$ shows the direction of propagation of sound wave of frequency 200 kHz.

Equations (3)-(7) were used for calculation of the decay coefficient for phononic crystal of asymmetric rods in water. The result is shown in Fig. 1. In this phononic crystal sound decays ~60 times faster than in free water due to formation of viscous boundary layer near each Al rod. The rate of decay depends on the direction of propagation, i.e. a phononic crystal with asymmetric unit cell behaves like an anisotropic viscous metamaterial. Note that the effective mass is also anisotropic. The frequency dependence of the effective decay coefficient is different from that in pure viscous fluid. The $\sqrt{\omega}$-scaling of $\gamma(\omega)$ is a clear evidence that the viscous layer give the principal contribution to dissipation of sound. The $\omega^2$-dependence of the decay coefficient observed in a viscous fluid is suppressed due to much stronger dissipation in the viscous layers, while they occupy much less volume.
Acoustic demultiplexer based on Fano and induced transparency resonances in slender tubes

Abstract

We give an analytical demonstration of the possibility to realize a simple phononic demultiplexer based on Fano and acoustic induced transparency resonances. The demultiplexer consists of a Y-shaped waveguide with an input line and two output lines. Each output line contains two stubs grafted either at a given position or at two positions far from the input line. We derive in closed form the expressions for a selective transfer of a single propagating mode through one line keeping the other line unaffected.

1. Introduction

Fano and EIT (Electromagnetically Induced Transparency) resonances \cite{1, 2, 3} have an atomic origin, but they have been the subject of several studies in classical systems such as coupled micro-resonators \cite{4, 5, 6}, photonic waveguides \cite{7, 8, 9, 10, 11}, acoustic slender tube waveguides and solid-liquid multilayers \cite{12, 13, 14, 15, 16, 17, 18, 19, 20, 21} as well as plasmonic nanostructures \cite{22, 23, 24, 25, 26}. Fano resonance can be explained as the product of two processes of constructive and destructive wave interferences that give rise to a resonance followed by an antiresonance over a narrow frequency range and can be manifested by an asymmetrical profile shape. In the transmission spectra, the Fano profile appears as a maximum near to a transmission zero \cite{27, 28}. When the Fano resonance falls between two antiresonances (two transmission zeros) it becomes EIT. In optics this phenomenon has shown potential applications to realize slow light and data storage of optical information \cite{29, 30, 31, 32}. Fano and EIT resonances are originally the product of a coupling between one or more discrete states and a continuum \cite{3}.

In general, to create this type of resonances in classical systems, one directly or indirectly connects two or more resonators with a waveguide. Among the simple structures giving a clear theoretical and experimental demonstration of such resonances, one can cite a guide connected with two lateral resonators at the same point (called a cross structure) or two different positions (called U-shaped structure).

In acoustics the U-shaped structure was first studied by El Boudouti et al. \cite{12} to show Fano and AIT (the acoustic analogue of EIT) resonances. A few years later, the same structure was studied by Santillan et al. \cite{13} to demonstrate AIT resonances and delayed sound. More recently, cross and U-shaped structures have been the subject of interest by Merkel et al. \cite{14} to experimentally show AIT and Fano resonances as well as the possibility to realize perfect absorption with such structures. Similar structures but with multiple stubs have been proposed by Long et al.\cite{33} to realize multiband and broadband absorbers for low-frequency sound. It is worth mentioning that cross and U-shaped photonic structures based on coaxial cables have been studied both theoretically and experimentally\cite{10, 11} in the radio-frequency domain. In addition, the cross structure has been proposed to study a Y-shaped demultiplexer based on EIT resonances\cite{34}. This demultiplexer consists on one input line and two output lines, each one containing a cross-shaped resonator.

Acoustic demultiplexers based on phononic crystals with different defects has been realized either through what is called add-drop filters\cite{35, 36} or multi-port channels\cite{37, 38}. Recently, three-port acoustic network has been used to study subwavelength control of absorption \cite{39} using resonators on each channel. Also, Three- and four-port configurations in presence of a resonator at the common junction have been designed such that the incoming waves are first coherent perfectly channeled to other channel before manipulating it to absorption \cite{40}. In this paper we propose two Y-shaped acoustic demultiplexers with two different configurations: the first structure is based on the cross-shape structure (Fig. 1) and the second one is based on the U-shape structure (Fig. 7). The demultiplexers in these two devices are based on AIT and Fano resonances. The aim consists of demonstrating the possibility of finding analytically the appropriate lengths of the different waveguide resonators in order to reach total transmission in one output line keeping the other lines unaffected. The demultiplexers proposed in this study have several advantages over those based on phononic crystals\cite{37, 38}, such as: i) the simplicity of the device manufacturing where only two resonators are needed on each output line instead of a periodic structure with a given defect, ii) the simplicity of the structure enables a full analytical calculation which allows to deduce
the exact expressions of the different lengths of the waveguides to achieve a perfect demultiplexing, iii) The possibility of increasing the quality factor of the filtered resonances to infinite values by detuning the lengths of the two stubs. This property is a feature of Fano and induced transparency resonances that does not exist in standard phononic crystals with defects in which filtering is performed using finite width Breit-Wigner resonances[37, 38, 41]. It should be pointed out that the validity of our results is subject to the requirement that the cross section of the slender tubes being negligible compared to their length and to the propagation wavelength. The assumption of monomode propagation is then satisfied.

The rest of the paper is organized as follows: in section 2 we shall give the analytical expressions of the lengths of the tubes that enables to realize a perfect demultiplexing for the cross structure. These analytical results are obtained from an analysis of the transmission and reflection coefficients and will be illustrated by numerical applications in standard acoustic slender tubes[13]. Section 3 gives the same results as in section 2 but for U-structure. The last section contains the concluding remarks.

Figure 1: Schematic representation of a Y-shaped demultiplexer with one input line and two output lines. Two stubs are grafted at the same position along each output line. The geometrical parameters are defined in the text.

2. Demultiplexer based on cross structure

2.1. Transmission and reflection coefficients

Consider the structure shown in Fig. 1, this structure is composed of an input line and two output lines, all fixed at point 1. The first output line contains two stubs of lengths \(d_1\) and \(d_2\) inserted on the same site 2 at a distance \(d_5\) from the input. Likewise, the second output line contains two stubs of lengths \(d_3\) and \(d_4\) inserted on the same site 3 at the distance \(d_6\) from the input 1. The possibility of realizing an AIT type resonance in a simple cross structure composed of two resonators of lengths \(d_1\) and \(d_2\) connected at one point along an infinite waveguide, has been the subject of several previous works [12, 13, 14]. In a cross structure, the AIT resonance is obtained by the entire stub of lengths \(d_0 = d_1 + d_2\). This resonance is trapped between two transmission zeros induced by the two elementary stubs of length \(d_1\) and \(d_2\).

The calculation of the transmission and reflection coefficients is carried out using the Green’s function method[42]. For simplicity, all waveguides are assumed being characterized by the same characteristic impedance \(Z = \frac{\rho c}{S}\) where \(\rho = 1.2Kg/m^3\) and \(v = 342m/s\) are respectively the density and velocity of the fluid inside the slender tubes (namely, air) and \(S = 3.14cm^2\) is the section of the guide. We have chosen the same parameters as those used in the experimental work by Santillan and Bozhevolnyi[13]. However, the resonators are supposed to be simple stubs instead of Helmholtz resonators with narrow neck in order to get analytical expressions for a perfect demultiplexing (see below), otherwise the calculation becomes cumbersome and only numerical simulation can be performed.

The analytical expressions of the transmission coefficients \(t_1\) and \(t_2\) along first and second output lines and the reflection coefficient \(r\) in the input line are obtained using the same procedure of calculation as for photonic waveguides[34]. We shall avoid the details of these calculations and give below the expressions of \(t_1\), \(t_2\) and \(r\) in closed form, namely

\[
t_1 = \frac{2C_1C_2(-C_0C_3C_4 + S'S_6 + jC_3C_4S_0)}{\chi_1 + j\chi_2},
\]

\[
t_2 = \frac{2C_3C_4(-C_4C_1C_2 + SS_6 + jC_1C_2S_0)}{\chi_1 + j\chi_2},
\]

and

\[
r = -\frac{\xi_1 + j\xi_2}{\chi_1 + j\chi_2}
\]

where

\[
\xi_1 = C_1C_2C_3C_4(S_5S_6 - C_3C_0) + C_1C_2S'C_6S_6 + C_3C_4S_5S_6 + SS'S_5S_6
\]

\[
\xi_2 = C_1C_2C_3C_4S_0 + C_1C_2S'C_5C_6 + C_3C_4S_5C_6 - S_0SS'
\]

\[
\chi_1 = 3C_1C_2C_3C_4(S_5S_6 - C_3C_0) + C_1C_2S'(S_0 + C_5S_0) + C_3C_4S(S_0 + C_5S_0)
\]

\[
\chi_2 = C_1C_2C_3C_4(3C_5S_6 + 3C_3S_6) + (C_5C_6 - 2S_5S_6)
\]

\[
(1 - S_5S_5 + C_3C_6 - S_0SS')
\]

and \(C_i = \cos(kd_i), S_i = \sin(kd_i)\) (i = 1-6), \(S = \sin(k(d_1 + d_2)), S' = \sin(k(d_3 + d_4)), S_0 = \sin(k(d_5 + d_6))\). \(k = \omega/v\) is the wave-vector of the sound wave in the slender tubes and \(\omega\) is the angular frequency.

In the absence of loss, the transmission coefficients in the two output lines are given respectively by \(T_1 = |t_1|^2\)
and $T_2 = |t_2|^2$ while the expression of the reflection $R$ in the input line is given by $R = |r|^2$. The transmission and reflection coefficients satisfy the energy conservation: $T_1 + T_2 + R = 1$.

2.2. Numerical results and discussions

Now, we are able to choose the precise parameters of the system to obtain a complete transmission in the two output lines with neighboring frequencies. Indeed, from Eqs. (1), (2) and (3), one can show easily that in order to realize $|T_1| = 1$, $T_2 = 0$ and $R = 0$, one should have $C_3C_4 = 0$ (i.e., $C_3 = 0$ or $C_4 = 0$), $S = 0$ and $C_6 = 0$. Similarly, in order to realize $|T_2| = 1$, $T_1 = 0$ and $R = 0$, one should have $C_1C_2 = 0$ (i.e., $C_1 = 0$ or $C_2 = 0$), $S' = 0$ and $C_5 = 0$. Now, in order to realize both $T_1 = 1$ and $T_2 = 1$ at two different and neighboring frequencies, we can show after some algebraic calculations that the six lengths $d_1$, $d_2$, $d_3$, $d_4$, $d_5$ and $d_6$, should satisfy the following conditions:

$$d_1 = \frac{d_0}{2} - \frac{\delta}{2}$$
$$d_2 = d_3 = \frac{d_0}{2} + \frac{\delta}{2}$$
$$d_3 = d_6 = \frac{d_0}{2}$$
$$d_4 = \frac{d_0}{2} + \delta,$$

where we have introduced a detuning parameter $\delta = d_2 - d_1 \neq 0$ between the two stubs along the output 1 (Fig. 1). This is a necessary and sufficient condition to realize an AIT resonance along the output 1. In addition, along this study we shall fix the length of the two stubs (i.e., $d_0 = d_2 + d_1$) which fixes the position of the AIT resonance along the output 1.

In order to illustrate the results above, we present in Fig. 2 the variation of the transmission coefficients $T_1$ and $T_2$ and the reflection coefficient $R$ as a function of the frequency $f$ for different values of $\delta = d_2 - d_1$ and for $d_0 = d_1 + d_2 = 8.57cm$.

Similarly, the length of the two stubs along the second line $d_0' = d_3 + d_4$ is chosen such that the second resonance induced by the first stubs falls at the vicinity of the one induced by the former stubs. In particular, we have chosen the same parameter $\delta$ representing the detuning between the AIT resonances and at the same time the separation between the transmission zeros of each AIT resonance (i.e., $d_0' - d_0 = d_2 - d_1 = d_4 - d_3 = \delta$). Figure 2 clearly shows that when the transmission along the first output (continuous curve) reaches unity ($T_1 = 1$), the transmission along the second output $T_2$ (discontinuous curve) and the reflection $R$ (dotted curve) vanish (i.e., $T_1 = R = 0$). As mentioned above, the AIT resonance in the first output falls at the same frequency $f_0 \simeq 2000Hz$ for all $\delta$ values, its width decreases when $\delta$ decreases and disappears for $\delta = 0$ (Fig. 2). In addition, the shape and width of the AIT resonance changes slightly when $\delta$ becomes negative (i.e., for a permutation of both stubs 1 and 2). The position and width of the resonance along the second line strongly depend on $\delta$.

Indeed, since the first resonance AIT has two transmission zeros around $f_0 = 2000Hz$, the position of the second AIT resonance falls above $f_0 = 2000Hz$ for $\delta < 0$ (Figs. 2(a),(b)), crosses the first resonance at $\delta = 0$ and reappears below $f_0 = 2000Hz$ for $\delta > 0$ (Figs. 2(c),(d)). This is illustrated in Fig. 3 where we have given the variation of the frequencies $f_1$ and $f_2$ of both resonances for different values of $\delta$. It can be noted that the frequency $f_1$ of the resonance along the first line remains constant at $f_0$ regardless the value of $\delta$, whereas the frequency $f_2$ of the second resonance falls above $f_0$ for $\delta$ negative ($\delta < 0$) then it reappears below $f_0$ when $\delta$ becomes positive ($\delta > 0$). The crossing
between the two resonances takes place for $\delta = 0$.

Figure 3: Variation of the frequency of the two AIT resonances along the two output guides as a function of $\delta$.

Figure 4 gives the quality factor $Q$ of the two resonances as a function of $\delta$. We remark that the quality factor is almost the same for both resonances; it decreases very rapidly as a function of $\delta$ and tends to infinity when $\delta$ tends to zero. This kind of resonance (with infinite lifetime) is called bound in continuum state\cite{43}, it represents a stationary mode in the cross stubs and do not interact with the incident waves in the main waveguides.

Figure 4: Variation of the quality factors $Q_1$ and $Q_2$ of the AIT resonances as a function of $\delta$.

In the previous results we have neglected the effect of loss on the AIT resonances. In Fig. 5 we have given the same transmission spectra as in Fig. 2(b) but in presence of damping. We have considered the same damping due to viscosity and thermal conduction in the resonators as in the experimental work by Santillan and Bozhevolnyi\cite{13}. One can see that the transmission does not reach unity because of the attenuation of sound in the guides, the energy transmitted remains less than 80% in both branches. Also, the effect of absorption on the amplitude of the AIT resonances becomes very important for resonances with narrow width.

In order to analyze the spatial localization of the different modes that can be filtered or stopped by the demultiplexer, we have calculated the displacement field along the two output lines of the system\cite{42}. Figure 6 gives the square modulus of the displacement field $|U|^2$ for the resonance $f_1 = 2000Hz$ with $\delta = -1.85cm$, i.e., $d_1 = 5.21cm$, $d_2 = d_5 = 3.36cm$, $d_3 = d_6 = 4.285cm$, $d_4 = 2.435cm$ (Fig. 2(a)). This mode corresponds to a filtered mode (full curve) in one line and a stopped mode (dashed curve) in the other line (Fig. 2(a)). Figure 6 shows that the mode $f_1 = 2000Hz$ is transferred along the output 1 (Fig. 6(a)), whereas it is stopped along the output 2 (Fig. 6(b)). The transfer of this mode along the output 1 is due to the excitation of both stubs of lengths $d_1$ and $d_2$ along this line as it illustrated in Fig. 6(c), whereas its stopping along the second line is due to the excitation of the stationary mode of only the stub of length $d_4 = 2.435cm$ as shown in Fig. 6(d). Similar results are obtained for the the resonance mode $f_2 = 2544Hz$, but this time the transfer occurs along the second line through the excitation of its double stubs of lengths $d_3$ and $d_4$, whereas the wave is stopped along the first line as a consequence of the excitation of the mode of one of its stubs of length $d_2 = 3.36cm$. These results clearly show how the lengths of the finite guides constituting the demultiplexer should be chosen appropriately in order to transfer a wave in one line keeping the other line unaffected.

3. Demultiplexer based on U-structure

As mentioned above, the U-shaped resonator along a waveguide was the subject of several studies in acoustics by different authors\cite{12, 14}. In particular, it was shown that such structures can present two types of resonances: AIT-type resonances when the two resonators have different lengths and Fano resonances when the two resonators have the same lengths. In this section we consider the U-shaped demultiplexer composed of an input line and two output lines, all connected at the same point 1 (Fig. 7). On the first output line we connect two lateral stubs of lengths $d_1$ and $d_2$ separated by a distance $d_0$. The stub of length $d_1$ is inserted in the site 2 at a distance $d_5$ from the input 1 and the stub of length $d_2$ is inserted in the site 3 at a distance
which fixes the po-

from the input 1
around
\( \delta \)
along the vertical stubs in each line. 1, 2 and 3 indicate
the entrance and the exit along each line (Fig. 1)
d5 + d0 from input 1. Similarly, the second output line contains
two lateral stubs of lengths \( d3 \) and \( d4 \) separated by a
distance \( d0' \). The stub of length \( d3 \) is inserted in the site 4 at
the distance \( d0 \) from the input 1 and the stub of length \( d4 \) is
inserted in the site 5 at a distance \( d0 + d0' \) from the input 1
(Fig. 7).

\( d_1 = \frac{d_0}{2} + \frac{\delta}{2}, \) \hspace{1cm} (12)
\( d_2 = \frac{d_0}{2} - \frac{\delta}{2}, \) \hspace{1cm} (13)
\( d_3 = \frac{d_0}{2}, \) \hspace{1cm} (14)
\( d_4 = \frac{d_0}{2} - \delta, \) \hspace{1cm} (15)
\( d_0' = d_3 + d_4 = d_0 - \delta. \) \hspace{1cm} (16)

Figure 8 presents the variation of the transmission co-
efficients \( T_1 \) and \( T_2 \) and the reflection coefficient \( R \) as a
function of the frequency \( f \) for different values of \( \delta \) around
\( \delta = 0 \). We can see clearly that for each \( \delta \), when the
transmission along the first output line (continuous curve)
reaches unity \( (T_1 = 1) \), the transmission along the sec-
ond output line \( T_2 \) (discontinuous curve) and the reflection
\( R \) (dotted curve) cancel out each other (i.e., \( T_2 = R = 0 \)).
Similarly, when the transmission along the second line (dis-
continuous curve) reaches unity \( (T_2 = 1) \), the transmission
along the first line \( T_1 \) (continuous curve) and the reflection
\( R \) (dashed curve) vanish (i.e., \( T_1 = R = 0 \)). As mentioned
above, the AIT resonance in the first output line falls at the
same frequency for all \( \delta \) values, its width decreases as \( \delta \)
decreases and disappears for \( \delta = 0 \) (Fig. 8), giving rise
to bound in continuum states[43]. In addition, the shape
and width of the AIT resonance change slightly when \( \delta \)
becomes negative (i.e., for a permutation of both stubs 1 and
2). The position and width of the resonance along the sec-
ond line strongly depend on \( \delta \).

Indeed, as the first AIT resonance has two transmission
zeros around \( f_0 = 2000Hz \), the position of the second AIT
resonance falls above \( f_0 = 2000Hz \) for \( \delta < 0 \), cross the
first resonance at \( \delta = 0 \) and reappears below \( f_0 = 2000Hz \)
for \( \delta > 0 \). This behavior is similar to the one obtained in
Fig. 3 for the cross-structure where the crossing between
the two resonances takes place for \( \delta = 0 \). Also, the varia-
tion of the quality factor \( Q \) of the two AIT resonances in the
two outputs lines as a function of \( \delta \), follows the same be-
behavior as in Fig. 4. In particular, \( Q \) increases rapidly when
the absolute value of \( \delta \) decreases and tends towards infinity
when \( \delta \) tends to zero.
Variation of the transmission along the output 1 (continuous curve), the output 2 (discontinuous curve) and the reflection in the input (dotted curve) of the demultiplexer as a function of the frequency $f$ for different values of $\delta$ and for $d_0 = d_1 + d_2 = 8.57\text{cm}$.

### 3.2. Demultiplexer based on Fano resonances

As mentioned in Ref.[12], in order to achieve a Fano resonance, one should take both stubs with identical lengths, but slightly different from $d_0/2$ (i.e., $d_1 = d_2 \neq d_0/2$) along the first output line. Similarly, we should take $d_3 = d_4 \neq d_0/2$ along the second output line. The explicit expressions of the eight different lengths $d_1, d_2, d_3, d_4, d_5, d_6$ and $d_0'$ should satisfy the following equations in order to obtain a total transmission along one output line keeping the other line unaffected

\begin{align}
    d_1 &= d_2 = \frac{d_0}{2} + \varepsilon, \quad (17) \\
    d_3 &= d_4 = \frac{d_0}{2} + \varepsilon, \quad (18) \\
    d_3' &= d_4' = d_0 + 3\varepsilon, \quad (19) \\
    d_0' &= d_3 \quad (20)
\end{align}

where $\varepsilon$ represents the detuning between the lengths of the different guides constituting the demultiplexer. Figure 9 gives the variation of transmission coefficients $T_1$ and $T_2$ and reflection coefficient $R$ as a function of frequency the $f$ for different values of $\varepsilon$ around $\varepsilon = 0$. From Fig. 9 one can see that both resonances are of Fano type, that is a resonance near a transmission zero. In addition, both resonances present different asymmetric line shapes (i.e., opposite Fano parameters[1]) in order to achieve a full transmission in one line and no signal in the other line. We can notice that for $\varepsilon = -0.925\text{cm}$ for example (Fig. 9(a)), the transmission along the first output (continuous curve) is unity ($T_1 = 1$) at $f = 1803\text{Hz}$, the transmission along the second output $T_2$ (discontinuous curve) and the reflection $R$ (dotted curve) vanish (i.e. $T_2 = R = 0$). Similarly, when the transmission along the second line (discontinuous curve) reaches unity ($T_2 = 1$) at $f = 1640\text{Hz}$, the transmission along the first line $T_1$ (continuous curve) and the reflection $R$ (dashed curve) vanish (i.e., $T_1 = R = 0$). Also, there exists a frequency between the two resonances for which the reflection along the input line reaches almost unity ($R \approx 1$), while the transmission along the first line $T_1$ (continuous curve) and the transmission along the second line $T_2$ (discontinuous curve) vanish (i.e., $T_1 \approx T_2 \approx 0$). This behavior does not exist in the case of AIT resonances (Fig. 8). In addition, we can see that for $\varepsilon < 0$, the resonance in the second line falls below the one in the first line (Fig. 9(a)) and when $\varepsilon$ increases both resonances fall close to each other and their widths decrease (Fig. 9(b)). For $\varepsilon = 0$, both resonances fall at the same frequency (around 2000 Hz), their widths vanish giving rise to bound in continuous states[43]. For $\varepsilon > 0$, the resonance in the second line falls above the one in the first line (Fig. 9(c)); its width increases when $\varepsilon$ increases (Fig. 9(d)). These results are summarized in Fig. 10 where we have plotted the frequencies of both resonances as function of $\varepsilon$. We can see that contrary to Fig. 3, the frequencies of both Fano resonances depend on $\varepsilon$. Also, the quality factors of the two resonances (not shown here) are almost identical and tend to infinity when $\varepsilon$ tends to zero. Finally, the amplitude of the filtered resonances in Figs. 8 and 9 can be affected considerably when loss is taken into consideration in particular for narrow resonances as in Fig. 5.

### 4. Conclusion

In this work we have studied a Y-shaped acoustic demultiplexer based on two different configurations. The first demultiplexer is based on a cross structure, in this case we used the AIT-type resonances presented by such structures to realize a perfect demultiplexing. We have given the analytical expressions of the lengths of the different guides to achieve a total transmittance in one output line canceling at the same time the reflection and transmission in the other lines. By taking into account the loss in the guides, we have shown that the property of demultiplexing still remains valid, however the amplitude of the output signal does not reach unity. In the second configuration we have studied the U-shaped structure for the design of the demultiplexer. In this case, we have shown two possibilities of demultiplexing by using either AIT symmetrical resonances or
Figure 9: Variation of the transmission spectra along the output 1 (continuous curve), the output 2 (discontinuous curve) and the reflection in the input (dotted curve) of the demultiplexer as a function of the frequency \( f \) for different values of \( \epsilon \) and for \( d_0 = d_1 + d_2 = 8.57 \text{cm} \).

Figure 10: Variation of the frequencies of the two Fano resonances as a function of \( \epsilon \).

Fano asymmetrical resonances. In both cases we have determined analytically the expressions of the lengths of the different guides to get the total transmission in one output line keeping the other lines unaffected. For both demultiplexers, we have shown that the frequencies of the filtered resonances as well as their widths (i.e., the quality factors) can be tuned by appropriately choosing the lengths of the different waveguides constituting these systems. The confinement of the filtered and stopped resonances along each line are shown through an analysis of the displacement field. The experimental results predicted in this work can be easily validated by simple experiments in the audible frequency range[13, 14, 33].

A bottom-up approach towards metamaterials and plasmonics
Spherically Confined Self-Assembly of Molecular Bottlebrushes – A Facile Route to Hierarchical Photonic Pigments

Richard M. Parker, Dong-Po Song, Tianheng H. Zhao, Giulia Guidetti and Silvia Vignolini*

Abstract
Hierarchical, structurally-coloured materials offer a wide variety of visual effects that cannot be achieved with standard pigments or dyes. However, their fabrication requires simultaneous control over multiple length-scales. Here we present a robust strategy for the fabrication of hierarchical photonic pigments via the confined self-assembly of bottlebrush block copolymers within emulsified microdroplets. The resultant highly-ordered concentric lamellar structure gives rise to a near perfect photonic multi-layer in the solid-state, with reflectivity up to 100%. Our system is particularly suited for the scalable production of photonic pigments, arising from their rapid assembly mechanism and size-independent, tuneable colour.

1. Introduction
Structurally-coloured materials are ideal candidates for photonic pigments, as they offer the possibility to manipulate the visual appearance in terms of both the colour and scattering response. Such effects are also found in nature, where vivid and metallic colours are often the result of intricate nano- and micro-scale structural motifs. Recently, the fabrication of photonic pigments from hierarchically-assembled photonic materials has been demonstrated by restricting the self-assembly of either colloidal particles or liquid crystals within the confined geometry of a micron-sized droplet. However, despite being extensively studied, such systems usually have strong intrinsic limitations in terms of formulation and scalability, which limits real-world application. Block copolymers provide a promising alternative for bottom-up fabrication of photonic structures. In particular, bottlebrush block copolymers (BBCPs), where a highly extended backbone is densely grafted with polymer branches, are well-suited for photonic materials as they can form lamellae with domain spacings large enough to produce a strong reflection in the visible spectrum. Here we present our recent work into the confinement of BBCPs within spherical microdroplets to yield intensely-coloured, hierarchical photonic pigments.

2. Results and Discussion
A series of (poly(norbornene)-graft-poly(styrene))-block-(poly(norbornene)-graft-poly(dimethylsiloxane)) bottlebrush block copolymers were prepared with number average MW of 3.3, 4.1 and 7.1 MDa. To produce hierarchical photonic pigments, the BBCPs were geometrically-confined within monodisperse microdroplets, generated in a single step within a flow-focusing microfluidic device as a chloroform-in-water emulsion. Upon drying, vivid, monochromatic microspheres were produced (Figure 1). The trend in reflected colour correlates with the MW of the constituent BBCP, with blue, green and red microspheres produced. Optical microscopy on an individual microsphere revealed a brightly-coloured reflection spot, with a corresponding sharp peak in the reflectance spectrum. This intense reflection, up to 100% reflectivity relative to a silver mirror, is due to a highly-ordered concentric multi-layer lamellar structure within the microsphere, as confirmed by electron microscopy.

The evolution of structural colour within the droplet was

![Image](https://via.placeholder.com/150)

**Figure 1:** Blue, green and red hierarchical photonic pigments prepared from BBCP1-3 respectively (*top*) and the corresponding reflectance spectra for individual BBCP microspheres (*bottom*).
monitored in real-time and correlated to the self-assembly process, where it was observed that the liquid-liquid droplet interface directs the assembly of the lamellar structure, promoting long-range concentric ordering and ensuring high reflectance from the microsphere by restricting any defects or disorder to the core. Furthermore, the choice of surfactant was found to be critical on this interfacially-templated process.

The colour can also be controlled by formulating microdroplets containing binary polymer blends,[9] with the colour of the blended microspheres lying between that of the two constituent BBCPs (Figure 2). This allows for a broad spectrum of photonic pigments to be readily prepared. Given that the colour reflected from a microsphere depends on the periodicity of the lamellae, the colour is also responsive to swelling in specific solvents. For example, BBCP1 microspheres were observed to reversibly shift from blue to red upon immersion in alcohols with decreasing – due to selective swelling of the poly(dimethylsiloxane) domains. The BBCP microspheres are also highly tolerant to the inclusion of contrast-enhancing additives, e.g. carbon black.

To understand the scalability of the fabrication process, the role of the drying rate was explored: microspheres formed in <30 min, were brightly coloured with longer drying times (e.g. 2 days) only leading to slightly higher reflectance and less observable defects. To explore the role of size on the optical properties, highly polydisperse microspheres were prepared by vortex-assisted emulsification. It was found that the reflected colour and as such the underlying microsphere nanostructure was not affected by the size of the templating microdroplet. Finally, the microspheres were embedded within a transparent matrix to evaluate the consequences of its hierarchical structure – only 2 wt.% of polydisperse BBCP2 microspheres were required to give a visibly green and non-iridescent colour under diffuse illumination.

3. Conclusions

We report a scalable approach for the fabrication of photonic pigments via the confined self-assembly of BBCPs. The obtained microspheres show strong, sharp reflectance peaks, with tuneable and responsive colours, arising from a well-ordered concentric multi-layer photonic structure. The self-assembly process is robust, with high tolerance to the initial droplet geometry and drying rate. The strong templating effect of the droplet interface, combined with the high surface-to-volume ratio leads to unprecedented long-range ordering of the lamellae, resulting in up to 100% reflectivity. As such, BBCP microspheres have great potential as photonic pigments to be used as a replacement for colorants in e.g. automotive paints or in photonic displays.

Abstract

We present spherical clusters, composed of dielectric or metallic inclusions, as a new kind of efficient and isotropic Huygens sources. We demonstrate that this design overlapping electric and magnetic resonances excited at visible frequencies. They may serve as building blocks for metasurface applications. We investigate their possible uses in high transmittance devices requiring a local phase control, and in thin absorber metalattices. They are particularly suited to bottom-up fabrication and self-assembly, offering an alternative to the classical lithographically fabricated metasurfaces.

1. Introduction

Recent progress in electromagnetic metasurfaces has shown that by arranging tailored Huygens sources on a plane, high transmittance surfaces could be produced to spatially control the wavefront of light and thereby construct flat optical components[1,2]. Huygens sources are characterized by highly asymmetric forward-scattering that results from the constructive interferences between the radiation of several modes. A Huygens dipole for instance is obtained by overlapping the radiation patterns of orthogonally oriented electric and magnetic dipoles of same amplitude and phase.

It has been shown recently that isotropic Huygens dipoles and multipoles could be obtained with colloidal particles [1]. The proposed systems are composed of clusters of nanoparticles and typically operate at optical frequencies.

The aim of our work is to propose design recipes of three-dimensional Huygens sources that may subsequently be used as individual building blocks for metasurfaces. We shall overview several Huygens particles and metasurface designs as well as review potential fabrication routes.

2. Clusters of nanoparticles as Huygens sources

Huygens dipoles and multipoles can be achieved artificially by creating spherical clusters of plasmonic or dielectric nano-inclusions. Such systems actually enable the independent tailoring of the electric and magnetic dipole/multipole moments both in frequency and in amplitude. This tuning is determined by the volume fraction and total amount of inclusions in the cluster. Furthermore, our numerical calculations – based on the T-matrix method [4] - show that they may be used to produce phase gradient metasurfaces, flat lenses or perfect absorbers and that the cluster concept is scalable to any wavelength. Our most important result is that the denser cluster geometries present giant scattering cross-section efficiencies that surpass the maximum achievable value by a theoretical spherical dielectric particles, as predicted by Mie theory.

Two typical designs are shown in Fig. 1. They consist in one case of a plasmonic cluster in one case and a dielectric cluster in the other. The scattering cross-sections of the particles when illuminated by an incident plane wave are plotted. In both cases broadband and resonant Huygens dipoles are obtained by overlapping the electric and magnetic dipole resonances. This shows that the cluster system is very versatile versatile. We provide several examples of structures to illustrate that both dipolar or extremely broadband sources can be achieved with either metallic or dielectric inclusions. Our approach to obtain such sources relies on the engineering of the refractive index of the structure, by varying the nature, amount, size, and volume fraction of inclusions.

(c) and (d) are the corresponding fraction of total energy scattered in the forward direction for the Ag and Si clusters respectively, when illuminated by a plane wave. (e) and (f) are the respective scattering diagrams in the E-plane (in blue) and H-plane (in red). Figure adapted from Dezert et al [Dezert].

3. From Colloidal Clusters to metasurfaces

When organized into 2D metalattices, Huygens sources allow to arbitrarily control transmitted waves [2]. Functionalities such as focusing, beam detection, vortex beam generation, holography, are widely explored in the literature. Our full wave numerical simulations show that silicon clusters periodically organized can induce a phase modulation of the transmitted wave in the full range between 0 and 2π, therefore unlocking beam shaping applications. On the other hand, lossy Huygens sources can be exploited to optimize light absorption [3]. Our work reveals the possibility to perfectly absorb an incident wave with an incident plane wave with an array of clusters. Systems based on dielectric as well as plasmonic structures will be presented.

4. Bottom-up fabrication routes

From an experimental point of view, clusters are particularly well-suited to bottom-up fabrication and self-assembly. They can be synthetized by making emulsions of two immiscible phases, one of which contains the nanoparticle inclusions. Therefore, they offer an alternative to the classical lithographically fabricated Huygens meta-atoms and can be made in large volumes. Examples of such synthesized particles will be shown. Figure 2 is an SEM image of preliminary attempts at fabrication of such clusters. Experimental characterizations of these systems will also be presented.

5. Conclusion

The cluster structure is a rich system as it is scalable and has tunable optical properties. Clusters are particularly suited to bottom-up fabrication and self-assembly, and can be synthetized in large amounts using a simple emulsification process. Furthermore, the ability to make Huygens systems from colloidal engineering separates the synthesis of the nanoresonator from the metasurface fabrication. Therefore, they offer an alternative to classical lithographically made Huygens meta-atoms and can be produced in very large quantities.

DNA-Based Self-Assembly of Plasmonic Nanoantennas

Sébastien Bidault

Institut Langevin, ESPCI Paris, CNRS, PSL University, Paris, France
E-mail: sebastien.bidault@espci.fr

Abstract
DNA nanotechnology provides numerous degrees of freedom to create hybrid plasmonic nanostructures for surface enhanced fluorescence and optical biosensing. We review some of our recent results.

Results and Discussion
Short DNA strands can be used as robust and versatile templates to produce plasmonic nanostructures with a fully controlled chemical environment. They allow the parallel production of millions of copies of gold particle dimers linked by a single DNA strand with gaps that can be controlled at the nanometer scale (Figure 1-a) [1]. In particular, a known number of fluorescent dye molecules can be easily introduced in such plasmonic antennas at the position where optical fields are strongly enhanced and confined. For instance, we demonstrated the deterministic introduction of individual fluorescent molecules in the gap between 40 nm gold particles and achieved single photon emission with decay rates enhanced by more than two orders of magnitude (Figure 1-b) [2].

The coupling between single dye molecules and plasmonic gap antennas can be further optimized by selecting nanostructures where the transition dipole of the emitter is aligned with the gold particle dimer axis [3]. Importantly, the efficiency of DNA-templated optical antennas can be optimized by increasing the size of the gold particles (60 nm – 80 nm) to enhance the excitation and emission rates of single fluorescent molecules by two orders of magnitude while reaching quantum yields as high as 70 % [4]. Furthermore, by introducing two dye molecules that act as a FRET ( Förster resonant energy transfer) pair, we show how field confinement in plasmonic antennas allows the modulation of non-radiative energy transfer processes [5].

The flexibility of DNA-based self-assembly also means that the morphology of the produced nanostructures can be modulated in-situ. For instance, the DNA template can feature a secondary structure, such as a hairpin loop, in order to actively modulate the distance between gold particles when introducing a specific DNA strand [6]. Importantly, single nanostructure scattering spectroscopy provides a direct estimation of interparticle distances in gold nanoparticle dimers linked by a short DNA double-strand [1]. This spectroscopic information can be inferred from simple widefield measurements on a calibrated color camera (figure 1-c) [7]. This allows us to monitor optically how the interparticle distance between 40 nm gold particles can be tuned, between 20 nm and ~1 nm, when modifying the local ionic strength. In particular, we use this spectroscopic technique to analyze the morphological stability of hybrid gold-DNA nanostructures when tuning the surface chemistry of gold particles or the local temperature [8, 9]. These results also open numerous perspectives for the active tuning of DNA-templated plasmonic nanoantennas under controlled physicochemical stimuli.

Self-Assembled Plasmon-Upconversion Nanoclusters for Cancer Theranostics

Wounjhang Park*

Department of Electrical, Computer & Energy Engineering, University of Colorado, Boulder, CO, USA

Abstract
Nanoclusters of upconversion nanoparticle and gold nanorod are synthesized by a modified PEGylation process and further conjugated with antibody to epidermal growth factor receptor to target bladder cancer. They are then used to simultaneous imaging and optoporation aided chemotherapy of bladder cancer with high selectivity.

1. Introduction
Upconversion nanoparticles (UCNPs) have recently gained research interest due to several favorable characteristics. Because UCNPs upconvert lower energy photons in the near-infrared (NIR) region into higher energy photons in the visible, they provide distinct advantages of no autofluorescence, deeper tissue penetration, and minimal tissue damage. Furthermore, in contrast to conventional fluorescent probes such as organic dyes and quantum dots, UCNPs do not exhibit photobleaching or blinking. Compared to two-photon fluorescence or second harmonic generation, upconversion efficiency of UCNP is many orders of magnitude higher.

Plasmonic nanostructures are well known for their ability to enhance local field and have been studied to enhance upconversion. Negotiating the tradeoff between the plasmonic enhancement and the unavoidable quenching, however, is an on-going challenge [1]. A promising alternative direction is to use plasmonic-upconversion nanoclusters for multifunctionality, rather than upconversion enhancement. In this approach, one must still deal with metal losses but enjoys greater freedom of engineering.

2. Results and Discussion
2.1. Synthesis of nanoclusters
We use a modified PEGylation process to synthesize nanoclusters of UCNPs and gold nanorods (AuNRs). First, UCNPs are made water soluble by using polymer, poly(maleic anhydride-alt-1-octadecene) (PMAO). When reacted with NH₂-PEG-SH and NH₂-EtOMe, PMAO turns amphiphilic and binds with UCNPs. NH₂-PEG-SH provides thiols for further reaction with gold while the NH₂-EtOMe acts as a stabilizer to minimize aggregation of UCNPs.

Then, the coated UCNPs bind with AuNRs through the gold-thiol bonding process. The AuNRs used in this work have an average width of 11 nm and length of 43 nm and has a localized surface plasmon near 800 nm [2]. It is noted that the plasmon resonance is not matched with either absorption or emission of UCNP, as the primary goal of this work is not to enhance upconversion but to achieve multifunctionality – upconversion luminescence for imaging/detection and plasmon-induced optoporation for therapeutics. Thus, we use small-size, detuned AuNRs for minimal luminescence quenching. As shown in Fig. 1, we achieved well-controlled synthesis of UCNP-AuNR nanoclusters and importantly UCNPs did not show any quenching.

Figure 1. (a) Electron microscopy images of UCNP-AuNR nanoclusters. A low magnification SEM image reveals successful UCNP-AuNR conjugation yield of 34%. The inset shows higher magnification TEM images of the UCNP-AuNR clusters. Scale bars indicate 100 nm. (b) Upconversion PL spectra of single UCNP and UCNP-AuNR nanocluster consisting of one UCNP and one AuNR. There is no significant PL quenching due to the addition of a single AuNR. Scale bar indicates 100 nm.

2.2. Cancer targeting and imaging
The UCNP-AuNR nanoclusters were then functionalized with C-225, an antibody to epidermal growth factor receptor (EGFR) via the standard EDAC reaction. Human bladder cancer cells are known to over-express EGFRs while normal urothelial cells don’t. Thus, when C-225 antibodies are present on UCNP surface, the nanoparticle will specifically bind to bladder cancer cell. The selective binding of C-225 conjugated UCNP-AuNR nanoclusters was tested by treating a mix of EGFR-positive (A549) and EGFR-negative (H520) cells, a well-established model of EGFR expression, with the UCNP-AuNR nanoclusters. Figure 2(a) shows non-overlapping
green (EGFR-positive) and red (EGFR-negative) fluorescence, clearly demonstrating selective binding of our nanoclusters to the EGFR-positive cells only. This mixture of EGFR-positive and EGFR-negative cells is a good representative of the in vivo situations where EGFR-positive cancer cells are scattered in the midst of EGFR-negative normal cells. Figure 2(a) therefore serves as a powerful evidence that the UCNP-AuNR nanoclusters will selectively bind only to the EGFR-expressing cancer cells in the eventual human application.

Next, we demonstrate the high-contrast upconversion luminescence imaging capability of the UCNP-AuNR nanoclusters. Figure 2(b) shows an upconversion fluorescence image of T24T bladder cancer cells, an EGFR-positive cell line, treated with our nanoclusters. Unlike the conventional fluorescence imaging, there is no background autofluorescence, providing high contrast.

![Fluorescence micrograph of a mixture of A549 (EGFR-positive) and H520 (EGFR-negative) cells.](image)

Figure 2. (a) Fluorescence micrograph of a mixture of A549 (EGFR-positive) and H520 (EGFR-negative) cells. (b) Upconversion fluorescence micrograph of T24T cells conjugated with UCNP-AuNR nanoclusters.

2.3. Targeted chemotherapy

We now demonstrate simultaneous upconversion imaging and optoporation capability. As shown in Figure 3(a), bladder cancer cells are identified clearly by the green upconversion fluorescence signal. We then irradiate only the region within the yellow circle with a femtosecond laser (energy of 8 pJ). The high peak power of the laser coupled with strong plasmon resonance of AuNR induces nanocavitation which in turn results in membrane disruption. This process, often called optoporation, is first demonstrated with red dyes. As depicted by Figure 3(a), we observe a bright red fluorescence, resulting from dyes entering the cells and becoming fluorescent. It should be noted that the UCNP-AuNR mediated optoporation is highly localized and does not affect the neighboring cells. This is in contrast to photothermal ablation which could affect the neighboring cells due to heat dissipation.

Next we demonstrate the efficacy of the optoporation-based selective chemotherapy. For this, we design an experiment where we use sub-clinical dosages of cisplatin and monitor the cell viability for 24 hours after femtosecond laser irradiation. The cell viability is measured by fluorescence microscopy in which we use a dye that stains only the dead cells. As shown in Figure 3(b), we achieve cell viability below 20% with only 30 min of exposure of 1.5 µM of cisplatin when we utilize optoporation to enhance the chemotherapy drug intake, while the control samples (nanoclusters+ laser but no cisplatin and cisplatin+ laser but no UCNP-AuNRs) maintain viability of over 60%. The effectiveness of our nanocluster is evident from the fact that effective cell killing is achieved with a much shorter incubation time and a substantially lower chemotherapy drug concentration than previous reports. Both the shorter incubation time and lower dosage of chemotherapy drug are critical requirements for clinical applications because a lower dosage will reduce adverse side effects and 2 hours is known to be the longest intravesical treatment time tolerated in humans.

![Fluorescence micrograph of a bladder cancer cell treated with both UCNP-AuNR and femtosecond laser.](image)

Figure 3. (a) Fluorescence micrograph of a bladder cancer cell treated with both UCNP-AuNR and femtosecond laser. (b) Cell viability for three groups of cells: nanocluster+ laser, cisplatin+ laser and nanocluster+ cisplatin+ laser.

3. Conclusions

We demonstrate efficient coupling of UCNPs with AuNRs through a PEGylation process. The new PEGylation process allows the formation of highly stable UCNP-AuNR nanoclusters and further functionalization with antibodies for active targeting of bladder cancer. We demonstrated the capability of simultaneous upconversion imaging and targeted chemotherapy enabled by selective optoporation. Upconversion imaging provides high-contrast images leading to high sensitivity detection of cancer. Upon detection, a subsequent irradiation by femtosecond laser results in a highly selective optoporation. This then enables highly targeted chemotherapy, which results in cell death with sub-clinical dosages of chemotherapy drug.

It should be noted that we have demonstrate the cell targeting in a mixture of EGFR-positive and EGFR-negative cells, which is a good representation of in vivo situation. Also, we have used active targeting with EGFR antibody and accomplished cell targeting within 2 hours. This is important because 2 hours is generally considered the longest intravesical treatment time tolerated in human. Our approach thus shows a promising pathway to highly targeted bladder cancer treatment compatible with the current clinical practice.

Correlated disordered nanostructures embedded in flexible film

Abstract

Metallic or dielectric nanostructures (NSs) modify the reflectance spectrum of functionalized glass surfaces and allow multiple or localized staining without using complex surface treatments. Here, we present the fabrication of metallic and dielectric NSs embedded in a flexible poly(dimethylsiloxane) (PDMS) film to modify its reflectance spectrum. The NSs are positioned with correlated disordered arrangements to avoid light diffraction and diffusion. PDMS enables fabrication of functionalized flexible and repositionable film which conforms to the shape of rigid transparent supports.

1. Introduction

Due to the increased interest for controlling the reflectance property of material surfaces for several optical applications during these last year, the research has been intensified to develop novel methods to nanostructure surfaces with nanowires, nanorods, nanodisks, or nanopillars with conical or pyramidal shapes[1-4]. The choice of materials, metals or dielectrics, as well as the dimensions of nanostructures depend on the required optical properties. In the field of solar cells silicon nanowires are commonly used to reduce reflection through destructive interference [5-7]. At the opposite, the reflectance of transparent display must be increased head-up display and augmented reality systems [8] in that respect thanks to the metal nanostructuration the reflectance spectrum and the apparent color can be controlled with a high spatial resolution down to subwavelength dimension. In order to avoid any diffraction and diffusion effects, the NSs are arranged following a correlated disorder. Besides, for a different objective, a substrate with fully random metallic nanoparticles has been proposed as a transparent display revealing a blue image by scattering effect in the plane of the substrate [9]. Patterned flexible films with micro and nanostructures allow other functions compared to rigid substrates. Authors report the interest of poly(dimethylsiloxane) PDMS for its mechanical, optical and physical properties and to obtain flexible functionalized film for different optical applications [10,11]. It is elastic, flexible and transparent. Its flexibility permits a good conformity on non-planar surface. For these points we propose to present a new manufacturing method to embed metallic and dielectric NSs with a correlated disordered arrangement in a flexible PDMS film.

2. Fabrication

The objective is to embed NSs in a flexible 2 mm thick PDMS film. Metallic and dielectric NSs are firstly fabricated by electron beam lithography. For metallic nanostructures, manufacturing process is schematized in Figure 1. E-beam lithography is made on molybdenum sacrificial layer (Fig. 1a) by a Nanobeam (NB4) system with an accelerating voltage of 80 Kv and a current of 2 nA. Preliminary step is a spin-coated PMMA A2 resist on molybdenum sacrificial layer deposited on a silicon substrate by sputtering. An Ag layer is deposited on lithographed resist and followed by a lift-off process (Fig. 1b). PDMS is then coated to embed metallic nanoparticles (NPs) in flexible substrate before a bake (Fig 1c).

Figure 1: Scheme of the developed process.

The usage of soluble sacrificial layer is necessary to successfully transfer the NPs to the PDMS film with no mechanical peeling. Flexible film with metallic nanostructure grating is separated from silicon substrate after dissolution of molybdenum in H2O2 (Fig. 1d). In the case of dielectric NSs, amorphous silicon (aSi) is deposited on molybdenum sacrificial layer before e-beam lithography, and a metallic mask is fabricated by lift-off
before reactive ionic etching of the aSi layer. Transfer of the Si NSs follows then the same process as in the case of metallic NSs.

3. Correlated disorder

Following our previous work [8], the NSs have been arranged according to a correlated disorder. The design of correlated disorder has been determined by using centroidal Voronoi tessellation algorithm applied on an initially random arrangement [12]. It is characterized by the structure factor (Fig. 2, right) determined by calculating the Fourier transform of the NS assembly pair correlation function. The structure factor is equal to zero for kD values lower than −2π: considering that k is the projection of wavevector 2π/λ and D the average distance between NSs, diffusion effect will be reduced for wavelength higher than −D.

![Figure 2: SEM image of correlated disorder arrangement of silver NPs, and calculation of the structure factor (Fast Fourier Transform of the pair correlation function).](image)

We have fabricated such assembly in the case of D~250nm for metallic NSs [8], and we have checked improvement of reflectance at λ =590nm with no parasitic diffusion neither diffractive effects. We will show preliminary results obtained in the case of similar NSs embedded in PDMS.

4. Conclusions

We have developed a new technological process in order to embed metallic or dielectric nanostructures in PDMS: the process is based on sacrificial layer, without requirement of mechanical peeling. In order to obtain transparent functionalized substrates without diffusion and diffraction effects, the nanostructures are arranged following a correlated disorder arrangement. Such flexible and repositionable substrates can be used in many applications like augmented reality or glazing functionalization.

Abstract

We report a method to incorporate non-functionalized gold nanoparticles (AuNPs) in oriented cylindrical phases of poly(styrene)-b-poly(vinylpyridine) (PS-b-P2VP) block copolymers, perpendicular to a substrate. The combination of AFM, TEM, GISAXS and spectroscopy allows complete characterization of the nanocomposites. AuNPs are produced by the ultra-sound reduction of a gold salt in the copolymer solution, prior to the deposition of the films by spin-coating. The AuNPs are found to be located within the PVP domains without any change in their orientation. Ellipsometric optical properties of these plasmonic AuNPs embeded into oriented cylinders show a definite extinction in reflectivity at a precise angle and incidence angle.

1. Introduction

Hybrid nanocomposites including noble metal nanostructures have gained great interest due to their unique optical properties. They are essential elements of nanophotonics which explore the possibility of modulating light propagation with a very small amount of matter using nanoscale phenomena. The occurrence of plasmons at metal/dielectric interfaces is indeed one of the key phenomena used in nanophotonics towards the fabrication of nanostructured noble metal–dielectric materials and surfaces. In this context, increasing interest focuses on the incorporation of gold nanoparticles (AuNPs) into block copolymer (BCP) matrices, which allows the combination of the localized surface plasmon resonance of the AuNPs with the ability of the BCP to self-assemble into well-organized 3D nanostructures such as lamellae, cylinders or spheres. Here, we report on the formation of PS-b-P2VP films organized in cylindrical mesophases and containing AuNPs, a geometry akin to hyperbolic ones which are very promising for providing unusual wave propagation. The incorporation of AuNPs in polymer was performed by a two step procedure: (1) the AuNPs were produced by sonication of the solution prior to (2) casting of films. This synthesis method avoids adding extra-species such as a ligand or a reducing agent in the solution. We also proved the efficiency of the seeded-growth method to obtain larger AuNPs exhibiting plasmon resonance. The processes of sonication and spin-coating of a gold-containing copolymer solution allow for an easy and controllable formation of self-organized plasmonic hybrid films. The full characterization of the perpendicular of PS-b-P4VP and PS-b-P2VP was achieved by Atomic Force Microscopy (AFM), Transmission Electron Microscopy (TEM) and Grazing-Incidence Small-Angle X-ray Scattering (GISAXS) experiments. First optical characterization of these films was achieved by variable angle spectroscopic ellipsometry. In particular, p-polarized visible radiation incident on the films containing the plasmonic nanoparticles presents an extinction accompanied by a phase jump at a specific wavelength and incidence angle. Furthermore, these wavelengths and angles were found to depend on the nanoparticle size.

2. Experimental

2.1. Materials

Two different diblock copolymers of poly(styrene)-block-poly-(4-vinylpyridine) (PS-b-P4VP) and one diblock copolymer of poly(styrene)-block-poly-(2-vinylpyridine) (PS-b-P2VP) were purchased from Polymer Source, Inc., and used as received. Gold(III) chloride (AuCl₃, 99.99%) and sodium bromide (NaBr) were purchased from Sigma Aldrich and used as received.

2.2. Film preparation

The PS₁₈₄-b-P4VP₁₇₃ and PS₁₇₆-b-P4VP₁₇₃ copolymers were dissolved in a mixture of toluene/tetrahydrofuran (THF) in order to yield 1 wt% solutions. These solutions were spin-cast at 2000 rpm for 1 minute to yield ~100 nm-thick films. The residual solvent in the spin-cast films was removed by placing the films in vacuum for 2 h. For some samples, solvent annealing in vapors of a mixture chloroform/ethanol (10 : 1) was performed for 1 min at 60°C. The films were then quickly removed from the vapor chamber and dried with nitrogen and finally placed in vacuum for 2 h.
2.3. In situ formation of gold nanoparticles (AuNPs) by sonication

Copolymer solutions were prepared as described above and then mixed with a 0.1 M AuCl₃ solution in toluene in order to obtain various gold/pyridine molar ratios (from Au/Pyr = 0.1 to Au/Pyr = 5.5). The solution was protected from light and stirred overnight. AuNPs were synthetized by sonication in a bath (Elmasonic P30H, 37 kHz, 120W) for a given time (from 1 to 10 min) at room temperature. The films were then spin-cast as described above. Seeded growth kinetics were studied by adding more gold salt (Au/Pyr = 2.0, each addition) in the copolymer solution containing the previously formed AuNPs (initially with a ratio of Au/Pyr = 0.5). The mixture was sonicated again to grow metallic gold on the surface of the AuNPs. This process of gold addition/sonication was repeated four times, in order to get AuNPs bigger in size.

2.4. Characterization

Atomic Force Microscopy, Transmission Electron Microscopy and GISAXS were used as described in Ref. 5.

3. Results and Discussion

Addition of a gold salt (AuCl₃) in the PS₂₇-b-P4VP; copolymer solution and further sonication leads to the formation of AuNPs as demonstrated by UV/visible spectroscopy, evidencing the decrease of the Au(III) peak at 325 nm. TEM image (Fig. 1) of a dropcast film from the solution shows that the AuNPs formed by sonication were confined inside the P4VP domains, due to the affinity between gold and the pyridine group of P4VP. The average NP diameter determined by image analysis on the TEM micrographs was found to be 2–3 nm and could reach up to 10 nm after the seeded growth process was used. The conservation of the perpendicular orientation of cylinders when AuNPs are incorporated in the PS27-b-P4VP7 films was evidenced by AFM, TEM and GISAXS experiments, leading to an anisotropic structure with plasmonic features localized in perpendicular cylinders. Only a moderate increase of the cylinders diameter due to AuNPs incorporation was measured. At different growth steps of the gold nanoparticles by sonication, the films were studied using variable angle spectroscopic ellipsometry. The information contained in the ellipsometry data can be represented as the (Ψ, Δ) angle pair of the complex ratio of p and s polarized reflectivities \( r = \rho/e^{i\Delta} = \tan(\Psi) \exp(i\Delta) \). The ellipsometric data of the films, show the existence of a cancellation of the ellipsometric intensity angle \( \Psi \), while the ellipsometric phase angle \( \Delta \) jumps abruptly of more than 180° at a given incidence angle and photon energy. In the example shown in Fig. 2, for the film with the AuNPs obtained by two growth cycles (AuNP diameter of 7 nm), this specific behavior occurs at an incident light energy of 2.55 eV and an incidence angle of \( \Theta = 65^\circ \).

![Fig. 1](image1.png)  
TEM picture proving AuNPs insertion in oriented polymer cylinders

![Fig. 2](image2.png)  
Annulation of \( \Psi \) and a jump in \( \Delta \) are visible for an energy of 2.55 eV (\( \lambda = 486 \text{ nm} \)) and an angle of incidence of \( \Theta = 65^\circ \).

4. Conclusions

We produced anisotropic films of the block copolymer PS-b-PVP containing in situ synthetized plasmonic AuNPs of controlled sizes between 2 nm and 4 nm aligned along oriented cylinders. This method offer a very controlled way for easily inserting dense population of small sized AuNPs (2 nm) in an organic nanostructured film. Finally, we demonstrate promising optical properties of these hybrid films since they exhibit a sharp extinction accompanied by a phase jump at a specific wavelength and incidence angle.

Second-harmonic generation from metal oxide metasurfaces and photonic crystals

Flavia Timpu¹, Viola Valentina Vogler-Neuling¹, Rachel Grange¹

¹Optical Nanomaterial Group, Institute for Quantum Electronics, ETH Zurich, Switzerland
*corresponding author, E-mail: ftimpu@phys.ethz.ch

Abstract

We fabricate barium titanate metasurfaces from thin films and woodpile photonic crystals from nanoparticles to exploit the bulk optical nonlinearities of this non-centrosymmetric metal oxide. We demonstrate efficient second-harmonic generation in both devices, which shows the potential of top-up and bottom-up fabrication for nonlinear versatile flat photonics.

1. Introduction

Metasurfaces and photonic crystals have the ability to reshape the wavefront over the scale of few wavelengths [1]. Thus, it is possible to modify the phase, amplitude and polarization of a wave using quasi-two-dimensional devices. Currently, metasurfaces with nonlinearities are mostly made of metals [2] or semiconductors [3]. These materials can suffer from high ohmic losses or absorption from the visible to the near ultraviolet (NUV) range. Additionally, in the case of metal metasurfaces, their second order nonlinearities such as second harmonic generation (SHG) originate mostly from their surfaces and asymmetric shapes, which limits their nonlinear conversion efficiency. Here, we use the dielectric metal oxide barium titanate (BaTiO₃, BTO), which is transparent from the NUV to the infrared range and has high second order susceptibilities. Due to the high refractive index of BTO, single BTO nanostructures have both magnetic and electric resonances [4], which can be combined to obtain novel properties such as tailored emission directivity. Based on the properties of single BTO nanoparticles, we design and fabricate BTO metasurfaces and photonic crystals by top-up and bottom-up approaches.

2. Results and discussion

2.1. Top-up fabrication

We deposit layers of BTO (Fig. 1a) by pulsed laser deposition. The crystal structure of the layer is determined by XRD measurements (Fig. 1b), while the thickness and its refractive index are measured by ellipsometry (Fig. 1c). We etch the BTO layer by a top-down fabrication method using inductively coupled plasma (ICP). The obtained metasurfaces (Fig. 1d) consist of a square lattice of nanodisks with variable heights, radii and periods. The measurement of the reflectance and transmittance are in good agreement with the simulations, which indicates that the refractive index is not altered by the fabrication process.

![Figure 1](image)

Figure 1: (a) AFM of a PLD grown BTO layer. (b) XRD measurement of the PLD grown BTO layer. The reflection peaks are labeled with the corresponding crystallographic planes of BTO. The continuum is caused by the amorphous glass substrate below the layer. (c) Measured refractive index of the BTO layer (solid black line). The ordinary (dashed purple line) and extraordinary (dotted blue line) refractive indices for bulk BTO are shown for comparison. (d) AFM of a BTO metasurface.

2.2. Bottom-up fabrication

We demonstrate a bottom-up soft nanoimprint lithography [5] fabrication technique to obtain nonlinear photonic crystals starting from dispersions of BTO nanoparticles (NPs) (Fig. 2a) and a sol-gel precursor. We use a silicon master mold to produce PDMS daughter molds. The PDMS molds are placed on dispersion layers spin coated on a glass substrate. This is followed by exposure to a UV lamp to cure the particle-sol-gel precursor solution in the mold in the form of woodpiles and removal of the PDMS mold. We stack several BTO NP woodpiles
using planarization layers (Fig. 2b), which are finally removed by calcination. We measure a photonic band gap at 560 nm by detecting the transmittance of the BTO woodpile photonic crystal.

![Figure 2](image)

Figure 2: (a) Schematic of the soft nanoimprint lithography process used to fabricate BTO woodpiles starting from a BTO NP-sol-gel precursor solution. (b) SEM micrograph showing two stacked layers of BTO woodpiles.

### 2.3. Second harmonic generation

We measure the SHG efficiency from the BTO metasurfaces and BTO woodpile photonic crystals in a home-built SHG transmission microscope. In the case of the BTO metasurface, we observe an enhanced SHG signal compared to the original unpatterned layer of BTO (Fig. 3a-b). This enhancement appears because the incident electric field is confined in the volume of the BTO nanostructure and also due to the formation of SHG diffraction orders. In case of the BTO woodpile photonic crystals, we observe that the SHG efficiency is reduced at the photonic band gap at 560 nm, as the light is trapped in the photonic crystal (Fig. 3c).

### 3. Conclusions

We showed that nonlinear BTO periodic nanostructures such as metasurfaces or photonic crystals can be fabricated from BTO grains or nanoparticles. Following the demonstration of SHG emission shown in this work, we will investigate if further properties of bulk BTO are present in BTO nanostructures.

![Figure 3](image)

Figure 3: (a) SHG efficiency of the unpatterned BTO layer. (b) SHG efficiency of the a BTO metasurface consisting of disks with a radius of 160 nm and a period of 600 nm. (c) SHG emission efficiency of a 8-layer BTO woodpile photonic crystal compared to an unpatterned layer of BTO NP-crosslinked sol-gel layer.

### Acknowledgements

Abstract
We designed and produced two-dimensional Silicon photonic crystal slabs on glass operating at near-infrared wavelengths. By tuning the slab thickness, we were able to systematically adjust the spectral position of leaky modes associated with strong near field enhancement effects, over several hundreds of nanometers. Near and far field characteristics of the photonic crystal slabs were examined numerically and experimentally. Proper design yields 100-fold enhanced near fields at 1550 nm enabling efficient photon up-conversion in future solar energy and telecommunication devices.

1. Introduction
Photon up-conversion, a non-linear spectral light converting process, consist of (i) the absorption of multiple low frequency photons, and (ii) emission of a single high frequency photon by fluorescent materials, such as nanoparticles. Up-conversion materials are of interest in bio photonics for background-free sensing [1], photovoltaics enabling the utilization of near infrared sub-bandgap photons of the absorbing material [2] as well as in telecommunication [3]. However, an efficient spectral light conversion process often requires high excitation intensities limiting its applicability in case of one-sun illumination and/or the detection of highly diluted substances. Advanced optical light management methods, such as engineering the leaky modes of photonic crystals (PhC) can open up practical applications by significantly enhancing excitation and emission of the electromagnetic radiation. By interaction of photon up-conversion materials placed on the surface of the PhCs with leaky modes the spectral conversion efficiency can be significantly increased. However, feasibility of large area application, reproducibility and being coast efficient is crucial for a PhC slab to be as a simple technological platform facilitating aforementioned applications. In this study, we have designed and realized Si PhC slabs, which exhibit leaky modes resonant with specific NIR wavelengths, by taking advantage of (i) non-toxicity, (ii) well developed technology, (iii) large area applicability, and (iv) high dielectric constant contrast with air of Si. Spectral and angular dependence of the near field enhancement factor and far-field behavior of leaky modes of the Si PhC slab were examined theoretically by optical simulations based on the Finite Element Method (FEM). Moreover, the far-field behavior of the leaky modes of the produced PhCs was experimentally measured by angle-resolved directional transmission (ARDT) measurements. The simulations and experimental angle resolved transmission and reflection results agree very well. The produced PhCs are hence a promising platform for enhanced photon up-conversion in bio photonics and photovoltaics.

2. Methods
2.1. Development of silicon photonic crystal slabs
Photonic crystal slabs were developed by a soft nano-imprinting lithography (NIL) based method. Hexagonal nano-pillar lattice were transferred to sol-gel spin coated 5 cm x 5 cm glass substrates from a master structure by a PDMS mold. The transferred pattern was UV cured prior to thermal curing at 600°C in order to form hexagonal silicon oxide (SiO₂) nano-pillar array. Amorphous Si (a-Si) with various thickness (84 nm to 125 nm) were deposited on the imprinted substrate by electron beam (e-beam) deposition method. After the deposited Si layer crystallized at 600°C under N₂ flow, the nano-pillars were etched successively by chemically and mechanically. Consequently, smooth and uniform Photonic crystal hole slabs were formed whose surface is imaged by scanning electron microscopy (SEM) and demonstrated in figure 1.

Figure 1: SEM image of the 84 nm silicon photonic crystal slab with lattice constant of 1000 nm.

2.2. Optical Simulation
The simulated electric field enhancement was obtained via finite element simulations using the commercial software JSMsuite. Periodic boundary conditions were applied in the
3. Results and Discussion

ARDT measurement is an effective technique which is capable of detection of resonant features originated from radiative resonance between leaky modes of a photonic crystal and incident radiation [4]. We experimentally detect spectral position of the leaky modes of the PhC slabs by ARDT measurements between 400 nm and 2000 nm. The measurements were performed by sweeping the angle of incidence from 0° to 60° by 2° steps through the high symmetry directions Γ → K and Γ → M with TE and TM polarized light in order to reveal spectral features of the leaky modes. The strong resonance features spanning NIR spectrum of the measured transmission spectra in figure 2 reveal the spectral distribution of the leaky modes.

Furthermore, the simulated field enhancement with respect to the Si Slab thickness is shown in figure 3 for the 1550 nm TE polarized radiation incident with varying angle of incidence between 0° to 60° on Si PhC slabs. The simulation results show that it is possible to enhance the field significantly, up to 100 times, inside the volume over the surface of the Si PhC slab either by changing the angle of incidence or thickness of the slab. However, most of the practical applications require light incident close to the normal incidence. Therefore, the leaky modes of the PhC slabs with various slab thicknesses were also experimentally studied by considering the resonant features around normal incidence. The measured resonance patterns of the Si PhC slabs in the figure 4, which shift towards to longer wavelength with the increasing Si slab thickness, demonstrate that how effectively spectral position of the leaky modes can be tuned and engineered by adjusting the slab thickness.

4. Conclusion

In summary, a feasible and large area applicable production procedure of Si PhC slab, whose leaky modes are resonant with external electromagnetic radiation, were demonstrated. Furthermore, the demonstrated production method makes us enable to tune resonant wavelengths of the leaky modes of Si PhC by changing an easily accessible experimental parameter (Si slab thickness). Thus, the produced Si PhC slabs can serve as a platform to enhance UC process at 1550 nm for telecommunication and photovoltaic applications.

Abstract

Silicon particles with sub-wavelength dimensions support intense electric and magnetic dipole scattering in the visible spectrum. They are one of the best candidates for the assembly of optical metamaterials. We propose a high throughput synthesis for the production silicon particles with Mie scattering in the visible spectrum. The produced particles have been assembled into a thin film by dip-coating. The optical properties of the individual particles and of the films have been characterized by single particle scattering, static light scattering and ellipsometry.

1. Introduction

Silicon particles have gained increasing interest in the community of metamaterials, as ideal building blocks for all-dielectric optical metamaterials. Dielectric metamaterials, based on Mie scattering, are a good alternative to plasmonic metamaterials, whose scattering efficiency is hindered by absorption losses in the visible spectrum [1], [2]. Mie theory describes the field scattered from a dielectric particle as a summation of magnetic and electric multipole resonances, called optical modes. The lowest frequency mode is the magnetic dipole scattering. The following higher frequency mode is the electric dipole scattering. The magnetic and electric dipole modes are very intense for silicon particles scattering visible light, thanks to the low imaginary part of silicon’s refractive index at optical frequencies [2]. To exhibit visible magnetic and electric dipole scattering, Si particles should range between approximately 75 and 250 nm [3]. Today, the main obstacle to all-dielectric optical metamaterials is the manufacturing of Si particles of appropriate size and morphology.

Zywietz et al. synthetized silicon particles, with controlled size and crystallinity, by laser printing of a Si wafer [4]. These particles exhibit magnetic and electric dipole scattering of visible light. Although this method succeeded in producing particles with the right size and crystallinity for optical scattering, it is not an efficient strategy.

In fact, to produce enough particles to assemble a material, a high throughput synthesis is required. Typically, bottom-up techniques respond to this requirement. To date, it is possible to produce small Si particles (1-15 nm) or large micrometer and sub-micrometer particles (300 – 2 µm) by bottom-up techniques [3], while the fabrication of Si particles in the right size range for optical dipole scattering remains an unaccomplished challenge.

The high throughput is not the only requirement to be met. Since the scattering wavelength depends on particles’ size [3], a batch of Si particles should be monodispersed in order to be apt for the assembly of a metamaterial. Moreover, monodisperse spheres auto-assemble very easily, forming ordered structures. P. Moitra and co-workers already proved that the auto-assembly of sub-micrometer spherical particles is an efficient method for the realization of a large scale dielectric meta-surface [1].

In this paper, we propose a modification of the synthesis published for the first time by L. E. Pell et al., [5] in order to produce monodispersed Si particles with visible magnetic and electric dipole scattering. The scattering properties of individual particles have been characterized by single particle scattering. Complementary static light scattering measurements have been performed on the colloidal suspensions of Si particles, to assess the quality of each batch in terms of size dispersion. In fact, if the size dispersion is too broad, no sharp peaks can be detected, and therefore the sample is not ideal for the assembly of a metamaterial.

Finally, thin films have been deposited by dip-coating, starting from a colloidal suspension of Si particles. The optical properties of the films have been characterized by ellipsometry.
2. Experimental

2.1 Material synthesis

Amorphous silicon particles were synthetized by thermal pyrolysis of trisilane in supercritical hexane, using a Ti grade 2 batch reactor, according to a procedure published by L.E. Pell et al. [5]. All the reactions were carried out at 460°C, for 10 minutes. Once the reactor is cooled to room temperature, the particles are collected and washed three times with chloroform.

2.2 Material characterization

The size and size distribution of Si particles was characterized by scanning electron microscopy, using a Zeiss Supra 40 VP, operated at 5 kV. Single particle’s scattering spectra have been collected using a set-up consisting of an inverted microscope equipped with a halogen white light source, a spectrophotometer and a ccd detector. Scattering spectra were collected between 400 and 1000 nm.

3. Results and discussion

The decomposition of trisilane in supercritical hexane has proven an ideal method for the production of Si spherical particles with Mie resonances in the near infrared region [6]. In this work, we attempt to reduce the size of Si particles, in order shift the electric and magnetic dipole scattering in the visible region.

The particle’s size can be tuned by adjusting the initial concentration of trisilane, as shown in the graph below (in figure 1).

Figure 1: Effect of the quantity of trisilane on particles' size

When a concentration of trisilane of 4 mM (corresponding to a volume of trisilane of 5 µL) is used, particles with size smaller than 400 nm can be obtained. When the concentration is further decreased to 2.4 mM (corresponding to a volume of trisilane of 3 µL), the particles’ size does not decrease sensibly. Therefore, for this study, we focused on a trisilane concentration of 4 mM. The produced particles, with size between 300 and 350 nm, exhibit magnetic and electric scattering in the visible spectrum (figure 2).

Figure 2: SEM image of particles realized by thermal decomposition of trisilane in supercritical hexane. The average size is 320 ± 28 nm (left). Scattering spectrum (top right) and dark field microscopy (bottom right) of a Si particle with diameter of approximately 300 nm.

1. Conclusions

Silicon particles with optical electric and magnetic dipole scattering have been synthetized according to an efficient bottom-up approach. This method is ideal for the assembly of optical metamaterials or metasurfaces, as it produces particles with a narrow size dispersion with a relatively high throughput.

Abstract

Phosphor material is reconfigured into a lateral photonic crystal structure such that the light-matter interaction can be enhanced, resulting in an improved color conversion efficiency. Following conceptual demonstrations, red and green photonic crystal phosphor plates are stacked in multiplicity on top of a blue light-emitting diode to generate white light of high quality and efficiency.

1. Introduction

The importance of phosphors has been revived with the emergence of phosphor-capped white light-emitting diodes (LEDs), where a GaN-based blue LED chip is combined with phosphor materials so that light with a wide emission bandwidth is generated cost-effectively. Phosphor development, however, has been predominantly materials-oriented and is quickly approaching its limitation. For a paradigm-shift in phosphor research, the authors’ group proposed and demonstrated, called photonic crystal (PhC) phosphors [1]. The basic idea behind PhC phosphors is to structurally engineer phosphor materials into periodic PhCs. A key point in the PhC phosphor design is to tune the associated photonic band-edge (PBE) modes to the phosphor excitation wavelength and thus to induce an enhancement in phosphor excitation efficiency.

2. Device fabrication

Our PhC phosphor consisted of a lateral one-dimensional (1D) PhC backbone as an array of Si3N4 strip lines on a fused quartz substrate, with densely packed CdSe–CdS–ZnS core–shell–shell colloidal quantum dots (CQDs) coated atop (Fig. 1). After the substrate was diced into 1 cm × 1 cm square pieces, a 1D PhC grating pattern with the period of \( \Lambda \approx 300 \text{ nm} \) and a duty-cycle of \( \sim 50\% \) was obtained by laser interference lithography, followed by the pattern transfer down to the Si3N4 layer using CF3/O2/N2 reactive-ion etching. CdSe–CdS–ZnS core–shell–shell CQDs, which were synthesized chemically, were dispersed in cyclohexane solution at 1.0 wt% and spin-coated at 2000 rpm to form a dense CQD film with no apparent void. A reference phosphor was prepared by spin-coating CQDs directly on a flat substrate, which resulted in a planar CQD film with a CQD amount equal to that of the PhC phosphor.

Figure 1: Schematic of the CQD 1D PhC phosphor structure in perspective, where cross-sectional structure and the groovy surface morphology are illustrated.

3. Fluorescence enhancement

Fluorescence spectra were measured for both the PhC and reference phosphors as functions of excitation wavelengths in the 410–510 nm range, which are summarized in Fig. 2. As can be seen from the figure, the fluorescence intensity for the PhC phosphor varies significantly with a strong enhancement for the excitation wavelength range of 430–480 nm, whereas the reference phosphor exhibits almost no variation. The fluorescence enhancement factor reaches its maxima 4.1 at 454 nm and 3.6 at 462 nm, which we attribute to two PBEs at the Brillouin zone center. These observation results are highly consistent with computer simulations based on the finite difference time-domain method.
4. White light generation

To demonstrate the viability and applicability of the technology, we prepared two batches of PhC phosphors using red (620 nm) and green (530 nm) CQDs and stacked them on top of a blue LED chip (450 nm) to produce high-quality white light efficiently—thus economically [2]. The two kinds of PhC phosphors are almost identical in terms of structure (except for the CQDs used) as they are excited at the same wavelengths by the same blue LED chip. We were able to generate a quality white light with the chromaticity coordinates (0.332, 0.341) using a stack sequence of PhC-R3G11, which stands for 3 red PhC phosphor plates and 11 green PhC phosphor plates on the blue LED chip. The same stack sequence of the reference phosphor plates, Ref-R3G11, exhibits the chromaticity coordinates (0.216, 0.206), which is strongly bluish white. It required significantly more phosphor plates to produce the ideal chromaticity coordinates (0.333, 0.333) only using the reference phosphor plates: Ref-R5G16. Figure 3 shows the photographs taken from the three kinds of stack sequences.

Figure 3: Photographs of LED+phosphor assemblies Ref-R3G11, PhC-R3G11, and Ref-R5G16 taken from directly above the sample assemblies (upper) and through the output port of the integrating sphere (lower).

5. Discussion

We have successfully demonstrated the concept and viability of the PhC phosphors, a totally new and paradigm-shifting approach for next-generation phosphors. Yet there still remain issues to be further refined and improved before the PhC phosphors can be accepted as an industrial standard, which include the elimination of excitation polarization dependence.

Cooperative Energy Transfer Controls the Spontaneous Emission Rate Beyond Field Enhancement Limits

Quantum emitters located in proximity to a metal nanostructure individually transfer their energy via near-field excitation of surface plasmons. The energy transfer process increases the spontaneous emission (SE) rate due to plasmon-enhanced local field. Here, we demonstrate significant acceleration of quantum emitter SE rate in a plasmonic nano-cavity due to cooperative energy transfer (CET) from plasmon-correlated emitters. The accelerated SE rate exceeds the rate acceleration experienced by individual emitters due to local field enhancement\(^1-2\). Using an integrated plasmonic nano-cavity, we realize up to six-fold enhancement in the emission rate of emitters coupled to the same nano-cavity on top of the plasmonic enhancement of the local density of states. The radiated power spectrum retains the plasmon resonance lineshape and frequency, with the peak amplitude proportional to the number of excited emitters indicating that the observed cooperative SE is distinct from superradiance\(^3\). Plasmon-assisted CET offers unprecedented control over the SE rate and allows to dynamically modulate the spontaneous emission rate at room temperature enabling an SE rate based optical modulator.

![Figure 1](image)

**Figure 1:** (a) SEM image of plasmonic nanocavity (PNC) array (scale bar= 5 mm). (b) SEM image of a cross-section of a single PNC that was cut using focused ion beam FIB (scale bar = 100 nm). (c) Schematic of the nano-pillar PNC. The quantum dots (QDs) are spin-coated on a polymeric scaffold, then an Au layer is deposited. (d) Schematic of a cross-section of a single nanopillar.
Here, we report the experimental observation of a cooperative SE from an ensemble of $N$ excited quantum emitters (QEs) resonantly coupled to a plasmon nanocavity (PNC) acting as a plasmonic antenna. We observe up to six-fold increase of the ensemble SE rate relative to the plasmonic LDOS enhancement which is linear in the excitation power. Simultaneously, the measured photoluminescence spectrum retains the plasmon resonance lineshape while the overall emission intensity increases linearly with the excitation power. These observations imply that the radiation is emitted by the plasmonic antenna following cooperative energy transfer (CET) from excited QEs. The linear dependence of the ensemble SE rate on the number of excited QEs (as opposed to total number of emitter) has not been observed previously. Such dependence as well as the incoherent nature of CET mechanism that does not require coherence buildup, in contrast to super-radiance, provides a unique possibility for dynamically controlling the SE rate in the same electromagnetic environment by varying excitation power. We experimentally exploit CET to dynamically control SE rate by modulating the excitation power, resulting in reversible increase and decrease of the SE rate at room temperature, which was only possible in previous works using complex photonic devices at cryogenic temperatures. The cooperative enhancement of the ensemble SE rate takes place on top of the plasmon LDOS enhancement for individual emitter’s SE rate paving the way towards SE rate control beyond field enhancement limits. This is particularly important for short-distance optical communication, to increase the modulation rate, and for optical data storage where faster SE rate increases data reading speed.

Figure 2: Left - Illustration of the energy transfer process at the basis of the CET. Incident light excites QDs that, subsequently, transfer their energy to excite localized surface plasmons (LSPs) which decay into a photon. Right - (a) Measured time-resolved photoluminescence for five different excitation intensities for the PNC (Top) and the reference Au film (Bottom). The SE lifetime is intensity dependent only for the PNC. (b) The fitted SE rate fast component (black spheres) and slow component (red spheres) for the PNC (Top) and for the reference Au film (Bottom). The fast and slow SE rate components vary by modifying $N$. The SE rate is linearly proportional to the excitation intensity.

Metasurfaces atop Self-Assembled Metamaterials

Ullrich Steiner

March 18, 2019

The replication of the triply periodic morphology of suitable self-assembled triblock-terpolymers into plasmonic metals has been used for the manufacture of optical metamaterials. While the chiral morphology of the single gyroid holds promise for negative refraction, several aspects of this metamaterial are yet not well understood. One issue poses the termination of the tri-continuous bulk morphologies at the two surfaces. Using a combination of simulations and experiments we show that the termination of the gyroid surface breaks the cubic symmetry of the bulk morphology, inducing a strong linear dichroism. Furthermore, certain terminations lead to the creation of surface cavities that support localise plasmon modes [1].

This presentation discusses the various aspects of the interplay of surface and bulk modes in polymer self-assembled metamaterials and gives an outlook to the further development of these materials.

Synthesis and characterization of plasmonic nanostructures
Plasmonic Horizon in Noble Metal Nanosponges

Thomas A. Klar

1 Institute of Applied Physics, Johannes Kepler University Linz, 4040 Linz, Austria

Abstract

Local electron-hole recombination in gold nanosponges can coherently excite plasmonic hot-spots only within a horizon given by the lifetime of localized plasmons and the finite speed carrying the information that a plasmon has been created.

1. Introduction

Gold nanosponges are three dimensionally (3D) fully percolated nanoparticles that consist of gold and air filaments of about 20 nm diameter and a diameter of the envelope in the range of 100 to 250 nm [1]. Such gold nanosponges are found to support broadband plasmonic resonances in the visible and the NIR. However, a simple assignment of an effective-medium permittivity to the nanosponges turns out to be impossible, despite the deep subwavelength size of their percolations. Scattering from individual Au nanosponges exhibits significant polarization dependence, even if the sponges show a circular circumference. This suggests that the internal pattern of each individual sponge needs to be respected to describe their optical properties correctly [2].

2. Gold intrinsic photoluminescence

Bulk gold shows photoluminescence (PL) with a negligible quantum yield of $\sim 10^{-10}$ [3], which can, nevertheless, be increased by several orders of magnitude in case of gold nanoparticles [4]. This bears, for instance, huge potential to use noble metal nanoparticles as fluorescent and unbleachable dyes in bio-imaging. The enhancement of the PL yield is commonly attributed to nanoparticle plasmons. Tuning the shape or geometry of gold nanostructures (e.g. via reducing the distance between two nanoparticles) allows for redshifting both the scattering and the PL spectra. However, while the scattering cross section increases with a plasmonic redshift, the PL yield decreases, indicating that the common simple picture of a plasmonically boosted gold luminescence turns out to be more subtle. Hence, we systematically varied the distance between the tips of two gold bipyramids on the nanometer scale using AFM manipulation and recorded the PL and the scattering spectra for each separation. We found that the PL intensity decreases as the interparticle coupling increases. This anticorrelation is explained by a theoretical model where both the gold-intrinsic d-band hole recombination probabilities as well as the field strength inside the nanosstructure are considered. Besides, we not only observe PL supported by dipolar plasmon resonances, but also measure PL supported by higher order plasmonic modes, in accordance with simulations [5].

3. Plasmonic Horizon

Combining both preliminary works, that on sponges and that on PL, together, we can now investigate what we call the plasmonic horizon. The gold intrinsic photoluminescence events are the most nanoscopic light bulbs to excite localized plasmons, basically localized on one unit cell. We argue that such nanoscopic light bulbs are a useful tool to investigate the plasmonic horizon [6]. This is formed by the short lifetime of a plasmon (on the order of 6 fs) and the finite speed with which the information that a plasmon has been created can be transported. This actually leads to the fact that a localized creation of a plasmon cannot reach throughout a plasmonic nanosponge larger than 120 nm in diameter within the lifetime of the plasmon. Based on this hypothesis, we can explain the fact that intermediately sized nanosponges of about 150 nm in diameter show a polarization dependent scattering, but far less polarization dependence in the PL spectra [6].

Abstract

Patterning nano-objects is an exciting interdisciplinary research area in current materials science, arising from new optical and optoelectronic properties and the need to device miniaturization. Nowadays, the optical, electromagnetic and mechanical properties of a material can be well-tuned via artificial design over its composition and shape in principle. However, this is still kept challenging and costly for complex engineering at the nanoscale. Here we demonstrate a facile and low-cost fabrication of silver nanoparticle metasurface with a holographic technique. Mimicking the liquid crystal molecules, the silver nanoparticles show a well-observed polarization-directed shape-dependent nanoparticle growth and large-area interference-patterned nanoparticle assembly. The silver nanoparticle metasurface possesses excellent chiroptical properties that can be further used for spin control of light. This facile, large-area, cost-effective metasurface creation technique could open pathways for the new synthesis of chiral metamaterials with a large degree of freedom control of the nanounit (i.e., nanoparticles) and the resulting chiroptical properties.
Au nanorods based core@shell SERS tags with incorporated Raman reporters

Abstract

In this work, we investigated the effect of synthetic parameters on the formation of a detectable gap inside SERS tags consisting of gold nanorods coated by 4-nitrobenzenethiol (NBT) and gold or silver shell. We found that the presence of a detectable intermetallic gap inside AuNR@NBT@Au nanoparticles can be tuned by synthetic parameters. For AuNR@NBT@Ag nanoparticles the intermetallic gap is indistinguishable. However, indirect experiments confirm that NBT molecules are inside the particles.

1. Introduction

SERS tags were developed as new type of probes for bioimaging [1]. SERS tags contain plasmon-resonant nanoparticles and Raman reporter molecules located in areas of high local electromagnetic field (so-called “hot spots”). With the optimal choice of nanoparticles, reporter molecules and the wavelength of the laser irradiation, such tags demonstrate a significant increase in the SERS signal from reporter molecules and have a stronger optical response compared to quantum dots and fluorescent molecules [2]. The localization of reporter molecules in a thin intermetallic gap inside the SERS tags led to the formation of so-called gap-enhanced Raman tags (GERTs) [3]. These tags have several important advantages. First, the incorporated molecules are protected from desorption and from external environment. Secondly, such tags demonstrate a more intensive SERS signal in comparison with SERS tags with surface adsorption of molecules. The SERS signal from reporter molecules inside GERTs is enhanced due to intense electromagnetic field inside the gap between metal surfaces. Indeed, for GERTs with a gold shell, it is possible to detect the gap using transmission electron microscopy [4]. However, for SERS tags with a gold core and complete silver shell, according to literary data, it is still impossible to detect a gap inside.

The aim of this work was to investigate the effect of synthetic parameters on the formation of a detectable gap inside the SERS tags with gold and silver shell. We also investigated the dependence of SERS signal on the presence of the gap inside SERS tags.

2. Materials and methods

2.1. Nanoparticle synthesis

Gold nanorods with a plasmon resonance at about 800 nm were synthesized as described previously [5]. After removing excess of reagents by double centrifugation, 4-nitrobenzenethiol (NBT) Raman reporter molecules were adsorbed on the surface of gold nanorods by the method from [4] followed by removing excess of unreacted NBT by triple centrifugation.

2.2. Silver and gold shell formation

Slow synthesis of silver shell on NBT-coated gold nanorods was performed by reduction of silver nitrate by ascorbic acid at 70°C during three hours. For fast growth, sodium hydroxide was added to this mixture and the reaction lasted for 10 minutes at room temperature.

Gold shell on AuNRs@NBT was slowly synthesized by regrowth protocol for gold nanorods [6] during twelve hours. Fast growth of gold shell was performed by reduction of hydrogen tetrachloroaurate by ascorbic acid in cetyltrimethylammonium bromide solution under vigorous sonication during twenty minutes.

After shell formation all SERS tags were washed by double centrifugation and resuspension in water.

3. Discussion

3.1. Nanoparticle characterization

According to TEM data initial gold nanorods have average L=42.1±7.1 nm, d=11.2±2.3 nm. TEM images of SERS tags with incorporated NBT molecules are presented at the Fig.1. On the TEM images SERS tags with a silver shell, the gold nanorod inside is clearly seen (Fig.1 (a, b)). For fast synthesized gold shell, the gold rod inside is also visible due to the presence of a thin gap (Fig.1 (c)). For slowly synthesized gold shell, the gap and the initial rod are not observed (Fig.1 (d)). It should be mentioned, that a distinct gap inside SERT tags is observed only in the case of fast synthesized gold shell (Fig.1 (c)). Thus, for SERS tags with gold shell it is possible to tune the presence of the intermetallic gap inside particles whereas for tags with
SERS spectrum does not change (data not presented). This means that NBT molecules are protected and located inside the SERS tags.

4. Conclusions

In this work we report on synthesis of gold nanorod-based SERS tags with incorporated NBT molecules. By varying the synthetic protocol for gold shell, we received SERS tags with inner gap or without it. For SERS tags with silver shells, the gap is always indistinguishable, although our indirect experiments confirm that the NBT molecules are inside the particles and are protected from the environment. For gold shell in both cases (with or without a gap), the SERS enhancement factor is about $4 \times 10^{4}$. SERS enhancement factor decreases in the row: AuNRs@NBT@AuSlow - AuNRs@NBT@AuFast - AuNRs@NBT@AgFast - AuNRs@NBT@AgSlow. To understand the SERS mechanism in the absence of a gap inside the nanoparticles, further research is required.

Abstract

We present several routes towards the generation of artificial optical magnetism in visible light. Our bottom-up strategies combine nano-chemistry for the fabrication of optically resonant building blocks and colloidal self-assembly for the fabrication of macroscopic 2D or 3D materials. Basically, two types of optical resonators are investigated, namely plasmonic and Mie resonators. In the first type, we show that the magnetic response can be optimized by a proper design of plasmonic nano-clusters. In the second type, the challenge is to produce nanoparticles of high refractive index. We show that the bottom-up approach enables the large-scale production of metallic nanoclusters exhibiting strong magnetic Mie resonances in visible light.

1. Introduction

The generation of artificial optical magnetism at high frequencies ranging from microwaves to visible wavelengths is one of the major breakthroughs in the field of metamaterials. Major successes have been obtained in the top-down approach whereby sub-wavelength elements are imprinted or carved on a substrate. In visible light, the bottom-up approach based on the large-scale synthesis of nano-sized optical resonators has proved its ability to produce a bulk magnetic material exhibiting non-natural values of the magnetic permeability. In this material, the resonators called “plasmonic raspberries” consist of a set of plasmonic nanoparticles evenly, but randomly distributed around a dielectric core. The ratio of the magnetic to electric dipole scattering cross-section of a single raspberry is about 1/3 and the magnetic permeability of the assembled bulk metamaterial ranges from 0.8 to 1.45 \( \mu_0 \) units. In order to increase the magnetic response of the metamaterial, we investigate in this work novel morphologies guided by numerical simulations of various plasmonic nano-clusters. We show experimentally that a significant increase of the magnetic dipole can be obtained by a well-controlled geometrical organization of twelve plasmonic satellites onto the dielectric core. Moreover, we show that a simple emulsification process can be used to synthesize large amounts of plasmonic clusters exhibiting a large and tunable magnetic response. These new results open the way to the fabrication of bulk magnetic metamaterials of large or zero permeability, and of Huyghens metasurfaces based on optical resonators of equal electric and magnetic response over a broad frequency range.

2. Plasmonic dodecapods

In the plasmonic raspberry model of Simovski and Tretyakov, a dense corona of metallic nanoparticles are randomly distributed at the surface of a dielectric core. Guided by numerical simulations, chemical routes have been developed to place 12 metallic satellites onto the faces of a dodecahedron (Fig. 1).

![Figure 1](image-url)

Figure 1: A - Scanning electron micrographs of the plasmonic dodecapods. B – Elemental analysis showing silica (green) and gold (red).

The optical response of the dodecapods (DDPs) has been measured by a polarization-resolved static light scattering. The ratio of the magnetic to electric scattering is shown in Fig. 2. It is increased by a factor >3 when compared to plasmonic raspberries of the same size with the same amount of gold.
3. Metallic clusters

The magnetic Mie resonance of a spherical particle constitutes another source of strong magnetic scattering. It is obtained when the wavelength inside the particle matches its diameter. A high value of the refractive index of the particle is then required to keep its size well below the wavelength in vacuum.

Crystalline silicon is a good candidate and strong chemical efforts are currently developed to synthesize silicon nanoparticles of controlled size. Another option was proposed in which the high refractive index results from the plasmonic resonance of a metallic nano-cluster. A controlled emulsification process, sketched in Fig. 3, can be used to synthesize dense clusters of gold nanoparticles which exhibit the targeted magnetic Mie-resonances. A suspension of gold nanoparticles is first emulsified in a continuous phase. In a second step, the solvent of the emulsion droplets is evaporated. The ratio of the magnetic to electric response, measured by static light scattering on the final clusters, reaches 30 to 60%, well above the highest values obtained for gold raspberries and gold dodecapods (see Fig. 2).

4. Conclusions

Nanochemistry and colloidal physics can be used to synthesize different types of nanoclusters exhibiting high levels of optical magnetism in visible light. The bottom-up approach enables cost-effective, large-scale production of such magnetic resonators, hence opening the way to the fabrication of 2D and 3D magnetic metamaterials.

Laser implantation of plasmonic nanoparticles into glass

Jürgen Ihlemann1, Jörg Meinertz1, Maximilian Heinz2, Manfred Dubiel2

Abstract
UV-laser irradiation of gold-coated glass leads to gold nanoparticle formation and, at sufficiently high laser fluence, to incorporation or implantation of these particles into the glass. A characteristic plasmon absorption peak around 550 nm is observed. Gold particles in SiO2-glass are obtained by implanting gold into SiO2 that is subsequently oxidized to SiO2. Spatially defined particle implantation is achieved by structured irradiation.

1. Introduction
The generation and controlled arrangement of metallic nanoparticles is very important for the fabrication of plasmonic devices. Silver and gold nanoparticles in glasses are attracting particular attention since the wavelength of their surface plasmon resonance (SPR) is in the visible spectral range, making such materials promising candidates for applications in optoelectronics and nanoplasmonics. Typically, silver nanoparticles in sodium silicate glasses are prepared by Ag+↔Na+ ion exchange process and subsequent thermal or laser treatment. However, this method does not allow creating nanoscaled arrays of particles localized in a certain way. Furthermore, this method is not suitable for gold.

2. Laser implantation of gold into soda lime glass
As glass cannot be doped with a sufficient concentration of gold, for the near-surface formation of gold particles in glass the following method is applied: The glass surface is coated with a thin gold film and subsequently irradiated with a pulsed excimer laser [1]. Moderate laser fluences lead to dewetting of the gold film and particle formation. At sufficiently high fluence, the particles are in part or completely embedded or implanted into the glass (Fig. 1). Using an ArF excimer laser (wavelength 193 nm) at a fluence below the threshold of ablation, gold nanoparticles are formed and partially implanted into the glass as can be seen from the colored appearance of the irradiated areas (Fig. 2) and the plasmon resonance peak in the absorption spectra (Fig. 3). After wiping off the loosely sticking particles, the remaining effect is only due to the implanted particles.

Figure 1: Scheme of laser induced particle formation and implantation.

Figure 2: Laser irradiated areas (193 nm, 140 mJ/cm², 10 pulses) on the air side (left) and the bath side (right) of soda lime float glass coated with 70 nm Au [1]. On the right side of each image, the non-implanted gold has been removed by wiping with a dry cloth.

Figure 3: Optical extinction spectra as a result of irradiating the gold coated tin bath side by 10 laser pulses at 140 mJ/cm². Spectra recorded before cleaning (solid line) and after cleaning (dashed line) of the laser spots with acetone; dotted line: basic glass.
3. Laser implantation of gold into fused silica

For the implantation of gold into pure fused silica, fluences of about 1 J/cm² at 193 nm laser wavelength are required. Using a SiOₓ (x ≈ 1) coated SiO₂-substrate, the implantation of gold into this coating can be accomplished at significantly lower fluences starting from 0.2 J/cm² (Fig. 4) [2]. Particles with diameters in the range of 10 to 60 nm are implanted to a depth of about 40 nm as identified by transmission electron microscopy (Fig. 5). An additional high temperature annealing step in air [3] leads to the oxidation of SiOₓ to SiO₂, without influencing the depth distribution of the particles significantly. Absorption spectra show a characteristic plasmon resonance peak at 540 nm. Thus, pure silica glass (SiO₂) with near surface incorporated plasmonic particles can be fabricated with this method. Such material systems may be useful for example as robust substrates for plasmonic applications.

Figure 4: Scheme of the laser induced implantation of gold nanoparticles into SiOₓ with subsequent oxidation of the matrix to SiO₂.

Figure 5: Transmission electron micrograph of laser implanted gold nano particles (left), EDX-analysis: Red = Au, Blue = Si/O, Green = Pt as cover layer (right) [2] (M. Seibt, Univ. Göttingen).

4. Spatial arrangement of nanoparticles

To achieve the implantation of nanoparticles in specifically defined areas, the laser irradiation is performed in a mask projection setup (Fig. 6). To obtain a linear grating consisting of implanted and non-implanted lines, a linear phase mask is applied, which is imaged onto the sample utilizing only the +/- first diffraction orders leading to a linear interference pattern. A resolution down to 1 μm wide lines and spaces is obtained this way (Fig. 7) [4].

Figure 6: Laser irradiation set-up for structured (line pattern) illumination.

Figure 7: Microscope image (transmitted light) of a line pattern obtained by structured irradiation of Au-coated glass (bath side) using a 40μm-phase mask and a fluence of 400 mJ/cm², 50 pulses [4]. Dark and bright lines represent the implanted and non-implanted regions. (Recorded after cleaning the surface with acetone.)

Abstract

Plasmonic nanoparticles have been of great interest as a subject of investigation due to their unique property of absorbing and scattering strongly certain frequency of light. This capacity of interacting with light makes plasmonic nanoparticles profusely used in many applications and produced following different methods and strategies. In this work we present the results of producing silver and copper nanoparticles by laser ablation in liquid and their capacity as antimicrobial agents.

1. Introduction

Nanoparticles and nanostructures of noble metals have received great attention in recent years due their unusual optical, electronic, and thermal properties. Their high specific surface area together with the corresponding quantum effects provide them new properties compared to those of material bulk. The new exceptional physical and chemical properties of noble metal nanoparticles make them very used and investigated in a wide variety of areas, such as nanomedicine [1], sensing and biosensing [2], photothermal therapy [3], drug delivery [4, 5], etc. The physicochemical properties of noble metal nanoparticles are determined by different aspects like size, shape, composition crystallinity, presence of impurities, degree of aggregation, etc., which are highly affected by the nanoparticle processing method. There is a wide range of methods and techniques for producing nanoparticles, which can be mainly classified into chemical, physical and biological processes [6-8]. Most of these methods use stabilizing molecules or other chemicals, which can result in the contamination of the synthesized particles. Laser ablation in liquids or in gas atmosphere enables obtaining nanoparticles with controlled size and without contaminants. On the other hand, regarding toxicity and antibiotic resistance it is well known that noble metal nanoparticles present some advantages over the organic compounds used for disinfection [9]. In this work we report the results of synthesising copper and silver nanoparticles by laser ablation in water and their antibacterial capacity against the growth of Staphylococcus aureus and Lactobacillus Salivarius, which play an important role in biofilm formation [10].

2. Experimental

Foils of Ag and Cu with 99.99% of purity were used as targets to be ablated. The laser beam was focused on the target to give a spot size about 0.15 mm diameter. The laser source consisted in a diode-pumped Nd:YVO₄, providing 15 ns pulses at 532 nm, 20 kHz, and 0.30 mJ of pulse energy. The morphology and microstructure of the synthesized nanoparticles were investigated by FESEM (JEOL-JSM-6700F) and HRTEM (JEOL-JEM 2010 FEG). The UV-Vis absorption was measured with a Hewlett Packard HP 8452 spectrophotometer. Antibacterial activity against Staphylococcus aureus and Lactobacillus Salivarius was assessed by minimal inhibitory concentration assays.

3. Results and discussions

In both cases the formation mechanism of the obtained nanoparticles in water is basically the same. The laser beam is focused on the upper surface of the submerged foil (Ag-Cu) heating up the target above its melting point, while the surrounding liquid is evaporated, which can react with the ejected species from the target, giving the final nanoparticles. Given the parameters of the used laser and its

![Image](Image309x248 to 415x319)
intensity on the target (10⁸ W/cm²), plasma plume can be formed and consequently different species such as ions, atoms and droplets confined by the liquid, nucleate and grow by coalescence to form the final nanoparticles. Figure 1 (a and b) shows the appearance of Ag and Cu nanoparticles obtained under the same conditions in water. The obtained nanoparticles show rounded shape and a tendency to agglomeration. This effect can be explained by the overlapping of the ablated material and the following pulse. All the obtained particles are crystalline. Regarding Ag nanoparticles, crystalline phases of metallic Ag and AgO2 have been detected, while in the case of Cu the colloid is predominantly dominated by the presence of CuO, since Cu is much more reactive than Ag. This result is in agreement with the UV-Vis absorption spectra of the obtained colloidal solutions as can be observed from figure 3. The peak about 400 nm is characteristic of surface plasmon resonance of spherical Ag nanoparticles, while the peak about 220 nm is due to the inter-band transitions indicating the formation of CuO.

Figure 3: UV-vis spectra of Ag and CuO colloidal solutions obtained by laser ablation in water.

Antimicrobial activity of the obtained solutions was evaluated through standard Optical Density measurements at wavelength of 600 nm (OD600). Staphylococcus aureus and Lactobacillus Salivarius, were cultured in in MRS broth (Scharlab SL, Spain). Cultures were incubated for 12 h at 37 °C before each assay. Bacterial suspensions were seeded onto agar plates. The agar plates were then incubated at 37 °C for 12-18 h and the colony forming units (CFU) were counted. As result both kind of particles exhibited high bactericidal capacity with reduction of CFU with regard to the control plates.

4. Conclusions

Colloidal solutions of Ag and Cu nanoparticles have been synthesized by laser ablation in water. All obtained nanoparticle are crystalline and present oxidation, especially the case Cu ones. All the obtained nanoparticles showed good bacterial activity against Staphylococcus aureus and Lactobacillus Salivarius.

Abstract

Bottom-up fabrication methods surely represent a niche within the broad field of nanofabrication of plasmonic structures, yet what they lack in terms of structure complexity is more than compensated by the ability to affordably produce ultradense, highly-packed and ultraclean structures over large areas. In this contribution we will review some of the most intriguing physics of spontaneously-arranged plasmonic nanostructures.

1. Introduction

More often than not, the success in a plasmonic experiment depends on the ability to finely control the morphology of the nanostructures involved. In this sense, there has been a clear evolution from pioneering experiments, that necessarily had to rely on bottom-up system fabrication towards more and more sophisticated top-down approaches, that allow to fabricate virtually any conceivable structure. Stating that lithography has made other fabrication methods obsolete would however grossly misjudge the impact of bottom-up techniques in present-day plasmonics. Experimental methods like chemical synthesis or self-organization are indeed able to achieve an atomic-level control of the system morphology that is so far unparalleled. Such a fine control can be fruitfully exploited in dedicated experiments with fundamental but also technological appeal.

In this contribution, we will provide an overview of recent experiments performed on 2-dimensional (2D) ultradense arrays of metallic nanoparticles (NPs) realized by self-organized template-assisted deposition. The generality of the method in terms of the target metal, and the possibility to obtain ultrafine and closely-spaced NPs was exploited to push the high-energy limit of plasmonics with ultraclean Al NPs [1,2], fabricate highly sensitive detectors with plentiful electromagnetic hot-spots [3], and exploit ultraclean environments for sample characterization [4].

2. Experimental

2.1. Fabrication

The systems under scrutiny are 2D arrays of metal NPs obtained by template-assisted physical deposition followed by thermal dewetting.

Figure 1: 2D arrays of metallic nanoparticles supported on nanopatterned insulating substrates. Top to bottom the images (1×1 µm²) refer to Au, Ag and Al, respectively.

The arrays were fabricated depositing the target material onto the self-organized nanometric uniaxial sawtooth pattern
that develops upon high-temperature homoepitaxial growth onto LiF(110) substrates [5].

Few nm of metal (typ.<5nm) were deposited at room temperature in high vacuum by molecular beam epitaxy at 60° of incidence with respect to the surface normal, and the samples were subsequently annealed at T=670 K in order to induce the thermal dewetting. Selected examples of array morphology are reported in Fig.1. Top to bottom, the arrays consist of Au, Ag and Al NPs. As apparent, the NPs are densely packed on the substrate, with small interparticle spacing and plentiful electromagnetic hot-spots. The typical NP size achievable is of the order of 10-30 nm, whereas the areal density typically exceeds 10^11 NP/µm^2. The arrays are homogeneous over the whole sample area (typ. 1 cm^2), making it straightforward to measure their properties without resorting to microscopy. This makes it incidentally easier to investigate these systems in technically-challenging environments such as vacuum, liquids etc.

2.2. Plasmonic Response

In Figure 2 we report transmission spectra of 2D arrays of Au, Ag and Al NPs (yellow, blue, red symbols, respectively).

The marked transmission dip in the spectra is the fingerprint of the Localized Surface Plasmon Resonance (LSPR) excitation in the arrays. The LSPR falls within the visible range for Au, across the UV-VIS for Ag and in the deep UV for Al. Here the ability to produce ultraclean and fine particles has been instrumental to push the LSPR energy of Al NPs to an unprecedented, and unsurpassed, value of 6.9 eV [1]. Also, the high density of NPs allows the realization of electromagnetically-coupled plasmonic resonators, whose collective LSPR is spectrally narrower than the incoherent superposition of individual resonances. The method easily lends itself to fabricate more complex materials in NP form, such as composition-graded nanoalloys. There, the LSPR response smoothly varies across the spectrum while maintaining an invariant morphology (Figure 3: transmission spectra of arrays of NPs of Au_xAg_{1-x} with a spatially-graded composition.). Such systems can be fruitfully exploited as hyper-SERS platforms for ultrasensitive detection [3].

Figure 2: transmittance spectra of 2D arrays of Al (red), Ag (blue) and Au NPs (yellow).

Figure 3: transmission spectra of arrays of NPs of Au_xAg_{1-x} with a spatially-graded composition.

Abstract

A reliable, sensitive and cost-efficient molecular detection could have a broad field of bioanalytical applications in fields ranging from clinical diagnostics over food safety to environmental applications. We describe here the use of localized surface plasmon resonance (LSPR), an effect based on collective oscillations of conduction electrons in gold nanoparticles under visible light irradiation, in order to realize a label free and multiplexed molecular detection.

Fig. 1: Scheme of LSPR detection. Left: A gold nanoparticle is acting as sensor, when modified with single-stranded capture DNA. Right: When complementary target (analyte) DNA is present, it will bind, and thereby change the refractive index (and so the LSPR resonance), which is read out in the spectrum (top).

1. Introduction

The detection of target molecules of interest is an important prerequisite for our modern life in order to keep and enhance the standard of living. It includes a vast range of applications, e.g. in the fabrication of goods and food, in medicine, but also in environmental protection and a variety of other applications. Although there is a long tradition in various technical approaches, there is still room for improvement regarding key parameters such as sensitivity, specificity, but also throughput and cost-efficiency. Any significant improvement in one of these factors enables a widening of the application field (or even opening a new one), so there is a constant quest for novel and superior approaches. Over time, methods that do not rely on the use of labels or markers were preferred due to cost, time and robustness issues connected with such additional elements. Especially the often lower sensitivity for label-free methods could be a limiting factor. Beside mechanical (quartz crystal microbalance and relating resonator methods), also electrochemical (electrical as well as optical methods have been studied for this purpose.

2. LSPR in bioanalytics

In bioanalytics, methods based on the interaction of visible light with the conduction electrons in thin metal (often gold) layers, which are called surface plasmon resonance (SPR), are often used. However, this approach requires rather complex realization of the incoupling of light into the metal-dielectric interface like prisms or gratings. Moreover, in its basic type, it is limited to one channel, making multiplexing complicate. A further development lead to a similar effect in metal nanostructures, resulting in localized surface plasmon resonance (LSPR). Here, a resonance can be observed spectroscopically, the wavelength position depends on factors related to particle properties (material, size, shape) and the environment [1]. The latter parameter is based on the refractive index of the space surrounding the particle. If the particle is utilized as biosensor, it is functionalized by receptor molecules, such as single stranded DNA (complementary to a desired target DNA). If one monitors now the LSPR of this structures during incubation with sample solutions, the binding of present target DNA would change the refractive index on the particles surface, and induce a measurable signal (wavelength shift), which is used as sensoric signal, and can be correlated to the presence of target molecules. A proof-of-principle of this approach for DNA detection was conducted on individual, single gold nanoparticle sensors [2]. In comparison with SPR, LSPR is sensing in a much more limited distance around the particles, which can be approximated by the particle diameter, in contrast to the hundreds of nm and more in the case of SPR [3]. This limited distance leads to a significantly decreased background signal in the case of typical biomolecular binding reactions which happen in the range of 5-10 nm distances.
3. Multiplexed LSPR

In the field of biomolecular detection, often a series of similar assays is of interest, like in the identification of the kind of antibody present, or the pathogenic species out of a whole family of organisms like E. coli. In such cases, single assays are not sufficient, and have to be paralleled. One possible approach to address this problem is the microarray (or chip) format, where an array of receptors is located on the substrate surface, and incubated with a solution containing (a mixture of) target molecules. Here, usually labeled molecules are used, such as by fluorescence (during previous PCR steps) in the case of DNA/RNA. Using LSPR, a similar miniaturized concept could be realized, with the advantage of avoiding the labels. Therefore, nanoparticles were chemically synthesized using conventional as well as microfluidic approaches [4], and arrayed on a glass substrate using a dispensing spotter [5].

In order to read-out the whole array in one step, a Fourier transform imaging spectrometer based on a Michelson interferometer was set up and demonstrated to be able to detect changes in the refractive index on the nanoparticles surfaces [6]. Finally, it could be shown that the instrument is able to detect and identify various DNA sequences from pathogenic fungi with this approach [7], demonstrating the proof-of-principle of this promising innovative method for multiplexed molecular detection.

Abstract

In this contribution we report synthesis of some silver and gold nanoparticles having spherical, decahedral and bipyramidal shape which have been covered with various protecting layers. Optical and structural properties of obtained nanomaterials was examined. It was found that the zirconia protecting layer exhibits significantly better durability in corrosive environmental conditions than standard silica nanolayer. Obtained nanoparticles were applied as optical nanoresonators for shell-isolated nanoparticle-enhanced Raman scattering (SHINERS) measurements of various pesticidies.

1. Introduction

Nanoparticles from metals from the 11 group in specific manner interact with light. Incident light with appropriate frequency excites collective oscillation of electron plasma, so called surface plasmon resonance (SPR). This leads to high local enhancement of the electromagnetic field. Therefore, such nanoparticles could be applied to enhance efficiency of some weak optical effects (like Raman scattering) which intensity depends on the intensity of the electromagnetic field. Theoretical calculations showed that the highest enhancement occurs on sharp tops and edges in case of anisotropic nanoparticles or in the gap between nanoparticles. Therefore, application of anisotropic plasmonic metal nanoparticles allows to rich significantly higher enhancement factor what allow to detect analytes in lower concentration range. However, direct interaction between metallic surfaces and some analytes could lead to their denaturation. Therefore, in some cases, nanometric layers of protecting oxide are deposited on nanoparticles surface. A protective layer keeps nanoparticles from agglomeration and prevents direct interaction between metallic surfaces and analyte molecule.

2. Experimental

Gold bipyramids were obtained due to seed mediated growth method described by Weizmann et al. [1]. In the first step gold nanoseeds were formed by the reduction of AuCl$_4^-$ ions by sodium borohydride. In the second step spherical nanoseeds growth in solution containing cetyltrimethylammonium bromide (CTAB) as stabilizing agent by reducing AuCl$_4^-$ ions by weak redactor - ascorbic acid. The decahedral silver nanoparticles were synthesized by photochemical transformation [2]. In the first step small semi spherical nanoseeds were formed by the reduction of silver ions by sodium borohydride in the presence of sodium citrate and L-arginine. After 10 minutes, the obtained sol of silver nanoseeds was transferred into a cylindrical glass reactor and illuminated by 470 nm light under constant stirring for 5 h at 35 °C. Spherical gold and silver nanoparticles were obtained due to standard citrate method. In most cases silica layer was deposited on plasmonic cores due to decomposition of tetraethoxysilane (TEOS) catalyzed by ammonia. Alternatively, nanometric silica layer was obtained by the decomposition of Na$_2$SiO$_3$ in the acidified solution. Zirconia layer were deposited according to the method reported by Krajczewski et al. [3]. In the first step the surface of nanoparticles was modified by L-arginine. Then, some portion of cyclohexene was added what leads to formation of two phase solution. To upper, organic phase, some amount of (3-mercaptopropyl)trimethoxysilane was added under stirring. After 30 minutes organic layer was carefully separated. Nanoparticles were stirred and redispersed in absolute ethanol .Then, appropriate amount of zirconia(IV) isopropoxide was added. Solution was vigorously stirred for 15 minutes, then nanoparticles were centrifuged and suspended in distilled water.

3. Discussion

Optical and structural properties of synthesized nanomaterials were carefully examined. Fig. 1. presents TEM micrographs of decahedral silver nanoparticles before and after deposition of silica layer.
Obtained nanostructures were tested as SHINERS nanoresonators. To do this, the same amount of various nanoparticles were dropped on chemisorbed monolayer of p-mercaptobenzoic acid on platinum plate. Then, SHINERS spectra was recorded. It was found that suitably thin protective layer do not dump electromagnetic field so much and nanoparticles still could be applied as nanoresonators. We found using dipyramidal gold nanostructures coated by silica layer, that we are able to detect thiram pesticide in trace amounts on tomato skin (12 ng/cm²).

4. Conclusions
In this work we presented various methods of synthesis of anisotropic silver and gold nanoparticles. Optical and structural properties were studied. Plasmonic cores were coated by nanometric protective layer of various oxides like silica, zirconia. Stability in various environmental conditions was tested. Finally, obtained nanoparticles were applied as SHINERS nanoresonators. It was found that the anisotropic noble metal nanoparticles coated by nanometric silica layer could be used to detect trace amount of pesticide like thiram or methyl parathion.
Synthesis, characterization and application of novel bifunctional magneto-plasmonic nanocomposites

Abstract

Herein we describe synthesis of some magneto-plasmonic nanocomposites consisting of Fe₃O₄ and various plasmonic nanoparticles. Optical and structural properties of obtained materials are carefully examined. TEM micrographs and XRD measurements confirmed formation of magneto-plasmonic nanocomposites. Application of external magnetic field allows to obtain highly organized substrate for repetitive SERS measurements, which allows to eliminate the so-called "coffee-ring effect", involving peripheral accumulation of nanoparticles.

1. Introduction

Gold and silver metal nanoparticles in a specific manner interact with light. Irradiation with incident light with appropriate frequency leads to excitation of collective oscillations of electron plasma, so called surface plasmon resonance (SPR). This leads to local high enhancement of electromagnetic field. Therefore, such nanoparticles could be applied to enhance efficiency of weak optical effects (like Raman scattering) which efficiency depends on intensity of the electromagnetic field. Theoretical calculation showed that the highest enhancement occurs on sharp tops and edges in case of anisotropic nanoparticles or in the gap between two nanoparticles. Therefore, application of anisotropic plasmonic metal nanoparticles allows to rich significantly higher enhancement factor what allows to detect analytes in lower concentration range. Moreover, coupling of anisotropic plasmonic metal nanoparticles with magnetic Fe₃O₄ nanoparticles leads to formation of bifunctional nanomaterials. In our study we report that application of magneto-plasmonic nanocomposite allows to prepare of highly organized substrate for SERS measurements.

2. Experimental

Magnetic Fe₃O₄ nanoparticles were prepared according to co-precipitate method proposed by Makovec et al. [1]. Solution of FeSO₄ and FeCl₃ was stirred, then appropriate amount of concentrated ammonia was added, during vigorously stirring. After 30 minutes next portion of ammonia was added, and pH of solution reached 11.6.

Obtained nanoparticles were washed by distilled water twice. Fe₃O₄ nanoparticles were functionalized with (3-aminopropyl)triethoxysilane (APTMS). Briefly, APTMS was added to the as-prepared sol of Fe₃O₄ to obtain a final concentration of APTMS equal to 0.1 M, and the obtained mixture was stirred for 24 hours. This led to a reaction between the Fe₃O₄ and APTMS – the methoxy groups of APTMS react with the hydroxyl groups at the surface of Fe₃O₄ forming strong Fe-O-Si bonds. The decahedral silver nanoparticles were synthesized by photochemical transformation [2]. In the first step small semi-spherical silver nanoseeds were formed by the reduction of silver ions by sodium borohydride in a presence of sodium citrate and L-arginine. After 10 minutes, the obtained sol of silver nanoseeds was transferred into a cylindrical glass reactor and illuminated by 470 nm light under constant stirring for 5 h at 35 °C. The silver nanocubes were prepared using a method developed by Xia et al. [3]. 60 ml of anhydrous ethylene glycol was heated at 160 °C for 1.5 h. Next, sodium sulfide and polyvinylpyrrolidone was added to solution. In the last step 5 ml of a 0.3 mM AgNO₃ solution in ethylene glycol were added to the boiling ethylene glycol, and the reaction mixture was boiled for another 20 min. Then, the reaction was quickly suspended by immersing the reaction flask in a mixture of ice and water. The resulting nanoparticles were then centrifuged with acetone three times and re-dispersed in water.

The hollow gold nanoparticles were synthesized using cobalt nanoparticles as sacrificial templates [4]. In first step cobalt nanoparticles were prepared due to reduction of cobalt salt by sodium borohydride. Subsequently, to formed cobalt nanoparticles, some amount of HAuCl₄ solution was added. Gold hollow nanoparticles was formed due to galvanic replacement mechanism.

In order to prepare magneto-organic nanocomposite plasmonic nanoparticles were added to a solution of APTMS-functionalized Fe₃O₄ nanoparticles, shaken gently, and left for 30 minutes. After this time, the agglomerates formed were concentrated by a magnetic field and then concentrated agglomerates were re-dispersed in water.
3. Discussion

Optical and structural properties of synthesized nanomaterials were carefully examined. Fe₂O₃ colloid is brown; however, after attachment to the γ-Fe₂O₃ nanostructures of various plasmonic nanoparticles the magneto-plasmonic conglomerate obtained took another distinctive color, depending on the plasmonic nanoparticles used. In a strong magnetic field, the color of the nanocomposite associated with the plasmonic nanoparticles is “transferred” to the sediment formed, leaving the solution colorless. Re-dispersing the sediment of the nanocomposites leads to sols that display a color typical for the attached plasmonic nanostructures. This indicates that the plasmonic nanoparticles are strongly connected to their magnetic counterpart. Fig. 2. present TEM micrographs of magneto-plasmonic nanocomposite with cubic and decahedral silver nanoparticles.

![Figure 1: TEM micrographs of nanocomposites with: (a) cubic–Ag, (b) decahedral–Ag nanoparticles.](image)

Obtained nanostructures were applied as highly organized substrate for repetitive SERS measurements. SERS measurements were carried out for few chosen analytes. Application of magneto-plasmonic nanocomposite provide low detection limit (for example of 18 ng/cm² for malachite green).

4. Conclusions

In this work we propose an easy and very efficient method for preparing conglomerates of magnetic Fe₂O₃ nanoparticles with various noble metal nanoparticles. Noble metal nanoparticles was attached to the Fe₂O₃ nanoparticles via organic linker (APTMS). As far as we know synthesized composites are the first examples of magnetic composites containing well defined anisotropic metallic nanostructures. The magnetic-plasmonic conglomerates have been used as highly organized substrate for SERS measurements.

Abstract
High Refractive Index Dielectric (HRID) nanostructures have become an alternative to metallic ones in the VIS-NIR due to their low-losses and magnetic response. In addition, they can be basic units in applications where directionality control of the scattered radiation is required. Here, we show that aggregates of subwavelength HRID particles, under strong electromagnetic interaction, can be efficient scattering units for redireciting the incident radiation towards a photosensitive substrate. Applications for optimizing the efficiency of photovoltaic devices (solar cells) are envisaged.

1. Introduction
High Refractive Index Dielectric (HRID) nanoparticles (NPs) have been vastly investigated in the last years due to their low-losses in the VIS-NIR ranges and also because of their unusual magnetic response in spite of being non-magnetic materials [1]. Scattering directionality exhibited by these structures manifest due to the coherent effects between their electric and magnetic resonances. Kerker et al. established that under certain conditions of the electric permittivity and magnetic permeability, scattered radiation can be concentrated either in the forward or backward region, being null or almost null in the backward or forward direction. This corresponds to the First Kerker (Zero-Forward) condition or Second Kerker (near Zero-Backward) condition [2], respectively. The first experimental evidence of these directionality effects was carried out in the microwave region [3] and its conclusions can be extrapolated to the nanometric scale because of the scalability of Maxwell equations (in this work we will keep the millimetric range for analogy to previous research). A lot of effort has been done to control the directionality properties of HRID subwavelength (SW) structures. More complex geometries (dimers, trimers or even oligomers) have been explored. In particular, it was shown that dimers of SW HRID spherical particles, with strong electromagnetic interaction, can redirect the incident radiation in the forward direction more efficiently than an isolated particle. A new Scattering Directionality Condition (SDC), denoted as near Zero-Backward (a 180° rotation of the traditional near Zero-Forward condition) shows up [4] due to the coupling effects between the components of the dimer. With respect to the Zero-Backward condition, it can be observed independently of the interaction effects between the particles. This suggests that by means of this dimer scattering unit, it is possible to achieve two spectral regions where the incident radiation is forward scattered, being null or almost null in the backward direction. They are observed at the frequencies corresponding to the Zero-Backward and near Zero-Backward conditions, respectively. Here, we analyze the electromagnetic behavior of isolated and aggregates (two (dimer), four and five particles) of HRID SW particles, placed on a dielectric monolayer/multilayer substrate of known optical properties with the objective of analyzing their performance for energy harvesting applications with photovoltaic devices.

2. Results
In general, SDCs are affected by the presence of the substrate. When its refractive index is moderately low (for instance, glass with \( n_e \sim 1.5 \)), the SDCs can still be observed. However, as the substrate refractive index increases, SDCs are hardly fulfilled [5].

Figure 1. The different analyzed geometries of SW HRID structures on a monolayer substrate. a) One particle, b) dimer, c) four particles and d) five particles. The particle gap distance is \( d = 3 \) mm. For the five-particle configuration, the distance between the side particles and the central one is \( d_2 = 0.85 \) mm. The particles radii correspond to \( R = 9 \) mm, except for the central particle in d), which is \( R_2 = 5 \) mm. Their electric permittivity is \( \varepsilon = 15.7 + 0.3i \).
All the analyzed geometries are illuminated by a plane wave propagating along the $-z$-axis and linearly polarized along the $x$- or $y$-axis.

To analyze how the presence of a substrate, with known optical properties, affects the electromagnetic radiation reaching the substrate when one of the previous nanostructures is located on it, we evaluate the parameter, defined as $s_{\text{subs}} = Q_{\text{eca subs}}/Q_{\text{eca}}$ [6]. $Q_{\text{eca subs}}$ and $Q_{\text{eca}}$ are the normalized scattering cross-section for radiation scattered into the substrate by the structure and its total normalized scattering cross-section, respectively. Physically, $s_{\text{subs}}$ represents the fraction of radiation that is scattered into the substrate. In Table 1 we show $s_{\text{subs}}$ integrated over the range $q = [0.6, 1.2]$ ($q$ is the size parameter) for the different configurations (see Fig. 1) when located on a monolayer dielectric substrate of refractive index $n_s = [1.5, 3.5]$. Also, different polarizations of the incident radiation are considered (all the structures are illuminated by a plane wave propagating along the $-z$-axis and linearly polarized along the $x$- or $y$-axis).

Table 1. $s_{\text{subs}}$ (%), integrated over all $q$ values ($q = [0.6, 1.2]$) for different substrate refractive indices $n_s$. Different particles configurations and polarizations of the incident radiation are considered.

</table>

As $n_s$ increases, $s_{\text{subs}}$ decreases for all the studied geometries and polarizations of the incident radiation. This decrease is more notorious when the electromagnetic interaction between the particles is strong (i.e. for an exciting plane wave linearly polarized along the $y$-axis and the configurations corresponding to four and five particles). For moderately low values of $n_s$ (i.e. 1.5), the largest values of $s_{\text{subs}}$ are obtained for the cases where the interaction effects are strong. This is because of the near Zero-Backward condition. However, with the exception of the five-particle geometry, for substrates made of silicon ($n_s = 3.5$, typical photovoltaic silicon layer in solar cells), the behavior is the opposite: $s_{\text{subs}}$ is higher for the isolated particle and the dimer illuminated by a plane wave linearly polarized along the $x$-axis (weak interaction effects). The fact that the five-particle geometry provides the highest $s_{\text{subs}}$ values, regardless of the value of $n_s$, is due to the large enhancements of the electric field in the particle gaps, which increase the absorption of radiation in the substrate. For the isolated particle and the four- and five-particle geometries, $s_{\text{subs}}$ is the same independently of the polarization of the impinging wave, due to symmetry. For $n_s = 1.5$, it is possible to redirect the incident radiation towards the substrate more efficiently by using aggregates. However, for $n_s = 3.5$, the isolated particle works better than aggregates. This is because of two different factors. On the one hand, for moderately low $n_s$, SDCs can be achieved. Due to the near Zero-Backward condition, $s_{\text{subs}}$ is larger for aggregate configurations than for the isolated one. Nevertheless, for high values of $n_s$, SDCs are not fulfilled. On the other hand, as $n_s$ increases, the reflection at the air-substrate interface increases too. To take advantage of this new SDC (near Zero-Backward condition) to optimize the performance of solar cells, we analyzed the electromagnetic behavior of the different configurations of HRID particles on a multilayer substrate. In particular, we place two antireflection dielectric layers on the photosensitive silicon substrate. The purpose of this multilayer structure is two-fold. First, by means of this graded-index coating, the reflection of the incident radiation is minimized. Second, the SDCs can be recovered as the difference in refractive index between air and the first antireflection layer is lower than between air and silicon. We have shown that for two antireflection layers, it is possible to recover the SDCs and obtain values of $s_{\text{subs}}$ for silicon substrates similar to those corresponding to a glass monolayer substrate.

3. Conclusions

In this work, we have evidenced that by using aggregates of subwavelength HRID particles with strong electromagnetic interaction, it is possible to redirect the incident radiation towards the photovoltaic silicon layer more efficiently than with isolated HRID particles. This is because of a new SDC, the near Zero-Backward. In order to take advantage of the SDCs for increasing the fraction of radiation scattered towards a silicon substrate, an antireflection multilayer coating should be used. In addition, thanks to this graded-index multilayer, the reflection at the air-substrate decreases. This research supports optimization of solar cells performance.

Abstract
Perovskite-silicon tandem solar cells are a promising concept for overcoming the limits of conventional silicon single-junction technology. Light management is doubtless a key issue for further boosting efficiency. We discuss the impact of photonic nanostructures on the optical performance of perovskite-silicon devices. We experimentally and numerically demonstrate shallow antireflective nanotextures, which are compatible with perovskite solution processing. We further showcase enhanced photon up-conversion using perovskite nanoparticles interacting with photonic nanostructures and discuss the applicability for spectral conversion of sunlight.

1. Introduction
Single-junction silicon solar cells are currently dominating the photovoltaic market, but they more and more approach the theoretical power conversion efficiency limit of 29.4%. Perovskite-silicon tandem solar cells are at present the most investigated concept to overcome this limit and to further boost efficiency [1]. Optimized light management is a key issue to tap the full potential of such tandem solar cells as often planar interfaces lead to undesired reflective losses and still large parts of the solar irradiance remain unused. Nanostructures with dimensions comparable to the wavelength of light enable systematic control of the light-matter interaction and are hence a promising measure for improving the optical performance of solar energy devices. Here, we experimentally and numerically investigate two different optical characteristics of photonic nanostructures in order to improve the performance of perovskite-silicon tandem solar cells. First, we develop shallow sinusoidal nanotextures at the interface between perovskite top and silicon bottom cell. We show that these structures not only reveal excellent broadband anti-reflective properties but also demonstrate the compatibility with perovskite solution processing, so far yielding highest single-junction efficiencies. We further consider a second characteristic of such nanophotonic structures: enormous near-field enhancement effects can occur when momentum and energy of the incident light and of a leaky mode of the photonic nanostructure match. We harvest these enhanced near-fields in order to increase the two-photon pumped photoluminescence of perovskite nanoparticles placed on a silicon photonic crystal structure. We sketch the way to efficient photon up-conversion in order to harvest so far unused near infrared parts of the solar spectrum.

2. Experimental and numerical methods
In order to meet the constraints for solar cell processing, we exclusively apply nanopatterning techniques allowing for large-area fabrication and high throughput, namely, nanoimprint-lithography in combination with dry- and/or wet-chemical etching. We implement shallow sinusoidal nanotextures with 500 to 750 nm period into the surface of silicon wafers. Perovskite thin films can be spin-coated onto this textured surface (see Fig. 1a). We further fabricate large-area silicon photonic crystal slabs for photon up-conversion experiments with perovskite nanoparticles (Fig. 1b). Optical simulations are performed using a commercial software (JCMsuite) based on the finite element method (FEM) and the rigorous solution of Maxwell’s equations.

![Figure 1: a) Spin-coated perovskite film on a silicon wafer with shallow nanotextured surface. b) Silicon photonic crystal slab without (left) and with (right) CsPbBr\textsubscript{3} perovskite nanoparticle coating.](image-url)
3. Results and discussion

3.1 Perovskite-silicon tandem solar cells

Planar interfaces in perovskite-silicon tandem solar cells often cause large reflective losses. We investigate by optical FEM simulations how well shallow sinusoidal nanotextures, which are compatible with perovskite solution processing (see Fig. 1a), can reduce reflection. Figure 2 shows the simulation domain as well as the absorption in different layers of the tandem device. With 300 nm texture period and height, optical reflection and parasitic absorption losses amount to 3.8 mA/cm² current density only.

Figure 2: (Left) Simulation domain for optical FEM simulations of a 500 nm-periodic sinusoidal textured 2-terminal perovskite-silicon tandem solar cell. (Right) Absorption profile and associated theoretical current density. A maximum achievable matched current density of 21.3 mA/cm² and power conversion efficiency of 31.8% can be reached (from [2]).

3.2 Spectral up-conversion

Spectral conversion in low light intensity conditions can significantly increase the thermodynamic limiting efficiency of solar cells by harnessing near infrared parts of the solar spectrum. Light confinement on photonic nanostructures permits decreasing the required irradiance level for photon up-conversion processes.

Figure 3: Photoluminescence signal of CsPbBr₃ nanoparticles on a nanostructured (green) and on a bulk (black) silicon film excited at λ = 925 nm. The left inset exemplifies a simulated 3D electric field energy distribution (from [3]). The right inset illustrates the underlying two-photon absorption process (from [4]).

Figure 2 shows the two-photon excited photoluminescence of CsPbBr₃ perovskite nanoparticles. By interaction with a leaky mode of a silicon photonic crystal slab as shown in Fig. 1b, a 15-fold enhanced photoluminescence is observed for an excitation at center wavelength 925 nm despite rather broadband excitation conditions (FWHM = 40 nm). Future design of photonic nanostructures aims at light confinement at λ > 1200 nm for up-conversion of to date unused parts of the solar spectrum.

4 Conclusions

We investigated the impact of photonic nanostructures on the optical performance of perovskite-silicon tandem devices experimentally and numerically. Shallow nanotextures promise both, a strong anti-reflective effect as well as compatibility with perovskite spin-coating. Strong near-fields on silicon nanostructures are found to boost photon up-conversion in perovskite nanoparticles.

Abstract

Advances in photovoltaics are mostly a quest for higher efficiency in the energy conversion for low-cost solar panels. This can be attainable by different strategies dealing with complex arrangements of materials to cover the whole spectrum. We have followed a different way by tailoring the geometry and subwavelength structures of auxiliary layer terminating the photovoltaic cell. This approach needs the full understanding of the interaction of light with nanostructures on ultra-thin films. The physical mechanisms involved in the proposed arrangement are funneling and guiding effects. The cell type platform able to support this nanostructures is selected as the one with larger margin of improvement, i.e., amorphous Si hydrogenated cells. This contribution shows how a proper dimensional and material set-up can increases the short circuit current more than 50%.

1. Introduction

When talking about efficiency in a solar cell, the short circuit current, \(J_{SC}\), is the variable to watch once the material selection has been done \([1]\). This parameter can be increased by customizing the geometry and selecting carefully the material of the front and back auxiliary layer of the cell. The goal is to have as much possible amount of light interacting with the active layer of the structure. Then, charge carriers are routed towards electrodes to establish a current deliverable to an outer circuit. This simple scenario is limited by the constrains imposed by charge mobility, free mean path, and usable spectral windows of the materials of the active layer. Besides, the fabrication constrains may jeopardize some good performance parameters of the involved materials. Then, geometry is playing a decisive role in the pursue of a higher efficiency.

Even though, multi-junction solar cells have established world record figures in efficiency, we have preferred to move towards the lower end of the pack, and see how a cheap technology can benefit from a dedicated and optimized design of the layers around the active region. Amorphous silicon hydrogenated cells (a-Si:H) in their classical and ultra-thin version are well capable of improvement. Their modest efficiency of around 10% is balanced with its low cost and easiness of fabrication. They are affected by a main issue related with the degradation due to the Staebler-Wronski effect (SWE) that strongly affect the charge carrier availability \([2]\).

Nanostructures and metasurfaces have been proposed to induce plasmonic effect that increases the absorption of the cell \([4, 3]\). Part of the effort is pointed towards the reduction of the light lost at the front interface. This requires the addition of antireflection coating that makes an impedance matching of the involved wave propagation and directs radiation to the inner layers of the cell. Also, we can fold the active layer of ultra-thin cell to trigger guiding and funneling mechanisms that expand the light interaction longer within the active layers \([5, 6]\). Another option to improve the performance of the cell is to channel light through nanostructured slots towards the active layer. In this contribution we will make a description of these geometries to show how metasurfaces can help solar cell technology to jump over the limits of previous technologies.

2. Geometric and material arrangement for a-Si:H cells

The starting point of the design is the commercial a-Si:H cell (see left layout in figure 1). This is composed of several layers stacking with plane-parallel interfaces. Each one of these layers contribute to the total short circuit current in different ways. In the right plot of Fig. 1 we show these contributions to the total absorption of the cell. However, the only radiation generating current is the one that is absorbed at the active layer. Actually, the relation between the calculated absorption and the short-circuit current is given as

\[ J_{SC} = \int \frac{q}{h c} A(\lambda) \Phi_{AM1.5}(\lambda) d\lambda, \]

where \(q\) is the electron charge, \(c\) is the speed of light in vacuum, \(h\) is the Planck’s constant, \(\Phi_{AM1.5}(\lambda)\) is the solar spectral irradiance in terms of the wavelength, \(\lambda\), and \(A(\lambda)\) is the spectral absorption rate that is directly related with the electric field distribution at the active layer as

\[ A(\omega) = \frac{1}{2} \omega \epsilon'' |E(\omega)|^2 \]

that is written in terms of the frequency, \(\omega\) and \(\epsilon''\) depends on the electric field distribution, \(E(\omega)\) and the imaginary part of the dielectric constant of the active layer material \(\epsilon''\). All these variables can be computed and accounted for using computational electromagnetism tools. Our analysis
has been made through a Finite Element Method package (COMSOL Multiphysics).

A first approach to improve the absorption at the active layer is to decrease light reflected back from the top electrode. This is possible by an antireflection coating that takes the form of a one dimensional subwavelength dielectric grating. The geometry of the grating makes possible to generate highly directional nanobeams that route radiation towards the active layer. An additional design that involves a two dimensional arrangement is presented here as a collection of nanoholes. They work as injectors that funnel light again towards the active layer, increasing absorption and improving the short-circuit current.

The same material arrangement presented in figure 1 is applicable to an ultra-thin a-Si:H solar cell. The main difference is the thickness of the active layer that is reduced from 350 nm to 150 nm. This thinning of the active layer benefits the charge carrier separation, mitigates SWE, but it also decreases the absorption of the active layer for wavelengths above 450 nm. To compensate this loss, we design a periodic corrugated template where the ultra-thin structure is deposited on conformally.

Each one of the previously presented alternatives have their own advantages and a comparison among them. Their performance, in terms of the short-circuit current, is reported in Table 1 for comparison. We may see that the improvement in $J_{SC}$ is larger than 30% for regular 350 nm thick cells, and more than 50% for ultra-thin cells. This better performance is obtained by taking into account light propagation within nanostructures. The main physical mechanism explaining this increase are: the generation of nanojets, and the guiding and funneling effects due to the existence of whole and the structural corrugation of the cell.

### 3. Conclusions

The performance of amorphous Silicon cells can be greatly improved by nanostructuring their geometrical arrangement. The front contact can be textured to avoid reflections and direct light towards the active layer. When even the active layer is shaped with slots, the funneling of the radiation towards these inner layers increases absorption, and the short-circuit current also increases. For ultra-thin a-Si:H cells, it is still possible to take advantage of the radiation behavior in the subwavelength domain if the whole cell structure is corrugated. The improvement of the short-circuit current is high enough to encourage researcher towards this approach.

Complex epsilon-near-zero materials enhances light absorption in ultra-thin solar cells

Marcella Bonifazi, Valerio Mazzone, Andrea Fratalocchi,

PRIMALIGHT, Faculty of Electrical Engineering; Applied Mathematics and Computational Science, King Abdullah University of Science and Technology (KAUST), Thuwal, Saudi Arabia
*corresponding author, E-mail: andrea.fratalocchi@kaust.edu.sa

Abstract

We engineered an epsilon-near-zero (ENZ) material from suitably disordered metallic nanostructures. We experimentally demonstrate that this nanomaterial increases up to a record value the absorption of ultra-thin light harvesting films at visible and infrared wavelengths with a broadband enhancement of 170% in the external quantum efficiency (EQE). In addition, we developed a cost-effective fabrication process that make these materials suitable to large scale production.

1. Introduction

Recently, many efforts have been devoted to enhance the performances of light harvesting systems and colloidal quantum dots (CQD) revealed itself to be most valuable approach in enhancing the performances of light harvesting systems. In fact, CQDs are used in a wide range of devices, from photodetectors [1] to photovoltaic and phototransistor devices [2] because they are cost-effective and have size-tunable emission. On the other hand, one of the biggest restraint with these materials is the compromise between the charge carrier extraction and the light absorption [3]. Different approaches have been proposed to overcome this limitation [4], but coupling light directly into the active layer by micro-structuring the substrate and introducing plasmonic nanostructures in CQD layer, seems to be the most effective [5]. The main drawback of this technology is that often most of the energy is localized inside the metal.

Here we present a new class of broadband epsilon-near zero (ENZ) materials based on disordered plasmonic nanostructures. These structures are able to localize broadband radiation within ultra-thin light harvesting films, greatly enhancing their absorption [6]. A theoretical investigation based on transformation optics allows us to obtain a material design effective for harvesting purposes Figure 1(a-b). In fact, these ENZ materials slow down light on scale smaller than the charge diffusion length and dramatically enhance the absorption. In addition to that, an innovative fabrication process make it suitable for large scale production.

2. Discussion

We developed a large scale process to fabricate suitable complex disordered ENZ metallic structures with completely controllable features. Figure ??a shows SEM cross sections of a fabricated sample, assembled by an electroplating process that grows a random networks of gold (Au) nanowires from a flat metallic Au substrates. By using an exact analysis based on transformation optics, we demonstrate that the complex metallic network of Figure 1a is exactly equivalent to a flat metallic panel with a series of ENZ nano-regions on top (Figure 1c), connected by areas of high dielectric constant. When a thin layer of absorptive material is deposited on top of the ENZ nanostructures, incoming radiation gets trapped inside the ENZ material, originating a quasi-static field localized in areas of 10 – 100 nm in proximity of the metal. In a series of AFM, Photoconductive AFM (PC-AFM) and Photoluminescence excitation (PLE) measurements, which are illustrated in Fig. 1d-e, we investigate the impact of ENZ nanostructures on the broadband absorption of an ultra-thin CQD film of 50 – 300 nm thickness. Figure 1d reports the PC-AFM map of one region of a sample, the spatial current distribution is illustrated as a pseudocolor in the plot and is superimposed on the surface topography of the sample, which is obtained by AFM. We observe a great current enhancement on the peak of the structures, where the ENZ regions are formed. To further prove that the electromagnetic localization happen proximity of the peaks of our nanostructures, figure 1e show a TEM image of our metasurface. It is clear that the light is concentrated in the bright areas near the tips and, in particular, it is shown that most of the radiation is collected in the active material side. Figure 1f, shows the results of PLE experiments, which measure the absorption increase in the CQD region for different electroplating times. For CQD thicknesses between 50 – 300 nm, we experimentally observed a dramatic absorption enhancement (∼400%) when compared to the PLE signal from an equivalent planar configuration, which becomes completely flat in the visible and infrared regions.

Thanks to its peculiar characteristics this innovative light harvesting device based on ultra-broadband ENZ material can be easily combined with ultra-thin absorptive film,

Correlation between Light Absorption and External Quantum Efficiency of Metamaterial Perfect Absorber Solar Cell

Wakana KUBO

Abstract

We examined the light absorption properties and device performance of the metamaterial perfect absorber (MPA) solar cell in order to clarify the contribution of plasmonic light confinement effect on the solar cell device performance. The metamaterial perfect absorber solar cell exhibited the enhanced external quantum efficiency (EQE) at the wavelength where the MPA can confine light into the active layer. This result is an evidence that the enhancement in EQE is strongly correlated to the light confinement acquired by MPA.

1. Introduction

Plasmonic solar cells have been intensively investigated since they have been proposed. [1] The researchers expect an enhancement in the device performance owning to the light absorption enhancement of the active materials acquired by plasmonic electromagnetic fields created at the vicinity of the metal nanostructures, followed by an improvement in the device performance.

In fact, there are some papers reporting enhancements in the device performance of plasmonic solar cells. Some of them showed the increase of device performances; however, the enhancements of EQE were observed at all of the absorption wavelength range of the active materials regardless of the plasmonic resonance wavelength. [2, 3] These results raise questions concerning the contribution of plasmons on the enhanced device performance of plasmonic solar cells.

Here, we propose to introduce metamaterial perfect absorber (MPA) into organic thin-film solar cell to clarify the contribution of plasmons on the device performance. Metamaterial perfect absorber consists of two distinct metallic structures sandwiching a thin dielectric film as a spacer, and it can confine the magnetic fields into the dielectric layer as a result of the coupling between the metallic nanostructure and the metallic film. The advantage of the MPA structure is that its position adjustability of the strong light confinement into active materials of solar cells. Proper designing and accurate fabrication of MPA configuration will enable us to adjust the light confinement mode of the configuration to the absorption wavelength of the active materials. And it cannot be realized by dispersed plasmonic nanostructures.

We fabricated a MPA solar cell by using top-down technique, and examined its light absorption properties and device performance. In previous investigations, we have found the MPA configuration can enhance the light absorption of the thin-film organic solar cells. [4-6] In this report, we compared the light absorption enhancement of the MPA solar cell with its device performance, and discussed the effect of plasmons on the device performance of the MPA solar cell.

2. Experimental section

A schematic of the MPA solar cell is shown in Fig. 1 (a). The solar cell consists of indium tin oxide (ITO), zinc oxide (ZnO), photoelectric conversion layer Poly[2,6-(4,4-bis-(2-ethylhexyl)-4H-cyclopenta [2,1-b;3,4-b′]dithiophene]alt 4,7 (2,1,3 benzothiadiazole);[6,6]-phenyl-C71-butyric acid methyl ester (PCPDTBT:PC71BM), molybdenum oxide...
In this research, a periodic silver nanostripe (Ag NS array) was used as a metal nanostructure (Fig. 1 (b)). The Ag NS has a width, pitch, and height of 82, 500, and 20 nm, respectively. Ag NS shows polarization dependence. Therefore, the extinction ratio of the plasmon excitation polarization to the plasmon non-excitation polarization was defined as the absorption enhancement (AE) factor. To examine the device performance, the external quantum efficiency (EQE) was measured. The EQE ratio was calculated by dividing the EQE measured under plasmon excitation polarization by the EQE measured under plasmon non-excitation polarization. The EQE ratio was compared with the AE factor.

3. Results and Discussion

Figure 2 (a) shows the absorption spectrum of PCPDTBT:PC$_{71}$BM, the active materials has an absorption edge around 1000 nm. The red line in Fig. 2 (b) represents the AE factor of the MPA solar cell. Absorption enhancement factor larger than the unity means that the absorption of the MPS solar cell is enhanced. Figure 2 (b) shows that the absorption enhancements were mainly observed at 650 and 880 nm. The blue line in Fig. 2 (b) represents the IPCE ratio of the MPA solar cell, and showed a deterioration of the device performance at 690 nm and an enhancement at 880 nm. In order to clarify the correlation between the light absorption enhancement and device performance of the cell, we calculated the magnetic field distributions by COMSOL Multiphysics finite-element solver. Figure 2 (c) shows the magnetic field distribution calculated at 650 nm where the absorption enhancement and the remarkable device deterioration were observed. Figure 2 (c) represents the light was confined at ITO side, resulting in a deterioration of the device performance due to a decrease of light absorption of the PCPDTBT:PC$_{71}$BM layer. On the other hand, Fig. 2 (d), a magnetic field distribution at 880 nm, where the enhancements in the light absorption and EQE ratio were observed, shows the light confinement into the PCPDTBT:PC$_{71}$BM layer. This light confinement in the active layer resulted in an enhancement of the EQE enhancement of the MPA solar cell via the light absorption increase of the active layer.

4. Conclusions

We clarified the contribution of the plasmonic light confinement properties on the device performance of a thin-film organic solar cell for the first time. These results will pave the way to propose highly efficient plasmonic solar cells.

Abstract

In this work, we present a strategy that achieves broadband optimal absorption in arbitrarily thin semiconductor materials for all energies above their bandgap. Our strategy follows an easy and scalable fabrication route enabled by soft nanoimprinting lithography with seamless integration in many optoelectronic fabrication procedures.

1. Introduction

The achievement of ultrathin films that strongly interact with light, absorbing photons over a wide spectral range is of central importance for applications such as sensing, energy harvesting, or biology among others. Strong broadband absorption is challenging in view of the intrinsic limitation in the absorption coefficient of every material, which is especially deleterious for infrared wavelengths. Many wave optics based designs are being currently investigated to surpass this limitation, from photonic crystals\(^2\)\(^,\)\(^3\) to plasmonics and microresonators. All these architectures\(^4\)\(^\text{–}^\text{6}\) provide new and exciting means of confining light in sub-wavelength thin films. Nevertheless, the absorption enhancements exhibited are typically restricted to a specific frequency range or mostly take place in the metal part. In sum, a photonic architecture capable of increasing the absorption of a semiconductor throughout its entire absorption coefficient has hitherto, remained elusive.

In our work, we demonstrate a germanium photonic architecture deposited on a metal film acting as a metasurface. Our metasurface sustains the simultaneous excitation of Fabry-Perot resonances, Brewster modes and plasmonic-photonic modes that result in an omnidirectional enhanced absorption in a Ge ultra-thin film of 70 nm from 400 nm until 1500 nm. This represents an unprecedented advance in broadband light harvesting, well beyond previous reports (see Figure 1).

Figure 1: Total absorption of the Nanostructured 70 nm dielectric superabsorber (Black) and absorption in the Germanium (Red) vs the absorption of a flat film of germanium over gold with the same thickness (70 nm) (Orange). Inset: Cross section scheme of the photonic structure.
The key aspects of our findings are:

1. The absorption in the metasurface exceeds over 100% that of a flat a-Ge film on gold over an impressive bandwidth of 1100 nm. Moreover, the high refractive index of the Ge renders the absorption profile of the metasurface independent to the angle of incidence of the incident light.

2. We provide the key design guidelines to tune the absorption profile of the metasurfaces and the physical origin beneath each resonant mode sustained by the architecture. With these findings, we show metasurfaces exhibiting strong broadband absorption (appealing to PV community) or NIR absorption peaks reaching 100% at the telecommunication windows (interesting to the photodetection field).

3. Remarkably, we fabricated the 16-mm\(^2\) Ge metasurfaces via nanoimprinting lithography\(^7\), the most promising method for mass-produced nanostructures. This inexpensive and large area technique adds feasibility to the exciting photonic properties described in the manuscript (Figure 2).

Conclusions

In summary, we demonstrate an 81% of total integrated absorption over a broad spectral range in an 80 nm germanium photonic crystal built on a gold layer. Through a rational design of the architecture, the absorption in the active layer exceeds over 100% that of a flat 80 nm a-Ge film on gold. Furthermore, the high refractive index of the semiconductor renders the absorption profile of the metasurface independent to the angle of incidence. The fabrication of these photonic structures follows a highly scalable nanoimprinting technique, which adds to the appeal of the enhanced optical properties described herein. We believe this metasurface has a tremendous potential for light harvesting applications such as photodetection, photocatalysis and photovoltaics.

Abstract

Nanowires are filamentary crystals with a tailored diameter ranging from few to ~100 nm. The special geometry and tailored dimensions result in photonic properties providing great potential in applications requiring enhanced light absorption. We will review how these properties can be used in different configurations for both photo-detection and energy harvesting applications.

1. Introduction

Semiconductor nanowires have attracted an increasing amount of attention thanks to their special properties. Especially interesting is the growth of III-V nanowires on silicon as they naturally allow the integration of the functionalities of the III-V and Si platforms. The dimensions and shape of the nanowires render them ideal for a variety of applications in photonics. The needle-like shape results also in a high degree of polarization response: light absorption is very low for incoming light polarized across the nanowire axis, while it is very high for light polarized along the nanowire axis. In this talk we will show it is possible to vary the intrinsic absorption and emission properties by engineering their size and/or by coupling the nanowires to plasmonic nanostructures.

2. Results

Nanowires are filamentary structures with a tailored diameter between the few and ~100 nm. They can be obtained in a freestanding manner or aligned on a substrate. Figure 1 shows scanning electron micrographs of compound semiconductor nanostructures considered here. Fig. 1a-e elucidates freestanding GaAs nanowire arrays on a silicon substrate with a tailored diameter down to 10 nm [1-3]. They can be used as absorber for a single or dual solar cell. We will explain how the absorption properties depend on the nanowire diameter and interwire distances [4,5] and how an array of nanowires of different compositions can act as a multiple-junction solar cell with conversion efficiencies up to 47% [6].

Figure 1: Scanning electron micrographs of types of nanostructures investigated here. a) GaAs nanowire array on silicon [1,2] b) droplet shrinkage; c) Further evolution of the tip resulting in conically tapered GaAs nanoneedles; d-e) Straight, ~10 nm radius nanowires on top of thicker nanowire stems The scale bar corresponds to 200 nm [3]. f) GaAs nanoscale membrane networks with an InAs nanowire on top [9].

We will then move to the use of freestanding structures for photodetection. Here, we will elucidate how the contacting scheme can provide a base for ultra-fast detection in the GHz regime [7].

Finally, we will explain how nanowires can also be used in their horizontal configuration for highly efficient photodetectors. Here, due to the reduced absorption cross-section in horizontal nanowires, coupling of the semiconductors with plasmonic structures is the key to guarantee high absorption [8,9].
3. Conclusions

In conclusion, we report how one-dimensional structures can be used for efficient and fast light absorption both for applications in photovoltaics and photodetection. The photonic principles can be applied from the UV down to the MIR range of the electromagnetic spectrum.

Total internal reflection using nano-gratings for enhancing the optical response of perovskite solar cells.

Eduardo López-Fraguas*,1, Braulio Garcia-Cámara1, and Ricardo Vergaz1

1GDAF-UC3M, Displays and Photonic Applications Group, Universidad Carlos III de Madrid, Madrid, Spain. *corresponding author, E-mail: edlopezf@ing.uc3m.es

Abstract

In this work, we propose the use of a simple transmission diffraction nano-grating to improve the optical absorption of a perovskite solar cell through the Total Internal Reflection (TIR) phenomenon in the active layer, enlarging the optical path and the photon absorption rate. We design the structure close to the active layer to avoid further optical losses. Although we considered perovskite solar cells, this can be also extended to other types like silicon or organic solar cells.

1. Introduction

The perovskite solar cells are one of the most promising recent technologies in the field of solar cells, due to the remarkable efficiency increment that they have shown in the last years, as well as their easy fabrication [1]. The use of roughness and nanostructured layers in perovskite solar cells are a typical way to increase their efficiency [2]. The searching of optical effects to enhance the light injection in the active layer usually takes into account nanostructured contact layers.

The larger the distance between the nanostructure and the active layer, the lower the intensity of the desired effect. Thus, our motivation in this work is to produce a diffractive effect by nanostructuring a layer as close as possible to the active perovskite layer, but still allowing the appearance of other interesting effects, such as directional scattering or dielectric resonances, which can improve further the light confinement and thus, the effective absorption.

We base our proposal in nanostructuring the TiO2 electron transport layer of a perovskite thin-film solar cell, a technique that can be performed just by applying photolithography to the FTO contact layer prior to TiO2 deposition. With this structure, we induce diffraction effects to achieve a Total Internal Reflection (TIR) in the opposed interface of the perovskite active layer. Thus, the increment of the optical path will lead to the enhancement of the absorption and by this effect, the increment of the short-circuit current. Further effects that increase light confinement are possible due to the dielectric nature of the nanostructure.

2. Simulation setup

In this study, we have modelled the optical behavior of a thin-film perovskite solar cell. The starting point is taken from [3], where they performed an analysis of a Methylammonium Lead Iodide (CH3NH3PbI3) solar cell, using TiO2 as an electron transport layer and without a hole transport layer. They finished the cell with two electrodes, one of gold (rear electrode) and other of Fluorine doped Tin Oxide (FTO, transparent front electrode). This simple thin-film planar structure shows a maximum short-circuit current Jsc of 16.43 mA/cm² at a certain thickness.

We propose a modification of this structure including a nano-grating in the interlayer between the FTO and TiO2 layer, in order to obtain a diffraction effect without changing any parameter of the remaining cell. We show a schematic slice of the proposed cell at Fig.1.

![Figure 1: Solar cell structure with the embedded nano-grating.](image)

When light impinges in this structure from top to bottom, it produces a diffraction effect that we are going to study, in order to achieve TIR inside the active layer, and thus increasing the optical path and absorption into it.

We have used the software COMSOL Multiphysics © to take into account both diffraction effects and all the possible absorption and losses that can appear in the interfaces and layers.
3. Theoretical calculations

The problem of the optical path in solar cells has important concerns due to the interface effects. From a classical point of view, and using the Snell’s law, (Eq.1), we can determine the refracted angle of an incident ray of light impinging in an interface between two different materials, with different refraction indices \(n_i\) and \(n_o\) as follows:

\[
n_i \cdot \sin \theta_i = n_o \cdot \sin \theta_o
\]  

(1)

If the output angle (refracted beam) is 90º, we will have the TIR phenomenon. Taking this into account, we can determine the minimum input angle (\(\theta_i\)) to produce TIR (Brewster’s angle) using Eq. (2):

\[
\theta_i = \sin^{-1} \left( \frac{n_o}{n_i} \right)
\]

(2)

On the other side, we can calculate the output angle of the \(m\) mode (\(\theta_m\)) from a diffraction grating by using Eq. (3):

\[
a \cdot \sin \theta_m = m \cdot \lambda
\]

(3)

Where \(a\) is the pitch of the grating, \(m\) is the diffraction order and \(\lambda\) is the wavelength of the light.

By combining these two effects, we can adjust the diffraction grating dimensions in order to tune its output angle, choosing the range in which it produces an incident angle in the next interface over the TIR angle, previously calculated.

4. Results

As both angles, \(\Theta\) and \(\Theta_m\), are wavelength dependent (Eq. 2 and 3), we can plot their dependence with wavelength using different grating dimensions. As an example, Fig. 2 shows the result of a diffraction pitch of \(a = 1\) \(\mu m\), with certain arbitrary dimensions in the rest of the layers. We can see that there are certain conditions (wavelength over 480 nm) in which we can achieve a TIR condition, i.e., the \(\Theta_m\) is bigger than the obtained \(\Theta_i\).

This result demonstrates that we can tune the dimensions of the proposed nanostructured TiO\(_2\) in order to achieve an improvement of the optical path. Our preliminary results show that an enhancement higher than a 10% in \(J_{sc}\) respect to the planar structure is achieved, taking advantage of both the increment in the optical path and a light confinement effect in the perovskite layer.

We will show the optimization of this structure with dimensions easily achievable through simple fabrication techniques, as well as some alternatives based on the dielectric resonances that allow directionality control.

![Figure 2: Output grating angle versus Brewster's angle. TIR condition appears for wavelengths higher than 480 nm.](image)

5. Conclusions

We propose the introduction of a nanostructure in TiO\(_2\) layer of a perovskite planar thin-film solar cell. The fabrication of this structure is a relatively easy task, if a photolithography technique is applied to the FTO previously to TiO\(_2\) deposition, or alternatively a nanoimprint technique is applied over the TiO\(_2\) layer. A dimension tuning of this simple grating can produce a performance of it in which the Brewster angle is achieved in the other active layer interface, thus increasing the optical path, and besides producing a light confinement in the active layer. We will show the improvements in short-circuit current that it produces for several configurations.

Abstract-In this report we discuss a novel type of perforated silicon metamaterials, possessing toroidal and anapole mode in visible spectral range due to destructive interference between electric and toroidal dipole moments. This type of metamaterial is simple fabrication process without complicated 3D toroidal geometry and exhibits a desirable physical effects like multipolar interactions. We shown how does it possible to split toroidal and electric dipoles excitation by changing geometry of metamolecules.
Some insights on the light management in halide perovskite solar cells and optoelectronic devices

Iván Mora-Seró1,*

1 Institute of Advanced Materials (INAM), Universitat Jaume I, Castelló 12006, Spain

*corresponding author, E-mail: sero@uji.es

Abstract

In this presentation some insights about light management in halide perovskite optoelectronic devices is provided. The introduction of light scattering nanoparticles can enhance the perovskite solar cell photocurrent by the improvement of performance by the incorporation of Au nanoparticles cannot be always assigned to plasmonic effects but to interface modification. The outstanding properties of halide perovskites can also be used to develop other optoelectronic devices as light amplifiers and photodetectors.

1. Introduction

Halide perovskites are receiving a huge attention in the recent few years. Undoubtedly this attention is mainly due to the outstanding power conversion efficiencies, surpassing 24%, reported for photovoltaic devices, fabricated with polycrystalline films from low cost techniques. This outstanding performance is based in the excellent properties of halide perovskite materials presenting direct bandgap with high light absorption coefficient, and a benign defect physics, allowing low recombination rates even in polycrystalline films.

As an optoelectronic device the light management plays a very important role, and the light conversion performance can be increased for example incorporating light scattering nanoparticles. Another way that has been explored in order to increase the performance is to use metallic nanoparticles to take advantage of the plasmonic properties. Here, we highlight the necessity of a systematic characterization in order to rule out another effects rather than the light management to justify the performance increase.

Finally, the outstanding optical properties can be use to develop alternative optoelectronic devices as light amplifiers and photodetectors.

2. Results and Discussion

In this presentations we provide some insights about the light management in perovskite solar cells and optoelectronic devices. First we will discuss about light scattering as an efficient way of light management in perovskite solar cells. One of the classical configurations of perovskite solar cells is the n-i-p configuration using as electron transporting material (ETM) a compact TiO2 with a mesoporous TiO2 scaffold deposited on top. For a long time this configuration produced the record perovskite solar cell performance as the mesoporous scaffold helps in the perovskite crystallization and also decreases the recombination rate. We have observed that the incorporation of SiO2 nanoparticles into the TiO2 mesoporous scaffold, see Figure 1, enhances the light scattering improving the photocurrent of perovskite solar cells and consequently the final photoconversion efficiency. Large SiO2 produce higher scattering but this effect has to be properly balanced with layer morphology, the loss in transparency, and the reduction of the effective refractive index by the introduction of the SiO2 nanoparticles. The addition of SiO2 also affects the slow processes in the perovskite solar cell.

Figure 1: Perovskite solar cell adding SiO2 nanoparticles into the TiO2 mesoporous scaffold, using TiO2 and spiro-OMeTAD as electron and hole selective contacts respectively.

This study indicates a way in which light management can be used to improve perovskite performance. There are other ways in which light management can help in the increase of perovskite solar cell performance, but it is necessary to clearly establish a causality effect with light management and exclude other possible effects as the modification of
morphology or affecting the interfacial properties. There are different examples in the literature where the use plasmonic effects of metallic nanoparticles are claimed to be the origin of performance enhancement observed after the addition of these nanoparticles. Here, we show that it is needed to be cautious to associate the effects observed by the addition of metallic nanoparticles with a plasmonic effect without further analysis as there are other ways in which this particles can affect the perovskite solar cell performance. Here we show that the efficiency enhancement observed by the addition of core/shell Au/SiO$_2$ nanoparticles added at the interface between TiO$_2$ ETM and the perovskite layer are not due to plasmonic effect but to a modification of the interfacial properties.\textsuperscript{[4]}

Finally, the outstanding optical properties of halide perovskite will be used to develop other optoelectronic devices as light amplifiers\textsuperscript{[5]} and light amplifiers couple with photodetectors,\textsuperscript{[6]} in both rigid and flexible substrates.

Abstract

Synchrotron infrared nanospectroscopy (SINS) combines the broad bandwidth and brightness of synchrotron infrared radiation with scanning near-field optical microscopy (SNOM) to enable vibrational spectroscopy spanning the entire mid-infrared region with < 20 nm spatial resolution. By using fast, sensitive custom-modified detectors, we have extended the wavelength range into the far-infrared, enabling direct probing of the tunable plasmon response in a gated graphene device and phonon modes in phase-change materials, such as VO2 and SmS.

1. Introduction

Infrared (IR) spectroscopy continues to be a powerful analytical method to probe molecular vibrations, low-energy electronic excitations, and related collective surface plasmon, phonon, or other polaritonic resonances in a variety of natural and engineered systems. Diffraction and the long wavelengths of infrared light have traditionally limited the spatial resolution of infrared techniques to the micron scale, thereby preventing measurements of nanoscale heterogeneity. The development of near-field IR techniques has changed this paradigm, opening the nanoscale to infrared analysis. Here, we highlight synchrotron infrared nanospectroscopy (SINS), which is a variant of scattering type, scanning near-field optical microscopy (s-SNOM) with synchrotron IR radiation as the light source [1]. The high spectral irradiance and large bandwidth of synchrotron radiation combined with s-SNOM enables broadband infrared spectroscopy with a wavelength independent spatial resolution of < 25 nm, a dramatic improvement over diffraction limited techniques by several orders of magnitude. The Advanced Light Source (ALS) at Lawrence Berkeley National Laboratory operates two infrared beamlines (Beamlines 2.4 and 5.4) with SINS instruments that are freely available to users with an approved scientific proposal. The technique has been widely applied to a growing range of applications in physics, chemistry, biology, materials, geology, atmospheric, and space sciences. We discuss the technical aspects of the technique and highlight several SINS measurements of plasmons, phonons, and phase-change materials.

2. SINS Experiment

2.1. Experimental Layout

A typical SINS experiment (Fig. 1) is based on an asymmetric Michelson interferometer, in which half of the incident synchrotron light is focused onto a metallic tip of an atomic force microscope (AFM), scanning in nanometer proximity to the sample, and the elastically scattered light is collected and directed onto an IR detector. The conductive tip effectively acts as an optical antenna by localizing and scattering the optical field in the near-field region of its nanoscopic apex, yielding a spatial resolution limited by the tip radius. The other half of the incident synchrotron radiation is directed to a moving reference mirror. The reflected light interferes with the tip-scattered light on the detector, creating a distance-dependent interference pattern that is Fourier-transformed to yield the near-field amplitude and phase spectra. Far-field background scattered light is reduced by demodulating the detected signal at higher harmonics of the tip-tapping frequency.

Figure 1: SINS experimental diagram

2.2. Spectral range

Synchrotron radiation from a bend magnet is spectrally broad, spanning the far-IR to x-ray regime. Thus, the primary bandwidth limitations for SINS measurements are
the beamsplitter and detector, not the source. For mid-IR applications, KBr/Ge or ZnSe beamsplitters are used in combination with mercury cadmium telluride (MCT) detectors. The highest sensitivity MCT detectors have frequency cutoffs around 700 cm\(^{-1}\), but the spectral range can be extended to frequencies near 500 cm\(^{-1}\) through different doping, albeit at the expense of detector sensitivity. We have recently expanded the spectral range into the far-IR by customizing a Ge:Cu detector with high bandwidth electronics [2]. When used in combination with a silicon or KRS-5 beamsplitter, this liquid helium-cooled detector has a low-frequency cutoff at 320 cm\(^{-1}\) (Fig. 2).

Figure 2: SINS 2nd harmonic amplitude spectra on a gold reference mirror with different detectors.

3. Examples

The extension of SINS measurements to the far-IR opens up a new nanospectroscopic window to directly probe far-IR electronic and lattice excitations, including the low energy free carrier response, surface phonon polariton waves and optical phonons in oxides and ultraslim van der Waals materials, skeletal deformations and conformational vibrations in molecular systems, and the highly tunable plasmonic regime of graphene plasmons.

3.1 Phase-Change Materials

Gilbert Corder et al. [3] used SINS to characterize different phases of SmS, a strongly correlated heavy fermion system that undergoes a semi-conductor-to-semimetal phase transition at modest pressures (6.5 kbar). The authors used contact-mode AFM to apply pressure to induce and control the local phase transition, and used a combination of SINS and laser-based s-SNOM to probe the nanoscale phase separation and locally probe the plasmonic resonances in the IR and visible regions. SINS spectra show an exciton peak at 468 cm\(^{-1}\) that blueshifts in the strained regions, caused by lowering of the 5d \(t_{2g}\) band, and subsequent transfer of 4f electrons into the hybridized state, increasing the baseline reflectivity. Access to the indirect gap and exciton resonances of the pristine and lithographically strained phases allowed the authors to distinguish the transitioned phases, which is not immediately clear at visible frequencies due to the golden color being present in both IV and fully metallic SmS.

3.2 Graphene Plasmons

Graphene has paved the way for a new generation of 2D optoelectronic materials by virtue of its inherently tunable IR and THz plasmonic response. Khatib et al. [2] used SINS to probe the full voltage-dependent nanospectroscopic IR plasmonic response in a pristine monolayer graphene flake (Fig. 3). At negative voltages, they observed a significant enhancement of the SINS amplitude and phase response and a nearly full suppression for high positive voltages above +50 V, approaching the intrinsic response of the underlying SiO\(_2\) (black curve). This behavior is consistent with gate tuning of the Drude free carrier response superimposed with the plasmon absorption in graphene. The spectral behavior and enhancement near the SiO\(_2\) resonances indicate a hybridization and strong coupling between graphene plasmons and the substrate surface phonons.

Figure 3: SINS amplitude (upper panel) and phase spectra (lower panel) at different gate voltages of a graphene device on SiO\(_2\), showing tuning of the plasmon response.

Abstract

Its peculiar band structure and electron transport characteristics naturally suggest graphene could offer a perfect platform for a new generation of high-performance devices operating in the THz range of the electromagnetic spectrum. This talk will review recent results in the development of high-speed modulators and plasmonic detectors; it will also discuss perspectives towards the implementation of graphene-based deeply sub-wavelength THz emitters and lasers.

1. Graphene-based THz devices

Graphene is attracting considerable attention for a variety of photonic applications, including fast photodetectors, transparent electrodes in displays and photovoltaic modules, and saturable absorbers. Owing to its high carrier mobility, gapless spectrum, tunable chemical potential, and frequency-independent absorption coefficient, it has been recognized as a very promising element for the development of detectors and modulators operating in the Terahertz (THz) region of the electromagnetic spectrum, which is still severely lacking in terms of solid-state devices [1].

In the last few years, progress in the realization of graphene-based THz photonic devices has advanced very rapidly. In this talk I will focus in particular on the realization of THz detectors based on antenna-coupled graphene field-effect transistors (FETs) [2,3], discuss the various mechanisms involved in their operation, and examine extension to other 2D materials and integration into future THz cameras. I will also address the development and applications of electrically switchable metamaterial devices [4] as well as the prospects for the use of graphene in a new generation of THz sources, either directly as active element, or as waveguide optical component (for instance acting as saturable absorber in laser mode-locking) [5]. Finally, schemes to implement coherent control of absorption in graphene and the possible entailing device / diagnostic applications will be analyzed [6].

Abstract
Nanostructured bulk metals can be more transparent than glass and for a bigger range of frequencies. We show that the transparency can go from the near infrared to any smaller photon energy. Also, we can easily tune and design the refractive index.

1. Introduction
Metals are highly opaque, yet we show theoretically and experimentally that densely packed arrays of metallic nanoparticles can be more transparent to infrared radiation than dielectrics such as germanium, even for arrays that are over 75% metal by volume.

Despite strong interactions between the metallic particles, these arrays form effective dielectrics that are virtually dispersion-free, making possible the design of optical components that are achromatic over ultra-broadband ranges of wavelengths from a few microns up to millimetres or more. Furthermore, the local refractive indices may be tuned by altering the size, shape, and spacing of the nanoparticles, allowing the design of gradient-index lenses that guide and focus light on the microscale (see figure a).

The electric field is also strongly concentrated in the gaps between the metallic nanoparticles, and the simultaneous focusing and squeezing of the electric field produces strong ‘doubly-enhanced’ hotspots (see figure b) which could boost measurements made using infrared spectroscopy and other non-linear processes over a broad range of frequencies, with minimal heat production.

1.1. Transparency
The underlying physics of the transparency of densely packed metal metamaterials can be understood by considering how the electrons in metals and dielectrics respond to an electric field. In metals, free electrons are driven to the surfaces until the field generated by the build up of surface charges cancels the applied field within the metal.

On the other hand, the electrons within dielectrics are bound to their parent molecules or atoms, which polarise in the presence of an electric field.

Although the metallic particles comprising the artificial dielectrics possess free electrons, these particles can be regarded as the ‘meta-molecules’ or ‘-atoms’ as the electrons are only free to move within the confines of the metallic particles, effectively mimicking a dielectric. It is worth noting that this effect is not connected with the creation of plasmonics bands due to the array periodicity.

2. Conclusions
In conclusion, low-loss effective dielectrics can be constructed from arrays of metallic nanoparticles. These arrays are highly transparent, at times even exceeding the transparency of real dielectrics renowned for their transparency to low energy radiation, such as germanium, and can be tuned locally by controlling the size, shape, and spacing of the particles.

Furthermore, and in contrast to metamaterials designed upon resonant effects, the effective index is essentially constant for all wavelengths greater than about 2 μm. This al-
lows the design of optical devices to guide or enhance light over an extremely broad range of frequencies, essentially without an upper bound on wavelength.

Abstract

Ribbons and discs based on doped graphene feature strong tunable plasmonic resonances. We show that excitation with THz radiation results in strong changes of transmission, even at moderate pump fluences. The response is due to a broadening and redshift of the plasmonic absorption line as charge carriers are heated. The response time is determined by the cooling of carriers, which is of the order of 10 ps.

1. Introduction

Optoelectronic effects in graphene have been studied extensively in a wide spectral range, in particular also in the THz frequency region. Making use of plasmonic effects in tailored micro- and nanostructures allows one to enhance the absorption at particular frequencies and to tune the resonance frequency by the structure size and the doping level, respectively [1]. This, together with spatial localization of the excitation, makes plasmonic effects attractive for optoelectronic device applications such as detectors, modulators, saturable absorbers or frequency multipliers [2]. Here we focus on time resolved studies of nonlinear effects in graphene based ribbons and discs.

2. Experimental

Various arrays of graphene ribbons and discs (typical size \(\sim 1 \text{\,\mu m}\) in arrays covering \(1.5 \times 1.5 \text{\,mm}^2\)) have been fabricated by electron beam lithography and subsequent oxygen-plasma etching. For one set of samples graphene grown by chemical-vapor deposition (CVD) was transferred to SiO\(_2\)/Si substrates. In these samples the plasmon resonance can be tuned by controlling the carrier concentration via a back-gate voltage [3]. Quasi-freestanding bilayer graphene of high structural quality grown epitaxially by thermal decomposition of SiC on the (0001) side and subsequent hydrogen intercalation is the base of another set of ribbons [4,5] and also discs. The linear absorption of the samples was characterized by Fourier transform infrared spectroscopy. The epitaxial samples exhibit stronger resonant absorption (35 \%) compared to the CVD grown sample (18 \%) and a four-times narrower Lorentzian linewidth. Comparing the results with calculations based on the Drude model yields a mobility of 3600 cm\(^2\)(Vs\(^{-1}\)) and a carrier concentration of \(9 \times 10^{12}\) cm\(^{-2}\) for the quasi-freestanding epitaxial layers. Single-color pump probe experiments were performed using a free-electron laser as a source of intense narrowband tunable THz pulses. The samples were kept at 15 K in a He flow cryostat.

3. Results and Discussion

Figure 1: Principle of the pump-probe experiment on ribbon samples (a). Sketch of the redshift and broadening of the plasmonic absorption (b). Pump-induced transmission as a function of time delay for various frequencies (c). Maximal pump-induced transmission change (d). The circles are experimental data (see part (c)), the line is calculated based on the hot-carrier model. Part (c) and (d) are adapted from Ref. [4].
The pump-induced change in transmission was measured in the experiments at different spectral positions within the plasmonic resonance. In one set of experiments the polarization of both the pump and the probe beam were orientated perpendicular to the ribbons in order to make use of the plasmonic resonance. The pump-induced change in transmission changed proportionally the square-root of the pump fluence, thus providing relatively strong signals at low fluence. For example, a transmission change of 5 % was achieved by excitation with 0.5 μJ/cm² for the epitaxial sample. To investigate the spectral response in a reliable quantitative manner, the pump polarization was oriented along the direction of the ribbons, while the probe polarization was kept perpendicular. Consequently, the excitation occurs via free-carrier heating, which is spectrally almost flat in the range of plasmonic absorption line. The probe pulse, however, still measures the plasmonic response of the heated electron system. The results are depicted in Fig. 1c-b for epitaxial ribbons with a resonance frequency of 3.9 THz. Induced absorption occurs below resonance, while induced transmission is observed at resonance and above resonance. The results can be explained by a nonlinear hot-carrier response of the thermalized electronic system. Heating of the electron gas by THz radiation requires the chemical potential to drop, in order to conserve the number of free carriers. Furthermore a broadening is induced by the increasing electron scattering rate for supercollision cooling [6]. A thermodynamic model that takes these effects into account provides excellent agreement with the experimental findings [4], cf. Fig. 1d.

Finally, first experiments were carried out on discs of quasi-freestanding bilayer graphene. Here, a plasmonic response is induced for all orientations of linearly polarized radiation. Particularly strong induced transmission is observed for circularly polarized radiation. For the case of circularly copolarized radiation a change in transmission of 2 % is reached for pumping with just 20 nJ/cm². Furthermore we show that discs are an ideal system to study nonlinear effects that go beyond the hot carrier response and stem directly from the non-equilibrium excitation.

4. Conclusions

We demonstrate strong nonlinear THz plasmonic response in graphene ribbons and discs. High quality samples provide particularly strong pump-induced transmission. The results from the ribbons are well explained by a hot carrier model, which predicts a red-shift and broadening of the plasmonic absorption by an increase of the electron temperature.

Abstract

Polaritons – hybrid light-matter excitations – play a crucial role in fundamental and applied sciences, as they enable nanoscale control of light. Polaritons with anisotropic propagation along the surface of vdW materials have been predicted, caused by in-plane anisotropic structural and electronic properties. Here we report anisotropic polariton propagation along the surface of α-MoO₃, a natural vdW material using infrared nano-imaging and nanospectroscopy techniques. In-plane anisotropic polaritons could enable directional and strong light–matter interactions, in applications such as bio-sensing, among others.

1. Introduction

Anisotropic optical materials exhibit numerous distinctive and non-intuitive optical phenomena such as negative refraction, hyper-lensing, wave-guiding and enhanced quantum radiation, which have been demonstrated typically with artificial hyperbolic metamaterials. However, further progress is limited by optical losses and the complexity of metamaterial fabrication.

The recent emergence of low-loss vdW materials opens the door to achieving anisotropic optical phenomena naturally, because their layered crystal structure leads to an intrinsic and strong out-of-plane (perpendicular to the layers) optical anisotropy. Prominent examples are hyperbolic phonon polaritons (PhPs)—infrared light coupled to lattice vibrations in layered polar materials—in hexagonal boron nitride (h-BN), which exhibit long lifetimes, ultra-slow propagation and hyper-lensing effects. Interestingly, when the layers of a vdW material are anisotropic (that is, when the permittivities along orthogonal in-plane directions are different), the polaritons are expected to propagate along the layers with an in-plane anisotropic dispersion. When the permittivities are different but of the same sign, the polaritons possess an elliptic in-plane dispersion, in which the iso-frequency contours (slices in two-dimensional (2D) wavevector space (kx, ky) of constant frequency ω) describe ellipsoids. When the signs are different, the polaritons possess an in-plane hyperbolic dispersion, in which the iso-frequency contours are open hyperboloids. Only recently, PhPs with in-plane hyperbolic dispersion have been demonstrated by fabricating an artificial metamaterial out of h-BN flakes [1].

Theory predicts polaritons with both in-plane anisotropies even for natural materials that exhibit an in-plane anisotropy of their electronic or structural properties. However, their experimental observation and verification has so far been elusive. Here we present the first images of in-plane elliptic and hyperbolic polaritons. We found them in thin slabs of α-phase molybdenum trioxide (α-MoO₃), a natural vdW polar semiconductor [2].

2. Discussion

To explore the polaritonic response of α-MoO₃, we performed polariton interferometry using scattering-type scanning near-field optical microscopy (s-SNOM, Fig. 1a). A vertically oscillating metallized atomic force microscopy (AFM) tip is illuminated with p-polarized infrared light of frequency ω and field E₀, while scanning an α-MoO₃ flake. The tip acts as a polariton launcher and scatterer, since it concentrates the incident field at its apex allowing polariton excitation but also scatters the polaritons reflected to the far field. The polaritons excited by the tip propagate away and are back-reflected at the flake edges, giving rise to interference fringes with a λ/2 spacing. Figure 1b shows s-
SNOM near-field amplitude images of an α-MoO₃ flake with thickness d = 250 nm taken at ω = 990 cm⁻¹ and ω = 900 cm⁻¹. At 990 cm⁻¹ (upper image in Fig. 1b), we observe that the fringe periodicity largely depends on the propagation direction, being λₓ = 950 nm and λᵧ = 1200 nm for the [100] and [001] crystal directions. Apart from the deep subwavelength-scale polariton confinement λₓy << λᵧ = 11.1 μm. This anisotropy becomes even more marked at ω = 900 cm⁻¹ (lower image in Fig. 1b), where the fringes are seen only parallel to the [001] direction. Accordingly, we assign each of these measurements to each of the two Reststrahlen bands: an upper one (Fig. 1b upper panel), the so-called elliptical regime and a lower one (Fig. 1b lower panel), the so-called hyperbolic regime.

![Schematic of the s-SNOM experimental configuration used to image an α-MoO₃ flake](image)

Figure 1: a, Schematic of the s-SNOM experimental configuration used to image an α-MoO₃ flake. A metallized AFM tip (yellow) is illuminated by p-polarized infrared light of frequency ω and electric field E_inc. It launches polaritons, which are back-reflected at the flake edges and subsequently scattered by the tip. The tip-scattered field is detected by a distant detector. b, Near-field amplitude images s4 of an α-MoO₃ flake with thickness d = 250 nm at illuminating frequencies ω = 990 cm⁻¹ (top panel) and ω = 900 cm⁻¹ (bottom panel).

For a better understanding of these phenomena, we model the α-MoO₃ as a 2D conductivity layer of negligible thickness compared to the incident wavelength surrounded with two dielectric half-spaces. This model also allows us to extract the unknown α-MoO₃ permittivity at infrared frequencies. We corroborate the model and the permittivity values extracted by performing numerical simulations of near-field images of an α-MoO₃ flake on SiO₂. From our analysis, we find εₓy,ζ > 0 and εₓz < 0 for the elliptical regime and εₓx < 0 and εᵧy,ζ > 0 for the hyperbolic regime. Furthermore, we find negative phase velocity for phonon polaritons in the elliptical regime and positive phase velocity for phonon polaritons in the hyperbolic regime.

Regarding phonon polariton lifetimes, τ, we measured record-high polariton lifetimes of 8 ps. Which are more than one order of magnitude larger than that of graphene plasmons and four times larger than that of isotopically enriched h-BN. We obtain the lifetime according to τ = L/V₆, where L is the decay length and V₆ the group velocity. Decay lengths are calculated fitting s-SNOM profiles to an exponentially decaying sine-wave function and group velocities are worked out by applying a numerical derivative to the ω-k phonon polariton dispersion (being ω the incident wavelength and k the phonon polariton wavenumber).

3. Conclusions

In short, we have shown for the very first time in-plane anisotropic phonon polariton propagation in α-MoO₃ (both elliptical and hyperbolic), with record-high phonon polariton lifetimes. Moreover, we have extracted the sign of the phonon polaritons phase velocity and the values of the α-MoO₃ permittivity at IR wavelengths. This finding may establish a route to directional control of light and light-matter interactions at the nanoscale.

Highly anisotropic phonon polaritons in natural biaxial hyperbolic van der Waals alpha-MoO$_3$

Zebo Zheng, Huanjun Chen*

State Key Laboratory of Optoelectronic Materials and Technologies, Guangdong Province Key Laboratory of Display Material and Technology, School of Electronics and Information Technology, Sun Yat-sen University, Guangzhou, China.

*corresponding author, E-mail: zhengzb5@mail.sysu.edu.cn

Abstract- We show that the van der Waals $\alpha$-MoO$_3$ can support naturally in-plane hyperbolic phonon polariton at mid-infrared frequencies. Because $\alpha$-MoO$_3$ is a biaxial crystal with three different Reststrahlen bands, where the permittivity is negative due to its lattice vibrations. Interestingly, due to the minimal spectral overlap between these bands, the material is hyperbolic in its natural state. However, unlike previously investigated uniaxial hyperbolic materials, the permittivities along all three axes are different, so in-plane hyperbolic dispersion is also observed.

Hyperbolic materials refer to those media exhibit permittivity tensor having one principal component with opposite sign with respect to the other two axes. They have been extensively studied for their exotic optical properties, particularly the highly confined electromagnetic fields with arbitrarily high momenta (1). This concept can be directly generalized to 2D media, where surface waves or guided waves are considered, and implemented using hyperbolic metasurfaces (HMSs) (2). These are flat photonic nanopatterned structures that support guided waves with in-plane hyperbolicity and can control the two-dimensional light propagation in unconventional way, giving rise to a variety of intriguing optical phenomena such as all-angle negative refraction, greatly enhanced photonic density of states, and wavefronts with concave curvatures (3). The necessity of patterning, however, typically leads to strong optical losses, and limits the actual confinement that can be reached. Furthermore, the electromagnetic responses of the HMSs are governed by the permittivity tensors that are derived from the effective medium theory, which is only valid in the long-wavelength limit where the structural periodicity is much smaller than the incidence wavelength. Consequently, the hyperbolic dispersion is constrained to a very small region in the reciprocal space, leading to rather limited electromagnetic wavevectors. Such an issue can in principle be alleviated by reducing the structural periodicities of the metasurfaces down to sub-10 nm scale. However, this should happen without bringing in additional surface roughness or defects, which is a great challenge for nano-fabrication techniques. Thus, the quest for a natural medium that can be used to achieve in-plane hyperbolicity without nanopatterning is a very important open problem in nanophotonics.

In a recent study, we demonstrated highly confined hyperbolic phonon polaritons (PhPs) in a new type of vdW semiconducting crystal, alpha-phase molybdenum trioxide ($\alpha$-MoO$_3$), grown by the thermal–physical-deposition method (4). Herein, we show that vdW $\alpha$-MoO$_3$ is actually a type of natural biaxial hyperbolic crystal and that it exhibits pristine in-plane hyperbolic dispersion in the mid-infrared range. First, we proposed a universal three-dimensional analytical dielectric and dispersion model for describing the hyperbolic PhPs in $\alpha$-MoO$_3$. Secondly, by utilizing the high-resolution optical scanning near-field nano-imaging techniques, the phonon polariton modes are launched, guided, and manipulated within the different hyperbolicity bands in thin $\alpha$-MoO$_3$ crystal flakes. In particular, the concave wavefront of a polaritonic mode originating from the in-plane hyperbolicity of the flake is directly imaged, which is an unmistakable signature of the preserved three-dimensional hyperbolicity of this 2D material. In addition, we measured for the first time the whole dispersion relations of the hyperbolic PhPs corresponding to the three Reststrahlen bands of $\alpha$-MoO$_3$ by combining scattering-type near-field scanning optical microscopy (s-SNOM) and photo-induced force microscopy (PiFM) techniques. Furthermore, potential applications of vdW $\alpha$-MoO$_3$ in focusing and manipulating mid-infrared electromagnetic fields at the nanoscale are demonstrated (5).

The homogenous biaxial hyperbolic vdW $\alpha$-MoO$_3$ crystal investigated here offers the prospect of planar nanophotonics without the need for complex nanopatterning, which is unavoidable in 2D artificial counterparts. The unique biaxial hyperbolicity can provide opportunity for controlling the nanoscale interactions in a direction-dependent manner. For example, Controlling and manipulation of dipole–dipole interactions with more freedom and the broadband super-Planckian thermal emission due to its high photonic density of states in mid-infrared region. This effect can pave the way for engineering the thermal emission at nanoscale. On the other hand, in principle, the wavevectors of the guided electromagnetic waves attained within $\alpha$-MoO$_3$ are only limited by the atomic crystalline periodicity; thus, very strong electromagnetic confinement can be reached. The confinement and manipulation of electromagnetic fields at the
nanoscale can be further enriched by introducing sophisticated nanostructures. Moreover, α-MoO$_3$ is also a semiconductor, which demonstrates the potential for applications of hyperbolic media in active optoelectronic devices because of their excellent electrical transportation characteristics, the tunability of their physical characteristics by external doping, and their high optical-to-electrical conversion efficacy.

Abstract
The terahertz properties of Bi₂Se₃ 3D Topological Insulator have been studied in the 0.2-5 THz spectral range. The linear response is described in terms of a Drude term and plasmon modes mainly related to the surface Dirac conducting states characterizing the low-energy electrodynamics of Bi₂Se₃. The intrinsic non linearity of Dirac states, when excited by strong THz fields, provide either harmonic generation and strong plasmon softening, opening the use of TIs for photonic devices.

Introduction
3D Topological Insulators (TIs) are quantum electronic materials characterized by an insulating electronic gap in the bulk, whose opening is due to strong spin-orbit interaction, and gapless surface states at their interfaces. Surface states in TIs are metallic, characterized by a Dirac dispersion, showing a chiral spin texture, and protected from back-scattering by the time-reversal symmetry. Dirac carriers in TIs are characterized by a Fermi energy of about 300 meV substancting single particle and plasmon excitations in the terahertz region of the electromagnetic spectrum [1]. In this paper we have studied the linear and non-linear electromagnetic properties of Bi₂Se₃ thin films. These films with a thickness from 10 to 100 nm, have been grown by Molecular Beam Epitaxy technique and show a high purity with a very low number of defects and Se out of stoichiometry [2]. This provided the possibility to observe by Angular Resolved Photoemission (ARPES) well defined Dirac cones at the Bi₂Se₃ surface with a reduced contribution from bulk bands to their low-energy electrodynamics [2].

1. Experiments
Single particles and plasmon modes have been observed in transmission by using THz radiation from 200 GHz to 5 THz. Linear spectroscopy has been performed through the radiation emitted by the SISSI THz/Infrared beamline at the Elettra Synchrotron facility in Trieste, Italy [3]. Non linear spectroscopy has been instead performed at the THz high-intensity facility TeraFermi@Elettra, producing sub-ps THz pulses with an associated electric field up to 2 MV/cm [4]. Non linear optical properties has been measured vs. the THz electric field through a home-made Michelson interferometer [4]. In Fig.1 we show the experimental apparatus for non linear spectroscopy.

2. Discussion
We observe a strong THz electric field dependence of both the single particle (Drude) and collective (plasmon) modes of low-energy electrodynamics of Bi₂Se₃ films. In particular,
the single-particle term when excited by a strong THz pulse is renormalized transferring spectral weight at high frequency thus realizing an effective mechanism for harmonic generation in the THz region. Plasmon modes are also modified generating a strong softening of their central frequencies. Both effects are associated to Dirac carriers generated by the non trivial topology of Bi$_2$Se$_3$.

3. Conclusions

THz measurements on Bi$_2$Se$_3$ topological insulator show a strong non linear response associated to Dirac carriers. This opens the possibility to use Bi$_2$Se$_3$ thin films for photonic devices like harmonic generators and frequency converters.

Photonic Crystals for Nano-Light in Twisted Bilayer Graphene

D.N. Basov
Columbia University

500 W 120 Street New York, NY USA

Abstract: Atomically relaxed twisted bilayer graphene hosts periodic arrays of topological conducting channels that act as a photonic crystal for surface plasmons.

Graphene is an atomically thin plasmonic medium that supports highly confined plasmon polaritons, or nano-light, with very low loss. Electronic properties of graphene can be drastically altered when it is laid upon another graphene layer, resulting in a moiré superlattice. The relative twist angle between the two layers is a key tuning parameter of the interlayer coupling in thus obtained twisted bilayer graphene (TBG). We studied propagation of plasmon polaritons in TBG by infrared nano-imaging. We discovered that the atomic reconstruction occurring at small twist angles turns the TBG into a natural plasmon photonic crystal for propagating nano-light. This discovery points to a pathway towards controlling nano-light by exploiting quantum properties of graphene and other atomically layered van der Waals materials instead of arduous top-down nanofabrication. University of Alberta
Edmonton AB T6G 2E1
Canada

E-mail: hegmann@ualberta.ca

The ability to directly probe ultrafast phenomena on the nanoscale is essential to our understanding of excitation dynamics on surfaces and in nanomaterials. Recently, a new ultrafast scanning tunneling microscope technique that couples terahertz pulses to the scanning probe tip of an STM was demonstrated (THz-STM), showing photoexcitation dynamics of a single InAs nanodot with simultaneous 0.5 ps time resolution and 2 nm spatial resolution under ambient conditions. Operation of THz-STM in ultrahigh vacuum now makes it possible to spatially-resolve sub-picosecond dynamics of single molecules and silicon surfaces with atomic precision. THz-STM also makes it possible to coherently control currents at the tunnel junction, as well as drive tunnel currents exceeding 100 GA/cm² through a single atom over sub-picosecond time scales. However, more work is needed to better understand the nature of terahertz-pulse-induced tunnel currents and nanoscale photoexcitation dynamics in various material systems using THz-STM. This talk will discuss how ultrafast THz-STM works, recent progress, operation in ambient versus UHV, and how THz-STM can provide new insight into ultrafast dynamics on the atomic scale, which is essential for the development of novel silicon nanoelectronics, nanophotonics, and molecular-scale devices operating at terahertz frequencies.

Abstract

In this work, we theoretically investigated the excitation of surface plasmon-polaritons (SPPs) in deformed graphene by attenuated total reflection method. We considered the Otto geometry for SPPs excitation in graphene. Efficiency of SPPs excitation strongly depends on the SPPs propagation direction. The frequency and the incident angle of the most effective excitation of SPPs strongly depend on the polarization of the incident light. Our results may open up new possibilities for strain-induced molding flow of light at nanoscales.

1. Introduction

Graphene is one of the materials which allow reaching the most possible miniaturization of nowadays devices just a one atomic layer of thickness. Moreover, it has a lot of non-trivial physical properties ranging from mechanical to optical. For plasmonic applications it is important that graphene carrier concentration can be tuned by chemical doping or applying an electric field, which allow varying its electrodynamic properties from highly conductive to dielectric. This feature makes graphene a very promising material for flatland photonics and plasmonics [1, 2].

For practical applications, it is highly desirable to have the effective tools for control of SPPs characteristics. Usually, this goal may be achieved by introducing into plasmonic structure some optically active materials [3, 4]. In contrast to such approach graphene may show an optical activity itself: its optical properties may be effectively manipulated by electric [5] and magnetic [6] field, by topological manipulations [7] or by deformations [8].

Despite a large number of works devoted to electric and magnetic field manipulation by SPPs in graphene, the impact of deformations on the plasmonic properties is not investigated enough. In this paper we investigated the excitation of SPPs on non-elastically deformed graphene (see Fig. 1). We found that such a structure shows high anisotropy of reflectance from graphene layer orientation (or orientation of deformations). Our results may pave the way for new straintronic methods of nanoscale light control.

2. Discussion

In this work, we theoretically investigated the excitation of surface plasmon-polaritons (SPPs) in deformed graphene by attenuated total reflection method. We considered the Otto geometry for SPPs excitation in graphene layer under external strain. We calculated the light reflectance from the structure, which allows concluding what part of the energy of the incident wave has passed into the excitation of SPPs. During the work, we investigated plasmonics of deformed graphene lattice, as illustrated in Fig. 1 (B).

The optical conductivity tensor for this modified graphene lattice has non-zero off-diagonal components [8] $\sigma_{xy} = \sigma_{yx} = 2\sigma_0(\omega)\beta s_p/\alpha$ and modified diagonal components $\sigma_{xx,yy} = \sigma_0(\omega)[1 \pm 2\beta s_p/\alpha]$, where $\sigma_0(\omega)$ is graphene conductivity, $\beta$ the electron Gruneisen parameter, $s_x$ and $s_y$ are the components of relative displacement of graphene sub-lattice $s$. A possible scenario for such deformation could occur in graphene grown on a substrate with an appropriate combination of lattice mismatch between the two crystals [9].

Color maps of the reflectance are shown on Fig. 2. One can see that in the deformed graphene the excitation pattern of surface plasmons differs from that of undeformed graphene. Excitation of SPPs by TM-incident wave is more efficient at lower frequencies. For TE-polarized incident wave excitation of SPPs occurs more significantly and at higher angles of incidence $\theta$. 
3. Conclusions

The calculations have shown that the deformed graphene is a good basis for the excitation of plasmons not only by TM-polarized waves, but also by TE-polarized incident waves, which is impossible to observe in an undeformed layer of graphene for THz frequency range. The frequency and angle of the most effective excitation of plasmons strongly depend on the polarization of the incident electromagnetic wave. This opens up new possibilities for controlling electromagnetic radiation on nanoscale.

Abstract

In this work, the phenomenon of second-harmonic generation in a hyperbolic metasurface based on graphene strips was investigated. Existence of phase matching between surface plasmon-polaritons (SPPs) at fundamental and second harmonic frequencies was shown. The phase matching condition may be satisfied just for certain angles of SPPs propagation. The dependencies of this angle on frequency and filling factor are investigated.

1. Introduction

Graphene (2D honeycomb-like lattice of carbon atoms) allows reaching the most possible miniaturization of just one atomic layer for nowadays devices. Its electromagnetic properties may be easily tuned from highly conductive to almost dielectric by tuning the carrier concentration. This feature makes graphene a very promising material for flatland photonics and plasmonics [1, 2].

Densely packed array of graphene stripes may support a hyperbolic surface plasmon-polaritons (SPPs), which attracts researchers attention by exciting optical properties [3, 4, 5]. Such an array forms a hyperbolic metasurface (HMSs). It supports highly localized low-loss SPPs, providing drastic increase of the light-matter interactions near the surface. Moreover, HMSs allow the very effective manipulation by SPPs varying from routing them towards specific directions within the sheet, dispersion-free propagation (canalization), and to the negative refraction.

Here, we consider the peculiarities of second harmonic generation (SHG) in graphene-based metasurfaces (see Figure 1), when the metasurface works in hyperbolic regime for both fundamental and second harmonic frequencies.

2. Results and Discussion

Electrodynamic properties of the above-mentioned metasurface may be described by diagonal conductivity tensor with the following components: $\sigma_{xx}^{\text{eff}} = (L \sigma_c)/(W \sigma_c + G \sigma)$, $\sigma_{yy}^{\text{eff}} = \sigma W/L$.

With this conductivity tensor, solving Maxwell’s equations with the boundary conditions of electric field strength continuity for tangential components and jump of tangential magnetic field strength due to currents in metasurface, one may calculate the dispersion relation of propagating SPPs:

$$(q_x^2 - k_0^2) \sigma_{xx} + (q_y^2 - k_0^2) \sigma_{yy} = 2i\gamma \omega (\varepsilon_0 + \mu_0 \sigma_{xx} \sigma_{yy} / 4)$$

where $\gamma^2 = q_x^2 + q_y^2 - k_0^2$, $k_0 = \omega/c$, $\omega$ is an angular frequency (time-dependence $\propto \exp(-i\omega t)$ is assumed), SPPs propagates with the wavevector lying in $xy$-plane $q = (q_x, q_y)$.

Solving this dispersion relation for both fundamental and second harmonic frequencies, it is possible to calculate an isofrequency contours and define the phase matching condition $2q_\omega = q_{2\omega}$.

Let us consider the structure with $L = 50 nm$, $W = 15nm$. Figure 2 shows an isofrequency contours calculated for such a structure at frequency 10 THz. One can see, that the phase matching condition is satisfied for certain angles of SPPs propagation.

This phase matching angle depends on frequency and geometrical parameters of the structure. Figure 3 shows the behaviour of phase matching angle under variation of frequency and for fixed geometrical parameters. One can see that the phase matching angle changes with the frequency in wide angular range.

As usually for graphene-based plasmonics, the frequency range for SPPs excitation varies from THz to mid-infrared depending on graphene chemical potential $\mu_{\text{ch}} [1, 2]$. At the frequencies corresponding to the condition of intra-band electron transitions in graphene (i.e. when $\hbar \omega \approx$...
$2\mu_{ch}$, imaginary part of its conductivity becomes negative (or, equivalently, its dielectric permittivity becomes positive) which means that graphene can not support any SPPs. This means that change of graphene chemical potential (by external gate voltage, for example) will lead to breaking of phase matching condition.

3. Conclusions

We have theoretically investigated a phase matching condition for SHG in graphene-based hyperbolic metasurfaces. We have found that it is possible to observe a SHG from SPPs at fundamental frequency to SPPs at doubled frequency, when the metasurface works in hyperbolic regime at both frequencies. Phase matching condition may be observed just for certain angles of propagation for SPPs. Phase matching angle depends significantly from frequency, geometrical parameters of the structure and properties of graphene.

Abstract

Graphene has extraordinary electro-optic properties and is therefore a promising candidate for monolithic photonic devices such as photodetectors. However, the integration of this atom-thin layer material with bulky photonic components usually results in a weak light-graphene interaction leading to large device lengths limiting electro-optic performance. In contrast, here we demonstrate a plasmonic slot graphene photodetector on silicon-on-insulator platform with high-responsivity given the 5 μm-short device length. We observe that the maximum photocurrent, and hence the highest responsivity, scales inversely with the slot width. Using a dual-lithography step, we realize 15 nm narrow slots that show a 15-times higher responsivity per unit device-length compared to photonic graphene photodetectors. Furthermore, we reveal that the back-gated electrostatics is overshadowed by channel-doping contributions induced by the contacts of this ultra-short channel graphene photodetector. This leads to quasi charge neutrality, which explains both the previously-unseen offset between the maximum photovoltaic-based photocurrent relative to graphene’s Dirac point and the observed non-ambipolar transport. Such micrometer compact and absorption-efficient photodetectors allow for short-carrier pathways in next-generation photonic components, while being an ideal testbed to study short-channel carrier physics in graphene optoelectronics.

Here, we report the design and characterization of a plasmonic slot graphene photodetector monolithically integrated on silicon-on-insulator. While our plasmonic slot design results in a comparable (absolute) responsivity compared to that of plasmonic graphene photodetectors recently reported by Ding et al., the underlying physics and relative performances are substantially different as discussed below; in brief our design utilizes hybrid slot plasmonic mode with a smallest slot width (15 nm) to date. Interestingly, the maximum photo-absorption is achieved for smallest plasmonic gap. To understand the short-channel effect of this novel design, we investigate a symmetric metal-contact work-function concept, which therefore requires a bias voltage to extract the photo-carriers. However, the generality of our observed results and short-channel explanation hold true for both the symmetric and the asymmetric metal work-function case. Our structure sits on top of the silicon-on-insulator (SOI) epitaxy layer. Besides providing a different integration method to the plasmonic graphene PD with conventional photonic integrated circuit, the silicon layer can be used as a back gate to achieve two device operation regimes (i.e. bolometric effect or photovoltaic effect) thus this PD design allows for dual operation (positive or negative photocurrent) depending on the gate voltage. Multiple devices with a variety of geometric dimension have been fabricated and studied, and the device featuring the smallest plasmonic slot gap size (15 nm) showed the highest responsivity of 0.35 A/W while being only 5 μm short and a bias of 0.2 V. This is about 15-times more efficient per device length than integrating graphene onto an SOI waveguide, enabled by the strong light-graphene interaction enhancement from the narrow plasmonic slot structure. As expected this device also shows broadband (here 100 nm tested) operation. We believe this compact yet high-responsivity photo-detector enables next-generation optoelectronics specifically for both dense integration and short temporal delays.

For graphene-based photodetectors, three different compelling mechanisms contribute to the photo-response, namely photo-thermoelectric (PTE) effect, photo-bolometric (PB) effect and photovoltaic (PV) effect. The PTE effect relies on the photon induced electron temperature difference between two different graphene doping regions, which is usually achieved by designing an asymmetric energy band profile from different material doping or spatially placing the photosensitive region away from the symmetric part (36). However, in our design, the same metal combination (Ti/Au) is used for the plasmonic slot which is simultaneously used to contact graphene. This results in a symmetric band diagram across

Figure 1. (a) 3-dimensional representation of the photodetector. (b) Cross sectional schematic of the device, where the Ti/Au metallic structures are in close proximity to each other for forming the plasmonic slot waveguide, as well as serving as the source-drain contact, while the p-doped SOI device layer silicon is used for back gate with a thin silica layer in between. (c) SEM image of fabricated photodetector, graphene is underneath the metal structure and the cross-sectional image as inset, here is a slot with slot gap width W = 30 nm and length L = 5 μm. (d) Zoom in view of the tapered region and slot, note that the graphene layer is slightly extended out from the slot region for a few hundreds of nanometers to ensure lithography alignment.
the active region, and therefore minimizes the contributions from PTE effect. Instead, a competing PB and PV effect is observed due to their inverse photocurrent polarity; that is, the PB contributes to a negative photocurrent due to the increased channel resistance from smaller mean free path for heated carriers, whereas photo-generated carriers from PV reduce the channel resistance. By varying the gate voltage to change the channel doping level, two distinct PB dominant vs. PV dominant regions were found for our devices (Fig. 2). Furthermore, this short-channel detector shows that the PV generated photocurrent peak (minimized PB) does not coincide with the same gate bias where the Dirac point. This is due to the metal-induced short-channel doping of the graphene sheet, which is no longer a negligible effect for devices with such short channel length, i.e. the physical channel length (slot width W) is shorter than the charge transfer region Ls.

In view of our results, here we compare the device performance in term of device compactness (1/device length) and responsivity per bias to the state of art integrated graphene photodetectors. In general, the photonic graphene integrated PD requires a larger device footprint to achieve significant absorption in graphene, due to the dimension mismatch between graphene and dielectric waveguide, hence a small mode overlap. For plasmonic PDs, for both PB and PV effect driven device, our short-channel device shows a higher responsivity-per-bias compared to recently reported graphene plasmonic detectors, despite the fact that the absolute absorption area is smallest in our device. We believe this superior responsivity per bias, along with the compact device footprint is a direct result of the ultra-short slot width W amongst these plasmonically enhanced PDs enabling higher absorption per unit device length and a shorter carrier drift path. To summarize, in addition to the device demonstration, our photocurrent measurements provides considerable insightful details on the transport in short channel devices, highlighting the role of the metal-graphene junctions and the governing mechanism in the charge transport region. We measure that under different back-gate voltage, the ultra-short graphene channel, in fact, displays a large mismatch between the channel net charge neutrality point and the Dirac point for graphene due to a significant influence of the metal contact doping into the ultra-short channel detector. This translates to a pronounced shift between the peak in PC and the Dirac Point, here reported for the first time. Also, the peculiarity of the short channel transport mechanism combined with the electrostatic doping, allows two distinct non-competing operation regimes having response in inversed polarities, which enables more system level functionality when integrated with PICs. Moreover, we provide the device performance, as function of the width of the slot. Smaller slot width yields a stronger field confinement, which ultimately leads to a larger photoresponse.

In conclusion, hereby, we demonstrated an ultra-compact graphene based plasmonic slot detector with a responsivity of 0.35 A/W and 0.17 A/W for bolometric and photovoltaic effect, respectively. This high responsivity was due to enhanced absorption in graphene enabled by the strong mode confinement in the ultra-short slot width, which is significantly smaller than the charge transfer region. We show that the voltage-bias normalized responsivity is not only the highest measured-to-date in integrated graphene photodetectors, but this ultra-narrow slot design also enables the most compact device to-date. Moreover, our work provides an alternative approach for integrated graphene plasmonic detectors, which could lead to engineering an entire class of short-channel optoelectronic devices for dense integrated photonic circuits.

Abstract
In this paper we study high-intensity nanojet (NJ) beams generated at the output of dielectric multi-material elements. The proposed method for generating condensed optical NJ beams relies on the complex electromagnetic phenomenon associated with the light diffraction on the edges of constitutive parts of the studied system embedded in a host medium with lower refractive index. The possibility of NJ shift and deviation in the near zone of such a microstructure illuminated by a plane wave is demonstrated via a double-material microstructure. We examine the dependence of NJ beam behavior and orientation on the materials and dimensions of the constitutive parts.

1. Introduction
The photonic NJ is a highly focused beam of light formed in proximity to the shadow surface of illuminated transparent dielectric particles with a size/diameter comparable or somewhat larger than the wavelength of the incident optical radiation [1]. The interest in the NJ effect is mostly related to the promises of its practical applications in multiple emerging application domains, including optical sensors, light communication systems, spectroscopy, optical trapping and manipulation. In this connection, the question of controlled NJ characteristics’ manipulation attracts a growing interest.

The physics of photonic NJs generated by spherical or cylindrical particles was studied using the Mie theory [2]. The analytical method of investigation of the near field focusing phenomenon for arbitrary-shaped microstructures was proposed in [3]. The latest studies have shown that both the NJ shape and intensity depend significantly on the shape, size and optical properties of the generating microparticules [1,4,5]. In a recent paper [6], we reported that the beam geometry and field intensity enhancement can be tuned by varying the curvature of the edge line of dielectric microstructures. The photonic NJ is created due to the constructive interference of edge diffracted waves from different segments of the edge line. The formation of a curved photonic jet, named “photonic hook”, by a single-material structure was discussed in [7]. The authors present a dielectric cuboid with the addition of a wedge-shaped prism made of the same material. It was also demonstrated that if the NJ is produced by a multi-material composite (for example a radially inhomogeneous particle consisting of several concentric shells with different refractive indices or graded refractive index material) the NJ characteristics can be changed significantly [8,9].

In this work we demonstrate a solution for the design of a NJ focusing component capable of deviating the focused beam in the near zone. The proposed solution is based on a combination of different dielectric materials. The possibility to control the deviation direction and the intensity of the generated NJ beam by changing the parameters of such system was considered.

2. Problem statement
Let us consider the cuboid geometry. A cross-sectional view of the double-material NJ element is schematically illustrated in Fig. 1. The proposed microstructure combines two dielectric materials, having different refractive indexes, in such a way that all the NJ beams, originating from different edges (associated with different blocks/layers) of the system, recombine and contribute to the formation of a total NJ beam. The structure parts are made of lossless isotropic dielectric materials. It is assumed that the double-material dielectric system with refractive indexes $n_2$ and $n_3$ ($n_2 > n_3$) is embedded in a homogeneous dielectric host media with a refractive index $n_1 < n_3$. The structure is illuminated by a TM-polarized plane wave propagating in the positive z-axis direction from below.

*Figure 1: Geometry of the system.*
Our analysis shows that the angles of deviation of the NJ beams caused by diffraction of a plane wave on the edges with a base angle of 90° (vertical edge in the example) are determined mainly by the ratio of indexes of the two media in contact:

$$\Theta_{\text{B1}} \approx \frac{90° - \Theta_{\text{TIR}}}{2},$$  

(1)

where \(\Theta_{\text{TIR}} = \sin^{-1}\left(\frac{n_l}{n_2}\right), \Theta_{\text{TIR}2} = \sin^{-1}\left(\frac{n_2}{n_3}\right), \Theta_{\text{TIR}3} = \sin^{-1}\left(\frac{n_l}{n_3}\right)\) are the critical angles of refraction, \(j=1,2,3\). Let us note that the length and intensity of these three NJ beams are different. The maximal intensity and minimal length correspond to the beam with highest ratio between the refractive indexes in the expression for \(\Theta_{\text{TIR}}\).

To explain the behavior of total NJ radiated by the double-material microstructure we should determine the points of intersection of these initial NJs associated with the edges of the system and radiated at the angles \(\Theta_{\text{B1}}, \Theta_{\text{B2}}\) and \(\Theta_{\text{B3}}\).

3. Parametric study

To analyze the features of the generated NJ beam we consider data for a 2D double-material microlens computed using software package CST MICROWAVE STUDIO. It was obtained that the position of the NJ hot spot is determined by the sizes and refractive indexes of the constitutive parts.

![Figure 2](image_url)

Figure 2. Power density distribution in xz-plane at \(\lambda = 550\text{nm}\) for the systems with parameters: \(n_1 = 1, n_2 = 1.8, n_3 = 1.6, W = 1200\text{nm}\), (a) \(H = 600\text{nm}\); (b) \(H = 900\text{nm}\).

For the microstructure with total width \(W \leq \lambda\) we observe a NJ beam shift towards the part with lower refractive index \(n_1\). Changing the refractive index \(n_1\) we can tune the position of the NJ hot spot. The NJ hot spot position in \(x\) does not depend on the height \(H\) of the system. Increasing the total width of the microelements \(W > \lambda\) we can distinguish two cases corresponding to different ratios between the refractive indexes of constitutive materials. For \(n_3 < \sqrt{n_1 n_2}\), the behavior of NJ beam will be similar to the \(W \leq \lambda\) case and changing \(n_1\) we just observe the NJ hot spot shift. This similar behavior is observed in Fig. 2a for a double-material microlens with \(n_3 > \sqrt{n_1 n_2}\) and \(H < H_A\) with \(H_A\) defined as the z-coordinate of point A (see Fig. 1) corresponding to the intersection between the NJs generated by the edges of the part with refractive index \(n_2\). For \(n_3 > \sqrt{n_1 n_2}\) and \(H \geq H_A\) we get the deviation of the total NJ beam towards the part with higher refractive index \(n_3\) (Fig. 2b). It was demonstrated that in this case the generated NJ will be parallel to the line MC, where point M corresponds to the middle of the second part with lower refractive index \(n_3\) and point C is the crossing point of the NJs generated by the external edges of the microstructure.

4. Conclusions

Our analysis has revealed that diffraction of a plane wave on a microlens based on the combination of different dielectric materials, can result in a deviation of the NJ away from the normal direction. The position of the NJ hot spot, angle of deviation, intensity and shape of NJ beam can be controlled by the refractive indexes and sizes of the constitutive parts. We also demonstrate that in a case of small particles having a total width less than the wavelength the NJ beam can be shifted from the axis of symmetry of the system by tuning the parameters of the blocks.

Abstract
Precise control over the topology of guiding systems is critical for photonic applications, such as topologically protected memory/logic and quantum communication devices. Within this work, we show that by integrating modulators with a photonic waveguide system, it is possible to realize ultrafast control over topologically nontrivial photonic states. We can achieve this task by combining a system of modulators with a silicon resonator array, enabling unparalleled optical/electrical control over the topology of the system with a synthetic magnetic field.

1. Introduction
Light control in photonic systems and improved robustness to imperfections or disorder are in high demand. Recently it has been shown that by breaking time-reversal symmetry in photonic systems, it is possible to realize topologically protected states which are resistant to perturbations and back-scattering. This effort has resulted in an increased interest in a new class of topologically ordered optical systems - photonic topological insulators [1,2,3]. Some of the approaches to realize topologically protected photonic states include using metamaterials exhibiting a magneto-optical/nonlinear responses, engineering photonic crystal dispersion, as well as introducing synthetic magnetic field for photons. Precise control of topologically protected states can potentially open new frontiers of light-matter interaction and lead to many applications, such as topologically protected memory/logic devices, compact optical isolators, unidirectional waveguide systems, and numerous quantum communication applications.

2. Discussion
There are numerous ways of synthesizing gauge magnetic field in a photonic system. Here, we utilize the approach proposed in [4] and use a 2D array of coupled ring resonators (Fig. 1d). These “site” resonators are coupled by evanescent fields to the ring waveguides, which provide transfer to their nearest neighbors, while “link” waveguides are detuned from resonance wavelength, thus making all the energy confined in the site rings. External gauge magnetic field is synthesized by shifting one of the link waveguides located horizontally between the site rings, in the vertical direction by offset $\xi$. With this shift, photons going anticlockwise (clockwise) around the plaquette acquire a phase shift of $\alpha$ ($-\alpha$), $\alpha = 2\pi \phi = 4\pi n_{\text{mod}} \xi / \lambda$. The Hamiltonian of such system can be written as,

$$H_0 = \sum_{x,y} \hat{a}^\dagger_{x,y} \hat{a}_{x,y} - J \sum_{x,y} \left( \hat{a}^\dagger_{x+1,y} \hat{a}_{x,y} e^{-i\alpha} + \hat{a}^\dagger_{x,y} \hat{a}_{x+1,y} e^{i\alpha} \right).$$

Here $\hat{a}^\dagger_{x,y}$ ($\hat{a}_{x,y}$) is a creation (annihilation) operator at a $(x,y)$ site, and $J$ is the effective tunneling rate between resonators. Figure 1 shows that a finite size system of coupled resonators with the gauge field supports topologically protected edge state as well as bulk states. Within this work, we propose employing a system of modulators to achieve tunability of the gauge magnetic field by modulating the effective refractive index of the link waveguides, i.e., to tune the Aharonov-Bohm phase $\alpha$, and hence, to control the topology. There are different ways of introducing phase modulation into a silicon-on-insulator waveguide. We consider the use of either thermal modulation of titanium nitride or optical/electrical nonlinear modulation.

Fig.1 (a) Hofstadter butterfly spectrum for a 15×15 resonator system. Eigenfunctions of the three different states: (b) $\alpha_M^{(1)} = 0.45$ - topologically protected state with unity Chern number $C_{+1}$, (c) $\alpha_M^{(2)} = 0.5$ (trivial state), (d) $\alpha_M^{(3)} = 0.55$ - topologically protected state with negative Chern number $C_{-1}$. Arrows show direction of propagation of probability currents in corresponding edge states.
of transparent conducting oxides (TCOs) for ultrafast control of topology of the system. Using the transfer matrix method, we analyze a dynamically tunable platform that integrates a thermal heater with a photonic system and comprises an array of 15×15 site microring resonators. To enable the gauge magnetic field \( \alpha_{M}^{(1)} = 0.45 \) the geometric offset of the link waveguides should be \( \xi = 215 \) nm. Thermal heaters are off: this regime corresponds to topological protection state \( \alpha_{M}^{(1)} \) with \( C_{+1} \) Chern number. Figure 2a shows field distribution of 15×15 resonator array at a working wavelength of \( \lambda = 1.305 \) \( \mu \)m.

Following the prediction of the tight-binding model, this state enables backscattering-free clockwise propagation of the topologically protected edge mode. An input power of 25 mW is applied to each thermal heater to realize topological phase transition which brings the system into the trivial state with \( \alpha_{M}^{(2)} = 0.5 \). All of the supported modes at this state are topologically trivial and correspond to bulk modes. Figure 2b depicts the field distribution corresponding to \( \alpha_{M}^{(2)} \) -state. By applying an input power of 50 mW, we realize topological phase transition that places the system into the topologically protected (\( \alpha_{M}^{(3)} = 0.55 \)) state with \( C_{-1} \). Figure 3c shows the topologically protected edge mode at this state; it corresponds to counter-clockwise propagating, backscattering-free edge mode.

3. Conclusions

In this work, we demonstrate the concept of the tunable topological phase transition realized in a photonic system arranged of a coupled ring resonator array. We show that by integrating an array of modulators in the system, it is possible to introduce an additional propagation phase, superimposed on top of the phase shift created by a geometrical offset of the link couplers. This approach opens up a new way to precise control over gauge magnetic field, which in turn leads to flexible, on-demand control over the topology of the photonic guiding systems.

Abstract

We discuss recent results for Anderson localization in synthetic photonic lattices. We present the results for the spectra and both dynamic and modal participation number for systems with both phase and coupling static disorder.

1. Introduction

Recently the topic of synthetic dimension attracted much attention in the field of photonics [1]. The concept of synthetic photonic dimension allows one to use extra degrees of freedom either via the frequency space of coupled resonators or pulse time-multiplexing in coupled fibre loops in addition or even instead of traditional geometric dimensions. In particular time-multiplexing can realize different multicomponent synthetic photonic lattices (SPL) that can model a variety of physical systems: from geometric mesh lattices to discrete time random walks [2, 3]. The dynamics of light in coherent SPLs is now quantified extremely well both theoretically and experimentally. On the other hand the effects of disorder on pulse evolution in such systems is a much less studied area. Here we present some recent theoretical results on Anderson localization in SPLs for both random phase and coupling modulation [4, 5, 6].

2. Theoretical model

Synthetic photonic lattices can be realized either by considering two linearly coupled fibre loops of unequal length [3] or an array of waveguides which are periodically coupled together in discrete interval [2]. The discrete “time” variable has either the meaning of the round trip number in a loop or the number of a physical layer in a mesh. For each round trip or layer number \( m \) the system is completely described by a two-component vector \( \mathbf{X}^m = (U_m, V_m) \) where discrete index \( n = 1, ..., N \) counts the time lag position in the two loops or array cites in the effective mesh. The dynamical evolution of the state of the system amounts to iterating a unitary map \( U_{m+1} = \mathcal{U} \mathbf{X}^m \) between the round trips. General localization properties in such systems can be studied by looking at the eigenstates of this step operator defined as solutions of \( \mathcal{U} \mathbf{X} = z \mathbf{X} \), \(|z| = 1\).

There are several ways in which disorder can be introduced into the system: either by inserting phase modulator(s) into one or both fibre loops thus realizing phase disorder [4] or/and modulating the coupling coefficient between the loops (e.g. via integrated Mach-Zehnder interferometers with switching time of 100 ns or less). Motivated by this we consider a generic static eigenproblem [3, 4, 5, 6]:

\[
\begin{align*}
z U_n &= e^{i\phi_{+}(n)} (\cos \theta_{n+1} U_{n+1} + i \sin \theta_{n+1} V_{n+1}) \\
% \begin{align}
% z V_n &= e^{i\phi_{-}(n)} (\cos \theta_{n-1} V_{n-1} + i \sin \theta_{n-1} U_{n-1})
% \end{align}
% \end{align}
\]

where it is assumed that random phases due to phase modulators \( \phi_{\pm}(n) \) are i.i.d. uniformly distributed in the interval \([-\Phi_+, \Phi_+]\) with the parameter \( \Phi_+ \) serving as the effective strength of disorder. The effective angles \( \theta_n \) are responsible for the coupling and are also assumed i.i.d. uniform in the interval \([\pi/4 - \theta_*, \pi/4 + \theta_*]\). The pulse in the longer loop \( (U_n) \) “overshoots” the location over one round trip by one time position similarly as the pulse in the longer loop \( V_n \) undershoots by the same amount. The dynamical evolution of the field distribution in both loops is obtained by iterating the map in the r.h.s. of Eq.(1).

3. Results and discussion

Theoretical results on Anderson localization for pure phase \( (\theta_* = 0) \) or coupling \( (\Phi_* = 0) \) disorder were obtained previously in Refs. [4, 5, 6]. It is known that in the presence of phase disorder all eigenstates are localized while in the case of pure coupling disorder there exist delocalized states near the band centre which however have minimal effect on pulse spreading due to their small overlap with the localized initial pulse [6]. Here we concentrate on the most general case of mixed disorder. In order to quantify localization phenomenon we study the so-called participation number (PN) defined for the shorter loop as \( P_U = (\sum_n |U_n|^2)^2 / \sum_n |U_n|^4 \) and similarly for \( V \). The PN serves as a measure of localization length in both loops and can be defined for each mode (modal PN) or in the dynamical settings where a single pulse introduced in an upper/lower loop evolves between round trips thus leading to dynamical PN \( P_{U/V} \). The results of both types of simulations runs are given in Fig.1. The numerical simulation of the pulse evolution was performed by iterating the map with \( N = 500 \) time positions (synthetic mesh points) subject to periodic boundary conditions. The results were averaged over an ensemble of 50 realizations of combined phase and coupling disorder. The left panel was obtained by numerical diagonalization of system (1) calculating the PN for each mode/loop and selecting the maximum value corresponding to the least localized mode. In the second pane we consider a pulse inserted in the shorter
loop at position $n_0 = N/2 = 250$ and follow the evolution of the dynamical PN for different types of disorder. For brevity only the results for the shorter loop ($U_{n_0}$) are shown. It is seen that the minimal participation ratio (minimum spread) is achieved largely by the coupling disorder alone and adding phase disorder contributes less than 10% to further delocalization. The ratio of the asymptotic levels of PN for two separate types of disorder is found to be: $P_{\text{as}}(\text{phase})/P_{\text{as}}(\text{coupling}) \approx 1.35$.

The typical SPL spectra are given in Fig. 2 (a). We plot quasi-energies $\beta$ (the effective propagation constants) given by the relation $\exp(i\beta_j) = z_j$ for $j$-th eigenmode. Without disorder there is a bandgap of the size $\Delta = \pi/2$ corresponding to the well known spectrum given by $\cos \beta = (1/\sqrt{2}) \cos(k)$ where $k$ is a properly normalized wavevector spanning a well-defined Brillouin zone $[-\pi, \pi]$. As the disorder is switched on the band-gap starts to close. Note however that the the coupling disorder alone does not appear to be able to close the gap completely as opposed to the phase disorder which manifests itself more strongly. The dependence of the bandgap on disorder levels is given on the second panel of Fig.(2).

**4. Conclusions**

To conclude, we have quantified the phenomenon of Anderson localization in synthetic photonic lattices subject to most general type of disorder combining both random phase and coupling modulation. It is shown that phase localization effects are generally much stronger than those of the fluctuating coupling coefficient. In the case of pure coupling disorder the bandgaps between the Floquet-Bloch modes is still open although diminished almost by a factor of 2. In both cases the disorder arrests the pulse propagation although the asymptotic participation number for the coupling disorder is found to be smaller signifying stronger localization.

Quantum information processing is a rapidly developing research field. The exploitation of quantum bits instead of classical bits offers key advantages for future technologies including secure communication and ultra-fast computation. Lab-size experiments on quantum information processes have already proven the validity of its concepts. However, any wide spread utilization will require dense integration of functionalities. This requires the realization of semiconductor integrated quantum photonic circuits on a single semiconductor chip with embedded sources, photon processing units and detectors on the single photon level. Among the different material platforms currently being investigated, direct-bandgap semiconductors and particularly gallium arsenide (GaAs) offer the widest range of functionalities, including single and entangled-photon generation by radiative recombination, low-loss routing, electro-optic modulation and single-photon detection. We review recent achievements in quantum integrated photonic components and circuits based on the GaAs technology platform [1]. All key functionalities, including single-photon sources and single-photon detectors, integrated auto-correlators and tuneable Mach-Zehnder interferometers have been realized and tested. These results lay the foundation for a fully-functional and densely integrated quantum photonic technology based on GaAs components.

Holey metal films for sensing applications - Impact of nonlocality on extraordinary optical transmission

Christin David1*, Johan Christensen2

Abstract

Electron-electron interactions in metals are neglected in classical electrodynamics. Though short-ranged, they can have a remarkable impact on the optical response of metals. The excitation of additional pressure waves and anomalous diffraction lead to a substantial change in the bandstructure and electromagnetic fields supported by a nonlocal holey metal film with respect to the classical local response approximation even at large geometrical parameters. In contrast to homogeneous nonlocal metal films, spatial dispersion is found to emerge also at normal incidence.

1. Introduction

First principle methods can accurately describe atomistic matter, but they are strongly restricted in the maximum system size that can be described with available computational resources [1, 2, 3]. Theoretical efforts continue to pursue the extension of classical electrodynamics to scalable, semi-classical descriptions, which allow describing much larger systems. In recent years, experiments to verify effects stemming from the quantum nature of free electrons in metal nanoparticles were made [4, 5, 6]. For instance, the Generalized Nonlocal Optical Response (GNOR) [7, 8] is based on coupling the hydrodynamic equation for the interacting, free electron gas to the electromagnetic wave equation [9, 10]. Hereby, the dynamics of the free electron gas at the nanoscale is corrected to include Coulomb interaction and diffusion effects via \( \bar{D}(\vec{k}, \omega) = \epsilon(\vec{k}, \omega) \bar{E}(\vec{k}, \omega) \) instead of using the common local response approximation \( \bar{D}(\omega) = \epsilon(\omega) \bar{E}(\omega) \) of classical electrodynamics, excluding the aforementioned short-ranged electron-electron interactions. This has recently been extended towards two-fluid models for semiconductors (separating electron and hole dynamics) [11, 12], as well as electrolytes (separating the dynamics of positive and negative ions) [13]. Such nonlocal effects are inherently nonlinear.

Here, we consider two-dimensional, subwavelength hole arrays in metal films, which are equally a source of nonlocal electron dynamics. We discuss the impact of spatial dispersion in plasmonic crystal films using GNOR extending established periodic crystal concepts such as the Rigorous Coupled Wave Analysis (RCWA) [9, 14, 15].

2. Discussion

Figure 1 depicts the different modules within RCWA. Different geometries are addressed via the Fourier transform of the permittivity describing a unit cell of the structure. Multilayers, homogeneous or structured, are combined with propagation steps using an iterative scattering matrix scheme. Introducing electron interaction effects alters parts of the standard modules. However, by evaluating the additional boundary condition given by the hydrodynamic equation in a first step, we can find a formulation that does not alter the iterative scheme of the propagation steps of the scattering matrices [9]. However, they add an additional, scalar eigenvalue equation which increases the computational effort moderately.

The excitation of additional pressure waves and anomalous diffraction leads to a substantial change in the band-
structure and electromagnetic fields supported by a nonlocal holey metal film with respect to the classical local response approximation, see Fig.2, even at surprisingly large geometrical parameters. In contrast to homogeneous nonlocal metal films [16], spatial dispersion emerges also at normal incidence. We discuss in detail the dependence on different illumination parameters and geometrical configurations of holey metal films. Assuming the presence filling of the holes with a dielectric of larger refractive index, we also discuss the shift of nonlocal features with the dielectric constant.

3. Conclusions

This impacts many concepts and applications in photonics such as imaging and extraordinary optical transmission (EOT). This contributes to the understanding of spatial dispersion in promising building blocks for photonic circuits, bio-chemical sensing and spectroscopy.

Abstract

The mid-infrared (MIR) spectral range offers various applications in chemical detection, food safety and biosensing. However, trace detection still remains challenge due to weak light–matter interaction between infrared light and nanoscale molecules. Fortunately, polar dielectrics have ability to achieve optical sub-diffraction confinement and in the MIR spectral range through surface phonon polariton (SPhP) modes. Here, we demonstrate SiC nanoring metasurfaces to achieve high local field enhancement and control the detection frequency by varying structure parameters.

Introduction

The mid-IR to THz spectral ranges offers a wealth of potential applications in astronomy, thermal radiation and imaging [1]. Among various applications, biological detection is particularly important because it closely related to human safety and health. However, the weak light–matter interaction between infrared light and nanoscale molecules reduces the detection efficiency. Fortunately, polar dielectrics possess ability to achieve sub-wavelength confinement in the mid-IR band through the stimulation of surface phonon polariton (SPhP) modes, which can be used to fabricate nanophotonics devices in MIR applications [2, 3]. Here we demonstrate 4H-SiC nanoring metasurfaces for MIR detection and sensing. Because of the strong local field confinement, the interaction between light and molecules are significantly enhanced. By tuning the outer radius, inner radius, and the period of metasurfaces, the nearly full Reststrahlen band can be effectively utilized.

Discussion

The SPhP modes excited in 4H-SiC are stimulated between the transverse optical phonon (TO) frequencies at 797 cm−1 (12.5 μm) and the longitudinal optical phonon (LO) frequencies at 973 cm−1 (10.3 μm), referred as Reststrahlen band. 4H-SiC nanoring metasurfaces can provide localized SPhP modes with low optical losses, high field confinement and broad band spectral tunability. Finite element theory (FET) simulations were performed with optical constants of 4H-SiC from Handbook of Optics. The metasurfaces are illuminated by p-polarized plane wave within the xz-plane at an incident angle of 25°. A typical reflection spectra from FEM calculation are shown in Fig. 1a with outer radius r_o=0.5 μm, inner radius r_i=0.25 μm, and period p=3 μm. Four reflection valleys are attributed to the excitation of SPhP modes. Fig. 1b and 1c demonstrate the normalized electric field intensity at first and second valleys. Strong field enhancement is obtained around SiC nanoresonators, which can be applied to improve detection sensitivity.

Figure 1: (a) simulation reflection spectra of 0.5 μm outer radius, 0.2 μm inner radius and 1 μm high 4H-SiC nanorings on a square lattice with 3μm period. (b) Normalized electric field intensity in the x = 0 plane and y = 0 plane for the m mode and d1 mode, respectively.

As discussed previously, the occurrence of monopole (m) stimulated by the vertical component of electric field is attributed to the negative permittivity of both the nanoring resonators and the underlying SiC substrate. Apart from the monopolar mode, three transverse dipolar modes (d1, d2 and d3) are excited by the inplane electric field. According to interaction between nanoring resonators and substrate, the first two dipolar modes are identified as bonding mode and last dipolar mode is identified as antibonding mode. As depicted in Fig 2a and Fig 2b, bonding mode corresponds to the condition that like charges distributed in both nanoring...
resonators and substrate, while antiboding mode corresponds to the condition that dissimilar charges distributed in nanoring resonators and substrate respectively.

Figure 2: 3D views of the charge density of three transverse dipolar modes. The insets show schematic charge configurations of one nanoring for the corresponding modes, with “+” and “−” denoting the charges. (a) d1 and d2 modes. (b) d3 mode.

By varying outer radius, inner radius, period of SiC nanoring metasurfaces, four resonance modes can be effectively tuned throughout the Reststrahlen band. Fig 3 demonstrates the tunability of SiC nanoring metasurface.

Conclusions

In summary, we demonstrate that SiC nanoring metasurfaces exhibit excitations of monopolar resonances and dipolar resonances. This intriguing resonances offer strong field confinement around the nanoring resonators. Furthermore, we details study all the modes supported in these metasurfaces and state their spectral dependence on the structure parameters through simulations. This work shows that SiC nanoring metasurface provide promising candidates in mid-IR nanophotonics.

Abstract

We report on the development of repeatable surface enhanced Raman scattering (SERS) probes realized onto optical fiber tips (OFTs) through nanosphere lithography. We first evaluated the SERS performances pertaining to different patterns with different nanosphere diameters and gold thicknesses, then the SERS-OFT performance. The analysis allowed us to identify the most promising SERS platform, exhibiting an Enhancement Factor of $4 \times 10^5$ and a SERS measurements variability lower than 10\%. Current activities are devoted to realize Lab-on-fiber SERS probes for human Thyroglobulin, a protein marker of differentiated thyroid cancer.

1. Introduction

SERS is an analytical technique that allows the detection of molecules at extremely low concentrations and with high specificity. The unique advantages offered by optical fibres represent a valuable platform for SERS sensors in biological and biomedical applications. Additionally, the use of self-assembly fabrication approaches to realize reproducible SERS active surfaces on the optical fiber tips can provide a significant technological advancement by granting low fabrication costs and high throughput.

Recently, the use of self-assembly in combination with optical fiber technology has been strongly revisited and revitalized. Indeed, alongside the “Lab on Fiber” technological advancements in the use of conventional lithographic approaches on the optical fiber tip, self-assembly techniques have progressed and have been demonstrated as a reliable tool for the fabrication of regular nanostructures on the optical fiber tip [1-2]. Lithographic processes based on breath figures formation or nanosphere self-assembly [3-5] have been successfully used to create well ordered and regular metal-dielectric patterns on the fiber tip. In particular, in a recent work, after assessing the process repeatability, proof of principle of the SERS ability of close-packed arrays (CPA) of polystyrene (PS) nanospheres, covered by thin films of gold, has been provided [5]. With regards to the selection of the optical fiber, an ideal fiber probe should have low dopant concentration in the fiber core, high numerical aperture (NA), and small core size, in order to reduce the background and to maximize both the collection efficiency and the coupling between the fiber and the Raman spectrometer. Nonetheless, these parameters are not independent and the “a priori” identification of the optimum configuration among different commercial fiber probes is not trivial.

Starting from the promising results achieved in terms of reproducible metal-dielectric patterns on the optical fiber tip, we first investigated the SERS performances through the evaluation of the Enhancement Factor (EF). Then, we selected several commercially available optical fibers and tested them to identify the best fiber platform providing the best performances in terms of Raman excitation/collection efficiency and related background. Current work is devoted to the functionalization of the identified fiber probes for the ex-vivo detection of human Thyroglobulin.

2. Experimental results

In order to measure the performances of the SERS surfaces, independently from the selected fiber probe,
we fabricated the SERS samples in planar configuration (on the coverslip slides, quartz CFQ-2557, UQG Optics, 150 µm thickness). The fabrication process follows the procedure described in ref [5]. In order to estimate the EF of the fabricated SERS active surfaces, we used the biphenylthiol (BPT) monolayer as benchmark analyte. The resulting EF as function of the CPA diameter and gold thickness, revealed that the highest measured EF of 4.0x10^5 can be achieved with the CPA geometry characterized by a PS diameter of 500 nm and nominal gold thickness of 30 nm. The different SERS substrates were investigated also in terms of repeatability by mapping the intensity of the BPT band at 1590 cm\(^{-1}\) within the same sample (intra-sample) and among different samples (inter-sample). Also in this case, the best repeatability has registered for the CPA samples with PS diameter of 500 nm and nominal gold thickness of 30 nm.

With regard to the selection of the most suitable fiber probe, we collected commercially available fibers with a core of pure silica and operating in the visible spectral range with different core diameter (ranging from 50 up to 400 µm), different cladding materials (fluorine-doped silica or hard polymer) and different NAs (from 0.22 up to 0.5). We show the Raman spectra (Figure 1), in the range between 750-1800 cm\(^{-1}\), obtained by illuminating the BPT solution, and collecting the scattered light through different optical fiber probes. When we use the fiber FG050LGA and FG105LGA, the silica band at 800 cm\(^{-1}\) is particularly intense obscuring the BPT peak due to v(S-C) around 757 cm\(^{-1}\). Similarly, also the three BPT peaks in the wavenumber region 950-1100 cm\(^{-1}\) have an unfavorable signal-to-background ratio. Interestingly, when we use the fibers with larger core diameter (FP200ERT and FP400ERT) and larger NA the interference with the silica Raman bands decreases and even the small BPT band at 757 cm\(^{-1}\) becomes visible. As a result, a good compromise to have a high intensity for the BPT fingerprint (which requires a small fiber core diameter) and a low silica background (which requires a fiber with large diameter) can be reached with the optical fiber FP200ERT, which maximizes the difference between the signal and the background.

3. Conclusions

In conclusion, we investigated the possibility to engineer Lab-on-Fiber SERS optrodes in order to provide advanced and repeatable SERS substrates integrated on the optical fiber tip. To this aim, we assessed the performances in terms of true EF pertaining to SERS substrates composed of hexagonally CPAs of PS nanospheres with different diameter (d = 500, 750, 1000 nm) and different gold film thickness (h = 20, 30, 40 nm). Additionally, the different SERS substrates were investigated in terms of SERS intensity repeatability (intra- and inter-samples). As a second important step towards engineering of the SERS optrode, Raman excitation/collection efficiency and related background pertaining to different commercially available optical fibers were investigated using a reference BPT solution as benchmark. As a result, we found that CPA geometry with PS diameter of 500 nm and nominal gold thickness of 30 nm exhibited the best performance and we selected the fiber probe with core in pure silica, 200 µm diameter and high numerical aperture (i.e. 0.5) because it offered a favorable trade-off between collection efficiency and background. Following these developments, current activities are devoted to the assessment and exploitation of the investigated sensing platform for human Thyroglobulin detection.

Abstract

Optical solar reflectors (OSRs) play a crucial role in the thermal control of a spacecraft. We present novel meta-surface-based OSRs using metal oxides, e.g. Al-doped zinc oxide (AZO) and vanadium dioxide (VO2). Our AZO-based meta-OSRs have been optimized for a high infrared emittance and low solar wavelength absorption. VO2-based meta-OSRs have demonstrated a superior emittance tunability and lower solar absorption than the planar film. Both meta-OSRs have been comprehensively tested for their robustness required by space applications.

Keywords: meta-surface, radiative cooling, perfect absorption, plasmonics, optical solar reflectors, transparent conductive oxide.

1. Introduction

Optical solar reflectors (OSRs) play a crucial role in the thermal control of a spacecraft since they are the physical interface between the thermal management system and the space environment. To avoid solar heating and achieve radiative cooling, an ideal OSR is required to reflective all energies in the UV/Vis/NIR spectrum and emit those at the thermal infrared spectrum (blackbody radiation spectrum). OSRs are conventionally formed through quartz tiles or silver-coated fluorinated ethylene propylene (FEP) foils. The former suffers for its poor mechanical robustness and launch cost and the latter is constraint for its low lifetime at harsh space environment. Therefore, there is a need for a thin-film technology using durable, radiation resistance hard coatings.

Recently, metal oxides have been investigated for their suitability in infrared plasmonics [1]. In this work, we report the results of H2020 Meta-reflector and Smart-Flex projects on a meta-optical solar reflector (Meta-OSR) based on Al-doped Zinc Oxide (AZO) and a smart Meta-OSR based on VO2. Here, VO2 is used for its thermochromic characteristics as dielectric below transition temperature and metallic above transition temperature and therefore forms a smart meta-OSR with a tunability against temperature change.

2. Results and Discussions

The proposed structure is a traditional Salisbury screen consisting of a stack of three layers: the metal back reflector, the dielectric spacer layer and the TCO meta-surface [2] [3]. The performance of an OSR is defined by its solar spectrum absorption (α) and infrared spectrum emittance at 300 K (ε). The emittance, ε, is defined as the averaging emissivity weighted by the theoretical blackbody spectrum at the operating temperature (T) in Kelvin:

$$\epsilon = \frac{\int_0^\infty \epsilon_T \rho(\lambda,T)d\lambda}{\int_0^\infty \rho(\lambda,T)d\lambda}$$

where $\lambda$ is the thermal conductivity, B(λ, T) is the blackbody spectral distribution at temperature T, given by Plank’s equation.

2.1. AZO-based Meta-OSRs

Figure 1a shows the proposed AZO-based meta-OSRs on flexible foil fabricated through nanoimprint patterning technique. The foil in the figure is 80 mm × 80 mm and the AZO array is designed as 1350 nm square with a gap of 250 nm. Figure 1b shows the UV/Vis and FTIR absorption spectra of a meta-OSR with an array of square varying from 750 to 1350 nm and a gap of 150 nm. The solar and 200 K black body spectrum are also presented as references. Infrared absorption are seen broader for square array than the planar film owning to the plasmonic resonance whilst the UV/Vis absorption are consistent in Fabry-Perot fringes. The optimized OSR gives an alpha of 0.16 and epsilon of 0.79. With a further UV reflective cladding, the performance can be further improved to alpha of 0.12 and epsilon of 0.80 and these performance well meet the requirement of space applications.
2.2. VO₂-based smart OSRs

Figure 2a shows the UV/VIS and FTIR absorption spectra of a VO₂-based smart meta-OSR with an array of VO₂ squares of 2.8 µm and a gap of 0.5 µm measured at 25°C and 80°C. The infrared absorption is significantly increased when temperature is increased to 80°C. For smart OSRs, the emittance tunability (Δε) is the figure-of-merit. Figure 2b shows extracted Δε as a function of square size at different gaps. Meta-OSRs for all feature size with a gap of 0.5 µm achieve higher Δε than planar film, whilst the Δε improvement decreases with the increase of gap size and even below the planar film. This is attributed to the reduction of VO₂ filling ratio of the whole surface. The best smart-OSR gives an emittance tunability of 0.49. In addition, the reduction of VO₂ coverage would positively contribute to a lower solar absorption.

3. Conclusions

We report metal oxide based meta-OSRs for space applications. The fabricated AZO meta-OSR shows an improved performance than the planar structure and the best structure shows an infrared emittance ε of 0.79 and solar absorption α of 0.16. The fabricated VO₂ smart meta-OSR show a superior emittance tunability Δε of 0.49. Both meta-OSRs have been demonstrated to be able for scaling up to large area flexible substrate through nanoimprint. Comprehensive robust tests have been performed to test their durability at harsh space environment.

Abstract
Radiation pressure from the sun can exert a force on spacecrafts that can either be beneficial, in the case of solar sail propulsion, or harmful, in the case of satellites in predefined orbits. Thus, there is a need for a way to control this radiation pressure. Here we present our latest work on switchable reflectivity materials to actively control the radiation pressure exerted on a spacecraft to enable real-time attitude control and maneuvering. We will discuss our first generation proof-of-concept devices, preliminary space environment testing, and provide a future outlook for this technology.

1. Introduction
Solar sails offer an opportunity for a cubesat-scale, propellant-free spacecraft technology to enable long-term and long-distance missions not capable with traditional methods. In principle, to propel such a craft, no mechanically moving parts, thrusters, or propellant are needed. However, in practice, attitude control is still performed using traditional methods involving reaction wheels and propellant ejection, which severely limits mission lifetime and increases costs. For example, the current state of the art solutions implored by the recent Near-Earth Asteroid Scout mission couple the solar sail subsystem with a state of the art propellant ejection gas system. However, gas thrusters have a limited supply of propellant, which reduces the lifetime of the mission to less than three years.

To replace the traditional gas thruster system for attitude control, we are using propellantless attitude control through an electrically switchable optical film [1]. The technology is based on a polymer-dispersed liquid crystal (PDLC), similar to IKAROS; however, my switching between transparent and diffusely reflective (rather than switching between specular and diffuse reflection) upon application of a voltage, a factor of >4 improvement is achieved. This technology removes the need for propellant, which will reduce weight and cost while improving performance and lifetime.

Figure 1: Reflective control device. (a) Schematic of a solar sail incorporating polymer dispersed liquid crystal (PDLC) devices along the edge to actively modify the radiation pressure. (b) PDLC device in operation changing between diffusely reflective (left) and transparent (right) states.

2. Discussion
The ability to control radiation pressure could enable a wide-variety of functionalities for solar sail missions. We have previously performed experiments to measure the radiation pressure on microcantilevers [2] and have recently exploited the wave nature of light to create optical forces that take advantage of interference effects in thin films [3]. Further, we have shown that PDLCs can be combined with photovoltaic materials to allow for self-powering of dynamically switchable reflectivity [4], which may have additional advantages in space missions.
3. Conclusions

In summary, the ability to actively control the reflectivity of materials may provide significant advantages over traditional actuation methods for advanced solar sail technologies.

Relative and Absolute Phase Control of Lasers

Firooz Aflatouni1,*

1Department of Electrical and Systems Engineering, University of Pennsylvania
*corresponding author, E-mail: firooz@seas.upenn.edu

Abstract
In this paper a review of our work on optical phased arrays and laser stabilization systems is presented. The relative phase between semiconductor lasers are controlled through heterodyne phase locked loops forming a laser phased array. An integrated Pound-Drever-Hall stabilization system is presented that reduced the frequency noise of a commercially available laser by more than 25 dB. In another PDH chip, the linewidth of a distributed feedback laser is reduced from 246 kHz to 7 kHz using an off-chip resonator.

1. Introduction
Relative phase control of lasers has many applications such as realization of high power efficient light sources through coherent power combining of multiple semiconductor lasers, phase modulation and demodulation, and laser phased arrays. To control the relative phase between semiconductor lasers, an array of lasers can be phase locked to a reference laser using an array of electro-optical phase locked loops (EOPLL), where the relative phases between the semiconductor lasers can be adjusted electronically [1][2]. Using this method, we have implemented a laser phased array and demonstrated beam-steering [3].

Absolute phase control of a semiconductor laser, where the laser phase noise is reduced, has many applications from coherent communication to spectroscopy and sensing. One method often used for laser phase noise reduction (and stabilization) is the Pound-Drever-Hall (PDH) method, where the frequency of a laser is measured using an optical frequency reference and the error signal in the electrical domain is fed back to the laser suppressing the frequency fluctuations of the laser. We have demonstrated an integrated PDH system, where an on-chip Mach–Zehnder interferometer is used as the frequency reference to reduce the frequency noise of semiconductor lasers by more than 25 dB [4]. In another work, we have implemented a PDH chip that reduced the linewidth of a distributed feedback laser from 246 kHz to 7 kHz using an off-chip resonator [5].

2. Relative optical phase control
Figure 1(a) shows the block diagram of a 2-element laser array where each laser is phase locked to a reference laser using a heterodyne EOPLL. In each EOPLL, the beat-note between the reference laser and the semiconductor laser (SCL) is amplified and down-converted using a heterodyning RF reference. Under the lock condition, the phase difference between the two lasers can be set by the phase of the RF reference [2]. The instantaneous relative phase between the two SCLs is detected by photo-detecting their beat-note after the beam-splitter. The photo-current is injected to the control voltage of a voltage controlled oscillator (VCO) shifting the heterodyning frequency of EOPLL 2 correcting for this relative instantaneous phase error. Figure 1(b) shows the beam-steering performed using the two-element laser phased array.

Figure 1. (a) Block diagram of the 2-element laser phased array. (b) The horizontal far-field intensity distributions demonstrating beam-steering by electronic phase shifts of $\Delta \phi_{1} = 0$, $\Delta \phi_{2} = 90^\circ$, $\Delta \phi_{3} = 180^\circ$, and $\Delta \phi_{4} = 270^\circ$. 
3. Absolute phase control of lasers

Figure 2(a) shows the block diagram of the implemented on-chip PDH system. An electrical local oscillator (LO) is used to modulate the output of the laser using a modulator generating sidebands around the carrier frequency. The phase modulated signal passes through the reference MZI. The MZI output is photo-detected and converted to a voltage and mixed with the output of the LO. The mixer output is low-pass filtered, and injected to the gain section of the laser to close the PDH feedback loop. Figure 2(b) shows the frequency noise of the laser before and after PDH stabilization where a 25.5dB frequency noise reduction is observed. Figure 2(c) shows the block diagram of the integrated PDH system with an off-chip Fabry-Perot cavity as the frequency reference.

Fig 2(d) shows the beat-note spectrum for free-running and PDH stabilized cases, where the FWHM linewidth of the free-running DFB laser (emitting 12 dBm) is reduced by a factor of 35 (from 246 kHz to 7 kHz). The resolution bandwidth for these measurements was set to 10 kHz.

Abstract

Spacecraft temperature stability and control is achieved using bulky solutions, like thermal heat pipes or technologies that use moving parts like mechanical louvres. Thermal control surfaces are an attractive alternative since they are mechanically compliant and solid-state solutions. We present micro-patterned silicon coated with a phase change material as a passive thermal control surface.

1. Introduction

Given the large external temperature variations in space ranging from 150K to 400K [1], spacecraft thermal control coatings play a critical role in spacecraft thermal management. Design, fabrication and optimization of these devices requires an in-depth understanding of the thermal coating’s solar absorptance and hemispherical emittance. Conventional solutions include thermal heat pipes [2,3] and mechanical louvers [4], while current state of the art coatings include electrically actuated electrochromic devices [5]. For select applications with zero solar irradiance incident on a spacecraft’s particular facet, i.e. solar absorptance is not a concern, we present an alternative passive thermal control coating that can maintain a target temperature coinciding with the transition temperature of the incorporated phase change material. In this design we use micro-patterned features coated with a phase change material to achieve thermal stability via passive, thermally actuated emissivity changes and show a 10x difference between high and low temperature states.

2. Achieving Dynamic Emissivity

To achieve passive thermal regulation, appreciable emissivity differences in the thermal coating above and below a target temperature must be achieved. To demonstrate the concept, we use vanadium dioxide (VO2), a phase change material, that exhibits appreciable electrical and optical refractive index swings between its dielectric and metallic states, delineated by a phase transition temperature of 68 °C [6].

2.1. Material and Optical Design

Our design consists of an array of electromagnetic impedance tapering silicon (Si) micro-cones coated with a thin layer of VO2. Transfer matrix method simulations were used to sweep through the parameter space (VO2 thickness, micro-cone height and pitch) to capture the broadband (2.5 µm to 30 µm) emissivity response. Shown in Fig. 1 is the emissivity response of an optimal design with micro-cone height, h = 10 µm, lattice constant, a = 1 µm, VO2 thickness, t = 40 nm and Si substrate thickness, tsub = 300 µm.

![Diagram](a)

![Graph](b)
2. Physical design parameters for the (a) VO$_2$ coated silicon micro-cones and (b) its emissivity below and above the phase transition temperature.

3. Thermal Balance

![Figure 2](image)

Figure 2: The temperature dependent model in [7] with the assumption of a 10 K wide phase transition is used to calculate the radiated power for the micro-cone coated, thin-film and uncoated, flat silicon substrate.

Taking the angle-averaged emissivity from the TMM simulations, we then calculate the radiated thermal power across the 2.5 µm to 30 µm spectral range as detailed in [7]. Fig 2 shows the total radiated power calculated for the micro-cone coated device exhibiting a $P_{rad}$ of 517 W/m$^2$ for the metallic (unfilled green circle) and 56 W/m$^2$ for the insulating (filled green circle) states at 330 K. For comparison, an uncoated silicon substrate and coated thin-film substrate are considered, as well. The uncoated Si exhibits zero thermal regulation while the VO$_2$ coated micro-cones, exhibit thermal regulation, but with a much smaller dynamic range between its metallic (unfilled pink diamond) and insulating (filled pink diamond) states, respectively.

4. Conclusions

We have investigated and shown a viable realization for thermal control using passive thermal coatings. Although, we have chosen a specific phase change material and micro-feature in this investigation, the design concept can be applied more broadly for other applications with specific target temperatures. Our device exhibits 20x improvement in temperature stability relative to an uncoated silicon substrate. This passive, solid-state solution could augment or replace current thermal radiatively cooled mechanical solutions.

Optical rectification and resonant absorption in active nonlinear metasurfaces
(Invited talk in SP23: “Photonics for space systems and propulsion”)

Abstract- Rectifying stripe-teeth metasurfaces, consisting of nanorectenna arrays with plasmonic near-infrared resonances, coupled to vertical Metal-Insulator-Metal (MIM) diodes having an insulating barrier layer, were designed and their current-voltage (I-V) measurements analyzed. Effects of barrier heights, thickness, dielectric constant, and effective mass on the I-V curves were examined. The nanorectenna arrays were illuminated by visible and near-infrared laser beams, which shifted their I-V curve, indicating rectifying power production. An interesting large increase in the forward bias current is much greater than what is attributable to structural effects and plasmonic field-enhancement. We attribute it to a novel optical rectification mechanism: out-of-equilibrium “hot-electron” energy distribution due to plasmonic resonant absorption by the optical Au nanowire antennas.

In a semiconductor, absorption is limited by the band gap. An array of nonlinear receivers or “micorectennas” could rectify any desired portion of the infrared frequency spectrum, very efficiently converting the incident THz field to direct current. Vertical metal-insulator-metal (MIM) diodes have produced power from optical-frequency fields, when coupled to an asymmetric metamaterial planar stripe-teeth Al or Ag array lying above the vertical diode. We recently published a model of MIM diodes and their predicted current-voltage (I-V) characteristics and rectification1.

Figure 1: (a) CCDC-Soldier Center model of a rectifying MIM diode; metal (-) electrode has the larger barrier height, and the “I” region is the barrier layer (thickness t) with a potential function U(x). (b) Model agrees with experiment over eleven orders of magnitude, for four different barrier (oxide) thicknesses for both forward bias (V < 0) and reverse bias (V > 0)1. (c) Plan view electron microscopy image of Au nanowire antenna-coupled-Al/Al2O3/Au diodes, showing Au stripe-teeth array (brightly-colored; teeth are along the x-axis) and overlapping Al counter-electrode (transparent stripe along y). Vertical MIM diodes form at the intersection of the Al stripe and Au teeth.

These stripe-teeth arrays are similar to stripe arrays that have demonstrated near-perfect absorption in the infrared,2 except that “teeth” along the x-axis are designed to resonate in the visible and produce an enhanced resonant a.c. z-field, determined by the length of the tooth, into the substrate. This optical rectification produced a d.c. voltage...
and direct current, which is extracted by the stripes. The z-field was rectified by the vertical diode, composed of Al/Al₂O₃/Au, with Al₂O₃ fabricated by atomic layer deposition (ALD). Barrier heights (substantially lower than the ideal Al₂O₃-Al and -Al barrier heights), thickness, dielectric constant, and effective mass were all fitted to match the I-V curves. Barrier heights and thickness lower than expected values could be caused by roughness of the ALD-deposited Al₂O₃. The barrier asymmetry rising from the work function differences at the interfaces, Δφ, was estimated to be ~ 0.25 eV.

The unilluminated I-V curve (black curve in Fig. 2a) is nonlinear, asymmetric due to Δφ, and centered at V=0. When laser-illuminated, the curve shifts away from V=0, indicating that power is produced (there is a short circuit current and an open circuit voltage), and also the forward bias current changes not only amplitude but also shape in response to the laser illumination. The unusual forward bias current change near resonance (in the red) suggests that this is related to the antenna resonant absorption. Considering photon energy alone, photon-assisted tunneling would be stronger in the blue. The increase in the forward bias current is unusual, and different from what straightforward MIM modeling would anticipate (simple voltage shift ΔV).

Figure 2: (a) Dependence of I-V curves on visible wavelength excitation of Au nanowire antenna-coupled-Al/Al₂O₃/Au MIM diodes. (b) CCDC-Soldier Center modeling explaining large increase in forward bias current with out-of-equilibrium electron energy distribution (effective temperatures shown with corresponding forward bias current) due to plasmonic excitation in the (-) electrode. The effect of out-of-equilibrium electron energy distribution in the (+) electrode, basically just on the reverse bias current, is also shown.

The shift of ΔV can be explained using the quantum rectification formulism of Tucker et. al. The large increase in the forward bias current can be explained by the excitation of electrons in the (-) (Au) nanoantennas out of equilibrium at plasmonic resonance to dominate the current, while there is little absorption in the large-area Al. A subtle but crucial difference exists between the single-electron treatment of photon-assisted tunneling in the literature and the out-of-equilibrium electron reservoir here, characterized by effective temperatures given in Fig. 2b, although both might be referred to as “hot electron plasmonics”. For the reverse bias current that flows from (+) to (-) in Fig. 1a, an electron distribution characterized by a high effective temperature in the (-) layer won’t strongly affect the current, since the thermally excited electrons aren’t primarily responsible for the current. This will be discussed with the aid of a full analysis and model of the I-V curves of nano-/micro-rectenna arrays, their responsivities to illumination, along with power and data beaming to these and related nano-enhanced metasurface receivers, for space and terrestrial applications.

Simulating the Dynamic Structural Stability of Ultrathin Lightsails

Michael D. Kelzenberg* and Harry A. Atwater

California Institute of Technology, Pasadena, CA
*corresponding author, E-mail: mdk@caltech.edu

Abstract

Laser-propelled lightsails have been proposed as a technologically viable means of deploying interstellar space probes. Here, we investigate the dynamic structural stability of such light sails, treating the sail as a free membrane rather than a rigid body. Using realistic values for strength and modulus, we show that spin-stabilized paraboloid lightsails can in principle exhibit mechanical stability and beam-riding behavior.

1. Introduction

The Breakthrough Starshot Initiative was announced in 2016 as a $100M philanthropic effort to develop technologies and lay the foundations for launching humankind’s first interstellar probe. [1] Scientists and engineers around the world are being challenged to build a 1-gm interstellar probe (“nanocraft”) that will travel 4.2 light years to reach Proxima Centauri B, the nearest known habitable-zone exoplanet, within ~20 years of launch. To accelerate the nanocraft to the required speed of 0.2c, a ~10 m² lightsail will be propelled by radiation pressure from an earth-based or earth-orbiting laser (“light beamer”) at incident power densities approaching 10 GW/m², over the course of ~10 minutes (i.e., ~10,000 Gs of acceleration). This concept for interstellar exploration has been studied in great detail by Lubin et al. [2]

A lightsail suitable for acceleration to relativistic speeds must satisfy several challenging requirements, including: (1) the materials themselves must be capable of reflecting high intensity light (potentially over a wide range of angles) without overheating; (2) the sail must be stable under acceleration and not deviate from the beam path; and (3) the sail must be strong enough to retain its shape and avoid crumpling or tearing under rapid acceleration. A study investigating the first requirement has resulted in a short list of candidate materials combining low absorption with high reflectivity, including crystals such as Si and diamond, 2-dimensional transition metal dichalcogenides of W and Sn, and amorphous materials including a-Si and SiO₂. [3] Certain reflector shapes, including cones [4, 5], hyperboloids [6], and paraboloids [7] have been predicted to offer stable beam-riding behavior. Nanophotonic designs for lightsails have also been proposed, which allow lightsail surfaces to achieve beam-riding stability. [8] However, these prior studies treated the lightsail as a rigid body, which is likely a poor assumption for meter-scale membranes made from <100nm thick materials and thus will offer negligible out-of-plane stiffness.

Here, we turn our attention to the dynamic mechanical performance of unconstrained lightsail membranes to investigate whether design approaches such as those referenced above can be realized with real materials, which have finite stiffness and strength. We develop a computational numerical approach to simulate sheets of thin materials, considering their linear elastic behavior in the time domain. In this initial report, we present simulations of non-rigid paraboloid lightsails.

2. Approach

We construct a triangular surface mesh to model the lightsail membrane. Vertices of the mesh are assigned positions along the desired (e.g., paraboloid) surface, with their spacing chosen to yield reasonably uniform edge length and aspect ratio among the triangles. The mesh is formed by Delaunay triangulation, then an array of unique edges is constructed to model the elastic behavior of the membrane. An example simulation mesh is plotted in Figure 1.

Each vertex is assigned a mass based on the membrane thickness, the area of the adjoining triangles, and the material density. Each edge is assigned a linear elastic coefficient (i.e., spring constant) based on the edge length, the membrane thickness, the area of the adjoining triangles, and the material’s Young’s modulus. This simplistic approach neglects the bending stiffness and the shear modulus of the material, but provides a reasonable first-order glimpse into the behavior of ultrathin membranes under tensile loading, which is the predominant type of loading for most lightsail applications of interest. Future efforts can improve upon this approach by considering the full linear elastic behavior of the lightsail material(s), and by considering non-isotropic material properties.

To simulate the acceleration and deformation of the lightsail, and the stability of its trajectory, we implement a finite-difference time-domain approach wherein we calculate the forces acting upon each mesh vertex, then calculate the resulting change in position and velocity over a finite time step Δτ. By choosing sufficiently small Δτ, such that the propagation of the membrane’s vibrational modes can be simulated with high precision on our computational platform, we can obtain reasonable predictions of the lightsail’s dynamic behavior.
In addition to simulating the mechanical response of the lightsail, we also calculate the temperature of the sail by assuming a fixed value of absorption \((10^{-5})\), emissivity \((0.8)\), thermal conductance, and heat capacity. We use values for crystalline Si for the latter properties, neglecting its anisotropy. We consider first-order thermal expansion by using a linearized coefficient of thermal expansion (CTE), again using a value of 2.3 corresponding to Si at room temperature. Future work can improve this approach by more accurately calculating the optical properties based on the sail’s composition and design, and taking into account the local angle of incidence. Furthermore, it should be noted that these and other properties can vary greatly with temperature, and that a linearized model may be inadequate to accurately describe these variations.

Finally, we consider the tensile strength of the material by comparing the instantaneous strain of each mesh edge to the material’s fracture strain given by the ratio of its ultimate tensile strength to its Young’s modulus. If this strain is exceeded, we conclude that the membrane has failed and thus would be inadequate for interstellar propulsion. For illustrative purposes, we allow the simulation to continue for some time, deleting all edges that have failed (and their adjacent triangles) from the calculation of optical and mechanical forces in the membrane. Note that this is not intended to accurately model the propagation of structural failure within the membrane.

3. Results

Results of a simulation of a paraboloid lightsail are shown in Figure 2. We have used material properties roughly corresponding to those of crystalline Si, neglecting its anisotropy, and assume a sail thickness of 43 nm (corresponding to ~ 1 g/m² areal mass density). We found that spin-stabilization is required to prevent the paraboloids from collapsing immediately upon the application of the accelerating forces. The figure depicts the acceleration of a lightsail having ~1 m² effective initial aperture area. The paraboloids are initially offset from the beam centerline to illustrate their beam-riding stability.

Abstract

We conduct two-scale homogenization of multilayered structures composed of nonmagnetic isotropic materials. The resulting effective model involves a relation between the electric field and electric displacement and non intuitive transmission conditions at the interfaces with the surrounding media. In transverse electric polarization, the model reduces to a fully local model and in transverse magnetic polarization, classical non local terms appear. Comparison with direct numerics shows that the model is accurate up to the critical conditions near total reflection.

1. Introduction

We present a generalization of the homogenization procedure presented in [1] for transverse electric polarized waves in a dielectric layered structure. It was shown that conducting this approach at the third order results in a fully local effective model, with an effective wave equation involving a permittivity frequency dependent and effective transmission conditions involving a parameter which depends only on the layering structure of the model. Near the critical conditions of total internal reflection reported in [2], this model has been shown to capture the scattering properties of the actual structure with an accuracy less than 1% up to \( kd \sim 1 \) (Fig. 1). Here, the procedure is performed on the Maxwell equations in three dimensions. The resulting model involved a generalized relation between the electric field \( \mathbf{E} \) and the electric displacement field \( \mathbf{D} \), revealing local and spatial dispersion of the effective medium. The transmission conditions between the effective medium and the surrounding media are in general non local well, in the sense where they involve tangential derivative of the fields. Expectedly, we recover the model of [1] in transverse electric polarization. For transverse magnetic polarization, the effective model reveals anisotropy and spatial dispersion by means of a fourth order spatial derivative of the magnetic field; it is also non local in the transmission condition.

2. The effective model

We start with the Maxwell equations in the dielectric (non magnetic) structure

\[
\begin{align*}
\text{rot}\mathbf{H} &= \partial_t \mathbf{D}, \quad \text{rot}\mathbf{E} = -\partial_t \mathbf{H}, \\
\text{div}\mathbf{D} &= \text{div}\mathbf{H} = 0, \quad \text{with} \quad \mathbf{D} = \varepsilon \mathbf{E},
\end{align*}
\]

and \( \varepsilon = 1, \varepsilon_a, \varepsilon_b \) is a function of \( z \). The effective model aims to describe the fields \( (\mathbf{E}, \mathbf{D}, \mathbf{H}) \) in an average sense which results in (a) an effective medium for \( z > 0 \) being homogeneous, anisotropic and possibly non local and (b) effective transmission conditions which in general differ from the usual continuities of \( \mathbf{H} \), of the normal component of \( \mathbf{D} \) and of the tangential component of \( \mathbf{E} \). The model is a generalization of that in [1] which hold for transverse electric polarized waves (with \( \mathbf{E}(x, z) \) polarized along \( \mathbf{e}_y \)). Below we report the resulting model in the harmonic regime (with time dependence \( e^{-i\omega t} \) in the air where we set the velocity to unity, and \( k = \omega / c \) the wavenumber).

\[
\begin{cases}
\text{rot}\mathbf{H} = -ik\mathbf{D}, & \text{rot}\mathbf{E} = ik\mathbf{H}, \\
\text{div}\mathbf{D} = \text{div}\mathbf{H} = 0
\end{cases}
\]

with, for \( z < 0 \) \( \mathbf{E} = \mathbf{D} \) and for \( z > 0 \)

\[
\mathbf{E} = \begin{pmatrix}
\varepsilon^{-1}_a(k) - \alpha \partial_{xx} & -\alpha \partial_{xy} & 0 \\
-\alpha \partial_{xy} & \varepsilon^{-1}_a(k) - \alpha \partial_{yy} & 0 \\
\beta \partial_{xz} & \beta \partial_{yz} & \varepsilon^{-1}_b(k)
\end{pmatrix}
\begin{pmatrix}
\mathbf{D}
\end{pmatrix}
\]

where \( (\alpha, \beta) \) are non dimensional constant parameters which depend on the structure of the multilayer. Next, the usual transmission conditions read as \( \|\mathbf{H}\| = \|\mathbf{E}_x\| = \|\mathbf{E}_y\| = \|\mathbf{D}_z\| = 0 \) are replaced by effective transmission conditions of the form

\[
\begin{align*}
\|\mathbf{H}\| &= -ia \mathbf{k} \times \mathbf{E}, \\
\|\mathbf{E}_x\| &= b_0 \partial_z \mathbf{D}_z, \\
\|\mathbf{E}_y\| &= b_0 \partial_y \mathbf{D}_z, \\
\|\mathbf{D}_z\| &= a \left( \partial_x \mathbf{E}_x + \partial_y \mathbf{E}_y \right),
\end{align*}
\]
where \((a, b)\) are constant parameters which depend only on the arrangement of the layer terminating the structure (at \(z = 0\) and at \(z = \ell\)). In the above relation, for a field \(F(x,y,z)\) being discontinuous, say at \(z = 0\), we defined \(\overline{F} = \frac{1}{2}(F(x,y,0^+) + F(x,y,0^-))\).

- The case of TE polarized waves— If we consider \(D\) and \(E = E(x,z)e_y\) along \(e_y\) (hence \(H_y = 0\)), then (2) reduces to a 2D problem in \((x,z)\); accounting for (3) and for the transmission conditions (4), the problem reads as

\[
\begin{aligned}
(\partial_{xx} + \partial_{zz})E + \varepsilon_{\parallel}(k)k^2E &= 0, \\
\|E\| &= 0, \quad \|\partial_z E\| = a k^2E. 
\end{aligned}
\] (5)

- For TM polarized waves, \(H = H(x,z)e_y\) and where \(E_y = 0\), (2), (3) and (4) simplify to

\[
\begin{aligned}
\varepsilon_{\perp}^{-1}(k)\partial_{xx}H + \varepsilon_{\parallel}^{-1}(k)\partial_{zz}H - \gamma \partial_{xxzz}H + k^2H &= 0, \\
\|H\| &= -a (ikE_x), \quad \|ikE_x\| = -b \partial_{x}E, 
\end{aligned}
\] (6)

with \(\gamma = (\alpha + \beta)\) and \(ikE_x = \partial_z H\) for \(z < 0\) and \(ikE_x = (\varepsilon_{\perp}^{-1}(k) - \alpha \partial_{xx})\partial_z H\) for \(z > 0\).

3. Numerical validation of the effective model

We inspect the scattering properties of the actual structures in the case of all dielectric layers (\(\varepsilon_x > 0, \varepsilon_y > 0\)) and in that of metal-dielectric succession (\(\varepsilon_x < 0, \varepsilon_y > 0\)). The solution of the actual problem is calculated numerically and it is compared to that given by the effective model which is given in a close form. We report in Fig. 2 the transmission at moderate \(kd = 0.5\) value for the succession of layers considered in [1, 2]. The anomaly is visible with different scattering for the direct order (a structure starting with a layer \(a\)) and the inverse order (starting with a layer \(b\)); as a result, the classical EMA fails in capturing this sensitivity to the layer arrangement (dotted grey lines). In comparison, our effective model is 0.1% accurate in both cases (additional results can be found in [1]).

We report in Fig. 3 an additional and interesting result coming from [3]; in this reference, a model based on the transmission through a metal-dielectric structure is analyzed through an operator effective medium theory involving electric dipoles, chirality and magnetic and electric quadrupoles. In the case \(kd = 2\), that is when thickness \(d\) is not much less than the incident wavelength. The authors remark that their model is not very accurate but it catches the resonances of the exact solution. They conclude that other homogenization models considered cannot be used at all outside their applicability ranges. What we show in Fig. 3 is that our model has exactly the same accuracy as the operator effective model of [3] which suggests an equivalence between both models, which is not immediate to establish.

Figure 2: Transmission against \(\sin \theta\) for all dielectric structures the case reported in [2], \(\varepsilon_n = 4, \varepsilon_m = 3, \varepsilon_s = 5, \varepsilon_b = 1, d_s = d_b\) and \(kd = 0.5, N = 20\); direct (left) and inverse (right) order. Direct numerics (plain black lines) and effective model (dotted blue lines).

Figure 3: Transmission against \(\sin \theta\) for metal-dielectric structure, as reported in [3], \(\varepsilon_n = 1, \varepsilon_m = 0.215, \varepsilon_s = -3, \varepsilon_b = 2.25, d_s = d_b\) and \(kd = 2\), \(N = 10\); same representation as in Fig. 2.

Abstract

Electromagnetic plane waves are attenuated by dissipative materials and amplified by active materials. However, by virtue of judicious design, certain nanoengineered materials may be neither wholly dissipative nor wholly active. In such materials, whether plane waves are amplified or attenuated can depend upon the direction of propagation or on the polarization state. The prospects of achieving simultaneous amplification and attenuation of plane waves and surface waves have been established theoretically and numerically using a variety of nanoengineered materials, including homogenized composite materials and nanostructured thin films.

1. Introduction

Tantalizing technological opportunities, and illuminating fundamental insights, can be offered by nanoengineered materials with exotic optical properties [1], as exemplified by metamaterials [2] and certain homogenized composite materials (HCMs) [3]. Our focus here is on amplification and attenuation in such materials. It is well known that active materials may be used to overcome the debilitating effects of dissipation in metamaterials [4, 5, 6, 7]. However, it is less well known that by judiciously combining active and dissipative component materials, the resulting composite material can simultaneously support both amplification and attenuation. A survey is presented here of recent results concerning nanoengineered materials, including HCMs, which exhibit simultaneous amplification and attenuation.

2. Homogenized composite materials

The electromagnetic attributes of an assembly of electrically small spheroidal particles, randomly distributed but identically aligned, made from isotropic dielectric materials, are indistinguishable from those of a homogeneous uniaxial dielectric material [3]. Furthermore, if one of the component materials is active but the other component material is dissipative, then plane waves propagating in the resulting HCM in certain propagation directions may be amplified but plane waves propagating in other propagation directions may be attenuated [8]. Similarly, a multilayer of alternate active and dissipative thin sheets may be electromagnetically indistinguishable from a homogeneous birefringent continuum which can control plane-wave polarization states [9]. Also, HCMs arising from certain active and dissipative component materials can simultaneously amplify incident light of one linear polarization state whilst attenuating incident light of the orthogonal polarization state [10]. This effect can be extended to circular polarization states in the case of chiral HCMs: that is, a chiral HCM may be conceptualized that can simultaneously amplify circularly polarized light of one handedness whilst attenuating circularly polarized light of the other handedness [11].

3. Electromagnetic surface waves

Combinations of active and dissipative materials also give rise interesting results when electromagnetic surface waves [12] are considered. For example, suppose one considers the propagation of surface-plasmon-polariton (SPP) waves [13] guided by the planar interface of an isotropic metal and an active uniaxial dielectric material, for the case in which the optic axis of the uniaxial partnering material lies wholly in the interface plane. By judicious choice of the constitutive parameters of the partnering materials, one can find that SPP waves propagating in certain directions in the interface plane are amplified but the SPP waves propagating in other directions are attenuated [14]. Furthermore, a critical propagation direction exists for which the SPP wave is neither amplified nor attenuated. Analogous results arise for (i) Dyakonov waves [15, 16] supported by the planar interface of two dielectric materials, one of which is anisotropic and the other is isotropic [17]; and (ii) electromagnetic surface waves somewhat akin to SPP waves and somewhat akin Dyakonov waves supported by the planar interfaces of certain isotropic chiral materials [18, 19].
4. Closing remarks

The adjectives ‘active’ and ‘dissipative’ must be applied with caution when one considers certain nanoengineered materials, because under some circumstances amplification and attenuation may be supported simultaneously. Materials that simultaneously support amplification and dissipation are promising for applications in optical communications and noise reduction, for examples.

Abstract

Homogenising metamaterials with local constitutive relations frequently fails when the characteristic length scale of the metamaterial is no longer much smaller than the wavelength. To improve the situation, we consider nonlocal constitutive relations and demonstrate an improvement in the effective description of metamaterials. We discuss the dispersion relations, the additional interface conditions, and study the emerging reflection and transmission coefficients. We validate our model by testing it on selected metamaterials of interest by comparing the electromagnetic response from a slab.

1. Introduction

The characterisation of optical metamaterials (MMs) is an important task in the field of electromagnetism. It provides us not only a fundamental, physical understanding of the wave propagation inside complex media, but also offers a guideline for tuning and for a targeted engineering of the electromagnetic response from the MM. Particularly interesting in the last years are materials with a negative index of refraction. This phenomena usually appears when the material has metallic inclusions and sustains a magnetic resonance that translates to a resonant magnetic susceptibility at the effective level. To homogenise the MM, the lateral period of the structure has to be much smaller than the wavelength of light. However, frequently it is only smaller than the wavelength. In such sitze regime the introduction of effective material parameters requires to track the information of the spatial derivatives of the mean fields as well [1]. Simply because the field variation across the unit cell cannot be neglected anymore as the structures are too large for that. Therefore, an effective medium approach that retains spatial dispersion is required. In other terms, spatial dispersion means that the auxiliary fields, $D$ and $H$, linearly depend on the macroscopic fields $E$ and $B$ and on their spatial derivatives, with spatially independent coefficients - the effective material parameters. This goes beyond the usually considered local responses, or local constitutive relations, which have been extensively studied in the past [2]. However, local approaches show severe limitations when the wavelength is only slightly longer than the lattice size, because the field of light at one position polarizes the material at a distant position, which is only captured by considering nonlocal constitutive relations. It is the purpose of our work, that we review, to establish a framework for the homogenization of MMs that considers such strong spatial dispersion (SSD).

2. Material Model and Results

To homogenise optical MMs with nonlocal constitutive relations, we proposed a macroscopic model for materials in Ref. [3]. For the sake of simplicity, we do not consider MMs that mix TE and TM polarisations. The MMs we consider are intrinsically achiral and are invariant under spatial inversion. As a consequence, the effective response function, that shall respect the same symmetry as the original structure, will only contain even derivatives of the electric field. An example of a structure that undergoes a negative index behaviour is the Fishnet MM. It is a bi-periodic structure consisting of a stack of two perforated metallic layers separated by a dielectric spacer and embedded in a non-dissersive host medium (See Fig. 1). Our model for nonlocality is

$$D(r,\omega) = \varepsilon(\omega)E(r,\omega) + \nabla \times \alpha(\omega)\nabla \times E(r,\omega) + \nabla \times \nabla \times \gamma(\omega)\nabla \times \nabla \times E(r,\omega),$$

(1)

where $\varepsilon(\omega)$, $\alpha(\omega)$, and $\gamma(\omega)$ are spatially independent effective material parameters. Bear in mind that the material is intrinsically non-magnetic, i.e., $H(r,\omega) = B(r,\omega)$. 

Figure 1: Fishnet MM. We consider a biperiodic structure with periods $\Lambda_x = \Lambda_y = 600$ nm and consider an extension of the thin film in $z$ direction of 200 nm. The fishnet consists of rectangular holes with the width $w_x = 100$ nm and $w_y = 316$ nm. They consist in a stack of layers made of two 45 nm Ag layers separated by a thin dielectric spacer, 30 nm of MgF$_2$, with $n_{\text{MgF}_2} = 1.38$. 

However, $\alpha(\omega)$ can be transformed, by means of a gauge transformation, to a local magnetic permeability that leads to artificial magnetization in such MMs. This is a consequence of finite-size structures where currents in a closed loops can be formed. The tranformation reads $\alpha_i(\omega) = \frac{1-\mu_i(\omega)}{\kappa_0 \mu_i(\omega)}$, where $\mu_i(\omega)$ is the $i$-th component of the local, effective magnetic permeability. The parameter $\gamma(\omega)$, however, is the actual nonlocal parameter associated to SSD.

We have solved the wave equation and discussed its multiple solutions in Ref. [3]. In particular, in contrast to local constitutive relation where only a single forward propagating mode is sustained for a given pair of transverse wave vector component and frequency, two plane wave solutions emerge in nonlocal materials. To unambiguously fix their amplitudes at an interface, additional interface conditions have to be introduced. We derived these additional interface conditions by means of weak formulations in Ref. [3]. For practical reasons, we have calculated the necessary Fresnel matrix to analytically express the reflection and transmission from a slab. In order to validate our model as well as our derived additional interface conditions, we compare the results produced by our homogenization approach against full wave numerical simulations. We consider topi­cal subjects such as the Fishnet as well as basic structures, e.g., spheres on a cubic lattice or wire media. Recent results can be found in Ref. [4]. In the conference, we will show the actual improvements in capturing the reflection and transmission coefficients from slabs with different thicknesses in the propagation direction and show that the nonlocal approach leads to more robust results compared to the local one. We will discuss the retrieved material parameters $\epsilon(\omega)$, $\alpha(\omega)$, and $\gamma(\omega)$ in depth as well.

The numerical data for the complex reflection and transmission coefficients of the fishnet MM have been calculated with the Fourier Modal Method (FMM) and are depicted in Fig. 2 (black curves), exemplary at the resonance frequency where the Fishnet has a negative index but depending on the angle of incidence. The comparison of this reference data to the reflection and transmission coefficients calculated using both local and nonlocal material laws is based on a least absolute deviations fit by optimizing the effective material parameters present in the respective model. We notice in Fig. 2 that the nonlocal model covers a larger parameter space of validity. The reflection and transmission coefficients evaluated with the retrieved effective material parameter are shown in blue for the local (WSD) and in red for the nonlocal (SSD) approach. Significant improvement can be seen when considering nonlocality. The local approach is only in agreement with the reference in the paraxial regime, while the nonlocal approach goes up to $50^\circ$. This implies that retaining nonlocal constitutive relations is required for a realistic homogenization.

3. Conclusion

To conclude, we have seen that local constitutive relations turn out to become insufficient beyond the paraxial regime for selected MMs. This insufficiency could be lifted by introducing nonlocal material parameters. We discussed the additional interface conditions and the reflection and transmission coefficients from a slab and compared those to the response of an actual structure. We have also shown the importance of the introduction of advanced material properties in order to guarantee a more realistic homogenization. Exemplary, we demonstrated the improvement on the fishnet material, but improvements in other structure, e.g., spheres on a cubic lattice or wire media structures are visible too.

Challenging the foundations of electromagnetism: the excitation fields D and H

Jonathan Gratus\textsuperscript{1,2,}\textsuperscript{*}, Paul Kinsler\textsuperscript{1,2}, Martin W. McCall\textsuperscript{3}

Abstract

Maxwell’s equations contain two auxiliary “excitation” fields, namely (D,H). These not only contain a gauge freedom, but have no way of being directly measured; as can be demonstrated by considering H inside a permanent magnet. This (D,H) freedom even allows us to defy global charge conservation in topologically non-trivial spacetimes (e.g. if a black hole forms and evaporates). We can also better understand the constitutive axion terms, and explore the possibility of a new treatment of electromagnetic current.

1. Introduction

Maxwell’s equations do not feature the actual values of the excitation fields, but only their derivatives. As a result there is debate in the literature [1, 2] as to whether excitations D and H really are physical fields which can be directly measured, or simply a potential for the charge and current. As shown in fig. 1 (see also [3]) the H-field in a permanent magnet can either be parallel or anti-parallel to the B-field, depending on which constitutive model you might choose. This is in stark contrast with the unambiguously physics electromagnetic fields E and B, where the integrated fields can be measured inside a material using the Aharonov-Bohm effect.

It is easy to see that Maxwell’s equations are invariant if we add a gauge \((\phi_g, A_g)\) to the excitation fields

\[
D \rightarrow D + \nabla \times A_g \quad \text{and} \quad H \rightarrow H + \nabla \cdot \phi_g
\]  

This new gauge freedom, is distinct from the gauge freedom associated with the potential for \((E, B)\).

2. A New Hope

There are two questions which arise naturally when we drop the existence of \(D\) and \(H\). How do we prescribe the constitutive relations, and what consequence arise as a result?

Our new approach re-evaluates the fundamental basis of the macroscopic Maxwell’s equations, bypassing the excitation fields completely, and instead directly connecting the electromagnetic field to the current. The constitutive relation for this new type of media combines Gauss’s Law, Maxwell-Ampère, and the constitutive tensor; all being represented instead by new functions \((\Psi^E, \Psi^B, \Psi^E_f, \Psi^B_f)\). Maxwell’s equations now become

\[
\begin{align*}
\nabla \cdot B &= 0, \\
\nabla \times E + B &= 0, \\
\Psi^E (E) + \Psi^B (B) &= \rho \quad \text{and} \quad \Psi^E_f (E) + \Psi^B_f (B) = J
\end{align*}
\]  

The functions \((\Psi^E, \Psi^B, \Psi^E_f, \Psi^B_f)\) cannot be modelled as tensors as they involve derivatives. Instead, we will present the alternative rules they must obey, notably the requirements of conservation of charge. A careful analysis of the symmetries of \((\Psi^E, \Psi^B, \Psi^E_f, \Psi^B_f)\) shows that, in the homogeneous non-dispersive case, they possess 55 free parameters: 20 more that the standard constitutive tensor. These fall into two classes.

Four of the new parameters describe the axion response of the material. If one were to express these in terms of the excitation fields, they would be of the form

\[
\begin{align*}
D_{ax} &= (t\zeta_t + x\zeta_x + y\zeta_y + z\zeta_z) B \\
H_{ax} &= -(t\zeta_t + x\zeta_x + y\zeta_y + z\zeta_z) E
\end{align*}
\]

where \(t\) is time, \((x, y, z)\) are the usual Cartesian coordinates and \((\zeta_t, \zeta_x, \zeta_y, \zeta_z)\) are the four axionic material constants. In the traditional approach, these would not be considered as valid terms in the homogeneous constitutive tensor, but, in contrast, when substituted into Maxwell’s equations they

![Figure 1: A comparison between the distinct models for the H fields in two standard pictures of magnetism: the bulk response model \(H^B = \mu^{-1} B - H_c\) (left), and the surface current model \(H^S = \mu^{-1} B\) and \(\sigma^S_B = n \times H_c\) (right). Observe the direction of the \(H\) field inside the magnet.](image-url)
Figure 2: An event is excised from spacetime. The resulting non-trivial topology, together with the non existence of \((\mathbf{D},\mathbf{H})\) breaks charge conservation.

give a perfectly valid homogeneous axionic response, i.e.

\[
\nabla \cdot \mathbf{D}_{\text{ax}} = \zeta \cdot \mathbf{B} \\
\n\text{and} \quad \nabla \times \mathbf{H}_{\text{ax}} - \mathbf{D}_{\text{ax}} = -\zeta \times \mathbf{E} - \zeta_t \mathbf{B} \quad (4)
\]

Thus we can model a medium with an axionic response together with a simple constant permittivity \(\varepsilon\) and permeability \(\mu\). Maxwell’s equations (2) become

\[
\nabla \cdot \mathbf{B} = 0, \quad \nabla \times \mathbf{E} + \mathbf{B} = 0, \quad \varepsilon \nabla \cdot \mathbf{E} - \zeta \cdot \mathbf{B} = \rho \\
\text{and} \quad \mu^{-1} \nabla \times \mathbf{B} - \varepsilon \dot{\mathbf{E}} + \zeta \times \mathbf{E} + \zeta_t \mathbf{B} = \mathbf{J} \quad (5)
\]

An interesting feature of such a medium is that electromagnetic wave with longitudinal components can propagate.

The remaining 51 parameters include the usual 35 given in the standard constitutive tensor. However they also give 16 new types of electromagnetic response. A traditional analysis could quite reasonably set these to zero, as they do not couple to electric charge or current. However, there is no reason why they cannot couple to something, and if that something did exist it would be interpretable as a new type of current and charge. We will briefly examine this exotic possibility, noting that in traditional notation it can be seen as arising from a (new) distinction that can be made between different instances of the same field components.

3. What are the consequences?

Although the arguments above are theoretic, it is possible to propose thought experiments where they have incontrovertible physical consequences. We will describe how (cf. [4]), given that a forming and evaporating black hole can create a topologically non-trivial spacetime, local charge conservation is no longer sufficient to also guarantee global charge conservation. As an example, in figure 2 we replace the evaporated black hole lifecycle with a simplified analogue, i.e. a spacetime with a single event removed. Before this event there is no charge or current, but, a nonzero charge nevertheless emanate from it. Another consequence is that if a charge passes through a wormhole, it need not leave that wormhole charged, as is traditionally believed.

4. Conclusion

We have challenged the notion that the excitation fields \((\mathbf{D},\mathbf{H})\) are measurable fields, interpreting them instead as gauge fields for the current. We have given a new model of the constitutive relations, which bypasses the need to define \((\mathbf{D},\mathbf{H})\). Analysing these relations we see there are an additional 20 parameters. Four of these are axions, while the remaining 16 require a new charge and current field.

We have shown that the consequence of these new relations mean that electromagnetic wave can have a longitudinal component and that we can break global charge conservation.

Abstract

At sub-nanometer length-scale, nonlocal and quantum effects are expected to influence the interaction between emitters and plasmonic systems, which unavoidably requires to go beyond classical models. Here, we apply state-of-the-art quantum hydrodynamic theory to investigate the quantum effects on strong coupling of a point-dipole emitter placed nearby metallic particles. In order to understand the effects of the quantum hydrodynamic model on the plasmon-emitter coupling, we compare our results with the conventional local response approximation and Thomas-Fermi hydrodynamic theory.

1. Introduction

Strong coupling in light-matter interactions requires enhanced optical field and small cavity volumes. Latest developments in the nanotechnology and nanofabrication techniques allow to engineer metallic structures supporting localized surface plasmons able to squeeze light in ever smaller nanovolumes, thus, offering an excellent platform to explore strong electromagnetic coupling in a plasmonic cavity. A quantum emitter placed inside a few-nanometer plasmonic gap shows a drastic change\footnote{Radoslaw Jurga, Khalid Muhammad, Fabio Della Sala, Cristian Ciraci} in its radiation dynamics compared to bare metal films. Such light-atom interactions are of particular interest in quantum computation, biosensing, nanolasing and active plasmonic applications. When coupling of a photon emitter with the surrounding plasmonic cavity is large enough so that the energy exchange happens before it is lost (or decayed) in the system, it is possible to enter the strong coupling regime where the emitter can reversibly exchange photons with the environment, hence leaving a signature in the optical emission spectra widely known as Rabi splitting\footnote{Radoslaw Jurga, Khalid Muhammad, Fabio Della Sala, Cristian Ciraci} [2, 3, 4].

Significantly large optical field confinement can be achieved in metallic structures with a few-nanometer or even subnanometer interparticle distances. At such small length scales, nonlocal and quantum effects come into play, which may have a non-negligible impact on the optical behavior the system\footnote{Radoslaw Jurga, Khalid Muhammad, Fabio Della Sala, Cristian Ciraci}. When a quantum emitter is brought to close proximity of such nanostructures, more dramatic changes can be expected in its emission spectra due to nonlocal and quantum effects. Many studies have highlighted the impact of nonlocality on light-matter interactions in the strong coupling regime\footnote{Radoslaw Jurga, Khalid Muhammad, Fabio Della Sala, Cristian Ciraci}. These nonlocal effects cannot be predicted in the framework of classical electrodynamics as revealed in several experiments\footnote{Radoslaw Jurga, Khalid Muhammad, Fabio Della Sala, Cristian Ciraci} and, thus, necessitating the development of efficient analytical and numerical models for correct description of electron dynamics.

2. Discussion

We investigate nonlocal and quantum effects on the optical properties of a photon emitter placed in a close proximity of plasmonic particles in tunneling regime by employing state-of-the-art quantum hydrodynamic theory (QHT). That is, the plasmonic system is considered in its complex dynamic including nonlocal effects, electron spill-out and tunneling, while the emitter is approximated as a point dipole.

The QHT can be summarized by the equation of motion of the electron gas written as a relation between the electric polarization $P$ and the electric field $E$\footnote{Radoslaw Jurga, Khalid Muhammad, Fabio Della Sala, Cristian Ciraci}

\begin{equation}
\frac{en_0}{m} \nabla \left( \frac{\delta G[n]}{\delta n} \right)_1 - \frac{e}{m} \nabla \cdot \sigma^{\text{(kxc)}} + (\omega^2 + i\gamma\omega) P = -\varepsilon_0 \omega_p^2 E, \tag{1}
\end{equation}

where $e$ and $m$ are respectively the magnitude of the charge and the mass of the electron, $n$ the spatially dependent electron density, $n_0$ the equilibrium density, $\gamma$ the phenomenological damping rate and $\omega_p$ the plasma frequency. The energy functional $G[n]$ contains the Thomas-Fermi and the von Weizs"{a}cker kinetic energy functionals and a local-density approximated exchange-correlation energy term\footnote{Radoslaw Jurga, Khalid Muhammad, Fabio Della Sala, Cristian Ciraci}. Eq. (1) includes an additional term $\sigma^{\text{(kxc)}}$, the viscoelastic kinetic-exchange-correlation tensor whose full expression is given in Ref. [7]. Its main effect is to take into account the nonlocal broadening of the spectra, especially relevant for geometries with small features\footnote{Radoslaw Jurga, Khalid Muhammad, Fabio Della Sala, Cristian Ciraci}.

Coupled to the continuity equation and Maxwell’s equations, Eq. (1) describes the nonlocal optical response of metals, takes into account the charge spill-out and the size-dependent spectra broadening. The equilibrium density $n_0$ is computed self-consistently and fed as input into the QHT linear response equation.
3. Conclusions

In the limit of the point-dipole approximation for the emitter considered here, nonlocality and quantum effects increase the oscillator strength threshold at which Rabi splitting can occur. This increase is caused by a decrease of the total decay rate, which is lower and broader when the QHT is used to describe the plasmonic environment.

Spatial dispersion and local field effects in metamaterials

A.A. Tishchenko$^{1,2}$

$^1$National Research Nuclear University “MEPhI”, Russia

*corresponding author, E-mail: tishchenko@mephi.ru

Abstract
In this report I discuss correlation between two key phenomena in metamaterials: spatial dispersion – non-local response of material – and local field effects. I consider 1D, 2D and 3D systems of interacting objects (meta-atoms), and two types of response functions: response to the macroscopic field existing in the system, which leads directly to the dielectric function, like the Clausius-Mossotti one; and the response to the field of external sources. The analysis is given for two competing approaches: i) the widely used description via two independent dielectric and magnetic functions, and ii) more general but less popular description through the tensor of dielectric function embracing both dielectric and magnetic properties.

1. Introduction
The phenomenon of spatial dispersion of dielectric function – the dependence of dielectric properties of a material from the wave vector, which is explained by the non-localness of the response of the material - was first mentioned, probably, by Gerzenshtein as early as in 1952 [1]. Since then this phenomenon has been widely investigated. It is usually assumed to be most pronounced in plasma [2], because of high electron mobility, but in fact plays key role near zeros of dielectric function, when spatial dispersion provides us with new types of electromagnetic waves in condensed matter [3]. It is also well-known to be responsible for the natural optical activity of some crystals (or gyrotropy). It proves, however, that the spatial dispersion is absolutely fundamental phenomenon, which is necessary, for instance, for the high temperature superconductivity to exist (the condition $\varepsilon(q,0)<0$ must be satisfied) [4]. The spatial dispersion plays a vital part in violation of the Kramers-Kronig relations [4], which are, in a sense, even more fundamental then basic Maxwell’s equations, because they are caused directly by the causality principle.

Though the role of spatial dispersion in metamaterials is very well known [5, 6], its potentials has not been exhausted. Interestingly, recently Im with coauthors have reinterpreted a dielectric bi-layer as a monolayer with non-local properties that change as the angle of the incident wave varies [7]; this effect makes this effective matching layer a promising ‘quarter-wave’ layer, i.e. very good candidate for ideal active anti-reflection coating.

On the other hand, for the microscopic properties of metamaterial to be calculated, one needs to calculate first the local fields, acting at the points in which the meta-atoms are. This problem can be solved within the so-called local field approach that operates with double-particle distribution functions, taking into account the effects of interaction in system of many particles. This method is then naturally suitable for taking into account the mutual disposition of the single meta-atoms, i.e., the structure of the material.

In this report I show how the local field effects lead to the non-locality of dielectric response of materials, and show it by the examples of 1D, 2D and 3D systems. Below are represented the generalized expressions linking dielectric function of metamaterial with microscopic properties of constituent meta-atoms and the double-particle distribution function defining the inner structure of the material.

2. Some analyitics
Let us consider dielectric properties of the material consisting of meta-atoms – small objects that are characterized by the polarizability $\alpha_{ij}(\omega)$. This value can have non-zero imaginary part, and can be tensor, which would suit for anisotropic meta-atoms. Based on the Maxwell’s equations, it is not hard to obtain the expressions linking the exact microscopic field $E_{mic}^{\alpha}(r,\omega)$, the field external of sources $E_{ext}^{\alpha}(r,\omega)$, and the local field $E_{loc}^{\alpha}(R_{ij},\omega)$, i.e. the field acting at the points in which the meta-atoms are disposed

$$E_{mic}^{\alpha}(r,\omega)=E_{ext}^{\alpha}(r,\omega)+\hat{A}_{ij}E_{loc}^{\alpha}(R_{ij},\omega).$$

Here tensor operator $\hat{A}_{ij}$ describes the contribution of the matter. Further, two types of averaging are used: the conventional one giving the average macroscopic field $E$

$$E_{loc}=E_{mic}^{\alpha}+\hat{C}_{ij}E_{loc}^{\alpha},$$

and the second one, being obtained with the help of averaging with double-particle distribution function, which reads

$$E_{loc}^{\alpha}=E_{mic}^{\alpha}+\hat{C}_{ij}E_{loc}^{\alpha}.$$
\[ e_y(q, \omega) = \delta_y + 4\pi n\alpha_y(\omega) \tau_{ij}^y(q, \omega), \]  
(4)

where

\[ t_y(q, \omega) = \delta_y - 4\pi n \left\{ \alpha_y(\omega) + \int d^2 l \left( \frac{l^2}{l^2 - k^2} \right) \alpha_y(\omega) f(1 - q) \right\}, \]  
(5)

and \( f(1 - q) \) is a Fourier-image of the radial distribution function.

In case of 2D structure (infinite surface filled up with meta-atoms) is reads

\[ e_y(q, z, \omega) = \delta_y + 4\pi n \alpha_y(\omega) \tau_{ij}^y(q, z, \omega), \]  
(6)

where

\[ t_y(q, z, \omega) = \delta_y + 4\pi n \int d^1 l S_2(1, \omega) \alpha_y(\omega) \eta(l) f(1 - q) \exp \{ilz\}, \]  
(7)

and the functions \( \eta(l) \) and \( f(1 - q) \) are parts of the Fourier-image of the radial distribution function as well.

Note, that in Eqs. (6) and (7) vector \( q \) is two-dimensional in contrast to Eqs. (4) and (5) in which it is 3D.

For example, in the long-wave limit, when the wavelength exceeds considerably the size of single meta-atoms (which is totally natural case for metamaterials), Eq. (6) becomes much simpler, with main values of tensor \( e_y \):

\[ e_\parallel(z, \omega) = 1 + \frac{4\pi n\alpha_\parallel(\omega) \eta(z)}{1 - \pi n\alpha_\parallel(\omega) \xi(z)}, \]  
(8)

and the value

\[ \xi(z) = \int d^2 l f(1) \exp \{-z|l|\} \]  
(9)

contains the information about the structure, while

\[ \eta(z) = (4\pi b^2)^{-1/2} \exp \left\{ - \frac{z^2}{4b^2} \right\} \]  
(10)

is the function, describing distribution of meta-atoms near the surface given by \( z = 0 \), \( b \) is the effective width of this quasi-monolayer.

Along with that, the system of Eqs. (2) and (3) let us find the expression linking the local field with the external one:

\[ E_{loc}^i(r, \omega) = \left( \frac{\delta_y - e^i d^j}{1 - \pi n\alpha_i(\omega) \xi(z)} + \frac{e^i \delta_y}{1 + 2\pi n\alpha_i(\omega) \xi(z)} \right) \tau_{ij}^x(r, \omega), \]  
(11)

where \( e^i \) is the \( i \)-th component of the vector normal to the surface. The expressions like Eq. (11) are very useful for the wide range of practical problems to be solved. For example, the problems of generation radiation by the charged particles beams from metasurfaces are solved more or less easily, e.g. [8, 9]. Moreover, it is very promising for the High-Resolution Cathodoluminescence Spectroscopy and Electron Energy Loss Spectroscopy – instruments that are being developed very actively nowadays [10].

3. Conclusions

The real report will contain not only the detailed discussion of what has been said above, but also the issues mentioned in the abstract: the comparison between two close in nature, but differing from point of view of analytics approaches, dealing with i) two independent dielectric and magnetic functions, and ii) the tensor of dielectric function embracing both dielectric and magnetic properties; the description for 1D systems (chains of meta-atoms – meta-wires); discussion of the difficulties concerning the existence of the boundaries in 3D case: here the theory allows obtaining dielectric function, including the so-called natural change of surface properties, caused by the change in the symmetry in formation of local fields near the surface (see, e.g., [11]) – but the expression linking the local field through the external one has been an unsolvable problem, being a stumbling block on the way of many practically interesting applications.

Abstract

It is notoriously difficult to emulate black hole physics with experiments on earth. This is especially true when emulating the event horizon, which requires controlling materials or experimental settings in time. In contrast, here, we show that hallmark phenomena such as a gravitational red shift can be imposed by a static metamaterial black hole. To this end, we solve for the spontaneous emission rate of a two-level emitter inside a metamaterial black hole, which serves as an electromagnetic clock.

1. Emulating black holes

The Schwarzschild geometry is the oldest and simplest solution of the Einstein field equations in general relativity. It describes how particles are affected by the gravitational pull of heavy spherical objects such as the earth, stars, black holes, and centres of galaxies [1, 2]. Black holes are particularly interesting deformations of space and time because of their nonreciprocal behaviour, i.e., their gravitational pull is so strong that within a Schwarzschild radius nothing can escape from it. The appearance of such an event horizon strongly depends on the observer. Co-moving observers who cross the event horizon of the black hole would not experience anything out of the ordinary, except that they would be unable to return. However, static observers at a large distance from the black hole would see quite a few extraordinary things, such as a gravitational red shift [7], an apparent slowing down of light [2], and Hawking radiation from the black hole [3].

Research on analogue systems of black holes has an impressive reach, encompassing a variety physics theories such as the physics of moving condensates [8], spatio-temporally modulated metamaterials [10], filaments in optically pumped nonlinear media [11], and atomic ensembles imposing slow light [12]. All of these proposals are based on the implementation of an artificial event horizon with time-dependent material properties, thus hoping to observe Unruh-Hawking radiation [9]. Besides these advanced proposals, which have given rise to much debate, there are several proposals of simplified electromagnetic emulations [5, 6, 13], such as refractive index distributions and waveguide-based proposals with singularities, that mimic the ray dynamics near a black hole. In particular, the singularities result in a rapidly varying phase, i.e., a phase catastrophe, and a low group velocity that prevents light from crossing them [12, 16, 17]. Hence, these singular systems emulate the viewpoint of an external observer at infinity, who is never able to see inside the event horizon.

2. Electromagnetic clocks

In this contribution, we show how transformation-optical metamaterials based on the Schwarzschild geometry [4, 5, 6] can emulate Schwarzschild black holes in a way that goes beyond ray dynamics. The idea is to capture the dynamic properties of the metamaterial black holes, such as the gravitational red shift and the slowing down of electromagnetic phenomena, by making use of an electromagnetic clock that consists of a two-level emitter, as visualized in Fig. 1. The two-level emitter with dipole moment \( \mathbf{d} \) is put at different radial distances \( r \) from the metamaterial black hole, with the usual permittivity and permeability distributions outside an event horizon with Schwarzschild radius \( R_s \)

\[
\bar{\varepsilon} = \text{diag} \left( 1, (1 - R_s/r)^{-1}, (1 - R_s/r)^{-1} \right) = \bar{\mu}.
\]

(1)

Note that the dipole moment can be either parallel (\( \parallel \)) or perpendicular (\( \perp \)) to the radial unit vector. For each distance, the spontaneous emission rate of the electromagnetic clock is determined by two contributions to Fermi’s golden rule at a transition frequency \( \omega_{eg} \):

\[
\gamma = \frac{\pi \omega_{eg}}{3 \hbar c_0} \left| -e \langle \psi_e | \mathbf{r} \cdot \mathbf{n}_d | \psi_g \rangle \right|^2 \left( \sum_{k\lambda} \left| \mathbf{n}_d \cdot \mathbf{u}_k^{(\lambda)} \right|^2 \frac{\delta (\omega_k - \omega_{eg})}{\rho(\omega_{eg})} \right) \sum_{k\lambda} \left| \mathbf{n}_d \cdot \mathbf{u}_k^{(\lambda)} \right|^2 \frac{\delta (\omega_k - \omega_{eg})}{\rho(\omega_{eg})}.
\]

(2)

The first contribution by the transition dipole moment with orientation \( \mathbf{n}_d \) is determined by the overlap integral between the excited state \( |\psi_e\rangle \) and the ground state \( |\psi_g\rangle \) orbitals. Our analytical calculations and finite-element simulations of the Schrödinger equation for the emitter inside the metamaterial show that its effective permittivity distribution deforms the orbitals in an exact, non-perturbative, and geometrical way, but only when the effective mass of the emitter \( \bar{m} \) is engineered to be anisotropic, i.e., \( (1 - R_s/r)m_{||} = \)
Figure 1: Visualization of a Schwarzschild black hole, with an effective measure of length along the surface. A two-level emitter with a dipole moment $d$ parallel (||) or perpendicular (⊥) to the radial direction is put at various distances from the event horizon ($r = R_s$) to probe the spontaneous emission rate.

$m_\perp$. This provides an additional equivalence relation, complementing those of transformation optics.

The second contribution is due to the partial density of states (PDOS), i.e., the distribution of photons $u_k$ with quantum numbers $k$ and polarization $\lambda$. Usually, it is assumed that the photons are coordinate-transformed plane waves [20]. Here, however, the plane wave expansion of the PDOS is incompatible with the spherically symmetric event horizon. We have developed an expansion based on vector spherical harmonics that does impose appropriate boundary conditions.

Overall, we show that a time-independent metamaterial black hole can modify emission rates and emission frequencies through a joint engineering of electronic (effective mass) and optical properties (transformation-optical metamaterials) in space.

Abstract

In this paper we examine the use of artificial electromagnetic media to mediate interactions between electromagnetic waves and charged particle beams. Where we consider the physics and application of interaction between artificial media and electron beams, and how this interaction can be used to create novel sources and amplifiers of EM waves.

1. Introduction

The realisation of artificial electromagnetic materials began a hundred years before the term "metamaterial" was introduced, with the work of Rayleigh and Bose in the 1890s. Although the first practical applications did not appear until the 1940s with the pioneering work of Kock[3], who considered these constructs as artificial dielectric materials. Renewed interest in these materials arose with the work of Pendry[4] on metamaterials. The term metamaterial was coined by Rodger Walser defined a metamaterial as; "...macroscopic composites having man-made, three-dimensional, periodic cellular architecture designed to produce an optimised combination, not available in nature, of two or more responses to specific excitation". Where the subwavelength scale of the cells in the metamaterial make the whole composite macroscopically uniform and treatable as an artificial material. Artificial electromagnetic materials, such as metamaterials, essential create an arbitrary, engineered, phase shift of an incident wave across the unit cell, which enables the dispersion relation of the media to be engineered in a controlled way.

To date numerous papers have been published on the electromagnetic properties of metamaterials at low power levels. In this paper we examine advances that have been made in studying metamaterials as slow wave structures for active electron beam-driven microwave devices. We discuss structures that do satisfy the Waslers definition of a metamaterial and those that do not, that offer novel engineered dispersion relations to discover novel beam/wave interactions that can be exploited for new technologies.

In this paper we bring together advances that have been made in studying metamaterials as slow wave structures for active electron beam-driven devices. We consider the ability of the sub wave length geometries to with stand high power, and we consider two scenarios where metamaterials are for EM amplification and for EM generation. In both configurations for effective energy transfer between beam and EM wave the phase velocity of the wave must approximately match the velocity of the electron beam. Where this is achieved by engineering the dispersion of the wave through the material to tailor the interaction between electron beam and wave.

2. Traveling Wave Amplification

In this section of the paper we consider the application of metamaterials to Traveling Wave Tubes (TWT). In a conventional TWT amplification of an EM wave is achieved by passing the EM wave to be amplified through a Slow Wave Structure (SWS) simultaneously with an electron beam, where wave and beam pass through the structure with similar velocities. Resulting in an interaction between beam transferring energy from beam to wave. In a conventional Waveguide TWT this is achieved by folded the waveguide (see figure 1)[5] to slow down the wave, generating Spatial Harmonics Wave Components parallel to the beam. The SHWC interact with the beam resulting in energy transfer.

Figure 1: The traveling wave structure considered here, consisting of a folded waveguide with a metamaterial insert, the electron beam passes through the middle of the structure. Figure taken from [6].

To ensure that the phase of the EM field is the same at each point wave and beam interact, the wave takes the long path around the folded wave guide, hence the period in the beam frame of reference is half the geometrical period of the structure shown in figure 1. In a conventional TWT the dispersion relation, frequency of operation and size of device are all determined by the physical dimensions of the
device. By inserting a metamaterial at the interaction points between wave and beam the metamaterial enables both the tailoring of the dispersion relation and an arbitrary phase shift of the wave [6].

Figure 2: Dispersion curve for a waveguide loaded with metamaterial, the dotted line represents the electron beam line. Figure 2 show the dispersion relation for a waveguide loaded with metamaterial, in the case presented the material has both negative permittivity and permeability at around 10GHz, as can be seen by the anomalous dispersion shown in fig2. The interaction of the loaded waveguide with perpendicular beam is shown by the dotted line. The power exchanged between wave and beam can be calculated via the perturbation approach of Madeys theory[6]. Figure 3 presents the results of the power exchange between wave and beam vs frequency for several beam energies, calculated via Madeys theory. As can be seen for different frequencies/voltages the configuration can act either as an amplifier taking energy from the beam into the wave, or as an accelerator taking energy from the wave into the beam. 

Figure 3: Increase in EM power due to interaction with an electron beam, for different electron beam energies. Figure taken from [6].

3. Traveling Wave Amplification

In this section of the paper we consider the application of metamaterials as an RF source. Where in the configuration we present a circular waveguide loaded with metamaterial shown in fig4. The metamaterial used in this configuration is a complementary split ring resonator, an all metal metamaterial. The media is “wrapped” into a cylinder around the electron beam. In this particular configuration we consider a thin gyro electron beam as a 20keV 500μA.

Figure 4 Circular waveguide loaded with metamaterial, where the beam passes on axis shown in red.

To examine the interaction between beam wave and metamaterials model the system of fig 4 was modelled using the particle-in-cell finite difference time domain simulation software MAGIC. The result of the interaction between wave and beam are shown in figure 5. Figure 5 shows that the system loaded with metamaterial triggers a strong EM wave production, where as the empty system produces negligible EM wave production.

Figure 5: Power as a function of time for both a metamaterial loaded waveguide and an empty waveguide of fig 4.

4. Conclusions

We see that a metamaterial TWT can offer an additional factor to controlling the gain-frequency characteristics, compared to the conventional TWT. The ability to arbitrarily control the phase shift of the wave with the metamaterial enables us to consider oversized or undersized. Although this approach does have the disadvantages that the bandwidth is Limited.

Abstract

In this work, we first demonstrate that pure dielectric photonic crystals can be used to realize effective nonlocal media with omnidirectional impedance matching effect, which allow near 100% transmission of light for all incident angles. Then, we show that by adding some loss into such effective nonlocal media, omnidirectional and broadband absorption can be realized with near 100% efficiency. We believe that the nonlocality enables new freedoms for light manipulation beyond the local medium framework.

1. Introduction

Transparent media are the foundation of almost all optical instruments, such as optical lens, etc. However, perfect transparency has never been realized in natural transparent solid materials such as glass because of the impedance mismatch with free space or air. As a consequence, there generally exist unwanted reflected waves at the surface of a glass slab, as illustrated in Fig. 1(a). It is well known that non-reflection only occurs at a particular incident angle for a specific polarization, which is known as the Brewster angle effect [1]. Our question is: is it possible to extend the Brewster angle from a particular angle to a wide range of or all angles, so that there is no reflection for any incident angle.

In addition, the virtual image formed by a glass slab placed in air is usually blurred to a certain extent [Fig. 1(a)]. Such a blur indicates the aberration of virtual images, and is caused by the mismatch of equal frequency contours (EFCs) between air (grey lines) and the glass (blue lines).

In this work, we propose to utilize the spatial dispersive effective parameters of pure dielectric PhCs to realize perfectly transparent media with omnidirectional impedance matching, which allows near 100% transmission of light at all incident angles. The equal frequency contours (EFCs) of such PhCs are designed to be elliptical and “shifted” in the k-space, and thus contain strong spatial dispersions. We demonstrate that at certain frequency regimes, such PhCs can allow maximal amount of light to pass through and create aberration-free virtual images. Moreover, we show that by adding some loss into such effective nonlocal media, omnidirectional and broadband absorption can be realized with near 100% efficiency. Based on this principle, photonic crystals composed of a large variety of dielectric materials can become perfect absorbers at a broad spectrum range.

2. Ultratransparent media with omnidirectional impedance matching effect

First, we find that omnidirectional impedance matching can be realized by utilizing effective medium with nonlocal parameters, i.e. permittivity and permeability that are dependent on the incident angle [2-4]. Interestingly, such an effective medium can be realized by using pure dielectric PhCs [5]. Moreover, the EFC of the ultratransparent PhC can be tuned to be a shifted ellipse (red lines) with the same height of the EFC of air (grey lines). By using ray optics, we prove that such an EFC endows the valuable ability of forming aberration-free virtual images, as presented in Fig.
Because of the shift of EFC, the PhC is beyond the local medium framework, and effective parameters are nonlocal (i.e. spatially dispersive). Interestingly, such nonlocality leads to additional phase modulation \(pd\), where \(p\) is the shift magnitude and \(d\) is the slab thickness [Fig. 1(b)].

In addition, numerical calculations confirm that such a PhC exhibits almost complete transparency (\(T>99\%\)) for nearly all incident angles \((-89^\circ, 89^\circ)\).

3. Omnidirectional perfect absorbers

Next, we show that when there is loss in the ultratransparent media with omnidirectional impedance matching effect, light energy will be gradually absorbed, as illustrated in Fig. 2. Therefore, this concept provides a straightforward way to realize omnidirectional near-perfect absorption by bulk materials without surface decoration [6].

![Figure 2: Illustration of an omnidirectional near-perfect absorber consisting of omnidirectional impedance-matched media with a small amount of material loss.](image)

For demonstrations, we simulated the distribution of electric fields when a point source is placed in front of the multilayer absorber, as presented in Fig. 3. It is seen that the radiated wave in the left side (air) is a well-defined cylindrical wave with no interference pattern induced by any reflection. This again confirms the omnidirectional characteristic of the mutilayer absorber.

![Figure 3: The simulated distribution of electric fields when a point source is placed in front of the multilayer absorber.](image)

4. Conclusions

In summary, we show that ultratransparent media with omnidirectional impedance matching effect can be realized by using pure dielectric PhCs with spatial dispersions. Moreover, by introduction appropriate material losses into such impedance-matched media, broadband and omnidirectional perfect absorbers can be realized.

Modeling large scale metamaterials for elastic waves control

Abstract

We’ve studied and proposed to apply the large scale metamaterials properties, which are based on the negative values of the Bulk modules $K$ and $G$; the Young modulus, of longitudinal elasticity, as well as on the negative mass density, in order to obtain elastic waves control. These negative values are obtained with the help of the local resonance of the elementary cells that lead to very dispersive properties of the metamaterials.

1. Introduction

We use scaled-up configurations of metamaterials for the control of very low frequency elastic waves, with application in seismic wave protection by designing meter-scale locally resonant elementary cells that lead to very dispersive metamaterials properties and low frequency stop bands, associated with negative values of Bulk moduli $K$ and $G$, Young modulus $E$ and mass density in the frequency range of interest for earthquake engineers ($0.1 – 10$ Hz).

2. Methods and contribution

In order to optimize the location of low frequency resonances associated with the stop band of interest for civil engineering, see Figure 1, we propose asymptotic estimates of eigenfrequencies. Equation (1) is an asymptotic estimate of eigenfrequency of a resonator and it encapsulates the density, shear modulus and bulk modulus of the material constituting a resonator, to optimize the location of low frequency resonances associated with the stop bands [1].

\[
f = \frac{1}{4\pi} \sqrt{\frac{\mu}{4\rho \lambda + 2\mu} \sum h_i^2}.
\]

We also introduced in [2] the concept of auxetic seismic metamaterials where our goal was to tune low frequency stop bands as we please, thanks to a negative Poisson’s coefficient, which makes unit cells contract when an axial force is applied, contrary to common, isotropic, elastic, natural materials, which have values of the Poisson coefficient constrained between 0 and 0.5, meaning that they laterally expand when an axial load is applied. In [2], we discovered that auxetic features of our specially designed seismic metamaterials permit to open very large band gaps at frequencies compatible with seismic waves.

Figure 1: First mode of iron spheres connected to concrete via 1 (left), 6 identical (middle), 6 asymmetric (right) iron ligaments [1].

Figure 2: Auxetic bow-tie element consisting of a concrete frame in air [2].

Such mechanical metamaterials are already known [3], and become increasingly topical, but were never used for seismic wave protection. In [2], we further proved that the sign and the value of the resulting Poisson’s coefficient, and
even the frequency of the band gaps, can be controlled by the angle made between elements of the frame within an elementary cell.

Another promising avenue to produce a radical change of the seismic reverberations is the creation of an artificial anisotropy by including, into a city map, some elements of different geometries, which are either full or empty. On a small scale, one could envision a design of a seismic cloak by controlling the soil artificial anisotropy with inertial resonators, buried in soil like in Figure 1, or simply placed above the soil like in Figure 3. This method inspired from earlier work on invisibility cloaks, requires some creative thinking at the interface between computer vision and artificial intelligence in mathematics and civil engineering and geophysics. As a result of a collaborative work within a multidisciplinary international team [4], we proposed an even more futurist urban design of metacities that could protect themselves from deleterious seismic waves [5]. Our proposal of transformed urbanism is born from the observation in urban seismology that some city layouts already exploit building resonances and site-city interaction to mitigate the propagating seismic field. We propose that this can be simply achieved via a spatially varying index (characterizing a quasi-conformal city map), which accounts for interaction between earthquake ground motion and multiple buildings in urban regions.

Figure 3: Creating an artificial anisotropy with inertial resonators judiciously placed within or above soil (Photo taken in Singapore).

3. Conclusions

In conclusion, we have seen that inertial resonators, which were introduced 20 years ago to achieve some acoustic neutrality [6] (this somewhat predates the field of cloaking), can be used to design seismic metamaterials that shield [1], or even detour [4,5], deleterious elastodynamic waves. Some large scale version of auxetic media that display a dynamically negative Poisson ratio, could prove useful to engineer new types of buildings’ foundations. The future of seismic metamaterials is bright.

Abstract

Predictive theory to geometrically engineer materials in continuum systems to have desired symmetry-induced effects is developed here by bridging the gap between quantum and continuum descriptions. We emphasise a predictive approach, the strength of which is demonstrated by the ability to design well-defined broadband edge states, valley-Hall networks and anisotropic quasicrystalline effects. We solely use semi-analytical models; this means we can concentrate cleanly upon issues such as group theory, and its influence upon the effects we see, without numerical distractions.

1. Introduction

Guiding waves, splitting, and redirecting them between channels, and steering waves around sharp bends in a robust and lossless manner is of interest across many areas of engineering and physics. Recent advances based upon ideas originating from topological insulators, translated to Newtonian wave systems, have inspired great interest. In particular, geometrically engineering valley-Hall photonic and phononic crystals to direct waves along interfaces in a robust tuneable manner has shown much potential. Herein, we elucidate the core concepts of these effects as well as a myriad of other exotic symmetry-induced phenomena. The group theoretic concepts used throughout transcend specific physical systems, hence, we opt to use easily solvable semi-analytical models.

2. Models

We choose to illustrate our theory within the context of flexural waves upon thin structured elastic plates, by doing so we emphasise the continuum nature of the model and show the generality of the basic ideas. These displacement eigenmodes are governed by the (non-dimensionalised) Kirchhoff-Love (K-L) equation

$$\left(\nabla^2 [\beta (x) \nabla^2] - \mu(x) \omega_n^2 \right) \psi_n \propto F(x), \quad (1)$$

and the reaction forces at the point constraints $F(x)$ introduce the dependence upon the direct lattice. This model has considerable advantages in terms of being almost completely explicit, and additionally the Green’s function is nonsingular; this leads to highly resolved solutions that enable us to interpret the results accurately. We shall also make use of a model that consists of the Helmholtz equation and periodic arrangements of small inclusions upon which the field is taken to be zero. The scatterers are then thin perfectly conducting wires or soft scatterers within acoustics.

3. Periodic structures

3.1. Hexagonal

3.1.1. Theory

Geometrical valley-Hall interfacial modes are contingent upon gapping Dirac cones [1]. In two-dimensional systems, there are only three symmetry sets that are guaranteed to yield Dirac cones, all of which occur on hexagonal lattices. These three cases are distinguished by their point groups at $\Gamma = (0,0)$ in Fourier space; these are $C_6v, C_6, C_{3v}$. We demonstrate that from these, three distinct edge states can be intelligently constructed (Fig. 1); two of these are imbued with a chiral flux that results in enhanced robustness against defects [2]. These interfacial states alongside the design paradigm espoused in [2] enables us to construct highly-efficient energy networks for classical systems (Fig. 2). The interfacial modes, within these networks, travel between geometrically distinct regions.
Figure 2: Different coloured regions in panel (a) represent geometrically distinct regions; source location indicated by green circle. Resulting scattered field shown in panel (b). Geometrically distinct interfaces result in edge states with different modal shapes.

3.1.2. Experiments

Experimental results based upon the earlier geometrical theory will also be shown for a metallic plate tesselated with magnets (Fig. 3). This experiment utilises the $C_{3v}$ case within a pinned plate model [2].

Figure 3: Structured elastic plate tesselated with magnets.

3.2. Square structures

The most commonly used models within the valleytronics community are based upon the hexagonal lattice. These are the only 2D structures that yield symmetry-induced Dirac cones. However, due to symmetry constraints, these hexagonal structures only produce valley-Hall energy-splitters that partition energy two-ways; we rectify this with an intelligently engineered three-way robust energy-splitter, the geometrical design of which is based upon the square lattice (Fig. 4). The resulting three-way broadband energy-splitter is shown within the contexts, of both, optics and elasticity [3, 4].

Figure 4: Demonstration of an optical valley-Hall three-way energy-splitter.

4. Aperiodic structures

The efficiency of the models used allow us to explore more exotic symmetry-induced phenomena; specifically, anisotropy within quasicrystals. We consider a structure periodic in some higher-dimensional space and then project it down to lower dimensional space where it becomes quasi-periodic. Quasicrystals possess broad band-gaps and demonstrate anisotropy with rotational symmetries that are unobtainable within periodic structures. Combining our semi-analytical models with a fully-fledged quasicrystalline generator allows for the efficient generation of exotic quasicrystalline patterns (Fig. 5).

Figure 5: Scattered 10-fold rotationally symmetric pattern. 10-dimensional periodic structure projected down onto a 2-dimensional plane.

Abstract
Recently, dielectric metasurfaces J-plate [1] allowed the most general conversion from any pair of orthogonal polarization states to the conjugate states with any value of orbital angular momentum. This is possible by controlling simultaneously the propagation phase, the Pancharatman-Berry (PB) phase and the form birefringence of each single element of the metasurface. J-plates can be used to generate structured light with both complex intensity as well as optical field distributions.

1. Introduction
Propagation phase and PB-phase can be independently controlled in a metasurface made of different size and differently oriented nano-elements that have all the same form birefringence value. In this way, propagation phase and PB-phase can be used independently. Arbitrary phase profiles can be then designed for illuminating circularly polarized light of opposite handedness. In the case of conversion of spin angular momentum to orbital angular momentum, this approach allows to impart arbitrary and different values of orbital angular momentum to opposite handedness circularly polarized light. Simple analytical solutions can be found for the propagation phase and the PB phase as a function of the azimuthal angle at the device plane.

However, the conversion scheme can be made more general [2] since any two orthogonal polarization states can be converted to the conjugate states with arbitrary value of angular momentum. There are in general no simple analytical solutions in this case. It is instead necessary to: (1) find the Jones matrix that represents the transformation; (2) solve for the linear eigenpolarizations on which to impart the characteristic phase shifts along x and y; (3) find the right element (from a library of simulated nano-elements) that in a specific position of the metasurface plane does the right transformation (polarization and phase).

2. Discussion
Figure 1 shows an example of a J-plate realization for circularly polarized beams that are converted into two helical modes with topological charge +3 and +4. Figure 1(a) shows the emerging beam representation on a high-order poincare sphere (HOPS) [3].

Figure 1: (a) Representation of the polarization base and orbital angular momentum modes on the high-order
Poincare sphere. (b) Intensity profile of a topological charge +3 beam imparted by a J-plate on a left-circularly polarized beam. (c) Interference with a spherical reference wave. (d) The same J-plate converts a right-circularly polarized beam into a beam with orbital angular momentum +4. (e) interference of the beam in (d) with a reference spherical wave.

The north and the south poles of the sphere are the right-circularly polarized beam with topological charge +3 and the left-circularly polarized beam with topological charge +4, respectively. For these vortex beams, the intensity profile and the spiral interference with a reference plane wave are showed in figures 1(b-e). When linearly polarized light illuminates the device, both vortex beams are generated producing characteristic structured intensities along the beam propagation.

3. Conclusions

In a dielectric J-plate, at each position (x, y) occupied by a nano-element, the birefringence, the overall phase delay and the orientation of the optical axes are controlled independently and simultaneously. This in fact results into an inhomogeneous distribution of phase delays, birefringence and axes orientation that cannot be obtained with any other single device.

Abstract
The physics arising from the orbital angular momentum (OAM) as a significant property of twisted light is enhanced considerably when combined with optical spin. The superposition of multiple beams involving twisted light in any desired geometry can in principle be generated in the laboratory, giving rise to optical fields that are rich in both total amplitude and total phase. Their effects on the dynamics of atoms immersed in them as well as the exchange of angular momentum in their interactions with matter are highlighted.

Introduction
The role of the optical spin (wave polarisation) of multiple ‘untwisted’ light in laser atom cooling and trapping is well known and has been shown to give rise to axial polarisation gradients [1]. It is also the basis for efficient laser cooling of atoms down to ultra-low temperatures. Light field distributions arising from the superposition of multiple twisted beams in one, two, and three space dimensions can, in principle, be created in the laboratory using computer-generated holograms. Inevitably the wave polarisations of the individual participating twisted beams collectively determine the overall vector field distributions.

This talk aims to highlight the effects for a variety of beam scenarios, including co- and counter-propagating beams of various combinations of wave polarizations and in various focusing arrangements, including shifted focused beams[2]. In practice the field intensity which controls the trapping presents regions of trapping sites. However, for the one- and two-dimensional cases, even multiple beams with the same linear polarizations show an interesting dependence of the overall phase function on the individual amplitude distributions, as well as the individual phase functions. The influence of the Gouy and curvature effects on the interference is highlighted for the case of multiple highly twisted, but axially shifted, Laguerre-Gaussian beams, in which case the interference leads to regions where there is a finite number of atom trapping sites.

Microwave magnetoelectric photonics based on magnetic-dipolar-mode resonators

Abstract

Microwave magnetoelectric photonics bridges microwave engineering, optoelectronics and magnetoelectric-coupling effects. Recently, it was shown that with use of quasi-2D ferrite disks with magnetic-dipolar-mode (MDM) oscillations one can observe near-field chirality in microwaves. The fields originated from a MDM ferrite disk, called magnetoelectric (ME) fields, carry both spin and orbital angular momentums. They are characterized by power-flow vortices and non-zero helicity. With use of MDM ferrite resonators we have unique microwave photonics devices.

1. Introduction

In increasing the capabilities of the optical and microwave techniques further into the subwavelength regime, quasistatic resonant structures has attracted considerable interest. Electromagnetic responses of electrostatic plasmon resonances in optics and magnetostatic magnon resonances in microwaves give rise to a strong enhancement of local fields near the surfaces of subwavelength particles [1]. We propose to realize subwavelength confinement in microwaves by using dipolar-mode (magnetostatic) magnon oscillations in ferrite-disk particles. Our studies of interactions between microwave electromagnetic fields and small ferrite particles with magnetic-dipolar-mode (MDM) oscillations show strong localization of electromagnetic energy. MDM oscillations in a ferrite disk are at the origin of topological singularities resulting in Poynting vector vortices and symmetry breakings of the microwave near fields. The energy, spin and orbital angular momenta of MDM oscillations constitute the key physical quantities that characterize the magnetoelectric-field (ME-field) configurations. In small ferromagnetic-resonance samples, macroscopic quantum coherence can be observed. Long range magnetic dipole–dipole correlation can be treated in terms of collective excitations of the system. In a case of a quasi-2D ferrite disk, the quantized forms of these collective matter oscillations – the MDM magnons – were found to be quasiparticles with both wave-like and particle-like behaviors, as expected for quantum excitations [2].

2. MDM-ME microwave photonics devices

We show that new subwavelength microwave structures can be realized based on a system of interacting MDM ferrite disks. Wave propagation of electromagnetic signals in such structures is characterized by topological phase variations. Unidirectional ME field resonant tunneling is observed due to the distinguishable topology of the ‘forward’ and ‘backward’ ME field excitations.

2.1.1. MDM-disk arrays

Interactions of microwave fields with an MDM ferrite disk and MDM-disk arrays open a perspective for creating engineered electromagnetic fields with unique symmetry properties [3].

Figure 1: The power-flow-density distribution on a vacuum plane (plane A) for a structure of the in-plane nine-particle array with a center of symmetry. An insert shows a TE10-mode rectangular waveguide with a ferrite-disk array.

2.1.2. MDM-ME ferrite sensors and microwave microscops

Strong energy concentration and unique topological structures of the near fields originated from the MDM resonators allow effective measuring material parameters in microwaves, both for ordinary structures and objects with chiral properties. Development of such subwavelength sensors for direct microwave characterization of microscopic material structure with application to biology and nanotechnology is a subject of high importance. The shown ME-field sensing is addressed to microwave biomedical diagnostics and pathogen detection and to
deepen our understanding of microwave biosystem interactions. It can be also important for an analysis and design of microwave chiral metamaterials [2–7].

Figure 2: Experimental setup for near-field characterization of chiral parameters based on MDM-ME ferrite sensors.

![Figure 3: MDM-ME microwave microscope and the twisted structure of the probe near field.](image)

Figure 3: MDM-ME microwave microscope and the twisted structure of the probe near field.

2.1.3. MDM-ME microwave antennas

Based on a small microwave antenna with a MDM ferrite resonator, we observe the topological ME effects in far-field microwave radiation. We show that the microwave far-field radiation can be manifested with a torsion structure where an angle between the electric and magnetic field vectors varies. We discuss the question on observation of the regions of localized ME energy in far-field microwave radiation [8, 9].

![Figure 4: MDM-ME microwave antenna and the near-field topology.](image)

Figure 4: MDM-ME microwave antenna and the near-field topology

3. Conclusion

Microwave ferrite structures with a reduced dimensionality brings into play new effects, which should be described based on the quantized picture and demonstrate the properties of artificial atomic structures. The subwavelength confinement of the fields due to ferrite particles with MDM oscillations is related to the field quantization and symmetry breakings. A distinctive feature of the near fields originated from MDM ferrite particles – the ME fields – is the presence of the helicity structure. Use of subwavelength MDM fields with energy localization and symmetry breakings opens a perspective for novel near- and far-field microwave applications. Unique topological properties of these fields can be used to study specific structural effects in natural and artificial materials. Presently, direct detection of biological structures in microwave frequencies and understanding of the molecular mechanisms of nonthermal microwave effects is a problem of a great importance. The question of effective characterization of chemical and biological objects in microwaves can be solved when one develops special sensing devices with microwave chiral probing fields. We showed that small ferrite-disk resonators with MDM oscillations may create microwave superchiral fields with strong subwavelength localization of electromagnetic energy. Based on such properties of the fields, we propose a novel near-field microwave sensor with application to material characterization, biology, and nanotechnology. Generation of far-field orbital angular momenta from near-field chirality of MDM structures is another subject of a great interest in microwaves. This will allow creation of localized microwave radiation with spin and orbital angular momentums. Such propagating twisted microwave fields can be used for material studies and communication systems with topological-phase modulation.

Abstract

We introduce the concept of two- and three-dimensional optical helicity lattices wherein the helicity of light alternates amidst a homogeneous electric field of the optical field energy density. Many of our lattices show regions of bright superchirality, where locally the helicity is larger than the modulus square of the electric field. Our helicity gratings create the possibility of trapping ultracold chiral molecules specific to their enantiomer in adjacent lattice sites.

1. Introduction

In optics helicity is a pseudoscalar which characterises locally the handedness of light [1, 2]. Similar to the varying intensity structure of conventional optical lattices it is possible to create helicity lattices by superimposing plane waves. To study the interaction of molecules with a varying helicity density landscape in isolation we construct helicity lattices with a homogenous energy density of the electromagnetic field by using orthogonal polarisations for the constituent plane waves [2].

In this way it is possible to construct one- and two-dimensional helicity lattices with two and three plane waves respectively. This suggests in turn that it is impossible to construct three-dimensional helicity lattices with a homogeneous energy density as there are at most three mutually orthogonal polarisations in space. However, if we relax the condition of a homogeneous energy density to apply only to the electric part and not the magnetic one, it is possible to construct larger superpositions for which the interference terms in the electric field cancel. In this manner a three-dimensional helicity lattice with a homogeneous electric part of energy density can be constructed [3].

2. Construction of superpositions

We work in the classical electrodynamics in free space and consider superpositions of $N$ plane waves, each of which has the same angular frequency $\omega = ck$. For a superposition of $N$ waves the resulting electric and magnetic fields are

$$\mathbf{E} = \text{Re} \bar{\mathbf{E}} = \text{Re} \left( \sum_{j=1}^{N} \tilde{E}_j e^{i(k_j \cdot \mathbf{x} - \omega t)} \right),$$

$$\mathbf{H} = \text{Re} \bar{\mathbf{H}} = \text{Re} \left( \frac{1}{i\omega} \sum_{j=1}^{N} \mathbf{k}_j \times \tilde{E}_j e^{i(k_j \cdot \mathbf{x} - \omega t)} \right).$$

The complex amplitudes $\tilde{E}_j$ define the polarisations, amplitudes and phases of the waves. Because light’s polarisation is transverse $\tilde{E}_j \cdot \mathbf{k}_j = 0$ has to hold for all plane waves.

2.1. Interference cancellation

The mean square of the electric field is given by

$$\frac{\omega}{2\pi} \int_0^{2\pi} \mathbf{E} \cdot \mathbf{E}^* dt = \frac{1}{2} \mathbf{E} \cdot \mathbf{E}^* = \frac{1}{2} \left( \sum_{j=1}^{N} \tilde{E}_j \cdot \tilde{E}_j^* + \sum_{i=1}^{N} \sum_{j \neq i} \tilde{E}_i \cdot \tilde{E}_j e^{i(k_i - k_j) \cdot x} \right).$$

If this is to be homogeneous, the second sum must vanish. The most obvious way to achieve this is to choose the constituent plane waves such that no two interfere, in which case $\tilde{E}_i \cdot \tilde{E}_j^* = 0 \forall i \neq j$. This can be done for at most three plane waves because there are three orthogonal polarisation directions possible. In this paper we recognise that it is also possible, however, to allow multiple pairs of waves to interfere, provided the associated interference patterns cancel. To appreciate this, suppose that there exists within the superposition a pair $(i \neq j)$ of interfering waves, with the spatial periodicity of the associated interference pattern being dictated by the wavevector difference $\mathbf{k}_i - \mathbf{k}_j$. If another pair $(i' \neq j')$ of interfering waves with the same wavevector difference $\mathbf{k}_i - \mathbf{k}_j = \mathbf{k}_{i'} - \mathbf{k}_{j'}$, can be identified, giving an associated interference pattern with the same spatial periodicity, then the two interference patterns will cancel provided that $\tilde{E}_i \cdot \tilde{E}_{i'}^* + \tilde{E}_j \cdot \tilde{E}_{j'}^* = 0$. The same reasoning applies for more than two pairs of interfering waves with the same wavevector difference. This is it this trick that allows us to superpose more than three plane waves whilst keeping the mean square of the electric field homogeneous.

3. Superchirality

The definition of helicity density stems from plasma physics and is known for arbitrary light fields in vacuum and for an arbitrary medium with linear response. As we are considering only monochromatic light fields we can use the simpler expression $\mathcal{H} = \frac{1}{i\omega} \text{Im}(\mathbf{E} \cdot \mathbf{H}^*)/c \omega$. The helicity density is bounded between $\pm \frac{1}{4\omega} (\epsilon_0 \mathbf{E}^* \cdot \mathbf{E}^* + \mu_0 \mathbf{H} \cdot \mathbf{H}^*)$. 

---

*Abstract*

We introduce the concept of two- and three-dimensional optical helicity lattices wherein the helicity of light alternates amidst a homogeneous electric part of the optical field energy density. Many of our lattices show regions of bright superchirality, where locally the helicity is larger than the modulus square of the electric field. Our helicity gratings create the possibility of trapping ultracold chiral molecules specific to their enantiomer in adjacent lattice sites.

1. Introduction

In optics helicity is a pseudoscalar which characterises locally the handedness of light [1, 2]. Similar to the varying intensity structure of conventional optical lattices it is possible to create helicity lattices by superimposing plane waves. To study the interaction of molecules with a varying helicity density landscape in isolation we construct helicity lattices with a homogenous energy density of the electromagnetic field by using orthogonal polarisations for the constituent plane waves [2].

In this way it is possible to construct one- and two-dimensional helicity lattices with two and three plane waves respectively. This suggests in turn that it is impossible to construct three-dimensional helicity lattices with a homogeneous energy density as there are at most three mutually orthogonal polarisations in space. However, if we relax the condition of a homogeneous energy density to apply only to the electric part and not the magnetic one, it is possible to construct larger superpositions for which the interference terms in the electric field cancel. In this manner a three-dimensional helicity lattice with a homogeneous electric part of energy density can be constructed [3].

2. Construction of superpositions

We work in the classical electrodynamics in free space and consider superpositions of $N$ plane waves, each of which has the same angular frequency $\omega = ck$. For a superposition of $N$ waves the resulting electric and magnetic fields are

$$\mathbf{E} = \text{Re} \bar{\mathbf{E}} = \text{Re} \left( \sum_{j=1}^{N} \tilde{E}_j e^{i(k_j \cdot \mathbf{x} - \omega t)} \right),$$

$$\mathbf{H} = \text{Re} \bar{\mathbf{H}} = \text{Re} \left( \frac{1}{i\omega} \sum_{j=1}^{N} \mathbf{k}_j \times \tilde{E}_j e^{i(k_j \cdot \mathbf{x} - \omega t)} \right).$$

The complex amplitudes $\tilde{E}_j$ define the polarisations, amplitudes and phases of the waves. Because light’s polarisation is transverse $\tilde{E}_j \cdot \mathbf{k}_j = 0$ has to hold for all plane waves.

2.1. Interference cancellation

The mean square of the electric field is given by

$$\frac{\omega}{2\pi} \int_0^{2\pi} \mathbf{E} \cdot \mathbf{E}^* dt = \frac{1}{2} \mathbf{E} \cdot \mathbf{E}^* = \frac{1}{2} \left( \sum_{j=1}^{N} \tilde{E}_j \cdot \tilde{E}_j^* + \sum_{i=1}^{N} \sum_{j \neq i} \tilde{E}_i \cdot \tilde{E}_j e^{i(k_i - k_j) \cdot x} \right).$$

If this is to be homogeneous, the second sum must vanish. The most obvious way to achieve this is to choose the constituent plane waves such that no two interfere, in which case $\tilde{E}_i \cdot \tilde{E}_j^* = 0 \forall i \neq j$. This can be done for at most three plane waves because there are three orthogonal polarisation directions possible. In this paper we recognise that it is also possible, however, to allow multiple pairs of waves to interfere, provided the associated interference patterns cancel. To appreciate this, suppose that there exists within the superposition a pair $(i \neq j)$ of interfering waves, with the spatial periodicity of the associated interference pattern being dictated by the wavevector difference $\mathbf{k}_i - \mathbf{k}_j$. If another pair $(i' \neq j')$ of interfering waves with the same wavevector difference $\mathbf{k}_i - \mathbf{k}_j = \mathbf{k}_{i'} - \mathbf{k}_{j'}$, can be identified, giving an associated interference pattern with the same spatial periodicity, then the two interference patterns will cancel provided that $\tilde{E}_i \cdot \tilde{E}_{i'}^* + \tilde{E}_j \cdot \tilde{E}_{j'}^* = 0$. The same reasoning applies for more than two pairs of interfering waves with the same wavevector difference. This is it this trick that allows us to superpose more than three plane waves whilst keeping the mean square of the electric field homogeneous.

3. Superchirality

The definition of helicity density stems from plasma physics and is known for arbitrary light fields in vacuum and for an arbitrary medium with linear response. As we are considering only monochromatic light fields we can use the simpler expression $\mathcal{H} = \frac{1}{i\omega} \text{Im}(\mathbf{E} \cdot \mathbf{H}^*)/c \omega$. The helicity density is bounded between $\pm \frac{1}{4\omega} (\epsilon_0 \mathbf{E}^* \cdot \mathbf{E}^* + \mu_0 \mathbf{H} \cdot \mathbf{H}^*)$.
For a superposition of \(N\) plane waves one has
\[
\mathcal{H} = \frac{-i}{4c\omega} \sum_{i,j=1}^{N} (\tilde{E}_i \cdot \tilde{H}_j^* - \tilde{E}_j^* \cdot \tilde{H}_i) e^{i(k_i - k_j) \cdot x}. \tag{3}
\]

When all waves are linearly polarised, the terms with \(i = j\) are zero and only the ‘interference terms’ remain.

Typically, our helicity lattices show regions of superchirality, that is regions where the local helicity density exceeds the mean square of the electric field \(\sqrt{\epsilon_0 \mu_0 |\text{Im}(\tilde{E} \cdot \tilde{H}^*)|} > \epsilon_0 \tilde{E}^* \cdot \tilde{E}\) [4]. Previous realizations of superchiral light relied on interference to create dark regions where the mean square of the electric field is smaller than the helicity density, but our lattices exhibit bright regions of superchirality, where locally the helicity density exceeds the homogenous modulus square of the electric field \(\sup \left(\sqrt{\epsilon_0 \mu_0 |\text{Im}(\tilde{E} \cdot \tilde{H}^*)|}\right) > \sup (\epsilon_0 \tilde{E}^* \cdot \tilde{E})\). That is, the local helicity is large compared to the squared electric field anywhere.

4. Explicit examples

In this section our graphics of the helicity structure will be \(4 \times 4 \times 4\) wavelengths large and we use blue for negative helicity and red for positive helicity. We will show diagrams to illustrate the superpositions for which we plot the helicity density. In these diagrams, gray arrows indicate wavevectors and electric field polarizations are indicated with yellow arrows. Green arrows to indicate the magnetic polarizations are included for reference, as well. Mutually cancelling pairs of interference terms are indicated by red lines, and interference terms contributing to the inhomogeneous helicity density are shown as black dashed lines.

5. Conclusion

Apart from being an optics curiosity, noninterfering superpositions of more than three waves raise new mathematical challenges and provide new ways to probe and manipulate chiral matter, such as the ability to trap ultracold atoms specific to their enantiomer in neighbouring sites of a helicity lattice.

Skyrmion structure in vector beams

School of Physics and Astronomy, University of Glasgow, Scotland, U.K.
*corresponding author, E-mail: s.gao.2@research.gla.ac.uk

Abstract
Vector beams have both a spatially varying amplitude and polarization, for light, or spin direction for electrons. Associated with these we find a topological feature, the skyrmion number, that is robust against any deformation during propagation. The simplest way to map out this feature is to use the associated skyrmion field. This is a transverse or divergence-less field and so has neither sources nor sinks. Mapping out the skyrmion field for these beams reveals constraints on the manner in which vector beams can be manipulated.

1. Skyrmion number
Skyrmions were introduced by Skyrme in 1962 [1] as a topological soliton for the pion field, aimed at explaining the stability of hadrons. Although this idea is not part of the mainstream particle theory, it has been adopted widely in many areas of physics including quantum liquids [2], magnetic materials [3, 4], and in the study of fractional statistics [5]. Recently they have been found in optics by the controlled interference of plasmon polaritons [6]. We show here that freely propagating paraxial beams in the form:

\[ |(\mathbf{r})_i| = u_0(|(\mathbf{r})_i|) + u_1(|(\mathbf{r})_i|) \]

also possess a non-trivial skyrmion field and with it an integer skyrmion number. Here \( u_0(r) \) and \( u_1(r) \) are two orthogonal spatial modes. The states \( |P\rangle \) and \( |V\rangle \) represent either any two orthogonal spin directions for the electron or any two orthogonal directions on the Poincaré sphere for a light beam.

Skyrmions are characterized by the topological integer \( n \), the skyrmion number, which can be evaluated as a surface integral of the form

\[ n = \frac{1}{4\pi} \oint_S \mathbf{M} \cdot \left( \frac{\partial \mathbf{M}}{\partial x} \times \frac{\partial \mathbf{M}}{\partial y} \right) dx dy, \]

where \( \mathbf{M} \) is the unit vector in the local effective magnetization field. For structured beams, this is the Bloch vector for electron beams or Poincaré vector for optical beams.

When the spatial modes \( u_0(r) \) and \( u_1(r) \) are two Laguerre-Guassian beams with the same focus but different winding number \( \ell_+ \) and \( \ell_- \) respectively, as depicted in Fig. 1, we find the simple value:

\[ n = \ell_+ - \ell_. \]

In a more complicated case where although \( u_0(r) \) and \( u_1(r) \) are still both Laguerre-Guassian beams, their ratio \( v(r) \) is more complicated and has the general form

\[ v(r) = f(\rho, z)e^{i\theta(\rho, z)}e^{i\ell_\Delta \phi}, \]

where \( \ell_\Delta \) is the difference between the winding numbers of \( u_0(r) \) and \( u_1(r) \) while \( f \) and \( \theta \) are real functions of coordinates \( \rho \) and \( z \). We find the skyrmion number is

\[ n = \ell_\Delta \left( \frac{1}{1 + f^2(0, z)} - \frac{1}{1 - f^2(\infty, z)} \right). \]

We note that this does not depend on the specific orientation of the spin or polarization, indeed performing a global spin or polarization rotation does not change this result.
Figure 1: This is an illustration of the paraxial beam given in Equation (1), when the two spatial modes are Laguerre-Gaussian modes with $\ell_+ = 1$ and $\ell_- = 0$ focusing at the same point: a) A schematic diagram of the beam; b) The $\mathbf{M}$ vector field when the phase difference is $\frac{\pi}{2}$; c) The $\mathbf{M}$ vector field when there is no phase difference between $u_0$ and $u_1$.

2. Skyrmion field

We can also understand the skyrmion number as the flux of a vector field, the skyrmion field, in the $z$ direction. The general form of this skyrmion field is

$$\Sigma_i = \frac{1}{2} \varepsilon_{ijk} \varepsilon_{pqr} M_p \frac{\partial M_q}{\partial x_j} \frac{\partial M_r}{\partial x_k}. \quad (6)$$

It is not difficult to verify that this field is divergence-less, which means that the associated field lines can form loops but have no sources nor sinks. This means that the field can neither be created or destroyed and that, for example, the creation of a beam with a total flux of the skyrmion field 1 is accompanied by the creation of a further beam with a total flux of skyrmion field $-1$. We note that the skyrmion field, being divergence-less, can be written as a curl of another vector field. We evaluate this quantity and note its similarity to the velocity field in the theory of superfluids [2].

Abstract

We consider the spin-dependent charge dynamics in quantum nanostructures in response to radiation fields with a topologically non-trivial wave fronts. We find that optical vortices, i.e. fields with spatially varying phase of the wave front, are well suited as a versatile tool for the ultrafast generation and control of spin accumulations. Vector beams with spatially varying polarization state induce rather different types of charge and spin dynamics. For instance, radially polarized vector beams drive radially breathing charge-density oscillations via electric-type quantum transitions while azimuthally polarized beams trigger a dynamic Aharonov-Bohm effect leading to an oscillating magnetic moment without affecting the charge dipolar transitions at all.

1. Introduction

The experimental availability of structured light fields for a large set of parameters fueled the intense recent research in this area. Structured fields with topologically non-trivial wave fronts have been employed for applications ranging from optical tweezers for microscale objects to electronics and life sciences, quantum information or optical telecommunications. Especially light pulses carrying orbital angular momentum (OAM) enable the photo-mechanics of moving, trapping and rotating nanostructured objects as well as atoms or molecules. Further, such beams were used to study otherwise inaccessible angular momentum states of atoms and solids. In addition, spin-orbit interaction allows a coupling to the spin of the angular momentum that has been transferred from the photons to the charge, which opens the way for using structured light for optospintronic applications, as will be discussed in this contribution in more detail.

On the other hand, vector beams exhibit a fundamentally different behavior in driving quantum matter. While their intensity profile is similar to optical vortices and OAM carrying beam, a radially and azimuthally polarized vector beams for instance do not trigger a unidirectional charge current in a quantum system but mainly radially-breathing charge response or a transient magnetic response.

Figure 1: Schematics of the light-driven spin Hall effect. A focused THz optical vortex beam (red circles) excites a circulating current $j$ (green arrow) upon the transfer of optical OAM to charge carriers confined in the quantum ring. Due to the spin-orbit interaction the circular orbital motion is accompanied by a drift spin-polarized current to ring edges. This leads to an accumulation of spin polarized charge density (indicated by arrows) at the ring boundaries which can act for example with a torque on an interfaced magnet.

2. All-Optical Generation of the Spin-Hall current by optical vortices

For the emergence of photo-induced spin Hall current (SHE) the spin-orbit coupling is crucial. Working within the Lorentz-gauge for vector potential of the incident light beam and accounting for the surrounding phonon bath, we evaluate the time evolution of the light-induced spin-dependent charge dynamics. To this end, we use within the single-particle picture the Hamiltonian

$$\hat{H}(t) = \hat{H}_0 + \hat{H}_{\text{int}}(t) + \hat{H}_{\text{ph}} + \hat{H}_{\text{B}}$$

where the unperturbed carriers in a quantum ring with confinement potential $V(r)$ are described by $\hat{H}_0$. The coupling to the laser fields is given in terms of $\hat{H}_{\text{int}}(t)$ while the phononic environment is characterized by the electron-phonon coupling $\hat{H}_{\text{ph}}$, and the bath $\hat{H}_{\text{B}}$. More details on the Hamiltonians can be found in the full paper [2].

Generally, the irradiation by a THz optical vortex leads to a directed circulating photocurrent that emerges due to the resonant excitation of the charge carriers and the simultaneous transfer of the OAM to them [1]. Moreover, a full-numerical solution of the three-dimensional Schrödinger equation extended to the spin degree of freedom reveals an accumulation of the spin-polarized circulating currents at
the central frequency characterized by the energy difference between the radial sublevels of the quantum structure (cf. Fig. 2). As evidenced by our numerical simulations of a quantum ring irradiated by a vector beam with radial and azimuthal polarization, the internal angular momentum state can not be changed. However, the radially polarized vector beam (RVB) triggers via electric transitions radial charge oscillations which one can interpret as a symmetric breathing charge-density cloud. We note that such a collective charge excitation is non-dipolar in contrast to the usage of spatially homogeneous laser fields. The evaluated local dipole moment is the same in all radial directions and oscillates with a frequency characterized by the energy difference between the radial sublevels of the quantum structure (cf. Fig. 2). As a result, the averaged total dipole moment is zero:

\[ \mathbf{d}(t) = \int \mathbf{r} \rho_e(\mathbf{r}, t) \mathbf{r} = 0 \]  

where \( \rho_e(\mathbf{r}, t) \) is the driven charge density. Furthermore, this charge response to the incident light field is of an electric-type [3].

In contrast, for the azimuthally polarized vector (AVB) beam we demonstrated that the associated electric contribution to the light-matter Hamiltonian \( H_{int}(t) \) vanishes in the cylindrically symmetric geometry since \( \mathbf{r} \cdot \mathbf{E}(\mathbf{r}, t) = 0 \). Thus, the AVB induces no electric (dipole) moment. In Fig. 2 we present the results of a full-numerical simulations which can be interpreted by first-order perturbation theory. It can be shown that the main contribution to the light-induced current is given by circulating currents:

\[ j_e(\mathbf{r}, t) = \frac{e^2}{m_0} \rho_e(\mathbf{r}, t) f_{AVB}(r) \Omega(t) \sin(\omega t) \]  

where \( f_{AVB}(r) \) describes the radial profile of the AVB, \( \Omega(t) \) is the temporal envelope of the pulse and \( \omega \) the central frequency. As a consequence, the charge density oscillates with the frequency of the driving vector beam field which means that, beyond transient effects, no directional time-averaged current is induced in \( \phi \)-direction. The oscillating circularly currents give rise to an oscillating magnetic moment \( \mathbf{m}(t) = 1/2 \int \mathbf{r} \times \mathbf{j}(\mathbf{r}, t) \) which is shown in Fig. 2. In line with the analytical predictions, the build-up and decay times are locked to the applied external field. Furthermore, the interaction is of a magnetic-type and represents a dynamical Aharonov-Bohm effect.

4. Conclusion

The present contribution represents an overview of new effects akin to the interaction of topologically non-trivial photonic fields with quantum matter. Both, charge and spin degrees of freedom of the confined carriers are affected in a unique way. It is well-known that optical vortices transfer OAM to charge carriers if the requirements on symmetry and energy landscape are fulfilled. In combination with the spin-orbit coupling an all-optical spin Hall effect can be generated.

Vector beams share some features with optical vortices but the corresponding fundamental light-matter interaction reveals marked differences. No angular momentum transfer is possible and no electric dipole moment can be induced for the systems that we studied. Nevertheless, we find interesting and remarkable effects on the charge carriers: radially polarized vector beams trigger via non-dipolar electric transitions radial charge oscillations while azimuthally polarized vector beams generate via a magnetic interaction oscillating magnetic moments.

Abstract

Light-matter interaction between a structured light and metallic structures allows for interesting plasmonic mode excitation with its unique selections rules. Importantly, the selection rule depends on the size of the structures and the shape of the structured light. Here, we compare two Archimedean spirals consisting of bent gold nanorods with different sizes when illuminated by an orbital angular momentum light. We show the vortex generation and control for a micrometer-sized spirals.

1. Introduction

In a gold nanoplate with Archimedean spiral shape grooves, a vortex of the surface plasmon polariton (SPP) field can be formed at the centre of the Archimedean spiral [1, 2, 3]. There is an optical analogue of the SPP vortex field, known as orbital angular momentum (OAM) light which has a vortex at the beam axis with non-zero OAM. A difference between SPP vortex and OAM light is that while for the SPP the field is confined at the two-dimensional surface and the evanescent SPP have an imaginary wavevector perpendicular to the interface and thus the confinement is associated with a transverse spin, OAM light has a real wavevector also with a component pointing along the propagation direction.

Due to the ability of encoding information in its optical phase, the OAM light has become attractive for quantum information and communication technologies. For these applications, it is essential to implement an efficient generation and detection of the OAM. Therefore, various plasmonic structures have been proposed and the light-matter interaction in these structures has been studied intensively [4, 5]. In this work, we explore the interaction of OAM light with Archimedean spiral metallic structures. We show that the Archimedean spiral structure offers the possibility to generate a vortex in the free optical field by considering a micrometer-sized structure made of bent gold nanorods. Moreover, we further analyse the resonance behaviour for a nanometer-sized structure illuminated by OAM light.

2. Theory

2.1. Archimedean spirals

An Archimedean spiral is a spiral whose radius increases when making a rotation following the polar equation

$$r(\phi) = r_0 + d \frac{\phi}{2\pi}$$

where $r_0$ is the starting radius and after one rotation the radius has increased by the distance $d$. This definition of an Archimedean spiral can be generalized by dividing a single rotation into $m$ elements. Then the radius $r_m$ for each element is given by

$$r_m(\phi) = r_0 + d \frac{\text{mod}(m\phi, 2\pi)}{2\pi}$$

where $d$ is the distance between the starting point of the one element and the end point of the other element and mod is the modulus function that gives the remainder of the division of $m\phi$ by $2\pi$. An example of a segmented Archimedean spiral ($m = 4$) is shown in Fig. 1.

2.2. Orbital angular momentum light

In general, a light carries both SAM and OAM. SAM of light is associated with polarization $s$ that is the difference in phase between the two electric filed components on a plane perpendicular to the light propagation direction. While a plane wave light has zero OAM, a structured light can have non-zero OAM if it has a phase change along

![Figure 1: Geometry of the Archimedean spiral structure with $m = 4$ elements in the $xy$-plane.](image-url)
the azimuthal direction around the beam axis. The OAM is quantified by the integer number \( \ell \) and the OAM light is also called ‘twisted light’ because it has a helical wavefront. Although several different mathematical descriptions are employed for a radial dependence, we here consider Bessel beams because they are exact solutions of Maxwell equations.

3. Results

3.1. Micrometer-sized spiral

First, we consider an excitation with an OAM light beam with \( \ell = \pm 1 \) as well as different polarizations \( s = \pm 1 \). The different rows in Fig. 2 display the fields for excitation with varying OAM \( \ell \pm 1 \) and the two columns correspond to the different signs of polarization \( s = \pm 1 \). Let us look at an excitation with positive polarization \( s = \pm 1 \) (left) and an OAM light beam with \( \ell = +1 \) in the first row and \( \ell = -1 \) in the second row. We find a vortex in the centre of the spiral, but the number of maxima is 5 for \( \ell = +1 \) and 3 for \( \ell = -1 \). In agreement with the number of maxima, the phase shows 5 and 3 jumps, respectively meaning that the topological charge of the vortex is \( v = 5 \) and \( v = 3 \). This indicates that the topological charge of the vortex \( v \) in a \( m \)-segmented Archimedean spiral can be calculated by

\[
v = |m + \ell|.
\]

Interestingly, the topological charge \( v \) does not depend on \( s \) with \( s = -1 \) leading to the same behaviour as \( s = +1 \).

3.2. Nanometer-sized spiral

Next, we look into whether an Archimedean spiral structure also can have a strong optical response at nanometer scales. In this nanometer-sized spiral case, localized surface plasmon resonances are expected to dominate the optical response [6]. For rotationally arranged nanoantennas, the resonances induced by OAM light can be very different to an excitation with plane waves and the resonance behaviour strongly depends on both the OAM and polarization of the light beams [4]. We found that the resonances are of different type compared to the excitation of plane wave and are thus classified as dark modes, which have a quadrupolar and an azimuthal character excited by OAM light of the parallel and anti-parallel class, respectively.

4. Conclusions

In conclusion, we have considered the interaction of OAM light with a metallic Archimedean spiral structure. Depending on the scale of radius in comparison to the excitation wavelength the Archimedean spiral behaves differently. For a micrometer-sized spiral, an optical vortex can be generated in the centre of the spiral and the topological charge can be controlled by the OAM value of the exciting field, while it is independent from the handedness of polarization. For a nanometer-sized Archimedean spiral, the optical response is dominated by the near-field and we found pronounced resonances originating from localized SSPs.

Controlling Internal Quantum States of Subwavelength Systems with Optical Vortices

Andrei Afanasev1*, Maria Solyanik-Gorgone1

Abstract
Quantized optical vortices, or the twisted photons, may carry preset amounts of angular momentum along their direction of propagation, thus allowing for quantum transitions otherwise forbidden for conventional plane-wave light. We address the question of the angular momentum transfer to internal degrees of freedom of quantum systems excited by the twisted photons, and discuss appropriate polarization observables. We will show that interactions of such beams generate parity-conserving single spin asymmetries due to presence of an orbital angular momentum, showing in circular dichroism even in the isotropic atomic matter. We extend our theory approach to the case of semi-conductor quantum dots and demonstrate associated spin-orbit effects for spin injection of photoelectrons in bulk GaAs.

1. Introduction
Conservation of angular momentum in the interaction of the photons with quantum systems leads to well-known selection rules that control allowed quantum states of the excited physical system. Quantized optical vortices, or the twisted photons, defy some of the known quantum selection rules. As was shown theoretically [1,2] and demonstrated experimentally with single trapped 40Ca ions [3,4], Zeeman sublevels of the excited atomic states are populated differently under twisted light, with the quantum transition probability strongly depending on the radial distance to the optical vortex axes at sub-wavelength scales. Moreover, in the field of the optical vortex, the conventional multipole transitions (e.g., E2-, M1) can be separated by mapping the dependence on the atom’s radial position within a vortex [5], thus providing a novel tool for multipole analysis.

2. Results and Discussion
In this work, we consider quantum states in III-V semiconductor (GaAs) excited by a twisted photon carrying total angular momentum along the direction of propagation equal to \(m\). First considered were a semiconductor quantum dot (QD), for which we employed an atom-like approach outlined in Refs.[1,2]. The results of calculations are shown in Figure 1.

Next, we developed a theory approach to spin transfer by twisted photons to photoelectrons in bulk GaAs. We show that spin polarization of the photoelectrons, that find wide applications in spintronics and polarized electron sources for particle accelerators, is in fact altered by the combined effect of orbital angular momentum and spin of the incident photons. The results, as shown in Figure 2, demonstrate that the polarization is different from plane-wave photon case (that is equal to \(\pm 50\%\) for unstrained GaAs for given circular polarization), while the difference strongly depends on the location of the photoelectron with respect to the vortex center, similarly to atom or QD cases.

Figure 1: Quadrupole transition rates for photoexcitation of a QD by Laguerre-Gauss (top plot) and BB (bottom plot) the twisted photons of wavelength \(\lambda = 550\text{nm}\), which corresponds to the spatial dimensions of QD of the order \(R_0\approx 10\text{nm}\)

Figure 2: Spin polarization of photoelectrons from QD and bulk GaAs for given circular polarization.
Figure 2: Photoelectron polarization in bulk GaAs sample as a function of the electron’s distance to the optical vortex center \( b \) measured in units of photon’s wavelength; (a) right circular polarization (b) left circular polarization. Long-dashed blue line is photons total angular momentum projection \( m_\gamma = -2 \), dot-dashed black is \( m_\gamma = -1 \), dashed red is \( m_\gamma = 0 \), solid green is \( m_\gamma = 1 \), dotted purple is \( m_\gamma = 2 \). See Ref. [5] for details of calculation.

3. Conclusions

We show theoretically that twisted photon beams have the capability of transferring the angular momentum degrees of freedom to electrons in semiconductors. The transfer signature may be observable in the form of altered angular momentum selection rules for the artificial atoms (i.e., quantum dots) or photoelectron polarization.

Abstract

Valley, as a binary degree of freedom in valleytronics, has been attracting great interests because of its distinctive topological behaviors and potential applications in information processing. Recently, the concept of valley has been introduced into photonic systems, and has motivated the study of valley-Hall photonic topological insulators (PTIs), which could support topological kink states at non-trivial domain walls. However, in the previous valley-Hall PTIs, the kink states only work at a single frequency band, limiting potential applications in multiband waveguides, filters, communications, and so forth. To overcome this challenge, we experimentally realize a valley-Hall PTI based on an inversion-breaking graphene-like structure in a substrate-integrated microwave circuitry, where the topological kink states exist at two separated frequency bands. Both the simulated and experimental results verify the existence of topological dual-band kink states. Moreover, the kink states are robust against the sharp bends of the internal domain wall with negligible inter-valley scattering. Our work may pave the way for multi-channel substrate-integrated photonic devices with high efficiency and high capacity for information communications and processing.

Abstract

We theoretically predict and experimentally observe nodal chains in a metallic-mesh photonic crystal across the entire Brillouin zone. These nodal chains are protected by mirror symmetry and have a frequency variation of less than 1%. We use angle-resolved transmission measurements to probe the projected bulk dispersion and perform Fourier-transformed field scans to map out the dispersion of the drumhead surface state. Our results establish an ideal nodal-line material for further study of topological line degeneracies with non-trivial connectivity. Keywords: Nodal Chains, Photonic crystal, Angle-resolved transmission measurements.

1. Introduction

Three-dimensional Weyl and Dirac nodal points have attracted widespread interest across multiple disciplines and in many platforms but allow for few structural variations. In contrast, nodal lines can have numerous topological configurations in momentum space, forming nodal rings, nodal chains, nodal links and nodal knots. However, nodal lines are much less explored because of the lack of an ideal experimental realization. In order to prompt the progress of the researches on nodal lines, we theoretically predict and experimentally observe nodal chains in a metallic-mesh photonic crystal.

2. Theoretical design

A nodal line is the extrusion of Dirac cone, arguably the most intriguing two-dimensional band structure, into three-dimensional momentum space. They share the same local Hamiltonian \( H ( \mathbf{k} ) = k_x \sigma_x + (k_x k_z + m_z) \sigma_z \), that can be protected by the PT symmetry forbidding the mass term of \( \sigma_z \) in the whole Brillouin zone. A single nodal line forms a closed ring, due to the periodicity of the Brillouin zone. And a nodal chain can be formed by two nodal rings touching at one point. The local chain Hamiltonian can be written as \( H ( \mathbf{k} ) = k_x \sigma_x + (k_x k_z + m_z) \sigma_z \), when \( m_z = 0 \) which can be guaranteed by the mirror symmetry \( M_z = \sigma_z \). According to the symmetry, we designed a metallic-mesh three-dimensional photonic crystal in fig. 1a. The fig. 2b shows the structure of chains in the Brillouin zone.

3. Experimental observation

3.1. Experimental sample

In experiment, we adopted aluminium as the material of choice for its high conductivity, low weight and low cost. The lattice constant is 11.6mm, and the rod width is 2mm. the sample is stacked with nine identical layers and each layer has 30×30 unit cells. The final size for one layer is 37cm×37cm×10.44cm.

3.2. Observation of bulk states by angle-resolved transmission measurement

We carried out angle-resolved transmission to measure the nodal-chain bulk states. A similar set-up as in ref. [1] is used. Figure 1 c-f show two measured and the corresponding theoretical results when the measured angle is 0°, 15°, 30°, and 45°. The experimental results are in good agreement with theory, which prove the realization of photonic nodal chains in experiment through the observation of bulk states.

3.3. Observation of surface states by field-scanning measurement

A nodal-line material is known to support a drumhead surface state, which is a sheet of surface dispersion enclosed by the projected nodal-line bulk state in the surface Brillouin zone. We performed Fourier-transformed field scans to measure the surface states of our nodal-chain sample. Figure 1 g and h show the theoretical surface dispersion and the experimentally observed surface dispersion, which agree with each other very well. It further proves the topological property of nodal chains.
4. Conclusions

We proved the discovery of photonic nodal chains through the measurements of bulk states and surface states in experiment. Our finding may inspire searches for ideal nodal lines in other material platforms, and stimulate experimental realization of non-trivial nodal-line structures, such as nodal links and nodal knots.

Abstract

We numerically simulate a Harper-Hofstadter model equipped with broadband optical gain, with the goal of extracting those general features of the lasing regime resulting from the chirality of the edge modes. We find ultraslow relaxation times well above threshold and, depending on the shape of the amplifying region, the opening of a convective instability region in which the competition between the two chiral edge modes emerges more clearly.

1. Introduction

Topological insulators are materials that behave as insulators in the bulk but have conducting edges; these edges have the ability to host a topologically protected conductance which is immune to disorder and backscattering impurities. A recent idea is to provide a topological insulator with some gain and then exploit the topological protection of its edge modes in order to possibly improve the emission of laser devices; experiments on top of 1D and 2D topological insulators have appeared in the last couple of years [1–5].

The goal of our study is to identify those features that stem directly from the chirality of the lasing edge modes, and therefore are peculiar to topological lasers only. This is done in a general way by not choosing a model tied to a specific platform and by focusing only on the basic effects.

2. Model

As we want to focus only on the topological nature of the lasing modes, we consider here the bosonic Harper-Hofstadter (HH) model [6, 7] without any loss of generality:

\[ H = \sum_{m,n} \left\{ \omega_0 a_{m,n}^\dagger a_{m,n} - J \left( a_{m,n}^\dagger a_{m+1,n} + e^{-i2\pi \vartheta_m} a_{m,n}^\dagger a_{m,n+1} + \text{h.c.} \right) \right\}, \]

where \( \omega_0 \) is the on-site energy, \( J \) is the hopping amplitude and \( a_{m,n} \) is the photon field at the lattice site \((m,n)\). The hopping along \( y \) has an \( x \)-dependent phase, proportional to the flux \( \vartheta = p/q \) of the synthetic magnetic field. For \( \vartheta = 1/4 \) (as in the present discussion) the system has two bandgaps, each of them equipped with a topological edge mode; these two modes have opposite chiralities.

We then simulate the time-evolution of the classical field amplitudes, with the addition of on-site losses \( \gamma_{m,n} \equiv \gamma \) and a broadband, saturable gain with spatial profile determined by \( P_{m,n} \) [8]:

\[ \dot{a}_{m,n} = -i [a_{m,n}, H] + \left( \frac{P_{m,n}}{1 + \beta |a_{m,n}|^2} - \gamma \right) a_{m,n}. \]

3. Results

We’ve simulated the system in two different configurations: a whole edge gain (WEG) configuration, in which we amplify the whole 1-site-thick edge of the lattice, and a partial edge gain (PEG) configuration, in which we amplify only a 1-site-thick strip of sites on one of the edges [8].

In the WEG configuration, we’ve witnessed the presence of a slowly-fading intensity “bump” that travels along the edge with group velocity \( v_g \); this bump is generated by the initial noisy state of the system but cannot be expelled from the edge due to the topological protection of the mode, resulting in long-time intensity oscillations of the laser emission.

Furthermore we observe that the lasing frequency, albeit unique for each realization, is randomly chosen from relatively broad distributions (Figure 1); this is actually common in ring lasers, where the modes are quantized with periodic boundary conditions. These modes are again selected depending on the initial noisy state, while the \( k \)-dependent spatial overlap between the edge modes and the amplify-
region produces a frequency-dependent effective gain, which is (roughly) maximized at the center of the bandgap.

In order to avoid these two effects, we can then try to amplify only part of the edge. In this PEG configuration, for a strip of moderate length, one indeed quickly finds a steady-state intensity profile with a single chirality (arrows in Figure 2(a-b)) and with a frequency which does not vary for different realizations (arrows in Figure 1).

In this case, however, the lasing threshold is much higher than in the WEG case because of the opening of a convective instability region. The threshold can be reduced by increasing the length of the amplifying strip, and the emission stays single-mode up to a certain critical length; after this point, the lasing profile splits into two sub-regions having opposite chiralities (Figure 2(c)) due to the competition between the two modes. The latter can be seen as wild temporal oscillations in the central overlap region, and can be suppressed by using a medium with a $\omega$-dependent gain.

Future works will analytically explain the ultra-slow relaxation rate of the intensity bump observed in the WEG configuration within the general theory of collective modes of a laser [9] in terms of the $k$-dependent effective gain, and will explore the consequences of having an amplifying medium with a frequency-dependent gain.

Nonreciprocity, Isolation and Time-reversal Symmetry in Nonlinear Devices

David E. Fernandes¹ and Mário G. Silveirinha²

¹ Instituto de Telecomunicações, Departamento de Engenharia Electrotécnica, Universidade de Coimbra - Pólo II, 3030-290 Coimbra, Portugal

Abstract

Here we highlight that nonlinear devices that operate as “electromagnetic diodes” for individual port excitations, cannot possibly provide a robust optical isolation under a simultaneous port excitation. Moreover, in the lossless case, typical nonlinear structures, despite being nonreciprocal, are time-reversal invariant, and thereby are inherently bi-directional.

1. Introduction

In electromagnetism, reciprocity is a consequence of linearity and time-reversal symmetry [1]. Reciprocal systems are inherently bi-directional and thus some microwave devices that are used in telecommunications networks, such as isolators and circulators, must rely on nonreciprocal elements. Typically, a nonreciprocal response is obtained with a magnetic bias [2]. However, this solution may be impractical in highly-integrated photonic platforms, and other alternatives to obtain a nonreciprocal response have emerged, such as using nonlinear effects [3] and others [4]-[7].

The mushroom metamaterial may be regarded as a wire medium [8] loaded with square metallic patches [9]. It possesses unusual electromagnetic properties that may enable the negative refraction of light and near-field imaging [10], amongst many other applications. In the nonlinear regime, these structures can allow for the realization of absorbers of high-power signals [11] and can exhibit a strong bi-stable response, which can be used to realize electromagnetic switches [12]. Here, we explore the possibility of using a mushroom metamaterial loaded with nonlinear elements to realize an “electromagnetic diode”, where the metamaterial is either nearly fully reflecting or almost transparent, depending on the excitation port [13]. We show that the nonlinear device does not provide port isolation in the scenario of a simultaneous excitation. Furthermore, in the lossless case the nonlinear metamaterial is time-reversal invariant, and thus is intrinsically bi-directional.

2. Diode Functionality vs. Port Isolation

Here we study the scattering of incoming plane waves by a nonlinear lossless asymmetric mushroom metamaterial slab. The plane waves illuminate the slab at both interfaces, as shown in Fig. 1a. We use the effective medium theory described in [12]-[13] to determine the nonlinear response of the lossless metamaterial to variations of the incident field amplitude at a fixed frequency. The chosen frequency is close to the strongest resonance of the metamaterial, so that the current delivered to the nonlinear lumped element becomes highly sensitive to small variations of the excitation field [12]. In Fig. 1b we show the transmission coefficient of the mushroom metamaterial as a function of the amplitude of the incident field for the individual excitations of ports 1 and 2. As seen, the relation between the incident field and the transmission coefficients is not univocal, leading to a bi-stable hysteresis response. Remarkably, the two ports can have a strong asymmetric response. Particularly, when the metamaterial is operated in the hysteresis branch where the excitation field decreases from very large values to around \( E^{\text{inc}} = 465 \text{ V/m} \), we have \(|T_1|/|T_2| \gg 1 \) with \(|T_1| \approx 1\). Thus, in this regime the mushroom metamaterial behaves as a “diode” for electromagnetic waves so that it is almost transparent for a top excitation and nearly completely opaque for a bottom excitation.

Importantly, for a simultaneous excitation of the two ports the structure no longer behaves as an electromagnetic diode. This is shown in panel c) of Fig. 1 for incident fields that guarantee that the wave scattered to port 1 has negligible amplitude in the 2nd time plateau, when any of the ports is individually excited (the relevant operating points are determined by the vertical dashed line of panel Fig. 1b). In contrast, Fig. 1c reveals that under a simultaneous excitation the scattered field is almost evenly distributed at both interfaces. Thereby, the port 1 is not isolated from port 2. Indeed, it is impossible to realize an isolator without material loss [13].

Furthermore, as theoretically shown in [13], in the lossless scenario the nonlinear device is time-reversal invariant and, thus, is inherently bi-directional, which is incompatible with the isolator functionality. This property...
extends and generalizes the concept of “dynamic” reciprocity introduced in [14] to arbitrary variations in time of the incoming waves. At the conference, we will present a full time-domain analysis illustrating the invariance of the nonlinear lossless mushroom metamaterial slab under the time-reversal operation and its consequences.

Figure 1: a) Geometry of the two-sided mushroom slab: the wires are embedded in air and connected to metallic patches through a nonlinear capacitors at the bottom interface, represented in the figure as blue rectangles, and through ideal short-circuits at the top interface. The lumped element is a parallel plate-type capacitor filled with a nonlinear Kerr-type dielectric. The details about all structural parameters are described in [12]-[13]. b) Transmission coefficient as function of the amplitude of the incident field. The arrows in the hysteresis loops indicate whether the excitation field amplitude is increasing or decreasing. The blue curves are for an excitation of port 1 and the black curves for an excitation of port 2. c) Envelope of the scattered field calculated at the top (black line) and bottom (green line) interfaces as a function of time. The time scale is normalized to the oscillation frequency $f$. The incident field (blue line) envelope has two plateaus: in the first plateau $|E^{inc,1}| = |E^{inc,2}| = 800$ V/m, whereas in the second plateau $|E^{inc,1}| = |E^{inc,2}| = 465$ V/m. For an individual excitation of the ports, the wave scattered to port 1 has negligible amplitude in the second plateau but for a simultaneous excitation it has amplitude comparable to that of the wave scattered to port 2.

3. Conclusions

We showed that the nonlinear mushroom-metamaterial may behave as an almost ideal electromagnetic-diode for individual port excitations. However, due to the inapplicability of the superposition principle the structure does not provide “isolation” between the two ports. In addition, typical lossless nonlinear devices are invariant under the time-reversal operation, and hence are intrinsically bi-directional [13].

Abstract

We propose strict electromagnetic analogues of the Haldane and Kane-Mele models in photonic crystals made of dielectric cylinders with honeycomb symmetry embedded in a metallic background with a nonreciprocal spatially variable pseudo-Tellegen response. In addition, it is shown using a duality transformation that the Kane-Mele model can be implemented in a reciprocal system made of matched anisotropic dielectrics with identical permittivity and permeability.

1. Introduction

The Haldane model [1] played a fundamental role in the development of topological concepts in electronics. This model describes the electronic properties of a graphene-type material under the influence of a periodic magnetic field with zero-spatial average. Furthermore, the Haldane model is effectively at the origin of the theory of topological insulators: the Kane-Mele model [2, 3] consists of two copies of the Haldane model with opposite magnetic field. However, despite the numerous connections between topological electronics and photonics developed in recent years [4, 5], so far there is no precise electromagnetic counterpart of these models, mainly due to the difficulties to mimic an effective magnetic field for photons. Here we propose a strategy to implement both models in photonic crystals.

2. Photonic Haldane model

It was recently shown [6] that the electronic Haldane model can be implemented in a 2DEG under the influence of a periodic electrostatic potential \( V(\mathbf{r}) \) with the honeycomb symmetry and of a magnetic vector potential \( \mathbf{A}(\mathbf{r}) \) that breaks the time reversal symmetry (see Fig. 1a). It can be demonstrated, by using an analogy between the time-independent Schrödinger’s equation describing this system and the 2D Maxwell equations, that a photonic analogue of the Haldane model can be implemented for TE-waves \( \mathbf{E} = E_z \hat{z} \) in a photonic crystal with honeycomb symmetry made of air cylinders embedded in a metallic background and with a spatially variable magnetoelectric coupling tensor of the form \( \mathbf{P} = \mathbf{P}(\mathbf{r}) \otimes \hat{z} + \hat{z} \otimes \mathbf{P}(\mathbf{r}) \) [7] (see Fig. 1b). This type of nonreciprocal magnetoelectric coupling, known as a pseudo-Tellegen coupling [8], turns out to be the photonic equivalent of the effect of a magnetic field on electrons [9]. The obtained structure is a precise photonic analogue of the Haldane model, i.e. only the phase with dominant broken time reversal symmetry leads to a non-trivial topology and supports, in the whole gap, unidirectional edge mode propagation protected against back-scatterings. To confirm this statement, the field in the 2D closed cavity depicted in Fig. 2a was computed with the finite-difference method (FDFD see [10]) under a dipole excitation and for frequencies in the band gap. As seen in Fig. 2b–c, the phase with a dominant broken time reversal symmetry is, as expected, topologically non trivial and supports unidirectional edge state whose direction of propagation is locked to the sign of the magnetoelectric coupling. Crucially, these topologically protected modes do not experience any backscattering at the corners of the cavity.

3. Photonic Kane-Mele model

By further imposing a matched permittivity and permeability in the same nonreciprocal system, it can be shown that TE and TM polarized waves become described by two copies of the previous model with opposite magnetoelectric coupling [7]. This paradigm constitutes an exact photonic analogue of the Kane-Mele model. Interestingly, it can be demonstrated [7, 11] that this nonreciprocal system is linked, through a duality transformation, to a much simpler...
Figure 2: (a) Schematic of the simulated cavity: the photonic crystal of Fig. 1b with an absorber located at the right-bottom region and surrounded by PEC walls. For the sake of clarity the pseudo-Tellegen response \( \xi(r) = \xi_0 \tilde{\xi}(r) \) is not represented in the figure. The \( z \)-component of the electric field in a structure with \( \omega_{\scriptscriptstyle p,1} = \omega_{\scriptscriptstyle p,2} \) and, \( \xi_0 > 0 \) in (b) and \( \xi_0 < 0 \) in (c).

reciprocal platform with the same edge-states. These findings evidenced the possibility of implementing the photonic Kane-Mele model with fully reciprocal materials made of matched non-bianisotropic dielectrics.

4. Conclusions

We used an analogy between the 2D Schrödinger and Maxwell equations to obtain an electromagnetic equivalent of the electronic Haldane and Kane-Mele models based on photonic artificial graphene with a spatially variable pseudo-Tellegen coupling. Interestingly, the Kane-Mele nonreciprocal platform is related through a duality transformation with a much simpler reciprocal system with the same edge states. Our analysis proves that the Kane-Mele model can be rigorously implemented using matched non-bianisotropic dielectrics and that such structures can support bi-directional edge states immune to back-scattering. Our findings make a connection between the fields of time-reversal invariant topological photonics, pseudomagnetic fields [12] and symmetry protected systems [11].

Abstract
We propose an innovative solution to break reciprocity and obtain one-way subwavelength light propagation. We theoretically demonstrate that the biasing of a graphene sheet by an electric drift current leads to the emergence of one-way surface plasmons. Our findings open interesting perspectives in nonreciprocal photonics and offer new opportunities to control the flow of light at the nanoscale.

1. Introduction
Lorentz reciprocity – a fundamental principle rooted in the linearity and invariance of Maxwell’s equations under time-reversal symmetry [1-2] – is an intrinsic feature of the vast majority of photonic systems. This fundamental law imposes that the level of wave transmission in linear photonic systems is invariant under the swap of the source and receiver positions [2]. Yet, nonreciprocal devices with strong asymmetric wave transmissions (e.g., isolators and circulators) are of critical importance in optical systems. Nonreciprocal responses are typically accomplished with magneto-optical materials (such as ferrites or other iron garnets) biased with a static magnetic field [3]. Remarkably, some of these nonreciprocal gyrotrropic platforms are inherently topological and support unidirectional backscattering-immune chiral edge modes [4-5]. Nevertheless, the need of employing an external biasing circuit, as well as the relatively weak magneto-optical responses and their associated high losses in the terahertz and optical regimes, hamper the integration of such nonreciprocal components in highly-integrated photonic systems. For this reason, great efforts have been devoted to develop magnetic-free nonreciprocal photonic solutions fully compatible with modern nanophotonic systems [6-11]. Recently [12], we have proposed a novel and promising platform to break the Lorentz reciprocity and achieve magnetic-free nonreciprocal subwavelength light propagation. In particular, we have theoretically demonstrated in [12] that by biasing a graphene sheet with a drift electric current it is possible to achieve broadband regimes of unidirectional propagation of surface plasmons.

2. Results and Discussion
The system under study is illustrated in Fig. 1(a). It consists of a graphene sheet surrounded by a dielectric with relative permittivity εs = 4 (e.g., SiO2 or h-BN). The graphene sheet is traversed by a direct electric current created by a static voltage drop applied across the sheet. As demonstrated by us in [13], in the presence of a drift current, the graphene conductivity associated with a longitudinal excitation (with in-plane electric field directed along x) is given by σxx(ω,kx) = (ω/ω)σg(ω,kx), where ω = ω−kv is the Doppler-shifted frequency, k is the wave number along x-direction (we only consider plasmons with k = 0 ), ν is the drift velocity, and σg(ω,k) is the nonlocal zero-temperature graphene conductivity reported in [14-15]. Interestingly, in the presence of an electron drift (i.e., for υ ≠ 0 ) σxx(ω,kx) ≠ σxx(ω−kx), and therefore, the electromagnetic response of the graphene sheet is nonreciprocal.

Figure 1: (a) A graphene sheet surrounded by a dielectric. A static voltage generator induces an electron drift in the graphene sheet. (b) Dispersion of the SPPs supported by the graphene sheet for several drift velocities ν. (c) Snapshots in time of E with arbitrary units for ν = 0 and frequency f = 30 THz. (i) Without drift (ν = 0); (ii) With drift (ν = ν / 2). The chemical potential of the graphene sheet is μ = 0.1 eV and the collision time is τ = 170 fs.
The dispersion characteristic of the SPPs supported by the drift-current biased graphene sheet can be obtained from
\[ 2i\omega c\varepsilon_{xx}(\omega,k_x)\gamma_k - \sigma_{xx}(\omega,k_x) = 0, \]
where \( c \) is the speed of light in vacuum, and \( \gamma_k = \sqrt{k_z^2 - \varepsilon_{xx}(\omega/c)^2} \) is the transverse (along \( z \)) attenuation constant. Figure 1(b) depicts the dispersion characteristic of the SPPs for different drift velocities \( v_x \). As expected, in the absence of the drift-current biasing (\( v_x = 0 \)), the graphene response is reciprocal, and thereby, the dispersion diagram is formed by two symmetric branches. In contrast, in the presence of a drift-current biasing, a clear symmetry breaking of the SPPs dispersion occurs. The degree of asymmetry of the dispersion diagram is more pronounced for higher drift velocities. Remarkably, the symmetry breaking caused by the drift-current biasing gives rise to broadband regimes of unidirectional propagation wherein the SPPs are allowed to propagate only along the \( +x \) direction (the direction of the drift current).

To further demonstrate the emergence of a unidirectional propagation regime in the drift-current biased graphene, next we consider a scenario wherein the SPPs are excited by a near-field emitter. The SPP fields excited by the near-field emitter are calculated using the formalism of Ref. [12]. Figure 1(c) depicts the \( E_z \)-field as a function of \( x \) and for \( z = 0 \) for a near-field emitter located at \( (x,z) = (0,0.5 \text{ nm}) \). In the absence of a drift-current bias, two identical counter-propagating SPPs are clearly excited by the emitter (Fig. 1(c)(i)). Quite differently, when the graphene sheet is biased by a drift-current, the response of the system becomes strongly nonreciprocal and the SPPs propagate only along the direction of the drifting electrons (\( +x \) direction) (Fig. 1(c)(ii)).

3. Conclusions

We have theoretically demonstrated that the electromagnetic response of a graphene sheet biased by a drift electric current is strongly nonreciprocal and enables the emergence of broadband regimes of one-way SPP propagation. In the talk, we will present these exciting results, as well as our most recent findings on this one-atom thick nonreciprocal plasmonic platform. In particular, we will also show that the drift-induced unidirectional graphene plasmons are protected against backscattering from obstacles and imperfections, similar to the “one-way” topologically protected chiral edge modes supported by topological photonic systems [4-5]. Furthermore, we will show that the drift-current biasing may provide optical gain, and thereby, may enable enhancing the propagation length of the graphene plasmons.

Abstract

Strain engineering is a powerful tool to shape the dispersion of Dirac materials. Here we use a honeycomb lattice of coupled polariton micropillars to implement tilted photonic Dirac cones, including type-III cones. To do so, we introduce a spatial asymmetry in the hopping of photons in the x and y directions of the lattice. When the hopping presents a spatial gradient, an artificial gauge field for photons is engineered, and photonic Landau levels are observed.

1. Introduction

Two-dimensional Dirac materials, i.e. materials whose electronic energy bands present a Dirac cone, are revolutionizing electronics. The linear dispersion characteristic of the Dirac cones results in striking phenomena like Klein tunnelling, ballistic transport and weak anti-localisation. When adding strain in a material with Dirac cones, or when considering high orbital bands, it has been recently shown that tilted Dirac cones and artificial gauge fields can be implemented\cite{1,2}. Bringing these properties to the photonics realm would enable the manipulation of photons in metamaterials and photonic lattices with novel properties. Moreover, the easy manipulation of the photonic dispersions in these systems brings the possibility of exploring new strategies to implement tilted Dirac dispersions.

A very suitable platform to study Dirac dispersions in photonics is lattices of polariton micropillars\cite{3}. In a semiconductor micropillar, photons are confined in the three directions of space: in the vertical direction they are confined via upper and lower Bragg mirrors that surround a semiconductor spacer acting as an optical cavity (see Fig. 1). In the horizontal direction, photons are confined thanks to the index of refraction contrast between the semiconductor spacer and air. Photons in the micropillar present a gapped spectrum with quantized energy levels with s-, p-, d-, ... symmetry. Photonic tunnelling between adjacent micropillars can be induced by making them overlap during the fabrication process. This feature has been used to explore bosonic Josephson physics\cite{4}. When extending the coupling to one- and two-dimensional lattices, energy bands for photons can be engineered\cite{5}. A remarkable case is that of a honeycomb lattice\cite{3}. The bands emerging from the coupling of the s-modes of each micropillar are analogous to the electronic bands emerging from the $p_z$ orbitals of graphene, and present Dirac cones for photons. The photonic $p$-bands have a richer spectrum with four bands, two of which are flat and the other two show Dirac crossings.

The micropillar lattices allow the control of the onsite energies via the size of each micropillar, the nearest-neighbours coupling $t$ via the physical overlap of adjacent micropillars, and direct access to the dispersion and wave functions in simple photoluminescence experiments. They are thus ideal to explore Dirac Hamiltonians. Here we report the observation of tilted Dirac cones and the implementation

![Fig. 1. Scanning electron microscope image of a honeycomb lattice of micropillars with a gradient of hopping in the horizontal direction ($t'\equiv t'(x)$).](image-url)
of gauge fields in a honeycomb lattice of polariton micropillars via artificial strain engineering.

2. Discussion

Artificial strain can be engineered in honeycomb lattices of micropillars by engineering the hopping of photons between adjacent sites. Homogeneous uniaxial strain can be implemented by modifying one of the three couplings $t'$, with respect to the other two $t$ (see Fig. 1), and keeping the same values all over the lattice. For the $s$-bands, increasing $t'$ induces the displacement of the Dirac cones in the Brillouin zone until their merging at $t''=2t[6]$. In the $p$-bands, increasing $t'$ with respect to $t$ gives rise to the emergence of a new type of Dirac cones, so-called type-III. This kind of Dirac cone is characterised by the crossing of two linear dispersions, one of which is horizontal (a flat band). We provide direct experimental evidence of the engineering of such Dirac cone [7]. Materials with this kind of Dirac cone have been recently proposed as promising for the study of artificial black hole horizons [8].

Strain engineering is also an excellent technique to implement artificial gauge fields in Dirac materials. In 2010, F. Guinea and co-workers proposed that a trigonal strain gradient in a graphene layer would create a gauge field and give rise to the emergence of Landau levels in the absence of an external magnetic field [9]. Experimental evidence of this idea has been reported by measuring the local density of states in strained graphene lattices [10]. However, access to the eigenfunctions remains elusive in electronic experiments. This would provide key information on the artificial-gauge-field origin of the Landau levels. Indeed, the eigenfunctions of the Landau levels in electronic graphene subject to an external magnetic field present a sublattice-valley symmetry: in the K valley, the wavefunctions corresponding to the $n=0$ Landau level are localised in the A sublattice, while in the K' valley, they are localised in the B sublattice. In the case of an artificial gauge field induced by strain, the wavefunction of the $n=0$ Landau level is localised in the A sublattice, both for K and K' points. This is a consequence of the preservation of time-reversal symmetry in this case: the induced gauge field has opposite signs in both valleys.

We have followed the proposal of G. Salerno and co-workers [11] and implemented an artificial gauge field in a honeycomb lattice of micropillars by introducing a spatial gradient in the hopping $t'$. We observe the emergence of Landau levels and provide evidence of the sublattice asymmetry in the $n=0$ wavefunctions associated to the presence of the gauge field.

Our work goes well beyond previous reports of artificial gauge fields in lattices of coupled waveguides, in which the presence of Landau levels was evidenced via their localisation properties [12]. We report direct observation of the gapped flat bands associated to the Landau levels. This is a very promising framework to study flat band physics in two dimensions in the presence of nonlinearities. The semiconductor micropillars we use are actually in the strong coupling regime, in which photons are mixed with excitonic excitations in a quantum well embedded in the micropillar. The presence of the excitonic resonance provides significant photon nonlinearities which could be used to explore interaction effects in Landau levels.

Abstract
This paper presents a new type of waveguide supporting robust propagation of an edge mode thanks to the property of parity, time-reversal and duality (PTD) symmetry. It consists of the combination of two dual parallel-plate waveguides with artificial impedance surfaces as sidewalls. In the particular case of PEC/PMC boundaries, a closed form solution is found for the supported mode through a mode matching procedure. Artificial impedance implementation through mushroom type metasurface is also discussed.

1. Introduction

Topological edge modes are immune to backscattering, and therefore exhibit robust scatter-free propagation along arbitrarily shaped pathways \cite{1}. Topological protection normally requires nonreciprocal elements \cite{2}. Recently, however, it has been shown that backscattering protection is also exhibited by unimodal structures which exhibit PTD-symmetry \cite{3}, i.e., which are invariant under the composition of the parity, time-reversal and duality transformations. A PTD-symmetric guiding structure supporting an edge mode was recently proposed in \cite{4}. It consists in the combination of two semi-infinite planar surfaces laid side by side and exhibiting complementary surface impedances. This structure supports a surface wave mode confined to the interface line between the two planes, with a wavenumber dependent on the surface impedance value. Although this surface wave mode is protected from backscattering thanks to the PTD symmetry property, the guiding structure may present radiation leakage, since it is not closed, and therefore a continuous spectrum of modes exists.

A unimodal PTD-symmetric edge waveguide can be obtained by coupling the structure in \cite{4} with an identical one located at a certain distance, with opposite positions of the impedance surfaces, so as to preserve the PTD-symmetry. The resulting structure can be seen as the pairing of two parallel plate waveguides (PPWs) with dual impedance walls. In the particular case in which the two surface impedance walls go to zero and infinity, respectively, the boundary conditions become of perfect electric conductor (PEC) and perfect magnetic conductor (PMC) type. For this structure, the expression of the supported mode can be derived in closed form, as shown in \cite{5}. In particular, it is found that the edge mode is TEM, and it is the only supported mode from zero frequency to the frequency at which the height of the PPW is equal to $\lambda/4$, where $\lambda$ is the wavelength of the dielectric contained in the PPW. This edge mode is protected against backscattering from any discontinuity that respects the PTD-symmetry, including transition to free space, if the PPW is empty.

2. PEC/PMC parallel plate waveguide junction

The geometry for the PEC/PMC edge waveguide structure is shown in Fig. 1. A difference of potential $2V$ is applied between the top and bottom PEC plates.

Figure 1: Geometry for the PEC/PMC edge waveguide structure.

Thanks to the TEM nature of the supported mode, the problem can be solved in the electrostatic regime. To this end, the electrostatic potential on either side of the interface $x=0$ is expanded into an infinite series of proper eigenfunctions. Then, continuity conditions are imposed at the interface, to obtain an infinite set of linear equations for the unknown expansion coefficients. For this particular structure, the linear system can be solved in closed form, leading to the following expression for the electrostatic potential:

$$
\psi(x, y) = 2V \sum_{n=0}^{\infty} c_n e^{-z_n} H_n^{(1)} \left[ \sin(\xi_n y) u(-x) - \cos(\xi_n y) u(x) \right] + 2\text{sgn}(x)V
$$

(1)
with

$$\xi_n d = 2\pi n + \frac{\pi}{2}$$

$$c_n = 0.7965 \frac{(2n)!}{(4n+1)(n!)^2} 4^n$$

$$n = 0, 1, 2, \ldots$$ \hspace{1cm} (2)

The potential distribution and the corresponding electric field distribution across the waveguide cross section are shown in Fig. 2 and Fig. 3, respectively.

![Figure 2: Potential distribution for the PEC/PMC edge waveguide.](image)

![Figure 3: Electric field distribution for the PEC/PMC edge waveguide.](image)

### 3. Implementation

In practice, impedance surfaces can be realized through metasurfaces. An example of metasurface which can mimic PMC behavior in a given frequency range is provided by mushroom type structures [6]. This kind of structure has been employed to design an edge waveguide based on the formulation provided in the previous section. The geometry for a single period of the edge waveguide is reported in Fig. 4. The unit cell of the mushroom structure has a size of 2.5mm x 2.5mm, and the dielectric is Rogers RO3003 ($\varepsilon_r=3$). The PPW height is 3mm. This structure has been analyzed with the eigenmode solver of CST; it was found that it exhibits a unimodal band between 9.33GHz and 14.84GHz.

![Figure 4: Geometry for the edge-waveguide structure based on mushroom MTS.](image)

The electric field distribution at 13.66GHz is shown in Fig. 5. As it can be seen, in the region above the mushroom MTS the field behavior is close to the one found for the ideal PEC/PMC edge waveguide.

![Figure 5: Electric field distribution in the cross-section of the edge-waveguide structure.](image)

### 4. Conclusions

A PTD-symmetric edge waveguide structure consisting of a couple of PEC-PMC PPW has been analysed, and a closed-form solution has been found for the fundamental supported mode through a mode matching procedure. This mode is immune from backscattering from PTD-symmetric discontinuities, including the transition to free-space. Numerical results relevant to a practical implementation of the structure have also been presented.

Abstract

The Chern topological numbers of a material platform are usually written in terms of the Berry curvature which depends on the normal modes of the system. Here, we use a gauge invariant Green’s function method to determine from “first principles” the topological invariants of photonic crystals. The proposed formalism does not require the calculation of the photonic band-structure, and can be easily implemented using the operators obtained with a standard plane-wave expansion.

1. Introduction

Topological systems have fascinating and intriguing properties, which can lead to novel physical effects and phenomena [1-8]. The Chern topological numbers of a material system are usually written in terms of the Bloch eigenmodes. Thus, from a computational point of view, the numerical calculation of the Chern invariants is a rather complex problem: it generally requires finding the photonic band structure and all the Bloch states in the Brillouin zone. The problem is specially challenging in the case of periodic systems, e.g., nonreciprocal photonic crystals. In a few recent articles [6, 7] it was shown that the gap Chern numbers can alternatively be written in terms of the system Green’s function. The theory is gauge invariant and does not require any detailed knowledge of the band structure or of the Bloch eigenstates. The method applies both to fermionic and bosonic platforms (even in case of material dispersion) and to non-Hermitian systems [6, 7]. Here, we illustrate the application of the formalism to ferrite photonic crystals. Specifically, we determine from first principles (i.e., without a tight-binding approximation) the gap Chern numbers of the photonic crystal relying on a plane wave expansion.

2. General formalism

Next, we briefly review the general Green’s function formalism reported in [6, 7] to characterize the Chern invariants of photonic platforms. Consider a generalized eigenvalue problem of the form \( \hat{L}_k \cdot \mathbf{Q}_{sk} = \mathcal{E}_k \mathbf{M}_g \cdot \mathbf{Q}_{sk} \) (\( n=1,2,\ldots \)), where \( \hat{L}_k \) and \( \mathbf{M}_g \) are operators (possibly non-Hermitian). The operator \( \hat{L}_k \) is parameterized by the real wave vector \( \mathbf{k} = k_x \hat{x} + k_y \hat{y} \) and the operator \( \mathbf{M}_g \) is independent of \( \mathbf{k} \). Here, \( \mathbf{Q}_{sk} \) are the generalized eigenstates of \( \hat{L}_k \) and \( \mathcal{E}_k \) are the generalized eigenvalues. The system Green’s function is defined by \( \mathcal{G}_k (\mathcal{E}) = i (\hat{L}_k - \mathbf{M}_g \mathcal{E})^{-1} \) [7]. The Green’s function has poles at the eigenfrequencies \( \mathcal{E} = \mathcal{E}_k \), but otherwise is an analytic function of frequency. The band gaps are vertical strips of the complex plane (no \( \mathcal{E} < \text{Re} \{ \mathcal{E} \} < \mathcal{E}_0 \) where the Green’s function is analytic. The gap Chern number is determined by [6, 7]:

\[
\mathcal{C} = \frac{1}{(2\pi)^3} \int \int_{\mathcal{E}_{gg}-\infty}^{\mathcal{E}_{gg}+\infty} \frac{d\mathcal{E}}{d\mathcal{E}} \text{Tr} \{ \partial_{\mathcal{C}} \mathcal{G}_k^{-1} \cdot \mathcal{G}_k \} \cdot \partial_{\mathcal{E}} \mathcal{G}_k^{-1} \cdot \partial_{\mathcal{E}} \mathcal{G}_k \}
\]

(1)

where \( \partial_{\mathcal{C}} = \partial / \partial \mathcal{C} \) and \( \mathcal{C}_{gg} \) is some “frequency” in the gap. We denote \( \partial_{\mathcal{C}} \mathcal{G}_k^{-1} = \partial_{\mathcal{E}} \mathcal{G}_k^{-1} / \partial \mathcal{C} \). The integral in \( \mathcal{E} \) is over the line \( \text{Re} \{ \mathcal{E} \} = \mathcal{E}_{gg} \) and \( \text{Tr} \{ ... \} \) stands for the trace operator.

3. Ferrite photonic crystal

Consider a ferrite photonic crystal formed by a hexagonal array of ferrites embedded in air [9], as illustrated in Fig.1. Assuming transverse electric (TE) polarization (\( \mathbf{E} = E_z \hat{z} \)) and propagation in the \( xoy \) plane it can be shown that the secular wave equation is of the form

\[
\hat{L}(-i\mathcal{V}) \cdot E_z = \mathcal{E} \mathbf{M}_g \cdot E_z \quad \text{with} \quad \mathcal{E} = (\omega / c)^2 \quad , \quad \mathbf{M}_g \cdot E_z = \varepsilon E_z
\]

and

\[
\hat{L} \cdot E_z = -\partial_{\mu} \left[ \frac{1}{\mu_{\text{eff}}} \partial_{\mu} E_z + \frac{ik}{\mu_{\text{eff}}} \partial_{\mu} E_z \right] - \partial_{\mu} \left[ \frac{1}{\mu_{\text{eff}}} \partial_{\mu} E_z + \frac{ik}{\mu_{\text{eff}}} \partial_{\mu} E_z \right] \cdot \mathbf{M}_g \cdot E_z
\]

(2)

Thus, \( \mathbf{M}_g \) is a multiplication operator and \( \hat{L}(-i\mathcal{V}) \) is a differential operator. In the above, \( \varepsilon = \varepsilon(x,y) \) is the permittivity, \( \mu = \mu(x,y) \) and \( \kappa = -im(x,y) \) are the diagonal and anti-diagonal elements of the permeability tensor, respectively, and \( \mu_{\text{eff}} = (\mu^2 - \kappa^2) / \mu \). For simplicity,
in this work we ignore material dispersion and take \( \varepsilon = 12 \), \( \mu = 1 \) and \( \kappa = 0.9 \). The Bloch modes associated with the wave vector \( \mathbf{k} \) are of the form \( E_i = \varepsilon_i (x, y) e^{i \mathbf{k} \mathbf{r}} \) with \( \varepsilon_i (x, y) \) a periodic function that satisfies \( \hat{L}_k \cdot \varepsilon_i = \varepsilon_i \mathbf{M}_g \cdot \varepsilon_i \), with \( \hat{L}_k = \hat{L} (i \nabla + \mathbf{k}) \). The band structure can be found using the plane wave method by expanding \( \varepsilon_i \) into plane waves, \( \varepsilon_i = \sum_j c_{j}^{\varepsilon} e^{i \mathbf{G}_j \mathbf{r}} \) (\( G_j = j \mathbf{b}_1 + j' \mathbf{b}_2 \) is a generic reciprocal lattice primitive vector) [10]. Thus, the operators \( \mathbf{M}_g \) and \( \hat{L}_k \) can be represented by matrices (in the simulations the plane wave method was truncated with \( |j| \leq N_{\text{max}} = 3 \)). The Chern topological number can be calculated by feeding the matrices that are used in the plane wave method into the integral \( (1) \). The band structure of a photonic crystal formed by ferrite cylinders with radius \( r = 0.2 \sqrt{2} a \) is shown in Fig.2. As seen, there is a complete band-gap delimited by \( 1.13 / a^2 < \varepsilon < 1.53 / a^2 \). The Chern number \( C \) is found through the numerical integration of Eq. \( (1) \) taking \( \varepsilon_{\text{gap}} = 1.3257 / a^2 \) as the mid-point in the gap. A generic wave vector in the Brillouin zone is of the form \( \mathbf{k} = \beta_1 \mathbf{b}_1 + \beta_2 \mathbf{b}_2 \) with \( |\beta_1| \leq 1 / 2 \) and generic \( \varepsilon' \) is of the form \( \varepsilon = \varepsilon_{\text{gap}} + i \xi \). Figure 3a depicts the integrand of Eq. \( (1) \) as a function of \( \beta_1 \) for \( \xi = 0 \) and \( \beta_2 = 1 / 3 \) (solid line) and \( \beta_2 = -1 / 3 \) (dashed line). As seen, the integrand is peaked near \( \beta_1 = \pm 2 / 3 \), which corresponds to the coordinates of the \( K \) and \( K' \) points, respectively. This reveals that the topological charge is concentrated near the two Dirac points. The integral is numerically evaluated using the trapezoidal rule. The Brillouin zone is sampled with \( N_{\beta_1} = N_{\beta_2} = N_{\xi} \) points. The integral along the imaginary axis is truncated at \( |\xi| \leq \varepsilon_{\text{max}} = 5 / a^2 \) and is sampled with \( N_{\xi} = 2 \times 50 \) points. Figure 3b shows that for sufficiently large \( N \) the numerical result approaches \( C = 1 \), consistent with the topological nature of the Chern number.

**Figure 1:** (a) Hexagonal array of ferrite cylinders. The distance between nearest neighbors is \( a \). (b) First Brillouin zone of the 2D lattice.

**Figure 2:** (a) Photonic band structure of the ferrite photonic crystal. (b) Zoom in of panel (a) around the \( K \) point.

**Figure 3:** (a) Integrand of Eq. \( (1) \) [in arbitrary units] as a function of \( \beta_1 \). (b) The numerically calculated Chern number \( C' \) as a function of \( N \).

The computation time is on the order of a few minutes in a standard personal computer. At the conference, we will present additional examples and in particular we will discuss how the effect of loss impacts the topological properties of the material.

Nanophononics and nanomechanics
Synthetic magnetic fields for on-chip phonons through nano-optomechanical interactions

John P. Mathew¹, Javier del Pino², and Ewold Verhagen¹,*

¹Center for Nanophotonics, AMOLF, Amsterdam, The Netherlands
*corresponding author, E-mail: verhagen@amolf.nl

Abstract
We demonstrate synthetic gauge fields for phonon transport in a nano-optomechanical platform. Employing time-modulated radiation pressure forces, we evidence nonreciprocal nanomechanical phase transfer. We show how this enables a new class of on-chip phononic topological insulators.

1. Introduction
Gauge fields are a subject of major interest in modern condensed matter physics, with fundamental implications ranging from the quantum Aharonov-Bohm effect to emergent topological phases of matter, to cite a few. The last few years have witnessed both experimental and theoretical effort in extrapolating these ideas to charge-less excitations such as photonic [1] and even macroscopic mechanical oscillator ensembles [2]. In contrast with electronics, where gauge-related phenomena can arise naturally as a result of real magnetic fields [3] gauge fields need to be artificially devised for charge-less excitations via structural-symmetry- or time-reversal-symmetry breaking [4]. The field of cavity optomechanics exploits the interaction, via radiation pressure force, of localized electromagnetic fields with micro- or nano-mechanical phononic modes. Remarkably, the high degree of controllability of these coupling could pave the way towards a suitable platform to extend non-trivial topological phenomena to mesoscopic on-chip applications via optomechanical circuits and arrays [5].

2. Results
Here we present a scalable, nanoscale optomechanical platform that enables the creation of a gauge field for phonons via optically-mediated dynamical modulation of the nanomechanical coupling. Our specific implementation consists of a sliced silicon photonics crystal nanobeam (cf. Fig 1a), supporting a defect-induced optical mode and two mechanical modes. The system is driven by an intensity-modulated field that tailors the radiation pressure force exerted on the mechanical modes and enables readout by a probe field (see Fig 1b). Due to the large optical losses, the system is operated in the bad-cavity limit and phonons are therefore addressed instantaneously by optical forces.

Fig. 1. (a) SEM image of a single optomechanical nanobeam device. The cavity mode, confined in the air gap between the two unequal halves of the nanobeam couples with its two fundamental mechanical eigenmodes. (b) Sketch of the experimental setup used. IM: intensity modulator, LP: linear polarizer, PBS: polarizing beam splitter, BPF: optical bandpass filter, PD: photodiode, UHFLI: Ultra High Frequency Lock-In amplifier. The UHFLI enables modulation of the intensity of the driving laser and demodulation of the probe laser intensity. (c) The optomechanical interaction gives rise to an effective phonon transfer between the intra-nanobeam mechanical modes and induces a large Rabi splitting in agreement with the theoretical model. (d) Furthermore, hopping of excitations between the two modes (b1,b2) is accompanied by a non-reciprocal phase imprint (represented at the top), as observed by phase measurements at frequency of the transferred mode for up and down transfer processes under varying modulation phase $\phi_m$ (bottom).
By tuning the modulation frequency in resonance with the frequency splitting of the mechanical modes, we demonstrate theoretically and observe experimentally (see Fig 1c) the emergence of a population transfer pathway between mechanical modes characterized by a coupling tunable by optical driving parameters and a non-reciprocal phase imprint. The existence of a non-reciprocal gauge associated with this transfer is corroborated via measurements of the demodulated phase of the transfer signal at a fixed frequency, shown in Fig 1d. Further exploration as function of the laser detuning elucidates the paramount role of the optical spring effect in the transfer process. Fig 2a shows the measured phase evolution for the transferred mode and suggests an optimal condition for the gauge transfer process.

Finally, we demonstrate theoretically how a possible extension of our nanobeam device to an array encompassing many periodically arranged nanobeams, with spatially resolved input phases, could be exploited to synthetically engineer topological phases in an optomechanical network. In particular, by forming a honeycomb lattice of nanobeams as seen in Fig2b, we show a phononic analogue of an integer Quantum Hall topological insulator, signaled by chiral propagation of the edge modes. Numerical estimates indicate the robustness of edge state propagation over large lattice distances in such an array, even in the presence of disorder and direct mechanical couplings between the nanobeams, and suggest this device could be implemented within state-of-the art technology.

3. Conclusions

The aforementioned results therefore show how optomechanical arrays built upon nanobeam devices represents a promising avenue for topologically protected transport of phononic excitations. Similar ideas could be exported to chiral acoustic waveguides suitable for quantum applications [6], and topological heat currents [7].

Abstract
The complete quantum solutions of the flux qubit-oscillator in the Fock state have been derived under the condition that the coupling strength is weak. The influence of parameters, such as the tunnel splitting, the coupling strength, the Josephson inductance, and the shunt capacitance, on the system was examined. In particular, upper and lower energy levels and the difference between them were analyzed in detail.

1. Introduction
Superconducting nanocircuits [1, 2] are simple quantum systems that can be potentially used for controlling universal quantum gates in quantum computers. According to the recent advance for realizing quantum-based technologies, these circuits became one of the main research subjects in quantum information science. As is well known, a basic unit for storing quantum information in quantum computers is qubit which is a two-level system. Several kind of qubits materialized on the basis of superconducting circuits are flux qubits, charge qubits, and phase qubits [1, 2]. We will focus on flux qubits in this work, which exhibit usual quantum properties such as discrete energy levels, entanglements, quantum interferences, and superposed quantum states.

The interaction of a two-level system with a harmonic oscillator became a highly emerging research topic over the years, while the operation of such an interacting system is actually the same as a single atom that has a large electric dipole moment coupled to the cavity mode of the microwave photons. Experimental realizations of not only flux qubits [3, 4] but also coherent tunable couplings between flux qubits [5] have been achieved. Moreover, the possibility of many other experimental manipulations with the flux qubit-oscillator upon rigorous theoretical backgrounds was also demonstrated.

Quantum dynamics of superconducting flux qubit-oscillators will be investigated in this work. Because the Hamiltonian for a superconducting flux qubit coupled to a harmonic oscillator is a somewhat complicated form, the direct evaluation of quantum solutions of the system is very difficult. For this reason, we do not know how to derive exact quantum solutions for this system yet. Only approximation and perturbation methods are available for treating the mechanics of qubit oscillators. In a conventional theory, rotating wave approximation (RWA) [6, 7] which neglects rapidly oscillating terms in the Hamiltonian is typically applied for this purpose. Although serious defects of this method in its application on quantum optics was well known from several decades ago [7, 8], this method is still potentially used because it provides solutions in a simple manner regardless of treating the field as classically or quantum mechanically.

In this work, we will use a different method which is the unitary transformation technique in order to increase the accuracy of the results. Unitary transformation with the matrix Hamiltonian will be performed without loss of the Hermitian nature of the matrix. The Hamiltonian can be simplified via such a transformation, leading to providing an easy way to identify the corresponding wave functions in the transformed system. This is our main strategy for deriving quantum solutions of the system in order to investigate the energy levels of the system.

2. Results
We consider a flux qubit coupled to a SQUID oscillator, which is illustrated in Ref. [3]. This coupling exhibits many interesting effects concerning the experiments of cavity quantum electrodynamics and ion/atom-traps, which facilitate the generation and detection of nonclassical states that are important in quantum devices. Further, such a coupling enables to produce a state entangled between multiple qubits, which are crucial in quantum-state engineering for quantum information processing [9]. This kind of entanglement is necessary in quantum computing, while the degree of the entanglement can be enhanced by increasing the relaxation time of the oscillator and/or the coupling strength [3]. The Hamiltonian of the system is composed of a qubit term, a harmonic oscillator term, and the term coupling between them.

The unitary transformation has been performed by two steps. From the first transformation, the Hamiltonian matrix was diagonalized. However, the evaluation of the Schrödinger equation in this transformed system in a straightforward way is still difficult because the transformed Hamiltonian is not so simple. For this reason, the second unitary transformation for further simplification has been carried out by introducing another unitary operator. The final Hamiltonian obtained through the two transformations is the coupling of two simple harmonic oscillators.
of which we can easily identify the Schrödinger solutions.

We have analyzed the upper ($E_{n,+}$) and lower ($E_{n,-}$) energy levels of the qubit and the differences between them, $E_{n,d}(= E_{n,+} - E_{n,-})$. We have confirmed that $E_{n,\pm}$ are represented in terms of modified angular frequencies $\omega_{\pm}$, respectively. $E_{n,d}$ are smallest when $\varepsilon = 0$ where $h\varepsilon$ is the qubit maximum persistent current, whereas they grow as the value $\varepsilon$ increases. On the other hand, $E_{n,d}$ do not vanish even when $\Delta = 0$, where $h\Delta$ is the minimum energy splitting. We have confirmed that $E_{n,d}$ increase as $\Delta$ grows. By the way, $E_{n,\pm}$ decrease when the overall inductance $L_t$ of the SQUID circuit increases. The informations developed here are useful for designing a flux qubit and a readout system of qubit signals.

We have also investigated the wave functions of the system. The wave functions $\psi_n(q, t)$ that are indispensable as a basic means for studying quantum features of the system were obtained. The overall wave function can be written as $\psi(q, t) = \sum_n c_n \psi_n(q, t)$ where $c_n$ are $n$th coefficients with the condition $\sum_n |c_n|^2 = 1$. This wave function is necessary for investigating various quantum informational properties of the flux qubit system coupled to the oscillator and can be directly extended to more generalized states such as coherent, squeezed, and thermal states.

3. Conclusions

Quantum features of a flux qubit coupled to a harmonic oscillator have been investigated in this work. Energy-level splitting in the dispersive measurements of flux-qubit states has been analyzed. Because the Hamiltonian of the system is a somewhat complicated form, the mathematical treatment of the system is not an easy task. Hence, special mathematical tools for treating the Hamiltonian are necessary. We have used the unitary transformation method for this purpose.

We have easily identified quantum solutions (wave functions) in the transformed system because the transformed system is a simplified one. Eventually, by transforming the wave functions in the transformed system inversely, the wave functions in the original system were obtained. The full wave function is crucial as the basic tool for investigating quantum properties of the system. Various quantum characteristics of the qubit system can be analyzed by making use of the wave functions. For instance, one can evaluate not only fluctuations of the canonical variables, but also the expectation values of the Hamiltonian and other physical observables. The time behavior of the system can also be analyzed on the basis of the wave functions.

Abstract

Picosecond acoustics utilizes short strain pulses generated by pulsed lasers to determine and affect properties of solid media. This represents two challenges in the field - to achieve stronger strain-induced effects and to generate stronger yet shorter strain pulses. Here we examine if a medium with insulator-metal transition, such as vanadium dioxide VO₂, may facilitate addressing both challenges.

1. Introduction

Strain pulses with sub-nanosecond duration constitute the new non-thermal avenue for controlling properties of solids on nanometer and picosecond scales. Therefore there is a demand for new ways to generate such pulses with higher amplitudes and with control over pulse parameters, as well as new mechanisms and materials to make the impact of these pulses more prominent.

Generation of picosecond strain pulses is conventionally realized via rapid thermal expansion of thin metallic film following femtosecond laser excitation [1, 2]. Resulting pulses are as short as a few picoseconds with amplitudes up to 10⁻² [2]. In semiconductors the strain pulse generation is commonly attributed to deformation potential rather than thermal expansion [3] leading to other durations and amplitudes of generated pulses. A material with insulator-metal transition would therefore allow an on-a-fly control of generated pulses. Among such materials the most potent is VO₂ which exhibits a photo-induced ultrafast first-order insulator-metal and structural phase transition (PIPT) [4, 9, 10].

Application of picosecond strain pulses has been shown to alter and control various properties of media on picosecond timescale. These include launching magnetization dynamics [5], generation of THz radiation [6] and electrical currents [7], etc. Still, picosecond strain pulses were not applied to study or control ultrafast phase transitions despite known role stationary strain has on their onset [8]. We start to fill this gap by showing the effect of picosecond strain on PIPT in VO₂ [9].

2. Experimental

2.1. Samples

For the strain pulse generation we used a 50 nm and 100 nm VO₂ films grown epitaxially by PLD on a r-cut Al₂O₃ substrate in [100]ₘ₁ orientation (for details see [10]). On the other side of the substrate, a 50 nm Cr layer was deposited allowing photoelastic detection of generated pulses.

For evaluating the effect picosecond strain has on PIPT we used a layer of epitaxial VO₂ nanohillocks with [020]ₘ₁ orientation grown by pulsed laser deposition (PLD) on a c-cut sapphire Al₂O₃ substrate (for details see [10]). The nanohillocks have height of 70±20 nm and lateral size of 200±60 nm. Here picosecond strain pulses were generated by 140 nm Al transducer film deposited on the back side of the substrate.

2.2. Experiment layout

The laser source is a 170-fs Yb:KGd(WO₄)₂ regenerative amplifier with 5kHz repetition rate and a central photon energy of 1.2 eV. For generation of picosecond pulses in VO₂, a conventional picoacoustics setup was used with two beams taken from the same laser source. One beam was incident on the VO₂ film acting as a pump to generate a strain pulse, the other passing via a motorized delay line was directed on the Cr film and served as a probe. We monitored the intensity of a reflected probe pulse as a function of the time delay at 295 K and 400 K.

To study the effect of strain pulses on PIPT the probe beam was incident on VO₂ nanohillocks and the pump beam was exciting the Al film. In order to induce PIPT in VO₂ we applied one more beam from the same source to directly excite the nanohillocks. Certain time delay was set between the moment of PIPT excitation and the moment of the strain pulse reaching VO₂.

3. Results and discussion

3.1. Generation of picosecond strain pulses in VO₂ film

First experiments on generation of strain pulses in 100 nm VO₂ film showed that these pulses after propagation through a 300 μm sapphire substrate have longer dura-
tion - up to 200 ps - for moderate pump beam fluence of \( J_{VO_2} = 14 \text{ mJ/cm}^2 \). Due to non-linear nature of strain pulse propagation in sapphire, longer pulse duration is one of the main markers for strong initial amplitude of the generated pulse [2].

Plotting the pulse duration and signal amplitude versus the fluence \( J \) of the laser pulse generating strain pulse in VO\(_2\), we obtained a distinct deviation of the monotonous increase between the PIPPT threshold \( J = J_T = 2.3 \text{ mJ/cm}^2 \) and saturation \( J = J_S = 6.4 \text{ mJ/cm}^2 \) fluencies obtained for this sample. This result is an indication of the alteration in the pulse generation process due to PIPPT.

Notably, the amplitude of the measured signals show a slight decrease with increasing fluence above \( J_T \) before starting to rise again. Our calculations show that such behavior could not be described solely by the change of parameters of heat-driven strain generation during the transition and the generated pulses are likely to be affected by lattice contraction in the growth direction [100] occurring during the PIPPT. This provides a new tool to study PIPPT in VO\(_2\). For details and further analysis see [11].

### 3.2. Effect of picosecond strain pulses on PIPPT

In these experiments we applied strain pulses with the largest amplitude we could get with Al transducer film, using pump beam fluence of 60 mJ/cm\(^2\). After nonlinear propagation through sapphire [2] they had amplitude \( \sim 0.1 \% \) and duration \( \sim 100 \) ps. The measured reflectivity change of VO\(_2\) nanohillocks was attributed to photoelastic effect. Then we applied the laser beam to the VO\(_2\) nanohillocks to excite the PIPPT before arrival of the strain pulse in VO\(_2\) and set it fluence larger than saturation value measured for this sample \( J > J_S = 20 \text{ mJ/cm}^2 \). Such fluence corresponds to a complete PIPPT. The observed signal was the same as photoelastic response measured at \( T = 360 \) K in temperature-induced metallic phase.

The main results were obtained for fluence of the beam exciting PIPPT being lower than the saturation value but still higher than threshold \( J > J_T = 6 \text{ mJ/cm}^2 \), which corresponds to incomplete PIPPT with some nanohillocks remaining in insulator phase. The front of the strain pulse was the first to arrive in nanohillocks, and then - while the pulse had not yet left VO\(_2\) - the PIPPT was excited. We found that for such fluencies the PIPPT is sensitive to strain amplitude and sign presented at the moment of laser excitation. Kinetics of the PIPPT at longer times is found to be insensitive to the dynamical strain still present in the nanohillocks [9]. This result opens a prospective to control the PIPPT in VO\(_2\) by varying the moment of excitation with respect to the strain pulse profile. Timing excitation with the maximal compression/tension in the strain pulse we achieved \( \sim 1 \% \) suppression/enhancement of the PIPPT, respectively.

Finally, we revealed that the strain affects the PIPPT by changing the amount of VO\(_2\) nanohillocks undergoing ultrafast phase transformation. The detailed analysis based on Landau phenomenological theory is presented elsewhere [9].

### 4. Conclusions

To conclude, we show that VO\(_2\) possessing an ultrafast photo-induced insulator-metal and structural phase transition is a novel promising choice of a material for tunable generation of picosecond strain pulses. Moreover, the ultrafast phase transition in VO\(_2\) can be successfully controlled by picosecond strain pulses on nanometer and picosecond scales.

Abstract

Acoustic damping of lithographed gold nanodisk vibrations was investigated using single-particle time-resolved spectroscopy. A strong influence of morphology (diameter/height ratio) on their vibrational quality factors was experimentally demonstrated and confirmed by numerical modeling. These findings thus open new possibilities for engineering the vibrational modes of nano-objects.

1. Introduction

The vibrational properties of nano-objects can be experimentally addressed using optics-based methods such as Raman and time-resolved spectroscopies, which enable the detection of a few vibrational modes and the measurement of their frequencies and, in certain conditions, of their damping rates. Experiments performed in the last 20 years in this field have clarified the dependence of vibrational frequencies on nano-object size, shape, crystallinity and environment [1]. In particular, their surprisingly accurate reproduction by continuum mechanics models, even in the case of ultrasmall (~1 nm) nanoparticles [2], has been demonstrated. However, many questions still remain open regarding the nature and efficiency of the mechanisms ruling vibrational damping. In contrast with vibrational frequencies, which are predominantly determined by intrinsic nano-object properties (e.g., composition, morphology and crystallinity) [1], damping rates are very sensitive to the properties of the nano-object/environment interface, which determine the efficiency with which acoustic waves are emitted from the nano-object. Additionally, a quantitative investigation of damping requires experiments on individual nano-objects to avoid the spurious inhomogeneous effects affecting measurements on nanoparticle assemblies. In this context, recent single-particle experiments performed on supported nano-objects have shown large interparticle fluctuations of vibrational damping rates, which were ascribed to variations of nanoparticle-substrate coupling [1], while those on suspended nanowires have evidenced the effect of intrinsic damping mechanisms, which become dominant when acoustic radiation by a nano-object is made inefficient [3]. In order to better understand vibrational quality factors, and in particular to investigate a possible dependence of damping rate on nano-object morphology, systematic time-resolved studies were performed on individual gold nanodisks (NDs) deposited on a sapphire substrate. NDs were chosen as their shape is characterized by only two dimensions, i.e., diameter D and height h (with their aspect ratio defined as $\eta = D/h$). Their production by electron lithography enables the easy variation of ND diameter and avoids the presence of surfactant molecules in their surroundings, which occurs for chemically synthesized nano-objects.

2. Linear and time-resolved optical experiments

Detection and optical characterization of NDs were performed using spatial modulation spectroscopy (SMS) [4], a quantitative single-particle technique based on the periodic displacement of a nano-object in the focal spot of a strongly focused light beam, which induces a modulation of the transmitted light power proportional to the extinction cross-section. The measured extinction spectra of individual NDs are dominated by their localized surface plasmon resonance (SPR), whose spectral position evolution with ND diameter was well reproduced by numerical simulations. NDs with a non-circular section could be identified from the significant polarization dependence of their extinction. They were found to present a more complex acoustic response (as compared to circular NDs) and were not considered for the vibrational damping investigations presented below.

Time-resolved experiments on individual NDs were performed by combining the SMS microscope with a two-color pump-probe setup based on a tunable Ti:Sa laser source delivering ~ 100 fs pulses. The output pulse train was split in two parts to generate the pump and the probe beams, a different wavelength being generated for one of them using second harmonic generation or an optical parameter oscillator. The measured time-resolved signals
contain contributions from the different relaxation mechanisms following sudden ND excitation by pump pulse absorption: ND internal thermalization (by electron-electron and electron-phonon scattering mechanisms), acoustic vibrations and cooling (by dissipaion of the thermal energy injected by the pump pulse). The oscillating part of the signals, associated to ND vibrations, was selected and analyzed.

Depending on ND aspect ratio, this oscillating component contains contributions from one or two acoustic mode(s), whose frequencies $f$, damping times $\tau$ and quality factors $Q=\pi f\tau$ were estimated. Measurements evidenced the existence of two particular morphologies (at specific values of aspect ratio) presenting a pronounced enhancement of acoustic quality factors, namely close to $\eta\approx 2.5$ (with $Q \approx 70$) and close to $\eta\approx 6$ (with $Q \approx 30$) (Figure 1a). This complex dependence of vibrational quality factors on morphology was found to contrast with the simpler one of ND cooling dynamics, which was shown to be mostly controlled by ND thickness.

### 3. Analysis

To obtain a physical insight for these enhancements, the acoustic properties of gold NDs were explored by finite-element simulations in the frequency domain accounting for the inhomogeneous ND environment resulting from their deposition on a substrate. Perfectly matched layers were used at the border of the simulation domain to avoid spurious acoustic reflections, and vibrational spectra were obtained by computing the average elastic energy stored in a ND as a function of the frequency of a periodical excitation (a uniform stress being chosen, as it corresponds to the experimental case). Excited vibrational modes appear as Lorentzian resonances in the computed spectra, enabling the determination of their associated frequencies and quality factors.

This finite-element analysis sheds considerable light on the experimental observations listed above, yielding frequencies similar to those of the experimentally detected modes and thus providing access to their associated displacement fields. The low-frequency oscillation detected for $\eta<2.5$ was ascribed to a mode with a mostly vertical displacement (mainly affecting ND height), whose excitation amplitude quickly decreases at small $\eta$, in agreement with experiments. Conversely, the only oscillation detected for $\eta>3$ corresponds to a mode with a mostly radial displacement profile. A strong decrease of the elastic energy transfer at the ND/substrate interface occurs for this mode at $\eta=2.7$, leading to very high ($>2000$) computed $Q$ value (Figure 1a). This is at the origin of measured $Q$ values for $\eta=2.5$, unusually high for supported nano-objects. The experimental maximal $Q$ value (70) remains however much smaller than the computed one, most probably because of intrinsic vibrational damping within the NDs [3].

Finite-element simulations were also performed for supported NDs with elliptical sections. These computations explained the richer acoustic response experimentally observed for NDs with a non-circular section. Indeed, they show that some vibrational modes not excited in the circular ND case become observable when the ND circular symmetry is broken. Moreover, the nature and associated displacement field of the additional detected modes could be understood by detailed comparison between experimental and simulated results.

![Figure 1](image.png)

**Figure 1.** a) Maximal quality factors among the dominant vibrational modes detected in time-resolved experiments (bottom) and predicted in finite-element simulations (top). b) Schematic illustration of the morphology-dependent damping of ND vibrational modes.

### 4. Conclusions

In conclusion, this study demonstrates that the quality factors associated to the vibrational modes of a supported nano-object strongly depend on its morphology [5]. In particular, much longer vibrations occur for some specific geometries, as if the nano-object was “isolated” from the substrate (Figure 1b), a situation interesting for developing nanobalance applications and for quantifying the internal sources of vibrational damping.

Abstract

We have used various ultrafast optical and optoelectronic techniques to study thermal transport phenomena in 2D materials, in particular processes that take place on the femtosecond, picosecond and nanosecond timescale. These processes include the phonon-mediated cooling dynamics of hot electrons in graphene, as well as the thermal diffusion of different heat and charge carriers in graphene and semiconducting layered materials. We will discuss some previous and some ongoing results related to these topics.

1. Introduction

Two-dimensional materials have given rise to many interesting phenomena in the area of thermal transport, such as the large thermal conductivity of graphene [1], and strongly anisotropic heat transport in WSe₂ [2]. We will discuss a number of observations in this field, which were made possible using ultrafast optical and optoelectronic techniques. First, we will discuss time-resolved photocurrent measurements showing that near-field coupling between hot electrons in graphene and hyperbolic phonons in the surrounding hexagonal BN (hBN) layers dominates the hot-electron cooling dynamics [3, 4]. Second, we will discuss results obtained using spatiotemporal scanning on suspended flakes of semiconducting layered materials, where we follow heat and charge diffusion in time and space with femtosecond temporal and nanosecond spatial resolution.

2. Near-field electron-hyperbolic-phonon coupling in hBN-graphene-hBN stacks: super-Planckian cooling

Absorbed light in graphene leads to heating of the electronic system on a timescale of tens of femtoseconds and to ultrafast generation of a photoreponse when the light is incident on a pn-junction. Using two femtosecond light pulses with a variable time delay incident on such a junction, one can study the heating-cooling dynamics of the electron system. In hBN-graphene-hBN stacks - currently the most promising architecture for electronic and optoelectronic graphene devices – we found that these cooling dynamic occur through a surprisingly efficient out-of-plane cooling mechanism [3, 4]. In this mechanism, the energy from hot graphene electrons is transferred through near-field radiation to hyperbolic phonon modes in the hBN layers above and below the graphene. This process is many orders of magnitude more efficient than Planckian radiation, owing to the large mode density of the hyperbolic phonons. The experimental observations are in agreement with the results of microscopic calculations based on this mechanism. Interestingly, when using thinner hBN encapsulation, the cooling time increases. Thus by changing the hBN hyperbolic phonon modes, the properties of nearby hot electrons in graphene are modified.

3. Heat diffusion through ultrafast spatiotemporal scanning

In ultrafast spatiotemporal scanning measurements, two femtosecond light pulses are incident on a material, while both the time delay as well as the spatial displacement between the two pulses is varied. Such measurements allow for extracting the diffusivity of different charge and/or heat carriers. We have applied this technique to suspended flakes of semiconductor layered materials. It is crucial to suspend the flakes, in order to avoid out-of-plane transport into a supporting substrate. Rather, we are exclusively sensitive to the in-plane diffusion of charge and/or heat. We will discuss our ongoing efforts into understanding the material parameters that influence the diffusivity of, in particular, excitons and phonons in these systems.

Anisotropic Thermal Magnetoresistance in Radiative Heat Transfer

A. Garcia-Martin*

Abstract

Here, we predict a huge anisotropic thermal magnetoresistance (ATMR) in the near-field radiative heat transfer between magneto-optical particles when the direction of an external magnetic field is changed with respect to the heat current direction. We illustrate this effect with the case of two InSb particles where we find that the ATMR amplitude can reach values of up to 800% for a magnetic field of 5 T, which is many orders of magnitude larger than its spintronic analogue. This thermomagnetic effect could find broad applications in the field of ultrafast thermal management as well as magnetic and thermal remote sensing.

1. Discussion

The possibility to create and manipulate nanostructured materials encouraged the exploration of new strategies to control the electromagnetic properties without the need to modify its physical structure, i.e. by means of an external agent. An approach is the combination of magneto-optically active and resonant materials (e.g. plasmonic modes), where it is feasible to control the optical properties with magnetic fields in connection to the excitation of resonances [1] (magnetoplasmonics). It has been shown that these nanostructures can be employed to modulate the propagation wavevector of SPPs [2], which allows the development of label free sensors with enhanced capabilities [3-5] or to enhance the magneto-optical response in isolated entities as well as films, in connection with a strong localization of the electromagnetic field [6-8]. Here we will show that they also play a crucial role in the active control thermal emission and the radiative heat transfer (RHT) between objects in the near and far field regime [9-11].

In particular we will show that the Near Field RHT between two MO particles can be efficiently controlled by changing the direction of the magnetic field, in the spirit of the Anisotropic Magneto Resistance in spintronics. This phenomenon, which we term anisotropic thermal magnetoresistance (ATMR), stems from the anisotropy of the photon tunneling induced by the magnetic field. We discuss this effect through the analysis of the radiative heat exchange between two InSb particles, and show that the ATMR can reach amplitudes of 100% for fields on the order of 1 T and up to 1000% for a magnetic field of 6 T. These values are several orders of magnitude larger than in standard spintronic devices. More importantly, this thermomagnetic effect paves the way for exploring heat transfer physics at pico- and even subpicosecond time scales, which are even shorter than the relaxation time of heat carriers. Moreover, we show that the heat flux is very sensitive to the magnetic field direction, which makes this effect very promising for the development of a new generation of thermal and magnetic sensors.

Optomechanical coupling in the Anderson-localization regime

Many fundamental observations in physics ranging from gravitational wave detection to laser cooling of a nanomechanical oscillator into its quantum ground state rely on the interaction between the optical and the mechanical degrees of freedom. Due to the scaling dependance of the coupling strength with size, lithography-grown optomechanical crystals, purposely designed semiconductor nanostructures, are used to enhance the coupling between the electromagnetic field and the mechanical vibrations of matter at the nanoscale. The confinement strategy and spatial overlap between the two fields is typically engineered through controlled point or line defects in otherwise regular dielectric and acoustic lattices. A bottleneck of this strategy relies on the sensitivity of particularly high $Q$-factor cavities to uncontrolled imperfections appearing during the fabrication process [1, 2]. A less typical strategy to confine light and sound consists of exploiting such spatial fluctuations [3]; they give rise to strong multiple scattering which results in confinement by recurrent interference. Quality factors reaching $Q \sim 10^6$ have been observed in photonic crystal waveguides (PCW) [4, 5], thus competing in performance with engineered defects in the same platform while being inherently robust against disorder.

We have studied the localization properties of electromagnetic radiation and mechanical motion in disordered periodic-on-average silicon nanobeams [6]. In these systems, disorder localizes both fields which can interact with each other as in standard engineered cavity optomechanical systems [7]. Due to the inherently complex nature of the interference process, disorder lacks an a priori mechanism to co-localize both fields, limiting the maximum achievable coupling rate $g_o$ in the Anderson-localization regime. To address this challenge, we propose using GaAs/AlAs vertical distributed Bragg reflectors with embedded geometrical disorder [8]. Due to a remarkable coincidence in the physical parameters governing light and motion propagation in these two materials, the equations for both longitudinal acoustic waves and normal-incidence light become practically equivalent for excitations of the same wavelength. This guarantees spatial overlap between the electromagnetic and displacement fields of specific photon-phonon pairs, leading to strong light-matter interaction. In particular, a statistical enhancement in the vacuum optomechanical coupling rate, $g_o$, is found.

The enhanced light-matter interaction induced by the co-localization of particular photon-phonon pairs allows exploring Anderson localization of high frequency ($\sim 20$ GHz) phonons with cavity optomechanics techniques, using Anderson-localized optical modes as a probe for read-out. As opposed to optics, where excellent point sources exist granting direct access to the localized field [3], the direct spatial and spectral resolution of Anderson-localized elastic waves remains elusive. The lack of practical phonon transitions in the solid state and their limited far field radiation complicate the read out of confined states. The strong co-localization effect in GaAs/AlAs multilayered structures is therefore a promising resource to overcome these limitations and explore Anderson localization of phonons at frequencies so far unexplored, as well as a testbed to explore field-localization phenomena with coupled excitations.

Modulation of the THz Emission by a Quantum Cascade Laser using Coherent Acoustic Phonon Pulses

Abstract

We use laser-generated coherent acoustic phonon (strain) pulses to modulate the electronic transport and THz emission of a 2.6 THz Ga(Al)As quantum cascade laser. The modulation amplitude is of the order of a few % and the rise time, limited by the measurement system response, is less than 1 nanosecond.

1. Introduction

As compact sources of intense THz radiation, quantum cascade lasers (QCLs) have applications in spectroscopy, imaging and communications. For a number of applications, it is essential to be able to modulate the THz emission, e.g.: for superimposing information, or to generate pulsed emission or tunable sidebands.

One way of modulating the QCL emission is to change the electrical pumping current [1]. A large modulation depth is possible and it is theoretically fast due to the ps electron dynamics of the QCL. However, the practical speed is limited by the ability to drive fast current changes in a highly reactive load. Another method is to use an electrically gated graphene-based modulator layer at the output of the QCL [2]. Depths of modulation up to 100% are possible with this method, but maximum modulation speeds have been limited to ~ 100 MHz, again due to the difficulty of driving reactive loads at high speed.

Here we describe an alternative method of QCL emission modulation using bulk acoustic (strain) waves consisting of coherent acoustic phonons with frequency ~ 100 GHz. Previously it was shown that short strain pulses could be used to modulate the electron transport in resonant tunneling devices at high speed [3]. This was due to transient changes to the device bandstructure, via the deformation potential electron–phonon interaction, as the strain pulse propagated through the device. Similar effects could be exploited to modulate a QCL, e.g. by changing the injection of electrons into the active region. The theoretical limit to the speed is the time it takes for the acoustic wave, travelling at the speed of sound, to travel through the resonant tunneling region, which is ~10 ps.

2. The experiment

The Ga(Al)As QCL structure designed to emit at about 2.6 THz was grown by molecular beam epitaxy on a semi-insulating GaAs substrate, and consisted of 88 repeat periods of the injector and active regions. The total thickness of the structure was about 14 microns. A QCL ridge, 2 mm long by 150 μm wide, was formed by etching and electrical contacts made to the top and back. The substrate was thinned to 150 μm and then polished, and a 100 nm aluminium thin film acoustic transducer deposited opposite the QCL ridge. The device was mounted in an optical cryostat, cooled to a temperature in the range 10 – 20 K and was pumped by 50-μs-duration current pulses of amplitude of up to I = 1.8 A and with a duty cycle 5%. The QCL emission was detected using a THz Schottky diode.

Single-cycle, bipolar, acoustic strain pulses, with an amplitude η ≤ 10⁻³ and duration =15 ps, were generated by exciting the transducer with ~100-fs-duration pulses from an amplified Ti:Sapphire laser, of 800 nm wavelength, with a repetition rate of 1 kHz (synchronized to the QCL pump current pulses), and average power in the range 1 – 10 mW. The generated acoustic pulses propagated across the substrate and entered the QCL stack, travelling vertically up through the structure to the top contact, whereupon they were reflected and travelled back down through the QCL stack. The acoustic-pulse-induced transient changes in the voltage across the QCL, V(t), were extracted by using a bias tee in the DC pumping line and measured on a 12.5 GHz sampling oscilloscope. Changes in the intensity of the QCL THz light emission, L(t), detected using the Schottky diode, were also displayed on the oscilloscope.

3. Results

Fig. 1 shows V(t) and L(t) measured for a QCL pumping current of 1.64 A. Time t = 0 is the moment of impact of the laser pulse on the acoustic transducer, the first acoustic responses occur at t = 32 ns, which is the time taken for the strain pulse to reach the QCL ridge. Further acoustic responses, decaying in amplitude, are seen to repeat with a period of 64 ns. These are due to multiple reflections of the
acoustic wave back and forth across the substrate. A closer look at the \( V(t) \) response (inset to Fig. 1) shows that the duration of the signal is about 6 ns. This is the time it takes for the strain pulse to travel through the QCL ridge in each direction, before and after reflection at the gold top contact. The polarity of the QCL contact voltage response implies an increase in the resistance of the device as the strain pulse propagates through the device. The rise time of the \( V(t) \) response is 0.8 ns, but this is apparently limited by the temporal response of the measurement system.

The corresponding \( L(t) \) shows a fast negative spike (reduction of THz emission) during the propagation of the strain pulse through the device. This is followed by a recovery and electrical ringing due to the parasitic reactances of the setup. Comparing the amplitude of the initial negative spike with the quasi-DC response of the Schottky detector, we find the modulation depth is 6%.

4. Discussion

We observed that the acoustic pulse increases the electrical resistance and reduces the THz output of the QCL as it propagates through the device. We have developed a theoretical model of the interaction of the acoustic pulse with the QCL: in essence, the acoustic strain pulse can be considered as a propagating potential distortion of the band structure with amplitude \( \eta \Xi_D \), where \( \Xi_D \) is the deformation potential constant (~ 10 eV in GaAs). As this passes through each period of the QCL structure, it detunes the resonant injection of electrons into the upper lasing level, thus affecting the transport and the THz emission. More detailed calculations show that the THz emission from the QCL may increase or decrease, depending on whether the QCL is biased at a current below or above the peak in the steady-state \( L-I \) curve as we have observed experimentally.

5. Conclusions

We have used laser generated picosecond acoustic (strain) pulses to modulate the THz emission from a QCL. The modulation depth obtained in our device was 6%, and the measured rise time of the QCL voltage response was 0.8 ns. However, the theoretical modulation speed is expected to be much higher: \( \sim 10 \) ps.

Abstract
We investigate the generation of phonons via inter-valley scattering by calculating the time-dependent relaxation of electrons and phonons on picosecond timescales in photoexcited GaAs, Ge and Bi. We simulate the time evolution of carriers and phonons based on first-principles band structure calculations, including electron-phonon and 3-phonon processes. We compare the simulations with data from time-resolved diffuse x-ray scattering experiments performed at the LCLS free-electron laser facility. We also compare our results in Bi to existing reflectivity experiments[1].

1. Introduction
Direct observation of out-of-equilibrium phenomena has only become possible recently, with the development of large scale free electron laser facilities, such as the LCLS in the US, SACLA in Japan, and FLASH in Germany, as well as ultra-fast probing techniques.[2, 3, 4] One such phenomena is the observation of the transfer of energy from optical sources, via electrons to atomic movement. These techniques provide an unprecedented way to benchmark the phenomena governing energy relaxation processes. To reach this advanced stage has required the development of both the ultra-fast X-ray scattering techniques[3, 5] and sophisticated first-principles electron and phonon scattering algorithms.[6, 7, 8, 9]

In this work, we calculate the phonon generation via electron-phonon scattering in Ge, GaAs and Bi. We compare our results in Ge to measurements of the diffuse X-ray scattering intensity near the Brillouin zone boundary, observed in a scattering geometry similar to that in Ref. [5], but with substantially higher resolution. In Bi, we compare our results of the carrier dynamics to reflectivity experiments in Bi nanomembranes.[1]

2. Summary of results
In Ge and GaAs we observe an increase in the intensity of the x-ray signal near the L-point in the Brillouin zone, over 3-5 ps, that lasts over 10ps. This is due to the non-thermal phonons generated by inter-valley scattering of hot carriers in the L and Δ valleys. We also observe other non-thermal features in the x-ray scattering intensity due to anharmonic phonon scattering. The observation of these phonons strongly depends on the material electronic band structure and is affected by the pump wavelength. In Bi our model accounts for the experimental observation of the relaxation of the reflectivity signal in 12-26 ps[1] after photoexcitation. We attribute this to electron-hole recombination via inter-valley electron-phonon scattering between the conduction bands at the L points and the valence band at the T point. The magnitude of this relaxation time suggests that the carriers are not relaxed within the period of the optical phonons, and thus do not adiabatically follow the phonon dynamics.

Study of the resonant modes of hypersonic acoustic cavities by an ultrafast pump-probe technique

Camille Lagoin, Daniel Garcia-Sanchez, Paola Atkinson, and Bernard Perrin*

Sorbonne Université, CNRS-UMR 7588, Institut des NanoSciences de Paris, F-75005 Paris, France

Abstract

We used an ultrafast pump-probe technique to characterize the acoustic properties of semiconductor micropillars designed for optomechanics experiments. We described the way to measure quality factors as high as 35000 of a 20 GHz cavity mode with subharmonic resonant excitation by a femtosecond laser oscillator which has a repetition rate of 80 MHz. The spatial profile of the modes has also been investigated and discussed.

1. Introduction

Optomechanical devices working in the range of a few tens of GHz would be very useful since they can be used at much higher temperatures than MHz resonators and contribute to ultrafast information processing. Micropillar semiconductor GaAs/AlAs superlattice cavities which confine simultaneously optical and sound waves appeared as a promising tool a few years ago [1]. Frequency and spatial profiles of micropillar optical cavity modes have been studied many times [2] and large quality factors have already been evidenced. In contrast there are only a few numerical and experimental studies of their acoustical resonant modes [3,7]. Such measurements at 20 GHz are quite challenging: this frequency seems too large for conventional piezoelectric excitation and too low for ultrafast pump-probe technique. Indeed, the lifetime of the acoustic mode is expected to be of the order of hundreds of ns or more which is much larger than what can be studied with a mechanical optical delay line and much larger than the interval between two laser pulses of a femtosecond laser oscillator. In this work we used a subharmonic resonant excitation technique to overcome this difficulty.

2. Experiments

The planar acoustic cavities are obtained with two Bragg mirrors made of λ/4 GaAs/AlAs superlattices surrounding a λ/2 GaAs cavity; the whole device has been grown on GaAs wafers with thickness around 370 µm. Depending on the samples, the number of periods in the Bragg mirrors is 15, 20 or 25 and the fundamental resonant mode frequency is 16 or 20 GHz. The micropillars are obtained by etching the planar cavities; both circular and square section have been studied with typical diameter (or side length) going from 8 to 64 µm.

We studied the resonant modes of the acoustic cavities with an ultrafast pump-probe technique. Since the device works simultaneously as an optical and acoustical cavity we could have a complex interaction between the pump and the probe in a configuration where pump and probe are incident on the same side of the device. Thus we chose a configuration already used to study acoustic nanocavities [8] where pump and probe are incident on the opposite sides of the device. Opaque 60-nm Al films were deposited on the backside of the wafer and on the top of the cavities: the pump pulse excites a broad acoustic pulse which propagates through the wafer and through the cavity. To get rid of phonon-phonon interactions both in the substrate and the cavity we worked at 20K. The surface displacement of the cavity surface is probed with a Sagnac interferometer [9]: the top aluminum film prevents any photoelastic contribution to the detection process within the cavity.

The delay line of our setup works up to 12ns and we used the subharmonic resonant excitation of the acoustic cavity mode by tuning the repetition rate of the laser [9] to be able to measure decay times of the resonant oscillation of the order of hundreds of ns. The pump beam is modulated at a frequency \( f_{mod} \) = 1 or 2 MHz and a lock-in amplifier is used for the detection. Combining the in-phase X and out-of-phase components Y of the lock-in and taking account for the cumulative effects of the successive pump pulses, it is straightforward to show that, close to a resonant frequency mode, we obtain two signals

\[
S^X(\tau) = X \pm iY \propto e^{i\omega_m \tau} e^{2\pi f_{mod} \tau} \frac{1-e^{-i(\omega_{mod} \tau)}}{e^{2\pi f_{mod} \tau} - 1},
\]

(1)

where \( \tau \) is the pump-probe delay, \( f^H = f_m \pm f_{mod} \), \( f_m \) and \( \tau_m \) are the frequency and lifetime of the mode. Usually no resonant peak at \( f_m \) appears on the Fourier transform of \( S^X(\tau) \) except when the ratio \( f^H / f_{mod} \) is very close to an integer \( n \). Then, plotting the peak amplitude in terms of the repetition rate \( f_{rep} \) we obtain a Lorentzian shape from which we can extract the resonance frequency \( f_m = n \times f_{rep} \mp f_{mod} \), the lifetime \( \tau_m \) and the quality factor \( Q = \pi f_m \tau_m \). Results for a planar cavity with 25 periods Bragg mirrors is reported on Fig. 1. The Lorentzian fit gives a lifetime of 550ns
corresponding to a quality factor of 35000, 3 times smaller than the theoretical expectation; the small bump on the right side is due to successive acoustic echoes in the substrate. With this technique, it has been possible to study the seventh harmonic (112 GHz) of a fundamental mode at 16 GHz which corresponds to an integer \( n = 1400 \).

Figure 1: Peak amplitude of the power spectrum of the surface displacement of a planar cavity with 25 periods Bragg mirrors (black dots). The Q factor estimated from the fit (red line) is 35000 (\( r_m = 550 \) ns).

The same kind of results have been obtained in circular or square section micropillars with typical size ranging from 8 to 64 \( \mu \)m. For the largest (64 \( \mu \)m) and smallest (8 \( \mu \)m) micropillars we still obtain a Lorentzian shape scanning the repetition rate of the laser but in between it departs clearly from this behavior and we can highly suspect that we are also exciting other close resonant modes [6]. To check this possibility, we performed the following experiment:

In a first step, the acoustic pulse is incident on the middle of a 32 \( \mu \)m square micropillar. Scanning the repetition rate, we observed two peaks separated by 15.8KHz = 2f_{mod,n} which corresponds to the two side bands of the pump \( f^+ \) in the excitation process (the pump is modulated at 2MHz and the integer \( n = 253 \)).

In a second step, we chose a repetition \( f_{rep} = f^- / n \) and perform a probe scan through the top of the pillar to obtain the modes profile. The acoustic pulse is incident on the left side of the micropillar The black dots gives the resonance amplitude for the signal \( S^- \); the shape of the signal is clearly asymmetric with respect to the middle of the scan although the fundamental resonant mode should be symmetric. The red dots correspond to \( S^+ \); the shape of the signal is more complex and evidences the fact that at least two side modes with higher frequencies are also excited.

Figure 2: Asymmetric excitation of the resonant modes of a square section micropillar (32\( \mu \)m). The red circle in the inset corresponds to the pump position; black and red dots gives \( S^- \) and \( S^+ \) in terms of the probe position along the blue arrow for a repetition rate of 79.9035MHz. The blue line is the maximum amplitude of the first acoustic echo.

3. Conclusions

It has been shown that very high acoustic quality factors can be measured with an ultrafast pump-probe technique and that a detailed investigation of the mode profile can be performed.

Abstract

We investigate inverted conical nanopillars as a mechanical resonators, considering their flexural modes. Nanopillars are well suited for dense integration into resonator arrays. Establishing coupling between neighboring nanopillars enables then the investigation of coupled resonator networks.

1. Introduction

Nanopillars are ideally suited as mechanical resonators in the scope of applications in sensing [1] as well as the investigation of phenomena such as collective dynamics. Inverted conical nanopillars, fabricated in a top-down process, allow access to a large frequency range. The inverted conical shape (cf. Fig. 1a) allows for extremely high flexibility at the clamping point of the resonators, as well as straightforward optical detection, owing to their relatively large heads.

Top-down fabrication of these nanopillars also allows for dense and well-controlled fabrication of nanopillar arrays. We investigate the dynamics of individual as well as the coupling between nanomechanical pillar resonators.

2. Experimental and results

Inverted conical GaAs nanopillars are fabricated in an electron beam patterning step combined with an anisotropic chlorine reactive ion etch. We investigate flexural modes as depicted in Fig. 1b exhibiting large amplitudes, which can be detected via SEM imaging as well as optical laser based detection. Top-down fabrication further allows frequency control through the geometry parameters (cf. Fig. 1a) of the nanopillar

\[ \omega = \sqrt{\frac{E}{\rho}} G(r, b, h) \]  

with geometry factor \( G(r, b, h) \) [2]. We further examine intrinsic coupling between two neighboring nanopillars. Based on studies of mode hybridization as well avoided level crossings, we can control the coupling strength solely through the geometry of the nanopillars. [3]

3. Conclusion

Nanomechanical pillar resonators are well suited for the investigation of collective dynamics owing to their well controlled frequencies and the straight-forward integration into large arrays (cf. Fig.1c).

Abstract

Our work thoroughly addresses the topic of synchronization of nanoscaled optomechanical (OM) oscillators. We demonstrate for the first time synchronization of a pair of mechanically-coupled OM cavities by means of a set of unequivocal experiments. We also show that the collective dynamics can be controlled by externally actuating over a single oscillator. Therefore, these results set a solid basis for realizing reconfigurable networks of OM oscillators displaying collective dynamics dominated by weak mechanical coupling.

1. Introduction

In 1665 Lord Christiaan Huygens discovered that two pendulum clocks, hung from the same wooden structure, were oscillating in perfect consonance but in opposite directions, i.e. the clocks were synchronized in anti-phase.

Essential conditions for spontaneous synchronization between two dynamical systems are [1]: i) both of them are self-sustained oscillators, i.e., capable of generating their own rhythms; ii) the systems adjust their rhythm due to a weak interaction; and iii) the adjustment of rhythms occurs in a certain range of mismatch of the individual systems. To date, there has been only a handful of reports claiming synchronization in coupled OM cavities [2]-[4]. Most of these works are rather controversial [5], since the systems operate in a rather strong-optical-coupling regime that makes them indecomposable. Indeed, the coupled OM cavities share a common optical mode, which in addition prevents extracting the dynamics of each cavity cannot in an independent way. On the other hand, a couple of reports have reported long-range synchronization between OM cavities placed in different chips [6],[7]. The coupling mechanism in these cases relies on modulating the optical excitation of one of the cavities with an electro-optical-modulator that reproduces the dynamics of the other cavity.

2. Results and discussion

In this work, we report synchronization of the mechanical dynamics of a pair of OM oscillators weakly coupled mechanically and completely isolated optically. The OM oscillators are independently driven to a state of high amplitude, coherent and self-sustained mechanical motion (mechanical lasing from now on) using a self-pulsing dynamics [8],[9]. Although the coupling is bidirectional, the synchronization dynamics is nearly of a Master-Slave type, given that the amplitude of the coherent oscillations is considerably larger in one of the cavities. Simultaneous recording of the optical transmission temporal traces of each of the two cavities allows concluding that, in the synchronized state, they mechanically oscillate in anti-phase, which is in agreement with the predictions of our numerical model with reactive coupling. Finally, we demonstrate that, when the coupled system is in a synchronized state, it is possible to disable it while actuating over one of the cavities with a heating laser, so that both cavities oscillate independently.

The geometrical configuration of two OM oscillators can be upscaled to realize complex networks comprising many more nodes without substantially increasing the technological requirements. Our structures can be optically excited by a common laser source by exploiting thermo-optic effects while still maintaining the weak interaction requirement for synchronization. These results are the first step towards building networks of weakly coupled OM oscillators able to display collective dynamics susceptible to
be modified by addressing single structures with external perturbations, thus enhancing the performances of single nano-mechanical oscillator systems and constituting a novel architecture for neuromorphic computing applications.

Abstract

Stochastic resonance is a general phenomenon usually observed in one-dimensional, amplitude modulated, bistable systems. We show experimentally the emergence of phase stochastic resonance in the bidimensional response of a forced nano-electromechanical membrane by evidencing the enhancement of a weak phase modulated signal thanks to the addition of phase noise. Based on a general forced Duffing oscillator model, we demonstrate experimentally and theoretically that phase noise acts multiplicatively inducing important physical consequences. These results may open interesting prospects for phase noise metrology or coherent signal transmission applications in nanomechanical oscillators.

1. Stochastic with electromechanical resonator

Stochastic resonance whereby a small signal gets amplified resonantly by application of external noise has been introduced originally in paleoclimatology [1] to explain the recurrence of ice ages and has then been observed in many other areas including neurobiology [2, 3], electronics [4], mesoscopic physics [5], photonics [6, 7], atomic physics [8] and more recently mechanics [9, 10, 11]. Implementation of stochastic resonances involves generally three ingredients: (i) the existence of metastable states separated by an activation energy, as in excitable or bistable nonlinear systems, (ii) a coherent excitation, whose amplitude is however too weak to induce deterministic hopping between the states, and (iii) stochastic processes inducing random jumps over the potential barrier. In the classical picture of a bistable system, this corresponds to the motion of a fictive particle in a double-well potential periodically modulated in amplitude by the signal and subjected to noise [12]. When an optimal level of noise is reached, the system’s response power spectrum displays a peak in the signal to noise ratio, unveiling the stochastic resonance phenomenon. The resonance occurs as a 'bona-fide' resonance in a frequency band around a signal frequency approximately given by the time-matching condition [13], i.e. when the potential modulation period is twice the mean residence time of the noise-driven particle. Experimental works on stochastic resonance are almost exclusively using amplitude modulation going along with additive amplitude noise or multiplicative amplitude noise [14, 15]. In this case, it corresponds to a pure one-dimensional effect.
phase noise observed on the bidimensional response of the oscillator (Fig. 2). This opens new avenues for stochastic resonance in bidimensional systems by allowing for instance stochastic amplification of mixed phase-amplitude modulated signals by complex value noise. We highlight that the system's response can be projected on any variable in phase space and that the amplification depends on the chosen basis. Finally, we derive a stochastic nonlinear amplitude equation for the forced stochastic Duffing oscillator, which describes qualitatively well our system (Fig. 2), and show that phase noise acts multiplicatively inducing important physical consequences.

![Image](https://example.com/image.png)

Figure 2: Experimental (red triangles) and theoretical (open black squares) spectral noise amplification in amplitude $R$ as a function of phase noise strength. (b) Experimental (blue circles) and theoretical (open black stars) spectral amplification in phase $Φ$ as a function of phase noise strength. (c) Experimental polar plot for phase noise ($0.44$rad) with maximum amplification, highlighting the shape of the two stable points as well as the directions imprinted by the modulation on the input phase or amplitude. The two dashed grey lines are guide for the eyes indicating the two distinct amplitude states and the dotted white line highlights the threshold.

### 2. Vibrational resonance with electromechanical resonator

Similarly to stochastic resonance, vibrational resonance show up in non-linear resonators sustaining metastable states. Instead of using broad band noise, vibrational resonance is implemented with a high frequency modulation (between the low frequency modulation of the weak signal and the mechanical frequency of the resonator). Here, the gain factor also features a resonant-like behaviour, with a well pronounced maximum for optimal external driving amplitudes. The maximum achieved gain factor is 20 much higher than for stochastic resonance.

Vibrational resonance is governed by an amplitude condition. It occurs close to the transition from bistability to monostability, during which the effective potential of the slow variable evolves from a rapidly oscillating double well to a single well with a parametric dependence on the high-frequency signal amplitude and frequency. As such, this phenomenon has some features in common with parametric amplification near the critical point. The shape of gain achieved in vibrational resonance consequently reflects the (here symmetrical) shape of the parametric gain in the system. By numerically investigating the amplitude equation, we show that the strength of the high-frequency driving can tune the system such that the low amplitude signal drive makes the system jump between the two branches. It is the basic physical phenomenon at the origin of vibrational resonance. In the absence of high frequency amplitude modulation, the system stays in the lower branch and the response is quasi linear. When the driving is increased, the system is tuned into resonance and this corresponds to a large signal amplification, provided the modulation amplitude is large enough. The amplification displays a sharp transition corresponding to the tuning of the system into the bistable region. For still higher driving the system stays in the upper branch where the response is sublinear, thus leading to de-amplification.

### 3. Conclusions

We have demonstrated stochastic and vibrational resonance with a unique and driven electromechanical photonic crystal membrane. This versatile platform allows coupling several of them either optically or mechanically. Multimode optomechanics has started to be explored in the last years for its promising applications in nonlinear signal processing. The use of coupled optical or mechanical modes can lead to interesting properties such as nonreciprocal states [16], spontaneous symmetry breaking [17] or noise-aided process which might have a strong impact in noise-aided applications including signal processing or sensing.

Abstract
We propose a scheme of atom-assisted cavity optomechanical system and demonstrate the electromagnetically-optomechanically induced transparency, where a transparent property of EOMIT (e.g. transparent point, width of transparent window) can be effectively tuned by several system parameters including the coupling strength between cavity field and atom, Rabi frequency of atom, optomechanical cooperativity as well as relevant detunings.

1. Introduction
Cavity quantum electrodynamics (CQED) has provided a ubiquitous platform for the interaction between atoms and cavity fields at single quantum level. And the realization of cavity optomechanics has coupled cavity fields to mechanical resonators. Currently, motivated by the rapid development of quantum information network, the bridge of the CQED and optomechanics has been demonstrated[1]. A wide range of physics appears, and one of the most interesting phenomena is the analogous electromagnetically induced transparency (EIT) in hybrid systems. Since the first observation of EIT in atom gas[2], the analogous EIT phenomenon has been realized in various systems, ranging from the CQED, multi-microcavities systems to cavity optomechanics[3]. However, the analogous EIT phenomenon in the hybrid atom-photon-phonon system has been absent.

Here, we theoretically study an atom-photon-phonon system, consisting of a single $\Lambda$-type three-level atom and an optomechanical cavity, which is driven by strong lasers at the red sidebands (see Fig.1). The innovation of our model lies in the combination of two kinds of interactions in the atom-photon-phonon system, one is the interaction between the atom and the cavity mode, the other is the interaction between the sideband driven cavity mode and the mechanical mode. Based on the above considerations, we demonstrate electromagnetically-optomechanically induced transparency (EOMIT), where the transparent point appears in the condition of satisfaction of two sets of two-photon resonance. We explain the mechanism of EOMIT from the perspective of dressed state theory and find the property of EOMIT (e.g. transparent point, width of transparent window) can be effectively tuned by several system parameters including the coupling strength between cavity field and atom, Rabi frequency of atom, optomechanical cooperativity as well as relevant detunings.

2. Atom-photon-phonon model setup
As schematically shown in Fig. 1(a), we study a hybrid atom-photon-phonon system consisting of an optomechanical cavity and a $\Lambda$-type three-level atom. The atom is confined inside the cavity and its excited and grounds states are labeled as $|1\rangle$ and $|2\rangle, |3\rangle$, respectively. The atomic transition $|1\rangle \leftrightarrow |2\rangle$ with energy level difference $w_{12} = w_{1} - w_{2}$ is coupled to the cavity field of frequency $w_{cav}$ with coupling coefficient $g$ and the detuning $\Delta_{cav} = w_{12} - w_{cav}$. While the transition $|1\rangle \leftrightarrow |3\rangle$ is driven by a classical, controllable field of frequency $w_{0}$ with Rabi frequency $\Omega$ and detuning $\Delta_{0} = w_{13} - w_{0}$. Fig. 1(b) shows the driven lasers associated with the system, the lasers of frequency $w_{0}$ and $w_{d}$ drive the atom and cavity respectively, while a weak laser with frequency $w_{p}$ probes the resonance of the cavity. The whole couplings existed in the system is shown in Fig. 1(c).

Based on the above considerations, in a rotating frame, the Hamiltonian of the hybrid system reads:

$$H_{1} = h\Delta_{cav}\sigma_{11} + h(\Delta_{cav} - \Delta_{d})\sigma_{22} + h(\Delta_{cav} - \Delta_{0})\sigma_{33} + h(\Omega\sigma_{13} + g\sigma_{12} + H.c.) + i\hbar\sqrt{2m\alpha}([\varepsilon_{a}a^{+} - \varepsilon_{p}^{a}a] + \varepsilon_{p}b^{+}e^{i(\Delta_{p} - \Delta_{d})t} - \varepsilon_{p}^{a}ae^{-i(\Delta_{p} - \Delta_{d})t})],$$

where the detunings are defined as $\Delta_{p} = w_{12} - w_{p}$, $\Delta_{d} = w_{12} - w_{d}$, $\Delta_{cav} = w_{12} - w_{cav}$, $\Delta_{0} = w_{13} - w_{0}$.

3. Electromagnetically-optomechanically induced transparency
In the red resolved sideband, we get the intracavity field induced by the probe light as Eq. (1). For numerical work, we use parameters from recent experiments: $g = 1MHz$, $\Omega = 2MHz$, $\alpha = 1MHz$, $\tau_{21} = 0.5MHz$, $\tau_{23} = \tau_{m} = 0.01MHz$, $\eta = 0.6$. 
Figure 1: (a) Scheme of the considered hybrid system. Three-level atom in configuration showing the cavity \( (w_{\text{cav}}) \) and control \( (w_0) \) fields coupling the transitions \( |2_i \leftrightarrow |1_i \) and \( |3_i \leftrightarrow |1_i \), respectively, and relevant detunings. (b) Three optical fields, a driven laser \( (w_d) \) drives the cavity at red or blue sidebands with a mechanical frequency \( w_m \) offset from the cavity field, a second laser \( (w_p) \) probes the cavity resonance while a third laser \( (w_0) \) controls the transition \( |3_i \leftrightarrow |1_i \) in atom. (c) Schematic illustration of decay channels and couplings among photons(a), phonons(b) and atom(c). (d) Absorption and dispersion spectra of propagating quantum light as a function of detuning \( \Delta_d = w_m \) and \( \Delta_0 = \Delta_{\text{cav}} = 0 \). There are four peaks and a transparent window under the condition \( \Delta_0 = \Delta_{\text{cav}} = 0 \). (e) The atom-photon-phonon eigenstates structure for the hybrid quantum system.

The effective cooperativity for optomechanical system
\[
C = \left( \frac{G \alpha}{r_a r_m} \right)^2 = 4.
\]

Figure 1(d) plots the absorption and dispersion spectrum of probe light as a function of detuning \( \Delta_p = w_p - w_{12} \) with \( \Delta_d = w_m \) and \( \Delta_0 = \Delta_{\text{cav}} = 0 \). It is shown that there are four peaks in the absorption spectrum and each peak corresponding to a steep slope in the dispersion spectrum. The position of each peak (a-d) locates at \(-2.29r_0\), \(-0.18r_0\), \(0.18r_0\) and \(2.29r_0\) respectively. Meanwhile, a transparent point appears under the condition \( \Delta_d = w_m \) and \( \Delta_0 = \Delta_{\text{cav}} = \Delta_p = 0 \). We also give an explicit physical reason for the peaks and transparent point using the dressed state language, whose eigenstates are shown in Fig. 2(e).

\[
\delta a = \frac{\sqrt{2\eta r_a \varepsilon_p}}{r_a + i(\Delta' + \Delta_p - \Delta_d) + \frac{G^2 a^2}{r_m + i(w_m + \Delta_p - \Delta_d)} + \frac{g^2}{r_21 + i\Delta_p} + \frac{\Omega^2}{r_23 + i(\Delta_p - \Delta_0)}},
\]

(1)

4. Discussion

we also demonstrate that the transparent point can be tuned by the relevant detunings and the width of transparent window can be increased by decreasing the coupling strength between cavity field and atom or increasing the Rabi frequency of atom and optomechanical cooperativity. The EOMIT can find its role in quantum state transduction and quantum memory. For example, the information carried by atom can be transferred to phonon with the help of photon, which has long coherence time and can be an ideal carrier for quantum memory. Also, the EOMIT has a positive effect to generating slow light as the width of transparent window can be controlled by atom, which is easy to implement in experiments.

5. Conclusions

We report the EOMIT in atom-assisted system and reveal the mechanism in terms of dressed state theory. Our work would bring great flexibility for manipulating light, which can be used for generating slow light and amplifying signal light.

Abstract

Ultrafast acoustic spectroscopy of single nanoparticles appears as a promising way to probe the elastic properties of matter at GHz to THz frequencies$^1$ or to perform local in-depth elastic nanoscopy$^{2,3}$. To date, ultrafast spectroscopy of the acoustic eigenmodes of nanoparticles are usually performed with single point measurements. For a nanosphere, the acoustic spectrum is then dominated by the purely radial breathing mode. However, the detection of acoustic eigenmodes involving a shear component of the particle surface displacement is highly desired to investigate the elastic properties of liquids$^4$, biological media$^5$ or nanocontacts$^{6-8}$ in the GHz to THz range. We demonstrate here that ultrafast microscopy of the acoustic eigenmodes of a single nanoparticle allows us to unveil such eigenmodes.

A movie of the picosecond dynamics of a single gold nanoparticle dropped on a silica substrate is recorded over 20 ns with an ultrafast pump-probe experiment. We demonstrate that spectro-imaging, i.e. the investigation of the spatially resolved acoustic spectrum, is ideally suited to push further the analysis of the vibrational landscape of the nanoparticle. This spectral analysis reveals a more complex acoustic spectrum of the nanoparticle and high order acoustic eigenmodes undetectable in single point measurements are detected. The frequency of these modes is shown to be influenced by the shear contact stiffness$^9$.

Optomechanics with hybrid carbon nanotube resonators

Alexandros Tavernarakis, Alexandros Stavrinadis, Alex Nowak, Ioannis Tsioutsios, Adrian Bachtold, and Pierre Verlot

Abstract

Nanomechanical systems are raising increasing attention. This is prominently due to their very low mass, yielding to much reduced sensitivity towards thermally induced decoherence. Here we report what appears the most extreme kind of nanomechanical resonator, consisting of a single-clamped carbon nanotube at the tip of which an efficient nano-optical scatterer has been added. Our system is reported the most sensitive ever demonstrated at room temperature. We also analyze the noise dynamics of our devices and reveal fundamental limitations of nanomechanical sensing.

1. Introduction

In twenty years, cavity optomechanics has established as a rapidly advancing research field aiming at developing macroscopic systems operating in the quantum regime (1). Important progress has been achieved in this direction, such as laser cooling of a macroscopic mechanical resonator in its groundstate(2), the demonstration of the quantum backaction in an interferometric measurement(3) and more recently the first evidence of quantum optomechanical entanglement(4). Further exploring the quantum regime and extending the application range of optomechanical systems requires drastic suppression of decoherence, which remains the main source of limitation. Several approaches are being developed, aiming at reducing the thermal noise, including electromagnetic trapping(5), tethered resonators(6), and dissipation dilution(7).

Here we present a novel approach based on hybrid carbon nanotube resonators, consisting of single-clamp suspended carbon nanotube at the tip of which a nano-optical scatterer is grown(8). Sensitive optomechanical detection is demonstrated and dynamical backaction analysed. The force sensitivity is calibrated at the sub-attonewton level at room temperature for the first time, representing a two orders of magnitude improvement compared to previous report(6). The frequency noise dynamics is also analyzed, showing the fundamental impact of nonlinearities on nanomechanical sensing. Our work opens the path towards implementing quantum optomechanical technology at room temperature.

2. Results

2.1. Hybrid carbon nanotube resonator

Our hybrid carbon nanotube resonators (CNT) consists of singly clamped suspended carbon nanotube resonators at the tip of which a nanoparticle is subsequently grown. Details on the fabrication of our devices can be found elsewhere(8).

Our devices have typical masses, resonance frequencies and quality factors ranging from $10^{-21}$ kg to $10^{-18}$ kg, 10 kHz to 10 MHz and $10^2$ to $10^4$ range, respectively.

2.2. Optomechanical coupling

Our devices are mounted on a 3D nanopositioning stage placed in a vacuum chamber. A single-mode Helium-Neon laser is focused on the sample by means of an aspherical lens with numerical aperture NA=0.55. The light scattered by the tip of the device is collected in reflection by means of an optical circulator and further sent to a fast avalanche photodetector. When the device is off-centered from the laser beam waist, the backscattered becomes sensitive to its mechanical motion, therefore enabling nanomechanical detection (see Fig. 2(a)). Sweeping the frequency of a piezo-driven excitation around the mechanical resonance frequency of the device, one retrieves a harmonic behavior enabling to determine both mechanical resonance frequency and mechanical quality factor (upper curve, Fig. 2(b)). Turning the excitation off, a noise peak is revealed, driven by the ambient thermal fluctuations (lower curve on Fig. 2(b)). Increasing the optical power up yields to the unexpected lowering of the nanomechanical fluctuations, as
demonstrated by the net decrease of the optomechanical spectrum area (see Fig. 2(c)). This is explained because of the presence of photothermal backaction, yielding to a cold damping force with negligible extra fluctuations being added. These results enable us to provide a direct calibration of the thermal force noise $S_{fT}=(0.7 \, \text{aN/Hz}^{1/2})^2$, that is the lowest ever reported thermal noise level for a solid state nanomechanical device operating at room temperature, 2 orders of magnitude lower compared to previous report(6).

2.3. Frequency noise dynamics

A regime of particular importance is that where the nanomechanical motion is coherently driven, which is at the basis of all phase-sensitive detection schemes (including e.g. scanning probe microscopy). The frequency noise of the nanomechanical device then becomes a prominent source of limitation, which has recently attracted intense attention. Here we report how the combined effect of intrinsically high thermally driven motion, nonlinear response and multimode nature of our devices generate frequency noise, acting as fundamental limits of nanomechanical sensing. We notably report the first demonstration of resonant squeezing, and the spectral broadening it induces on its paired, orthogonal vibration mode (see Fig. 3).

3. Conclusions

We have reported the first ultra-sensitive detection and control of a single-clamp carbon nanotube resonator. Our system is so far the most sensitive ever demonstrated at room temperature, opening novel perspective both in Science and Technology. We also demonstrate, intrinsic noise mechanisms, establishing fundamental limits of nanomechanical sensing.

Abstract

Implementing sustainable methods for cooling is urgent, due to global warming and the high energy consumption associated to modern cooling technologies. In this work, we propose self-assembled colloidal arrays as an energy-efficient solution for above-ambient radiative cooling. We show that the temperature of a crystalline silicon wafer is lower during daytime when the thermal emitter is placed on its surface. This structure can be used to remove heat passively from devices that currently undergo critical heating during operation.

1. Introduction

Today, temperature regulation at the macro and microscale is one of the major contributors to the energy demand of society [1]. Cooling is particularly energy-consuming, accounting for 15% of the global energy use and 10% of green-house gas emissions. Furthermore, a tenfold growth in the demand of cooling technologies is expected in the next 30 years, mainly due to global warming [2]. Here, we propose an array of SiO₂ microspheres on a Soda-lime slab as an above-ambient radiative cooler. This structure can improve the thermal performance of devices that undergo critical heating during operation without the need of additional energy or electricity for removing heat from a surface.

2. Methods and results

The working principle of the proposed cooling device is based on the interaction of the transverse optical phonons and equally polarized electromagnetic waves, which results in an intense evanescent field confined at the surface of a polar-dielectric interface. Such surface excitations, so called surface phonon polaritons (SPhP), have the ability to enhance thermal energy conduction [3], and, in the presence of a grating, they can be diffracted to the far-field as infrared thermal energy [4]. We also use the differential polar-dielectric boundaries from the spherical shape of the microspheres, that result in an effective impedance matching between the polar and the dielectric media (silica/air) over a large spectral range [5], for enhancing the emissivity of the material in the IR transparent window of the atmosphere. This passive thermodynamic mechanism evacuates heat from a hot surface and deposits it into outer space at 3K, which acts as a heat sink.

In this work, we will present a theoretical study using an in-house developed rigorous-coupled-wave analysis (RCWA) code was performed to predict the optimal colloidal structure which maximizes the emissivity in the atmospheric infrared transparency window for the greatest range of emission angles. Based on the theoretical results, we will show how an optimal thermal emitter can be used to passively radiate heat from a surface into the out space, cooling it down passively, i.e. without external energy or electricity input.

3. Conclusions

In summary, we will present here a novel thermo-functional material for above-ambient passive radiative cooling. It consists of an array of SiO₂. Our structure behaves as a nearly perfect thermal blackbody. We analyze its radiative cooling performance by measuring the temperature cycle of the proposed structure and we prove its performance as an above-ambient daytime cooler. So far a temperature difference of 12 K has been achieved for a thermal emitter on a bare silicon substrate using the proposed radiative cooler, which compares well with the 8 K temperature difference of a water tank reported for an 80 μm thick film of randomized glass-polymer hybrid metamaterial [6].

Abstract

We introduce the concept of topological invariants to nanophononics and implement a nanophononic semiconductor system supporting a robust topological interface state at 300 GHz. We optically probe this mode through Brillouin spectroscopy and coherent phonon generation experiments. This type of topological interface states could become part of novel devices requiring resonant nanoacoustic structures such as compact integrated Brillouin light sources operating at ultrahigh frequencies.

Acoustic phonons constitute a versatile platform for the study of fundamental wave dynamics, including Bloch oscillations and other localization phenomena. Many of these studies were inspired by their counterparts in optics and electronics. In these fields, the consideration of topological invariants to control wave dynamics has already had a great impact for the generation of robust confined states. Interestingly, the use of topological phases to engineer nanophononic devices remains an unexplored and promising field.

Here, we introduce the concept of topological invariants to nanophononics and experimentally implement a nanophononic system supporting a robust topological interface state at 300 GHz [1]. The state is constructed through band inversion, i.e., by concatenating two semiconductor superlattices with inverted spatial mode symmetries [2]. The existence of this state is purely determined by the Zak phases of the constituent superlattices, i.e., the one-dimensional Berry phase.

We experimentally evidence these novel modes through Brillouin spectroscopy [1] and coherent phonon generation and detection using pulsed laser schemes [3]. The reported topological interface states could become part of novel devices requiring resonant nanoacoustic structures such as compact integrated Brillouin light sources operating at ultrahigh frequencies [4].

Abstract

Intense picosecond Terahertz pulses are used to drive coherent phonons dynamics in nanometric films of topological insulators Bi₂Te₃ measured in time-resolved experiments. The possible coherent phonons excitation mechanisms are discussed.

1. Introduction

Over the last decade, the development of high-power ultrafast laser systems led to the emergence of ultrafast picoseconds Terahertz pulses, which provide a new tool for studying fundamental aspects of light-matter interactions [1]. For instance, THz-driven ballistic charge currents in semiconductors [2, 3], THz-induced dynamics in metallic ferromagnets [4] or High Harmonic Generation in solids [3] have been investigated. Topological insulators exhibit peculiar physical properties and are stated to be the next generation of electronics and spintronics devices [5]. Using low photon energy excitation with THz pulse opens new possibilities to study their electronic and lattice properties. Here, we demonstrate the possibility to generate both coherent optical and acoustic phonon modes with a picosecond THz pulse in the topological insulator Bi₂Te₃ with a photon energy (~2 meV) way below the material band gap (~200 meV). The latter was never observed in the literature at our knowledge.

2. Discussion

In our experiments, we study prototypical topological insulators Bi₂Te₃ in a THz pump/visible probe setup by measuring ΔT/T(τ), the relative change of transmission of the visible probe as a function of the pump/probe delay τ. Both pump and probe pulses are generated by an amplified Ti:sapphire laser system (pulse energy 3 mJ and duration 120 fs, central wavelength 805 nm, repetition rate 1 kHz). The main fraction of the laser is used to induce optical rectification in a stoichiometric MgO-doped LiNbO₃ crystal by the tilted pulse front method [6, 7], which generates ultrashort single cycle THz pulses with a duration of around 1.6 ps (full width half maximum), a pulse energy of roughly 1 μJ and a spectrum centered at 0.5 THz (photon energy of ~2 meV) spanning frequencies from 0.2 to more than 1 THz. The remaining fraction is used as probe pulses at 402 nm wavelength obtained by frequency doubling in a BBO-crystal. The THz pulse impinges the sample at normal incidence while the probe’s incident angle is roughly equal to 20°. The experiments were performed in air at room temperature. The generation of ultrathin Bi₂Te₃ nanofilms was performed by the Molecular Beam Epitaxy technique in the co-deposition mode on a freshly cleaved Mica substrate [8].

Typical transient is shown in the Fig. 1a) for a nanofilm of thickness 6 nm. The measured ΔT/T(τ) exhibits a fast rise and a slower decay, reflecting the excitation and then the relaxation of hot carriers generated by the THz pulse. The initial electronic excitation process is not in the scope of the paper, but due to the sample growth method we expect to have carriers in the conduction band (n-doped), which can lead to electronic response in the transients due to THz excitation. We will focus here on the oscillating part of the signal exhibiting two different periods, which can be easily identified in the probe transmission change ΔT/T(τ) and is related to coherent excitation of an optical phonon mode and of an acoustic phonon mode. Fig. 1b) displays the oscillatory signal and allows to extract the two different frequencies of 1.85 THz, which corresponds to the optical A1g phonon mode, and 0.18 THz, which corresponds to the fundamental breathing mode of the thin film. The latter reflects the elastic properties of the sample at the nanoscale. Similar measurements were performed in nanofilms with different thicknesses. The observed acoustic oscillation period increases with the film thickness as shown by Fig. 1c). In contrary, we did not measure any change in the optical phonon frequency.

The generation mechanisms of the optical and acoustic phonons modes are different. Concerning the optical raman-active A1g phonon mode, it has been recently shown that terahertz sum-frequency excitation can be an efficient way to excite raman-active mode with a terahertz pulse [10]. Concerning the fundamental breathing mode generation, it has been shown that thermoelasticity effect is negligible compare to electron-phonon deformation potential in a recent all optical pump/probe experiment [9]. However, the excitation process by a THz pulse is not established yet. In this communication, we will discuss the
different possible excitation mechanisms for the coherent acoustic phonons generation.

Abstract
Molecular cavity optomechanics is a new description of surface enhanced Raman scattering, and in return, surface enhanced Raman spectroscopy provides a new method for constructing and studying high coupling strength cavity optomechanics system. Moreover, pulsed excitation with duration time shorter than the phonon decay time, along with two-dimensional atomic crystals with well-defined arrangement and lattice orientation, facilitates the quantitation and simultaneously resolution of the time scale and the space scale. Here we show some results based on such a platform.

1. Introduction
The vibrational properties of molecules can be used as feature for analysis detection. Owing to ‘hot spot’ effect, surface enhanced Raman spectroscopy (SERS) enable a sensitive way to realize single molecular detection [1,2]. The vibrational pumping regime in surface enhanced Raman scattering [3,4] links Raman active nanomaterials to cavity optomechanics [5]. In this paradigm, plasmonic nanocavities with blue (or red) detuned light excitation with respect to the cavity resonance wavelength would lead to the amplification (or cooling) of the vibration of molecules, showing as the nonlinear emission of the Stokes and Anti-Stokes Raman scattering. Raman process induced by such dynamic back action can be distinguished from normal Raman scattering by power- and wavelength- excitation dependence of anti-Stokes/Stokes intensity and its anomalous ratios. Nonlinear power dependence of SERS intensity based on a pulsed molecular optomechanics configuration has been demonstrated [6]. However, for the quantity and the orientation of molecules are hard to be manipulated, it is not precise enough to get the quantitative feature of such a molecules cavity optomechanics. In our previous work [7], we show the advantage of two-dimensional atomic crystals probe where the orientation of molecules is well defined naturally and the quantity of molecules can be estimated with smaller deviation.

2. Experiment and Result
Here, we adopt a molybdenum disulfide (MoS₂) spaced nanoparticle-on-mirror (MoS₂-NPOM) system with wavelength- and power-dependent SERS measurements (Fig. 1). In this configuration, two-dimensional monolayer MoS₂ is placed between an ultrasmooth gold film and a nanoparticle with an additional Al₂O₃ fabricated within the gap using atomic layer deposition. Atoms or molecules filled in the gap have a well-defined lattice orientation such that the lattice vibrations are precisely aligned with the plasmonic field components (Fig. 1). By means of grating and tunable filter sets, 50-fs pulses with full width at half maximum about 40 nm (80 MHz repetition rate) are spectrally filtered as pulses with full width at half maximum about 1.5 nm (Fig. 2b). By rotating the grating and tunable filter sets, we can get wavelength spanning the spectra of the pulses. In this way, we can achieve wavelength tunable excitation in narrow band. Furthermore, we can manipulate the resonance of cavity by changing the thickness of Al₂O₃ in surface coating and in gap. Finally, we get excitation of wide-range detuning condition. Our result show that the dark-field scattering spectrum remains nearly unmodified after the whole experiment. The Stokes/anti-Stokes (not simultaneously) spectra and the power dependence excited by wavelength of 800 nm (slightly blue detuned) are shown in Fig. 2.

Figure 1: Schematic of surface-enhanced Raman excitation spectroscopy system as well as monolayer molybdenum disulfide (MoS₂) spaced nanoparticle-on-mirror.
Figure 2: (a) Dark-field scattering from MoS$_2$ spaced single silver NPOM before (black) and after (red) pulse irradiation. The inset in shows the dark-field optical image. (b) Spectra of excitation source before (black) and after (red) filtered. (c) Stokes (red) anti-Stokes (blue) spectra. (d) Power dependence of Stokes/anti-Stokes.

3. Discussion

From present results, nonlinear anti-Stokes and linear Stokes emission are observed. Because anti-Stokes emission is likely disturbed by environment and nonlinear Stokes emission has its power threshold, here needs for deeper study before coming to a demonstrably conclusion. It is possible that the power we use now is not strong enough for MoS$_2$ crystal or the coupling of different atoms interfere and cancel. As expected, all the results have good repeatability. In summary, this two-dimensional atomic crystal spaced NPOM system combined with tunable pulsed excitation is a robust platform for quantitative research on molecular cavity optomechanics.

Abstract

Brillouin light scattering is a fundamental interaction between light waves and small acoustic vibrations which gives rise to inelastic light diffusion with a frequency shift by an amount that corresponds to the acoustic phonon frequency [1]. Due to their strong light confinement capabilities, optical fibers have been early recognized as an ideal medium to exploit the Brillouin scattering for applications in e.g., lasers, telecommunications, microwave photonics and optical sensing [2,3].

Introduction

The rich and complex dynamics of light and sound interactions in tiny optical waveguides has recently gained much interest because of their experimental realization in emerging key areas of photonics.

For instance, we demonstrate recently for the first time the generation of a new class of surface acoustic waves in a subwavelength-diameter silica nanofibers and term this new effect as surface acoustic wave Brillouin scattering (SAWBS) [4]. In such thin silica wires, boundary conditions induce a strong coupling of shear and longitudinal displacements, resulting in a much richer dynamics of light interaction with hybrid acoustic phonons.

Using numerical simulations based on electrostriction and experimental results, we show that SAWBS results from the stimulated optical excitation of Rayleigh-type surface-ripple waves propagating at a velocity of 3400 m/s along the optical nanofibers surface and giving rise to new useful RF sidebands around 6 GHz in the scattering spectrum. As these new acoustic resonances are strongly sensitive to microwire surface, SAWBS opens new interesting opportunities for various sensor applications.

We proposed an original technique based on Brillouin backscattering that allows for the accurate diameter measurement of nanofibers [7].

Abstract

The recently growing research field called “Nanophononics” deals with the investigation and control of vibrations in solids at the nanoscale. Phonon engineering leads to a controlled modification of phonon dispersion, phonon interactions, and transport [1]. Nonetheless, it requires new theoretical and experimental methods, especially when combined with low dimensional physics, which is one of the most promising routes for thermal management.

Nanowires (NWs) form an ideal template to study thermal transport behavior at the nanoscale thanks to the intrinsic 1D nature of transport in these materials, as well as the possibility to obtain different types of heterostructures, under different geometries, combining different materials and/or crystal structures that would not be possible in bulk materials [2]. However, measuring the thermal conductivity of single NWs is a non-trivial problem, for which a wide range of measurement schemes are currently being used, all with their respective advantages and disadvantages [2].

In this talk, we discuss how phononic properties can be engineered in nanowires and the challenges and progresses in the measurement of the thermal conductivity of nanostructures.

The concept of phonon engineering in NWs is exploited in superlattice (SL) NWs. We experimentally show that a controlled design of the NW phononic properties can be decided à la carte by tuning the SL period.

Furthermore, Raman thermometry is used to probe the temperature profile along the NWs upon application of a thermal gradient, enabling the differentiation between ballistic and diffusive flow regimes (Figure 1).

Abstract
The talk gives an overview of the recent experiments with metallic ferromagnetic films, in which a nanoscale periodic pattern results in formation of the localized phonon modes of sub-THz frequencies. In the time-domain experiments, we investigate the effects related to the resonant interaction of the phonon and magnon modes excited by femtosecond laser pulses. A variety of experimental observations includes the phonon driving of the magnetization precession, the magnon driving of coherent phonons and the magnon-phonon strong coupling.

1. Introduction
Active search of the effective methods to manipulate spin and elastic excitations at the nanoscale has gained the interest to the magnon-phonon interaction in magnetically ordered materials. The most interesting phenomena are observed at conditions of the magnon-phonon resonance, when magnons and phonons with, both the same frequencies and wave vectors can form a hybridized state. Various effects related to the magnon-phonon interaction have been recently observed in ferromagnetic dielectrics, which possess extremely weak damping for both phonons and magnons. In contrast, in ferromagnetic metals, where the damping is much stronger, the magnon-phonon interaction remains almost unexplored. In the present research, we overcome this limitation and show that a ferromagnetic metal can be a perfect platform for manipulating of magnons and phonons at the nanoscale. We use periodic nanoscale patterning of thin (Fe, Ga) layers to form the desirable phonon spectrum. The resonant interaction between the localized phonon modes and the modes of the discreet magnon spectrum yields bright experimental manifestations, which are observed directly in the time-resolved magneto-optical experiments.

2. Studied structures and experimental technique
The studied structures are based on an alloy of Iron and Gallium, i.e. Galfenol. The combination of the high Curie temperature (\(>900\) K), the large saturation magnetization and the enhanced magnetostriction in this metallic ferromagnet allows studying the magnon-phonon interaction and related effects at ambient conditions [5-8]. The main studied structures are one-dimensional nanogratings formed by parallel grooves milled by focused ion beam (Raith Velion FIB-SEM) in Fe\(_{0.81}\)Ga\(_{0.19}\) films of 60 and 120 nm thicknesses. The nanogratings have lateral size of \(10 \times 10\) \(\mu\)m\(^2\) and the following structural parameters: groove width \(a=100\) nm, groove depth \(h=5\pm25\) nm, lateral period \(d=200\) nm. The lateral pattern results in formation of the localized surface phonon modes in 10-20 GHz frequency range and adds the spatial harmonics with the in-plane wave vector \(k=2\pi d\) to the discreet magnon spectrum of a plain film.
In the experiment, the studied structures are excited by the 150-fs pump laser pulses (1050 nm, 80 MHz) focused to the spot of \(10\) \(\mu\)m diameter at the front side of a nanograting, or at its back side (through the GaAs substrate, which is transparent at this wavelength). The used excitation density is of \(\sim1\) mJ/cm\(^2\). The response of a nanograting is measured by means of the probe laser pulses (780 nm, 150 fs, 80 MHz) focused at the nanograting front side to the spot of \(1\) \(\mu\)m diameter. The probe and pump lasers are synchronized with controlled detuning of their repetition rates (800 Hz in the performed experiments). This allows detecting the transient signals in the scheme of asynchronous optical sampling (ASOPS) [10] in the time window of 12.5 ns with the resolution limited by the probe pulse duration. We measure the transient reflectivity, \(\Delta R(t)\), to monitor the coherent lattice vibrations and the transient polar Kerr rotation, \(\Delta \psi(t)\), which reflects the time evolution of the magnetization. By applying external magnetic field, \(B\), we tune the magnon spectrum (its spectral content and position).
to achieve the resonant conditions for certain magnon and phonon modes.

3. Experimental results

As an example, Figure 1 shows the fast Fourier transforms (main panels) of the Kerr rotation signals $\Delta \Psi(t)$ (insets) measured in the plain film of 120-nm thickness [panel(a)] and in the nanograting with $h=20$ nm and $d=200$ nm milled in this film [panel (b)]. The transient signals reflect the precessional response of the magnetization on the femtosecond optical excitation. The signals and their FFTs are significantly different in the plain film and in the nanograting. The rapid (within $\sim 100$ ps) decay of $\Delta \Psi(t)$ in the plain film is determined by fast dephasing due to the contribution of the exchange magnon modes, which are clearly visible in the FFT spectrum (indicated by the arrows). In contrast to this, in the nanograting the magnetic response is determined by the localized phonon modes, which drive the magnetization precession within their lifetimes. In the presented experimental conditions, the phonon modes with frequencies $f_{ph1}$ and $f_{ph2}$ are in resonance with the two lowest magnon modes, which dominate in the precessional signal, while the other magnon modes are suppressed. The localized phonon modes have alternative (quasi-longitudinal and quasi-transverse) polarizations and significantly different spatial distributions. This allows controlling the phonon driving efficiency by spatial overlap of certain phonon and magnon modes at resonance. We show that at certain magnetic fields, only one of two phonon mode gives dominating contribution to the magnetization precession.

4. Conclusions

The experimental result presented above demonstrates the simplest effect, i.e. the resonant phonon driving of the magnetization precession, among other bright manifestations of the magnon-phonon interaction observed in our experiments. In the shallow nanograting we demonstrate the strong magnon-phonon coupling, which is manifested by anti-crossing of the magnon and phonon modes at the resonant conditions. We have also detected the 10-times amplification of the localized phonon mode driven by magnons at the magnon-phonon resonance. We demonstrate the interplay of these effects, which are controlled by the grating parameters and by direction and strength of the external magnetic field. We are convinced that our observations pave the way to effective manipulation of coherent spin and lattice excitations at the nanoscale.

Abstract

What ultimately limits mechanical dissipation of quantum nanomechanical resonators? The authors report on an experimental and theoretical investigation that consistently answers this question. The work is carried on crystalline semiconductor nano-devices, operated from cryogenic to room temperature, whose coherence properties are shown to be ruled by surface Two Level Systems. These fluctuating entities set the ultimate limit to the frequency-Q product of resonators, a widely used figure of merit for quantum operations.

Detailed summary

The physical origin of nanomechanical dissipation is a topic of curiosity and debate, motivated by a vast number of applications. Ultralow-dissipation nanomechanical resonators represent a key ingredient for optomechanics, which investigates the interaction of light and mechanical motion \cite{1,2}. They are becoming crucial in weak-force resolution, mass sensing, and mesoscopic quantum operations, like mechanical state preparation or entanglement between mechanical systems.

Here we report on a systematic study of nanomechanical dissipation in high-frequency (≈300 MHz) semiconductor optomechanical disk resonators \cite{3}, in conditions where clamping and fluidic losses are negligible. Phonon-phonon interactions are shown to contribute with a loss background fading away at cryogenic temperatures (3 K). Atomic layer deposition of alumina at the surface modifies the quality factor of resonators, pointing towards the importance of surface dissipation. The temperature evolution is accurately fitted by two-level systems models, showing that the nanomechanical dissipation of resonators directly connects to microscopic material properties. Two-level systems, notably at surfaces, appear to rule the damping and fluctuations of high-quality crystalline nanomechanical devices, at all temperatures from 3 to 300K. The models lead to Q expectations beyond 10\textsuperscript{9} at milliKelvin temperatures \cite{3}.

Surface waves beat phonons in polar ultra-thin films

Sebastian Volz

Laboratory for Integrated Micro-Mecatronic Systems, CNRS, Institute of Industrial Science, The University of Tokyo, Tokyo, Japan
*corresponding author, E-mail: volz@iis.u-tokyo.ac.jp

Abstract
Thermal transport becomes less efficient as structures scale down since phonon-boundary scattering becomes predominant, therefore thermal management becomes more challenging in micro-electronic or optical devices. Here we aim at revealing the predominance of Surface Phonon-Polaritons (SPhPs) in thin film heat conduction. SPhPs are evanescent electromagnetic waves coupled to optical phonons and propagating along the interfaces of polar dielectrics. Through theoretical demonstration, SPhP propagation length reaches ten micrometers and SPhP spectral range reduces to the one of Surface Phonon-Polariton resonance in semi-infinite systems [1]. Consequently, SPhPs contribution to heat flux along a surface is usually found negligible.

We have shown that thin film geometries allow for drastic changes in the surface evanescent electromagnetic field in terms of spectrum broadening and of propagation length. In thin silica films with thicknesses smaller than 1 micron, propagation length can reach centimeters and more, and evanescent waves exist in the full spectral range [2]. Our calculations predict that those two modifications yield guided radiative heat fluxes higher than the one carried by phonons.

Moreover, thermal conductivity contributed by SPhPs can be further enhanced by increasing temperature. Nevertheless no experimental result directly proves neither the existence of a SPhP heat channel nor the enhancement of thermal conductivity in thin film due to those carriers. We experimentally measure effective in-plane thermal conductivity of amorphous SiN thin films and show that it can indeed be significantly increased by surface SPhPs when the film thickness scales down.

Engineering of electron, photon and phonon thermal fluxes on small length scales is important for different ICT devices ranging from sensors to CMOS circuits. Mastering the different energy/particle channels at the nanoscale enable, especially, high sensitivity detectors and compact refrigerators. In this communication, we discuss on phonon engineering methodologies and physics for thermal radiation detectors and micro-coolers targeting to enhance their performance. Experimental realizations and results will be shown to back up our phonon engineering postulates and theoretical estimates.

Thermal radiation detectors (bolometers) are utilized in different application fields from chemical sensing to thermal imaging. Our main focus here will be on nano-thermoelectric detectors [1,2], where photon absorption can be boosted by nano-structured low heat capacity absorbers and thermal transduction can be enhanced by the methodologies of nano-scale thermoelectrics. Low heat capacity enables small thermal time constant and we will demonstrate fast and efficient thermal detector IR pixels operating at room temperature.

On the electro-thermal microcooler side we will show how phonon engineering can be adapted to significantly enhance refrigeration performance. We will show experimental results and also discuss the ultimate performance limits. Our working horse here is semiconductor-superconductor (Sm-S) junction. In the experimental proof-of-concept the refrigerated mass is suspended directly from these junctions. Thus the detrimental heat from due to phonons is defined by the Kapitza resistance at the junctions. We demonstrate significant thermal isolation and show electro-thermal cooling of 40 % [3]. This operation principle is in strong contrast to the conventional superconductive electro-thermal devices that operate against the volumetric electron-phonon coupling.

Non-Hermiticity in optical microcavities

Jan Wiersig* and Julius Kullig

Institut für Physik,
Otto-von-Guericke-Universität Magdeburg
Postfach 4120, D-39016 Magdeburg, Germany

Abstract

We discuss two aspects of non-Hermiticity in optical microcavities. First, we theoretically demonstrate third-order exceptional points in whispering-gallery cavities. Second, we reveal the role of mode nonorthogonality in the dynamics of waves propagating in open systems with localized losses.

1. Introduction

Optical microcavities are the key elements for modern light-emitting devices such as single-photon emitters, ultralow-threshold lasers, and sources of entangled photon pairs. An important subclass are whispering-gallery cavities, e.g. microdisks and microtoroids, where the light is trapped for a long time by total internal reflection at the boundary of the cavity. An optical mode in such a cavity therefore has a high quality factor $Q = \text{Re}\omega/(-2\text{Im}\omega)$, where $\omega$ is the complex-valued resonant frequency of the mode. Deforming or perturbing the boundary of whispering-gallery cavities can be beneficial for several applications, e.g. directional free-space light emission and mode discrimination, see [1] for a review.

Optical microcavities, and in fact all real physical systems, are open systems. The emerging field of “non-Hermitian physics” deals with the resulting phenomena such as mode nonorthogonality and spectral degeneracies, so-called exceptional points (EPs). In contrast to conventional degeneracies, at an EP not only eigenvalues but also the corresponding eigenstates of the non-Hermitian Hamiltonian coalesce [2]. A number of experiments have proven the existence of EPs in various physical systems including optical microcavities [3]. Applications of EPs are, for instance, ultrasensitive sensors for single-particle detection [4, 5] and orbital angular momentum microlasers [6]. Third-order EPs, involving three eigenstates, have been experimentally realized only recently using coupled acoustic cavities with asymmetric dissipation [7] and in parity-time-symmetric photonic molecules [8]. Of particular interest is the higher sensitivity to perturbations if compared to second-order EPs [8].

In this contribution, we discuss two aspects of non-Hermiticity in optical microcavities, namely third-order EPs and the role of mode nonorthogonality in the dynamics of propagating waves.

2. Third-order EPs in optical microcavities

One well-known mechanism to create second-order EPs in whispering-gallery cavities is asymmetric backscattering of light as reviewed in [9]. Here, we introduce two further mechanisms which allow to create third-order EPs in such systems.

The first example is an optical microdisk of radius $R$ with a class of extremely weak boundary deformations, which weakly couple the given modes with azimuthal mode numbers $m > p > q$. Using a perturbative approach the specific deformation can be determined as [10]

$$
\frac{r(\phi)}{R} = 1 + 2\epsilon_1 \cos [(m-p)\phi] + 2\epsilon_2 \cos [(p-q)\phi] + 2\epsilon_3 \cos [(m-q)\phi] + 2\sigma_p \cos (2p\phi) + 2\sigma_q \cos (2q\phi)
$$

with polar coordinates $(r, \phi)$ and five independent deformation parameters $\epsilon_1$, $\epsilon_2$, $\epsilon_3$, $\sigma_p$, $\sigma_q$ which have to be adjusted to result in a third-order EP. Figure 1 shows the corresponding characteristic cubic root topology of the frequencies in the vicinity of the EP when two parameters are varied.

The second example is a microdisk with a concentrically layered refractive index profile. For a triple-layered cavity we verify and discuss the emergence of a third-order EP and its higher sensitivity to perturbations [11].

3. Role of nonorthogonality in systems with localized losses

Away from an EP, the dynamics of a wave packet in a microcavity (or in an open quantum system) can be described by a superposition of the modes (energy eigenstates). Naively, one would expect that the decay of the modes directly determine the decay of the total wave intensity. However, this is not the case for systems with localized losses, such as at the boundary of a microcavity without absorption in the bulk. Here, we demonstrate that the nonorthogonality of the modes plays the decisive role [12]. It can, to a large extent, compensate the initial decay of the modes leading to a transient power-law decay of the wave intensity with a potentially large exponent.

Abstract

Coherent perfect absorber and laser for nonlinear waves are introduced. As an example, we consider an array of optical waveguides, in which waveguides with gain and absorption are incorporated. The results are generalized to setups with nonlinear active and absorbing waveguides, in particular, characterized by additional nonlinear dissipation or gain. Two-dimensional arrays are also considered.

1. Introduction

An optical optical media with localized dissipation or gain can coherently absorb incident radiation or emit waves. These phenomena are known in optics already for long time [1, 2]. Rapidly growing interest in such systems and their applications was triggered by more recent works (see e.g. [3, 4]), where, in particular, the physical properties of coherent lasing and absorption were related to the existence of spectral singularities (SS) of the respective nonlinear potentials. In a notion of a coherent perfect absorber (CPA) and its interpretation as a time reversed laser was introduced. A SS as a mathematical is known in literature since the original work [5] (the term SS was introduced in [6]).

By its definition a SS is a linear object: it characterizes interaction of linear waves with linear non-Hermitian potentials. Recently, in [7] there has been introduced a concept of a CPA for a nonlinear waves, as a linear localized potential totally absorbing nonlinear waves. In [7] this phenomenon was observed experimentally on matter waves loaded in an optical lattice where a dissipative potential was induced by a narrow electronic beam. Here we present theoretical consideration of optical systems implementing CPA and lasers for nonlinear waves.

2. Spectral singularities for nonlinear waves

Why SSs for nonlinear waves are challenging? (i) The “linear” arguments do not work: there is no well defined transfer matrix connecting left- and right- incident waves because the problems where either the incident or transmitted radiation is given, have different solutions. (ii) Interactions among the modes does not support interference in the linear sense. Thus results on scattering of monochromatic waves do not give any more an answer on the scattering of wave packets used in experiments, and no coherence arguments perfectly working in the linear case can be applied. (iii) Even if a CPA can exist in a nonlinear medium, its realization remains an open question because there are no general methods of determining parameters necessary for the observation of the phenomenon. (iv) Realization of plane waves may be practically impossible due to instabilities.

We argue that all above challenges can be overcome, and observation of a CPA or a laser in the nonlinear case, in a definite sense, can be even simpler that in the linear system. To this end, however we have to clarify these concepts.

The requirements for a nonlinear solution to be CPA or laser are reduced to the following properties: (i) it be stationary processes; (ii) it must be observed for monochromatic waves; (iii) it must consist of waves propagating respectively inwards and outwards of the non-hermitian potential, and (iv) it must have a linear limit, which is the CPA or laser in the conventional sense.

3. One-dimensional arrays

We consider two waveguide arrays placed in two (generally speaking different) left (“L”) and right (“R”) media and separated by an active or absorbing waveguide at the site \(n = 0\) [Fig. 1]. The waveguides have Kerr nonlinearity \(\chi\) (either positive or negative). The media determine the coupling coefficients (we consider them positive, \(\kappa_{L,R} > 0\)). Light propagation in such an array is described by the discrete nonlinear Schrödinger equations

\[
\begin{align*}
\dot{q}_n + i\kappa_L (q_{n-1} + q_{n+1}) + \chi |q_n|^2 q_n &= 0, & \text{for } n \leq -1, \\
\dot{q}_0 + i\kappa_L q_{-1} + \kappa_R (1 - \frac{\gamma}{2}) q_0 + \left(\chi - \frac{\Gamma}{2}\right) |q_0|^2 q_0 &= 0, \\
\dot{q}_n + i\kappa_R (q_{n-1} + q_{n+1}) + \chi |q_n|^2 q_n &= 0, & \text{for } n \geq 1.
\end{align*}
\]

(1)

Here \(\dot{q} = dq/dz\), \(z\) is the propagation distance, \(\gamma\) and \(\Gamma\) are linear and nonlinear gain (\(\gamma > 0\), \(\Gamma > 0\)) or dissipation (\(\gamma < 0\), \(\Gamma < 0\)).

Nonlinear solutions satisfying the requirements, formulated above reads

\[
q_n = e^{i\beta z} \begin{cases} 
\rho e^{\pm ik_1 n} & \text{for } n \leq 0, \\
\rho e^{\mp ik_2 n} & \text{for } n \geq 0.
\end{cases}
\]

(2)
The propagation constant of nonlinear solution reads
\[ \beta = 2\kappa_L \cos k_1 + \chi \rho^2 = 2\kappa_R \cos k_2 + \chi \rho^2, \tag{3} \]
and upper (lower) signs stand for CPA (lasing) solutions.

One finds that there exist the lower and the largest values of the loss and gain for which respectively CPA and lasing are possible:
\[ \sqrt{2|\kappa_L^2 - \kappa_R^2|} < |\gamma + \Gamma \rho^2| \leq 2(\kappa_L + \kappa_R). \tag{4} \]

Due to instabilities in the case of \( \chi > 0 \) (\( \chi < 0 \)) only fast (slow) CPA or lasing of nonlinear waves can be observed.

4. Two-dimensional arrays

The above results are generalized to the two-dimensional (2D) waveguide arrays. Now a CPA or laser represents a discrete absorbing or lasing “layer” (a 1D array of waveguides). The field in each waveguide \( q_{n,m} \) is specified by two indexes \( n \) and \( m \). For fixed \( m \) and running \( n \), one recovers the aD case considered above, while changing \( m \) establishes the second dimension. The absorbing or lasing layer is situated at \( n = 0 \) with \( m \) running through all integers. The media at both sides of the absorbing or lasing layer are considered equal. Such 2D array is modeled by
\[
\begin{align*}
iq_{n,m} + \kappa \Delta_2 q_{n,m} + \chi |q_{n,m}|^2 q_{n,m} &= 0, & \text{for } n \neq 0, \\
iq_{0,m} + \kappa \Delta_2 q_{0,m} - \frac{\gamma}{2} q_{0,m} + \left( \chi - \frac{\Gamma}{2} \right) |q_{0,m}|^2 q_{0,m} &= 0
\end{align*}
\]
where \( \Delta_2 q_{n,m} = q_{n-1,m} + q_{n+1,m} + q_{n,m-1} + q_{n,m+1} \).

The nonlinear CPA or lasing solution can be found as
\[ q_{n,m}(z) = \rho e^{i\beta z + i\omega m + \pi |n|} \tag{5} \]
where \( \nu \in (-\pi, \pi) \) is a free parameter tuning the angle of incidence (angle of emission) of the nonlinear wave with respect to the absorbing or lasing layer; \( \beta = 2\kappa (\cos k + \cos \nu) + \chi \rho^2 \) is the nonlinear propagation constant provided the condition \( 4\kappa \sin k = \mp (\gamma + \Gamma \rho^2) \) is satisfied. The upper and lower signs in (5) correspond to CPA and laser. We study the stability of the solution (5) and its evolution in the unstable case numerically.

5. Conclusion

We presented the generalization of the concept of spectral singularities on the case when a linear non-Hermitian potential is placed in a nonlinear medium, which without potential supports propagation stable monochromatic carrier waves of constant amplitude. Since both nonlinear CPA and nonlinear laser solutions represent attractors, they are achieved along the evolution and thus do not require too demanding constraints on the initial conditions. Small initial deviations from the exact nonlinear solution are damped along the propagation. By reducing the intensity of the input beam it is possible to achieve the regime of linear CPA and laser, where the conditions of the destructive interference are satisfied automatically. The reported solutions can be used for rectification of the phase gradient and for the equalization of the amplitudes of input beams.

Abstract

We propose theoretically to realize a ring laser based on honeycomb-type topological photonic crystals. Using the topological interface states as the cavity modes, we demonstrate a single-mode lasing over a large range of gain value. This lasing phenomenon is available up to frequencies of visible lights and is robust against disorders.

1. Introduction

Topological insulators have attracted much attention because of their quantized edge states [1], which also inspired the study of topological physics in bosonic systems [2-12]. Especially, the edge states of photonic topological insulators (PTIs) robust to disorders and immune to backscattering offer a huge potential in the design of optical devices. Very recently, several PTI lasers have been reported [13-15]. In this work, we construct topological interface states in the all-dielectric honeycomb-type photonic crystals [8-10] and use them for lasing in a ring cavity. As compared with previous works, our design can be realized with the matured processing technologies on photonic crystals.

2. Model

The topological ring cavity based on honeycomb-type photonic crystals is shown schematically in Fig. 1 [8-10]. We investigate the system by a tight-binding equation of motion, where the nontrivial topology of the photonic crystal in the inner part and the topological interface modes are derived by tuning the real-number hopping integrals.

Figure 1: Schematics of the topological ring cavity used for lasing. The part inside the red hexagon is topological photonic crystal, and the outside part is the trivial photonic crystal, which is based on cylinders of a dielectric material with different deformations of honeycomb structures. Gains are introduced on the red sites along the interface.

3. Results

3.1. Single-mode lasing

In the ring cavity, the eigenmodes are given by the linear combinations of the \( \{ p_x \} \) and \( \{ d_x \} \) modes defined in the unit cell of honeycomb lattice [8], where the coefficients depend on the azimuthal angle [16]. Upon introducing gains, we find that the mode mostly uniform along the interface becomes lasing beyond a threshold gain and its intensity increases linearly with the gain value. Importantly, the single-mode lasing is achieved up to a gain as large as 25 times of the threshold value.

3.2. Robustness

We also find that our single-mode lasing is much more robust against disorders as compared with a laser formed by whispering-gallery ring cavity, while the intensities of these two cases are comparable in absence of disorders.

4. Conclusions

With the photonic topology generated by photonic crystals made of dielectric materials, the present design for robust ring laser can be fabricated by the matured semiconductor technologies. Our system is also expected to provide a good platform for the study on topology physics in non-Hermitian and nonlinear systems.

Abstract

We report on the first experimental implementation of coherent perfect absorption in a disordered medium. With this process corresponding to the time-reverse of random lasing at threshold, our microwave experiment constitutes the first “random anti-laser”. Our approach relies only on the multi-modal scattering matrix of the system based on which we achieve more than 99.78% absorption of the injected intensity. We expect our approach to be suitable for numerous applications in which waves need to be perfectly focused, routed or absorbed.

1. Introduction

One of the most successful concepts that has emerged from the field of non-Hermitian wave engineering so far is that of coherent perfect absorption [1-4] – an effect analogous to the time-reversal of coherent emission of radiation at the lasing threshold. Such coherent perfect absorbers (CPAs) have already been realized in a number of experiments [3,4], but have remained limited to setups involving simple slab geometries. Here we combine the concept of a coherent perfect absorber with the concept of random lasing [5]. A random laser is a disordered gain medium that is pumped sufficiently strongly to emit coherent laser light. Time-reversing such a single-mode random laser mode results in a highly complex wave state that impinges on the disordered structure and gets perfectly absorbed there (without any back-reflection to the asymptotic region). We build such a random anti-laser using a microwave setup and demonstrate its ability to absorb a suitably shaped incoming wavefront with close to perfect efficiency.

2. Theory

The crucial quantity behind the CPA concept is the scattering matrix that relates the injected fields to the outgoing ones, $\psi_{\text{out}} = S \psi_{\text{in}}$. In Hermitian systems, zeros of the scattering matrix $S$ are generally located in the upper half ($\text{Im}(\omega) > 0$) of the complex plane of frequency $\omega$, whereas poles are located in the lower half ($\text{Im}(\omega) < 0$). Adding gain to the system moves the poles up towards the real $\omega$-axis where the system turns into a random laser as soon as the first pole hits the real $\omega$-axis. Also the opposite is possible: adding loss to the medium will turn it into a random anti-laser (disordered CPA) at those frequencies and loss values where one of the $S$-matrix zeros crosses the real $\omega$-axis. At these parameter configurations, a random anti-laser mode $\psi_{\text{CPA}}$ is an eigenstate of the scattering matrix $S$ with eigenvalue $\lambda_{\text{CPA}} = 0$, i.e. $S \psi_{\text{CPA}} = 0$, where $\psi_{\text{CPA}}$ is the incoming radiation field and the empty 0-field is the outgoing one.

3. Experimental realization

Fig. 1a shows our experimental setup consisting of an aluminum waveguide where the disordered medium is implemented by 60 randomly placed cylindrical Teflon scatterers. Four transverse modes are open at the operation frequency, requiring four antennas on each side (left and right) to control all degrees of freedom of the injected microwave field. In the center of the scattering region we place a monopole antenna where the absorption strength can be tuned simply by varying the length of this central absorbing antenna inside the waveguide. This microwave setup allows us to measure the full scattering matrix of the disordered medium (including transmissions and reflections from both sides) as well as to inject arbitrarily shaped wavefronts into the disordered in a broad frequency interval. Our experimental procedure to realize a random anti-laser is now the following: we first measure the $S$-matrix of the system as a function of frequency (in a broad interval to ensure that many $S$-matrix zeros are contained in it) and of the absorption strength of the central absorbing antenna (as determined by the penetration depth into the waveguide). In a next step, we evaluate the eigenvalues of these $S$-matrices and identify those parameter configurations for which the absolute value of the smallest $S$-matrix eigenvalue dips almost to zero. In the last step, we inject the $S$-matrix eigenstate with the smallest eigenvalue (the CPA state) into the system and evaluate its properties, in particular its degree of absorption.
Figure 1: (a) Experimental setup of the random anti-laser: Microwaves are injected into an aluminum waveguide through eight external antennas (four on each side). The central scattering region of the waveguide contains a set of randomly placed Teflon scatterers simulating a disordered medium. A monopole antenna in the center of the disordered region (central antenna) provides a tunable absorption strength through which the CPA state is completely absorbed. (b) Scattering signatures of a CPA state: Incoming and outgoing intensities ($I_{\text{in}}$ and $I_{\text{out}}$) of a CPA state injected by the external antennas compared to the reflection signal $R$ measured at the central antenna when injecting microwaves there. Both the ratio $I_{\text{out}}/I_{\text{in}}$ and the reflection coefficient $|R|^2$ show a pronounced minimum close to the CPA-frequency around 7.1 GHz.

4. Results and Discussion

Following the protocol outlined in section 3, we find CPA states where more than 99.78% of the injected intensity gets absorbed, as illustrated by the blue curve in Fig. 1b, where we show the ratio between the outgoing and the incoming microwave intensity ($I_{\text{out}}/I_{\text{in}}$) of a CPA state as a function of the signal frequency. We have also devised a number of independent tests that confirm unambiguously that we have indeed realized a disordered CPA rather than a coherent enhancement of absorption (CEA) [6]. For example, we expect that a CPA state is primarily absorbed by the central antenna (and less by global absorption in the metallic waveguide). Therefore, the time-reverse of this state should be a harmonic signal that enters through the central antenna without any back-reflection. Indeed, we find by injecting microwaves through the central antenna that its frequency-dependent reflection coefficient $|R|^2$ shows a pronounced minimum close to the frequency where we found the CPA state independently, see red dashed curve in Fig. 1b.

5. Conclusions

In summary, we present the first experimental realization of a random anti-laser, which provides proof of principle that coherent perfect absorption can also be realized in arbitrarily composed systems such as disordered media. We expect our findings [7] to be relevant for practical applications such as perfect focusing of electromagnetic signals and sound fields in complex environments such as in an office space or in biological tissue. Our results also serve as a bridge between the two highly active communities of wavefront shaping [8] and non-Hermitian physics [9].

Abstract—We discuss experimental results on dynamically encircling an exceptional point in coupled waveguides and electrical resonator circuit systems.

Recently, encircling an exceptional point (EP) and consequent time-asymmetric dynamics have attracted significant attention because it produces robust chirality. When a non-Hermitian system slowly changes to encircles an EP in a system’s parameter space, time-dependent states undergo time-asymmetric evolution where final states differ depending on encircling direction. This chirality is robust to the parametric-path change as long as it encircles an EP. The time-asymmetric mode conversion has been experimentally demonstrated in the metallic waveguides and opto-mechanical systems [1, 2].

Here, we introduce two experimental demonstrations of dynamically encircling an EP. One is a Si-base waveguides coupler that produces broadband unidirectional mode conversion, and the other is an electrically tunable circuit system that enables observation of full dynamics in the time-domain.

In the waveguide experiment, two coupled waveguides are precisely designed to encircle an EP in the parameter space {ΔnR, ΔnI} by changing the width of waveguide and position of the side-patched slab waveguide that generates radiative loss. Symmetrically coupled mode is launched, output waveguide mode measured by the interferometric method for the forward and backward propagation direction. We observed unidirectional mode conversion over the full-telecommunication band.

In the circuit experiment, two RLC resonators having different dissipation rate coupled through a varactor diode which provides electrically tunable capacitance. One of the resonators also has a varactor diode to control its resonance frequency. Changing coupling strength and frequency detuning in time-domain, the proposed circuit is manipulated to encircles an EP. With the circuit system, we measured entire time-dependent state information during the system encircles an EP including non-adiabatic state jump which is not observed in the previous experiments.

Abstract

Topological physics enables protected transport along edges of materials. Interestingly, such edge transport can flow not only on edges in real-space, but also on the interface of a synthetic space, such as modal space or spin space. Here, we report the first experimental realization of photonic topological insulators in synthetic dimensions. Our work on these synthetic space concepts leads to combining high-dimensional physics and long-range connectivity with a plethora of optical phenomena such as PT-symmetry, Topological lasers and more.

1. Introduction

Topological insulators enable protected transport along edges of materials, offering immunity against scattering from disorder and imperfections. Traditionally, the underlying model for topological insulators is a spatial lattice in two or three dimensions. However, in recent experiments topological edge-states were observed in a lattice with one spatial dimension and one synthetic dimension - the intrinsic energy modes of cold atoms [1–3]. This striking phenomenon is related to high dimensional topological physics and long-range connectivity, due to the nature of the modal degree of freedom[4]. Soon thereafter, in photonics, topological transport in synthetic dimensions – photonic modes which are not intrinsic, were theoretically proposed[5,6]. These systems can exhibit high-dimensional phenomena such as four-dimensional quantum Hall effect and Weyl points along with applications such as topologically protected mode converters and more[7]. Here, we present the first experimental realization of photonic topological insulators in synthetic dimensions[8]. We demonstrate topologically protected transport of an optical wavepacket through a two-dimensional (2D) waveguide array, engineered such that it has one synthetic dimension in modal space, while its other dimension is in real space. This opens the door for experiments combining high dimensional physics and long-range connectivity with a plethora of physical phenomena ranging from PT-symmetry to Anderson localization and topological photonics. Our experimental realization can also lead to observing new phenomena in cold atoms[9].

2. Photonic topological insulator in synthetic dimensions

We describe our system as follows: consider a one-dimensional array of N evanescently-coupled waveguides arranged along the y axis (columns) and propagating in the z direction. This array has N propagating eigenmodes with different propagation constants, which form an equally-spaced ladder of modes in a synthetic space. To create a 1D lattice of coupled modes, we spatially oscillate the array along its longitudinal dimension (Fig.1a). Next, we can

Figure 1: (a) A column of evanescently coupled waveguides oscillating spatially. The supermodes of the columns are coupled due to the oscillations of the waveguides. (b) M columns as in (a) placed next to each form a lattice in synthetic dimensions with one spatial and one modal degree of freedom (edge-state in yellow). (c) Columns arranged in a 2D lattice (unit cell in grey), the column oscillate along the black line lines, each column couples to four other columns during a period (d) The 3D geometry of the lattice of (c) in synthetic dimensions. (e-g) Experimental measurements of a propagating edge-state in synthetic dimensions as it is seen in real space (top), and the matching description of the propagation in synthetic space (bottom).
arrange M of these oscillating columns one next to the other. This adds a spatial dimension to the system (along the x axis). The first dimension is the supermode spectrum of each column, and the second dimension is the spatial location of the column in x. When the oscillations of the columns have a relative phase $\phi$ between one another, the light acquires a total phase of $\phi$ upon encircling a plaquette in synthetic space resulting in topological edge states (Fig.1b). This approach allows increasing the dimensionality further by arranging 1D oscillating columns as the unit-cell of a 2D lattice (Fig.1c-d). Furthermore, long-range connectivity (which can lead to further dimensionality increase) can be achieved by adding more frequencies of oscillations.

We study experimentally the evolution of the edge states in our synthetic topological system, we propagate a paraxial beam at $\lambda=633$[nm] through the 2D lattice fabricated in fused silica. Our experimental results (Fig.1e-g(top)) show a wavepacket propagating on the edge of synthetic space. We show that it is robust to disorder and bypasses the corner of synthetic space (Fig.1e-g(bottom)). We hope our study will open the door for observing new high dimensional and long-range physics both in photonics and in cold atoms.

Abstract

We theoretically discuss limitations in the operation of sensors based on parity-time symmetric gain-loss resonator pairs initially operating near the exceptional point. In particular, we show how mesoscopic fluctuations in resonator pair ensembles produce a detuning in the frequencies of the constituent resonators, while thermal noise leads to an exponential divergence of the initial states. We therefore show that considerable effort is required in order to exploit the sensitivity of such sensors in its full potential.

1. Introduction

Parity-time symmetric systems of coupled gain-loss resonators operating near the exceptional point have been attracting considerable interest in recent years, as it has been proposed that extremely sensitive sensors can be designed, exploiting the energy splitting of the two coalescing eigenfrequencies, which scales with the square root of any perturbation [1]. However, this sensitivity can be as much of a curse for practical applications as it is a blessing, because even minor deviations of the operating point can lead the system away from the exceptional point, thus diminishing its sensitivity [2, 3], even if this, somehow ambiguous, sensitivity is defined in the most favourable way [4]. Here we discuss how operation at the exceptional point and the applications that depend on it are affected by two fundamental issues that cannot be avoided in practice: sample-to-sample fluctuations in ensembles of resonator pairs, and (thermal) noise.

In what follows we consider a pair of resonators, one characterised by a damping rate \(g/2\) and the other by an equal amount of gain. The two resonators are coupled through a coupling parameter \(\kappa\) and, within coupled-mode theory [5] their dynamics is described by a Schrödinger-like equation

\[
\begin{align*}
\dot{a}_1(t) &= \left(\omega_1 - ig/2 - i\kappa/\sqrt{\pi}\right)a_1(t), \\
\dot{a}_2(t) &= \left(\omega_2 + ig/2 + i\kappa/\sqrt{\pi}\right)a_2(t),
\end{align*}
\]

where \(a_i(t)\) \((i = 1, 2)\) are the complex amplitudes of the two resonator modes, and \(\omega_i\) their corresponding eigenfrequencies. The eigenvalues of the above effective Hamiltonian can be obtained straightforwardly as

\[
\Omega_{\pm} = \bar{\Omega} \pm \sqrt{1 - (G + i\Delta)^2},
\]

where \(\bar{\Omega} = \omega/\kappa, G = g/2\kappa\), the central frequency \(\bar{\Omega} = (\omega_1 + \omega_2)/2\kappa\), while the normalised detuning of the two resonances is denoted by \(\Delta = (\omega_1 - \omega_2)/2\kappa\).

2. Fluctuations near the exceptional point

From Eq. (2) one immediately sees that, in the limit of low gain \((G \ll 1)\), the imaginary part of the eigenvalues behaves as \(\Omega_{\pm} \simeq \mp G\Delta\). This means that the finite detuning breaks the parity-time symmetry associated with perfectly aligned resonators, for which the eigenvalues are purely real [6].

To further evaluate the role of fluctuations, we assume an ensemble of resonator pairs with a Gaussian distribution of the detuning parameter

\[
P_0(\Delta) = \frac{1}{\sqrt{2\pi}\sigma} \exp(-\Delta^2/2\sigma^2),
\]

where \(\sigma\) is the distribution variance. Such a distribution can be interpreted either as the result of fabrication tolerance or as originating from temporal fluctuations, assuming that an ergodic approximation to the system dynamics is valid. Then one can show [2] that the eigenfrequencies also acquire a relatively broad distribution around the exact solution of Eq. (2), as we schematically show in Fig. 1, described by

\[
P(\Omega') \simeq \frac{1}{\sqrt{2\pi}\sigma} F \left(\frac{\Omega' - \bar{\Omega}}{\sqrt{\sigma}}\right),
\]

where \(F(x) = (\frac{2}{\pi})^{1/2} |x| \exp(-\frac{1}{2}x^2)\), and \(\Omega'\) is the real part of \(\Omega\).

3. Time evolution in the presence of noise

To explore the time evolution of the exceptional point in the presence of noise, we assume that the operating point of the system is perturbed by some time dependent real-valued fluctuation \(\Lambda(\tau)\) \((\tau = \kappa t\) being a rescaled time) which can be represented as a Fourier integral

\[
\Lambda(\tau) = \int_{-\infty}^{\infty} d\omega b(\omega) \exp(-i\omega\tau).
\]
The phase of the function \( b(\omega) \) is assumed to fluctuate randomly and arbitrarily quickly in \( \omega \), while its modulus is a smooth function of \( \omega \) [7]; it is connected to the fluctuation power spectrum \( P_0(\omega) \) through \( P_0(\omega) = |b(\omega)|^2 \). We assume the overall fluctuation power to be finite, so \( P_0(\omega) \) must cut off at high frequencies, and we distinguish between low-frequency and quasistatic fluctuations (drift), which are eliminated by a stabilisation circuit, and high-frequency fluctuations (noise). In other words, we assume that \( \Lambda(\tau) \) vanishes in a neighbourhood of \( \omega = 0 \), if only to prevent the system from permanently drifting away from the exceptional point. Then \( P_0 = 0 \) for \( |\omega| < \omega_\text{min} \). The characteristic auto-correlation function of the noise, \( \Gamma(\tau) \), is approximated as a Dirac distribution

\[
\Gamma(\tau) = \int_{-\infty}^{\infty} d\tau' \Lambda(\tau') \Delta(\tau' + \tau) \approx \zeta \delta(\tau),
\]

with the constant \( \zeta \) formally given by \( \zeta = \int_{-\infty}^{\infty} d\tau' d\tau \Lambda(\tau') \Delta(\tau' + \tau) \). Then one can show [3] that, after some characteristic time, the system enters a regime where the norm of any initial state grows exponentially, following to a very good accuracy the equation

\[
|\Lambda \alpha_i(\tau)| \approx \exp \left( \sqrt{2\zeta \tau} - 1 \right).
\]

This means that a system with noisy system parameters can be operated at the exceptional point for a time no longer than \( \tau_\text{max} = 1/\sqrt{2\zeta} \). A stabilization circuit could then try to stabilise the norm of the state, moving one system parameter away from the exceptional point, and the system will either settle at this new equilibrium point or the feedback circuit will become unstable and enter oscillations. Reduction in noise comes therefore at the price of increased tendency for oscillation of the system parameters (detuning, gain or loss).

4. Conclusions

In summary, we have theoretically explored how realistic experimental conditions affect the operation of sensors based on the exceptional point of parity-time symmetric gain-loss resonator pairs. We have shown that fluctuations, noise, and statistical averaging all rapidly lead the system away from the exceptional point. Maintaining operation at the exceptional point for long, experimentally relevant times, requires therefore careful design of an appropriate feedback system.

Abstract

We propose a new optical amplifier geometry based on exceptional points. Compared to its standard counterpart device, the proposed structure relaxes the limitation imposed by the gain-bandwidth product.

1. Introduction

Signal amplification is one of the most fundamental processes in optical science and engineering. Optical amplifiers (OAs) can be classified into traveling [1] or standing [2] waves devices. The former offers a larger bandwidth at the expense of the attainable gain values. On the other hand, the latter can have larger gain due to the power recycling in the resonator, allowing for a smaller device size. However, the resonant condition leads to a very narrow bandwidth. This fundamental limitations pertinent to cavity-based optical amplifiers is known as the gain-bandwidth product.

Here we introduce a new OA scheme based on optical resonators operating at exceptional points (EPs) – a special type of singularities at which two or more eigenstates coalesce [3, 4]. We show that the gain-bandwidth product of the proposed device scales differently from that of standard resonators, which leads to superior performance.

2. Setup and theoretical description

The proposed structure consists of a microring resonator coupled to two identical waveguides, one of which is terminated by a mirror, as shown in Fig. 1(a). Optical gain \( g \) is applied to the ring where the amplification process takes place. In the absence of any excitation, the above system is described by the following effective Hamiltonian [5]:

\[
i \frac{d}{dt} \begin{bmatrix} a_{cw} \\ a_{ccw} \end{bmatrix} = H \begin{bmatrix} a_{cw} \\ a_{ccw} \end{bmatrix}, \quad H = \begin{bmatrix} \Omega & 0 \\ -2i\gamma r e^{i\phi} & \Omega \end{bmatrix}
\]

Here \( r \) is the magnitude of the field reflection coefficient of the mirror, \( \Omega = \omega - \omega_0 - i(2\gamma + \alpha - g) \) where \( \omega \) and \( \omega_0 \) are the input signal angular frequency and resonant frequency, respectively. Additionally, \( \alpha \) and \( \gamma \) are the decay rates due to radiation/material loss, and coupling to waveguides, correspondingly. The Hamiltonian \( H \) is a non-diagonalizable Jordan matrix that features an EP [6]. By using the coupled mode theory, we obtain the scattering coefficient between the input and output ports:

\[
s_{s1} \equiv \frac{s_5}{s_1} = \frac{4re^{i\phi} \gamma^2}{[i(\omega - \omega_0) + 2\gamma + \alpha - g]^2} \quad (2)
\]

Note that this expression is valid only below the lasing threshold \( g = 2\gamma + \alpha \). The maximum value of the amplification (at resonance) is \( G_{EP} = \max|s_{s1}(\omega_0)|^2 = 16r^2\gamma^4/(2\gamma + \alpha - g)^4 \). On the other hand, the bandwidth is given by \( B_{EP} = 2F(2\gamma + \alpha - g) \) with \( F = \sqrt{2} - 1 \). Compared to amplifiers based on diabolic points (DPs) that arise from Hermitian degeneracies, the bandwidth is reduced by a factor of \( F \), while the gain is enhanced according to the quadratic relation \( G_{EP} \propto r^2G_{DP}^2 \). This leads to the following expression for the gain-bandwidth product for the OA operating at an EP:

\[
\chi_{EP} \equiv \frac{4}{G_{EP}} \cdot B_{EP} = 4F \sqrt{r\gamma} \quad (3)
\]

Equation (3) shows that the gain-bandwidth product for the EP regime scales differently than the case of DP, in which \( \chi_{DP} = \sqrt{G_{DP}} \cdot B_{DP} = 4\gamma \).
3. Results

To demonstrate the advantage of the proposed amplifier operating at an EP, we compare its performance with DP-based amplifier in two different situations: (1) When they both share the same bandwidth but have different maximum amplification; and (2) When they both exhibit the same maximum amplification but have different bandwidth. In both cases, we take \( r \approx 1 \). In the first scenario, we fix the bandwidth by choosing the pump values to be \( \tilde{g}_{\text{EP}} = F^{-1} \tilde{g}_{\text{DP}} + 2(1 - F^{-1}) \), where \( \tilde{g} = (g - \alpha) / \gamma \). In our simulations, we used the same values for \( \tilde{g} \) but different gains \( \gamma \). Under these conditions, the amplification enhancement is \( G_{\text{EP}} / G_{\text{DP}} = 4F^4 / (2 - \tilde{g}_{\text{DP}})^2 \). Similarly, in the latter case, the bandwidth enhancement factor (for fixed maximum amplification) is \( B_{\text{EP}} / B_{\text{DP}} = \sqrt{2F} / \sqrt{2 - \tilde{g}_{\text{DP}}} \) and the required pumping is \( \tilde{g}_{\text{EP}} = 2 - \sqrt{2(2 - \tilde{g}_{\text{DP}})} \). Note that the EP-based OAs delivers a better performance only when \( \tilde{g}_{\text{DP}} > 2\sqrt{2F^2} \approx 1.17 \).

In order to confirm these predictions and explore realistic implementations, we consider a semiconductor-based optical structure having the following physical parameters: waveguide width \( w = 0.25 \mu m \) (for both the straight and the ring waveguides), ring radius \( R = 5 \mu m \), edge-to-edge distance between the ring and either waveguides \( d = 0.15 \mu m \). To implement the mirror, we assume a thin layer of silver with thickness of 100 nm. The material refractive index is \( n_1 = 3.47 \) (relevant to Si and AlGaAs implementations) and the background index is taken to be \( n_2 = 1.44 \) (silica for example). Figure 2 (a) and (b) present the comparison between the proposed EP-based amplifier and the standard device when DP = 1.8, where the clear advantage of the former is evident.

4. Conclusions

In conclusion, we have introduced a new design paradigm for optical amplifiers based on Jordan exceptional points. An important feature of the proposed structure is the unique scaling of its gain-bandwidth product which is different from standard amplifiers, and allows for achieving more gain or larger bandwidth of operation.
Controlling photonic systems via topological anomalies

Henning Schomerus

1Department of Physics, Lancaster University, Lancaster, UK
*corresponding author, E-mail: h.schomerus@lancaster.ac.uk

Abstract
Anomalies are the term by which we denote that topological states respond in characteristic ways to external probes. Here I show that such anomalies extend naturally to photonic systems, where they take on extra significance in the presence of gain and loss.

1. Introduction
The anomalous response of topological states to probes that break the underlying symmetries underpin the utility of these states in many prospective applications. Examples are unidirectional currents in response to external magnetic fields in the quantum Hall effect and analogous surface currents in Weyl and Dirac materials. In the original electronic setting, these topological states are protected by symmetries that are intimately related to the fermionic character, where charge is conserved and stable quasiparticle excitations emerge above the Fermi sea. None of these constraints are natural in photonic systems where loss, gain, nonlinearities and bosonic coherence are normal occurrences. In particular, the properties of photonic systems and operation modes of corresponding devices are often determined by a competition between modes of different life time, as dictated by the gain and loss. As I here set out, topological symmetry protection has a direct bearing on these effects, and offers practically useful tools to design and manipulate photonic components.

2. Making anomalies visible
To set the scene I consider a direct translation of a fermionic anomaly to the photonic setting. This is the chiral anomaly, which when realized in momentum space yields directed currents while when realized in real space yields characteristic intensity patterns. I discuss the realization of a real-space chiral anomaly in a fiber-optical photonic quantum walk [1] (see Fig 1). There, an interface between coin operations (determining the settings of polarizing beam splitters) gives rise to spatially confined states with alternating circular polarization patterns that switch around from round-trip to round-trip of the photonic signal through the circuit.

Figure 1: Supersymmetric polarization anomaly in a quantum walk. a) Coin operations. b) Polarization pattern of the topological state. c) Quasienergy band structure of a topological phase. d) Color representation of winding around a 3-dimensional torus. e) Fibre-optical realization.

3. Gain and loss
To understand the origin of these alternating patterns I point out that photonic quantum walks display an unexplored additional symmetry, akin to a supersymmetry (SUSY) but related to the unitary time evolution operator (hence a unitary SUSY). This extra symmetry gives rise to a third winding number, which complements the winding numbers known from chiral systems and determines the polarization patterns in the round trips.

Given the translation of fermionic anomalies to photonic structures, these states can now be manipulated in real space by gain and loss. I first discuss how the chiral symmetry extends to this case, and formally takes on the form of a charge-conjugation symmetry known from fermionic superconductors, but applied to an effectively nonhermitian Hamiltonian [2,3,4]. Gain and loss then directly influence the lifetime of the topological state, giving a precise meaning to the notion of a life-time anomaly. First proposed theoretically in [2] and [3], these life-time anomalies have now been realized in a wide range of active and passive photonic structures [5-11].
4. Classification and two-dimensional systems

Conventional classifications of fermionic topological systems invoke the spatial dimensionality of the system. Interestingly, by utilizing the effects of gain and loss described above the boundaries between these symmetry classes become less clear. I describe these complications for two-dimensional resonator arrays yielding the formation of nonhermitian bulk and surface Fermi arcs [12], Lieb lattices supporting gain/loss selected corner states [6] and compactons [13], and anomalous Landau levels [2,14]. Reassuringly, all these states still display anomalous features, which therefore serve as a unifying principle in the categorization of these systems.

5. Conclusions

Photonic topological systems offer many features that go beyond the original setting, with gain and loss being particularly prevalent and important. Under these circumstances one needs to revisit the notion of topological protection and robustness; for instances, in many cases the definition of topological quantum numbers becomes unclear. Against this backdrop it appears that anomalies offer a unifying principle that survives the transition to systems with gain and loss, and at the same time identifies the practically most useful features of the corresponding devices.

Abstract

We show here that state-of-the-art double-quantum-dot circuit-QED (DQD-cQED) system can be controllably tuned to show non-Hermitian quantum dynamics governed by an effective PT -symmetric Hamiltonian. We show this by rigorously deriving the effective dynamics from a microscopic model of the set-up. This also reveals the effect of thermal and quantum fluctuations on the PT symmetric system.

1. The set-up

The schematic diagram of the set-up is given in Fig. 1. The DQD Hamiltonian is,

$$\hat{H}_{DQD} = \frac{\varepsilon}{2} (\hat{n}_1 - \hat{n}_2) + V\hat{n}_1\hat{n}_2 + t_c (\hat{c}_1^{\dagger}\hat{c}_2 + \hat{c}_2^{\dagger}\hat{c}_1),$$

(1)

where $\hat{n}_\ell = \hat{c}_\ell^{\dagger}\hat{c}_\ell$, and $\hat{c}_\ell$ is the fermionic annihilation operator of the $\ell$th site. The DQD Hamiltonian can be diagonalized by the transforming to the fermionic operators $\hat{A}_\alpha$, which are related to $\hat{c}_\ell$ via the following transformation,

$$\begin{pmatrix} \hat{A}_1 \\ \hat{A}_2 \end{pmatrix} = \Phi \begin{pmatrix} \hat{c}_1 \\ \hat{c}_1 \end{pmatrix}, \quad \Phi = \begin{pmatrix} \cos(\theta) & \sin(\theta) \\ -\sin(\theta) & \cos(\theta) \end{pmatrix},$$

$$\tan(\theta) = \frac{2t_c}{\varepsilon + \sqrt{\varepsilon^2 + 4t_c^2}}. \quad (2)$$

In the transformed basis, the system Hamiltonian is given by,

$$\hat{H}_{DQD} = \frac{\omega_q}{2} (\hat{N}_1 - \hat{N}_2) + V\hat{N}_1\hat{N}_2,$n$$

$$\omega_q = \sqrt{\varepsilon^2 + 4t_c^2}, \quad (3)$$

where $\hat{N}_\alpha = \hat{A}_\alpha^{\dagger}\hat{A}_\alpha$.

The bosonic system Hamiltonian is

$$\hat{H}_B = \omega_0 (\hat{b}_1^{\dagger}\hat{b}_1 + \hat{b}_2^{\dagger}\hat{b}_2) + \lambda (\hat{b}_1^{\dagger}\hat{b}_2 + \hat{b}_2^{\dagger}\hat{b}_1) \quad (4)$$

The cavity-DQD coupling Hamiltonian is,

$$\hat{H}^{fb} = g_0 (\hat{c}_1^{\dagger}\hat{c}_1 - \hat{c}_2^{\dagger}\hat{c}_2)(\hat{b}_1^{\dagger} + \hat{b}_1). \quad (5)$$

All baths are modelled by non-interacting systems with infinite degrees of freedom. For the phononic bath and the baths attached to the bosonic cavities, the degrees of freedom are bosonic. For source and drain baths attached to the DQD, the degrees of freedom are fermionic. All system-bath couplings are bilinear except for the coupling to the phononic bath, which is given by

$$\hat{H}_{DQD-\text{ph}} = \epsilon (\hat{n}_1 - \hat{n}_2) \sum_{s=1}^{\infty} \lambda_s (\hat{B}_s^{\dagger} + \hat{B}_s). \quad (6)$$

Here, $\hat{H}_{\text{ph}} = \sum_{s=1}^{\infty} \Omega_s \hat{B}_s^{\dagger} \hat{B}_s$, is the phononic bath.

2. The effective PT symmetry

We consider the regime where,

$$V \gg \mu_1 \gg \frac{\omega_q}{2}, \mu_2 \ll -\frac{\omega_q}{2}, \kappa_1, \kappa_2, g_0, \Gamma \ll \omega_0, \quad \omega_0 \approx \omega_q, \quad \beta \gg 1/\omega_0, \quad \Gamma \gg \kappa_1, \kappa_2. \quad (7)$$

After integrating out the fermionic part and the bosonic baths, we have the effective equations of motion for the
Table 1: Set of parameters chosen for numerical plots. These parameters are very much within reach of the state-of-the-art experiments.

The bosonic system,

$$\frac{d}{dt} \begin{pmatrix} \hat{b}_1 \\ \hat{b}_2 \end{pmatrix} = -i \hat{H}_{eff} \begin{pmatrix} \hat{b}_1 \\ \hat{b}_2 \end{pmatrix} - i \left( \frac{\hat{\xi}^*_1(t) + \hat{\xi}_A(t)}{\hat{\xi}^*_2(t)} \right),$$

is equivalent to

$$\hat{H}_{eff} = \left( \omega_0 + i(\Delta N_{ss} \frac{g^2 \Gamma}{\lambda + i \frac{\Gamma^2}{\lambda}} - \frac{\kappa_1 + \kappa_2}{2}) \right) \lambda \left( 1 + \frac{\Delta N_{ss} g^2}{\lambda + i \frac{\Gamma^2}{\lambda}} \right),$$

where

$$g = g_0 \sin(2\theta), \ \Delta N_{ss} = \langle \hat{N}_1 \rangle_{ss} - \langle \hat{N}_2 \rangle_{ss}.$$  \hspace{1cm} (9)

The effective non-Hermitian Hamiltonian is $\mathcal{PT}$-symmetric if

$$\Delta N_{ss} \sin^2(2\theta) = \left( \frac{\lambda^2 + \Gamma^2}{g_0^2 \Gamma} \right) \left( \frac{\kappa_1 + \kappa_2}{2} \right).$$ \hspace{1cm} (10)

### 3. Conclusions and further (on-going) work

In this on-going work, we have been able to show that an extension of an already state-of-the-art quantum experimental set-up [1,2] can be tuned to show $\mathcal{PT}$-symmetric dynamics. The fundamental question of quantum fluctuations in such set-ups remain to be thoroughly explored. This is possible within the formalism we have developed.

Demonstration of a two-dimensional PT-symmetric crystal: Bulk dynamics, topology and edge states

Lukas J. Maczewsky, Mark Kremer, Tobias Biesenthal, Matthias Heinrich, Ronny Thomale, and Alexander Szameit

1 Institut für Physik, Universität Rostock, Germany
2 Department of Physics and Astronomy, Julius-Maximilians-Universität Würzburg, Germany
*corresponding author, E-mail: lukas.maczewsky@uni-rostock.de

Abstract

We report the first implementation of a two-dimensional PT-symmetric crystalline structure. Using a novel isotropic loss mechanism in a photonic setting, we probe both bulk and edge properties, and study the interplay between PT-symmetry and topology in this system.

1. Introduction

One of the fundamental percepts of quantum mechanics is that in order to properly describe a physical system, its associated Hamiltonian has to be real-valued. The well-trodden path to fulfill this condition is to demand the Hamiltonian to be Hermitian. In their seminal work of 1988, Carl M. Bender and Stefan Boettcher showed that parity-time (PT) symmetric Hamiltonians may likewise exhibit real spectra [1]. As it turned out, these notions can be readily implemented in the field of photonics, where the associated complex-valued potentials translate to arrangements of refractive index, gain and loss for electromagnetic waves. Experiments along these lines allowed the verification of numerous hallmark features of PT symmetric systems [2]. However, to date, various technological challenges prevented researchers from going beyond arrangements with single spatial dimension. In this work, we present the first experimental realization and characterization of a two-dimensional PT-symmetric system utilizing photonic waveguide structures with judiciously tailored discrete refractive index landscape and tailored loss structure. In this vein, we explore a non-Hermitian 2D topological phase transition and its connection to the emergence of mid-gap states.

2. PT-symmetric waveguide lattices

A system is PT-symmetric of its Hamiltonian $H$ fulfills

$$ [H, PT] = 0 , $$

where $P$ is the parity operator and $T$ the time-reversal operator, respectively. Due to this relation, $H$ and $PT$ share the same set of eigenstates. A necessary condition arising from these demands is that $V(-r) = V^*(r)$ holds for the complex potential $V$ [1]. In the paraxial Helmholtz regime, the refractive index landscape plays the role of the quantum mechanical potential, hence [3]

$$ n(x,-y) = n^*(x,y) . $$

Our system is based on photonic graphene, i.e. a honeycomb lattice of straight waveguides [4] as sketched in Fig.1 (a). In order to implement the above relation, we introduce differential loss to the two elements of the unit cell, as indicated by the blue and yellow shading in Fig.1 (a). Since this configuration is known to exhibit complex eigenvalues, i.e. reside in the phase of broken PT symmetry, we moreover apply a strain ($\epsilon$) along the horizontal bonds (shown in Fig. 1(a)) to enforce unbroken PT symmetry. We realized these ideas by using the femtosecond laser writing technique [6]. In particular, repeated dwelling of the focal spot along the waveguide trajectory was used to create microscopic scatter centers that, at properly chosen concentrations, yield the desired additional isotropic loss (displayed in Fig. 1(b)). By adjusting the fill factor and the dwelling time, the propagation losses are continuously tunable in a wide range. In turn, the lattice strain is implemented by changing the ratio of the lattice site separations along the horizontal and diagonal bonds in Fig. 1(a), respectively.

In this vein, we were able to observe the transition from broken to unbroken PT-symmetry in a two dimensional system. As indicator, we made use of the fact that in the broken-PT phase, some eigenmodes experience loss, while others remain lossless. This results in a characteristic dependence of the overall output intensity on the specific site that was excited. In contrast, in the presence of the appropriate strain, all eigenvalues become real and no mode is experiencing loss. As a result, the output intensity no longer depends on the injection site. We experimentally verify this behaviour by extracting the standard deviation of the output intensities [7] when launching in 6 different lattice sites. The results are shown in Fig. 1(c), together with a theoretical graph calculated within the tight-binding approximations, clearly confirming the transition from ‘broken’ to ‘unbroken’ PT-symmetry.
Figure 1: (a) Schematic of the investigated photonic graphene based structure. The yellow and blue colors of the lattice sites indicate different losses, while the red and gray connections indicate strained and unstrained bonds, respectively. (b) Illustration of the dwelling mechanism to induce precise amounts of artificial propagation losses. (c) Calculated and measured strain dependence of the standard deviation of the output power over 6 different single site excitations. (d) & (e) Exemplary intensity patterns of the end facet, illustrating the presence and absence of an edge state.

3. Discussion

As it turns out, this transition is closely linked to a topological phase transition, as indicated by the shading in Fig. 1(c). The topological characterization is retrieved from the winding number of a Su-Shrieffer-Heeger (SSH) model perpendicular to the edges [8], resulting in the presence (or absence) of a topological mid-gap state (i.e. an edge mode). In the Hermitian case, the topological invariant changes at a threshold strain of $\tau=2$. However, as soon as gain/loss is introduced, this behavior changes, as displayed in Fig. 1(c). Furthermore, ‘unbroken’ PT-symmetry and the presence of an edge mode are mutually exclusive. This is the result of the second condition for PT-symmetry, mentioned above. Since the edge modes are not eigenstates of the PT operator, they inevitably break PT-symmetry. As the topological phase transition is linked to the presence or absence of these edge states, they can readily serve as its indicator. By quantifying the localization in terms of the fraction of a wave packet remaining within the marked edge waveguide (Fig. 1(d,e)), we find that this value drops from $(43.5 \pm 1)\%$ to $(6.3 \pm 1)\%$ as our system changes its phase.

4. Conclusions

In summary we have designed and experimentally realized a two-dimensional PT-symmetric crystalline structure based on photonic graphene. For this purpose we developed a new technology to introduce tunable artificial losses. In addition to observing the phase transition associated with the breaking of PT symmetry, we also shed light on its close connection to a second, topological phase transition. Our results pave the way towards a wide range of future investigations in high-dimensional non-Hermitian settings. Now, their combinations with nonlinearity or single-photon interference are in the reach of experiments.

Abstract

Controlling the flow of an intense light beam by means of a much weaker one is a dream whose realization may open the way to potentially disruptive data elaboration techniques. However, since light interacts with itself very weakly and only under precise circumstances, this task has proven elusive for long times. In this abstract we show that a loss-gain multilayer – either thin-film based or metasurface-based – may implement perfect, asymmetric, full-optical control if non-Hermitian photonics concepts are appropriately exploited.

The last decade welcomed the concept of coherent perfect absorption (CPA), where an appropriately tailored optical field is completely absorbed by an object which, under ordinary circumstances, would appear only partially opaque [1]. In the simplest, two-port CPA object, the relative phase and intensity of two input beams dictate the amount of light absorbed, which can switch from zero to unity (relative to input energy) thus implementing a perfect light-light switch [2]. However, when attempting to extend this concept to the situation where the phase of a weak beam is used to control the intensity of an intense beam, it turns out that unavoidable losses are present due to a fundamental limitation in the structure of the scattering matrix.

The key idea to overcome this kind of limitation stems from recent observations about photonic elements that contain both gain and loss. Actually, the co-presence of gain and loss, which mathematically results in non-Hermitian Hamiltonians, was first studied in the framework of theoretical quantum mechanics, particularly in the case of parity-time (PT) symmetric systems, since it leads to alternative theories about the mathematical nature of observables. These studies triggered a flourishing literature in the photonics community, since non-Hermitian and PT-symmetric permittivity landscapes imply extremely unusual solutions of the Maxwell equations and, consequently, novel photonic functionalities [3-5]. One of such phenomena is coherent absorption in loss/gain structures. In its simplest version it occurs when a two-port photonic device, like a multilayer that contains materials with both loss and gain, is illuminated with two coherent beams. The multilayer can either work in the ordinary, wavelength-scale regime (e.g., Fabry-Perot resonator), or in the subwavelength regime, where conducting layers (e.g., natural ones like graphene or artificial ones like metasurfaces) are appropriately arranged (Fig. 1a). The overall output intensity from this object (Iout = |s₁|² + |s₂|²) depends sinusoidally on the relative phase of the input beams (Δϕ = arg(s₁⁺/ s₂⁺)), as illustrated in Fig. 1b. Notably, the minimum/maximum values of Iout depend on the relative intensity between the input beams, that in the figure is indicated with the parameter x = (|s₁|² - |s₂|²)/(|s₁|² + |s₂|²). It can be shown that the curve that describes the phenomenon is an ellipse. As it can be noticed in the region x > 0, the object can act either as a lossy or a gainy component, depending only upon the externally imposed relative phase Δϕ. This observation has far-reaching consequences. Suppose indeed that one’s interest is to switch an intense light beam with a much weaker one; this means that the system must operate at a point where |x| ≈ 1.

Figure 1. Panel (a), schematic of a loss-gain two-port coherent intensity control system. The loss and gain elements may be implemented, as illustrated here, by means of conducting sheets (graphene or metasurface), or by means of dielectric layers. Panel (b), normalized output intensity as a function of the relative phase Δϕ between input beams and of the relative amplitude x.
Suppose also that the device only contains lossy elements. In order to have the largest possible modulation depth, one may think of appropriately engineering the ellipse shape, however, an ideal situation will never be reached due to a fundamental limitation. This is illustrated in Fig. 2a: because of energy conservation, the ellipse is constrained in the region $0 < I_{\text{out}}/I_{\text{in}} < 1$, and the phase control will only allow for a limited span of the output intensity. In other words, even if the ellipse is fully optimized, i.e., if the system is capable of both coherent perfect absorption and coherent perfect transparency (CPA and CPT), a sole relative phase control is not sufficient for an efficient switching of a strong beam by means of a weak beam.

This limitation can be overcome by relying on an appropriate loss/gain structure. Indeed, by these means the limitation dictated by energy conservation is lifted, and the ellipse shape can be engineered as illustrated in Fig. 2b. Now, simply sweeping by $\pi$ the relative phase between the input beams will switch the strong signal off and on in a perfect way (Fig. 2d).

Numerical analysis on a prototypical structure, i.e., on a two-layer gain-loss slab, revealed that there exists a family of solutions to the problem, hence proving the feasibility of the CPA/CPT concept in a practical framework. We believe that this concept may prove useful in fully-optically controlled signal elaboration systems.

Abstract
Photonics has become the primary testbed for Parity-Time-symmetric systems and a wide range of its implications in classical systems. However, the intersection between quantum optics and PT-symmetry remains largely uncharted. Here, we report on the first observation of quantum interference achieved by entangled biphotons in lossy directional couplers. We observe the generalized version of the well-known Hong-Ou-Mandel, and find that the underlying non-trivial loss distribution systematically displaces photon bunching with respect to the Hermitian case, as predicted by our theory.

1. Introduction
Parity-Time(PT)-symmetric physics have been intensely studied since their first description by Bender & Boettcher in 1998 [1]. Especially in photonics, numerous PT-symmetric effects and systems were investigated [2]. However, since all of those experiments were performed with classical light or single photons the observation of a multi-particle quantum interference in PT symmetric arrangements remains elusive to this date. We close this gap by exploring two-photon interference in a lossy directional coupler and characterize the underlying generalized Hong-Ou-Mandel (HOM) interference [3]. In optics, complex potential landscapes such as required by PT symmetry can be implemented by establishing a symmetric real part of the refractive index in conjunction with an antisymmetric imaginary part (i.e. gain/loss) [4]. Optical waveguides are a particularly versatile tool to construct such distributions in a discrete framework. However, in the quantum regime, the introduction of gain would fundamentally change the character of a propagating quantum state by inevitably introducing thermal noise [5]. Instead, we make use of entirely passive systems: By choosing an appropriate loss distribution, the behavior of the system can be separated into a global loss factor and the desired dynamics of the PT-symmetric system [6]. The object of our following considerations is a passive PT-symmetric coupler, in which two waveguides interact over a distance z, see Fig. 1 A. Rapid undulations introduce Markovian effective losses, resulting in the desired complex refractive index distribution (B).

2. Theory of the PT-symmetric coupler
We theoretically describe light propagation in the lossy directional coupler by a quantum master equation in Lindblad form, i.e.

\[ \dot{\rho}(z) = -\frac{i}{\hbar} [H, \rho] + \gamma (2 a_L \rho a_L^+ + [a_L^+ a_L, \rho]) = \mathcal{L} \rho, \]

where \( \gamma \) is the loss rate in waveguide \( L \). We chose a rigorous approach providing information on the full quantum state of the system based on a Lie algebra treatment. This yields an igen-deco mposition of the density matrix, and the resulting analytical solution for the intensities is plotted in Fig. 2.

Figure 1: The lossy directional coupler. (A) In a pair of coupled waveguides, undulations selectively introduce losses to facilitate the desired effective complex index distribution illustrated in (B).

Figure 2: Analytical solution of the intensity in the directional coupler in the Hermitian case (red) and the PT-symmetric case (black).
In the conventional Hermitian case (black), the intensities evolve as sine- and cosine squared, and after half the coupling length $L_c$, the intensities in both waveguides are identical. In the PT-symmetric case, the evolution of light launched into the L or R waveguide differs strongly: For a $|1,1>\) input state, the coincidence rate of finding the photons in different outputs is described by the density matrix:

$$\Gamma(z) = e^{-2\gamma z} \left(\frac{\gamma^2 - 4 \kappa^2 \cos(\omega z)}{\omega^2}\right)^2.$$

Here, $\omega = \sqrt{4 \kappa^2 - \gamma^2}$ is the damped oscillation frequency of the system. Our analytical solution holds for the unbroken PT-symmetry case, i.e. for losses that do not exceed twice the coupling. The resulting coincidence function is plotted in Fig. 3, in the Hermitian case the HOM dip occurs at half the coupling length. In the PT-symmetric case, the asymmetric loss alters the interference such that the minimum occurs after a shorter propagation length, as indicated by the dashed vertical lines. The region, which admits for photon bunching, is limited by the PT-symmetry breaking threshold and outlined in gray.

3. Measurement of the HOM-Dip in PT-symmetry

For the experiment, a set of lossy directional couplers of identical couplings with different propagation lengths was implemented to sample light at different $z$ positions. A corresponding set of conventional Hermitian couplers served as baseline reference. The couplers were fabricated with a coupling constant of $\kappa = 0.25 \text{ cm}^{-1}$ and loss coefficient $\gamma = 0.2 \text{ cm}^{-1}$ for the probe wavelength of 815 nm light. As predicted by theory, the antisymmetric loss distribution leaves a distinct signature in the passive PT-symmetric couplers. For the correlation measurement, our experiments were conducted with photon pairs synthesized by type-I spontaneous parametric down conversion, the coincidences were recorded by avalanche photo detectors. The results are shown in Fig. 3.

4. Conclusions

In conclusion, we present the first observation of multi-particle quantum interference in a PT symmetric system. From our experiments, we find that coincidence minimum in the PT-symmetric case is systematically shifted and occurs earlier than in the Hermitian case, in close agreement with the theoretical predictions.

Abstract

Using standard telecommunication equipment, we implement parity-time ($\mathcal{PT}$) symmetry in one- and two-dimensional synthetic lattices with tunable gain, loss and phase modulation. By exploiting its non-Hermitian dynamics, we realize different parity time symmetric configurations, observe unidirectional invisibility, $\mathcal{PT}$-Bloch oscillations and solitons in one- and two-dimensional lattices.

1. $\mathcal{PT}$-symmetry in 1D synthetic lattice

The $\mathcal{PT}$-symmetry in 1D synthetic lattice consists of two coupled fiber loops having slightly different lengths ($\Delta L=600$ m) and periodically switching between gain and loss (see Fig 1a). Following the concept of time-multiplexing (1), subsequent pulses passing through the short and long loop cause a pulse to spread on a time mesh lattice with discrete arrival times being equivalent to positions in the spatial domain (see Fig. 1b,c). When a pulse travels through the long or short loop, it will not only step in time from $m$ to $m+1$, but will also be slightly delayed thus hopping from position n to $n+1$ or $n-1$, respectively. The 1D $\mathcal{PT}$ lattice presents real-valued eigenvalues if a suitable phase modulation scheme ($\phi$) is applied. By exploiting the fiber nonlinearity, a train of 20ns long rectangular optical pulses having a Gaussian envelope inserted into the system forms a discrete $\mathcal{PT}$ soliton for higher input power. Its profile and behaviour follows the conservative self-trapped waves by the nonlinear Schrödinger equation (see Fig. 2a).

In general, its dynamics exhibits prominently features, such as unidimensional invisibility and $\mathcal{PT}$-symmetric saturable absorbers [2]. Also, $\mathcal{PT}$-Bloch oscillations in 1D lattice can be implemented by a time-dependent phase gradient $\phi(m) = m \varphi_0$ (see Fig. 2b). Inserting a Gaussian wave packet in the broken $\mathcal{PT}$-symmetric configuration (without phase modulation), it is periodically amplified during Bloch oscillations due to the partially complex band structure. Interestingly, a new branch of Bloch oscillations appears (secondary emissions) each time the wave packet passes through an exceptional point (see left picture in fig. 2b). In contrast, for resonant Bloch gradient ($\pi/31.0$), a pseudo-Hermitian propagation is restored, where the total energy stays constant over many time steps [3] (see right picture in fig. 2b).

![Fig. 2: a) 1D discrete $\mathcal{PT}$ soliton [2]. b) $\mathcal{PT}$-Bloch oscillations in 1D lattice [3].](image)
2. $\mathcal{PT}$-symmetry in 2D synthetic lattices

Following a concept developed in [4], we present a novel protocol for realizing $\mathcal{PT}$-symmetry in two-dimensional synthetic lattices based on short and long-range coupling. Our experimental platform (see Fig. 3a) is based on two pairs of slightly dissimilar coupled fiber loops, where each fiber patch is approximately 30 km long. A synthetic 2D mesh lattice is implemented by exploiting a time multiplexing technique. As shown in Fig. 3a, an initial seed pulse is injected via a fiber optical coupler into the outer left loop and splits into two pulses at the first 50/50 coupler at the entrance of the two inner loops. The lengths of the inner two loops differ by $\Delta L_{\text{inner}}=600$ m ($\Delta T_{\text{inner}}=3$ μs), while that of the outer loops by $\Delta L_{\text{outer}}=6$ m ($\Delta T_{\text{outer}}=30$ ns). After passing through the second 50/50 coupler, the pulses are split into four that in turn propagate through the outer loops back to the first 50/50 coupler. In this stage, the ordered sequence of pulses arrives at the first coupler with a mean round trip time $T=300$ μs and starts its journey again. Crucially, the pulse arrival time allows for a straightforward mapping from the temporal evolution through the fibers onto an equivalent 2D spatial mesh lattice (see Fig. 3b). By propagating through the inner long / short loop $x$ increases / decreases by one, which is equivalent to a step to the right / left on the 2D synthetic lattice. Afterwards, by propagating through the outer long / short loop, $y$ increases / decreases by one, respectively, and thus the pulse makes a step up / down on the lattice. In this way, any path through the 2D lattice can be interpreted as a combination of roundtrips through the four different loops. The arrival times of the pulses at the photodetector are measured, sampled electronically and mapped onto a 2D discrete lattice spanned by the $x$ and $y$ coordinates. A 2D $\mathcal{PT}$-symmetry can be realized by applying a balanced gain/loss space-dependent protocol on the lattice (red and blue circles in Fig. 3b). Additional, unbroken $\mathcal{PT}$-symmetry is only fulfilled when a phase modulation scheme is applied (light blue diagonal lines in Fig. 3b).

A specific-like region of the Brillouin zone can be excited by launching a train of rectangular pulses containing a Gaussian envelope $G(x,y)=\exp[-(x^2+y^2)/w^2]$ along $x$- and $y$-axis (see Fig. 3c) with a variable amplitude ($A$) and a fixed width ($w$) of 6 positions ($1/e$ drop of intensity). We realized a stable linear propagation in the 2D $\mathcal{PT}$-symmetric lattice (see Fig. 3d,e), which changed dramatically for higher power levels. Stable 2D solitons formed for input powers of about 1mW (see Fig. 3f,g), while higher power levels (above 4mW) caused a collapse of the field distribution (see Fig. 3h,i). The latter one causes a locally spontaneous $\mathcal{PT}$-symmetry breaking, leading to power increase and a nonlinearly self-accelerating localized spike, which is rather unusual for a discrete system.

Abstract

Chiral systems impose circularly polarized waves which do not preserve their handedness under the combined space- and time-reversal operations and, as a result, seem to be incompatible with systems possessing PT symmetry. Here we show that in certain metamaterials, PT symmetric permittivity, permeability and chirality is possible; in addition, real eigenvalues are maintained even if the chirality goes well beyond PT symmetry, thus enabling advanced polarization control of PT symmetric systems.

1. Introduction

The concept of Parity-Time (PT) symmetry, which was originally introduced in the context of quantum mechanics [1] (referring to systems with a non-Hermitian Hamiltonian which commutes with the combined action of Parity and Time operators) was very quickly transferred in optics, where PT-symmetric systems can be more easily realized, by properly combining loss and gain media. This extension of PT-symmetry to optical systems led to novel phenomena, such as coherent perfect absorption, the PT-laser absorber, and anisotropic transmission resonances [2,3].

However, the combination of PT-symmetry and chiral metamaterials (i.e. metamaterials lacking any mirror symmetry plane [4]) remains highly unexplored. In this work we derive the necessary conditions for a chiral system to be PT-symmetric and we examine how the obtained general results are modified if PT invariance is imposed. To our surprise, we find that both the eigenvalues of the scattering matrix and the PT-related functionalities are still preserved, independently of whether the PT requirement is violated in chirality. This unexpected result turns out to be of utmost importance for chiral systems, because it allows retaining an unbroken PT phase with all its benefits and controlling the chirality simultaneously and independently from the PT-related functionalities. This finding enables new optical capabilities, such as anisotropic transmission resonances with polarization conversion and unidirectional polarization conversion with no reflection, as we demonstrate explicitly with simulations in realistic chiral metamaterials.

2. Conditions for PT-symmetric chiral systems

To find the conditions for PT-symmetry in chiral systems we cast Maxwell’s equations into an eigenproblem with a Schrödinger-like Hamiltonian and we require that the Hamiltonian commutes with the PT operator [5]. The eigensolutions are circularly polarized waves, which change their handedness upon space reversal \((x\rightarrow-x, y\rightarrow-y, z\rightarrow z)\), thus implying an apparent incompatibility of chiral systems with PT-symmetry. This limitation can be overcome if systems that respect a reduced spatial parity, such as space reflection by a plane (instead of a point), are considered. Such systems possess material parameters that change for example only along the \(z\)-direction \((x\rightarrow-x, y\rightarrow-y, z\rightarrow z)\), as shown in Fig. 1; for waves propagating along the \(z\)-direction, we find that the conditions for the material parameters, so as to have a PT-symmetric chiral system are:

\[
\begin{align*}
\varepsilon(z) &= \varepsilon'(z) \\
\mu(z) &= \mu'(z) \\
\kappa(z) &= -\kappa'(z)
\end{align*}
\]

In Eqs. (1) \(\varepsilon\) is the electric permittivity, \(\mu\) the magnetic permeability and \(\kappa\) the chirality parameter, which connects the electric and magnetic fields in the chiral constitutive equations [6].

Figure 1: A system for the realization of PT-symmetric chiral structure. The necessary conditions are: \(\varepsilon_+ = \varepsilon'_+, \mu_+ = \mu'_+, \kappa_+ = -\kappa'_+\) and \(L_+ = L'_-\). The subscripts + and − in the amplitudes of the incoming \((b,c)\) and outgoing \((a,d)\) waves denote right-handed and left-handed circularly polarized waves (RCP/LCP), respectively.
3. Chiral systems with PT-symmetry and beyond

Below a critical value, the so-called Exceptional Point (EP), the eigenstates of non-chiral PT-systems are known to be unimodular, despite the presence of gain and loss (above the EP the system is not unitary anymore) [1-3]. Here, we find that in the presence of chirality the eigenvalues of the scattering matrix do not change, i.e. the EP is preserved, unaffected by chirality. Hence, characteristic phenomena related to PT-symmetry, such as unidirectional invisibility, can be tailored independently of chirality and can be expanded to account for circularly polarized waves.

In Fig. 2, we demonstrate the response of a non-magnetic ($\mu_0 = \mu_i = 1$) system with $n_e = 2.2+0.15i$, $n_i = 2.2-0.15i$ ($n = \sqrt{\varepsilon \mu}$ and positive/negative imaginary part accounts for gain/loss) and $\kappa_s = -0.1-0.1i$, $\kappa_i = 0.1-0.1i$ (sign of imaginary part accounts for preferential absorption of Right/Left Circularly Polarized (RCP/LCP) waves). The two slabs have equal length $L_0 = L_1 = L/2$ and the eigenvalues of the scattering matrix, as well as the transmitted and reflected power are shown as a function of the normalized frequency $\omega L/c$ ($c$ is the vacuum speed of light). In $T_0$ (transmission) and $R_0$ (reflectance) the subscript $i$ ($j$) indicates the outgoing (incident) polarization (i.e. $+/-$ accounts for RCP/LCP waves). For our system we find that $T_{--} = T_{++} = R_{-+} = R_{++} = 0$ and that $T_{++}, T_{--}$ are the same regardless of the illuminated side. However, depending on the side from which the system is illuminated, different reflected powers can be achieved. In particular we find that $R_{i++} = R_{i--} = R_i$ and $R_{j++} = R_{j--} = R_j$, where the subscript $L$ or $R$ denotes incidence from ‘Left’ or ‘Right’, respectively.

In Fig. 2a $\kappa_j = -\kappa_i^*$, i.e. $\kappa$ satisfies condition (1) and hence $\text{Re}(\kappa)$ changes sign across the system, resulting overall in zero optical activity, $\theta = 0$. On the other hand $\text{Im}(\kappa)$ preserves its sign across the entire system, resulting in nonzero ellipticity, $\eta \neq 0$, and hence $T_{+-} \neq T_{-+}$. Practically, after the operation point of zero reflection at $\omega L/c = 15.68$, there exist multiple reflectionless points with $\theta = 0$ and $\eta = 45$ deg. At those points full conversion of linearly polarized waves into circularly polarized waves occurs, the handedness of which is controlled by the sign of $\text{Im}(\kappa)$.

In Fig. 2b $\kappa_j = \kappa_i^*$, i.e. $\kappa$ does not satisfy condition (1). In this case only $\text{Im}(\kappa)$ is spatially odd, leading to $\eta = 0$ (and $\theta \neq 0$) and $T_{++} = T_{--}$. This relaxed condition does not affect the eigenvalues $\lambda$ of the scattering matrix, as predicted [6]. In this case the reflectionless operation points correspond to unidirectional pure optical rotation of a linearly polarized wave. At $\omega L/c = 15.68$, in particular, $\theta = 90$ deg., i.e. $x$-polarized waves are fully converted to $y$-polarized waves and are transmitted entirely without reflection.

4. Conclusions

We have shown that the combination of chirality with PT symmetry in $\varepsilon$ and $\mu$ is possible in certain systems. The unexpected $\kappa$-independence of the PT-phase turns out to be of utmost importance, as it enables advanced polarization control of PT symmetric systems.

![Figure 2: PT-chiral system of length L with n = 2.2+0.15i (n = \sqrt{\varepsilon \mu} and $\mu = 1$). The chirality is (a) $\kappa = \pm 0.1+0.1i$ and (b) $\kappa = 0.1\pm 0.1i$. Abstract
Abstract symmetries are a powerful framework to study propagation dynamics in photonic devices described by mode-coupling theory. We will show that the cyclic group can help us go beyond the nearest neighbor approximation in periodic multicore photonic devices. In addition, we will show that it is possible to design devices with cyclic composite symmetries that provide us with port replication. We will discuss how the cyclic repetition of a non-Hermitian dimer allows for port switching and replication.

1. Introduction
Symmetries play a fundamental role in physics, as they are connected to conservation laws. The mathematical framework to study continuous differentiable symmetries is Group Theory and it provides us with valuable tools to find analytic solutions to differential equations. Of course, the design of differential equations with a prescribed symmetry, where the solution is known, is also possible. Our program pushes for the latter in optics where quantum inspired symmetries have been used to engineer novel devices \cite{1}. Photonic devices described by mode-coupling theory provide a perfect platform for design based on symmetry; e.g. multicore fibers, waveguide arrays, micro-ring arrays, etc.

Here, we will focus on a photonic device with cyclic symmetry, that is the, device remains invariant to discrete rotations, Fig. 1. We call the repetition photonic device a black-box. We assume that the internal dynamics of this black-box can be described by mode-coupling theory as well as the interactions between each of these black-boxes. Thus, the whole device can be described in terms of the block couple-mode matrix,

\[ M = \begin{pmatrix}
    B & G & \cdots \\
    G & B & \cdots \\
    \vdots & \vdots & \ddots \\
    B
\end{pmatrix} \]

(1)

where the $B$ blocks determine the dynamics of the black-box and the $G$ blocks define the coupling between copies of the unit cell.

In the following, we will discuss the cyclic group, the symmetry related to discrete rotations, and show that it can help us go beyond nearest neighbor modelling in coupled mode theory. Then, we will show that we can use it as the foundation of composite symmetries that will allow for the replication of dynamics. In particular, we will focus on the cyclic repetition of a loss-based non-Hermitian dimer to show that there exists a reference frame where it is evident that the device possesses an underlying PT-symmetry, that we can use to control the dynamics in the photonic device. This allows us to design a device with different dynamics that can be controlled by the input state and will be replicated at the output of the device.

2. The model
Let us study first the underlying cyclic symmetry of the device. We have discusse in the past that it is possible to use the Fourier matrix \cite{2},

\[ [F]_{p,q} = \frac{1}{\sqrt{n}} e^{i \frac{2 \pi}{n} (p-1)(q-1)} \]

(2)

to diagonalize the coupled-mode matrix of a cyclic repetition of an identical unit cell. For an array of $N$ identical guiding cores, it is possible to find the normal modes,

\[ \tilde{u}_j = F^\dagger \cdot \hat{e}_j, \]

(3)
and their corresponding propagation constants,

\[
\lambda_j = \begin{cases} 
2 \sum_{k=1}^{m-1} \{ g_k \cos \left( \frac{\pi}{m} (j-1)k \right) \} + g_m (-1)^{j-1}, \\
2 \sum_{k=1}^{m} \{ g_k \cos \left( \frac{2\pi}{2m+1} (j-1)k \right) \}, 
\end{cases}
\]

where \( m = N/2 \) when \( N \) is even and \( m = (N - 1)/2 \), considering all neighbor couplings \( g_k \) and the standard orthonormal basis \( \hat{e}_j \). The duplicity of propagation constants is not an issue due to the fact that all the normal modes are mutually orthonormal.

As a unit cell, we will consider the non-Hermitian dimer,

\[
M_d = \begin{pmatrix} n + 2i\gamma & g_d \\ g_d & n \end{pmatrix},
\]

composed by two guiding cores with identical real part of the refractive index but one of them lossy, with a loss rate \( 2\gamma \), and the other lossless. It is possible to show that an effective imaginary propagation constant \( n_{bias} = n + i\gamma \) can be factored from the dynamics to provide an effective PT-dimer with gain/loss rate \( \gamma \) and the standard regimes PT-symmetric dimer [3, 4, 5].

The cyclic symmetry allows us to calculate an effective coupling matrix that is isolated block diagonal, the off-diagonal blocks become zero and the diagonal blocks become the matrix,

\[
M_j = \begin{pmatrix} i\gamma & \Gamma_j \\ \Gamma^*_j & -i\gamma \end{pmatrix},
\]

where the effective couplign constants are given by \( \Gamma_j = g_d + g_N e^{-i\frac{2\pi}{N}j} \). Choosing an adequately initial amplitude vector,

\[
\mathcal{E}(0) = \frac{1}{\sqrt{N}} \sum_{j=0}^{N-1} e^{i\frac{2\pi}{N}j} \hat{e}_j \otimes \mathcal{E}_D(0),
\]

where the normalized vector field amplitude \( \mathcal{E}_D(0) \) refers to the initial state that will impinge on each copy of the dimer, provides replication, up to a phase, of the dynamics provided by each of these isolated effective PT-symmetric dimers,

\[
\mathcal{E}(z) = \frac{1}{\sqrt{N}} \sum_{p=0}^{N-1} e^{i\frac{2\pi}{N}j} \hat{e}_p \otimes e^{iM_jz} \mathcal{E}_D(0), \tag{8}
\]

in the composite system. In other words, a permutation of the phases in the initial field amplitudes controls the dynamics in the output.

3. Discussion

Figure 2 shows a comparison of analytic theoretical with finite element simulation results for a photonic device composed by three lossy-lossless dimers. We show port switching in the effective frame, Figure 2(a) where we normalize to the total instantaneous power, and the laboratory frame, 2(b) where we don’t renormalize and the effect of losses is seen. Additionally, we can select a regime that provides port mixing in the effective, Figure 2(c), and laboratory, 2(d), frames.

4. Conclusions

The cyclic group as foundation for the design of composite photonic devices allows for port replication and dynamics switching if used in addition to unit cells showing different operation regimes. Control of the dynamics is provided by the relative phases in the input signal. We provided a simple example where the repetition of a lossy-lossless dimer provides switching and mixing of the input signals.

Abstract

I will present our recent results on two distinct topological aspects of non-Hermitian physics. First, I discuss the unconventional quantum phase transition and critical phenomena in the parity-time-symmetric sine-Gordon model, which can be realized in ultracold atoms. Second, I talk about the role of topology in nonequilibrium phases of non-Hermitian systems and present a possible topological classification and its relevance to the Hatano-Nelson model.

1. Introduction

Studies of phase transitions and critical behavior in non-Hermitian systems date back to the discovery of the Lee-Yang edge singularity. On another front, the real-to-complex spectral phase transition has been found in a broad class of non-Hermitian Hamiltonians that satisfy parity-time (PT) symmetry. Recent experimental and theoretical studies on non-Hermitian systems in optics, metamaterials, and weakly interacting open quantum systems have already revealed their intriguing physical properties. However, the previous works mainly concern the classical (one-body) aspects and the role of strong correlations has yet to be clarified. Moreover, a generic aspect of topology in non-Hermitian systems has been largely unexplored. We aim to fill this gap and create a bridge between the fields of non-Hermitian physics and condensed-matter physics.

2. Results

2.1. Quantum criticality

Quantum critical phenomena originate from collective behavior of strongly correlated particles and lie at the heart of universal low-energy properties in many-body systems. The strong correlation between quantum particles is particularly prominent in a low-dimensional system. We identify what types of non-Hermitian perturbations are relevant to one-dimensional low-energy properties and address how they qualitatively alter the underlying quantum critical behavior [1]. Specifically, we show that, in the presence of the PT-symmetric non-Hermitian perturbation, a combination of spectral singularity and quantum critical point results in a nontrivial renormalization group fixed point that has no counterpart in Hermitian systems. Moreover, we found anomalous renormalization group flows violating the $c$-theorem, which lead to enhancements of superfluid correlations in stark contrast to a topological transition in the Berezinskii-Kosterlitz-Thouless paradigm (see Fig. 1). Our field-theoretic arguments provide a universal

Figure 1: Quantum critical phenomena in PT-symmetric many-body systems. (a) 3D phase diagram in the parameter space $(K, g_{tr}, g_{i})$, where $K$ and $g_{tr}$ ($g_{i}$) characterize the strength of the inter-particle interaction and the depth of the real (imaginary) part of a complex potential, respectively. The Mott-insulator (MI) and Tomonaga-Luttinger Liquid (TLL) phases are separated by the surface of the topological Berezinskii-Kosterlitz-Thouless (BKT) transition for $K > 2$ and that of the PT transition for $K < 2$. (b) Hyperbolic RG flows in a PT-unbroken region ($g_{i} < g_{tr}$), which reproduce the conventional flow diagram in the sine-Gordon model. (c) RG flows on the two phase boundaries separated by an unconventional fixed line (thick black line). (d) Anomalous RG flows in a PT-broken region ($g_{i} > g_{tr}$), which violate the $c$-theorem. Along each flow, the TLL parameter $K$ monotonically increases, indicating the anomalous enhancement of the superfluid correlation.
model-independent perspective to one-dimensional quantum critical phenomena subject to non-Hermiticity. The non-Hermiticity can naturally arise in the context of dissipation and continuous monitoring of ultracold atoms, and a concrete experimental setup to test our theoretical predictions has been proposed.

2.2. Nonequilibrium phases

We establish a systematic theoretical framework to characterize and classify non-Hermitian systems in terms of their topological aspects [2]. The two guiding principles are dynamical viewpoint as nonequilibrium phases and the constraint such that the energy spectrum neither touches nor crosses the base point (see Fig. 2). In particular, we study one-dimensional non-Hermitian lattices belonging to class A in detail, and identify the topological winding number and reveal an exotic bulk-edge correspondence. Historically, this model has been known as the Hatano-Nelson model. We also give a systematic classification based on K theory and obtain the periodic table. Time permitting, I will also discuss unconventional nonequilibrium quench dynamics and the subsequent thermalization in a PT-symmetric dissipative many-body lattice model [3, 4].

Figure 2: (a) Energy spectrum (thick lines and dots) of a Hermitian insulator. We can always perform band flattening, i.e., continuously deform the spectrum into \{E_-, E_+\} with \(E_- < E_F < E_+\), where \(E_F\) (red dot) is the Fermi energy. In particular, we can choose \(E_\pm = \pm 1\) for \(E_F = 0\). (b) Energy spectrum of a non-Hermitian system forming a loop that encircles a base point \(E_B \in \mathbb{C}\). (In the figure, we set \(E_B = 0\) for simplicity.) While the shape can be deformed continuously, the loop can never shrink to a single point without crossing the base point.
Quasi-Normal-Mode Approach for Dissipative Systems - Classical and Quantum Regime

Kurt Busch $^{1,2,*}$

$^1$ Humboldt Universität zu Berlin, AG Theoretische Optik & Photonik, 12489 Berlin, Germany
$^2$ Max-Born-Institut, 12489 Berlin, Germany

*corresponding author, E-mail: kurt.busch@physik.hu-berlin.de

Abstract

An approach is presented for modeling the response of localized electromagnetic resonators using quasi-normal modes, which represent the natural, dissipative modes of the resonators with complex frequencies. For many problems of interest in optics and nanophotonics, the quasi-normal modes constitute a powerful modeling tool, both in the classical and the quantum regime.

1. Introduction

On the classical level, and combined with a bi-orthogonal approach this approach provides a coherent, precise, and accessible derivation of the associated theory and leads to an efficient coupled-mode theory [1]. In turn, this enables an illustrative connection between different modeling approaches in the literature and allows for a multitude of applications.

On the quantum level, this approach leads to a novel quantization scheme for the electromagnetic field in dissipative and open systems [2]. Contrary to many “modes-of-the-universe” approaches that utilize the microscopic Maxwell equations together with a set of uncontrolled approximations, this scheme is based on the macroscopic Maxwell equations and thus leads to the correct classical limit. Applications for certain leaky and hybrid cavity-QED systems/effects including cavity enhanced spontaneous emission rates are developed and shown to agree well with corresponding semi-classical results.

Bloch-oscillations in a lattice with passive PT-symmetry

Eva-Maria Graefe and Bradley Longstaff

Department of Mathematics, Imperial College London

Abstract

A tight-binding lattice with losses from every other lattice site is considered. In the absence of losses, if a static tilt is applied to the lattice the continuous dispersion relation is replaced by a discrete spectrum with equidistant spacings that lead to periodic dynamics. In particular, an initially broad wave packet will perform the famous Bloch oscillations, effectively mapping out the band structure of the untitled system. The presence of losses leads to a number of intriguing changes explored here.

1. The model

We consider a tight-binding lattice with losses from every other lattice site, that could be realised in a number of experimental setups, including cold atoms in optical lattices with particle losses or arrays of optical wave guides. This leads to a Schrödinger dynamics with an effective non-Hermitian Hamiltonian of the form

\[ \hat{H} = -\sum_{j=-L}^{L-1} (|j+1\rangle\langle j| + |j\rangle\langle j+1|) \]

\[ + \frac{i\gamma}{4} \sum_{j=-L}^{L} ((-1)^j - 1) |j\rangle\langle j|, \]

where the hopping element has been set to unity and where \( \gamma \in \mathbb{R} \) denotes the loss rate. While the system has a passive \( PT \)-symmetry, this is broken for arbitrarily small loss rates, leading to two complex mini-bands, which below a critical loss strength are connected at exceptional points. We investigate the dynamics arising when applying an additional static tilt \( \Delta \sum_{j=-L}^{L} j |j\rangle\langle j| \). A similar system has briefly been investigated before in [2] and [3].

2. Results

Here we show how the exceptional points in the band structure leave characteristic fingerprints in the dynamics of a broad beam, while remarkably there are no exceptional points in the spectrum of the full system including the tilt. We use semiclassical arguments developed in [1] to show how the dynamics maps out the real part of the dispersion relation, while inter-band transitions occur around the exceptional points in the dispersion relation. We provide an estimate for the percentage of population transfer by deriving an analytic solution to a non-Hermitian Landau-Zener problem approximating the bands around the exceptional point.

Intensity fluctuations and mode correlations in strongly coupled nanolasers

A. M. Yacomotti¹, M. Marconi¹, A. Pan², F. Raineri¹, A. El Amili², J. A. Levenson¹ and Y. Fainman²

Abstract-We investigate second order correlations in a bimodal nanolaser and relate them with mode-intensity fluctuations. We first discuss the predictions as a function of the system “size”, determined by the inverse of the spontaneous emission ($\beta$) factor. The modal cross correlation decreases from $g_{ij}^{(2)}=1$ in the “thermodynamic” limit ($\beta^{-1}>10^4$) to $g_{ij}^{(2)}=2/3$ in the “mesoscopic” limit ($\beta^{-1}\sim 10-100$). This is the consequence of flat potential transitions at the origin of large intermode energy fluctuations. We experimentally verify such a limit and confirm the flat potential scenario by means of probability distribution measurements of the mode population imbalance.

It is well established that the intensity correlations of a classical light beam cannot reach values below $g_{ii}^{(2)}(\tau=0)=1$, where $g_{ii}^{(2)}(\tau=0)$ is the second order coherence of a mode i at zero time delay ($\tau=0$). As long as a multiple beam source is considered, such as the output of a coupled cavity array, the nature of the fluctuations is not only contained in the auto correlation properties of the beams (alternatively, modes), but also in the cross correlation features between them. For instance, independent single photon sources with indistinguishable photons are expected to verify $g_{ij}^{(2)}(0)=0$ (i,j stand for the two sources), which is the manifestation of quantum interferences of the optical paths, usually known as photon coalescence in a Hong Ou Mandel experiment.

**Figure 1:** Left: Minima of second order cross correlation as a function of the $\beta$ factor in coupled lasers. Blue squares: numerical simulations of a semiclassical model with Langevin noise. Right: Experimental second order mode correlations as the pump power is ramped up in time. Top: Intensity traces for bonding (B, blue) and antibonding (A, red) modes. Pump ramp duration=6 ns. Thick lines: average. Bottom: left axis, $g_{BB}^{(2)}$ (blue), $g_{AA}^{(2)}$ (red), and $g_{AB}^{(2)}$ (green) corresponding to $10^4$ time traces; right axis,
mean values (solid) and variance (dashed lines) of the mode population imbalance.

As long as two independent classical fields are considered, the mutually incoherent phases lead to a limit of $g^{(2)}_{ij}=0.5$ for independent sources. However, mode-to-mode interactions in coupled cavities can produce strong intermode intensity fluctuations, which can decrease the second order cross correlation functions to values significantly below 0.5, down to $g^{(2)}_{ij}(0)=0$ in the general case. Here we show that two coupled nanolasers operating in the mesoscopic regime, $\beta\approx0.01$, exhibit a second order cross correlation of $g^{(2)}_{ij} \approx 0.69$, compatible with the predicted 2/3 limit originated by flat potentials at the mode switch transition.

Figure 1 (left) shows the prediction of $g^{(2)}_{AB}$ in a two evanescently coupled cavity laser system (“B” and “A” refer to “bonding” and “antibonding” modes of the photonic dimer) as a function of the system “size”, which can be defined as the inverse of the spontaneous emission ($\beta$) factor of the laser cavities. Clearly, $g^{(2)}_{ij}$ tends to 1 in the thermodynamic limit ($\beta^{-1}>>1$), whereas a limit $g^{(2)}_{ij}=2/3$ is observed for $\beta^{-1}$-values as small as $\sim10$.

Figure 1 (right) shows experimental results of two lasing modes in a strongly coupled photonic crystal cavity nanolaser system [1,2] as the pump power is ramped up. A minimum of $g^{(2)}_{AB} \approx 0.69$ can be observed at the mode switching point. Such a minimum coincides with a zero-crossing of $\langle x \rangle$, and a maximum of $\Delta x$, where $x$ is the mode population imbalance $x=(I_B-I_A)/(I_B+I_A)$, in good agreement with the theoretical predictions of a mean field semiclassical model. Such a model predicts flat probability distributions of $x$ at the switching point, which directly implies $g^{(2)}_{AB}=2/3$. In order to experimentally test such scenario, we have measured the probability distributions $P(x,I_{tot})$, Fig. 2. These get dramatically stretched at the switching point. As a result, $P(x,I_{tot})$ becomes flat at the switching point, which confirms the predictions. Note that other dynamical mechanisms of mode interactions such as mode bistability would result in bi-modal distributions rather than flat ones.

In conclusion we have shown, both theoretically and experimentally, a “mesoscopic” limit of the modal cross correlation functions of strongly evanescently coupled laser cavities, $g^{(2)}_{ij}=2/3$. An avenue is now open to study correlations at the few photon level, which might exhibit quantum features such as photon entanglement.

**REFERENCES**
The concepts of nonreciprocal properties in photonics as well as materials have recently become quite significant due to their technological implications [1]. In general, nonreciprocity arises due to mainly three reasons: nonlinearity, asymmetric property tensors and spatio-temporal modulation. However, it can be further enhanced in non-Hermitian (e.g. parity-time or PT-symmetric) and topological settings. For example, many useful properties of materials such as optical diode effect crucially depend on the interplay between chirality, reciprocity as well as broken spatial and temporal symmetries. One notable example is that of nonreciprocal directional dichroism. I will discuss the conditions for non-reciprocity of ferro-rotational order in a variety of materials and suggest the use of linear optical gyration and vortex beams as possible ways to detect ferro-rotational domains [2]. Next, I will discuss how to generalize the notion of vector order parameters to second- and higher-rank tensor order parameter. I will also elucidate how to achieve high-temperature optical diode effect. Finally, as a different example, I will consider a PT-symmetric photonic Kagome lattice [3], which is a two-dimensional network of corner-sharing triangles. At each lattice point a PT-symmetric dimer is placed, where a dimer represents a pair of strongly coupled waveguides. The frustrated coupling between waveguide modes leads to a dispersionless flat band consisting of spatially localized modes. The beam evolution in the waveguide array results in an oscillatory rotation of the optical power along the propagation direction. We also observe long-lived chiral structures that originate from the nearly flat bands of the Kagome structure when the lattice is subject to a narrow beam excitation.

Abstract

In this presentation, I will present our recent research on thermoplasmonics, with focus on hybrid plasmonic systems enabling radiation sensing and harvesting of energy from random light fluctuations.

Noble metal nanostructures have attracted much attention due to their unique optical properties. Enhanced light absorption in these nanostructures makes them ideal nano-sources of heat. While discrete nanostructures such as nanodisks have received much interests for thermoplasmonics, we showed that metal nanohole arrays can be as efficient light-driven heat sources, as used to create heat gradients and induce thermoelectric potentials over an ionic thermoelectric material.\[^1\] Moreover, we demonstrate that the fast heating process in plasmonic nanostructures allows energy harvesting even from solar-light fluctuations, based on a hybrid device combining plasmonic nanodisks arrays with a pyroelectric material.\[^2\] At the end, I will discuss our most recent study showing that merging these two aforementioned systems can provide interesting enhancement effects with regards to the rate of the thermoelectric response and the voltage derived from the device.\[^3\]

Abstract

We report a near-infrared selective thermal emitter based on rod-type Si photonic crystals, which can be operated at temperatures above 1300 K. A thermo photovoltaic energy conversion system using this selective thermal emitter is also discussed.

1. Introduction

Thermal emitters generally exhibit a broad spectrum and are widely used for various light sources from the far-infrared to the visible range. However, in many applications involving non-dispersive infrared sensing and thermophotovoltaics (TPV), only a specific spectral component that is much narrower than the blackbody spectrum is utilized. Therefore, it is important to develop a narrowband thermal emitter that achieves high emissivity at a target wavelength while suppressing emission at other wavelengths as much as possible to increase the energy utilization efficiency.

So far, we have developed selective thermal emitters based on simultaneous control of bare material absorption and photonic states [1-6]. Specifically, for spectroscopic applications in the mid-to-long-wavelength infrared range, we utilized intersubband transitions in n-doped semiconductor quantum wells to control the bare absorption spectrum of a material, and fabricated a photonic crystal (PC) structure using such material to achieve a narrow thermal emission spectrum [1-2]. Ultrafast modulation (\textasciitilde MHz) of thermal emission has been also realized by changing the emissivity using an applied electric field [3]. For TPV applications, near-infrared selective emitters that can operate at high temperatures are important for the improvement of energy conversion efficiency. In this abstract, we discuss selective thermal emitters based on Si rod photonic crystals [5] and also discuss TPV systems that utilize them.

2. Emitter design

Thermal emission spectrum from an emitter can be controlled by varying the temperature and the emissivity spectrum. Emissivity spectrum can be controlled by selecting the bare absorption spectrum of the material consisting of the emitter, and by designing photonic states of the emitter. For TPV applications, it is important to suppress emissivity at wavelengths longer than the bandgap wavelength of the target photovoltaic (PV) cell to improve the system efficiency. In contrast, emissivity at wavelengths much shorter than the bandgap wavelength of the PV cells does not need to be suppressed because intensity of the blackbody radiation rapidly decreases at the shorter wavelength side of its peak. Figure 1 shows our strategy, where (A) an interband absorption of a semiconductor and (B) resonances of a photonic structure are combined to produce high emissivity at the near-infrared range and very low emissivity at longer wavelengths. Finally, the emissivity spectrum is shaped into a narrowband intensity spectrum by the falling tail of the blackbody spectrum, as shown in (C).

We utilized an interband transition of Si for (A) because Si has a high melting point of 1687 K and the bandgap is appropriate for near-infrared thermal emission. Fig. 2 (A) shows the theoretical absorption coefficient spectra of intrinsic Si at various temperatures calculated by taking into account both the interband transition and the free-carrier absorption owing to the intrinsic carriers generated at elevated temperatures. Figure 1: Strategy to obtain a narrowband selective thermal emission spectrum at the near-infrared wavelength. (A) Interband absorption spectrum of a semiconductor. (B) Photonic resonance of a micro structured emitter. (C) Emission intensity spectrum.
temperatures. It can be seen in the figure that the spectra exhibit step-like increases at wavelengths shorter than 1.2–1.5 μm, even at temperatures above 1000 K. For the control of the photonic resonance (B), we utilized rod-type PCs (Fig. 2 (B)). This structure exhibits resonance effects with a minimal Si filling factor, which is important for the suppression of non-resonant longer-wavelength emissions from the intrinsic free carriers generated at elevated temperatures.

Figure 3 shows examples of theoretical thermal emission spectra from the Si rod-type PC emitters at 1400 K. We designed two types of emitters: one was for Si PV cells (black solid line) and the other was for InGaAs or GaSb PC cells (gray solid line). It can be seen in the figure that near-infrared narrowband thermal emitters with suppressed longer wavelength components can be obtained.

Figure 2: (A) Theoretical absorption coefficient spectra of intrinsic Si. (B) Photonic crystal consisting of a square array of Si rods.

Figure 3: Theoretical thermal emission spectra of Si rod-type photonic crystal emitters for Si PV cells (black solid line) and InGaAs or GaSb PV cells (gray solid line).

3. Experiment

Figure 4 shows the experimental thermal emission spectrum of a Si rod-type PC emitter at 1400 K observed from the vertical direction [6]. The emitter was designed for InGaAs PV cells and fabricated on a MgO substrate. The MgO substrate is transparent at mid infrared region and resistant to high temperatures. It can be seen in the figure that thermal emission concentrated below ~1800 nm was experimentally obtained at the very high operating temperature of 1373 K. (We have previously realized Si-rod PC emitters for Si PV cells [5]).

In addition, we fabricated a TPV system by using the Si-rod PC emitters and PV cells, as schematically shown in Fig.

5. In this system, we placed InGaAs PV cells on both sides of the emitter, and formed reflectors at the backsides of the PV cells for the recycling of the spectral components not absorbed by the PV cells. The details, including energy conversion efficiency, will be discussed in the conference.

Figure 4: Experimental thermal emission spectrum of a Si rod-type photonic crystal emitter at 1373 K.

Figure 5: Schematic of TPV system utilizing a Si-rod photonic crystal emitter.

4. Conclusion

We have realized a near-infrared selective thermal emitter based on Si rod-type PCs on a MgO substrate, which can be operated at temperatures above 1300 K. A thermo-photovoltaic energy conversion system based on this emitter is also discussed.

Near field based energy applications – thermophotovoltaics and photonic refrigeration by controlling the chemical potential of photons

Linxiao Zhu, Anthony Fiorino, Dakotah Thompson, Rohith Mittapally, Edgar Meyhofer, and Pramod Reddy

Abstract:
We will talk about our recent experiments of near-field based energy applications. First, we will show a 40-fold enhancement of thermophotovoltaic electricity generation rates by maintaining a nanoscale gap between a thermal emitter and a photovoltaic cell. Secondly, we will show the realization of photonic refrigeration by controlling the chemical potential of photons. We achieved net cooling on a planar device by suppression of radiation from a reverse-biased photodiode, and enhancement of photon transfer from the planar device.
Resonant laser processing for fabrication of nanobiophotonic devices

Xiaolong Zhu, Airidas Žukauskas, Andreas Raimund Stilling-Andersen, Anders Kristensen

DTU Healthtech, Technical University of Denmark, DK-2800 Kongens Lyngby
Presenting author: xizhu@dtu.dk

Abstract
Functional nanophotonic devices realized by the state-of-the-art nanofabrication technologies have offered the control of light with nanoscale precision, which are boomingly used in advanced bio-sensors and bio-imaging systems. Most of the functional nanophotonic devices rely on the ability to precisely control its individual meta-elements within the subwavelength scale. The absorption in metallic or dielectric elements provides a new route for photo-to-thermal conversions and processing. Here, we introduce a resonant laser processing (RLP) technique as a flexible photo-thermal post-writing technology for mass-customization of optical devices.

1. Introduction
Optical functional devices with photonic crystals, plasmonics or metasurfaces are designed photonic textures which have the capability of manipulating the amplitude, phase, polarization, activity, spin and quantum-entanglement of light. They can be made on metallic as well as dielectric or hybrid materials with the state-of-the-art nanofabrication facilities. Their optical properties are defined by the material composition, geometry, arrangement, orientation, topology and environment of each meta-element. The absorption in metallic or dielectric meta-elements provides an avenue for photo-to-thermal conversions. We developed a resonant laser processing (RLP) technique as a flexible post-writing technology for mass-customization of optical devices.[1-4] Strong on-resonance energy absorption under pulsed laser irradiation locally elevates the lattice temperature of individual optical meta-elements in an ultra-short time scale. In the RLP process, rapid melting allows for surface-energy-driven morphology changes and sintering or annealing of individual meta-elements with associated modification of the optical properties of the reflected and transmitted light from the devices. By controlling of the RLP process, we can manipulate the material and structural properties of the optical devices with a very high precision. Combined with the use of prefabricated large-area templates, RLP is a promising approach for the fabrication of next-generation low-cost optical devices for bio-sensors and bio-imaging systems.

2. Result and discussion
A light trap was born after the invention of the laser, it came to be known as optical tweezers for its direct applications in capturing things by light induced pressure and force. Nano-scaled optical metalens with dielectric and metallic structures are popular light tapping structures.[5,6]

Figure 1: a. The concept of RLP, which is based on photo-to-thermal conversions and processing. b. Microscope image of ultrathin metalens printed onto silicon based metasurface templates. c. The characterized focus spot at the focus plane. Scale bars in b and c: 20 µm.
In this work, we report an in-line optofluidic light trapping device by introducing a metalens fabricated by nanosecond pulsed laser processing at the surface of a silicon metasurface.[7] We post-processed silicon based metasurfaces with morphology-dependent double resonances in the visible and in the near infrared. With the excitation of fundamental order resonance in the visible, the loss-assisted on-resonance photo-thermal melting of silicon ensures that the writing process only takes place at certain threshold, causing a resonance configured adaptive processing for resulting the desired metalens. Under coordinating the double-resonance phase matching condition dynamically, RLP in the visible allows for the morphology changes of the silicon metasurface with associated spatially modification of the optical phase and the transmittance in the near infrared by shifting the double-resonance coordinate.

Figure 1a shows the concept of laser printed flat optics by using a Nd:YAG laser (wavelength 532 nm, pulse length 2 ns)[4], illustrated by the writing of a Fresnel metalens on a silicon metasurface template comprising hybridized nanodisk and nanohole arrays[2]. Figure 1b presents an optical micrograph of the laser printed Fresnel metalens working at near infrared. We achieved a metalen with a full-wave-half-maximum of 2.29 um in the focus (Figure 1c), a focal length of 113 um and an efficiency of 16.98 %. The metalens is further integrated into an optofluidic devices for optical trapping experiments using a lasing wavelength of 1064 nm.[7]

3. Conclusions

In conclusion, as an alternative process to using state-of-the-art and expensive fabrication methods, we demonstrate that RLP is a powerful tool for the fabrication of ultrathin multi-functional optical devices. The concept of RLP makes the meta-optics closer to reality by providing a path for mass-production and ready-for-applications processes. This may pave the way of ultrathin flat optics into consumer nanobiophotonic products in the near future.

Abstract
Vertical antenna arrays of few-micron height and pitch, illuminated with a tunable mid-infrared laser, provide intense electric field hotspots far from the solid substrate. These hotspots do not suffer from the high thermal conductivity of the substrate and therefore, if a material with resonant vibrational fingerprint is present, thermal hotspots are generated, with local temperature increase of up to 100 K. Applications in nanoscale thermophoresis, photocatalysis and remote energy transfer are envisaged.

1. Introduction
Local photothermal effects produced by focused laser beams allow for fast and contact-less energy transfer to specific locations. In this context, plasmonic nanoantennas allow one to both circumvent the diffraction limit and obtain nanoscale thermal hotspots with very strong temperature gradients [1]. In the mid-infrared (IR) range, antenna arrays fabricated by lithography on solid substrates allow for the exploration of new designs for local heat generation, in which coherent enhancement of the e.m. field plays a key role [2]. We have previously developed vertical antenna arrays for use as sensors based on the Surface Enhanced Infrared Absorption (SEIRA). Indeed, due to SEIRA, the strong apical electric field hotspots can become a thermal hotspot generator if an IR-absorbing material is placed at the antenna apex (see sketch in Figure 1) [3].

2. Experiment
Nanoscale surface thermal hotspots with local temperature up to 400 K (with a base temperature of 295 K) are obtained by focusing a mid-IR laser beam on the antenna array. The laser is an external-cavity tunable quantum cascade laser (MIRcat-xB by Daylight Solutions) continuously tuned around the vibrational absorption line of target molecules (wavenumber resolution is 1 cm⁻¹). Typical power in pulsed mode is up to 300 mW. The temperature increase is indirectly visualized by recording the photothermal expansion signal with a silicon cantilever probe for atomic force microscopy (AFM-IR, NanoIR2 by Anasys Instruments). The actual value of the temperature increase in a sphere of diameter 300 nm (red circles in Figure 1) is determined by comparison with thermal simulations.

Figure 1. Sketch of the experimental setup. An AFM probe illuminated by a focused mid-IR tunable laser beam, senses the thermal expansion of a thin molecular layer on top of the vertical antenna array.

Figure 2: Electron microscope image of a vertical antenna array. Height is 2.7 µm. Antennas are fabricated by local amorphization of a polymer film by a focused ion beam, removal of the unexposed polymer, and gold evaporation.
The plasmonic structure consists of a square array of vertical gold-coated rods of height $h = 2.7 \, \mu m$, 250 nm in diameter, with an array pitch $p = 4.0 \, \mu m$ (Figure 2). When illuminated with a monochromatic mid-infrared radiation beam at specific resonant frequencies, set by coherent enhancement designed by carefully selecting both $p$ and $h$, the structure generates field-enhancement hotspots at the rod apexes. Embedding the antenna array in a polymer layer with low thermal conductivity, of thickness identical to the antenna height, results in a quasi-planar surface thermally isolated from the solid substrate. A strong IR-absorbing molecular layer (in this case, 120 nm thick film of hydrogen silsesquioxane, HSQ) is then located on top of the surface. HSQ has a vibrational fingerprint at 1070 cm$^{-1}$ ($\lambda = 9.3 \, \mu m$) whose intensity depends on the maximum temperature seen by the material [4], therefore the array was designed to resonate precisely at that IR wavelength. The absorption at 1070 cm$^{-1}$ of the material portion located on top of each antenna, measured by AFM-IR, was found to depend on laser power (Figure 3): the HSQ material undergoes a smooth transition from amorphous to reticule when the temperature increases, and the peak intensity at 1070 cm$^{-1}$ is a measure of the density of reticule bonds created by the temperature increase [4]. Finite-element simulations (COMSOL multiphysics, Figure 4) confirm that the $T$ increase if of the order of 1 K/mW in the hotspot region of approximately 300 nm diameter.

3. Discussion

The use of SEIRA effect as photothermal transducer instead of electromagnetic field dissipation in the metal also solves a long-standing contradiction of the generation of nanoscale thermal hotspots using metal antennas anchored on a solid substrate: to maintain the absorbed thermal energy in a nanoscale region of space, the photothermal transducer should feature low thermal conductivity, but metal films and solid substrates generally feature high thermal conductivity. The fundamental mechanism of SEIRA heating is the non-radiative decay of highly excited vibrational states, which is physically different from plasmon dissipation. SEIRA heating does not take place in the metal, but in the molecules forming the dielectric layer on the top of the antenna surface, which generally features low thermal conductivity. Therefore, with appropriate electromagnetic and thermal engineering, the contradiction can be solved and strong thermal hotspots can be obtained.

4. Conclusions

Local temperature increase of up to 100 K is obtained in hotspots with diameter around 300 nm at the apex of vertical antenna arrays with coherent plasmonic field enhancement in the mid infrared ($\lambda = 9.3 \, \mu m$). Applications in nanoscale thermophoresis, photocatalysis and remote energy transfer are envisaged.

Abstract
Bismuth-based nanostructures present unique optical properties related with their giant near-infrared interband transitions. At longer wavelengths in the infrared, their giant refractive index and small extinction coefficient make them efficient light harvesters. In this presentation, we explore the potential of different kinds of bismuth-based nanostructures (nanospheres, nanocylinders and nanolayers) for achieving a spectrally tunable perfect absorption of light in the mid-to-far infrared and discuss the suitability of such nanostructures for thermal photonics.

1. Introduction
Bismuth (Bi) and its chalcogenides (Bi, Sb, Te, Bi, Sb, Se, Bi, Sb, Te, Se,) are becoming increasingly appealing to the photonics community owing to their unique optical properties. Such properties arise from their peculiar electronic structure, which enables giant near-infrared interband transitions implying a negative dielectric permittivity in the ultraviolet-visible and a giant refractive index in the mid-to-far infrared. Such features are especially relevant to efficiently harvest light in nanostructures, because of plasmonic effects and strong dielectric confinement, respectively. Up to now, many works have aimed at harnessing the ultraviolet-visible plasmonic properties of Bi-based nanostructures, especially for applications in photocatalysis and for the development of thermally-switchable optical filters. In contrast, very few works have aimed at exploring the optical properties of Bi-based nanostructures in the mid-to-far infrared and their potential for thermal photonics. In this presentation, we report the mid-to-far infrared optical properties of bulk Bi and its chalcogenides. We show that nanostructures of such materials are excellent candidates to achieve a perfect absorption of light tunable over the mid-to-far infrared. Finally, we discuss the implication of these findings for thermal photonics. In particular, we consider the applicability of such nanostructures for thermal camouflage and the spectral shaping of thermal radiation.

2. Results
2.1. Optical properties of Bi and its chalcogenides
It is only a few years ago that the bulk optical properties of Bi and its compounds have been characterized accurately. Especially, we reported for the first time the broadband characterization of the refractive index and extinction coefficient of Bi from the far infrared to the ultraviolet. In a broad wavelength region from the mid infrared to the far infrared, it presents a giant refractive index (n ~ 10) and a small extinction coefficient (k ~ 1). Bi chalcogenides show comparable trends, yet with a slightly smaller n.

2.2. Spectrally tunable perfect absorption in Bi-based nanostructures
Because of their giant refractive index and small extinction coefficient, such materials are outstanding candidates for achieving a strong absorption of infrared light in nanostructures around selected wavelengths. The absorption mechanism depends on the type of nanostructure involved. For 3d-confined nanostructures such as nanospheres or nanocylinders, absorption is achieved by lossy dielectric Mie resonances. In 1d-confined nanostructures - or nanolayers - absorption can be achieved by designing resonant vertical cavities. In this presentation, we make an emphasis on the design of simple 1d- and 3d- confined Bi nanostructures enabling perfect absorption at selected wavelengths in the infrared. Especially, we demonstrate that very simple Bi/dielectric/metal resonant vertical cavities enable angle-independent perfect absorption in a Bi nanolayer more than 100 times thinner than the perfect absorption wavelength, and that such wavelength can be efficiently tuned from 3 to 20 µm by controlling the layer thicknesses. Such outstanding compactness and tunability stand on the surprising fractal interference mechanism of the cavity, which is enabled by the giant n and small k of Bi.

3. Discussion
Achieving perfect absorption of light in nanostructures at selected wavelengths in the mid-to-far infrared is of utmost importance for thermal photonics. Combining nanostructures absorbing at different wavelengths enables the design of very thin coatings with tailored reflectance matching the spectral regions considered for thermal camouflage applications. Furthermore, according to Kirchhoff’s law, such reflectance tailoring is also interesting for achieving very thin coatings with tailored infrared emissivity, and thus the spectral shaping of thermal radiation.
4. Conclusions

The unique optical properties of Bi and its chalcogenides make Bi-based nanostructures excellent candidates for achieving the perfect absorption of light at selected wavelengths in the infrared. They can be therefore be used as the building blocks of very thin coatings presenting a tailored infrared reflectance and emissivity, as required for thermal camouflage and the spectral shaping of thermal radiation. Interestingly, such very thin coatings do not require complex patterning and can even be fabricated with lithography-free processes, in contrast with usual thermal photonics solutions such as metal-based metasurfaces.

Abstract

Thermoplasmonic response of indirect (silicon, Si) and direct (gallium-arsenide, GaAs) bandgap semiconductor nanoparticles is studied and compared with the results from metallic (gold, Au) nanoparticles. Si nanoparticles present high values of quality factors for the resonances while the spectral selectivity of the absorption efficiency in GaAs nanoparticles is maintained at elevated temperatures in contrast to the Au nanoparticles. Furthermore, results from the multiscale modeling of plasmonically enhanced control of radiation using spherical semiconductor inclusions in a composite will also be presented.

1. Introduction

Plasmonically enhanced absorption or scattering of radiation on the mesoscale forms the basis of promising applications in a wide variety of fields such as: biosensing, photothermal therapy, photocatalysis, solvothermal chemistry, energy harvesting, magnetic recording for data storage, control of radiative heat transfer and so on [1, 2, 3]. In a major part of the applications based on plasmonics, noble metals - Au and silver (Ag) - have been the materials of choice. However, it is also now widely acknowledged that these materials suffer from problems of poor thermal and chemical stability accompanied by significant dissipative losses under high-temperature conditions. These issues have thus prompted a quest for materials with better thermoplasmonic properties. In this regard, semiconductor micro- and nanoparticles have lately attracted a lot of attention because they exhibit low ohmic losses, are thermochemically more stable, and exhibit highly tunable plasmonic resonances through bandgap engineering, control over dopant concentration and dielectric environment. Here, we present results from our recent work on the multiscale modeling of plasmonically enhanced control of radiation in composites with semiconductor inclusions [1, 2]. Furthermore, a comparison of the size-dependent thermoplasmonic behavior of undoped indirect (Si) and direct (GaAs) bandgap semiconductor nanoparticles with the metallic (Au) particles that are characterized by a complete absence of the bandgap is also presented [1].

Figure 1: A schematic illustrating the Monte Carlo model of propagating photons inside composites with scattering inclusions for modeling the transport of the incident radiation. An infinitesimally thin beam of incident photons is scattered within the composite layer until the photons are absorbed or exit the system. The random distribution of small open circles represents the inclusions that serve as scattering and absorption centers for the photons. The photon weight is progressively decremented as it executes a random motion in the composite. The direction of photon exit from the composite is characterized by the angle $\alpha$ in the Monte Carlo model. This angle $\alpha$ varies with each random trajectory and for a large number of photons cumulatively gives rise to diffuse reflectance or transmittance. $n_i$ and $n_f$ represent the refractive indices of the surrounding medium and the composite layer, respectively [2, 3].
Multiscale modeling of radiation transport in micro/nanocomposites is carried out using a three-step process [2]. The first step involves the computation of the temperature dependent dielectric permittivities for Au, Si and GaAs. Next, these temperature dependent dielectric permittivities are employed to numerically compute the Mie scattering and absorption coefficients along with the asymmetry factor that determines the proportion of forward- to back-scattered radiation. These characteristic Mie parameters for a spherical nanoparticle of given size are then utilized in a Monte Carlo algorithm to determine the reflectance, absorbance and transmittance spectra for a micro- or nanocomposite with particle inclusions at a low volume fraction of 1-5% (Figure 1) [2]. For the Monte Carlo simulations, the real part of the refractive index of the composite layer is computed using the Effective Medium Theory.

2. Theory and Methods

We have investigated the thermoplasmonic response of indirect (Si) and direct (GaAs) bandgap semiconductor nanoparticles and compared it to that of metallic (Au) nanoparticles [1]. Furthermore, we have studied the temperature dependent multiscale radiative transport in composites of these materials [2, 3]. Our results indicate that, unlike metallic nanoparticles, semiconductor nanoparticles allow for a much better control of radiation on the nanoscale because of the stability of their scattering and absorption resonances at elevated temperatures. This renders them particularly promising for thermoplasmonic applications such as solar thermophotovoltaics, photocatalysis, and solvothermal chemistry that require operating at high temperatures for desired optimal performance.

3. Results and Discussion

A broadening and redshifting of the scattering and absorption resonances with an increase in the temperature and the particle radii is observed in nanoparticles of all three materials including Au, Si, and GaAs [1]. Our results indicate that semiconductor nanoparticles maintain the strength of their scattering and absorption resonances at high temperatures compared to the metallic Au nanoparticles (Figure 2). Enhanced absorption resonances at elevated temperatures are observed due to the phonon-mediated interband electronic transitions in the indirect bandgap Si nanoparticles at shorter wavelengths. On the other hand, the magnitude of the absorption resonances for the direct bandgap GaAs nanoparticles stays close to constant for similar wavelengths at higher temperatures. Si and GaAs nanoparticles exhibit Fano resonances, in both the scattering and absorption spectra, due to the presence of sharp higher order electric and magnetic Mie resonances against a background of broad quadrupole or dipole modes. The ratio of the radiative to dissipative damping decreases with an increase in temperature for all the nanoparticles. However, this ratio is observed to be about 1-2 orders of magnitude greater for the Si and GaAs nanoparticles. This points to the excessive heating of Au nanoparticles at elevated temperatures due to increased Drude damping of plasmonic resonances and enhanced absorption at longer wavelengths.

Abstract

Wavelength-selective light absorbers and emitters, or spectroscopic energy transducers for light, are expected to provide wide variety of applications in energy harvesting, remote and perceptive sensors for IoT devices. Especially, narrowband perfect absorption and emission in the infrared (IR) region are critical prerequisites for modern spectroscopy and energy applications such as non-dispersive infrared (NDIR) gas sensors, multi-wavelength pyrometers, IR radiative heaters, and thermophotovoltaics. The technology to control thermal emission and absorption is rapidly progressing recently with the development in the field of plasmonics and metamaterials. In this talk, we demonstrate our methodology to achieve narrowband perfect absorption and thermal emission based on 2D and 3D nano architectures combined with IR plasmonic materials [1-6]. We introduce some of our recently developed uncooled infrared detectors combined with spectroscopic perfect absorbers for wavelength-selective infrared ray detection. The MIM metamaterial IR sensors with pyroelectric/thermoelectric detection exhibit resolutions better than 1μm with wide acceptance angles. By adopting Gires-Tournois structures (asymmetric Fabry-Perot resonators), Tamm plasmon polariton, and aperiodic structures composed of low-loss dielectrics and metal reflectors, wavelength resolution better than 50 nm was achieved at operation wavelengths in the mid infrared region. The same design can be adopted also to narrowband thermal emitters when it is fabricated with refractive dielectrics and conductive ceramics.

1. Introduction

Perfect narrowband absorption and emission in the infrared (IR) region are critical prerequisites for modern spectroscopic applications such as multi-wavelength pyrometers, non-dispersive infrared (NDIR) gas sensors, IR radiative heaters, and thermophotovoltaics. Within the past decade, artificial photonic structures, such as plasmonic metamaterials and photonic crystals, have been used to realize spectrally selective absorbers and emitters. We present our recent study on the development of perfect absorbers based on the metal-insulator-metal structures. We also discuss the design and the fabrication of narrowband perfect absorption based on several different layered structures, such as Gires–Tournois (GT) etalon (Assymmetric Fabry-Perot resonator), Tamm-plasmon polariton, and aperiodic layered structures. The MIM metamaterial IR sensors with pyroelectric or thermoelectric detection exhibited resolutions better than 1μm with wide acceptance angles. By adopting GT structure with, the wavelength resolution goes lower than 50 nm at resonance wavelength of 3-4 μm. Such structures also shows sharp thermal emission when they are fabricated with refractory materials and heated at high temperatures. These devices will open a new avenue for potential applications in multiband temperature sensing, infrared-color imaging, and NDIR gas sensors for security gas sensors and combustion analysis.

2. Discussion

Figure 1a shows the photo of a fabricated four-wavelength detector, which has a width of 0.5 cm and length of 1 cm. This design demonstrates the hybrid plasmonic-pyroelectric device can be easily integrated on a standard CMOS platform and achieve multispectral selectivity without any additional bulky optical filters. Figure 1b shows the optical microscopy images of the top view and back view of a single sensing element with an active area of 200 x 200 μm. The sensing area is thermally well-isolated from the body of the device.

The scanning electron microscope (SEM) images of the hexagonal arrays of Al disk resonators (Figure 2 a-d) shows that the Al disk array fabricated on top of the membrane structures is well-defined and homogeneously distributed. The simulated absorption spectra are shown in Figure 2e. The reflectivity spectra of the fabricated devices were measured using a Fourier transform infrared spectrometer with a microscope. The reflectance spectra were normalized with respect to the reflectance from a gold film. The absorptivity values were 0.92, 0.93, 0.85, 0.87 at 3.3, 3.7, 4.1 and 4.5 μm, and the wavelength resolution were 0.94, 1.02, 1.1, 1.2 μm FWHM, respectively. The fabricated device demonstrated the spectrally selective detection of IR radiation in the range of 3.3 to 4.5 μm, that locates in the atmospheric window, and exhibited the FWHMs in the
range of 0.9 to 1.1 μm, and the spectral responsivities of 125-128 mV/W, respectively. These results demonstrate the feasibility and great potential for MEMS-based multispectral hybrid plasmonic-pyroelectric infrared detector with remarkable wavelength tunability, compactness, and high spectral resolution.

3. Conclusions
We have demonstrated that metal(disk)-insulator-metal(plate) structures and 1D layer structures, such as Gires-Tournois (GT) Asymmetric cavity structures, can be utilized as high-efficiency narrowband photothermal transducers working in the infrared region. The quad-wavelength pyroelectric microsensors were fabricated for multicolor IR sensing application and exhibited excellent wavelength selectivity. The GT layered structure exhibited very high wavelength selectivity with sharp resonant absorption at the vibrational peak of methane (3.3 μm) with an excellent quality factor of 151, which is higher than that of any layered-type uncooled infrared detectors studied so far.

Figure 2. (a-d) Scanning electron microscope (SEM) images of the fabricated disk array patterns at four resonance wavelengths. (e), (f) Simulated and measured absorptivities of the perfect absorbers at four wavelengths.

Next we directly integrated a distributed Bragg reflector 3(SiO$_2$–Si)–SiO$_2$–based GT resonator onto a pyroelectric LiTaO$_3$ single-crystal slab [6]. We intentionally chose Al as the material for the back reflector for three reasons: first, it exhibits low-loss and high-optical response plasmonic properties similar to Au and Ag in the near-to-mid IR region; second, no adhesion layer is required to fix the oxide layer on Al; and third, Al is widely used as one of the industry-compatible base metals.

Figure 3. Gires-Tournois resonator-based narrowband pyroelectric IR detector fabricated by adopting DBR-cavity-metal design and loaded on LTO single crystal slab: (a) schematic illustration, (b) measured reflectivity and spectral responsivity[6].

The spectral responsivity curve exhibited an absorption peak at 3.3 μm, which matches to the absorption band of water and methane. The FWHM of the reflectivity spectra is as narrow as 22 nm, corresponding to a Q-factor of 151, which is two to four times higher than that of recently reported multilayered absorbers and detectors base on photothermal transduction. To the best of our knowledge, this is the first time that an on-chip GT resonator-based perfect absorber achieves such a high spectral resolution.
Photothermal epoxy curing with plasmonic nanoparticles: From modeling to experiments

Abstract

Epoxy materials are widely used for efficient bonding and repair of composite materials. Plasmonic nanoparticles can be employed as heat source to improve curing of epoxy films. We theoretically show how the nanoparticle-assisted photothermal curing is a four-stage process: a rapid plasmonic temperature increase, a slow curing initialization, a temperature increase due to cured epoxy direct light absorption and a final stage that completes the chemical transformation. Experiments confirm theoretical predictions and further demonstrate how the plasmon-assisted curing forms stronger bonds than conventional thermal curing.

1. Introduction

Composite materials have been replacing metals in several sectors (e.g. aviation, automotive, robotics) to improve performance. Unlike metals, composite materials often require heat during their assembly and lifecycle. For example, during repairing, high-temperature epoxy resins are regularly employed to bind composite materials. Usually this process requires oven heating, thus posing significant challenges when large parts need to be treated or when components include temperature sensitive materials. The possibility to selectively dissipate heat in localized regions to trigger the epoxy curing only where it is needed would be crucial in this field. When two composites need to be joined, the epoxy is deposited at their interface, and this is the only region which actually requires heat. Laser heating represents a possibility for the curing of buried junctions in the wavelength range where the composite is partially transparent to the radiation. However, the approach can be inefficient if the epoxy is a weak absorber in its uncured state.

Recently, it has been shown that nanoparticles close to their plasmon resonance act as efficient heaters and enable in situ epoxy curing [1,2]. In our study we examine a different regime where plasmonic nanoparticles are combined with an epoxy resin transparent to laser radiation in its uncured state and absorptive upon curing [3]. This combination allows for an initial localized temperature increase through plasmonic nanoparticles followed by a self-reinforcing process given by the epoxy absorption. The synergetic effect allows the curing of buried junction at lower laser powers, thus preventing potential damages to components in proximity to the interface.

Figure 1: A - Temperature (solid black), curing state (dashed red) and curing rate (dotted blue) dependence on time (log scale) of a 40 nm Au nanoparticles covered FM 300 epoxy film. B - Comparison between experimental results (dotted blue) and theoretical calculations (solid black) for the temperature increase of a FM 300 epoxy film sample over time. An input power of $P_{in} = 5$ W/cm² and a nanoparticle density $\rho_{NP} = 2.2 \cdot 10^{10}$ NP/cm² are considered. [3]

The concept is of general interest since interrelated optothermal properties need to be analyzed whenever nanoparticles are placed in a temperature sensitive matrix, such as biological tissues, polymers or phase-changing media. Here we give a detailed theoretical time-dependent description of the steps involved in the nanoparticle-assisted photo-thermal curing process, identifying four major thermal...
regimes. Experiments confirm theoretical predictions and, additionally, demonstrate how the resulting bonds are stronger than conventional thermal curing.

2. Results and discussion

The investigated system consists of a 2-dimensional random array of 40 nm Au nanoparticles (NPs) sandwiched between a supporting glass and a 0.2 mm epoxy film. The sample is laser irradiated at a wavelength of 532 nm while the temperature is measured through an infrared (IR) camera. A Finite Element Method (COMSOL) model has been developed to describe the electromagnetic and thermal processes accurately [3]. Fig. 1A shows the calculated temperature (black, solid), cure progress (red, dashed) and cure rate (blue, dotted) at the center of the epoxy film from the time the laser is switched ON until the resin is fully cured. Four distinct opto-thermal phases can be identified. (i) **Plasmonic heating (pink region)** – Temperature quickly increases due to the efficient heat dissipation in the nanoparticles: during this phase the cure progress is close to zero while the cure rate starts increasing. (ii) **Initial curing phase (green region)** – A first temperature plateau is reached at ~130°C where the cure begins while the curing rate remains approximately constant. (iii) **Acceleration phase (tan region)** – The curing rate reaches its peak due to the increasing optical absorption in the epoxy glue. As consequence, the cure state rapidly increases. (iv) **Final curing phase (light blue region)** – Both the heat generated in the NPs and within the epoxy are balanced by the heat exchanged with the background. The final temperature plateau (~200°C) is reached when the curing rate stops as the chemical transformation is complete. Fig. 1B shows the comparison between theoretically predicted and measured temperature in the case of a FM300 epoxy covered by a Au NPs array (2.2 NPs/cm²) heated by a scanning laser at 532nm, with incident intensity 5W/cm². All four curing stages described above can be recognized in the temperature measurements.

![Image](image-url)

**Figure 2:** Lap shear measurements for four samples of increasing nanoparticle concentration: 0, 5.5⋅10⁹ NP/cm², 1.1⋅10¹⁰ NP/cm², and 2.2⋅10¹⁰ NP/cm², following identical photocuring conditions of laser intensity (1.55 W/cm²), illumination area (1 in x 1 in), and duration (30 min). [3]

To test the efficacy of the plasmonic NPs assisted bonding, four samples, partially cured using different NP concentrations, have been mechanically tested. The parameter of interest is the maximum load that a bonded junction can sustain. Fig. 2 shows lap shear measurements in which the samples were pulled along the bond axis until the bond broke. The sample cured employing the largest density of NPs (~22⋅10⁹ /cm², pink line) failed at 1800 N (407 lbs). The sample cured without NPs failed at 1300 N instead. Further numerical analyses and experiments [3] confirm the important interrelations among the parameters employed for the process. The four curing stages can be tailored in terms of duration and temperature levels not only by modifying the laser power but also by changing the nanoparticle density, shape, and material. Different nanostructures can be considered to interact with radiation at different wavelengths, thus widening the range of applications of this approach.

3. Conclusions

We have theoretically and experimentally investigated how laser bonding of composite materials can take advantage of plasmonic nanoparticles for a better performing photo-curing process. The concentrated heat dissipated in the nanoparticles provide a localized thermal source which promotes a faster curing and leads to stronger bonds. Upon curing, the epoxy itself starts absorbing laser radiation in a self-sustaining heating process. The local nature of the efficient plasmon heat generation avoids the exposure of thermally sensitive parts to high temperatures and represents a major improvement for practical bonding of composite materials. Earth abundant materials (e.g. aluminum) and other epoxies may be utilized to ease the commercialization of this approach.

Thermo-plasmonics on vanadium oxide and silicon-based infrared sensor platforms

Xu Fang

School of Electronics and Computer Science, University of Southampton, UK  
E-mail: x.fang@soton.ac.uk

We present recent experimental and numerically simulated results in integrating plasmonic nanostructures with vanadium oxide and silicon thin films for developing infrared sensors with various functionalities. We also present a theoretical model, the modified Maxwell Garnett model, for interpreting hysteresis in vanadium dioxide.

A microbolometer is a type of photodetector that utilises the dependence of material resistivity on temperature in the light detection. Its unique properties such as extremely broadband response and room-temperature operation have led to its widespread use in various applications. Its relatively simple sensor structure, at the same time, provides an ideal platform for nanoengineering.

We demonstrate both numerically and experimentally that plasmonic nanostructures fabricated on top of thin films of vanadium oxide and silicon, the two most commonly used sensing materials in microbolometers, regulate the distribution of light and heat at the nanoscale. This phenomenon is used to develop functionalities such as wavelength and polarisation sensitivity in the photodetection [1]. This result may be used to improve the performances of a variety of vision systems in the infrared.

We further present a theoretical model for interpreting optical hysteresis, where the optical properties of a material depends on not only the current temperature but also those in the history [2]. Hysteresis is a phenomenon that crucially affects the performances of vanadium oxide-based infrared sensors. The standard Maxwell Garnett model, a theoretical model widely used in effective medium analysis, is modified here to allow it to be used in hysteresis analysis. The model requires very few input parameters, providing a phenomenological approach to describing electromagnetic hysteresis in not only vanadium dioxide but also may other phase change materials.

Thermal emission engineering
with confined plasmons in semiconductors

Angela Vasanelli, Simon Huppert, Yanko Todorov, Djamal Gacemi, Carlo Sirtori

Laboratoire de Physique de l’Ecole normale supérieure, ENS, Université PSL, CNRS, Sorbonne
Université, Université Paris-Diderot, Sorbonne Paris Cité, Paris, France

Email: angela.vasanelli@ens.fr

Bulk plasmons are collective excitations of a three dimensional electron gas. As any quantum entity, also plasma waves undergo size confinement when they lay in a thin film with thickness smaller than their wavelength. The resulting confined plasmon modes are called Berreman or Ferrel – Berreman modes and they are coupled to free space radiation. Consequently, in the earliest works on plasmons, the confinement has been exploited to probe their existence through the measurement of transmittance, reflectance and absorbance of thin metallic films [1–4].

Bulk plasmons can also be confined in highly doped semiconductor layers. In this case Berreman modes are in the mid-infrared range, at wavelengths set by the doping, and are characterized by a sharp resonance with quality factor in order of 20 [5].

In the last years, we have established that Berreman modes are strongly coupled with mid-infrared radiation. We have demonstrated that, when a Berreman mode is coupled to a resonant microcavity mode, the ultra-strong light-matter coupling regime can be achieved up to room temperature, with a record value of 92% of the relative Rabi energy [6]. Furthermore, such a phenomenal interaction with the electromagnetic field appears also in the absence of a microcavity and it gives rise to superradiance [7].

In this talk we will present how the strong interaction of confined plasmons with the electromagnetic field has been exploited to engineer active and functional mid-infrared thermal emitters [8,9]. In our devices, based on highly doped GaInAs layers, the electron gas is excited by a current flowing in the layer plane, allowing frequency modulation of thermal emission up to 50 MHz. Optical emission is engineered by exploiting the strong interaction of the plasmons with the electromagnetic field. In the superradiant regime a critical coupling sets the plasmon radiative decay equal to the excitation rate (~ps⁻¹) [8]. This allows realizing directional and quasi-monochromatic incandescent sources without using any photonic structure, but only exploiting the superradiant nature of plasmons. On the other hand mid-infrared plasmons ultra-strongly coupled with the fundamental mode of a suitably designed metallic microcavity generate THz emission [6].

Abstract

Dynamic and successive control of thermal emissivity are critical problems for related applications such as radiative heat management and thermal camouflage. Previous experimental works have not explored the ability of spatial resolved emissivity control with large dynamic range and reconfigurability. In this work, phase transition material (vanadium dioxide, VO2) as a dynamic element is deployed to enable dynamic emissivity modulation. Large dynamic range of emissivity during phase transition (0.2@insulator phase VO2 and 0.9@metallic phase VO2) is achieved with designed planar structured cavity. By exploiting the hysteresis of VO2 partial phase transition, successive control of emissivity is partially achieved in this device which has shown spatial resolved multilevel emissivity modulation at ~69 °C in experiment. The results of this work show potential applications of phase transition material based devices in the field of thermal information management in a feasible way.
Porous Thermochromic Nano-composite for Smart Window Systems

Abstract
Nano-porous thermochromic VO2 thin film has been studied as a smart coating in a fenestration system to gain thermal modulation ability depending on the ambient temperature. Both analytical calculation and numerical simulations have been carried out to study the optical performance of the porous thin film. Additionally the functionality of the designed coating on glass has been characterized for the special needs of a smart window.

1. Introduction

About 40% of the primary energy used in the European Union is connected with the buildings sector. Up to 60% of the total energy loss of a building is coming from its windows. For achieving sustainable buildings, many fenestration systems have been proposed [1]. In our research, thermochromic material vanadium dioxide (VO2) is explored for a smart window design. VO2 is a thermochromic material [2], that undergoes a reversible metal-semiconductor transition at a critical temperature (Tc) of 68˚C. Above Tc, VO2 film is highly reflective for near-IR and functions as a heat barrier to reduce energy consumption due to cooling and air-conditioning. Thermochromic materials switch passively and therefore do not need an external switching system, leading to a simple and low cost smart window design. Even though decades of research on VO2, the main challenges to further bring it to the market remain till this day: the high switching temperature Tc, low luminous transmittance Thum and the solar modulation ability ΔTsol. In this paper we propose a porous thin film construction of VO2 thin film aiming to solve some of the above issues.

2. Porous VO2 thin film and smart windows

Tc can be reduced by metal ion doping to the room temperature (20-30˚C). However, the doping often leads to low Thum and undesirable ΔTsol. To obtain higher Thum and ΔTsol various approaches have been developed, such as nanothermochromic [3], porous films [4, 5], biomimetic surface structures [6], multi-layered coating [7], etc. Nano-porous VO2 structures can be relatively easily realized through coating process. The nano-porous thin film is a promising construction to increase the Thum and to improve on the color appearance of the coating.

2.1. Design of functional nano-porous VO2 thin films

The functionality of the coating for fenestration system can be quantified using luminous transmission Thum and solar modulation ΔTsol. Luminous transmission is defined as the transmission of the sunlight through a coating or a system in the visible light range:

\[
Thum = \frac{\int_\lambda \phi_{\text{thum}}(\lambda) \cdot T(\lambda) d\lambda}{\int_\lambda \phi_{\text{thum}}(\lambda) d\lambda}
\]

where \(\phi_{\text{thum}}\) is the sensitivity of human eye, \(T\) is the transmission spectrum and \(\lambda\) is the wavelength. The solar transmission can be defined as:

\[
Tsol = \frac{\int_\lambda \phi_{\text{sol}}(\lambda) \cdot T(\lambda) d\lambda}{\int_\lambda \phi_{\text{sol}}(\lambda) d\lambda}
\]

where \(\phi_{\text{sol}}\) is the solar spectrum. Then the solar modulation is the difference of the solar transmission of the thermochromic coating at high (above Tc) and low (below Tc) temperatures:

\[
\Delta Tsol = Tsol_{\text{low}} - Tsol_{\text{high}}
\]

2.2. Optical modelling of the nano-porous structure

When nano-pores are present in a thin film, the effective refractive index of the mixture medium can be calculated using effective medium approximations (EMAs) [8], those include Maxwell-Garnett (MG) theory, Lorentz-Lorenz (LL) model and Bruggeman (Br) theory. Then the porous thin film can be treated as a homogeneous thin layer in a multilayer system to calculate the transmission, reflection and absorption of the stack using any multilayer solver. To test the accuracy of the EMAs and to choose the most suitable model, the Finite Element Method based rigorous
full wave simulations are performed to compare the calculation results.

2.3. Results

The optical performance of the glass coated with nanoporous VO$_2$ thin film is calculated with both EMA plus transfer matrix method (TMM) and FEM solver COMSOL [9]. The comparison of the calculation results are shown in Figure 1.

Figure 1: Comparison of the multilayer calculation results of using EMA+TMM and FEM.

We have found that the MG theory gives the best matching with FEM simulation result. Therefore it is chosen as the EMA for the rest of the calculation done in this paper.

2.4. Design for smart windows

For a smart thermal modulating coating on windows, the thin film or the coating should have $T_{\text{lam,low}}>0.6$ and $\Delta T_{\text{sol}}>0.1$. To achieve those goals, the porous VO$_2$ thin film has been studied for varying porosity and layer thickness and the results are shown in Figure 2.

Figure 2: Left: $\Delta T_{\text{sol}}$ and right: $T_{\text{lam,low}}$ of the porous VO$_2$ thin film for varying porosity and layer thickness.

Furthermore, we have analyzed the color appearance of the coated glass using colorimetry [10]. The result is shown in Figure 3. The transmission color of the porous VO$_2$ thin film becomes more neutral when the porosity increases and layer thickness reduces as expected. The color neutrality is a very important aesthetic criteria for a fenestration system. However to make the system smart with thermal modulation ability, the coating should contain sufficient thickness and restricted porosity. A trade-off between those factors yields a design of a desired product.
Mid-IR emission at high modulation rates with incandescent metasurfaces

Abstract

We report a numerical and experimental study of a metasurface patterned with arrays of nanowires, that reaches an emissivity close to 1 at 4 microns and can be operated at modulation rates up to 50 MHz.

1. Introduction

Light sources such as LEDs suffer from a significant decrease of their performances, in particular of their efficiency, when operated in the mid-infrared. In contrast, whereas it is easy to use thermal emission to generate blackbody radiation in the mid-infrared, the intrinsic slowness of the cooling of a thermal emitter generally prevents thermal sources from being modulated faster than a few hundreds of Hz. Here, we aim at developing incandescent sources operating a

2. Discussion

In this work, we use a different approach and circumvent the issue of cooling time by using tiny sub-wavelength thermal emitters [1] deposited on a cold substrate. The design is based on a local form of Kirchhoff law recently introduced [2]. We use 20 nm thick platinum wires that can cool down by thermal diffusion on a few nanosecond time scale so that they can be switched on and off up to a few tens of MHz. The dimensions of the wires and the spacer are designed to achieve total absorption at a given wavelength in the platinum. Using a local version of the Kirchhoff’s law, we show that such a structure with good absorptivity also has a good emissivity in the IR.

Our design consists of a grating of thin platinum wires that act both as thermal emitters and as nanoantennas. Its dimensions are optimized to maximize the absorption cross-section of the wires in the infrared. Thus, we tailor the surface of a substrate to create a metasurface. Finally, we apply an electrical current to heat the wires by Joule effect. We report experimental data showing thermal emission in the mid-infrared using this process. By modulating the heating current at high frequencies, we observe a modulation of the thermal emission at rates up to 30 MHz.

Parity-Time and related symmetries in Photonics, Plasmonics, Acoustics
Chiral symmetry in non-Hermitian systems: product rule and Clifford algebra

Li Ge

Department of Physics and Astronomy, College of Staten Island, CUNY, Staten Island, NY 10314, USA

Abstract

Chiral symmetry provides the symmetry protection for a large class of topological edge states. It exists in non-Hermitian systems as well, and the same anti-commutation relation between the Hamiltonian and the chiral operator, i.e., \( \{ H, \Pi \} = 0 \), still warrants an energy spectrum that is now symmetric about the origin of the complex energy plane. Here we show two general approaches to construct chiral symmetry in non-Hermitian systems, with an emphasis on lattices with detuned on-site potentials that can vary in both their real and imaginary parts. One approach relies on the simultaneous satisfaction of both non-Hermitian particle-hole symmetry and a non-Hermitian bosonic anti-linear symmetry, while the other utilizes Clifford algebra satisfied by the Dirac matrices.

Chiral symmetry plays an important role in the study of topological phases of matter [1, 2]. It warrants that the energy spectrum of the system is symmetric about a well-defined energy level, such as the Fermi level or the energy of an uncoupled orbital, which is chosen as the zero energy. Recently [3], the exploration of chiral symmetry in non-Hermitian systems [5] has also attracted fast growing interests, especially with the advent of topological photonics and lasers [6]. In non-Hermitian systems, the energy spectrum is complex in general, and chiral symmetry, defined by the anti-commutation relation of the Hamiltonian and a linear operator, warrants that the complex spectrum is symmetric about the origin of the complex energy plane. As a consequence, a non-Hermitian zero mode, with its energy right at the origin of the complex plane [3], can still exist similar to its Hermitian counterpart.

The easiest way to construct a non-Hermitian system with chiral symmetry is to start with a Hermitian system with two sublattices (such as in a tight-binding square or honeycomb lattice) and no detuning between onsite potentials. One then introduces asymmetric couplings that lift the Hermiticity of the system [3], which can be applied to both periodic [4] and non-periodic systems. This approach, however, does not utilize one important benefit provided by the non-Hermitian platforms in optics and photonics [5], namely, the availability and tunability of gain and loss, which is represented by an imaginary detuning between different lattice sites.

To eliminate such restrictions, we propose in this work two general approaches to construct non-Hermitian chiral symmetry. In the first approach we introduce a product rule where chiral symmetry, denoted by \( \Pi \) below, results from the simultaneous satisfaction of non-Hermitian particle-hole (NHPH) symmetry [3, 4, 7, 8, 9] and a non-Hermitian bosonic anti-linear symmetry. The former is defined similarly to its Hermitian counterpart, i.e., with the Hamiltonian \( H \) anticommuting with an antilinear operator \( \Xi \); the latter is defined as a commutation relation between the Hamiltonian and an antilinear operator \( \Lambda \), with parity-time symmetry [10] being a specific example. As we will exemplify below, the advantage of this approach lies in the fact that both NHPH symmetry and bosonic anti-linear symmetry are straightforward to implement in optics and related fields. One example is shown in Fig. 1.

In the second approach, we discuss how Clifford algebra can be used to generate non-Hermitian chiral symmetry for \( 4 \times 4 \) Hamiltonians, independent of NHPH and bosonic anti-linear symmetries. Through the discussion of several
examples, we show that the Dirac matrices can be arranged to maintain chiral symmetry in the presence of complex detunings between on-site potentials. Given by
\[ \gamma^0 = \begin{pmatrix} 1_2 & 0 \\ 0 & -1_2 \end{pmatrix}, \quad \gamma^j = \begin{pmatrix} 0 & \sigma_j \\ -\sigma_j & 0 \end{pmatrix} \] (j = 1, 2, 3) \tag{1}

in terms of the identity matrix and Pauli matrices, the Dirac matrices are used in the Dirac equation to describe relativistic quantum mechanics. Together with
\[ \gamma^5 = \begin{pmatrix} 0 & 1_2 \\ 1_2 & 0 \end{pmatrix}, \] \tag{2}
they satisfy the Clifford algebra
\[ \{\gamma^\mu, \gamma^\nu\} = 2\eta^{\mu\nu}1_4 \quad (\mu, \nu = 0, 1, 2, 3, 5), \] \tag{3}
where \(\eta^{\mu\nu}\) is a (diagonal) metric with signature (+, −, −, −, +).

This defining property of Clifford algebra is particularly appealing in the construction of chiral symmetry: by designing the Hamiltonian as a superposition of the Dirac matrices, we have a straightforward way to determine its chiral operators. As a simple example, let us first consider
\[ H = g_1\gamma^5 - g_2\gamma^1 \] \tag{4}
depicted schematically in Fig. 2(a), featuring one symmetric coupling and one asymmetric coupling. Using Eq. (3), we know immediately that its chiral operators can be \(\gamma^0, \gamma^2, \gamma^3\) as well as \(g_2\gamma^5 - g_1\gamma^1\) upon proper normalization. In addition, we also note that
\[ \{\gamma^j, \gamma^k, \gamma^l\} = 0 \] \tag{5}
holds when \(j \neq k\) and \(l = j\) or \(k\) (otherwise \(\{\gamma^j, \gamma^k, \gamma^l\} = 2\gamma^j, \gamma^k, \gamma^l\}). Therefore, \(\gamma^1, \gamma^5\) is also a non-Hermitian chiral symmetry in this case.

If the Hamiltonian contains the product of two Dirac matrices, for example,
\[ H = g_1\gamma^5 + g_2\gamma^0\gamma^1 \] \tag{6}
as shown in Fig. 2(b), it remains a simple task to verify that the chiral operators can be \(\gamma^0, \gamma^1\) using Eq. (5). In addition, by noticing the relation
\[ \{\gamma^j, \gamma^k, \gamma^l\} = 0 \quad (j \neq l \neq k, k = 1, 2, 3), \] \tag{7}
we also identify \(\gamma^1/\gamma^5\) as another non-Hermitian chiral symmetry.

We will discuss more complicated constructions using Clifford algebra. Here we just note that the two examples given in Fig. 2 still have two sublattices without detuning. Therefore, we naturally expect them to have chiral symmetry with respect to the operator \(P_A - P_B\), where \(P_{A,B}\) are the sublattice projection operators. The difference of these two sublattice projection operators is exactly \(\gamma_0\) in this case, but the more general analysis based on Clifford algebra has revealed that these systems have many more chiral operators of different forms.

Figure 2: Systems with non-Hermitian chiral symmetry constructed by simple combinations of the Dirac matrices. The couplings \(g_1, g_2\) are not restricted to be real.

Abstract
It is shown that inhomogeneous broadening of the spectral line of active impurities may sustain simultaneously parity (P) and time (T) symmetries of a medium, in a finite range of field frequencies, what is forbidden by the causality principle in media without broadening. If a spectral width of a propagating pulse is less than the inhomogeneous broadening, the medium for such a pulse becomes quasi-PT-symmetric. The effect of the broadband quasi-PT symmetry in a finite frequency domain, is illustrated by examples of unidirectional diffraction of pulses in Bragg and Laue geometries, propagating in photonic crystals.

1. Introduction
The concept of parity-time (PT) symmetry in the non-Hermitian optics requires delicate balance between real and imaginary parts of the dielectric permittivity [1,2]. The last requirement for the distribution of absorption and gain, described by the imaginary part of the dielectric permittivity, strictly speaking, is applicable for a given frequency of light. This point has fundamental importance in optical applications, in view of the causality principle. Mathematically, this is expressed through the Kramers-Kronig relations, which can be satisfied only for isolated frequencies [3]. Therefore, the major development of the PT-symmetric optics is achieved, so far, within the paraxial approximation proposed in [2], rather than with optical pulses, as initially suggested in Ref. [1].

In the present work we show that imperfectness of atomic resonances may allow for sustaining PT symmetry in strongly dispersive media. The PT-symmetric optical properties are significantly restored for broadband radiation if the width of the pulse spectrum δω is substantially less than the width of the inhomogeneously broadened spectral line γ_r of a resonant dispersive medium. We call it quasi-PT symmetry for broadband radiation [4]. Media with inhomogeneously broadened spectrum line are suitable for exploring short pulse dynamics in quasi-PT-symmetric environment.

2. Unidirectional zero diffraction and a spatially localized pulse dynamics in a quasi-PT-symmetric structure
Using spectral method [4] we solve the boundary diffraction problem of picoseconds pulse propagation in quasi-PT-symmetric photonic crystals (PhC) with strong material dispersion under condition of dynamical Bragg diffraction in Laue and Bragg schemes (Fig. 1) beyond the paraxial approximation.

Figure 1: Schematic illustration of the Bragg (left panel) and Laue (right panel) diffractions [4]. Solid and dashed arrows show the central wave-vectors of the pulses incident from the left and right (Bragg diffraction) and with positive and negative incidence angles (Laue diffraction). Red and blue arrows correspond to the pulses reflected and transmitted by the PhC. The central wave-vectors of resonantly interacting waves in the PhC, q_i and q_f, are also shown.

Figure 2 shows the amplitudes |A_i(t)| illustrating the phenomenon of unidirectional diffraction reflection of an incident Gaussian pulse by a layered medium in the Bragg geometry for the left (upper row) and right (lower row) incidence at exact exceptional point (EP) and Bragg condition. The phenomenon consists in propagation of the pulse incident from the left hand side of the layered medium [Figs. 2(a) and 2(e)] with negligible reflection and strongly enhanced diffractionally reflected signal in the case of right incidence [Figs. 2(b) and 2(f)].

In presence of weak inhomogeneous broadening, a wide quasi-monochromatic nano-second pulse is totally transmitted [reflected] at the left, Fig. 2(a) [right Fig. 2(b)] incidence. However for the same medium but for a short
The intensity of the pulse field $\gamma_2^* \sim \delta \omega$ and $\gamma_2 \gg \delta \omega$.

pico-second pulse having spectral width $\delta \omega \sim \gamma_2^*$, the PT-symmetric effects are strongly suppressed. Now one observes partial transmission and reflection of the pulse for both left [Fig. 2(c), c.f. panel (a)] and right [Fig. 2(d), c.f. panel (b)] incidence. Transmitted and reflected pulses emerge strongly deformed. Significant increase of the inhomogeneous broadening, ensuring $\gamma_2^* \gg \delta \omega$, results in enhancement of the unidirectional reflection: there is almost total transmission of the pulse for the left [Fig. 2(e)] and enhanced reflection for the right [Fig. 2(f)] incidence. In this last case, the Gaussian shape of the incident pulse is almost restored. So, we have demonstrated the restoration of effect of unidirectional diffraction for a short pulse in quasi-PT-symmetric PhC.

Under the quasi-PT-symmetric light-matter interaction, we describe the dynamics of a short spatially localized pulse propagating in the extended medium, when the length of propagation significantly exceeds the pulse size. The boundary problem of dynamical Bragg diffraction in the Laue geometry [Fig. 1 (right panel)] for a short laser pulse in a PhC with strong material dispersion is solved. In Fig. 3(a) and Fig. 3(b), the intensity of the field of an extended quasi-monochromatic pulse with long duration $\tau = 100$ ps and the size $\tau c >> L$, where $L$ is the PhC’s thickness, is represented. If the angle of incidence is positive, the pulse propagates in a periodic Bragg structure with gain and loss as in a continuous conservative medium, i.e. without diffraction, absorption and amplification. The medium is transparent. With the sign of angle changing $\theta < 0$, Fig. 3(b), the pulse Bragg diffraction occurs, as well as its significant amplification and spatial expansion take place. This effect of unidirectional diffraction Bragg reflection disappears in dispersive media with the decreasing of pulse duration [$\tau = 1 ps$ and $\gamma_2^* \sim \delta \omega$ in Fig. 3(c), (d)].

Under the quasi-PT-symmetric condition, $\gamma_2^* \gg \delta \omega$, one can observe again the unidirectional Bragg reflection for spatially localized short pulse [Fig. 3(e), (f)].

3. Conclusions

We have demonstrated the dynamics of short spatially localized optical pulse propagation in quasi-PT-symmetric medium with strong material dispersion and beyond the paraxial approximation. In such a medium, the propagation of pulses with a finite frequency spectrum becomes possible due to a significant restoration of the PT-symmetric properties of the structure under the broadening of the spectral line of the resonant medium. This opens up great opportunities for controlling the pulse dynamics by means of small variations of the radiation frequency.

Abstract

Parity-time-symmetric couplers with odd time reversal are introduced. In such systems the waveguides with gain and losses are coupled by anti-PT-symmetric media. We describe constraints imposed by the symmetry on spectral characteristics of the guided modes. As an application, we propose a coherent switch operating with a superposition of binary states. We also discuss coherent perfect absorption and lasing by non-Hermitian optical potentials embedded in such waveguides.

1. Introduction

During the last decade, parity-time (PT) symmetric systems were in the focus of intensive studies in different branches of physics [1], and especially in optics [2, 3]. Until recently, the most of applications were concerned with the time reversal symmetry characterized by \(T^2 = 1\) (respectively \((PT)^2 = 1\)), which in quantum mechanics corresponds to the physics of bosons (below it is referred to as even PT symmetry). Fermions, however are described by odd PT symmetry, where the time reversal operator obeys \(T^2 = -1\). In particular, this is the case of \(T = i\sigma_2 K\), with \(\sigma_2\) being the Pauli matrix, and \(K\) being the elementwise complex conjugation [4]. It turns out that in optical (and more general, physical) systems such symmetry can be also realized [5, 6]. Such symmetry can be achieved in coupled rotators that have balanced gain and loss, and the arms of which are connected by means of an anti-PT-symmetric medium, i.e., medium characterized by the dielectric permittivity satisfying the relation [7]: \(\varepsilon(x) = -\varepsilon(-x)\). Here we report on two examples of implementation and use of the odd PT symmetry.

2. Coherent switch.

Consider propagation of two birefringent waveguides coupled to each other by an anti-PT-symmetric medium [5]. The electric fields are written as \(E_1 = [e_1 A_1(z)\psi_1(r) + e_2 A_2(z)\psi_2(r)]e^{i(q - \delta)z}\), \(E_2 = [e_3 A_3(z)\psi_3(r) + e_4 A_4(z)\psi_4(r)]e^{i(q + \delta)z}\). Here \(r = (x, y)\), \(\psi_j(r)\) are transverse distributions of the modes, \(A_j(z)\) are slowly varying field amplitudes, and \(2\delta\) is the mismatch between propagation constants in the waveguides. It is assumed that polarizations in each waveguide are mutually orthogonal: \(e_1 \cdot e_2 = e_3 \cdot e_4 = 0\), and in different waveguides are mutually rotated by angle \(\alpha\), ensuring the relations \(e_1 \cdot e_3 = e_2 \cdot e_4 = \cos \alpha\) and \(e_1 \cdot e_4 = -e_2 \cdot e_3 = -\sin \alpha\) where \(\alpha\) is the angle of mutual rotations of the polarizations in different waveguides.

The evolution equation for the slowly varying amplitudes \(A = (A_1, A_2, A_3, A_4)^\top\) \((\top\) stands for transpose) reads \(i\dot{A} = H_\delta A\) where

\[
H_\delta = \begin{pmatrix}
\delta \sigma_0 & i\kappa C^\dagger \\
-\delta \sigma_0 & -\delta \sigma_0
\end{pmatrix}, C = \begin{pmatrix} e^{-i\varphi} \cos \alpha & -e^{i\varphi} \sin \alpha \\
e^{-i\varphi} \sin \alpha & e^{i\varphi} \cos \alpha \end{pmatrix}
\]

\(\sigma_0\) is the 2 \times 2 identity matrix, \(\kappa\) is the coupling between the waveguides, and \(\varphi\) and \(\theta\) are the phase mismatches of the transverse distributions: \(\psi_2 = \psi_1 e^{i\varphi}, \psi_4 = \psi_3 e^{i\theta}\). The guided eigenmodes modes are double-degenerated with the propagation constants, \(b_\pm = \pm \sqrt{\delta^2 - \kappa^2}\), each having an invariant subspace spanned by two PT-conjugate eigenvectors, \(A_\pm^{(1)}\) and \(A_\pm^{(2)} = PT A_\pm^{(1)}\).

The double-degeneracy of eigenstates is protected by the odd PT symmetry, i.e., in such a coupler, one simultaneously affects both modes with the same propagation constant. This allows one to perform switching between a superposition of binary states. We consider the coupler illustrated in Fig. 1. Two couplers, with \(\delta = -\delta\), are connected by two decoupled waveguides having balanced loss \(-\Gamma\) and gain \(\Gamma\), and a mismatch between the propagation constants \(\pm \delta\). The lengths of the couplers are equal and chosen as \(L = \pi/(2\sqrt{\delta^2 - \kappa^2})\). The decoupled segment which disrupts the odd PT symmetry has the length \(\ell = \pi/(2\delta_0)\).

The field in the coupler is expressed through the evolution operators \(U_{\pm\delta}(z, z + L) = -iH_\pm\delta/\sqrt{\delta^2 - \kappa^2}\). The evolution operator of the decoupled segment is: \(U_0(z, z + \ell) = \text{diag}(ie^{-i\Gamma\ell}, ie^{-i\Gamma\ell}, -ie^{i\Gamma\ell}, -ie^{i\Gamma\ell})\). The output (at \(z = 2L + \ell\) and input (at \(z = 0\)) fields are related by:

\[
\hat{A}_{\text{out}} = U_{-\delta}(L + \ell, 2L + \ell)U_0(L, L + \ell)U_\delta(0, L)\hat{A}_{\text{in}}.
\]

The switch is controlled by \(\Gamma\). Let the input signal with polarization \(\hat{A}_{\text{in}} = (\cos \chi, \sin \chi, 0, 0)^\top\) be applied to the waveguide 1. Then \(\hat{A}_{\text{in}}\) is characterized by a free parameter \(\chi\) (the red vector at the input in Fig. 1). If the central waveguides are conservative, \(\Gamma = 0\), the output signal is \(\pi/2\)-phase-shifted and is detected only at output of the first waveguide \(\hat{A}_{\text{out}}^{(0)} = i\hat{A}_{\text{in}}\). If \(\Gamma = \Gamma_{\text{sw}} = \ell^{-1}\ln(\delta/\kappa)\),

Now we consider stationary scattering problem for a two component field $\psi = (\psi^1, \psi^2)^T$: $H\psi = k^2\psi$ where $k$ is the spectral parameter and the non-Hermitian Hamiltonian is given by

$$H = -\frac{d^2}{dx^2}\partial_0 + \hat{U}, \quad \hat{U} = \begin{pmatrix} U_0(x) & V_2(x) \\ V_2(x) & U_1(x) \end{pmatrix}$$

with $U_{0,1}, V_2 \rightarrow 0$ at $x \rightarrow \pm\infty$ [6]. The Hamiltonian $H$ is odd-$PT$ symmetric if the conditions $U_0(x) = U_1^*(-x)$, and $V_2(x) = -V_2^*(-x)$ are satisfied.

Since the system is two-component the field asymptotics are given by

$$\psi(x) \rightarrow a_1 e^{ikx} |\uparrow\rangle + a_2 e^{-ikx} |\downarrow\rangle + a_3 e^{-ikx} |\uparrow\rangle + a_4 e^{ikx} |\downarrow\rangle,$$

$$\psi(x) \rightarrow b_1 e^{ikx} |\uparrow\rangle + b_2 e^{-ikx} |\downarrow\rangle + b_3 e^{-ikx} |\uparrow\rangle + b_4 e^{ikx} |\downarrow\rangle,$$

where $|\uparrow\rangle = (1, 0)^T$ and $|\downarrow\rangle = (0, 1)^T$. In terms of the column vectors $\mathbf{a} = (a_1, a_2, a_3, a_4)^T$ and $\mathbf{b} = (b_1, b_2, b_3, b_4)^T$ the transfer matrix $\mathbf{M}$ is defined as

$$\mathbf{b} = \mathbf{Ma}, \quad \mathbf{M}(k) = \begin{pmatrix} \mathcal{M}_{11}(k) & \mathcal{M}_{12}(k) \\ \mathcal{M}_{21}(k) & \mathcal{M}_{22}(k) \end{pmatrix},$$

where $\mathcal{M}_{ij}$ are $2 \times 2$ matrices.

Define $\Delta(k) = \det \mathcal{M}_{22}(k)$. There exist two types of the spectral singularities (SS). Weak SS is the (real) wavevector $k_*$ at which $\Delta(k_*) = 0$ while $\mathcal{M}_{22}(k)$ remains nonzero matrix. Strong SS $k_*$ corresponds to the zero matrix $\mathcal{M}_{22}(k_*) = 0$. We show that the SS are self-dual, i.e. if $k_*$ is a SS (for $k_* > 0$ it corresponds to laser), then $-k_*$ is a SS too (it corresponds to coherent perfect absorber (CPA)).

We illustrate laser and CPA based on odd–$PT$–symmetry using a specific example of the non-Hermitian matrix potential $\hat{U}$ consisting of one waveguide with localized gain and another waveguide with localized absorption, which are coupled by a antisymmetric medium which is also localized in transverse direction. We detect and consider weak self-dual SS and their splitting into complex-conjugate eigenvalues, the latter being the bound states characterized by propagation constants with real parts lying in the continuum. We also report a counter-intuitive restoration of the unbroken odd–$PT$–symmetric phase subject to the increase of the gain-and-loss strength.

Coupled resonances with dynamic modulation for selective wavelength conversion

Galaad Altares Menendez, Bjorn Maes*

Micro- and Nanophotonic Materials Group, Faculty of Science, University of Mons, Mons, Belgium
*corresponding author, E-mail: bjorn.maes@umons.ac.be

Abstract

We present a method to obtain efficient and selective frequency conversion using a system of two time-modulated cavities. This setup allows to tailor the conversion process by controlling important parameters such as the inter-cavity coupling and the external excitation frequency. We describe the process extensively, with for example an important role for the dynamic modes of the coupled system, the Floquet modes.

1. Introduction

In previous work, Ginis et al. [1] proposed a frequency comb generation principle based on time modulation, where the comb was generated from an incident plane wave via a time modulated graphene sheet. This mechanism is useful to create a wide range of frequencies. In our previous work [2] we expanded upon that idea using plasmonic resonances [3] in graphene ribbons to improve the efficiency and the tunability of the process. However, that setup was limited in the sense that it is difficult to target the generation of a specific frequency. In this work we use a system of two coupled cavities, allowing their interference to achieve selective frequency conversion. We study this system with temporal coupled mode equations [4], and show that the Floquet modes of the dynamic system play a crucial role for the conversion efficiency.

2. Setup and coupled mode theory

The system under investigation is sketched in Fig. 1(a). It consists of two cavities, each supporting one mode with amplitudes \(a(t)\) and \(b(t)\). These modes are coupled to each other via the coupling constant \(\kappa\). In our case, the mode \(a\) is dark, while the mode \(b\) can radiate to the outside (and thus has a decay rate \(\gamma\)). A possible implementation using graphene plasmonic resonances in ribbon arrays with different widths (\(D_1\) and \(D_2\)) is represented in Fig. 1(b). The coupled equations for this system are [5]:

\[
\begin{align*}
\frac{da(t)}{dt} &= i\omega_1 a(t) + i\kappa b(t) + s(t) \quad (1) \\
\frac{db(t)}{dt} &= i\omega_2(t) b(t) + i\kappa a(t) - \gamma b(t) \quad (2)
\end{align*}
\]

where \(\omega_1\) and \(\omega_2\) are the resonance frequencies of the two cavities and \(s(t)\) is the source. Note that the dark mode \(a\) is directly excited by the source, and that only the resonance frequency \(\omega_2\) is time-dependent, in particular:

\[
\omega_2(t) = \omega_2 + \delta \sin(\Omega t) \quad (3)
\]

where \(\delta\) is the modulation amplitude and \(\Omega\) is the modulation frequency.

3. Floquet modes

In the absence of time-modulation, the system eigenvalues are \(\omega_{\pm} = \frac{\omega_1 + \omega_2}{2} \pm \frac{1}{2}\sqrt{(\omega_1 - \omega_2)^2 + 4\kappa^2}.\) These two frequencies are represented as a function of \(\kappa\) in Figure 2 by the red dashed lines. However with the introduction of a time modulation, the system supports so-called Floquet modes [6] (blue lines in Fig. 2), analogous to the Bloch-modes in spatially periodic systems.

Figure 1: (a) Representation of the system of coupled resonances. (b) Potential implementation using two coupled arrays of graphene ribbons. Each cavity corresponds to a plasmonic resonance in the graphene array, where different ribbon widths \((D_1\) and \(D_2\)) provide different resonance frequencies. The ribbons are repeated in the horizontal direction creating two vertically offset gratings.
Figure 2: Dashed red lines: static resonance frequencies for the degenerate case \((\omega_{\pm} = \omega_{1,2} \pm \kappa)\). Blue lines: Floquet modes of the system for the degenerate case, where \(\omega_{1,2} = 2\pi \times 10^{13}\) rad/s, \(\Omega = 2\pi \times 2.5 \times 10^{11}\) rad/s and \(\delta = \Omega/2\).

The Floquet frequencies form a band structure and can exhibit anti-crossings, leading to bandgap-like features. The modulation amplitude \(\delta\) is the parameter responsible for the bandgap size: a larger \(\delta\) yields a wider anti-crossing. These modes play a crucial role in the frequency conversion efficiency.

4. Selective frequency conversion

The temporal modulation leads to the excitation of new frequencies in the system, organized as a comb. The frequency components inside the comb are always separated by the modulation frequency \(\Omega\), as seen in Fig. 3. We mainly focus on the first two generated sidebands \((\omega_0 \pm \Omega\) where \(\omega_0\) is the incident frequency). In general, we note that the frequency conversion process is much more efficient when the incident frequency is equal to a Floquet frequency.

Furthermore, the system parameters permit in some cases to achieve selective frequency conversion. In Fig. 3 for example, the frequency conversion to the upper sideband is clearly more efficient than the conversion to the lower sideband. Interestingly, this asymmetric conversion mainly happens when the source frequency is equal to a Floquet frequency at the edge of the anti-crossing \((\kappa = \Omega/2)\). And this process is particularly efficient there, which is reminiscent of bandgap effects in Bragg structures.

In addition, it is also possible to efficiently convert with the same efficiency to both sidebands, leading to symmetric combs. This type of conversion mainly occurs around the first band crossing, when \(\kappa = \Omega\) (see Fig. 2).

5. Conclusions

We describe how to achieve selective frequency conversion using a system of two time dependent coupled cavities. This process is particularly efficient at an anti-crossing, and different types of conversion can be achieved. This phenomenon is rather general and can be applied to any physical system of coupled resonances.

Non-Hermitian transformations with optical metasurfaces

Andrey A. Sukhorukov

1 Nonlinear Physics Centre, Research School of Physics and Engineering, The Australian National University, Canberra, ACT 2601, Australia
*corresponding author: Andrey.Sukhorukov@anu.edu.au

Abstract. We present theoretical and experimental results demonstrating non-Hermitian transformation of classical and quantum states of light with ultra-thin dielectric metasurfaces. We introduce a new conceptual approach for implementing arbitrary complex birefringence with polarization-dependent transmission, based on tailored interference from specially engineered nano-resonators in the metasurface. The fabricated metasurfaces demonstrate new regimes of polarisation control for enhanced measurements and unconventional interference with classical and quantum light, and discuss analogies with Parity-Time symmetric transformations.

A new regime of non-Hermitian complex-valued birefringence has been recently suggested [1], extending the notion of real-valued birefringence through the specially introduced polarization-sensitive loss or gain. This can enable fundamentally new possibilities for polarization control, such as amplifying the angle between polarization vectors to improve detection sensitivity. However, a practical realization of complex-valued birefringence concept was missing. In particular, the theoretical approach in Ref. [1] was based on a complicated metamaterial with loss and gain, which is challenging to fabricate and not suitable for quantum applications.

Here, we report on a new conceptual approach for implementing arbitrary complex-valued birefringence with pairwise birefringent elements using high-index dielectric nanostructured metasurfaces. We formulate a practical design principle, which is optimal for achieving any desirable polarization transformation. While loss is inherently necessary for implementing non-Hermitian birefringent transformations, our all-dielectric metasurface design achieves the mathematically minimum required amount of loss through tailored diffraction without any material absorption.

Fig. 1: (a) Scanning Electron Microscope (SEM) image of a representative unit cell composed of two different nanoresonators. (b) Transformation of polarization states with the complex-birefringent metasurface, visualized on a Poincare sphere. Two close input state vectors (purple arrows, left) are brought to orthogonal (right) after passing through the metasurface. (c) Output angular separation \( \theta_{\text{out}} \) for a pair of input states with angle difference \( \theta_{\text{in}} \) computed from experimental transfer matrix; dashed lines correspond to the states illustrated in (b).
We designed, fabricated and characterized amorphous silicon metasurfaces realizing complex birefringence, where diffraction is used as a loss channel. A scanning electron microscope (SEM) image is shown in Fig. 1(a). This design transforms a pair of very close input polarization states [Fig. 1(b, left)] into output orthogonally polarized states [Fig. 1(b, right)]. This polarization mapping is enabled by the non-conservative transformation provided by the complex birefringence. Under the Stokes formalism of polarization states, this transformation is equivalent to the distortion of states on the surface of the Poincare sphere in a nonuniform manner [see grids in Fig. 1(b)]. Based on experimental measurements, we determine the dependence of the output angle ($\theta_{\text{out}}$) between the polarization states on the relative input angle ($\theta_{\text{in}}$), see Fig. 1(c). Depending on the angle between the input linear polarization states, the output angle of polarization difference can be either amplified (as marked by dashed lines, corresponding to Fig. 1(b)) or scaled down.

The metasurfaces realizing non-Hermitian complex-birefringent transformations can find applications for precise polarization measurements and state discrimination in classical and quantum optical platforms.

Abstract
A pair of anisotropic exceptional points (EPs) of arbitrarily high order are found in a class of random non-Hermitian systems carrying non-reciprocal hoppings. Both Eigenvalues and phase rigidity show different asymptotic forms near the anisotropic EPs in two orthogonal directions in the parameter space, making them anisotropic EPs. Some universal features are observed to govern the critical exponents of the phase rigidity near an anisotropic EP, which depend on the dimensions of the Hamiltonian. Such system has order-2 EPs forming multiple ellipses that converge to the two high-order EPs in the parameter space and these ellipses coalesce to form a ring of high-order EPs for some particular configurations.

1. Introduction
Non-Hermiticity can bring interesting new phenomena [1]. Extensive research effort has been devoted to classical-wave systems involving material carrying gain/loss or having radiation leaking into open space. Exceptional points, at which both eigenvalues and eigenstates coalesce, often occur as square-root singularities and they account for many fascinating properties of non-Hermitian systems, including unusual reflection and transmission. In this work, we consider systems in which the non-Hermiticity comes from asymmetric hoppings between sites instead of the gain/loss usually considered in PT-symmetric non-Hermitian systems. We found that a pair of arbitrarily high order EPs exists in such systems even in the presence of randomness. Near the EPs, eigenvalues and phase rigidity exhibit anisotropic behaviors. The critical exponents of phase rigidity are found to certain universal rules. The two high-order EPs are the common vertices of multiple ellipses comprising order-2 EPs. For some configurations, a ring of high-order EPs occurs due to the coalescence of the ellipses.

Results
To illustrate the idea, let us consider a non-Hermitian system represented by a $N \times N$ Hamiltonian $H' = H + \lambda s^j_j$, where

$$H = \begin{pmatrix}
0 & \tau_1 & 0 & 0 \\
\tau_2 & 0 & \tau_1 & 0 \\
0 & \tau_2 & 0 & \ddots \\
0 & 0 & \ddots & \ddots & \tau_1 \\
0 & 0 & \ddots & 0 & \tau_2 \\
0 & 0 & \ddots & 0 & 0
\end{pmatrix},$$

with $\tau_1 = \tau - 1, \tau_2 = \tau + 1$, and $s^j_j = S^j_j / j \hbar$ with $S^j_j$ being the $z$ component of the spin-$j$ operator and $j = (N - 1)/2$. The non-Hermiticity comes from asymmetric hoppings, $\tau_1 \neq \tau_2$. Such systems can be realized by coupled ring resonators [2], electronic circuits [3] or cold atoms in optical lattices [4]. The eigenvalues are

$$E_m = 2\sqrt{\tau^2 - 1} \cos \left( \frac{m \pi}{N + 1} \right), m = 1, 2, \ldots, N.$$  (2)

All $N$ eigenstates coalesce to a single one at $\tau = \pm 1$ with eigenvalue $E = 0$, leading to an EP of order $N$. In the $(\tau, \lambda)$ plane, $(\pm 1, 0)$ are two EPs of order $N$. These two EPs exhibit anisotropic behaviors in both eigenvalues and phase rigidity, which is defined by $R = \langle \psi^l | \psi^R \rangle$ with $\psi^l (\psi^R)$ denoting left (right) eigenvectors. When $\lambda = 0$, the eigenvalues of $H'$ reduce to square-root forms given by Eq. (2). In contrast, eigenvalues take linear forms, i.e., $E_m = \lambda (j + 1 - m) / j$ when $\tau = \pm 1$, where $m = 1, 2, \ldots, N$. Thus, eigenvalues exhibit different behaviors in different directions in the parameter space near an EP. Thus $(\tau, \lambda) = (\pm 1, 0)$ are two anisotropic EPs of order $N$ for $H'$. To characterize eigenstates near an anisotropic EP,
we calculate the phase rigidity near the anisotropic EP at \((\tau, \lambda) = (1, 0)\) in the \((\tau, \lambda)\) plane and find \(R_i \propto [\Delta]^{(N-1)/2}\) with \(\Delta = \tau - 1\) when \(\lambda = 0\), and \(R_i \propto [\Delta]^{N-1}\) when \(\tau = 1\). The exponents of phase rigidity are respectively \((N-1)/2\) and \(N-1\) in the two orthogonal directions, exhibiting anisotropic behaviors.

These EPs and their anisotropic behaviors persist even in the presence of certain types of disorder. We consider the following Hamiltonian with disorder,

\[
H_{ds} = \begin{pmatrix}
  c_i \lambda & a_i \tau & 0 & 0 & 0 \\
  b_i \tau & c_i \lambda & a_i \tau & 0 & 0 \\
  0 & b_i \tau & c_i \lambda & \ddots & 0 \\
  0 & 0 & \ddots & \ddots & a_n \tau \\
  0 & 0 & 0 & b_{n,i} \tau & c_n \lambda
\end{pmatrix},
\]

(3)

where \(a_i, b_i, c_i\) are arbitrary real numbers with \(a_i, b_i > 0\).

When \(a_i = b_i = 1\) and \(c_i = (j+1-i)/j\), \(H_{ds}\) reduces to \(H' = H + \lambda \mathbf{s}\). We find that \((\tau, \lambda) = (\pm 1, 0)\) remain anisotropic EPs even in the presence of randomness. All eigenvalues take the square-root form, which can be expressed as \(E_i = \pm d_i \sqrt{\tau_{i1} \tau_{i2}}\) when \(\lambda = 0\), where \(d_i\) are constants. Near each anisotropic EP, say \((1, 0)\), the eigenvalues of \(H_{ds}\) show anisotropic behaviors: \(E_i \approx \pm d_i \sqrt{2\Delta}\) with \(\Delta = \tau - 1\) along \(\lambda = 0\), and \(E_i = c_i \lambda\) along \(\tau = 1\). The critical exponents of phase rigidity are \((N-1)/2\) and \(N-1\) for all eigenstates, independent of \(a_i, b_i, c_i\).

We observed multiple elliptical trajectories formed by order-2 EPs in the form of \(\tau^2 + A_i \lambda^2 = 1\) with \(A_i\) being some positive number, which share the two order-\(N\) EPs as their common vertices. The coalesced eigenvalues on each ellipse are proportional to \(\lambda\), that is \(E = B_i \lambda\). The values of \(A_i\) and \(B_i\) depend on the specific values of \(a_i, b_i, c_i\).

If the values of \(a_i, b_i, c_i\) are taken so that the Hamiltonian have the following form

\[
H' = \tau s_i^j - i s_i^j + \lambda s_i^j,
\]

(4)

where \(s_i^j, \mu = x, y, z\) are spin matrices, all ellipses of order-2 EPs coincide and form a ring of order-\(N\) EPs: \(\tau^2 + \lambda^2 = 1\). Every point on the ring is an anisotropic EP.

We want to compare the order-\(N\) anisotropic EPs found in this work with conventional order-\(N\) EPs. The phase rigidity near the EP in the Hamiltonian \(H'\) behaves as \(R_i \propto [\Delta]^{(N-1)/2}\) with \(\Delta = \tau - 1\) when \(\lambda = 0\). The exponent \(\sigma = (N-1)/2\) is very different from \(\sigma = (N-1)/N\) for the conventional order-\(N\) EPs. The difference results from distinct singular behaviors in the eigenvalues near an EP. For \(H'\), multiple pairs of square-root singularities, i.e., \(\sqrt{\Delta}\), share the same EP, whereas for a conventional order-\(N\) EP, all eigenvalues are from a single \(N\)-th root singularity, i.e., \(\sqrt[2]{\Delta}\).

2. Conclusions

For a class of random non-Hermitian systems carrying non-reciprocal hoppings, two high-order anisotropic EPs are found to be the converging point of multiple order-2 EP ellipses in the parameter space. For some particular configurations, the ellipses coalesce to form a ring of high-order anisotropic EPs.

Topological protection and quantum noise in nonlinear photonic systems

Henning Schomerus*1

1Department of Physics, Lancaster University, Lancaster, UK
*corresponding author, E-mail: h.schomerus@lancaster.ac.uk

Abstract

Many prospective applications of topological photonics involve intrinsically nonlinear media, such as in lasers, plasmonic structures, or excitonic condensates. As I show here, one of the main underlying symmetries known from the linear context extends seamlessly to these situations. This allows us to precisely define topologically protected dynamically stable states, which either may be stationary states replicating zero modes, or power-oscillating states.

1. Introduction

Topological lasers and condensates [1-6] offer means to confine and manipulate coherent and collective states of light and matter in versatile ways. In particular, the confinement and coherent feedback can be obtained without mirrors based on suitable photonic lattice structures with small geometric adjustments. The original design of these systems relied on the hop that the topological protection of the cold-cavity modes has bearing for the above-threshold operation modes, which however strongly depend on the nonlinear response in the system. This poses the question whether topological protection persists under nonlinear conditions. In this work I provide a framework that answers this question both from a practical as well as from a fundamental perspective. The main ingredient is a dynamical extension of the topological symmetries known from the linear case. As it turns out, these considerations also have implications for the effects of quantum noise in these systems.

2. Origins and implications of nonlinearities

In topological lasers and condensates there are two main types of nonlinearities – those that change the lifetime of states, such as observed in gain saturation, and those that nonlinearly shift the resonance frequency, as e.g. captured by the line-width enhancement factor in lasers, or induced by excitonic interactions in exciton-polariton condensates. Both effects are not accounted for in the linear cold-cavity description of these systems. Consider e.g. a coupled-mode theory of a system with discretely coupled modes, as e.g. supported by microresonators, pillars, or waveguides in a structured system. Such systems display a chiral symmetry if the discrete components populate two mutually coupled sublattices A and B, such that

\[ \omega A = T_{AB}B, \quad \omega B = T_{BA}A, \]

with suitable coupling matrices \( T_{AB} \) and \( T_{BA} \) that we take to be real. The system then displays a chiral symmetry realized by the invariance \((A,B,\omega) \rightarrow (A,-B,-\omega)\). Hence the spectrum of such a system is symmetric in \( \omega \), and the corresponding topologically protected states are zero-modes with \( \omega = 0 \). In the presence of linear gain and loss, where

\[ \omega A = i\Gamma_A A + T_{AB}B, \quad \omega B = i\Gamma_B B + T_{BA}A, \]

we encounter an analogous invariance \((A,B,\omega) \rightarrow (A',-B',-\omega')\), which formally agrees with the charge-conjugation symmetry encountered in a superconductor [1,7,8]

Zero modes now have a fixed frequency \( \text{Re}\, \omega = 0 \) but can have a variable life time from \( \text{Im}\, \omega \).

Spectral characterizations such as this are adapted to linear systems, but do not have a precise meaning in nonlinear systems. In that case, I propose to directly study the dynamical problem [9-11].

For illustration consider a system with real-space gain saturation, whose dynamical evolution is given by [9,10]

\[ i\frac{dA}{dt} = i\Gamma_A(|A|^2)A + T_{AB}B, \quad i\frac{dB}{dt} = i\Gamma_B(|B|^2)B + T_{BA}A, \]

with real nonlinear functions \( \Gamma \) describing the gain and loss. As we now can check directly, this system remains invariant under the substitution \((A(t),B(t)) \rightarrow (A'(t),-B'(t))\). This constitutes a dynamical symmetry between different solutions that persists in the nonlinear case. For stationary states with harmonic time dependence \( \sim \exp(-i\omega t) \) it reduces to the nonhermitian charge conjugation symmetry above. The corresponding zero modes can be written with real amplitudes \( A \) and imaginary amplitudes \( B \), thus display a characteristic spatial phase pattern. Furthermore, this dynamical formulation of symmetries allows for symmetry-protected cycles, where \((A(T/2),B(T/2)) = (A'(0),-B'(0))\). This gives rise to power-oscillating
solutions that are again protected by symmetry. These modes have been termed twisted modes, and do not have a counterpart in the linear system.

3. Extensions using geometric symmetries

It is also possible to identify situations in which similar considerations hold for the additional presence of nonlinear interactions that shift the resonance frequencies. Our main proposal employs the parity symmetry, and hence realizes a situation analogous to PT symmetric systems, but with the charge-conjugation symmetry C replacing T. This leads to systems of the form [11]

\[ i \frac{dA}{dt} = i \Gamma(|A|^2)A + TB, \quad i \frac{dB}{dt} = i \Gamma^*(|B|^2)B + TA, \]

where \( \Gamma \) is now complex but the same functions \( \Gamma \) and couplings \( T \) now appear in both equations. One now confirms that these equations remain invariant under the substitution \( (A(t), B(t)) \rightarrow (B^*(t), -A^*(t)) \). Based on these relations we can again define zero modes and we can now defined nonlinear zero modes and twisted modes.

4. Stability and noise

To assert whether such topologically protected dynamical states can be realized and observed in physical systems we need to consider their stability against perturbations. At the same time, such an analysis gives a characterization of these states in terms of their intrinsic levels and sensitivity to quantum noise. I present a detailed analysis in terms of Bogoliubov excitations, and show that the topological modes indeed display characteristic excitations and therefore provide a characteristic response to external probes. We find that these systems offer particularly favourable switching mechanism between the topological solutions, which can take the form of Hopf bifurcations [9,10] or infinite-period bifurcations [11].

5. Conclusions

The characterization of nonhermitian topology poses many challenges, which become even more pressing when nonlinearities are involved. As described in this work, a promising way forward is to ask whether symmetries exist between the stable dynamical solutions of the system [9-11]. Self-symmetric solutions provide a natural extension of the zero modes known from linear systems, while twisted modes displaying power oscillations define a new class of symmetry-protected solutions that do not have a linear counterpart. The proposed systems offer new switching mechanisms that make them attractive for device applications.

Nonlinear scattering by PT-symmetric layered periodic structures with gain and loss saturation effects

O. Shramkova¹*, G. Tsironis²

¹Technicolor Research & Innovation, Cesson Sévigné, France
²University of Crete, Heraklion, Greece

*corresponding author, E-mail: Oksana.shramkova@technicolor.com

Abstract
We investigate the effect of gain saturation on scattering characteristics of PT-symmetric periodic stacks of the layers with balanced loss and gain. Closed form solutions for calculating the transmission and reflection of nonlinear system have been obtained. It is shown that the non-reciprocal response of the nonlinear medium depends on parameters of the stack, angles of wave incidence and saturation intensity. The effects of nonlinearity on the exceptional points and symmetry breaking are systematically examined.

1. Introduction
The discovery of parity-time (PT)-symmetric media, motivated by fundamental studies of PT-symmetric quantum Hamiltonians [1], has shown significant potential for advancing toward the goal of new metamaterial design. PT-symmetry can lead to many exotic features of optical systems, including double refraction, unidirectional invisibility, nonreciprocal propagation, coherent perfect absorption, selective lasing and other intriguing nonlinear effects [2-4]. A necessary condition for an optical structure to be PT-symmetric is that its complex refractive index distribution satisfies the condition \( n(\vec{r}) = n^*(\vec{r}) \). However, the transition to a complex spectrum, which is called PT-symmetry breaking, appears upon the increase of the strength of imaginary part of \( n(\vec{r}) \).

To date, most of the studies in optical realizations of PT-symmetric media have connected stacked layers and films [5-8]. The research in this topic was primarily focused on the linear phenomena, whereas the nonlinear effects have attracted the growing interest only lately. The problem of plane wave scattering by the layered PT-symmetric grating with longitudinal distribution of loss and gain saturation inside the unit cell was explored in [9]. It was shown that the strong nonreciprocal response of the structure and the bistability effect depend on the gain and loss saturation value, on the value of input intensity and on the side of electromagnetic wave incidence. Moreover, gain and loss saturations can force the transition from broken symmetry phase to a PT-symmetric. To analyze the layered structure authors used the transfer matrix method dividing each layer of primitive cells into narrow stripes. As the result, the approximate expression of the output intensity, the reflection and transmission coefficients, as a function of the incident wave intensity, was obtained.

The aim of this paper is to explore the scattering characteristics of periodic layered structure with balanced distribution of loss and gain, when dispersion and saturation nonlinear effects are taken into account. We provide a nonlinear model describing the field evolution in the periodic semiconductor layered system in the presence of saturable gain. The obtained solution enable fast quantitative analysis of the incidence angle effect on the scattered field intensities.

2. Problem statement and main equations
Let us consider a finite PT-symmetric periodic stack composed of dielectric layers of identical thickness \( d \) and complex-conjugate dielectric permittivities \( \varepsilon \) and \( \varepsilon^* \) (\( \varepsilon \) and \( \varepsilon^* \) are positive) corresponding to balanced gain (G) and loss (L) regions. The layers are of infinite extent in the x0y-plane. The system is PT-symmetric about \( z=0 \). Let plane wave be incident at angle \( \Theta_0 \) on a structure of thickness \( L=2N \), where \( N \) is the number of structure periods. It is surrounded by linear homogeneous medium with dielectric permittivity \( \varepsilon_0 \) as shown in Fig. 1.

Figure 1: Geometry of the problem.

The complex nonlinearity we use were derived using the two-level model. By assuming that the intensity of propagating waves is much less than the saturation intensity, the nonlinear susceptibility can be expressed as [10]:

\[
\chi_j \approx \varphi_j \frac{\delta_j - i}{1 + \delta_j} + \varphi_j \frac{i - \delta_j}{(1 + \delta_j^2)} \left| \frac{E_j}{E_t} \right|^2, \tag{1}
\]

where \( \delta_j = (\omega_j^2 - \omega_0^2) / (\omega_j \gamma_j) \) and \( \omega_0 \gamma_j \) is the emission frequency, \( \gamma_j \) is the gain/absorption linewidth;
\[ \varphi_j = \alpha_j \frac{\omega_j}{\gamma_j}, \quad \alpha_j \] is the dimensionless gain/absorption coefficient, \( k_0 = \omega/c \). We use positive parameters \( \alpha_1 \) and \( \gamma_1 \) when referring to the amplifying medium with \( \text{Im}\varepsilon_1(\omega) < 0 \). To satisfy Kramers-Kronig relations, in the case of absorbing media with \( \text{Im}\varepsilon_1(\omega) > 0 \) we take \( \alpha_2 < 0 \) and \( \gamma_2 > 0 \), which ensures the causality of dielectric permittivity.

Solving the non-homogeneous Helmholtz equation perturbatively under the assumption that the nonlinear terms are small, enforcing the boundary conditions of field continuity at the interfaces of the stacked layers and using the modified transfer matrix method we obtain the closed-form expressions for the reflection/transmission coefficient of the TM waves outgoing from the nonlinear PT-symmetric periodic stack. The nonreciprocity of the scattering process can be directly inferred from the analysis of the obtained expressions.

3. PT-symmetry breaking

To elucidate the features of nonreciprocal scattering by nonlinear non-Hermitian system with gain saturation, the scattering characteristics of the TM waves have been examined numerically. It was observed that the influence of nonlinearity leads to considerable differences between the scattering characteristics of the corresponding linear and nonlinear systems and are pronounced in the frequency range close to the emission frequency.

![Figure 2: Eigenvalues of the S-matrix for the nonlinear system at \( \varepsilon_{a_0} = \varepsilon_{a_2} = 10.9 \), \( \omega_{a_1} = \omega_{a_2} = \omega_0 = 1 \) THz, \( \gamma_1 = \gamma_2 = 0.066 \) THz, \( d = 0.2 \) mm, \( \alpha_1 = \alpha_2 = \alpha_0 \), \( N=40 \). (a) - \( \Theta = 0 \); (b) - \( \alpha_0 = 0.01 \). Solid red lines correspond to the eigenvalues \( \lambda_{a_1} \), blue dashed lines are for \( \lambda_{a_2} \).

To measure the breaking of PT symmetry, we use a scattering S-matrix [3]. To gain insight in the effect of the nonlinearity on the symmetry-breaking transition the eigenvalues \( \lambda_{a_2} \) have been simulated at variable parameters of the system (Fig.2). The analysis of the eigenvalue spectrum dependence demonstrates that the PT-symmetry of nonlinear stack is broken, but we can get a set of points corresponding to the PT-symmetric phase of S-matrix changing the angle of electromagnetic wave incidence.

4. Conclusions

We have investigated the asymmetric and non-reciprocal features of the reflectance and transmittance of a multilayered structure with balanced distribution of loss and gain, when dispersion and saturation nonlinear effects are taken into account. The transition between symmetric and broken phases in the non-Hermitian system with gain and loss saturation effects has been considered.

Abstract- It was recently shown that arbitrary non-Hermitian optical potentials based on local Parity-Time (PT-) symmetry may control the flow of light, due to the asymmetric mode coupling. We propose periodic non-Hermitian potentials to efficiently regularize the complex spatial dynamics of broad-area semiconductor (BAS) lasers and Vertical-Cavity Surface-Emitting Lasers (VCSELs). Light generated from the entire active layer is concentrated on the structure axis, confined in an intense central narrow beam opening the path to design compact, bright broad-area lasers.

Semiconductor lasers are compact and efficient coherent light sources yet being generally unstable due to their large aspect ratio and to the lack of a transverse mode control mechanism. Spatial random fluctuations and spatiotemporal instabilities degrade the spatial beam quality and laser coherence \cite{1}. This intrinsic instability gives rise to different nonlinear modal interactions such as filamentation and hole burning, limiting possible applications. Common techniques to control the complex dynamics of BAS and VCSELs semiconductor lasers generally compromise their compactness while reducing the power conversion efficiency.

The present paper proposes a novel solution to the need for a general physical mechanism to stabilize the complex dynamics of semiconductor lasers, while improving the beam quality emission. In recent years, non-Hermitian spatially modulated materials have provided a flexible platform to manipulate light wave dynamics. Simultaneous refractive index and pump modulations have already shown the capability to suppress spatial instabilities in nonlinear optical systems, particularly in BAS and VECSEL devices \cite{2}. A remarkable class of such materials is the one globally holding PT- symmetry \cite{3}, which may be regarded as particular class of non-Hermitian systems fulfilling spatial Kramers-Kronig relations \cite{4}. Such materials allow unidirectional light transport arising from the unidirectional mode coupling. In turn, it was shown that local PT-symmetry may lead to light localization and enhancement at a selected point \cite{5} or complex potential may be specially designed using a local Hilbert transform, to control flow of light favoring arbitrary vector fields directionality using periodic, quasiperiodic or random background potentials \cite{6}.

We now show how axisymmetric non-Hermitian potentials efficiently regularize VCSELs radiation achieving a stable bright emission, see Figs 1.a-e. Dephased periodic (radial) refractive index and gain-loss modulations accumulate the generated light from the entire active layer and concentrate it around the structure axis to emit narrow beams. We perform a comprehensive analysis to explore the maximum central intensity enhancement and concentration regimes. We observe such lasers can be operated in stationary or pulsating oscillatory regime depending on the relative amplitude and phase of the index and gain-loss modulations. The results indicate stabilization occurs coinciding when the coupling between transverse modes is inwards, while
not fulfilling perfect PT-symmetry. We also apply an analogous scheme to control and improve the spatiotemporal dynamics in BAS lasers, see Figs.1e-f. In the proposed modulated BAS devices, the structure in divided into two half-spaces with two symmetric PT-symmetric potentials, by introducing a modulation both in the pump and refractive index. The generated light is directed towards the symmetry axis, see Fig.1g, forming a narrow and bright and temporally stable emitted beam, see Fig.1h.

The study uncovers rich possibilities for various configurations which could be extended beyond periodic non-Hermitian potentials assuming different random, quasiperiodic complex profiles of the background potential. The reported field regularization effect is universal, and we expect the proposed mechanism to be applicable to regularize the radiation from actual broad aperture lasers and microlasers.

Abstract

We discuss recent progress on active parity-time symmetric plasmonic systems. We discuss interactions based on encircling-an-exceptional-point, which are reciprocal in the linear regime, but become nonreciprocal in the nonlinear regime over a very broad optical bandwidth. We present an implementation based on plasmonic waveguides incorporating an IR140-doped PMMA gain medium.

Synthetic optical materials having a carefully-structured complex refractive index distribution, following non-Hermitian Hamiltonian analogs, have attracted significant attention because of their interesting optical behaviour [1]. Such materials enable functions such as uni-directionality, non-reciprocity, and unconventional beam dynamics.

The interplay between gain and loss, especially in low-loss (long-range) plasmonic systems is interesting because parity-time (PT) symmetric and exceptional point systems become readily accessible, leading to practical experimental demonstrations. Example systems include plasmonic waveguide Bragg gratings incorporating structured and unstructured gain media enabling distributed feedback lasing [2], and single-sided reflection [3]. Single-sided diffraction as a holographic lattice transitions through the exceptional point is also an interesting phenomenon [4].

We show that interactions based on encircling-an-exceptional-point, which are reciprocal in the linear regime, may become nonreciprocal in the nonlinear regime over a very broad optical bandwidth (limited mainly by the bandwidth of the nonlinearity) [5]. Recent experiments in passive Si-based optical waveguides confirm modal evolution that trace out adiabatic and anti-adiabatic parametric paths around an exceptional point [6].

We describe a plasmonic coupled-waveguide structure that combines an encircling-an-exceptional-point parametric evolution with a gain saturation nonlinearity (following the theory of [5]), and discuss progress on the experimental realization of the concept, aiming towards an integrated on-chip asymmetric amplifier.

Abstract

Nonreciprocal transmission of sound through a phononic crystal with asymmetric metal rods in viscous background (water) is studied within a wide range of frequencies. Nonreciprocity in transmission is observed if sound wave propagates along the directions with broken P-symmetry. The transmission remains reciprocal along the P-symmetric direction. Experiments are performed for periodic and disordered samples. In the latter case the nonreciprocity is observed for localized states in the regime of exponentially weak transmission.

1. Introduction

Two common concepts of nonreciprocity in sound propagation are based on nonlinear effects and on local circulation of fluid. Both types of acoustic systems have been successfully fabricated in the recent years. Nonlinearity is introduced through specially designed electronic circuits which connect linear scatterers [1, 2]. In active acoustic devices, the T-symmetry is usually broken due to rotation of the background fluid that in the case of local vortices becomes topologically equivalent to presence of external magnetic field [3], and in the case of global rotation leads to Doppler shift [4]. Practical realization of both concepts requires additional devices to be installed with their own power sources. Here, we explore viscosity of fluid as a natural factor of T-symmetry breaking and propose a passive nonreciprocal acoustic device.

2. Periodic structure

Reciprocity theorem is hold for wave equation due to time-reversal symmetry. In viscous fluid acoustic oscillations of local velocity $v(r)$ follow the Navier-Stokes equation, which is not time-reversible,

$$\rho \ddot{v}_i - \frac{\partial}{\partial x_k} (\lambda \nabla \cdot v) = \frac{\partial}{\partial x_k} \left[ \eta \left( \frac{\partial v_i}{\partial x_k} \right) \right] + \frac{\partial v_k}{\partial x_i} \left( \xi \nabla \cdot \dot{v} \right), \quad i = x, y, z. \quad (1)$$

Here $\rho = \rho(r)$ is the mass density, $\lambda(r)$ is the bulk elastic modulus, and $\eta(r)$ and $\xi(r)$ are the viscoscity coefficients.

However, broken T-symmetry does not necessarily lead to nonreciprocity. Here we demonstrate that the necessary condition for nonreciprocal propagation in a viscous fluid is broken P-symmetry, which can be achieved by introducing asymmetric scatterers in a viscous environment. The experiment was done with a phononic crystal of Al rods in water [5]. The rods have asymmetric cross-section as shown in Fig. 1. The measured transmission spectrum shown in Fig. 2 exhibits signatures of strong nonreciprocity if sound wave propagates along axis of broken P-symmetry (axis $y$).

Unlike this, the spectra of transmission along axis $x$ are practically reciprocal, while T-symmetry remains bro-
broken by viscous losses. But due to P-symmetry these losses are the same for two opposite directions. Thus, the nonreciprocity is not manifested.

3. Disordered structure

The asymmetric scatterers may be arranged in a structure which is periodic along one direction and disordered along another, see Fig. 3. Since P-symmetry is broken along both directions the corresponding transmission spectra are nonreciprocal. Due to specific arrangement of the scatterers the transport properties along axis $x$ of this 2D system are the same as for truly one-dimensional disordered system. Then all the eigenstates are exponentially localized and the logarithm of transmission decays linearly with sample length. The latter property was measured experimentally and simulated numerically. The results presented in Fig. 4a. In the experiment it is impossible to separate decay due to viscous losses from that due to disorder. Numerical results obtained for viscous and inviscid water clearly show that the viscous decay gives small contribution. Thus, the linear decay presented by red symbols in Fig. 4a is a signature of Anderson localization of sound. Nonreciprocity in the regime of localization is manifested in slightly different slopes of the lines in Fig. 4b, i.e. in different localization lengths observed for the opposite directions of incoming sound wave.

Active Electroacoustic Resonators and their Application to Non-Hermitian Acoustics

Romain Fleury

Laboratory of Wave Engineering, School of Electrical Engineering, EPFL, Station 11, 1015 Lausanne, Switzerland

Email: romain.fleury@epfl.ch

We will discuss our recent experimental progress on developing active acoustic resonators that provide independently tunable acoustic properties, namely the possibility to control at will their resonance frequency, absorption losses, and radiative losses. We will describe how this can be achieved using electroacoustic systems such as loudspeakers, by employing a real-time single sensor feedback control strategy similar to what is used for broadband acoustic impedance control [1], but adapted using a demodulation/modulation scheme to provide a more flexible control of the complex impedance. We will present measurements on a single controlled meta-atom for which the resonance frequency, as well as radiative and non-radiative quality factors, can be tuned independently. We will also demonstrate the possibility to target a given value of the input impedance of the resonator, which allows us to design acoustic metamaterials with any scattering potentials, including non-Hermitian. We will discuss an application example for such active acoustic meta-atoms to the observation of constant-amplitude waves through a disordered non-Hermitian metamaterial, a concept developed by collaborators at TU Wien [2,3] and validated in our laboratory [4].

The radiation of an emitter does not depend only on its intrinsic properties but also on the surrounding photonic environment, the notion of which is essential in the developments of lasers, quantum optics and other light-matter interaction related fields. However, in conventional wisdom, an emitter radiates into photonic eigenstates in the weak coupling regime and does not alter the property of the latter. Here, we report a counterintuitive phenomenon where the radiation field of a dipole in a parity-time symmetric ring resonator displays the opposite handedness to the coalesced eigenstate of the system (Fig. 1) [1]. This finding, to the best of our knowledge, is the first time the wave function of a Jordan vector is revealed in a physical system. We employ this phenomenon to construct vortex radiation with controllable topological charge from a single quantum dot embedded plasmonic nanocavity, demonstrating an enhancement of the Purcell factor by three orders of magnitude. Our scheme enriches the intriguing physics of an exception point in the quantum region and may open a new paradigm for chiral quantum optics and vortex lasers at nanoscale.

Abstract

The principle of Parity-Time symmetric optics is exploited for realization of electrically injected single frequency DFB lasers based on industry-adopted design and fabrication approaches. Experimental evidence is provided for “unidirectional” gain discrimination mechanism induced by the complex refractive index Bragg grating. This is expected to enhance lasers’ resistance to parasitic optical feedback. The experimental results showing an apparent correlation between the gratings real-to-imaginary phase shift and the laser feedback resistance are corroborating theoretical prediction.

1. Introduction

The advent of the concept of Parity-Time (PT) symmetry and the progress in nanofabrication technologies, witnessed triggered the appearance during the past decade of new type of artificial optical materials where the refractive index (real and imaginary) \( n(r) \) behaves akin the complex potential of the original idea [1]. Since then, academic teams have achieved demonstrations that make use of integrated optics as a laboratory vehicle but without genuine industrial perspective [2-6].

The aim of the present work is to exploit asymmetric reflection properties of Parity-Time symmetric Bragg gratings (PTSBG) to enhance the resistance of distributed feedback (DFB) lasers to the optical feedback, in the spirit of the IEEE 802.3 standard for isolator-free sources in optical networks. Due to the narrow-band “unidirectional” reflection of PTSBG introducing an additional gain discrimination mechanism, it is expected that the coherence of such a laser would be highly tolerant with respect to the parasitic reflections along the optical path [7,8]. This is one of the worst network impairment issues, currently addressed by the costly means of garnet-based optical isolators.

2. Results and discussion

Based on the same gain medium, index-coupled (IC), loss-coupled and complex-coupled (CC) DFB lasers with different phase shifts between loss and index grating profiles were fabricated, using industry-adopted design and fabrication approaches. The complex-coupled Bragg grating is achieved through the technological realization combining a metallic Bragg grating ensuring modulation of the imaginary part of the complex effective index profile with a shifted dielectric Bragg grating modulating the real part of the effective index profile (Fig. 1a).

![Fig. 2. a) SEM view of PTSBG with \( \pi/2 \) phase shifted dielectric and metallic Bragg gratings; b) Emission spectrum of PTSBG DFB laser at 1549.5 nm.](image)

The characterization of the fabricated CC DFB lasers showed a reduction in threshold compared to equivalent third-order loss-coupled DFB lasers, and improved single frequency operation and yield compared to third-order index-coupled DFB lasers. High spectral purity laser emission with typical side mode suppression ratio (SMSR) ~50dB, as shown in Fig. 1b, was demonstrated. Real and imaginary parts of the effective index modulation as well as reflection spectral response were investigated by external optical probing of the laser cavities, the former in order to refine the guidance modelling of this particular geometry, and the latter to assess the impact of the phase shift. The specific phase shift of a quarter period, matching the PT-symmetric configuration, is found to show highly asymmetric mode selection, with unidirectional amplification in reflection.

The resistance of the CC DFB lasers to external optical feedback was further investigated. The obtained results show an apparent correlation between the gratings phase shift and the feedback resistance. In contrast, no significant improvement was found with respect to IC DFB lasers.
Strategies for the optimization of the Bragg grating complex index profile aiming to achieve performances beyond the current state of the art for DFB lasers will be discussed.

3. Conclusions

This first milestone on the application of PT-symmetry to the design and fabrication of DFB lasers compatible with industrial fabrication provide interesting prospects on the improvement of existing technologies. This work reinforces the interest of this concept for the design of feedback tolerant DFB lasers, and their integration in an all PT-symmetric laser-modulator system.

Abstract

Bi$_2$Se$_3$ is one of the most studied Topological Insulator. Thanks to its pretty large band gap and unique Dirac cone in the energy-momentum dispersion, Bi$_2$Se$_3$ mirrors indeed a representative candidate for investigating the electrodynamics of Dirac fermions in a graphene-like material.

Collective oscillations of Dirac electrons, i.e. Dirac surface plasmons, in a topological insulator have been demonstrated to exist for the first time in Bi$_2$Se$_3$ in 2013 [1]. The Dirac plasmonic dispersion has been measured in five samples of Bi$_2$Se$_3$ thin films on sapphire substrate patterned with micro-ribbons of width from 2 to 20 μm. The actual plasmonic resonance has been extracted from FTIR measurements and compared to the theoretical Dirac dispersion, finding a very good agreement.

Recently, we addressed the intrinsic nonlinearity of Bi$_2$Se$_3$ Topological Insulator, due to its linear Dirac energy-momentum dispersion. As in graphene, nonlinear properties like saturable absorption and harmonic generation have been shown in a topological insulator in [2]. Moreover, theoretical papers proved the nonlinear effects even on a patterned topological insulator, predicting a softening of the surface plasmon in presence of tens kV/cm of electric field.

The THz beam provided by our beamline TeraFERMI at the Free Electron Laser (FEL) Fermi at Elettra in Trieste (Italy) [3] provides very intense THz electric field in the MV/cm range. TeraFERMI was built up in 2015 at the seeded FEL Fermi, which works in a single pass-single bunch mode at 10 or 50 Hz, covering the spectral range from 100 to 4 nm. TeraFERMI is based on a Coherent Transition Radiation source that provides high intense, broadband and short (about 1 ps) pulses. Such a THz beam can push nonlinear materials well into their nonlinear regime. The beamline experimental setup fulfills the capability to address nonlinear regime by measuring both fluence-dependent transmission/reflection spectra and pump-probe response.

Particularly, the case of Dirac plasmon in Bi$_2$Se$_3$ perfectly fits with the potentiality of TeraFERMI. Here we show the THz control of the Dirac plasmon by TeraFERMI electric field. Our data of two samples of Bi$_2$Se$_3$ thin films on sapphire substrate with micro-ribbons of 4 and 20 μm exhibit a redshift of the plasmonic resonance with respect to the incoming electric field. This is the first demonstration of Dirac plasmon tunability with THz light in a topological insulator.

Ratchet and magneto-ratchet phenomena excited by THz radiation in semiconductor nanostructures and graphene with lateral superlattices

Sergey Ganichev

1Terahertz Center, University of Regensburg, 93040 Regensburg, Germany
*corresponding author, E-mail: sergey.ganichev@ur.de

Abstract
The paper overviews experimental and theoretical studies of terahertz radiation induced ratchet and magnetic ratchet effects in graphene and semiconductor nanostructures with a lateral superlattice (SL). We show that the ratchet photocurrent induced in such samples is caused by the combined action of a spatially periodic in-plane potential and the spatially modulated radiation due to the near field effect of light diffraction. The magnetic quantum ratchet effect is observed in diluted magnetic heterostructures and additionally requires an external magnetic field applied normal to the sample surface. We present symmetry arguments allowing a phenomenological analysis of the respective phenomena, then outline the microscopic theory and finally discuss the main experimental findings.

1. Introduction
Generally, nonequilibrium spatially-periodic non-centrosymmetric systems are able to transport particles in the absence of an average macroscopic force. The directed transport in such systems, known as ratchet effect, has a long history and is relevant for different fields of physics, for review see e.g. [1, 2, 3, 4, 5]. If this effect is induced by electromagnetic radiation it is usually referred to as photogalvanic effect [6]. A novel situation emerges if a lateral superlattice is superimposed upon a two dimensional electron system (2DES): THz radiation shined through a periodic grating, drives the ratchet current through the modulated 2DES, for reviews see e.g. [3, 5].

We begin the review with a short overview on the structures and methods used for the study of THz radiation induced ratchet effects in semiconductor nanostructures and graphene with a lateral one-dimensional potential. Then we give an introduction to the basic concepts and present experimental findings.

2. Terahertz radiation induced ratchet effects
Modulated potentials have been obtained fabricating either a sequence of metal stripes or inter-digitated comb-like dual-grating-gate (DGG) structures, both on top of a 2DES. Examples of such structures deposited on graphene are shown in Fig. 1. By applying different voltages to the two gratings, we can control the photocurrent behaviour for different structure asymmetry, carrier type and density.

Figure 1: Cross section, photograph and sample geometry sketch of metal finger structure deposited on large area epitaxial graphene, see panel (a) and (b), and interdigitated grating gates deposited on the exfoliated monolayer graphene flake, see panel (c) and (d). Here, $d_1, 2$ and $a_1, 2$ are the width of metal stripes and the spacing in-between, respectively.
spect to other electronic ratchets, and propose a model picture to interpret the observed photocurrents.

3. Magnetic quantum ratchet effects

Magnetic quantum ratchet effects, for review see [8], have been recently observed in (Cd,Mn)Te/(Cd,Mg)Te diluted magnetic heterostructures and CdTe/CdMgTe QWs superimposed with lateral asymmetric superlattices [9]. We show that application of an external magnetic field $B$ along the growth direction results in the ratchet current exhibiting sign-alternating $1/B$-periodic oscillations with amplitudes immensely larger than the ratchet signal at zero magnetic field, Fig. 3. The photocurrent consists of the polarization insensitive Seebeck ratchet, as well as of the polarization sensitive magnetic quantum ratchet current, whose direction and magnitude are determined by the orientation of the THz electric field (linear magnetic ratchet effect) and/or by the direction of the field rotation (circular magnetic ratchet effect). We show that the observed magneto-oscillations with enhanced photocurrent amplitude result from Landau quantization and, for (Cd,Mn)Te at low temperatures, from the exchange enhanced Zeeman splitting in diluted magnetic heterostructures.

Abstract

We report on massless Dirac fermions in two-dimensional system based on III-V semiconductors. Using a gated Hall bar made on a three-layer InAs/GaSb/InAs quantum well, we restore the Landau levels fan chart by magnetotransport and unequivocally demonstrate a gapless state in our sample. Measurements of cyclotron resonance at different electron concentrations directly indicate a linear band crossing. Analysis of experimental data allows us not only determining velocity of the massless fermions but also demonstrating significant non-linear dispersion at high energies.

1. Introduction

Since relativistic Dirac-like character of charge carriers was demonstrated in monolayer graphene [1], two-dimensional (2D) massless Dirac fermions (DFs) are intensively studied in condensed matter physics. There are several systems [2] or high-temperature d-wave superconductors to the surfaces of three-dimensional (3D) topological insulators, in which the presence of 2D massless DFs was revealed. Their universal features, such as suppressed backscattering [3], Klein tunneling [4], or their specific response to impurities and magnetic field [5] hold great promises for new nano-scale electronic devices.

Among quantum well (QW) systems, a single-valley spin-degenerate Dirac cone at the Γ point of Brillouin zone was theoretically predicted [6,7] and experimentally observed [8] in HgTe/CdTe QWs. At a critical width, the band gap in these QWs vanishes and the band structure changes from trivial to inverted. The key advantage of QWs over other systems is based on the ability to adjust DFs velocity by adjusting the strain and thickness of the layers. It allows varying the ratio between kinetic energy and Coulomb interaction, which results in a rich variety of phenomena involving massless DFs [9]. However, the massless DFs in HgTe QWs appear only at a fixed temperature, since the temperature changes open a band gap resulting in a non-zero rest-mass of the particles [10-14].

Alternative III-V semiconductor QWs, in which massless DFs have been theoretically predicted, are symmetric three-layer InAs/Ga1-xInxSb/InAs QWs confined between wide-gap AlSb barriers [15]. Depending on their layer thicknesses, these QWs host trivial, quantum spin Hall insulator and gapless state. However, in contrast to the HgTe QWs, the three-layer QWs have a temperature-insensitive band-gap, as it has been recently shown by terahertz spectroscopy [16]. Another expected difference of massless DFs in InAs/Ga1-xInxSb/InAs QWs is the large tunability of quasiparticle’s velocity, which can be varied from 1·10⁵ m/s to 7·10⁵ m/s depending on x and the layer thicknesses [15]. The latter offers the possibility not only to tune the electronic properties [3,4,6] of the DFs but also to achieve specific non-trivial states induced by electron-electron interaction [17-19].

2. Outline of the talk

In this work, we report striking evidence of the presence of massless Dirac fermions in InAs/GaSb/InAs QWs embedded between AlSb barriers. Measuring magnetoresistance of a gated Hall bar, we restore the Landau level (LL) fan chart in our sample, as firstly performed by Büttner et al. [8] in HgTe QWs. Our experimental data clearly evidence a gapless state. We also measure cyclotron resonance (CR) at different electron concentrations varied by bipolar persistent photocconductivity (PPC) inherent for InAs-based QWs [20-22]. The latter is also known as an optical gating and allows changing an electron concentration in the QW by several times. By analyzing the dependence of the cyclotron mass as a function of the concentration, the massless DF velocity is deduced. To analyze these data, we use both realistic band structure calculations based on an eight-band Kane model [15] and analytical approach involving a simplified Dirac-like Hamiltonian [7]. Experimental dispersion of the massless DFs is in good agreement with realistic band structure calculations.

Abstract
We report on stimulated emission at wavelengths up to 20μm from HgTe/HgCdTe quantum well heterostructures with wide-gap HgCdTe dielectric waveguide, grown by molecular beam epitaxy on GaAs(013) substrates. The mitigation of Auger processes in structures under study is exemplified, and the promising routes towards the 20–50 μm wavelength range, where HgCdTe lasers may be competitive to the prominent emitters, are discussed.

1. Introduction
The problem of developing compact terahertz (THz)/long-wavelength emitters is one of the hottest topics in the applied physics. There is a spectral «gap» \( \lambda = 20 – 60 \mu m \) in which no quantum cascade lasers (QCLs) are available (except for several specific wavelengths near 20 μm), since the majority of QCLs are based on A3B5 materials with strong lattice absorption in this spectral region. Among compact semiconductor lasers, only lead salt lasers cover a part of this gap (up to 46 μm), but their figures of merit are rather low due to formidable problems in growth technology. On the other hand, modern MBE delivers high quality HgTe/CdHgTe quantum well (QW) structures that allow tailoring the bandgap for interband transitions at \( \lambda = 20 – 60 \mu m \) and have TO phonon frequencies low enough to enter this wavelength range. In addition, HgTe/CdHgTe structures offer strongly non-parabolic dispersion law resembling that of graphene but with finite gap and finite carrier masses that set a considerable energetic threshold for Auger processes.

2. Results and discussion
We report on stimulated emission at wavelengths up to 20μm at 20K and 2.8 – 3.5 μm at 210K from HgTe/HgCdTe quantum well heterostructures with wide-gap HgCdTe dielectric waveguide, grown by MBE on GaAs(013) substrates. The mitigation of Auger recombination (AR) in structures under study is exemplified, and the promising routes towards the 20–50μm wavelength range, where HgCdTe lasers may be competitive to the prominent emitters, are discussed. The next one we conclude that Peltier cooled operation is feasible in lasers based on such structures, making them of interest for spectroscopy applications in the atmospheric transparency window from 3 to 5 μm. We demonstrate stimulated emission (SE) under pulsed and cw optical pumping from HgTe/CdHgTe QWs at wavelengths as long as 11 – 20 μm [1-3], which is almost fourfold increase over previous works. We show that a significant increase in operating temperature (by ~80 K) and wavelength is possible by introducing the additional strain in QW structure to modify the carrier spectrum in the valence band due to suppression AR. We show that the side maxima, arising in the valence band when the QW width is increased, is a critical issue for radiative properties of the material since they enhance AR. On the other hand, implementing narrow HgTe/CdHgTe is performed to suppress the AR and increase the operating wavelength and operating temperature

![Fig.1. Stimulated emission spectra for structures under study at different temperatures (solid curves). SE was obtained under pulsed pumping with 2300 nm wavelength and 10 kW/cm² intensity for Structure#1 (T = 8K, T = 50K) and 65 kW/cm² for Structure#2 at 175K. SE at cw excitation with 7W/cm² intensity at 900 nm wavelength is presented for Structure#2 at 8K. Dash curves show PL spectra obtained with the same cw pumping source at 5 W/cm² intensity for Structure#1 (T = 8K, T = 50K) and 1 W/cm² for](attachment:fig1.png)
of HgCdTe based lasers far-infrared from 10 to 20 µm. Experimental results agree well with theoretical calculations of energetic threshold for AR performed in the framework of Kane 8x8 Hamiltonian model as were performed in [4, 5].

Implementing such structures, we demonstrate stimulated emission (SE) under pulsed [1-3] and continuous wave (cw) (Fig. 1) optical pumping at wavelengths as long as 9.5 – 19.5 µm, which is almost fourfold increase over previous works. Being recalculated to the equivalent threshold current, the threshold is only 500 A/cm² for λ = 20 µm at 8K – 45K. In principle, such low threshold current density allows development of continuous wave diode lasers. We show that the side maxima, arising in the valence band when the QW width is increased, is a critical issue for radiative properties of the material since they enhance Auger processes. We show that a significant increase in operating temperature (by ~80 K) and wavelength is possible by introducing the additional strain in QW structure to modify the carrier spectrum in the valence band. Using Kane 8x8 Hamiltonian and Bernevig-Hugh-Zhang four-band model to calculate radiative and Auger recombination times, respectively. Carrier lifetime measurements agree well with the calculated data. The subnanosecond carrier lifetimes have been explored via the pump-probe measurements of a sample’s transmission [3]. For HgCdTe QW with 20 meV, corresponding to 4.8 THz frequency, the carrier lifetime is no less than 100 ps for carrier density of 10¹¹ cm⁻² that is sufficient to achieve population inversion. One can estimate a threshold pumping intensity of 10 kW/cm² for an optically pumped laser exploiting such QWs as an active media. Thus, implementing narrow HgTe/CdHgTe is the promising route to suppress the Auger recombination and increase the operating wavelength of HgCdTe based lasers in far-infrared/THz (20 – 60 µm) range.

Abstract

1. Plasmons, collective oscillations of electron systems, can efficiently couple light and electric current, and thus facilitate developing many optoelectronic devices. Despite considerable effort, it has proven challenging to implement plasmonic devices operating at terahertz frequencies. With lowering the operation frequency down to the THz domain, momentum relaxation rate has to be below the plasmon frequency, which, in turn, requires ultra-high electron mobility. The material capable to meet this challenge is graphene that has been proved to support long-lived electrically tunable plasmons.

2. Introduction

Here we report on plasmon-assisted resonant detection of terahertz radiation by antenna-coupled graphene transistors that act as both plasmonic Fabry-Perot cavities and rectifying elements. We demonstrate this long-sought resonant regime [1] using field effect transistors (FETs) based on high-quality van der Waals heterostructures. In particular, we employ graphene encapsulated between hexagonal boron nitride (hBN) crystals which have been shown to provide the cleanest environment for long-lived graphene plasmons [2-4]. Exploiting the gate-tunability of plasmon velocity, we switch our detectors between more than 10 resonant modes, and use this functionality to measure plasmon wavelength and lifetime [5].

In addition to their potential applications in high-responsivity detection and on-chip spectroscopy of the THz radiation, our devices also represent a convenient tool to study plasmons under conditions where other approaches may be technically challenging. Due to their compact size and far-field coupling, our photodetectors can easily be employed to carry out plasmonic experiments in extreme cryogenic environments and in strong magnetic fields, as well in studies of more complex van der Waals heterostructures. As an example, we apply our approach to probe plasmons in graphene/hBN superlattices and unveil collective modes of charge carriers in moiré minibands.

Quantum phenomena with collective excitations in confined systems

Elementary excitations in dense media are renormalized by their mutual interaction, giving rise to quasiparticles with new collective properties. Such renormalization occurs for instance in highly doped semiconductor layers where Coulomb interaction ties together all single electronic excitations and gives rise to a bright collective mode [1] with a huge optical dipole. These excitations correspond to confined plasmons.

In the past few years we have investigated electronic many-body states in quantum wells as a valuable platform to probe some of the most fundamental phenomena of quantum electrodynamics, which are usually the realm of atomic physics. Indeed, each many-body electronic state is a bosonic quasi-particle confined perpendicularly to the plane of the quantum well. While considering the first two energy levels of the harmonic ladder, the quasi particle can be regarded as a macro-atom carrying all the interaction with the electromagnetic field [2]. When such an excitation is coupled to a microcavity mode, it reaches straightforwardly the ultra-strong light-matter coupling regime [5] at room temperature. Furthermore, identical macro-atoms located in spatially separated quantum wells, within a sub-wavelength distance, have a huge interaction with the vacuum field by exchanging real and virtual photons [3]. This results into a superradiant mode displaying a large cooperative Lamb shift [4]. Finally, we have observed experimental signatures on the energy spectrum of these many-body states that arise from its size confinement. This effect produces a set of energy resonances given by the folding of the excitation dispersion.

All these fundamental quantum effects have been investigated in optoelectronic devices [7], paving the way towards a new generation of devices in which light-matter interaction is tailored by collective phenomena.

Abstract

Transition-metal dichalcogenides (TMDs) are exemplary low-dimensional semiconductors. By breaking the inversion symmetry inherent in their bulk crystals, various exotic physical phenomena have been realized. We studied electrical responses under light illumination in such non-centrosymmetric TMDs belonging to a few different point groups, and observed a large photovoltaic effect induced by the reduction of the crystal symmetry.

1. Introduction

The unit cell of bulk TMDs is composed of two layers. The inversion centre in the unit cell is located at the van der Waals gap. The inversion symmetry can be broken simply by isolation of monolayers, and/or application of external electric field. Many peculiar phenomena and functionalities have been realized in such non-centrosymmetric TMDs [1-3]. The bulk photovoltaic effect (BPVE) is one of the fundamental physical phenomena that requires inversion symmetry breaking which is not studied in TMDs so far [4]. This effect can be distinguished from the ordinal photovoltaic effect that is observed at the interface of two different species, for instance, p-n junctions and metal-semiconductor Schottky junctions, because the BPVE does not require any interface.

Monolayer TMDs have a non-centrosymmetric $D_{3h}$ crystal symmetry. Materials in this point group should exhibit BPVE upon irradiation of linearly polarized light [4]. Circularly polarized light will not induce BPVE due to the mirror and rotational symmetries. These remnant symmetries are broken when 2D sheets are rolled up to form quasi-one dimensional tubular structure (Fig. 1). BPVE is expected regardless of the optical polarization of the incident light when mirror and rotational symmetries are broken [4]. Here, we studied the BPVE in WS$_2$, a representative member of TMDs, in three different forms, namely, centrosymmetric bilayer and non-centrosymmetric monolayer as well as nanotube (NT).

2. Experiment

WS$_2$-NTs were chemically synthesized [5] and then dispersed on a SiO$_2$/Si++ substrate. Isolated nanotubes were selected under an optical microscope. WS$_2$ flakes were mechanically exfoliated by an adhesive tape from single crystals grown via chemical vapour transport (CVT) [6]. The electrodes were patterned using electron-beam lithography. After its development, Cr (5 nm) and Au (200 nm) were evaporated.

The WS$_2$-NTs used in this study have multiwall and hollow core as shown in the representative transmission electron microscopy (TEM) image in Fig. 2a. Their outer diameter is in average 100 nm. The electron diffraction (Fig. 2b) indicates that the chirality of each layer of the wall is different. A detailed characterization of the WS$_2$-NTs can be found in literatures [5,7].
All measurements were performed under high vacuum conditions at room temperature. Samples were placed under a home-built optical microscope and are illuminated by laser with one of following three wavelengths: 532 nm, 632.8 nm, or 730 nm, through an x50 objective. The wavelength of 632.8 nm is almost resonant to the direct gap energy of WS₂ [7,8]. The laser spot size is approximately 1-2 µm as determined from a fit of the laser profile to Gaussian. The electrical signal were acquired using a source-measure unit under continuous illumination.

3. Results and discussion

$I-V$ characteristics at dark and under light illumination were mainly studied. The $I-V$ curve at dark passes through the origin, while under illumination finite short-circuit current ($I_{sc}$) and open-circuit voltage ($V_{oc}$) are recognized. This fact indicates the existence of the photovoltaic effect in WS₂-NTs.

Although the laser spot size is about half of the separation between two electrode, the photovoltaic effect due to charge separation at the Schottky barrier contacts may occur if the diffusion length is in the micro-meter scale. In order to assess this possibility, $I_{sc}$ was recorded while the laser spot was scanned from one of two electrodes toward the other. If the observed photovoltaic effect is induced by the charge separation at the Schottky barrier, $|I_{sc}|$ increases with the laser spot approaching electrodes. In addition, the sign of $I_{sc}$ should reverse between two electrodes. We found that the spatial dependence of $I_{sc}$ in WS₂-NT does not match the feature of Schottky barrier photovoltaic effect discussed above, suggesting the existence of the BPVE. As a comparison, a WS₂ monolayer device with similar lateral dimension is fabricated as well. The spatial dependence of $I_{sc}$ in this monolayer device is consistent with the Schottky barrier photovoltaic effect.

The BPVE in TMD monolayers are likely quite small and buried in the features of the Schottky photovoltaic effect, since the group theory does predicts BPVE in TMD monolayers [4]. In contrast, BPVE in WS₂-NT is largely enhanced and overwhelms features from Schottky photovoltaic effect. Considering the small absorbance of the WS₂ monolayer as well as the small diameter of WS₂-NT, the total photon absorption in WS₂ monolayer is about half of that in WS₂-NT assuming 100% absorption in WS₂-NT. Nevertheless, the BPVE, evidenced from the $I_{sc}$ when the laser spot is away from contacts, in WS₂-NT is more than orders in magnitude larger than that in WS₂ monolayer. Both WS₂ monolayer and NT have non-centrosymmetric structure. However, the former is non-polar while the latter is polar. Therefore, the large enhancement of the BPVE in WS₂-NT is likely owing to the polar structure.

4. Conclusions

We discovered a bulk photovoltaic effect in WS₂-NT. The large suppression of the similar effect in WS₂ monolayer implies the importance of the polar crystal structure beyond the mere inversion symmetry breaking.

Towards High Efficiency Detectors and Sources for Field-Ready Quantum Nanophotonics
Limits to the fidelity of on-demand single photon sources using quantum dot-cavity systems

S. Hughes

Department of Physics, Queen’s University, Kingston, Ontario, Canada K7L 3N6

Abstract

A quantum dot coupled to an optical cavity has recently proven to be an excellent source of on-demand single photons. We investigate the factors associated with pulsed excitation that can limit simultaneous efficiency and indistinguishability, including excitation of multiple excitons, multi-photons, and pump-induced dephasing, and find for realistic single photon sources that these effects cause degradation of the source figures-of-merit comparable to that of phonon scattering. We also compare and contrast semiconductor cavity systems with metallic resonator systems.

The use of photons as easily manipulated quanta for quantum information processing applications, as well as fundamental studies, has led to the desire to create high-fidelity sources which can produce single photons “on demand” [1–3]. The single photon source (SPS) should produce photons efficiently (ideally, where each trigger pulse produces one and only one photon) which are of an indistinguishable quantum character (i.e., a pure quantum state), in addition to other desirable parameters including scalability and source stability over time. Semiconductor quantum dots coupled to an optical cavity have recently proven to be an excellent source of on-demand single photons [4–8]. Typically, applications require simultaneous high efficiency of the source and quantum indistinguishability of the extracted photons. While much progress has been made, both in suppressing background sources of decoherence and utilizing cavity-quantum electrodynamics to overcome fundamental limitations set by the intrinsic exciton-phonon scattering inherent in the solid-state platform [9, 10], the role of the excitation pulse has been often neglected.

This talk will discuss the key factors associated with pulsed excitation that can limit simultaneous efficiency and indistinguishability, including excitation of multiple excitons, multi-photons, and pump-induced dephasing. We will show that, for realistic SPSs, the role of pulse excitation causes degradation of the source figures-of-merit comparable to that of intrinsic phonon scattering. We present rigorous open quantum system polaron master equation models of quantum dot dynamics under a time-dependent drive which incorporate non-Markovian effects of both photon and phonon reservoirs, and explicitly show how coupling to a high Q-factor cavity suppresses multi-photon emission in a way not predicted by commonly employed models. We then use our findings to summarize the criteria that can be used for single photon source optimization [11]. We also show how short pulses manifest in a time-dependent Purcell factor that is suppressed during the pulsed excitation process, causing a departure from the usual Fermi’s golden rule.

Nanoplasmonic resonators offer another class of “cavity system” that can enhance the light-matter interactions for SPS applications, and there have been various works published on how to increase the Purcell factor as well as on how to increase the output (radiative) beta factor [12, 13]. Huang et al. [14] demonstrated room-temperature SPS emission from QDs coupled to plasmonic nanocavities, using silver nanocubes, and measured impressive Purcell factors in excess of 500; and Lyamkina et al. [15] showed how one can deterministically integrate semiconductor quantum emitters with plasmonic nano-devices, demonstrating enhanced spontaneous emission of single near-surface (<10 nm) InAs quantum dots. Most of these metal resonator works agree that two of the most important metric for efficient SPSs are the Purcell factor and output beta factor or quantum efficiency; unfortunately, these two properties are not mutually exclusive, even at the level of a single mode. In terms of the single photon purity [8, 16], fast SPS emission and suppression of multi-photon emission with $g^{(2)}(0)<0.1$ has been achieved by quasi-resonant excitation at low excitation power. However, to the best of our knowledge there has not yet been any reported measurements of the two-photon interference for metal based SPSs, which is required to quantify the indistinguishability of the emitted photons. Using a recent quantization scheme for quasinormal modes [17] (the dissipative modes for any open-cavity structure [18]), we will highlight the main challenges for metal based SPSs and compare these with semiconductor cavity systems.

Generating and routing single photons in GaAs nanophotonic circuits

Leonardo Midolo

Center for Hybrid Quantum Networks (Hy-Q), Niels Bohr Institute, University of Copenhagen, Blegdamsvej 17, 2100-DK Copenhagen Denmark

Abstract

We report the latest advances in controlling single-photon emission and routing using photonic integrated circuits with embedded quantum dots. These include methods for performing on-chip resonance fluorescence, actively routing photons within a chip, and efficiently couple them into optical fibers. These results constitute key steps to develop scalable emitter-photon interfaces with high efficiency and coherence.

1. Introduction

In recent years, semiconductor quantum dots (QDs) in GaAs have been suggested as a promising alternative to, e.g., spontaneous parametric down-conversion, for single-photon generation and quantum information processing, mainly due to their ability to provide on-demand photon emission and near-unity coupling to optical waveguides [1]. Nevertheless, the integration in GaAs circuits, and the solid-state nature of the emitters, make it highly challenging to simultaneously fulfill all the requirements for coherent emission, routing, and processing of single photons. The most prominent technological challenge is to boost the total efficiency of photonic qubits, which demands a fully-integrated approach with nearly lossless devices. Here, we report some of the recent efforts that we have taken towards improving the excitation schemes for QDs and to implement active routing of single photons within a GaAs optical circuit.

2. Waveguide-based resonance fluorescence

Generating highly indistinguishable resonance fluorescence requires pumping the QDs with resonance fluorescence excitation schemes. This is commonly achieved by focusing a laser on the QD, tune it to an individual excitonic transition, and extinguish its signal using cross-polarized detection. Here, we present a novel method to excite the emitter without a free-space objective, i.e., with an entire waveguide-based approach relying on multi-mode waveguides where the laser and the emitter couple to two distinct optical modes in a controllable way. We achieve an extinction ratio between resonance fluorescence and pump photons higher than 100 using a simple on-chip mode filtering technique. The indistinguishability is measured via a Hong-Ou-Mandel experiment, which results in >90% visibility of interference between two consecutively emitted photons. Such approach enables realistic pathways for removing free-space optical setups for exciting the emitters, since both the laser pump and the emitted photons can be coupled to a chip with, e.g., high-efficiency gratings [2].

3. Nanomechanical routing of single photons

Another important functionality is to scale up the number of photons that can be emitted by a single QD. To achieve this goal, a key requirement is to develop reconfigurable circuitry that does not introduce excessive loss or emitter decoherence. Such circuitry would enable routing and switching photons into different optical channels, enabling spatial de-multiplexing of photons. The existing routing mechanisms, based on thermo-optic and electro-optic effects are too slow or require very large footprints, limiting both scalability and efficiency. We report a nanomechanical single-photon router based on gap-variable directional couplers, with electro-mechanically controllable splitting ratio. Such device enables us to route single photons emitted by embedded QDs with extinction ratios >20 dB and nW-level power consumption. The reduced device footprint (<30 μm²) and the small dimension involved, allow us to achieve sub-microsecond switching time (~370 ns) and a total insertion loss of 0.67 dB/switch [3]. These results are key to implementing networks of re-configurable quantum gates and schemes for on-chip de-multiplexing with more than 10 photons.

Abstract

The on-chip generation of quantum states of light is a fundamental requirement for integrated photonic quantum technologies. Many photonic integrated chip platforms exhibit an intrinsic material nonlinearity which can be used for quantum state generation. We focus on engineering photon-pair sources in silicon photonics. This platform offers the ability to construct photonic circuits of unparalleled size and complexity. Nonetheless, careful engineering of the classical and quantum source physics is needed to construct high-performance sources for next-generation quantum technology applications.

1. Introduction

Engineering the quantum state of light on-chip is a key enabling technology for quantum photonic applications. Two complementary routes to generating photons on-chip have been pursued: single-photon emitters (quantum dots, colour centres, etc) and parametric photon-pair sources. We choose to develop parametric sources that make use of the intrinsic material nonlinearity of silicon to generate photon-pairs through the process of spontaneous four-wave mixing (SFWM). These sources can be integrated with complex photonic and electronic circuits, with zero-change required to the fabrication process [1]. Motivated by the goal of large-scale linear optics quantum computing and quantum simulation, ever-larger demonstrations of on-chip quantum information processing (QIP) have been performed [2]. Nonetheless, current large-scale demonstrations employ basic source designs that fall short of the stringent performance requirements necessary for a scalable monolithically integrated QIP platform. In particular, current designs achieve only limited purity and heralding efficiency, and require both off-chip spectral filtering and single photon detection. Although there has been a wealth of theoretical research into advanced source designs, this has largely focussed on improvements in the purity only and has yet to be experimentally demonstrated. Currently, the most advanced demonstration of on-chip photon-pair generation has demonstrated an interference visibility of 72% between two independent ring resonator sources [3]. We examine the system-level requirements for photon-pair sources for QIP applications and report developments that we believe will overcome the limitations of current source designs.

2. Source Engineering

2.1. System-level requirements

Any QIP platform will have to be robust to errors. Although the exact error thresholds are dependent on the encoding scheme used we can identify system-level source metrics that will have to be targeted for linear optical QIP:

- single photons: parametric sources produces photon-pairs probabilistically. Nonetheless, heralding with number-resolving detectors and active multiplexing should allow the creation of a near deterministic single-photon source [4].
- heralding efficiency: the efficiency with which a photon can be heralded is limited by the detection efficiency, source design (photon extraction efficiency) and material and waveguide scattering losses.
- heralded photon purity: the purity of the heralded photon sets an upper limit on the nonclassical interference visibility, which is a fundamental requirement for the high-fidelity operation of quantum gates.
- low noise: the low conversion efficiency between pump photons and generated photon-pairs typically demands > 100 dB pump rejection filtering. The monolithic integration of single-photon detectors and sources on-chip, will require high-extinction on-chip filtering and engineering of the optical environment around sources to contain scattered light and avoid blinding of on-chip detectors.

2.2. Technical requirements

The system-level requirements for a QIP photonic source can be translated into technical requirements for our parametric photon-pair source designs, some of which we discuss below.

2.2.1. Schmidt mode engineering

Parametric sources produce photons in pairs. Due to energy and momentum conservation constraints, these photon-pairs will in general exhibit spectral correlations that can be described by the bi-photon state [5]:

\[ |\psi\rangle = \int \psi(\omega_1, \omega_2) a_1^\dagger(\omega_1) a_2^\dagger(\omega_2) d\omega_1 d\omega_2 |\text{vac}\rangle. \]
By the Schmidt decomposition it is always possible to write this as the sum of factorisable photon-pair states:

$$|\psi\rangle = \sum_{i} \lambda_i \hat{A}_i^\dagger (\omega_1) \hat{A}_2^\dagger (\omega_2) |\text{vac}\rangle,$$

where $\lambda_i$ are the Schmidt values and $\hat{A}_i^\dagger$ are creation operators on the broadband single-photon modes. This expansion provides a convenient basis from which to calculate the purity of the heralded single-photon state: $P = \sum |\lambda_i|^4$. The engineering of spectral correlations to improve source purity has been the focus of significant research. Standard ring-resonator designs exhibit an upper-limit to the purity of 93% and designs have been proposed that overcome this limit [6]. We demonstrate chromatically coupled ring-resonators that show strong modulation of the resonance linewidth, allowing modification of the Schmidt modes for enhanced heralded photon purity (see Fig 1).

### 3. Conclusions

Engineering parametric photon-pair sources for QIP applications will require a system-level approach to the requirements of a monolithically integrated platform. We are engineerig photon-pair sources that satisfy the full range of classical and quantum engineering challenges necessary for scalable on-chip QIP in a silicon photon platform.
Metrology for single-photon detectors and sources

Angela Gamouras
National Research Council Canada, Ottawa, Canada
*corresponding author, E-mail: angela.gamouras@nrc-cnrc.gc.ca

Abstract
National metrology institutes around the world have been working to provide characterization techniques and reference standards for few-photon technologies including single-photon detectors and sources. As advances are made towards on-chip integration of single-photon sources, detectors, and other optical components, methodologies for effectively characterizing these quantum integrated circuits will need to be developed. This presentation will discuss ongoing efforts in this area, including the need for consistency in the measurement of performance metrics for deterministic and probabilistic single-photon sources.

1. Introduction
Few-photon technologies have extended from applications in quantum information science (e.g. quantum computing, quantum cryptography, etc.) to numerous areas including spectroscopy, single molecule detection, remote sensing, and monitoring the environment [1]. These quantum technologies depend on the accurate detection of single photons, and in some cases rely on specific parameters for the individual photons themselves. Current and future implementations of quantum information and communication technologies will only be as effective as our measurement capabilities. National metrology institutes have developed several characterization techniques for single-photon detectors [2, 3], and now with commercially available devices for quantum key distribution [4], these methodologies have been extended to these systems [5]. As the quality of single photons from solid-state quantum emitters improves [6, 7] and as photonic integrated circuits begin to incorporate sources and detectors on a single chip [8, 9], additional efforts are being made to address the need for robust metrics when characterizing these devices.

Abstract

Semiconductor nanowires offer a powerful platform for engineering light at the nanoscale by controlling their size and shape in order to guide light efficiently and minimize undesired reflections. In this work we have shaped the nanowires with a unique tapering to realize bright quantum dot based entangled photon sources and high efficiency single photon detectors with high speed and timing resolution over an unprecedented bandwidth.

1. Introduction

In the first part of the talk I will discuss the on-demand generation of entangled photon pairs with a quantum dot in a tapered nanowire waveguide [1-3]. These results will be put in perspective with respect to state-of-the-art entangled photon sources with the viewpoint of going beyond in the future towards near-unity fidelity and efficiency. Reaching near-unity fidelity and efficiency has proven elusive with leading photon technologies due to the probabilistic nature of the generation process.

In the second part of the talk I will present our recent results towards efficient single-photon detectors based-on semiconductor nanowire p-n junction arrays operating at room temperature [4]. Due to the unique nanowire shape and device design we achieve broadband high-efficiency photodetection from the UV to the near infrared with peak efficiencies exceeding 80%. Such capability is beneficial for numerous applications including remote sensing of low power signals, acquiring high resolution images at long range and quantum communication, and advantageous for sensing applications requiring portability.

Abstract

We have realized a photodetector whose capacitance is less than 1 fF by using InP-based buried-heterostructure photonic crystal platform. We show that this ultrasmall-capacitance photodetector enables an amplifier-free and bias-free photoreceiver, which generates sufficiently-large on-chip output voltage without use of any electric power. In addition, we have also realized a electro-optic modulator whose capacitance is also less than 1 fF, which shows record-low consumption energy (42aJ/bit). Recently, we have integrated a fF photodetector with a fF electro-optic modulator via load resistor, which presents three-terminal optical nonlinear (transistor-like) functionalities, such as switching with signal gain. We believe these achievements pave the way to a novel form of optoelectronic information processing which has OE/EO conversions with very fine granularity.

1. Introduction

Traditionally, optical-to-electrical (OE) and electrical-to-optical (EO) conversions are considered as energy-consuming parts in optoelectronic signal processing systems. Generally, we should decrease the number of OE/EO conversions to make efficient optoelectronic systems. In this presentation, we are going to demonstrate that it is indeed possible to greatly improve the efficiency and latency of OE/EO conversions by making the capacitance of OE/EO converters small. Our recent achievement shows that the energy cost of OE/EO conversions can be reduced down to fJ/bit level, which is comparable or even smaller than the energy cost of cutting-edge photonic devices [1].

Although the gate capacitance of CMOS transistors have been decreased year by year, down to less than fF levels. The capacitance of conventional photonic devices such as photodetectors (PDs) and electro-optic modulators (EOMs) are still rather large (100 fF to pF range). Recently, however, we have succeeded in reducing the capacitance of PDs and EOMs down to less than 1 fF by use of buried-heterostructure photonic crystal technologies.

2. fF photodetector

Figure 1 shows our fF-PD based on a buried heterostructure photonic crystal waveguide with a later p-i-n junction [2]. As a result of the strong light confinement achieved by photonic crystals, its electrostatic size is extremely small, and the estimated device capacitance is as small as 0.6fF. More importantly, the fF-PD exhibits excellent performance as regards the bandwidth ($)f_{\text{th}} = 29\ \text{GHz}$, 40Gbps NRZ operation), the responsivity (1A/W), and the dark current (< 100 pA), despite of its small size. We have monolithically integrated this fF-PD with a load register, and experimentally demonstrated surprisingly large light-to-voltage conversion efficiency (4 kV/W) without any electric amplifier [2].

Fig. 1. Schematic of fF-PD based on a photonic crystal.

In addition, we have demonstrated that a photonic crystal PD can be operated at high frequency (20 Gbps) even under a forward bias condition. This should enable zero-bias operation with a large load resistor (such as 7 kΩ). This suggests that this tiny PDs can be operated at high frequency without any electric power [3, 4].

The fF PD has also another advantage in terms of its noise characteristics because it is free from thermal noise from electric amplifiers [4].
3. fF electro-optic modulator

With the same scenario as the previous section, it is possible to reduce the device capacitance of EOMs. Figure 2 shows our fF-EOMs based on a buried heterostructure photonic crystal waveguide (a) and nanocavity (b). Owing to the strong light confinement of photonic crystals, we have achieved the energy cost of 1.8 fJ/bit for (a), which is the smallest value for waveguide-based EOMs [5]. Furthermore, the nanocavity-based EOMs (b) present extreme small capacitance (0.6 fF) and can be operated at 40 Gbps with the record-low energy cost (42 aJ/bit), which is the smallest value for any types of optical modulators [6].

![Fig. 2. Schematic of waveguide-based (a) and nanocavity-based EOMs within a photonic crystal.](image)

4. fF optoelectronic integration

Recently, we have integrated a fF PD and a fF EOM via a load resistor as shown in Fig. 3 [6]. Such optoelectronic integration (O-E-O device) has been known to realize an optical three-terminal transistor-like device which essentially functions as an all-optical nonlinear processing device, but the previous O-E-O devices suffered from the large capacitance, thereby leading to substantially large energy cost or slow operation speed. In the present study, we have solved these problems by directly integrating fF OE and EO devices on the photonic crystal platform and achieved excellent various coordinated nonlinear operation at 10 Gbps. We have experimentally verified that the total device capacitance of this O-E-O device is about 2 fF, which is the first experimental demonstration of optoelectronic integration at fF level as far as we know. Furthermore, the required optical pulse energy for this nonlinear device is 1.6 fJ/bit. More importantly, this O-E-O device exhibits a signal gain of 3.6 dB, which has been difficult to achieve in conventional all-optical devices.

![Fig. 3. Schematic of fF O-E-O three-terminal device.](image)

5. Summary

We believe that fF OE/OE conversion technologies may have an impact on various optical information processing systems. Since we have tended to think that we have to reduce the number of OE/OE conversions to realize efficient processing systems, the present result may lead to a certain paradigm change because we may be able to incorporate OE/OE conversion in a very fine granularity scale. For example, it may become meaningful to consider OE/OE conversion even within a computation circuit, leading to novel optoelectronic computation scheme.

Abstract

We investigate various ways of tailoring the induced circular dichroism in nanostructures with different geometric configurations (end-to-end, side-by-side assembly nanorod configurations or nanorod with core-shell structure) and explore the key factors affecting the chiroptical responses. It is revealed that the interplay between the local field enhancement and backaction, and the morphology of the nanorod with core-shell structure play important roles in the chiral properties of the hybrid nanostructures.

1. Introduction

The chiral optical properties of various systems are of great importance in understanding biological processes and have many applications. Hybrid nanostructures of different geometric configurations, such as end-to-end, side-by-side assembly nanorod configurations, core-shell structured nanorod with different morphology/aspect ratio, show different chiroptical properties. They provide us much opportunities of exploring the keys factors affecting the chiral responses. Our theoretical and experimental studies indicate that the interaction between the molecules and metallic nanorod can be modulated by geometric configurations and leads to tunable chiral optical properties. Our work not only sheds light on understanding the relationship between the configuration of plasmonic nanostructure assemblies and geometry-manipulated circular dichroism (CD), but also paves the way for predictive design of plasmonic biosensors or other nanodevices with controllable optical activities from the UV to the NIR light range.

2. The induced plasmonic circular dichroism in different assembly configurations

We systematically study the optical properties of the chiral cysteine-directed assemblies of Au@Ag core-shell nanocrystals (CSNCs) and Au/Ag nanorods with end-to-end (ETE) and side-by-side (SBS) configurations. We consider core-shell nanocrystal assemblies (with ETE or SBS configuration) incorporating the dipole of cysteine (CYS) at the center of the gaps. The dominant contribution of CD comes from CYS-induced plasmonic circular dichroism (PCD). The CD signal of the nanocrystals is given by the difference of optical absorption ($Q_{CSNC}$) between the left/right circularly polarized fields, that is, $CD_{CSNC} = Q_{CSNC}^L - Q_{CSNC}^R$ with $Q_{CSNC}^{L/R} = \int dV(E_L + E_R)^* (E_L + E_R)$. The CD signal of the nanocrystals is given by $g = CD_{CSNC}/Abs_{CSNC}$. The theoretical and experimental results are shown in table 1.

Our studies show that the PCD response of Au, Ag, and Au@Ag CSNC assemblies is the combined contribution from both the electromagnetic field effect at the hotspots and the geometry-dependent electromagnetic backaction. Thus, different geometric configurations (ETE & SBS) lead to different electromagnetic fields at hotspots and backaction amplitudes, which brings about interesting geometry-dependent chiral characteristics for Au@Ag CSNC, Ag and Au NR assemblies.
3. Tuning the chiroptical properties by the morphology of nanorod with Au-CYS-Au core-shell structures

We perform studies of the chiral properties of the nanorod with Au-cysteine (CYS)-Au core-shell structures. The core-shell structured nanorod has different morphology depending on the concentration of CYS. We propose an effective medium approach consisting of a Au NR core, a chiral molecular shell and outer shell of Au or mixture of Au and solution. The effective dielectric permittivity \( \varepsilon_{\text{eff}} \) for core material A with inner geometric factor \( L^{(1)} \) and shell material B with outer geometric factor \( L^{(2)} \) is

\[
\varepsilon_{\text{eff}} = \varepsilon_A \frac{(1 - L^{(1)})fG}{1 + L^{(1)}fG}, \quad G = \frac{\varepsilon_B - \varepsilon_A}{L^{(2)}\varepsilon_A + (1 - L^{(1)})\varepsilon_B}.
\]

The absorption of nanoparticle can be calculated based on the formula

\[
C_{\text{abs}} = k \cdot \text{Im} \left[ \frac{G}{L^{(1)}\varepsilon_{\text{eff}} + (1 - L^{(1)})\varepsilon_B} \right].
\]

The CD signal is the difference between the absorption of left and right circularly polarized light. In the calculation based on above formula, we first obtain \( \varepsilon_{\text{Au@CYS}} \) by using the values of \( \varepsilon_{\text{Au}} \) and \( \varepsilon_{\text{CYS}} \). Then we use the formula again to calculate \( \varepsilon_{\text{Au@CYS@Au/sol}} \). \( \varepsilon_{\text{Au/sol}} \) is calculated based on the Bruggeman effective media theory.

Figure 1: The circular dichroism for nanorod with Au-CYS-Au core-shell structures in the presence of different concentration of CYS: 0.4\( \mu \)M; 0.04\( \mu \)M; 4nM.

Our studies show that the induced circular dichroism from CYS and the related morphology lead to nonmonotonic dependence of circular dichroism on the concentration of CYS as shown in figure 1.

4. Conclusions

We have performed systematic studies of induced circular dichroism of nanostructure with different assembly configurations and/or core-shell structures. We have found that the interplay between the local field enhancement and backaction, and the morphology of the nanorod determine the chiral responses of the hybrid nanostructures.

Abstract

A strong coupling system is realized by using silver nanogrooves as meta-atoms and surface Bloch waves launched by periodic nanogroove arrays. This system is found to be analogous to electronic band structure in solids but with more flexibility. Due to directly sharing the free electrons in the metallic medium, the plasmonic gap modes coherently couple with surface Bloch waves when they overlap with each other in real- and momentum-space. A giant Rabi splitting on the order of 400-500 meV can be experimentally achieved.

1. Introduction

Plasmonic metamaterials have unique properties to manipulate and amplify optical process at subwavelength scales. Metasurface is a class of metamaterials with one layer of artificially engineered structure. The building block, the meta-atom, is typically made of metallic nanostructure. By designing their spatial arrangement one can obtain the desired collective modes, in a manner analogous to how atomic levels are coupled in the solid to form the electronic band structure. In real solids, valence states and core levels are separated in energy space, leading to little coupling between them. In periodic plasmonic metasurfaces, we show that the energy levels of the localized (plasmonic meta-atoms) and delocalized (plasmonic surface Bloch wave) surface plasmon polaritons (SPPs) based on nanogroove array on silver single crystal can be tuned independently. This tunability then lead to spectacularly strong coupling between them with a Rabi splitting as high as 420 meV. Localized plasmonic resonance (LSPR) coupled with surface lattice resonance (SLR) based on discreet nano structures, such as nanodisks or nanowires, had been reported before, but only moderate Rabi Splitting was observed. The coupling between them is through electric field and photon, and the corresponding free electrons are still localized in nanodisk or nanowires. Hence, in this work, we present a coupling system of nanogroove array on silver substrate (free electrons can be shared each other and propagate without scattering field as coupling media) to be analogous to electronic band structure in solid state physics, as well as obtain giant Rabi Splitting via strong coupling.

2. Results

Figure 1a shows the schematic diagram between groove-LSPR and lattice-SPP. From a microscopic perspective, if the LSPR and lattice-SPP are separated in energy-momentum space, or the LSPR is broadband (low plasmon density), this groove array can be seen as well-known SPP grating coupler, and we can get general SLR on the grating and SPPs away from the grating. However, if the LSPR is narrowband (high plasmon density), and overlapped with lattice-SPP in energy and momentum space, it could achieve strong coupling and plasmon energy state can be separated with a gap (Rabi splitting).

To systematically study the strong coupling in such groove array, we fabricated 17 gratings on single crystalline Ag plate using FIB milling, as shown in Fig. 1b. The groove depth is fixed at 140 nm, and the pitch varies from 154 nm to 730 nm. Figure 2 shows some typical angle-resolved reflectance spectra and corresponding fitting results. From the fitting results we can see clear strong coupling between groove-LSPR (linewidth ~160 meV) and the lattice-SPP (linewidth ~150 meV), and the maximum Rabi splitting is as big as 420 meV, which to our knowledge, is the biggest value in pure plasmonic system.

3. Discussion

Due to the strong coupling, plasmons are hybridized to the upper and lower branch modes. The electric field within the gap is completely parallel to the surface, and there is
basically no electric field within the groove at zero detuning, resulting a nearly unit reflection. In the strong coupling region, the on-resonance dipole moment replaces the ordinary off-resonance dipole moment to generate the lattice-SPP. In hybridized states, the SPPs generated by all the groove FP modes form the lattice-SPPs and propagating along the surface, and interact back to the groove-LSPRs. The whole process is done through the high confinement of parallel parallel electric field in nanogroove and sharing the same free electrons in continue metal. In comparison, for the case of discrete nanoparticle array, the coherent oscillation in lattice is done by scattering light from local oscillator with point spread function coupled to neighbor

nanoparticle in phase with incident light.

The lattice bandgap is enlarged to quasi bandgap by strong coupling with LSPR within a small range of wave vector. The experiment shows that the lattice bandgap leads to weakening the intensity of middle branch (Fig. 2), and the corresponding weighting fractions from the fitting results show the localized plasmon energy transfer to upper and lower branches resulting to quasi bandgap. Furthermore, the maximum Rabi splitting happens while the upper and lower branches having the same weighting fraction of compositions from any of the coupling modes (LSPR, lattice-SPP (0, +1) and lattice-SPP (0, −1)). Again, it is also located at point of three modes crossing each other in energy-momentum space. By engineering the pitch size, the lattice bandgap can be tuned and matched to the LSPR mode forming the giant Rabi splitting and quasi bandgap, which always occurs at Γ point (p = 480 nm) and Brillouin zone boundary (p = 688 nm). It is hard to realize engineering the band structure in nature material but can be done in metasurface.

4. Conclusions

To sum up, we have fabricated 17 GSLR samples of plasmonic meta-atom system and studied the strong coupling of the metallic groove arrays to be analogized forming the electron band structure in solid. Giant Rabi splitting over 420 meV was observed using both angle tuning and pitch tuning. The mechanism of such giant Rabi splitting was based on strong parallel electric field within the grooves and especially sharing the same free electrons between lattice-SPP and groove-LSPR. Furthermore, three modes crossing and coupling each other in energy-momentum space by tuning the pitch further enhance the Rabi splitting and forming quasi-bandgap. It realizes obtaining and engineering the artificial band-structure through meta-atom system and plasmonic Bloch wave. This meta-atom system has potential to be a device with adding electric gate to modulate the artificial band-structure and apply in many fields, such as solar energy device, nano laser, all optical switch and modulator, sensor, nonlinear optics devices and enhanced chemical reaction.

Abstract
To bridge the gap between the cavity quantum electrodynamics and chiral photon-emitter coupling, we propose the coupled photonic crystal and metallic nanoparticle structure, where through strong local field with high helicity, both weak and strong couplings between the circularly polarized emitter and photons are obtained with almost the unidirectional photons propagating, which can be utilized in directional quantum light sources.

1. Introduction
Cavity quantum electrodynamics (CQED) studies the light-matter interaction at a single quanta level \([1, 2]\). In traditional CQED, by compressing the optical mode volume into the region of several hundreds of micrometers, weak and strong couplings have been achieved. Recently, through reducing the optical mode volume into micro/nano scale, the CQED has achieved great success in photonic crystals, plasmonic nanocavities, whispering guided resonators, and various hybrid photonic systems, which paves a way to nanolaser, on-chip quantum devices, and scalable quantum networks.

Besides the ultrasmall mode volume, transversely confined light in the photonic structures induces the local spin of light, whose handedness has a one-to-one relation with respect to the propagation direction of the optical field enforced by time-reversal symmetry. If one puts a circularly polarized emitter in these structures, the propagation direction of the emitted photons will be locked by the handedness of local spin, so-called the chiral photon-emitter coupling \([3]\). Hence, the propagation isolation of photons is able to avoid the signal disturbance and improve transmission efficiency, which can be utilized in some nonreciprocal quantum information components, e.g., chiral entanglement, quantum gates, switchings, isolators, and circulators.

However, in the coupling between the circularly polarized emitter and photons, to simultaneously realize the strong interaction of photon-emitter and propagation direction lock of photons at the nanoscale, which will bring novel applications in nonreciprocal quantum devices, has not been reported yet.

2. Results
Here, by combining the advantages of the CQED and chiral coupling, we propose the coupled structure consisting of W1 PC and Ag nanoparticle (AgNP), where high quality nanocavities are formed to guarantee an achievement of both weak and strong couplings \([4]\). Through strong local field with high helicity in nanocavities, coupling strength of photon-emitter can be greatly enhanced, accompanied by almost unidirectional propagation of emitted photons. In weak coupling regime, total decay rate reaches over 4000\(\gamma_0\) (\(\gamma_0\) is the spontaneous emission rate in vacuum), among which the rate of photon emission into the PC waveguide is 124\(\gamma_0\), which is one order larger than that with only W1 PC. While for the strong coupling, by using a low loss band-edge mode, the linewidth of fluorescence spectra of Rabi splitting is about one-tenth of that with only the AgNP. For both cases, \(~95\%\) photons propagate unidirectionally. Moreover, though the mode design, the coupled structure is capable of routing different wavelength photons into opposite propagation directions.

3. Conclusions
In summary, we have established a photonic interface of chiral CQED by proposing the coupled photonic crystal and plasmon nanoparticle structure. We state that the key element of chiral CQED is the joint action of strong local field and its high helicity, which provides a strengthened light-emitter coupling with good directionality of emitted photons. The results bridge the fields of the CQED and the chiral coupling, which greatly enriches the contents of light-emitter interaction at the nanoscale. By combining the advantages of these two fields, we provide a possible platform in coupled photonic structures for nonreciprocal quantum light sources, quantum circuits, and scalable quantum network.

Abstract

For the next generation of optical computing, a novel and cost efficient approach is needed. This future development requires both tailored control over nanometer-sized building blocks on large area and a fundamental understanding of the strong as well as coherent coupling mechanisms [1, 2]. Currently, practical demonstrations are scarce, and are limited in terms of how many devices may be fabricated in parallel. To realize fabrication on a larger scale, a synergy between optical metasurfaces and colloidal self-assembly will be leveraged. This requires, on the one hand, applying concepts from metamaterials and, on the other hand, using pre-existing quantum emitter and plasmonic nanoparticle building blocks, which form an organized structure on large area by reducing their free energy [2-4]. We discuss our recent achievements in finite-difference time-domain modelling, large area self-assembly of tailored building blocks as well as time and space resolved optical characterization to fabricate cost-efficient, programmable and up-scalable photonic devices.

1. Plasmonic metasurfaces by colloidal self-assembly

Self-assembly methods show a clear advantage in comparison to size-, time-limited and cost-intensive electron (ion) beam or pick-and-place methods, such as optical tweezers and scanning probe microscopy. On the other hand, self-assembly mechanisms are programmable, scalable and robust; this makes this method very important for applications in electronics, sensing and optics. Metasurfaces are artificial structures, which obtains its properties from a two dimensional periodic structure and not properties of the individual components [4]. We define such individual component as plasmonic atom (Figure 1a). Thus isolated plasmonic atom of various size can be fabricated using a surface-supported overgrow process. At this technique the microscope glass slide with gold nanoparticle was carefully withdrawn from the growing solution [5]. Thus plasmonic atom can be a metallic nanoparticle of various diameter, shape and material [6-8]. Mie-theory calculations of a gold nanoparticle in water show an increase as well as red-shift in the effective absorption cross section.

Figure 1 Colloidal atoms and polymers by directed self-assembly: Well-defined plasmonic colloids or (a) atoms can be rationally assembled into (b) molecules. (a) A substrate-supported grows of gold nanoparticle[5] and simulated extinction cross-section (Q) of various diameters. (b) Substrate induced hybridization into bounding and anti-bounding plasmon modes, which can be fabricated by Langmuir Blodgett technique. Copyright 2014, American Chemical Society.

Figure 1b shows a plasmonic molecule, which can be excited by a simple break of symmetry using a dielectric substrate. Such plasmonic hybridization into bonding and anti-bonding mode is a result of the coherent coupling between the dipolar and quadrupolar resonance [9]. Especially the anti-bonding mode shows superior sensing properties [10]. Add one particle step wise to another particle results in red-shift of the plasmonic resonance until
the radiative damping gets dominant [2]. Such plasmonic oligomers (particle number greater than one and less than 10) and plasmonic polymers (particle number greater than 10) can be fabricated using template-assisted self-assembly [3] (Figure 2a). Among other applications such particle chain assemblies can be used to propagate light below the diffraction limit [11, 12]. Moreover, such colloids can be assembled into a periodic structure where the plasmon resonance can coherently couple to the diffraction mode of the grating. Such interaction results in a high quality surface lattice mode (see Figure 2b). This plasmonic crystals (hexagonal packed) can be fabricated using a floating method at a water air interface to achieve centimeter squared scalable gain nanoantenna at a reasonable price is the first step into colloidal nanophotonic devices.

2. Spectroscopic properties of plasmonic metasurfaces

Similar how a chemist designs its molecules, polymers and crystals, we design our colloidal metasurfaces for photonic applications. The key is that each atom can be replaced by single particle source such as fluorescent particle or quantum dot. This approach opens up a large horizon in coherent coupling of the single photon sources with the plasmonic system to achieve unique optical properties. Recently, we infiltrated fluorescent emitters (rhodamine B) into the silica shelled gold nanoparticle. In close contact to metallic substrate the colloidal particle results in a colloid-to-film coupled nanoantenna (nanocavity) with enhanced radiative properties [6]. Thus nanometer sized, high-quality and up-scalable gain nanoantenna at a reasonable price is the first step into colloidal nanophotonic devices.

Abstract

Plasmonic quasi-periodic structures are well-known to exhibit several surprising phenomena with respect to their periodic counterparts, due to their long-range order and higher rotational symmetry [1]. Thanks to their specific geometrical arrangement, plasmonic quasi-crystals offer unique possibilities in tailoring the coupling and propagation of surface plasmons through their lattice, enabling a plethora of fascinating phenomena. In this work we investigate the extraordinary transmission phenomenon occurring in specifically patterned Thue-Morse gold nanocavities and the polarization dependence of their cavity modes.

1. Introduction

The control and manipulation of light-matter interaction through metallic nanoapertures enables several applications in plasmonic biosensing, tunable and selective wavelength filters, increased signal in surface enhanced Raman spectroscopy for single molecule detection, and near-field optics. Furthermore, tailoring plasmonic resonances in particularly designed nanoplasmonic devices, surface plasmons (SPs) have also been exploited as information carriers, thanks to their ability to confine, concentrate, and channel light through subwavelength structures. However, it is well-known that far-field measurements can not clearly distinguish the role of SPs, due to the bound nature of their electromagnetic field, whose salient features arise in the near-field propagating regime. Scanning near-field optical microscopy (SNOM) enables the opportunity to visualize the surface plasmon-mediated mechanisms as well as the enhanced transmission phenomenon through particular patterned structures, beyond the diffraction limit. In this framework, quasi-crystals (QCs) exhibit long-range order and higher rotational symmetry, but no translational one, demonstrating to special features with respect to their periodic counterparts. Here we report on near and far-field spectral properties of quasi-periodic plasmonic gold nanocavities (NCs), obtained by patterning a Thue-Morse (T-M) array of nanoholes in a polymeric film and evaporating a thin gold layer on the fabricated QC. This type of configuration allows unique coupling possibilities between propagating and localized surface plasmons. We demonstrate Extraordinary Transmission (EOT) through subwavelength T-M patterned nanocavities, as a consequence of the strong coupling between surface plasmon polaritons (SPPs) and cavity plasmon resonances (CPRs). SNOM investigations confirm that NCs are the only source of transmitted light via SPPs strong coupling with CPRs in such subwavelength quasi-structures. Furthermore, this plasmonic coupling enables polarization and size-dependent cavity modes in T-M structures with increased nanocavities diameter, causing the appearance of surface plasmon pattern waves which reduces the overall EOT effect.

2. Results and Discussion

T-M patterned structures with different diameters (Ø), as well as a dodecagonal structure, have been fabricated by means of a nanolithography procedure reported in [2] (Fig. 1a). Scanning electron microscopy (SEM) images confirm the fabrication of T-M and dodecagonal quasi-periodic patterns (see Figure 1b,c). Figure 1d reports the schematic and beam path of the SNOM system used to perform near- and far-field optical experiments in transmission mode. The optical investigation of the quasi-periodic nanocavities has been performed by means of a SNOM (Alpha 300S by WITec) used in confocal transmission mode. The acquired transmitted signal has been compared and normalized to that of an unpatterned gold film of the same thickness (\( \lambda_{exc} = 532nm \)). We observe a 3.15-fold and a 2.9-fold enhancement in PMT counts in the case of samples with diameters of 250 and 400nm (Sample-A and -B). On the contrary, transmitted signals through samples with larger diameters (500 and 750nm, Sample-C and -D) are comparable
with the reference. Same behavior has been obtained in far-field with an un-coherent white light. To better understand the physics behind this enhanced transmission mechanism and to investigate localization of electromagnetic fields inside the obtained NCs, SNOM technique has been used in order to obtain super-resolution imaging, beating the optical diffraction limit. A linearly polarized laser beam (532 nm) has been tunnelled through an Al-coated aperture SNOM tip, with a diameter of about 60 nm, in order to collect near-field information. Figure 2 reports the topographic (a, b) and transmitted optical near-field images (c, d) of sample-B and -C (diameters 400 and 500nm), respectively, showing the formation of different cavity modes. The incident polarization induces the appearance of donut-type modes in sample-B, whereas three intense spots are present in sample-C. We performed numerical simulations, based on the finite difference time domain (FDTD) method, on all the different T-M structures, obtaining very good results.[3] Some ellipsometric measurements have been performed in order to highlight the presence of particular modes related to the quasi-crystal structure.

3. Conclusions

In conclusion, this work explores the fascinating and unexpected near- and far-field optical phenomena observed in quasi-periodic structures. Patterned plasmonic nanocavities make such quasi-periodic structures very particular and enable the strong coupling between surface plasmon polaritons propagating on the gold surface with the cavity resonances of each nanocavity. We demonstrated enhanced transmission mechanism via polarization-independent near-field responses in the subwavelength Thue-Morse arrays of plasmonic nanocavities and report the ellipsometric response of these structures.

Optically Thin Plasmonic Nanohole Metasurfaces: Fano Interferences and Strong Coupling

Evan S H Kang and Magnus P Jonsson

Laboratory of Organic Electronics, Department of Science and Technology, Linköping University, Sweden

E-mail: evan.kang@liu.se

Abstract

In this presentation, I will present our recent research on optically thin plasmonic nanohole metasurfaces.

Plasmonic nanohole metasurfaces have been intensely investigated due to their usefulness in multitude of applications, including biosensors, optical trapping, light-to-heat conversion, and strongly coupled systems. Introducing nanohole arrays in metal films has been regarded as responsible for both extraordinary optical transmission (EOT) for opaque films (≈200 nm) and suppressed transmission for ultrathin films (≈10 nm). Accordingly, plasmon resonances were assigned to transmission peaks for thick films and to transmission dips for ultrathin films. For the intermediate film thicknesses, however, the lack of consensus on the resonance assignment often results in misinterpretation of results and impedes our understanding of underlying physics.

I will first demonstrate the evolution from suppressed to enhanced optical transmission through nanohole arrays with increasing metal film thickness using Fano description. Here, I will also discuss how to define the true plasmon resonances, which can be far from both peaks and dips observed in transmission spectra [1]. Based on our results, I then explore strong plasmon-exciton coupling phenomena in optically thin hybrid nanohole metasurfaces [2]. Distinct features of optically thin hybrid systems including directional absorption will be discussed.

Plasmon Enhancement of Luminescence Upconversion

Wounjhang Park*

Department of Electrical, Computer & Energy Engineering, University of Colorado, Boulder, CO, USA
University of Colorado Cancer Center, Aurora, CO, USA

Abstract
This paper presents a comprehensive theoretical framework for plasmon enhancement of luminescence upconversion and also a systematic experimental study demonstrating the enhancement mechanisms. Finally, metal-insulator-metal design was used to achieve a record high 1200x enhancement in upconversion.

1. Introduction

Upconversion luminescence materials combine two or more low energy photons to generate single high energy photons. This nonlinear upconversion is most efficiently achieved by energy transfer upconversion or excited state absorption via long-lived intermediate energy levels of the upconversion luminescence material. Unlike the nonlinear susceptibility based upconversion mechanisms, such as high harmonic generation or optical parametric oscillation, upconversion luminescence can occur with low power excitation and with an incoherent excitation source, and thus has applications in photovoltaics, displays, bioimaging and therapeutics.

Upconversion nanoparticles (UCNPs) are particularly useful for biomedical applications as they have excellent photostability, narrow emissions bands with high color purity, and low cytotoxicity. Additionally, the near-infrared excitation falls within the biological transparency window allowing for deep penetration into biological tissue. However, a wide spread use requires a much improved upconversion efficiency, for which plasmonic nanostructures are ideally suited. This paper presents the theoretical foundation of plasmon enhancement of upconversion, experimental results demonstrating the enhancement mechanism and a metal-insulator-metal structure exhibiting over 1000x enhancement.

2. Results and Discussion

2.1. Theory of plasmon enhanced upconversion

Luminescence upconversion involves three distinct physical processes: absorption, energy transfer and emission. For absorption, the absorption cross section is given by

$$\sigma = c \mu_0 \omega \Im(\alpha) \frac{|E|^2}{|E_0|^2}$$

where $c$ is speed of light, $\mu_0$ is vacuum permeability, $\omega$ is angular frequency, $\alpha$ is atomic polarizability and $E$ and $E_0$ are local and incident field, respectively. Emission rate depends on the photon density of states, which can be estimated by the Green dyadic,

$$\rho = \frac{6\epsilon_0}{\pi c^2} |\vec{n}_d \cdot \Im(\bar{G}\vec{r}_0,\omega) \cdot \vec{n}_d|$$

where $\bar{G}$ is the Green dyadic and $\vec{n}_d$ is the unit vector along the dipole orientation. Alternatively, radiation rate can also be calculated by evaluating the total radiated power from a classical dipole, which is known to accurately predict quantum mechanical radiation rate with a difference of a constant factor. Finally, energy transfer rate is also determined by the Green dyadic,

$$w_{lt} = \frac{2\pi}{\hbar^2} \epsilon_0 c^2 |\vec{d}_t \cdot \bar{G}(\vec{r}_d,\vec{r}_t,\omega) \cdot \vec{d}_0|^2$$

These transition rates can then be linked together in a set of rate equations containing all states involved in upconversion. Solutions of the rate equations provide the full description of the upconversion processes and how they are affected by plasmonic nanostructures.

2.2. Experimental study

For systematic experimental study of plasmon enhanced upconversion, we use a simple silver nanograting structure (Figure 1a). Nanograting is fabricated by the laser interference lithography (LIL) and 100 nm thick UCNPs layer is deposited by a layer-by-layer technique. A 30 nm thick Si$_3$N$_4$ layer is deposited between silver and UCNPs to alleviate quenching. The upconversion luminescence intensity exhibits the classical quadratic power dependence in the weak excitation regime and linear in the strong
excitation regime. The quadratic power dependence is a signature for two-photon upconversion process and when the intermediate energy level saturates, the power dependence becomes linear. This system exhibits an overall enhancement of 16x and 3x of the green luminescence in the weak and strong excitation regimes, respectively. The rate equation analysis indicates that we have an absorption enhancement of 3x and energy transfer enhancement of 1.7x in this system. To further investigate the energy transfer process, we conducted a more detailed time-resolved study probing the decay and rise of upconversion luminescence. The results are summarized in Figure 2, which show that the energy transfer rate can be enhanced by a factor of 1.7 while the energy transfer efficiency is enhanced by 50%. This study confirms the rate equation analysis conducted on the luminescence intensity results.

Figure 2. The blue curves referring to the left y-axis correspond to the rise rate of UCNPs on silver nanograting (dash line) and on silver film (solid line) respectively for different excitation power densities. The red curves referring to the right y-axis correspond to the internal upconversion efficiency of UCNPs on silver nanograting (dash line) and on silver film (solid line) respectively for different excitation power densities.

2.3. Metal-insulator-metal structure

Our previous study clearly suggests that the absorption enhancement provides the greatest overall upconversion enhancement thanks to the quadratic scaling. Metal-insulator-metal (MIM) design is one of the most effective structure for strong light confinement and thus absorption enhancement. We therefore conduct numerical simulations to optimize the MIM geometry to achieve resonance at 980 nm and thus maximize enhancement in absorption. MIM structures are fabricated using LIL. Briefly, LIL is used to create a nanohole array on a photoresist film on silicon substrate. We then sequentially deposit gold, UCNPs and gold layers on top, followed by lift-off to produce MIM arrays on silicon (Figure 3a). Optionally, we can detach the MIMs from the silicon substrate and disperse them in water to create MIM colloidal solutions for biological applications using a simple lift-off process we recently demonstrated.5

We then conduct steady state and transient photoluminescence (PL) spectroscopy over a wide range of excitation power densities. The PL intensity show quadratic power dependence in the weak excitation regime while becoming linear in the strong excitation regime as the intermediate level begins to saturate. Comprehensive electrodynamic simulations and a thorough analysis of the rate equations are performed to quantify the effects of plasmon enhancement and quenching and we obtained excellent agreement between the theoretical predictions and the experimental results. The maximum enhancement factor is around 1200, which is the highest value ever reported for upconversion enhancement. Finally, we use poly-vinyl alcohol to lift off all MIMs from the silicon substrate and disperse them in water. We then use the colloidal MIM for cancer cell imaging. Figure 3(b) shows the composite image obtained by overlaying a brightfield micrograph of bladder cancer cells and the upconversion fluorescence micrographs under 980 nm excitation. Compared to free UNCPs, we observe comparable fluorescence intensity using approximately 1000 times smaller concentration of MIMs. This result is consistent with the over 1000-fold enhancement observed in the PL measurements for MIMs on the silicon substrate.

3. Conclusions

We present a comprehensive theoretical framework describing the plasmon enhancement of luminescence upconversion. Quantum electrodynamic theory describes light-matter interaction at each ion while rate equation provides a description for the interplay among various processes involved in upconversion. By a series of photoluminescence and time-resolved photoluminescence spectroscopy, we demonstrate the mechanism responsible for the overall enhancement of upconversion in a plasmonic nanostructure. Based on the fundamental understanding, we designed an MIM structure exhibiting strong local field enhancement and consequently absorption enhancement. A record high 1200x enhancement was achieved and the MIMs have been used to demonstrate fluorescence imaging of cancer cells.

Emission spectra of plasmon-exciton hybrid systems: A simple model

Xiaoguang Li

Institute for Advanced Study,
Shenzhen University, Shenzhen, 518060, China
*corresponding author, E-mail: xgli@szu.edu.cn

Abstract

Absorption spectra of a plasmon-exciton hybrid system can be qualitatively or even quantitatively studied by using the classical or quantum model with coupled oscillators. However, the emission spectra of plasmon-exciton hybrid systems are still largely unexplored, which presumably is due to the relatively slow emission process frequently interfered by other faster transition channels. Here, we describe a simple phenomenological model, which can evaluate both the absorption and emission spectra by selectively excluding some transitions during the emission process.

1. Introduction

The couplings between the metal plasmon and molecular exciton in metal-molecule hybrid systems have been extensively studied in the past two decades. The absorption spectra of the hybrid systems have been well explored in different systems from weak to strong coupling regimes [1], and can be well described by using the classical or quantum model with coupled oscillators [2, 3, 4]. For the emission process, we may expect that it has the same spectral line-shape as the absorption because it is basically the time reversal process of the absorption. Clearly, we know that it is not true for the individual molecule system because the fast vibrational relaxation usually occurs before the emission. Some intriguing features for the emission of hybrid systems, including the peak shifting and splitting, have been observed in the earlier studies [5, 6], and the discrepancy between the absorption and emission can be clearly seen [6]. Here, we present a simple phenomenological model to simultaneously capture the characteristics of both the absorption and emission spectra.

2. Model description

To evaluate both the absorption and emission, we start from the model introduced in our previous study for the absorption of the hybrid system [4]. Based on the linear response theory, the non-interacting response function of the hybrid system can be written as

\[
\chi^0 = \begin{pmatrix}
\frac{n_p}{\omega - \omega_p} & 0 \\
0 & \frac{n_c}{\omega - \omega_c}
\end{pmatrix}
\]  

(1)

where the subscripts \(p\) and \(c\) stands for the plasmon and exciton, respectively, \(n_i\) indicates the density, and \(\omega_i = \omega_i - \Gamma_i/2\) with \(\omega_i\) and \(\Gamma_i\) standing for frequency and linewidth of the corresponding state, respectively. Then, the interaction between the plasmon and excitons is introduced as

\[
K = \begin{pmatrix}
0 & V_{pc}^* \\
V_{pc} & 0
\end{pmatrix}
\]  

(2)

and the plasmon-exciton interacting response function \(\chi\) of the hybrid system is obtained from the Dyson equation as

\[
\chi = \frac{\chi^0}{1 - \chi^0 K} = \begin{pmatrix}
\chi_{pp} & \chi_{pc} \\
\chi_{cp} & \chi_{cc}
\end{pmatrix}
\]  

(3)

The function \(\chi_{ij}\) indicates the response of state \(i\) to the excitation on the state \(j\). For example, \(\chi_{pc}\) indicates the response of the dipole exciton to the field added on the plasmon. The induced charge density is linearly depended on the external field as

\[
\rho_{ind} = \left(\begin{array}{c}
\rho_p \\
\rho_c
\end{array}\right) = \chi V_{ext} = \begin{pmatrix}
\chi_{pp} & \chi_{pc} \\
\chi_{cp} & \chi_{cc}
\end{pmatrix} \begin{pmatrix}
V_p \\
V_c
\end{pmatrix},
\]  

(4)

where \(V_i\) indicates the coupling between the state \(i\) and external field, and \(\rho_p\) and \(\rho_c\) are the induced charge oscillation on the metal and molecule. The absorption of the system depending on the charge oscillation out of phase with the external field is obtained as

\[
\sigma = \text{Im} \left( \begin{pmatrix}
V_p^* & V_c^*
\end{pmatrix} \begin{pmatrix}
\rho_p \\
\rho_c
\end{pmatrix} \right) = \text{Im}(V_p^* \rho_p + V_c^* \rho_c).
\]  

(5)

As the time reversal process of the absorption, the emission is expected to give the same spectral line-shape as the absorption. However, the emission process will be largely disturbed by some fast nonradiative processes, including the Landau damping of the plasmon and the vibrational relaxation of the molecule. Due to the vibrational relaxation, the emission peak of the molecule will red-shift to lower energy. By incorporating this effect, we could use an exciton with lower energy \(\omega_x\) coupled with the plasmon, which would give a spectrum with different peak shifting as in the absorption. For the Landau damping, we expect that it will quickly change the induced charge density \(\rho_p\) in the metal, and thus largely modify the emission spectrum.

3. Discussion

We consider the whole emission process involving three consecutive steps: the absorption, decoherence, and emission with new coherent hybrid state. First, the absorption spectrum of the hybrid system is evaluated as shown
in Fig.1(a), where the spectra of the plasmon coupled with two different excitons have been shown. The blue solid line indicates the absorption due to the plasmon coupled with the exciton at 1.8 eV. We assume that the exciton will exhibit Stokes shift by losing 0.1 eV energy due to the vibrational relaxation, and thus gives the intrinsic emission peak at 1.7 eV. The absorption induces charge oscillation on the metal and molecules, forming the coherent wave packet oscillating between plasmon and exciton states. In the next step, the coherence will be lost very quickly due to the plasmon damping [7], as well as the vibrational relaxation of the exciton. After this decoherence, we believe the radiative process is then dominated by the charge oscillation on the molecule only, and thus the emission spectrum is evaluated similar as absorption spectrum except that we consider only the term involving $\rho_c$ in Eq. (5).

Figure 1: (a) The absorption spectra for hybrid system with the plasmon energy at $\omega_p = 1.8$ eV, and exciton energy at 1.8 eV (blue) and 1.7 eV (green). (b) The emission spectra for $\rho_p$ and $\rho_c$. The absorption (c) and emission (d) spectra (vertically shifted) for the plasmon energy from 1.0 to 2.8 eV. The coupling strength are chosen as $V_p = 0.6$ and $V_c = V_{pc} = 0.1$ for both excitons. The linewidth for plasmon and exciton are 0.7 and 0.1 eV, respectively.

The emission spectra show negative region due to the interference contribution mentioned in our earlier studies [4]. This issue can be fixed by introducing finite contribution from the $\rho_p$ part, which should be more carefully discussed in the future studies. Figure 1(d) shows that as the plasmon energy red-shifts across the intrinsic energy of the emitted exciton, the emission peak will slightly red-shift and then exhibit a large linewidth broadening at the large detuning energy. Essentially, the emission is launched by the charge oscillation on the molecule, and the spectrum includes the direct emission of the molecule and the emission by first transfer energy to plasmon. The later one induce the peak shifting and broadening. It is intriguing to notice that both the features of the emission peak shifting and spitting as the plasmon energy change have been observed in the earlier study [5].

4. Conclusions

In summary, we develop a simple phenomenological model to deal with the absorption as well as emission of the strongly coupled plasmon-exciton systems. We hope the present result could stimulate more efforts along this direction.

Optical Diversity of Metal Nanoparticles Modified by Stilbene Compounds: Plasmon Coupling, Raman Resonance Enhancement and Fluorescence Quenching

Elena Solovyeva*, Alexey Smirnov, Olga Odintsova, Vlad Deev

Chemistry Institute, Saint-Petersburg State University, Saint-Petersburg, Russia
*corresponding author, E-mail: solovyeva.elena.v@gmail.com, e.solovieva@spbu.ru

Abstract

In this work, we investigated the optical properties and surface chemistry of gold and silver nanoparticles modified by mono- and 4,4'-bifunctional stilbene compounds. Based on SERS spectra, UV-vis and TEM data, the linking of nanoparticles accompanied by plasmon coupling was revealed for 4,4'-diaminostilbene but remains under question for 4,4'-dimercaptostilbene. Ligand to metal charge transfer, occurring exclusively in the regions of plasmon coupling, was established. Analytical enhancement factors were calculated. Optical activity of modified nanoparticles was also investigated by fluorescent spectroscopy.

1. Introduction

The noble metals nanoparticles (NPs) have unique property known as localized surface plasmon resonance arising in result of interaction of light with the conduction electrons. The individual plasmonic nanoparticles can be assembled in various patterns for creation of promising metamaterials. The surface structures with short interparticle gap are the most preferable due to plasmon coupling providing a higher optical activity. The linking of metal NPs by organic modifiers is one of the powerful chemical approaches for fabrication of substrates with closely spaced NPs. The molecules having two functional groups on the opposite ends usually serve as the organic linkers. The excellence of bifunctional linkers is that they allow not only controlling the interparticle distance [1] but also creating the highly ordered spatial networks of NPs or nanocrystals [2-3]. This work represents the continuation of previous study of linking the metal NPs by stilbene derivatives [4]. Here, we consider extended list of mono- and 4,4'-bifunctional stilbene compounds and an influence of molecular structure on the optical properties of modified NPs. The investigation of organic modifiers with various degrees of substitution but close in a chemical nature allowed to distinguish the contributions from the effect of plasmon coupling and resonance charge transfer into enhancement of Raman scattering. This achievement is significant as for fundamental describing of plasmon coupling effect as for the correct assessment of capabilities for analytical detection.

2. Experimental

The initial Ag and Au NPs were prepared in the colloidal state by a reduction from the salts in accordance with the standard procedures. Their further modification was carried out by a quantitative addition of methanol solution of stilbene compound under vigorous stirring. To obtain the NPs with different surface coverage, the solutions with various modifier concentrations were used. 4,4'-diaminostilbene (DAS), 4,4'-dimercaptostilbene (DMS), 4,4'-dibromostilbene (DBS), and 4-aminostilbene (AS) were used for the modification of Ag and Au NPs. The surface enhanced Raman scattering (SERS) spectra were acquired on a LabRam HR800 (Horiba Jobin Yvon) spectrometer using 488 and 633 nm excitation lines. The ultraviolet-visible (UV-vis) absorption spectra were recorded on a UV-1800 (Shimadzu) spectrophotometer with quartz cell of 1.0 cm path length. The emission spectra were registered on a Fluorog (Horiba Jobin-Yvon) spectrometer. The images of silver nanoparticles were obtained with a Zeiss Libra 200FE transmission electron microscope (TEM) at an accelerating voltage of 200 kV.

3. Discussion

A surface coverage by organic modifiers can strongly influence on the properties of metal NPs. Therefore, the NPs with different numbers of molecular adlayers have to be considered for firstly applied modifiers. SERS response registered from NPs modified by stilbene derivatives showed two types of dependence on surface coverage. As can be seen from Fig. 1, the non-monotonous curve is characteristic for bifunctional 4,4'-stilbene derivatives, namely DAS and DMS, which are able to chemisorb on a surface. For DBS, which functional groups have a weaker affinity to the metal surface, the type of dependence turned out to be the same as for stilbene derivative with a single substitution. Regular growth of SERS intensity with increasing concentration corresponds to conventional Langmuir's adsorption without significant transformations in the molecular adlayers while the non-monotonous change testifiers the more complex processes occurring on the interface.
The nanoparticle agglomerates observed on TEM images and appearance of long-wavelength band in the absorption spectra of Ag NPs modified by DAS clearly showed the formation of linked NPs at submonolayer coverage [3]. But it is not so obvious in case of DMS. The type of SERS spectra dependence on surface coverage evidences about possible linking, but TEM and UV-vis data did not give the reliable proofs. Despite the literature data talking about linking Ag NPs via DMS bridges [5], another possible reason of observed spectral changes can conclude in the reorientation of DMS molecules from convex to unbent state. A resonance character of Raman enhancement was established in the case of DAS adsorbed in the regions of plasmon coupling. Ligand to metal charge transfer was revealed based on the UV-vis data and overtones appeared at the higher wavenumbers in the SERS spectra. To differentiate the contributions to SERS signal from plasmon coupling, charge transfer and ordinary electromagnetic mechanism, the analytical enhancement factors (AEF) were calculated (Table 1). The advantage in Raman enhancement in case of linked NPs is four orders of magnitude due to plasmon coupling.

</table>

An optical activity of modified NPs was also investigated by fluorescent spectroscopy. Different responses were revealed for NPs linked by DAS and single NPs covered by AS. Fluorescent quenching corresponding to linear dependence on NPs concentration correlated with the Stern-Volmer equation was obtained only for AS.

### 4. Conclusions

In accordance with the obtained data, the following important findings were made: i) at sub-monolayer surface coverage, bifunctional aminostilbenes coordinate with two Ag nanoparticles simultaneously that leads to the plasmon coupling in the obtained agglomerates. The stilbene derivatives with single substitution adsorb on metal nanoparticles by ordinary layer-by-layer way; ii) plasmon coupling gives the additional contribution in the Raman enhancement of four orders of magnitude; iii) the ligand to metal charge transfer may arise exclusively in the regions of plasmon coupling even if it is absent on the uniformly amplifying surface. Generally, this work represents the simple method to controllable effect on the structural, plasmonic and optical properties of noble metal nanoparticles by the new class of modifiers based on stilbene compounds.

Tuning phase matching conditions in second harmonic generation via the excitation of higher order plasmonic mode in waveguides

Ning Liu* and Brian Corbett²

1 Department of Physics and Bernal Institute, University of Limerick, Co. Limerick, Ireland
2 Tyndall National Institute, University College Cork, Cork, Ireland
*corresponding author, E-mail: ning.liu@ul.ie

Abstract

Plasmonic waveguides, with characteristic strong electric field confinement at the dielectric-metal interface, have found many applications in nonlinear optics. However, the dispersion relationship of fundamental plasmonic mode works against the phase matching condition required for strong second harmonic generation. Here we show that by exciting higher order plasmonic modes, phase matching condition can be satisfied in plasmonic waveguides.

1. Introduction

Because of the strong electric field confinement present in plasmonic waveguides, researchers have been trying to take advantages of the field enhancement for various nonlinear processes. Among them, second harmonic generation (SHG) has been explored on metallic structures along and on the combination of nonlinear materials and metallic structures. Non-centrosymmetric compound III-V semiconductors such as GaInP are known to have strong nonlinear coefficients. For nonlinear semiconductor waveguides in close vicinity to metal, strong SHG is expected. However, realistic semiconductor material possesses nonlinear dispersion relationship \((k_{2\omega} \neq 2k_{\omega})\) [1]. For surface plasmon propagation at semiconductor-metal interface, the difference between \(k_{2\omega}\) and \(2k_{\omega}\) is further widened [2]. In other words, the coherent length of SHG is extremely short, usually within few microns. It is therefore necessary to find a proper phase matching mechanism to fully exploit the strong field enhancement and high nonlinear coefficients of the semiconductor-metal waveguides.

2. Results and Discussion

In order to reduce the propagation loss inherent to the metal substrate, an air-semiconductor waveguide-insulator-metal hybrid plasmonic waveguide geometry is applied. A quaternary AlGaInP multi-layer structure is used for the nonlinear waveguides [3]. A laser beam is edge coupled into the waveguide. When a proper polarization angle of the laser beam is chosen, higher order plasmonic mode are excited [4], where phase matching condition can be achieved for SHG, as shown in Fig. 1.

Figure 1: (a) SHG from plasmonic mode without proper phase matching condition, (b) SHG from plasmonic mode with proper phase matching condition.

This phase matching mechanism also depends on the dimension of the waveguides and the crystal orientation of the material.

3. Conclusion

In summary, we have explored the possibility of using higher order plasmonic waveguided modes to achieve phase matching in SHG of nonlinear hybrid plasmonic waveguides. This study further widens the applications of plasmonic waveguides in integrated plasmonic circuits.

Abstract

Nonlinear optical quasicrystal metasurfaces to control the radiation of the second harmonic generation (SHG) will be presented. The metasurfaces are based on the geometric phase controlled plasmonic meta-atoms with local rotational symmetry, which are ordered quasiperiodically according to two quasicrystalline tilings. We found that the far field radiation of SHG waves are determined by both the tiling schemes and the local symmetry of meta-atoms. The proposed concept may open new avenues for designing nonlinear optical sources with metasurface crystals.

1. Introduction

Metasurfaces, as the two-dimensional artificially engineered surfaces, have enabled abundant optical functionalities and hold great potentials for applications in integrated optics thanks to their compactness and flexibilities of design. In the context of linear optics, how to elaborately order the meta-atoms in metasurfaces is vital for realizing specific optical functionalities such as focusing, beam-splitting, generation of optical vortex, etc. In addition to the periodic lattices, the adoption of quasicrystalline structure may also bring new degrees of freedom to the optical functions of metasurfaces, e.g. the Penrose-type plasmonic metasurfaces have been used for symmetry-induced optical isotropy [1] or linear optical phase control [2].

Recently, the research of optical metasurface goes into nonlinear optical regime. The key issues in this field mainly involve how to control the amplitude, phase and polarization of light in nonlinear optical processes. Strong localization of electromagnetic waves in vicinity of the metasurface can be used to boost the efficiency of SHG, third harmonic generation and four-wave mixing, etc. There has also been strong interests to locally control the phase of nonlinear waves by using electric poling method, but only until recently, they can be continuously manipulated with the help of nonlinear geometric P-B phase of meta-atoms [3,4]. Apart from this, the nonlinear polarizations can also be well controlled by the local symmetry of meta-atom and the polarization of fundamental wave (FW).

Now it is timely to pay more attentions to the relationship between local and global symmetries of metasurfaces, which may introduce new degrees of freedom to control the nonlinear optical radiation in the far field. As shown in Fig. 1, we take the advantages of both the nonlinear P-B phase controlled meta-atoms and various quasicrystal tiling schemes to construct the nonlinear optical quasicrystal metasurface (NOQCM).

![Figure 1: Illustration of the linear and nonlinear optical diffractions of the nonlinear metasurface (a-b). The SEM images show (c) the Penrose-type metasurface, (d) the asymmetric HQC metasurface and (e) the symmetric HQC metasurface. Scale bars, 1 μm.](image)

2. Design and Fabrication of NOQCMs

The nonlinear meta-atoms used to construct the NOQCM is a gold nanostructure with three-fold (C3) rotational symmetry. As the inversion symmetry is broken in the C3 meta-atom, SHG is allowed and could be greatly enhanced when the localized plasmon resonance of the fundamental wave (FW) is excited. The gold meta-atoms are then ordered according to two quasiperiodic tilings, namely the famous Penrose tiling, and the newly proposed hexagonal quasicrystalline (HQC) tiling [5]. Compared to the extensively investigated Penrose structures, the HQC metasurface we designed is the first experimental
demonstration of its kind. To make use of the P-B phase, two distinct orientation distribution of the meta-atoms are deployed to form different HQC metasurfaces, one is asymmetric (Fig. 1d) and the other symmetric (Fig.1e). The NOQCMs are fabricated by using standard electron beam lithography followed by the metal lift-off process.

3. Far Field Radiation of the NOQCM

The far field radiation the nonlinear optical quasicrystal metasurfaces is investigated in both linear and nonlinear optical regimes (Fig. 2). For the linear optical experiment, the unpolarized laser beam of wavelength 635nm is normally incident onto the metasurfaces. In the transmission direction, diffraction patterns with ten-fold and six-fold rotational symmetries are observed for the Penrose and HQC metasurfaces, respectively. The diffraction patterns from the symmetric and asymmetric design of HQC samples in Fig. 2b and 2c are almost identical. This is mainly because that the incident light is propagating along the optical axis of the C3 meta-atom and its polarization state is insensitive to the orientation directions of the meta-atoms. As is expected, the global symmetry regarding how to order the meta-atoms plays vital roles in determining the linear optical diffraction of the quasicrystal metasurfaces.

Based on the measured spin dependent SHG responses (not presented), the nonlinear far field radiation of the Penrose and HQC metasurfaces are measured at the resonant fundamental wavelengths of 1275 nm and 1250 nm, respectively. The FW is left circular polarized, while the SHG of right circular polarization is recorded. It is found that the ten-fold and six-fold rotational symmetries of optical diffraction pattern also exist in the nonlinear optical regime. However, a phenomenon worth to be mentioned is that the SHG diffraction pattern of the symmetric HQC metasurface (Fig. 2f) exhibits significant peripheral spots, but its central spot disappears. A theoretical dipole radiation model, enhanced with the nonlinear P-B phase theory, is then developed for interpreting the far field nonlinear optical radiations. The calculated far field radiation patterns (not shown) of the NOQCMs are well consistent with the experimental results. An easy way to to understand the missing central spot in Fig. 2f is the destructive interference of the SHG waves produced by adjacent C3 meta-atoms in Fig. 1e, such interference is utilized in ref. [6] to encode an image.

4. Conclusions

In summary, we have designed and fabricated nonlinear optical quasicrystal metasurfaces by assembling the geometric P-B phase controlled plasmonic meta-atoms into the macroscopic quasicrystal lattices. We successfully demonstrate that the nonlinear SHG radiation in the far field can be manipulated by both the local and global symmetries of the metasurface crystals. It is anticipated that the concept of quasicrystal metasurfaces not only represent novel strategy for controlling far field nonlinear optical radiations, but also offers an integrated platform for quantum information processing, optical modulation, all-optical optical switching and so on.

Abstract
Plasmonic photocatalysts hold the potential of transforming visible light into chemical energy [1]. Here we performed a spectral screening study on the energy of the extracted hot-holes in a 80 nm Au nanoparticle that photocatalyze an electro-polimerization reaction. We demonstrate that Landau damping is the absorption channel that leads to the most energetic carriers for plasmonic photocatalysis [2].

1. Introduction

Single-particle techniques are key to unearth the underlying mechanisms of hot-carrier generation, transport and injection as well as to disentangle the role of the temperature increase and the enhanced near field at the nanoparticle-molecule interface [2, 3]. Gaining a nanoscopic insight of these processes and their interplay could aid in the rational design of plasmonic photocatalysts.

Here, electrochemistry and single-particle dark-field microscopy and spectroscopy are combined to study the role of a photoexcited Au nanoparticle (AuNP) in the electro-oxidation of aniline to polyaniline. Electrochemistry provides a way to control the energy of the electrons in the metal nanoparticle and at the same time allows to compute the overpotential needed for the electrochemical reaction to proceed. This also serves as a method to quantify the photocatalytic effect of the illuminated AuNP.

2. Discussion

Wavelength-dependence studies show that the overall energy requirements of the electrochemical reaction can be reduced up to ~35% when exciting the NP at it plasmon resonance. In order to understand the mechanism behind this photocatalytic effect, a single particle nanothermometry technique based on anti-stokes photoluminescence emission is implemented. It is shown that even if the total absorbed energy at each excitation wavelength is the same, the reactivity of the hot-holes follow the plasmon resonance profile. The effective energy of the reactive hot holes is in the range of 0.028eV to 0.24eV. These results shed light on the role of the absorption processes in plasmonic photocatalysts and the maximum energy of the reactive hot holes at the surface of a 80 nm AuNP.

Our spectral screening study allowed us to explore the influence of the different absorption channels in the final energy of the extracted hot-holes. Four different mechanisms of carrier generation through plasmon decay have been identified – interband absorption, phonon (or defect) assisted absorption, electron-electron scattering assisted absorption, and Landau damping (or surface collision assisted absorption). The excitation wavelength determines the relative contribution of each mechanism and therefore the energy distribution of the generated carriers. We found that the maximum energy of the carriers is reached when Landau damping is the favored excited channel.

3. Conclusions

Here we shed light on an important aspect of plasmonic photocatalysis by measuring the energy of the generated hot-holes in a single 80 nm gold nanoparticle. We found that the extracted energy of the hot-holes is about 0.24 eV. Among the different absorption pathways that can lead to hot-carrier generation in plasmonic nanoparticles, we found that Landau damping – a surface collision process – is responsible for producing the most energetic carriers. Single-particle measurements allowed to disentangle the role of temperature increase, intense electromagnetic near fields and hot carriers for an electro-polymerization reaction. These results could aid in the rational design of plasmonic photocatalysts with highly energetic reactive-sties.

Continuously tuning the coupling strength of bow-tie nanoantennas by strain variation

Abstract

Plasmonic coupling effects show a strong distance dependence for few nanometer gaps. The coupling of individual nano-bowties is reversibly tuned by fabricating antennas on flexible polymers, enabling their use as plasmon rulers or strain sensors.

1. Introduction

The coupling strength and spectral positions of the plasmon resonances of gap antennas strongly depend on the respective gap distance [1]. Creating antenna dimers such as bowties with gaps down to less than 10 nm allows for high electric near-fields in the gap region that can be used as highly confined sensing volumes. When attempting to evaluate the spectral characteristics of different antennas with similar gaps however, the comparison is strongly hampered by the unavoidable nanoscale fluctuations between nominally identical antennas due to the limits of the nanofabrication processes [2]. Therefore the strategy to prepare bowtie nanoantennas on flexible substrates is pursued, such that studies of the gap dependence can be performed at the individual nanostructure level.

2. Discussion

In this presentation the fabrication of sparse arrays of gold nano-bowtie antennas on flexible PDMS (polydimethylsiloxane) substrates is illustrated. The samples are prepared by electron beam lithography and a lift-off process on a silicon sample with a thin sacrificial chromium layer. In the subsequent transfer process, a sheet of PDMS is placed on top of the nanostructures, and the chromium is dissolved, leaving the bowties on the surface of the PDMS. Individual nano-bowties are then investigated by dark-field spectroscopy using a pinhole to select only the signal from single structures. This way the reversible spectral properties of bowties under different amounts of strain are demonstrated, and the spectral features are assigned via comparison to numerical simulations [3]. In Figure 1, an example of the spectra of a bowtie antenna with a 12 nm gap under 0%, 25% and 50% strain are shown, increasing the gap width to 18 nm. The spectra can be modeled by Lorentzian fits, showing the presence of three plasmonic modes at different wavelengths. The mode at the shortest wavelengths close to 700 nm corresponds to an excitation of the base of the bowtie and is only little affected. The central mode is hardly visible. The longest wavelength mode results from an excitation of the bowtie along its long axis and is strongly influenced by the coupling conditions between the two bowtie triangles.

![Figure 1](image-url) Change in the spectral properties corresponding to the scheme in Fig. 2 (a) due to hybridization and coupling. Image adapted from [3].

By suitable orientation of the nanostructures either parallel or perpendicular to the direction of strain, an increasing strain level can lead to either increasing or decreasing gap widths, see Figure 2. When strain is applied perpendicular to the bowtie axis, the original lithographically defined gap size can be further decreased due to the necking of the flexible substrate. This way, gaps in the single digit nanometer regime can be reached and further investigated. The resonance wavelength of the coupling mode is shifted according to an exponential power law. Evaluating the spectral shift of the coupling mode in terms of this plasmonic ruler equation [4], the structures have the potential to act as strain sensors. Starting with few nanometer gaps, the regime of quantum plasmonics comes within reach.
3. Conclusions

By preparing bowtie antennas on flexible substrates, the coupling strength within one and the same individual nanoantenna can be continuously and reversibly tuned. An increasing blue- or redshift is observed when the strain in the direction of the bowtie’s long axis is increased or decreased, respectively. The opposite behavior can be induced by rotating the bowtie by 90° relative to the strain. In this configuration the pre-defined gaps can be further minimized.

Abstract

Starting from the Fokker-Planck-Landau theory of electron collisions, we derive a novel set of hydrodynamical equations accounting for the ultrafast dynamics of silver, demonstrating that absorption saturates owing to the quenching of electron collisions. Our results hold great potential for mitigating absorption of plasmonic materials, thus opening novel avenues for the development of low-loss plasmonic circuits and solid-state attosecond pulse sources along with ultra-efficient nonlinear control at the nanoscale by near-zero index media.

1. Introduction

Plasmonic materials and metamaterials (MMs) have attracted over the last decade a great deal of interest owing to their capacity to confine light down to the nanoscale. Such a peculiar property ensues from the coupling between photons and plasma waves excited within plasmonic media such as metals, transparent conductors, or graphene enabling the excitation of surface plasmon (SP) modes. The tight confinement provided by SP modes in plasmonic media and MMs has opened several possibilities to enhance light-matter interaction and nonlinear optical processes, enabling the control and manipulation of light at the nanoscale along with the development of nano-sized optical interconnects, super-resolution techniques, surface-enhanced spectroscopy, and optical cloaking.

Most of the above mentioned innovative applications have been developed thanks to the continuous advances in nanofabrication techniques, which have exploited mainly noble metals as plasmonic materials, particularly gold and silver owing to the lower scattering rate of free electrons as compared to other metals. However, except for sensing and surface-enhanced spectroscopy where metal absorption only limits the resonance quality factor, the amount of loss in current plasmonic devices such as interconnects, switches, modulators, and detectors is far too high for practical applications. More recently, graphene, oxides and nitrides, and polar dielectrics have risen as promising materials for infrared plasmonics with smaller absorption owing to the lower electron density. Further strategies for loss mitigation involve quenching of interband absorption via self-induced-transparency plasmon solitons [1], reduction of surface roughness, and embedding gaining media in plasmonic setups. The ultrafast response of plasmonic media to sub-picosecond temporal pulses of electromagnetic (EM) radiation generally involves heating of electrons and the lattice with a complex dynamics involving exchange of energy from hot electrons to the lattice via electron-phonon scattering. Heating is a primary consequence of absorption and is generally undesirable since it leads to material damage. Reducing the time-duration of EM pulses to the femtosecond regime is a promising strategy to quench absorption and heating since it enables the achievement of high peak intensity with reduced transfer of energy to hot electrons. Here, we investigate the ultrafast nonlinear dynamics of plasmonic media under excitation by temporal pulses of EM radiation with duration of few femtoseconds. Start-
ing from the Boltzmann equation for the electron plasma, and accounting for electron-electron and electron-phonon collisions through the full collisional integral, we derive a novel set of hydrodynamical equations (HDEs) describing electron collisions beyond the standard damping approximation [2]. We find a complex analytical expression for the effective electron damping that depends non-linearly on the electron current and reduces to the Drude-like damping in the limit of small driving intensity, while it quenches for high driving peak intensity owing to the reduced Coulomb interaction of electrons with ions.

2. Discussion

Borrowing the Fokker-Planck-Landau theory of collisions we model electron dynamics in plasmonic materials beyond the RTA. We solve the Boltzmann equation following the method of moments, which enables us to obtain a hierarchy of hydrodynamical equations that are fully equivalent to the FPLE. Since we are interested only on the zero [electron density \( f \) \( \left[ d w f(r, w, t) = n(r, t), \text{ such that } \int d r n(r, t) = N \right] \)], first [current density \( \frac{d w w f(r, w, t) = n(r, t) v(r, t) \right) \), and second [energy density \( \left( m/2 \right) \int d w \left[ w - v^2 f(r, w, t) = \left( 3/2 \right) n(r, t) k_B T_e(r, t) \right] \), moments, we truncate the hierarchy by neglecting higher-order terms obtaining the solution

\[
f(r, w, t) \approx \frac{n(r, t)n^{3/2}}{[2\pi k_B T_e(r, t)]^{3/2}} e^{-\frac{m|w-v(t)|^2}{2k_B T_e(r, t)}}.
\]

The moments \( n(r, t), v(r, t), \) and \( T_e(r, t) \) satisfy the hydrodynamical equations (HDEs)

\[
\begin{align*}
\partial_t n + \nabla \cdot (n v) &= 0, \\
\partial_t v + (v \cdot \nabla) v + \frac{3k_B}{m n} \nabla (n T_e) &= \frac{1}{m} F_{\text{eff}} - \Upsilon v \\
\partial_t T_e + \frac{2}{3} T_e \nabla \cdot v + v \cdot \nabla T_e &= Q,
\end{align*}
\]

where

\[
\Upsilon(r, t) = \gamma \frac{M v^3}{2 v_T^2} \left[ F(v/v_T) - e \frac{v^2}{v_T^2} \right],
\]

\[
Q(r, t) = \gamma_m \frac{M v^3}{2 k_B v_T} \left[ F(v/v_T) - \frac{T_e v_T^2}{T_0 v_T^2 - \frac{v^2}{v_T^2}} \right].
\]

\( F_{\text{eff}} = -e E - ev \times B \) is the external effective force, \( v_T(T_e) = \sqrt{2k_B(T_0/M + T_e/m)} \)
and \( v_T(T_0) = v_T(T_0) \) are the OKE and equilibrium thermal velocities, respectively, \( \gamma_m = 2m e^2/(m + M), \gamma = 8\pi C_{el} n_0 \sqrt{M/m(m + M)/3(2\pi k_B T_0)^3}, \) and \( F(v/v_T) = (\sqrt{v/v_T} \text{erf} v/v_T) \). The parametric functions \( \Upsilon(v, T_e) \) and \( Q(v, T_e) \) are depicted in Fig. 1 for silver. The novel HDEs reported above in Eqs. (2) constitute a substantial extension of traditional HDEs used to model the EM response of plasmonic materials, where \( \Upsilon \simeq \gamma \). Note that, in the limit of small electron current \( v/v_T << 1 \) and electron heating \( T_e - T_0 << T_0 \), Eq. (3a) reduces to \( \Upsilon \simeq \gamma \) (see Fig. 1), thus recovering the RTA, while Eq. (3b) reduces to \( Q \simeq -\gamma \frac{d e}{v_T} (T_e - T_0) \), which describes relaxation towards equilibrium via electron-phonon scattering. Conversely, our results indicate that damping \( \Upsilon \) quenches for \( v/v_T >> 1 \) (see Figs. 1a,c).

3. Conclusions

In conclusion, starting from the Boltzmann equation in the weak coupling assumption, we have developed a novel set of hydrodynamical equations able to describe the ultrafast nonlinear dynamics of electrons in silver. We find that the collision-induced damping quenches for ultrashort pulses with infrared carrier wavelength and peak intensities of the order of \( \text{GW/cm}^2 \), leading to absorption saturation. Although ultrafast nonlinear dynamics in metals has been experimentally investigated by several groups, typically these studies have focused on EM pulses with time duration \( \geq 100 \text{ fs} \). Furthermore the inherently high dispersion of silver leads to efficient temporal broadening of the EM pulse over propagation and intraband absorption saturation has not been observed yet. We conclude that dispersion management techniques and temporal plasmon solitons can constitute promising strategies for counterbalancing temporal dispersion and enabling absorption mitigation in silver-based plasmonic devices, thus opening novel avenues for the development of low-loss plasmonic circuits.

Single-molecule sensing mediated by localized plasmon resonances

Peter Zijlstra, Rachel Armstrong, Michael Beuwer, Matej Horacek, Yuyang Wang
Eindhoven University of Technology, Department of Applied Physics and Institute for Complex Molecular Systems, De Rondom 70, 5612 AP, Eindhoven, The Netherlands
Author e-mail address: p.zijlstra@tue.nl

Abstract: I will outline recent advances in the plasmon-enhanced detection of single molecules and their application toward single-molecule biosensing and single-molecule biophysical studies.

Future optical sensors should report quantitative and reliable data with high signal-to-noise ratio on short timescales. Single-molecule sensing holds great promise to achieve this because the digital signals allow for the detection of very low concentrations, whereas single-molecule sensitivity gives access to different populations in a seemingly homogeneous distribution. Optical detection of single molecules mostly relies on their fluorescence because of the high contrast of this technique against the background. However, the majority of native biomolecules such as proteins hardly fluoresce at all, requiring a different approach for their detection. Plasmon-enhanced detection circumvents the need for labelling by allowing direct optical detection of weakly emitting and completely non-fluorescent species.

In the past decade several mechanisms for plasmon-enhanced single-molecule detection have been demonstrated, including (1) by plasmonically enhancing the emission of weakly fluorescent biomolecules, or (2) by monitoring shifts of the plasmon resonance induced by single-molecule interactions. I will outline recent advances in both approaches at the single-particle and single-molecule level, and will describe their application toward biosensing and single-molecule biophysics.
Collective effects on periodic arrays of plasmonic nanostructures

Alejandro Manjavacas\textsuperscript{1,*}

\textsuperscript{1}Department of Physics and Astronomy, University of New Mexico, Albuquerque, USA

*corresponding author, E-mail: manjavacas@unm.edu

Abstract
We will discuss some interesting effects arising from the collective interaction in periodic arrays nanostructures.

1. Discussion
Periodic arrays are an exceptionally interesting arrangement for plasmonic nanostructures due to their ability to support strong collective lattice resonances, which arise from the coherent multiple scattering enabled by the array periodicity. Thanks to these exceptional properties, periodic arrays are being exploited in a wide variety of applications, including ultrasensitive biosensing, nanoscale light emission, and color printing, to cite a few [1]. In this talk, we will discuss the response of arrays with multi-particle unit cells using an analytical approach based on plasmon hybridization, which provides a simple and efficient way to design periodic arrays with engineered properties [2], as the ones depicted in Figure 1. We will also discuss how the interplay between the response of the individual constituents and the collective interaction determines the ultimate limits of the field enhancement provided by these systems. We will finish by addressing the effect that the presence of edges, as well as disorder, have on the response of these systems [3].

Figure 1: Plasmonic arrays with multi-particle unit cells. (a) Reflectance of a square array with period $a = 800$ nm and two particles per unit cell, arranged as shown in the inset. Both particles are silver nanoshells with silica cores. The inner and outer radii are $R_i = 40$ nm, $R_o = 50$ nm for particle 1 and $R_i = 50$ nm, $R_o = 60$ nm for particle 2. (b) Imaginary part of the dipole induced in particle 1 (red curve) and particle 2 (blue curve). (c),(d) Same as (a),(b) but for the array shown in the inset of (c). These results show how, by controlling the relative positions of particle 1 and 2 within the unit cell, it is possible to engineer the response of the array. (Figure adapted from [2]).
The role of the thermo-optic nonlinearity of metals in plasmonic-assisted photocatalysis

Ieng Wai Un¹, Yonatan Dubi², Yonatan Sivan¹

¹Unit of Electro-optic Engineering, Ben-Gurion University, Israel, ²Department of Chemistry, Ben-Gurion University, Israel,

*corresponding author, E-mail: sivanyon@bgu.ac.il

Abstract

We show that a failure to account for the thermo-optic nonlinear response of the metals leads to significant overestimates of the temperature developing in illuminated metal-dielectric composites used for photocatalysis. This error is then frequently interpreted incorrectly as non-thermal (i.e., “hot”) electrons action. As an alternative, we provide a purely thermal self-consistent model that explains the observed experimental data.

The possibility to use high energy (aka “hot”) electrons in illuminated plasmonic nanostructures for applications such as photo-catalysis, sensing, up-conversion attracts a lot of interest recently. A complete theoretical model of this problem should account for the non-equilibrium nature of the electron distribution in the metal, but also for the possibility of both the electrons and the underlying lattice to heat up under continuous wave (CW) illumination. As shown in a series of recent works [1,2], the latter thermal effects dominate completely the photo-catalysis, whereas the non-thermal effects (associated with the so-called “hot” electrons) are more than a billion times weaker. A critical review of some of the most famous experimental papers on the topic has shown that the thermal effects in those papers were grossly underestimated, leading to an incorrect interpretation of the results as due to “hot”-electron action [2,3,4]. A re-interpretation of the experimental data in those papers with a purely thermal model provided an essentially perfect fit to all experimental data (with the bare minimum of fitting parameters) [2,3,4].

The model used so far in [3,4] assumed that the temperature of the plasmonic nanostructure grows linearly with the incoming intensity. However, for sufficiently high intensities, the temperature of the metal and environment rises significantly so that their permittivities are modified significantly with respect to their room temperature values. This, in turn, causes the scattering to be modified with respect to the linear prediction. This thermo-optic nonlinear response was studied in detail for a single spherical particle in [5,6], but so far, not for metal particle composites.

Here, we perform detailed numerical calculations of the temperature of such particle composites at high temperatures, which include the temperature dependence of the metal and host permittivities, as well as the thermal conductivity of the host both for monochromatic and pulsed illumination schemes. We show that the temperature developing in the composites can be even 50% lower than the linear prediction employed so far in [3,4]. As a confirmation, we show that the predictions of the simulations are in good agreement with the temperatures extracted from several papers reporting experimental measurements of temperatures and reaction rates. This further strengthens the interpretation of plasmonic effects in photocatalysis as purely thermal effects (rather than as the result of non-thermal (“hot”) electron action) and emphasizes the difficulty in an experimental isolation of these “hot” electron effects from stronger, far more conventional and well-established effects.

Backward groove-regulated light wave resonance inside a subwavelength metallic slit

Jian-Shiung Hong and Kuan-Ren Chen*

Department of Physics, National Cheng Kung University, Tainan 70101, Taiwan
*corresponding author, E-mail: chenkr@phys.ncku.edu.tw

Abstract

Grooves patterned at the exit side of a subwavelength metallic slit are known to manipulate the transmitted light profile. We study the groove effect and find a backward coupling mechanism. The transmitted light is scattered by the grooves and then re-enters into the slit. This causes a phase delay of the reflected wave and is considered a reduction in the resonant film thickness. The traveling wave in the slit can be more in phase to significantly enhance the transmission.

1. Introduction

The optical response of subwavelength structures in metal films [1] is extensively studied to understand the enhanced transmission mechanism. For a single subwavelength slit pierced in a metal film, the forward coupling of the incident light causes the funneling of the incident energy to enhance the light transmission [2]. Grooves patterned at the entrance side of the film can further increase the funneling of the incident light into the slit [3]. The transmitted light through the slit can be forward coupled with the grooves patterned at the exit side of the film to affect the light spatial distribution in the exit space, such as controlled beaming [4] and beyond-limit focusing [5]. The mechanism for a subwavelength slit and coupling grooves at the exit side is well studied [6].

We analytically study the effect of the exit-side grooves and discover a novel backward coupling mechanism that causes a part of the scattered light to flow back into the slit to change the resonance condition. This backward coupling mechanism can increase the phase of the wave reflected at the exit boundary in the case studied. As a result, the film thickness at resonance is effectively reduced. The roundtrip wave can be made more in resonance so as to significantly enhance the transmission.

2. Reflection at the slit exit

Figure 1(a) shows a subwavelength slit in a metal film patterned with multiple grooves. Without loss of generality, the film is made of a perfect electric conductor (PEC). A p-polarized wave of wavelength $\lambda_0$ is incident inside the slit. After the transmission, it is both radiated into free space and scattered by the grooves [6].

Suppose that the system is divided into two regions: region I for $z > 0$ and region II for $z < 0$. By defining the boundary magnetic field $U_0'$ and its normal derivative $DU_0'$ at each opening for $l$ from $-L$ to $L$, we obtain a set of equations based on Green’s theorem:

$$\sum_{k=-L}^{L} I_{0,k} DU_0'^k = 2 - \frac{i}{k_0} DU_0^0, \quad (1a)$$

$$\sum_{k=-L}^{L} I_{l,k} DU_0'^k = \frac{1}{k_0} \cot(k_0d) DU_0'^l, \quad (1b)$$

where

$$I_{l,k} = \frac{i}{2} \int_{kp-a}^{kp+a} H^{(1)}_0(k_0|x - lp)|dx. \quad (2)$$

Now, we analyze the field in the slit. Given $U_0^0 = 2 - (i/k_0) DU_0^0$ for $|x| < a$, Eq. (1a) indicates

$$U_0^0 = 1 + \frac{k_0 I_{0,0} - i}{k_0 I_{0,0} + i} \frac{2}{i} \sum_{j=1}^{L} I_{0,j} DU_0^j. \quad (3)$$

We obtain that the first term is the incident field, the second term represents the field reflected at the interface of the slit exit, and the third term indicates the sum of the fields scattered by the $\pm j$th grooves as the radiated cylindrical wave from the grooves to the slit.
opening for \( j \) from one to \( L \) and coupled backward into the slit. We illustrate the reflection inside the slit and this backward coupling from the \( \pm j \)th grooves in Fig. 1(b). The slit-reflected field and the groove-scattered fields will propagate away from the interface.

The sum of the fields are considered as the effectively reflected field by the interface. We assume that the effective reflection coefficient is \( r_L \). The field inside the slit can be expressed as \( U_1(x, z) = U^r_1(x, z) - r_L U_j^i(x, 0) \exp(ik_0 z) \). By comparing this expression at \( z = 0 \) with Eq. (3), we obtain \( r_L = r_0 + r_g^L \), where

\[
r_0 = \frac{k_0 I_{0,0} - i}{k_0 I_{0,0} + i}, \quad r_g^L = \frac{-2i}{k_0 I_{0,0} + i} \sum_{j=1}^L I_{0,j} D U_j^0.
\]

are the intrinsic slit reflection coefficient and the contribution coefficient from the grooves, respectively. In our case, we obtain \( \arg(r_L) \) is increased with \( L \).

3. Resonance inside the slit

In the slit of thickness \( b \), the effectively reflected wave at the exit interface is again reflected at the entrance interface and the reflection coefficient at the interface is \( r_0 \) without the patterned grooves. Due to the reflection at both interfaces, an incident plane wave on the slit will travel in roundtrips after the transmission through the entrance interface. Suppose that the magnetic field of the incident plane wave at \( z = b \) is \( U_j^b = \exp(-ik_0 b) \). For \( 0 \leq z \leq b \), the magnetic field in the slit is

\[
U_s(z) = U_j^b e^{ik_0 z} e^{-i k_0 z} r_L e^{ik_0 z} \frac{1}{1 - r_L r_g^L e^{2i k_0 z}},
\]

where \( t_0 = 2i/(k_0 I_{0,0} + i) \) is the transmission coefficient of the entrance interface. The electric field is obtained from \( E_{xs}(z) = (-i/k_0) \partial_z U_s(z) \). The transmittance from the roundtrip-wave model is \( T_s = \text{Re}(E_{xs}(z) U_s^*(z)) \).

The resonance condition is satisfied when

\[
2k_0 b_{\text{res}, q} + \arg(r_g) + \arg(r_0) = 2q\pi,
\]

where \( q \) is a positive integer and \( b_{\text{res}, q} \) is the film thickness at resonance. As \( L \) increases, \( b_{\text{res}, q} \) will be slightly reduced due to the increased phase of \( r_L \) in our case. For a film thickness \( b \) slightly smaller than \( b_{\text{res}, q} \), the roundtrip wave inside the slit will be closer to the resonance condition so that more incident energy can be transmitted. Figure 2 shows the resultant transmittance \( T_s \) yielded for each \( L \) when \( b \) is 6% of \( \lambda_0 \) smaller than \( b_{\text{res}, 1} \). We obtain that, in addition to the enhanced transmission when \( L = 0 \) [2], significant 70% more incident energy is transmitted.

4. Conclusions

We discovered a backward coupling mechanism for the grooves patterned at the exit side of the metal film to regulate the resonance. The phase of the effective reflection coefficient is increased for the case studied. Our analysis based on the roundtrip-wave model shows that the increased phase causes an effective reduction of the film thickness required to satisfy the resonance condition. As a result, the roundtrip wave in a slit of the film thickness being slightly smaller than that of resonance can be more in phase so as to transmit significantly more light energy.

Abstract
The highly-confined nanogap plasmons in nanocube-over-mirror (NCOM) system possess huge enhancement of electric field and local density of states (LDOS)[1, 2], and these fascinating properties make NCOM to be an idea platform to study the light-matter interaction. Here, we demonstrate the coupling between the neutral excitons in monolayer TMDs and the magnetic plasmons in NCOM. In this geometry, we found that huge PL enhancement and Rabi splitting are achieved simultaneously, whereas the circular emission of PL can be manipulated by shifting the plasmon resonance through depositing alumina layers.

1. Introduction
Transition metal dichalcogenides (TMDs) are widely attracted due to its fascinating optical and electric properties. The transition dipole moment μ of monolayer TMDs is huge, which facilitating the light-matter coupling[3, 4]. Here, we found that coupling between excitons in monolayer WSe₂ and magnetic plasmon mode in NCOM reached intermediate regime. And huge PL enhancement (~1700 times) and Rabi splitting were achieved simultaneously. Such huge PL enhancement mainly comes from the enhancement of emission (~410 times) process. Another fascinating property of monolayer TMDs is the valley selection rule[5], which make the PL emission preserve the same chirality as the circular polarized excitation light. Here we found that the circular emission of the MoS₂ can be manipulated by the magnetic plasmon in NCOM. The circular polarization of the PL was enhanced but negative due to the plasmon modulation.

2. Results and discussion
Figure 1a shows the sample geometry of the NCOM coupled with monolayer WSe₂. Normalized scattering spectra for different alumina deposition were shown in Figure 1b. The scattering spectra was taken by a s-polarized light, because the s-polarized light can excite a pure magnetic mode rather than the dipole-dipole mode according to our recent research[2]. An apparent splitting of the scattering spectra (highlighted by a grey dashed line) at the exciton peak position was found. After fitting the scattering spectra with the two coupled-oscillators model, we found a 35.0 meV Rabi splitting (shown in Figure 1c). The splitting is smaller than the plasmon linewidth (~120 meV) but comparable with the exciton linewidth (~40 meV), indicating that the coupling between the magnetic plasmon mode and excitons in WSe₂ is in the intermediate regime. Besides, the PL spectra (shown in 1d) demonstrate a huge enhancement of PL was achieved in this system. So in this system, the Rabi splitting and PL enhancement can be achieved simultaneously. The real enhancement of PL due to the interaction with magnetic plasmon mode reaches nearly 1700 times. 410 times of the PL enhancement comes to the interaction with magnetic plasmon coming from the excitation process. Such high emission brightness of excitons is owing to that the coupling is just in the intermediate regime[6].

A monolayer MoS₂ was used to couple with the NCOM, the sample geometry is shown in Figure 2a. The plasmon resonance was shifted by coating alumina on top of the silver nanocube (shown in Figure 2b). We excited the sample with a 633 nm left circular (σ⁻) light, and then we collected the left circular and right circular (σ⁺) light respectively. The PL intensity against the plasmon resonance is shown in Figure 2c. We then calculate the circular polarization according to \( ρ = \frac{I(σ⁻)-I(σ⁺)}{I(σ⁻)+I(σ⁺)} \). So we can see that the circular polarization can be tuned very well by coating the alumina. A circular polarization nearly -18% can be realized which is much higher than the background (~5%) MoS₂ without silver nanocubes on it, but this circular polarization changed its sign. This manipulation of the circular polarization is probably due to the tilt angle between the bottom side of the silver nanocube and horizontal plane.

3. Conclusions
In conclusions, we demonstrate that huge emission enhancement and Rabi splitting can be achieved simultaneously in the NCOM coupled with monolayer WSe₂ system. Besides, the circular emission from the monolayer...
MoS$_2$ can be manipulated by the magnetic plasmon mode in NCOM. Meanwhile, the circular polarization changed with shifting the plasmon resonance by alumina depositing. We believe that NCOM coupled with TMDs system is an ideal platform for the study of light-matter interaction.

Abstract

The time-resolved investigation of surface plasmon polaritons by means of photoelectron imaging after femtosecond laser pulse excitation has developed into a mature technique over the last years. By using a normal-incidence geometry in a photoemission electron microscope it has become possible to record slow-motion movies of surface plasmon propagation and to spatio-temporally resolve standing plasmon waves. Analyzing the energy distribution of emitted electrons shows that above threshold ionization and strong-field emission from plasmonic foci is possible.

1. Introduction

Surface plasmon polaritons (SPPs) are longitudinal waves in the electron system of selected metal surfaces that are coupled to an oscillating electric field with unique properties. Imaging of SPPs in time and space can be accomplished by means of time-resolved nonlinear photoemission microscopy (PEEM). Figure 1 (a) shows a sketch of the experimental setup used at the University of Duisburg-Essen. A commercial low-energy electron microscope (ELMITEC GmbH) is operated in photoemission mode. Femtosecond laser pulses from a Ti:Sapphire oscillator (central wavelength $\lambda = 800$ nm, pulse duration $< 15$ fs) impinge on the sample along the surface normal and liberate electrons by means of a nonlinear emission process. The emitted electrons pass through an electron-optical magnification system where they can also be energy-filtered. Ultimately, the spatial distribution of the emitted electrons is imaged on a screen.

For the experiment discussed here, we start with a polycrystalline Ag film and use a focused Ga ion beam to mill grooves with the shape of concentric circles into the film. A cross-section through a resulting structure is sketched in Fig. 1 (b). At the grating couplers on the left and right of Fig. 1 (b) the femtosecond laser pulses are coupled into SPPs that propagate across the surface and that are imaged in our normal-incidence pump-probe PEEM experiment [1]. Since the laser pulse intensity is approximately equal across the milled structure, each laser pulse simultaneously excites SPPs on either side of the grating coupler. Here, we will only discuss the SPPs that are propagating towards each other, i.e., towards the center of the coupler. The circular shape of the grating coupler ensures focusing of the SPPs into the center of the circle. The innermost ring of the grating coupler has a diameter of 40 $\mu$m by design, which implies that the counter-propagating SPPs, advancing with a phase-velocity of 97.9% of the speed of light in vacuum [2] ($v_p \approx 293.5$ nm/fs) need approximately 68 fs to arrive in the center of the circle. At this time the exciting $< 15$ fs laser pulse is already over. When the two counter-propagating SPPs transiently form a standing wave in the center of the ring, any electron emission (in addition to the photoemission background) must be explained by electron emission from the SPP. To semantically distin-
Figure 2: Plasmoemission from a SPP focus. (a) Energy-filtered PEEM image showing third order emission in the center of the circular grating coupler. The highest electron yield is observed near the focus spot. The concentric fringes surrounding the focus originate from a standing SPP wave and resemble a spacing of $\lambda_S/2$. The scalebar has a length of 1 $\mu$m. (b) Energy distribution of electrons emitted from the focus. To overcome the work function, at least a third order process is necessary. The spectrum also shows fourth and fifth order emission. The inset illustrates the mechanism of this above-threshold ionization, where more energy quanta are absorbed from the SPP field than would be required to just overcome the work function barrier.

In our experiment with the circular grating coupler, the combination of SPP focusing and spatio-temporal separation of light and SPP allows us to study electron emission from strong plasmonic fields in more detail. Figure 2 shows experimental results obtained near the focus of the SPP. Panel (a) shows an energy-filtered image with the focus in the center. The two counter-propagating SPPs coming from the left and from the right meet in the center of the circular grating coupler and form a standing wave with fixed positions of nodes and anti-nodes. As electrons are emitted from the anti-nodes of the transverse part of the SPPs standing wave electric field $E$, concentric phase-fronts with a separation of half the SPP wavelength, $\lambda_S/2$ are visible. Due to the focusing, the SPP field strength and the emitted electron yield close to the focus are much stronger than at other areas on the surface.

Inserting an aperture into one of the conjugate image planes within the microscope’s beam path, centering the aperture on the focus point, and analyzing the energy of the emitted electrons from the focus point provides further information about the emission mechanism. Figure 2 (b) shows an energy spectrum of the electrons emitted from the focus. The energy scale has been offset using the literature value of the work function of polycrystalline Ag of $\Phi_{lit} = 4.26$ eV [4]. As the energy of SPP quanta is only $E_S = \hbar \omega = 1.55$ eV, any emission process below third order is suppressed because of the work function of the sample. The energy spectrum in Fig. 2 (b) shows unexpectedly high electron energies and exhibits several distinct steps that are separated by $E_S$ in energy. Emitted electrons with such high energies can be explained by higher order nonlinear emission processes. The higher the order of the process, the lower the emission probability, and accordingly, the steps in the spectrum resemble replicas of the Fermi-edge for the different emission orders. Note that the quantitative determination of the electron temperature is not possible due to the limited energy resolution of the used energy filter.

In the spectrum of Fig. 2 (b), emission of up to the fifth order is observed. The inset in Fig. 2 illustrates this above threshold ionization in an energy-level picture. Not only can we unambiguously conclude from the data that the nonlinear electron emission is caused by plasmoemission, but we can also demonstrate that the SPP field in the focus is strong enough to enhance nonlinear emission pathways.

In conclusion, focusing of SPPs with appropriate excitation structures provides a promising pathway to study highly nonlinear electron emission. Improving the focus quality and enhancing the SPP excitation will push the system into the plasmonic strong-field regime, where field emission becomes the dominating emission channel. Such experiments are currently under way.

Abstract
In surface plasmon polariton-enhanced nonlinear photoemission from gold surfaces, several pathways can lead to the emission of electrons. In addition to the well-established two-photon absorption, emission purely from the plasmonic field can occur. More complex emission mechanisms come into play when there are interferences between the surface plasmon polariton and a probing femtosecond laser pulse. Here we use a pump-probe experiment to describe how the different contributions of plasmon and probing laser field can be disentangled.

1. Introduction
Electron emission from metal surfaces under illumination by light proceeds by simultaneous or subsequent absorption of one or more photons, depending on the intensity of the incident light and the work function of the metal. Likewise, in the presence of surface plasmon polaritons (SPPs), the electrons can absorb energy from the plasmon wave and also be ejected from the metal surface. Figure 1 (a) illustrates these two possible emission pathways in an energy diagram. Both have been isolated and identified in the past, and they were referred to as photoemission and plasmoemission, respectively [1]. When both SPP and light fields are simultaneously present, it is more difficult to separate photon-related from SPP-related contributions to the overall emission yield. Here, we demonstrate that such separation can be achieved by using photo-emission electron microscopy combined with optical pump-probe techniques. We show that in a pump-probe experiment with individual control over the pump- and probe-pulse intensities different emission mechanisms would be distinguishable by their characteristic nonlinearities.

2. Experiment
We use time-resolved nonlinear photoemission electron microscopy (PEEM) and combine it with a Ti:Sapphire laser to observe SPPs in a pump-probe experiment. In such an experiment, as sketched in Figure 1 (b), a first linearly polarized (pump) laser pulse incident on a grating coupler excites a SPP which then propagates across the surface. A time-delayed second linearly polarized (probe) laser pulse interferes constructively with the SPP pulse and locally increases the nonlinear photoemission yield. Given the velocity of the SPP (almost the speed of light in vacuum) it is clear that such an experiment requires femtosecond time scales. In our case, the used laser pulses are < 15 fs short, and the relative precision in the time delay (\(\Delta t\)) between pump- and probe pulse is of the order of 50 attoseconds. We use focused ion-beam milled grating couplers to effectively convert our \(\lambda = 800\) nm laser pulses into SPPs. For the single-crystalline Au(111) platelets that we are using as plasmonic material, such excitation results in long-range SPPs of a wavelength of \(\approx 780\) nm. Since the work function of the Au platelets is of the order of 5.3 eV, we have to deposit a submonolayer of Cs prior to our experiments in order to enable a two photon (or two plasmon) emission process.

3. Results and Discussion
Figure 2 shows a result from a time-resolved experiment at a pump-probe delay time of \(\Delta t \approx 70\) fs. The grating coupler used for excitation of the SPP is on the left, next to a static wave pattern that is due to the interference of the pump beam with the SPP it excites. Further away from the...
coupler a modulation of the background intensity is visible (labeled by $E_P E_P$) that resembles the near-field diffraction pattern of a slit. At a distance $15 - 20 \mu m$ away from the grating coupler, a prominent wave interference pattern is formed (labeled by $E_P E_L$). Unlike all other features in the experiment, the location of this interference pattern depends on delay time.

To better understand the different elements that contribute to the overall electron yield in Fig. 2, we describe the contrast as the temporal integral of the time-dependent coherent superposition of all electric fields at the surface [2]. Due to the normal-incidence geometry for our laser pulses relative to the surface plane, the light field has no spatial dependence. Furthermore, we only consider SPPs that were created by the pump pulse, and we neglect any SPPs that would be created by the probe laser pulse. In a one-dimensional description the expected yield is then given by

$$Y(r, \Delta t) \propto \int |E_P(r, t) + E_L(t + \Delta t)|^4 \, dt. \quad (1)$$

This yield model can be independently applied for the transverse and the longitudinal part of the SPPs' electric field [1]. For the pump-probe experiment described here, a discussion of the longitudinal fields is sufficient [3]. Expanding Eq. (1) highlights several individual emission paths

$$Y \propto \int E_P^4 + 4E_P^3 E_P + 6E_P^2 E_L^2 + 4E_L E_P^3 + E_L^4 \, dt. \quad (2)$$

Note that in Eq. (2) the position and time-dependence were suppressed for clarity. The $E_P^4$ contribution simply accounts for a two photon photoemission background. In the same way, the $E_P^3 E_P$ term describes the time-integrated plasmoemission from the longitudinal field of the SPP. The remaining three terms are interferences between the longitudinal SPP field and the probe laser pulse. The $E_P^2 E_P^2$ term describes an emission process where both a photon and a plasmon are absorbed by the electron before it can be liberated from the Au. The $E_P^3 E_P$ and $E_L E_P^3$ are more complex emission pathways. All the interference terms have in common, however, that for an experiment they predict different scaling behaviour for both SPP strength and laser pulse strength.

To disentangle the contributions of the individual terms to the emission, we thus measured the electron yield at the point of overlap of the probe and SPP pulses as functions of both the probe and SPP pulse intensities. Key to achieving these measurements is the fact that the SPP intensity is determined by the strength of the pump pulse that can be adjusted independently of the probe pulse. In this manner we can experimentally verify the presence of all the individual electron emission pathways suggested by all the fundamental level.

4. Conclusion

In our study we identified both experimentally and theoretically the emission pathways for electrons in SPP enhanced nonlinear photoemission. By adjusting the SPP and laser field strength independently, we were able to experimentally verify the existence of all theoretically predicted pathways. Several emission mechanisms exist, into which SPP and laser pulse enter with different exponents. While this can be easily understood in a semi-classical electrodynamic picture, our study paves the way for a deeper understanding of SPP-light interference at a more fundamental level.

Summary

The challenges to be solved in silicon photonics at telecom wavelengths are still of several kinds. Among these, two important locks concern the realization of integrated optical amplifiers essential for re-amplifying attenuated signals, and the realization of fast electro-optical modulators (>>10GHz) with low power consumption (<1fJ/bit) [1]. The approaches used in the literature to address these two locks have led to a wealth of proposals and works, including the hybrid integration of III/V semiconductors on silicon by sticking vignettes or full plate, or more rarely by monolithic growth. This solution, based directly on pre-existing mature solutions, raises co-integration problems, both in terms of materials and photonic integration (coupling of Si guide light to III/V guides, etc.), but has already demonstrated several very solid proposals. However, it presents difficulties related to the complexity of processes and technologies, without integration into a complete CMOS process flow [1].

In this context, our presentation will summarize our recent contributions on the two key functions mentioned above. Our approach to light amplification is based on the integration of Erbium-doped materials and brings a strong innovation to the field through the integration of state-of-the-art active materials combined with a proper choice of slot silicon nitride waveguides. We report ultra-high onchip optical gain in Erbium-based hybrid slot waveguides with a monolithic, CMOS-compatible and scalable atomic layer deposition (ALD) process. The nature of ALD provides a versatile tool to atomic scale engineering of the gain layer properties and an efficient integration with SiN waveguides and other photonic structures. We demonstrate 20dB/cm of modal gain at \( \lambda = 1.53 \mu \text{m} \), which opens up very interesting perspectives for the creation of light sources and their transcription into various integrated system-level functions [2].

In another complementary direction, the signals thus produced or amplified must be encoded by electro-optical modulation for the realization of optical links. We started from the observation that beyond the physical mechanisms leading to index modulation by refraction, a significant part of the contribution to the energy dissipation of the modulators was due to the type of resonators or interferometers used. An electro-optical modulator exploiting the plasma effect (refraction on free carriers) and integrating a phase modulator into a Mach-Zehnder interferometer geometry, for example, consumes several ps/bit. This is mainly due to the size of the interferometer (several mm), which brings back high structural capacities. The use of nanoresonators, such as nanobeams cavities, provides a very significant downscaling factor but is still insufficient to achieve the targeted consumption levels (about 1 fs/bit). The reason lies in the classical form of the optical resonances used (Lorentzians), which leads to a necessary strong modulation to detune the resonance from its maximum. We have recently shown that a complete paradigm shift could be achieved in the consumption of plasma electro-optical modulators when an asymmetric Fano resonance is considered. We have specially proposed and designed an original Fano cavity structure based on the electromagnetic coupling of two pre-existing resonances in a single silicon guide geometry [3]. This single guide geometry offers a generic platform of Fano cavities directly applicable to the production of electro-optical modulators characterized by a set of merit factors superior to those obtained previously due to the very abrupt transmission of the Fano resonance. All these results will be detailed and supplemented at the conference by the most recent experimental results obtained.

Scaling of monolayer 2D photonic crystal surface emitting lasers for 3D integrated photonics (Invited)

Weidong Zhou and Xiaochen Ge

Department of Electrical Engineering
University of Texas at Arlington, Arlington, Texas, USA
(wzhou@uta.edu)

Abstract:

Free-space coupled membrane photonic devices are highly desirable for 3D optical interconnects, free space communications, imaging, sensing, and ranging applications. Based on transfer printing processes, heterogeneously integrated active photonic crystal devices can be built on the common silicon platform. In this talk, I will report recent progresses related to hybrid integrated photonic crystal surface-emitting membrane lasers on silicon substrate, based on QW gain material and transition metal dichalcogenide monolayers. Issues to be discussed related to thermal performance, charge injection, and scaling towards energy efficient optical interconnects.

Abstract

We demonstrate a tunable grating coupler with low power consumption, fabricated via a standard complementary metal–oxide–semiconductor process. The grating coupler locates on a freestanding silicon-on-insulator strip waveguides. The air gap between the grating structure and the silicon substrate enhances the heating efficiency. We achieve a central wavelength thermal shift of 55 nm with 19.5 mW input power, a tuning efficiency of 2.82 nm/mW. The dynamic response with rise time and fall time are 0.16 ms and 0.74 ms, respectively.

1. Introduction

Silicon-on-insulator (SOI) is recognized as one of the most attractive platforms for photonic integrated circuits (PICs) due to the compatibility with CMOS foundries, as well as the potential of low-power, high-capacity interconnects for electronic-photonic integrated circuits (EPICs) [1]. To couple the guided mode from a SOI platform to a single mode fiber, one can use a grating coupler that eliminate the index mismatch between two modes. However, in practice, the central wavelength of grating coupler could vary randomly due to many reasons [2–4]. For photonic integrated circuits, this variation introduces significant optical losses. A tunable grating coupler that can dynamically change central wavelength is ideal to compensate the wavelength drifts. Most common ways of making tunable grating couplers are changing the refractive index of the grating via thermal-optical effect [5] or using micro-electro-mechanical system (MEMS) actuation [6]. Nevertheless, they suffering from high power consumption (0.23 nm/mW) [5] or narrow tuning range [6]. Here, we introduce a new tunable grating coupler design based on an efficient thermal tuning principle, by employing micro-heaters and freestanding silicon-on-insulator strip waveguides. As a result, this design significantly enhanced the thermal tuning efficiency by one order of magnitude compared to previous demonstrations.

2. Results

The schematic diagram of the tunable grating device shown in Fig. 1. A TE-mode focused grating coupler is located on a 220 nm SOI platform, and suspended from the silicon substrate (Fig. 1(a)). We remove the whole Si substrate and part of silicon under the coupler to form a thermal insulation buffer layer, shown as a cross-section diagram in Fig. 1(b). SiO2 supporting arms are surrounding the suspended grating coupler. A zig-zag-shaped heater locates on the side of the grating region to heat up the device. We pattern and use a higher resistivity metal (NiCr) near the grating region where thermal tuning is required, and a lower resistivity metal (Ti-Au) making conductive arms on the sides. A thin electrical insulation layer (Al2O3) with 10-nm thickness is sandwiched between the heater and silicon, also provides efficient heat conduction from the heater to silicon substrate.

Fig. 2 investigates the theoretical power-thermal efficiency difference between air buffered and non-air buffered grating coupler, based on the Poisson’s Equation. Fig. 2(a) and (b) shows the air buffered grating coupler has more than 300K higher temperature achieved at same heating power of 20mW. In Fig. 2(c) we confirmed this difference increases as heating power increase. And Fig. 2(d) shows the center wavelength shifts at different heating power, ranging from 1530nm to 1600nm in 20mW power increment.

Fig. 3 shows the fabricated devices in SEM (a) and optical (b) view, and characterization results via optical transmission measurements. The width of the etching windows and micro heater is 7 μm and 1.5 μm, total footprint of the device is about 81 μm by 100 μm including a 24 μm length taper serving as a mode field transformer from ridge waveguide to
strip waveguide. Fig. 3(c) shows the measured coupling spectra of the tunable grating coupler under different heating power. The maximum coupling efficiency at different heating power varies between -7 dB and -6.5 dB is due to the dispersion of silicon’s thermo-optic effect [7]. The 1 dB bandwidth is around 30 nm within heating power range. Moreover, the central wavelength is shifting from 1535 nm to 1590 nm while heating power is increasing from 0 mW to 19.5 mW, well matched to the simulation results. Fig. 3 (d) shows a plot of the central wavelength versus the heating The dynamic response of the tunable grating coupler, shown in Fig.4, is investigated by applying a square-wave electrical power. The thermal tuning efficiency, extracted from the slope of the curve, is approximately 2.82 nm/mW. The heating power is approximately 2.82 nm/mW. The heating (10%-90%) and cooling (90%-10%) times were estimated to be 0.16 ms and 0.74 ms, respectively.

3. Conclusions

In summary, we have designed and demonstrated a tunable grating coupler capable of changing the central wavelength with low power consumption on the SOI platform using the direct heating method and thermal isolation designs. The tunable range of central wavelength is 55 nm (from 1535 nm to 1590 nm) at a heating power from 0 to 19.5 mW, and a coupling efficiency of 2.82 nm/mW has achieved. The response time of this device is 0.16 ms (the heating time) and 0.74 ms (the cooling time). This coupling efficiency can further be optimized by depositing and patterning overlay amorphous silicon. Moreover, the manufacturing procedure is highly scalable and fully CMOS-compatible.

Abstract

We demonstrate a lithium niobate Michelson interferometer (MI) modulator on silicon-on-insulator platform with half the voltage-length product (Vπ·L) compare to silicon based Mach-Zehnder interferometer (MZI). A single MI modulator shows the electro-optic modulation efficiency of 1.2V·cm and insertion loss of 3dB. The -3dB electro-optic bandwidth is approximately 16 GHz, and the optical eye diagrams, operating at 30 Gbit/s and 40 Gbit/s, with dynamic extinction ratios are measured at 10 dB and 6.8 dB respectively.

1. Introduction

Silicon photonics on the silicon-on-insulator (SOI) platform is the most promising technology in CMOS foundries [1]. However, optical modulation in the silicon material mainly relies on free-carrier plasma dispersion effect, which leads to high absorption losses and nonlinear voltage response [2]. Lithium niobate (LiNbO3, LN) shows potential in electro-optic (EO) modulation due to its physical properties: large EO coefficient (30pm/V), strong Pockles effect, wide bandgap (wide transparency window), and good temperature stability (typical L>10 V·cm). Nevertheless, commercial bulk LN modulators are still based on indiffused or proton-exchange waveguide with low refractive index contrast and low EO modulation efficiency (typically Vπ>10 V·cm). Previous research work shows the thin film based Lithium niobate on insulator (LNOI) has emerged as a promising platform for micro-structuring devices [4-5]. The cross-section of LNOI photonic waveguide is less than 1μm, which lead to small mode size and tight mode confinement. More recently, integrated LN modulator with low loss, low drive voltage and high bandwidth have been demonstrated [6]. In this work, we take advantage of thin film LNOI platform and design a MI modulator, which using loop waveguides as mirror reflectors and half the Vπ·L than a MZI modulator.

2. Results

Fig.1 shows the design layout of a hybrid Si/LN MI modulator. The MI modulator consists of one 2×2 3dB Si MMI, two etched LN arm waveguides, and two 1×2 3dB MMI connecting two silicon waveguide loop mirrors. The hybrid Si/LN modulators consist of silicon waveguide layer, LN waveguide modulation layer, VACs and gold microwave electrode. The device is fabricated through wafer bonding technology by benzocyclobuten (BCB). The top LN waveguides is formed by dry-etching x-cut 600-nm thick LN membrane (NANOLN), and was connected with the bottom Si waveguide layer through VACs. Light can be coupled from Si inverse taper to LN ridge waveguide in high coupling efficiency.

To evaluate the performance of a MI modulator, we performed half wave voltage (Vπ) measurements with a 100-kHz triangular voltage sweep for both MZI and MI. Fig. 2 shows the results for both case, we keep the same waveguide and electrodes design. In Fig. 3(a) the 3-mm-long MZI modulator has an 8.4V mod voltage difference for a pi phase shift in signal, corresponding to 2.5 V·cm of Vπ·L. While this value drop to half (1.2 V·cm) in the 1-mm-long MI modulator, and keeping a DC extinction ratio of >25 dB (see inset). This indicates the MI structure has doubled modulation efficiency compare to the MZI structure.
Fig. 2. 100 kHz triangular voltage scan of (a) a 3-mm-long MZI modulator and (b) a 1-mm-long MI modulator with the similar waveguides and electrodes design.

Fig. 3 shows the non-return-to-zero (NRZ) open eye diagrams at 30 Gbit/s and 40 Gbit/s to evaluate the high-speed digital data transmission performance of the device. The analog signals are generated by Agilent E8257D and amplified by SHF 807 to peak-to-peak voltage (Vpp) of 6.1 V before sending to a modulator. Eye diagrams are obtained from wide-bandwidth oscilloscope (Agilent DCA-X 86100D) without additional compensations. When the modulator is biased at just below the quadrature point, we measured the dynamic extinction ratios are 10 dB at 30 Gbit/s and 6.8 dB at 40 Gbit/s, which are shown in Fig. 3 (a) and (b). Our devices operate at data rates higher than 3 dB EO bandwidth because of the high-quality electrical signal system. The energy consumption of a MI modulator can be estimated by $W_{\text{bit}} = (V_{\text{pp}}/2)^2/(BR)$, where $B$ is the bit-rate and $R$ is the 50 Ω load. At bit-rate of 40 Gbit/s, the energy consumption of MI modulator is approximately 4.6 pJ/bit.

3. Conclusions

We demonstrate a hybrid silicon and lithium niobate MI modulator in a compact footprint (0.1 mm$^2$) with doubled modulation efficiency compare to a MZI modulator. The insertion loss of a 1-mm long MI modulator is less than 3dB, and the lowest figure of merit $V\pi L$ in monolithic LN platform of 1.2 V·cm is achieved. This allows a COMS-level voltage when the modulation length increase to 5 mm while keeping the data transmission in Gbit/s range. In the high-speed data transmission experiment, we show an open optical eye diagram data rates up to 40 Gbit/s with 6.8 dB extinction ratio. As the LN platform is proposed to be a good candidate for high-speed linear quantum key distribution (QKD) applications, our design will satisfy the requirements of efficient and high-speed QKD system. Moreover, for the hybrid Si/LN platform, it is ideal for integrated microwave photonic (MWP) devices on SOI circuits.

Abstract

We show how plasmonics can be integrated with the silicon photonics platform to enable new electro-optic devices. Different active materials are integrated with a plasmonic slot waveguide technology to achieve highest speed modulators and photodetectors on a lowest footprint. It is discussed how the unique properties offered by plasmonics enables new opportunities for the field of microwave photonics.

1. Introduction

Plasmonics has early on promised a revolution in the field of optics [1]. Plasmonics can offer smallest confinement with highest field intensities [2]. In combination with nonlinear materials, sub-wavelength confinement enables strongest light-matter interactions [3] allowing new optoelectronic devices with ultra-compact footprints [4]. The advantages offered by plasmonics have enabled a variety of new devices, finding applications in optical interconnects [5], microwave photonics [6], sensing [7] and atomic-scale devices [8, 9]. In particular, owing to its compact footprint, plasmonics can offer unprecedented bandwidths for optical modulators [10, 11] and photodetectors [12, 13]. The unique advantages offered by plasmonics in terms of high-speed and low footprint capabilities are essential for high-speed fiber-wireless applications [14].

Virtual fibers – high-capacity fiber-wireless links – become economically interesting for dense urban or residential areas, such as shown in Fig. 1. The last few meters of a fiber-to-the-home link is bridged by a high-capacity wireless link. Low-cost and compact devices consuming low energy are required to make such applications practical. Most fiber-to-wireless transmitters and receivers rely on high-speed electronics. With the wireless carrier frequency shifting towards the millimeter-wave and terahertz spectrum [14], the electronics becomes very costly and complex. It is therefore of great interest to have electro-optic devices capable of directly converting the optical signal to the wireless domain and vice-versa.

Here, we show how plasmonics can enable new devices for the fields of microwave photonics. In particular, we show how the plasmonic-organic platform [15], which combines plasmonic slot waveguides with organic nonlinear materials, can enable new wireless receivers for high-data-rate millimeter wave links without consuming any electrical...
power. In addition, we show a new type of high-speed photodetector based on amorphous germanium taking advantage of plasmonics to achieve highest speed and efficiency.

2. Microwave Plasmonic Devices
To realize direct wireless-to-optical and optical-to-wireless converters for future high-capacity wireless links, electro-optic modulators and photodetectors with bandwidths going beyond 100 GHz are required. Integrated plasmonics is a promising platform for such electro-optic devices.

2.1. Microwave Plasmonic Mixer
Combining the strong modulation efficiency of recently demonstrated plasmonic modulators with a resonant antenna allows one to directly modulate the phase of an optical carrier by a wireless signal [6, 7]. The structure of the device is shown in the inset of Fig. 1. The plasmonic subwavelength waveguide enables confinement of the optical mode and the wireless signal to a sub-100 nm gap. This leads to an almost perfect overlap of both signals resulting in a very strong nonlinear interaction. Such a device was used in the demonstration of a transparent fiber-wireless link transmitting 10 and 20 Gbit/s over wireless distances of 1 and 5 m [6]. The demonstrated wireless receiver required no electrical power.

2.2. High-speed Plasmonic Photodetector
The speed limitation of photodetectors is defined by its RC time constant and transit time, i.e. time required for carriers to be extracted. Plasmonics enables to shrink the size of the active region to sub-100 nm. This way, very fast carrier dynamics can be achieved. In addition, the metal forming the plasmonic slot waveguide is simultaneously used as electrical contact. This reduces the resistance and capacitance of the device dramatically. A metal-semiconductor-metal plasmonic waveguide photodetector with amorphous germanium as the active material was proposed, see Fig. 2. An electro-optic bandwidth beyond 100 GHz was measured with an internal quantum efficiency of 36% [12]. The device was used in a data reception experiment, receiving up to 72 Gbit/s on-off keying (OOK) data which was only limited by the available equipment. New generation of detectors have already shown the possibility for 100 Gbit/s OOK reception [13].

The Si photonics platform is attractive for fabricating compact and low-cost optical transceivers with low power consumption. On the platform, heterogeneous integration of III-V semiconductors is the key technology for integrating high-efficiency Mach-Zehnder modulators and laser diodes. Here, we review our recent work on heterogeneously integrated III-V/Si Mach-Zehnder modulators and lasers with a membrane III-V semiconductor structure, which provides a high optical confinement factor for low power consumption and easy integration with Si waveguide circuits.

Fig. 1(a) shows a schematic of the membrane InGaAsP/Si Mach-Zehnder modulator [1]. The Mach-Zehnder modulator has a metal-oxide-semiconductor (MOS) capacitor structure with 100-nm-thick n-type InGaAsP, 10-nm-thick SiO$_2$, and 110-nm-thick p-type Si layers. By accumulating the majority carriers at the semiconductor/SiO$_2$ interfaces, the phase of the lightwave is mainly modulated by the large carrier plasma effect and band filling effect of the n-type InGaAsP layer. Thanks to the large optical confinement factor with the membrane structure, a large overlap between the optical mode field and carrier distribution is obtained. In addition, the high electron mobility of the n-type InGaAsP layer is beneficial for small free-carrier absorption. The fabricated device showed $V_{L}$ of 0.09 V/cm and the phase shifter loss of around 2.6 dB/mm. Both the $V_{L}$ and phase shifter loss are much smaller than those of conventional Si MOS capacitor Mach-Zehnder modulators.

Fig. 1(b) shows a schematic of the lateral current injection membrane laser diode on the Si waveguide [2]. The thickness of the laser diode (0.23 µm) is much smaller than that of the conventional laser diode (~2 µm). Since the effective refractive index of the membrane InP-based layer is comparable to that of the typical ~200-nm-thick Si waveguide layer, the membrane laser diode efficiently couples to widely developed Si photonics circuits. The fabricated 500-µm-long distributed feedback laser diode showed a threshold current of ~6 mA and a fiber coupled output power of 4.6 mW in the C band. Thanks to the small active volume and low effective refractive index of the membrane layer, low threshold current and efficient optical coupling to the Si waveguide were obtained.

Abstract

Quantum photonics opens a new era of technology revolution deeply embedded in quantum mechanism. Silicon integrated quantum photonics is of particular interest able to integrate mass of quantum photonic components on a single silicon chip. Here we present our recent work on silicon photonics for advanced quantum applications, including high-dimensional quantum quantum key distribution, high-dimensional quantum entanglement, and Hong-Ou-Mandel interference of two independent lasers on silicon for quantum communication.

1. Introduction

Over the past decades, free space optics has greatly pushed the research of quantum photonics and its applications in quantum key distribution, quantum simulation, and quantum computation. Silicon photonics, able to integrate a large amount of photonic components in a single chip with complementary metal-oxide semiconductor (CMOS) compatible fabrication process, is a versatile platform for development of quantum technologies with intrinsic stability, high precision, and dense integration [1]. Here we present our recent work on silicon integrated quantum photonics, including high-dimensional (HiD) chip-to-chip quantum key distribution (QKD) with high photon information efficiency and enhanced noise-resilience, on-chip creation and manipulation of HiD-quantum entanglement states, and Hong-Ou-Mandel (HOM) interference of two independent semiconductor lasers on silicon necessary for measurement device independent (MDI) quantum communication.

2. Quantum key distribution

QKD is an attractive quantum technology that shares secret keys between two parties (Alice and Bob) with ultimate security. Traditional QKD is based on binary signal formats (qubits), such as the BB84 protocol, and information efficiency is limited to 1 bit/photon. HiD-QKD employing HiD quantum states (qudits) provides higher information efficiency (>1 bit/photon) and better noise resilience [2]. However, implementing HiD-QKD with traditional free-space optics is extremely challenging in terms scalability and stability, which can be effectively handled by silicon photonics. As shown in Fig. 1(a), Alice chip is able to create any four-dimension quantum state within three mutually unbiased bases (MUBs) M0, M1 and M2,

\[ M0 = \begin{pmatrix} |A⟩ + |B⟩ \\ |A⟩ - |B⟩ \\ |C⟩ + |D⟩ \\ |C⟩ - |D⟩ \end{pmatrix}, M1 = \begin{pmatrix} |A⟩ + |C⟩ \\ |A⟩ - |C⟩ \\ |B⟩ + |D⟩ \\ |B⟩ - |D⟩ \end{pmatrix}, M2 = \begin{pmatrix} |A⟩ + |D⟩ \\ |A⟩ - |D⟩ \\ |B⟩ + |C⟩ \\ |B⟩ - |C⟩ \end{pmatrix} \] (1)

where |A⟩, |B⟩, |C⟩, and |D⟩ represent the quantum states related to the four individual cores of a multi-core fiber. The HiD quantum states are sent through a multicore fiber (MCF) and received by Bob chip, who is able to receive the quantum states in any of three MUBs. With standard QKD protocol,
we achieved low quantum bit error rate (QBER) below both coherent attack limit and individual attack limit, as presented in Fig. 1(b) and (c).

3. High dimensional quantum entanglement

Apart from the promising potential of qudits in quantum communication, as presented above, qudits can also be used to strengthen the violations of generalized Bell and Einstein-Podolsky-Rosen (EPR) steering inequalities [4], provide richer resources for quantum simulation, and offer higher efficiency and flexibility in quantum computing. Previous work on qudits entanglement systems incur limitations in terms of controllability, precision, and universality, which represent bottlenecks for further developments of HiD technologies. We demonstrate a large-scale silicon quantum photonic circuit to implement qudit entanglement [5], as shown in Fig. 2(a) and 2(b), which can generate and manipulate HiD entanglement state with certified dimensionality up to 14, providing an experimental platform for the development of multidimensional quantum technologies.

![Fig. 1. (a) Schematic on-chip generation and manipulation of HiD quantum entanglement state. (b) fabricated silicon quantum chip, and (c) experimental quantum state tomography of generated 12-dimensional quantum state, indicating a fidelity of 81%.

4. High dimensional quantum entanglement

Despite the great potentials of QKD, practically, implementations are always imperfect, which opens loopholes that undermine the security of the protocol. A well-known example is the detector side channel attack, which can be exploited to hack QKD systems [6]. To tackle this vulnerability, measurement device independent QKD (MDI-QKD) was introduced and demonstrated [7, 8], where a third untrusted party, i.e., Charlie, performs a Bell-state measurement on the quantum states sent by the two trusted parties, i.e., Alice and Bob, allowing them to establish a secret key based on time-reversed entanglement. A successful implementation of MDI-QKD requires high-visibility two-photon interference, i.e., HOM interference, between Alice’s and Bob’s quantum states. When the single photons are replaced with weak-coherent pulses (WCPs), HOM interference still occurs, but with a diminished visibility of 50%. We obtained, for the first time, to the best of our knowledge, high-visibility HOM interference between WCPs generated by independent gain-switched III–V on silicon waveguide integrated lasers (see Fig. 3(a)) [9]. Experimental visibility of $V = 46 \pm 2\%$ is achieved, as shown in Fig. 3(b), paving the way towards implementation of metropolitan QKD networks based on silicon photonics with fully integrated WCP sources.

Application opportunities for Field-Programmable Photonic Integrated Circuits

Daniel Pérez-López*, Prometheus DasMahapatra, José Capmany,
1Photonics Research Labs, Universitat Politècnica de València, Spain

Abstract
The advent of a new generation of programmable photonic integrated circuits (PICs) has paved the path for cost-effective solutions for a wide variety of applications which employ at least one photonic-based subsystem. Here, we review the main characteristics of programmable PICs and analyze their trade-offs and performance in the different fields of application: telecommunications, datacentres, radio-over-fiber, microwave photonics processing, high-performance computing and sensing.

1. Introduction
Integrated photonics is the science and technology that enables the integration of a large number of waveguide elements and specific devices/performance blocks in order to perform optical processing on a chip. Traditionally, both, industry and academia have mainly focused on the design and optimization of Application Specific Photonic Integrated Circuits (ASPICs) whereby all the stages involved in the development of a PIC are tailored to optimize the chip performance, power budget, consumption, and footprint [1]. This strategy involves the optimization of photonic-based systems through multiple time-consuming cycles of custom design, fabrication, packaging and testing, leading to solutions that are far from being cost-effective for low and moderate volumes. Only very large volumes benefit from economies of scale, but such applications are not there yet, beyond datacenter interconnects and transceivers [2].

A paradigm shift in PIC design explores the development of multipurpose programmable circuits [3-5]. This aims at designing generic integrated optical hardware configurations which, by suitable programming, can implement a variety of functionalities that can be extended to basic or more complex operations in many application fields, enabling a new generation of field-programmable PICs that will potentially offer cost-effective and ready-to-use programmable solutions.

2. Field-Programmable Photonic Integrated Circuits
A field-programmable PIC integrates a large number of programmable components that can be configured via software. In such PICs, we can find two subcategories: The first one deals with fixed circuit topologies and targets very few applications. They allow a limited degree of reconfiguration by only affecting certain design parameters. The second category comprises of a more versatile approach, enabling both the modification of circuit topology and design settings. A recently proposed architecture is the Field-Programmable Photonic Arrays (FPPA) as illustrated in Figure 1. FPPAs include a subset of components or high-performance building blocks (HPBs) that are often present in different optical processing system architectures for undertaking specific tasks: delay lines, beam-splitters, optical filters, dispersive components, (de)-multiplexers, as well as optical sources, amplifiers and electro-optic modulators and photodetectors, to cite a few. All of them are interconnected to a reconfigurable optical core that enable the (1) smart and flexible routing between the desired components, allowing the user to define their custom circuit scheme and (2) the synthesis of conventional processing blocks constructed using Tunable Basic Processing Units as primitive blocks [4].

This scheme enables the use of a generic hardware for multi-functional processing and applications.

Once designed, the FPPA workflow is detailed in a very recent article, [3]. It starts with the initial application initialisation or circuit configuration together with the main targeted specifications, followed by an area and performance optimization, the technology mapping, and place and route tasks and final evaluation. The steps contained in the generic design flow can be done automatically either by the software layer or, the user, or by a mixture of both, depending on the automation and the capabilities of the FPPA software tier.

Figure 1: (a)Top-Level description of the basic processing units that build up the Field-Programmable Photonic array (b) Implementation and hardware embodiment of the photonic design,
3. Applications

Programmable photonics and FPPAs in particular can find applications in any field requiring optical processing functionalities either in fixed or dynamic conditions, as shown in Figure 2. In this section we list and briefly analyse the potential implementation in different fields:

*Telecommunications and datacentres*: Future communication scenarios and protocols demand a higher degree of flexibility. The FPPAs can be programmed to perform optical interconnects between their optical ports, smart routing of the different channels and software-defined commutation for software-defined networks. In this sector, advanced FPPAs can be employed to a new generation of flexible transceivers and software-defined networks engines.

*Radio-over-fiber and microwave photonics for wireless communications*: FPPAs incorporating electro-optical components can be programmed to perform the interfacing between these two physical domains, provide flexibly in band and functionality [5]. In addition, FPPA architecture allows the potential implementation of multiband / multichannel capability.

*High-performance computing*: a set of integrated beam-splitters can be interconnected to define any linear optical operation [6]. This capability is being employed by state-of-the-art demonstrators. FPPAs can be programmed for these multiport interferometry tasks.

*Sensing*: In this field, several photonic integrated circuits have been proposed for both the direct implementation of sensing functions and as interrogator systems to feed and process the information in the optical domain. The FPPAs can potentially be employed in the last scenario.

4. Conclusions

Here, we have reviewed the main definitions associated with general-purpose, field-programmable photonic integrated circuits. They are proposed as a platform to realize a wide variety of applications that deal with or employ optical signal processing.

Abstract

We report results of laser processing on amorphous silicon and silicon-germanium films deposited on planar substrates. Pre-patterned a-Si waveguides were recrystallized and refocused to enhance their material and optical properties. Formation of millimeter long crystal grains and surface roughness of 0.52 nm enable optical losses to become as low as 5.3 dB/cm. Laser-driven phase separation in the binary alloy of a-SiGe allows fabrication of composition graded microstructures with Si-rich and Ge-rich regions. A composition tuning capability of 40% was demonstrated.

1. Introduction

Polycrystalline semiconductor materials have the potential to exhibit both optical and electronic functionalities that are comparable with single crystal platforms, but with much more flexibility in the fabrication process. However, to obtain good quality of polycrystalline materials, the process temperatures need to be higher than 900 °C [1], rendering them incompatible with CMOS devices. We have developed a laser processing method for the fabrication of low loss p-Si waveguides with a low thermal budget [2].

Another set of material for laser processing is binary semiconductor alloys such as SiGe, which have attracted a growing interest of the photonics industry over the past few years, due to their tunable material, electrical and optical properties. Bandgap and optical properties of Si₁−ₓGeₓ can be modified by changing the material composition through x [3]. Laser inscription of compositional microstructures in crystalline SiGe core silica clad fibres has been recently shown during the local heating of the core by a CO₂ laser [4]. However, spatial control of the phase separation in SiGe alloys for fabrication of photonic devices has yet to be demonstrated on planar substrates.

2. Fabrication

The fabrication process of a-Si films begins with the formation of a 4.6 µm thick thermally grown buried oxide layer on top of the c-Si substrate. A thin film of a-Si with a thickness of 480 nm is then grown using a hot-wire chemical vapor deposition (HWCVD) technique with silane (SiH₄) as the only precursor. HWCVD allows low temperature deposition at 320 °C with low hydrogen concentration. Following the deposition, e-beam lithography and plasma etching were used to pattern a series of straight waveguides with widths of 0.5 µm, 1 µm, 1.5 µm and 2 µm in the a-Si film.

The a-SiGe films were directly fabricated on silicon wafers, which were dipped in buffered hydrofluoric acid (HF) for 3 minutes to remove the native oxide before deposition. Then, 400 nm thick SiGe films were deposited by plasmon enhanced chemical vapour deposition (PECVD) using SiH₄ (5 sccm) and GeH₄ (50 sccm) precursors with an RF power of 15 W at a pressure of 300 mTorr and a temperature of 200 °C. Initial atomic content of Ge is 60%.

3. Laser processing

Laser processing of a-Si and a-SiGe films was carried out with the setup shown in Figure 1. The light source is an Argon ion laser emitting continuous wave (CW) radiation at 488 nm with a maximum power of 350 mW. The setup includes 3D motorized stages capable of programmed movements at speeds ranging from 0.01 mm/s up to 100 mm/s. The power was adjusted using a polarization cube and a half wave plate. The beam was focused on the top surface of the samples using 10x and 20x objective lenses to produce a spot diameter of 4.7 µm and 2.5 µm, respectively. A pellicle beam splitter, a CCD camera and a white light source were used to image the surface of the samples.

Figure 1: Schematic of experimental set-up for laser processing. HWP is half-wave plate.
4. Material and optical characterizations

Micro focus X-ray diffraction (XRD) with a highly collimated beam provided by a synchrotron source was used to assess the presence of crystals in the laser-processed regions and collect information about their length, orientation and lattice constant. The XRD setup was established in a grazing incidence configuration to avoid strong diffraction from the c-Si substrates. In addition, X-ray fluorescence spectroscopy was used to assess the presence of Ge in the p-SiGe tracks. We also performed a set of micro-Raman spectroscopy measurements before and after laser processing. The line width of the Raman peaks were used to optimize power levels and scan speeds. The optical quality of the p-Si waveguides was assessed by measuring the linear propagation losses using the standard cut-back technique.

5. Results and Discussion

5.1. Laser crystallization and reflowing of amorphous silicon waveguides

As a consequence of the complete melting during laser annealing, the a-Si waveguides were reshaped while in liquid state by surface tension that acts on the liquid-air interface. Therefore, the initially rectangular cross section of the a-Si waveguide forms a semi-circular shape, as shown in Figure 2. Here, the SEM micrograph in (a) is an un-processed 2 μm wide a-Si waveguide, whilst the SEM micrograph in (b) is a 2 μm wide p-Si waveguide, which has been laser processed with 200 mW at 0.1 mm/s.

![Figure 2: SEM micrographs shows cross-section of a 2μm wide waveguide before (a) and after (b) laser processing.](image)

Micro-Raman spectroscopy, Secco etching and X-ray diffraction measurements reveal the high crystalline quality of the processed waveguides with the formation of millimeter long crystal grains. Optical losses as low as 5.3 dB/cm have been measured, indicating their suitability for the development of integrated circuits.

5.2. Laser inscription of composition graded polycrystalline silicon-germanium microstructures

Laser assisted melting of SiGe alloys induces phase segregation of Si and Ge atoms producing Si-rich and Ge-rich regions. Our results show that the spatial profile and amount of phase segregation in the Si-Ge thin films can be engineered by controlling the scan speed of the laser. Depending on the scan speed, two different types of spatial redistribution for Ge can be achieved as shown in Figure 3. Speeds below a threshold (5 mm/s) result in Si-rich regions at the centre of the track. However, above the threshold speed, a Ge-rich region is obtained at the centre between two lower index Si-rich lateral regions, which can help to promote optical waveguiding in the Ge-rich core. Moreover, higher Ge content can be obtained by using higher scan speeds. We have control over the size, composition gradient and direction of p-SiGe microstructures written by the laser.

![Figure 3: Optical microscope image shows two polycrystalline tracks inscribed in an amorphous SiGe film on c-Si wafer by a CW Ar+ ion laser at different scan speeds. Inset pictures show speed dependent spatial redistribution of Ge as given by the X-ray fluorescence intensity of Ge.](image)

6. Conclusions

We have demonstrated laser processing of amorphous semiconductors on planar substrates to fabricate low loss p-Si waveguides and composition graded p-SiGe microstructures. A key feature of our technique is the low thermal budget, which makes it compatible with CMOS fabrication processes. Laser processing of semiconductors can pave the way for various photonic and optoelectronic devices to be used in novel integrated platforms.

Microresonator Soliton frequency combs
Tobias J. Kippenberg
EPFL, Switzerland

Optical frequency combs\(^1,2\) provide equidistant markers in the IR, visible and UV and have become a pivotal tool for frequency metrology and are the underlying principle of optical atomic clocks, but are also finding use in other areas, such as broadband spectroscopy or low noise microwave generation. In 2007 a new method to generate optical combs was discovered based on high Q optical microresonators\(^3,4\). Such microresonator frequency combs have since then emerged as a new and widely investigated method with which combs can be generated via parametric frequency conversion of a continuous wave (CW) laser inside a high Q resonator via the Kerr nonlinearity. Over the past years the a detailed understanding of the comb formation process has been gained, and regimes identified in which dissipative temporal solitons (DKS) can be generated, that not only provide low noise optical frequency combs but moreover give access to femtosecond pulses. Such DKS have unlocked the full potential of soliton micro-combs by providing access to fully coherent and broadband combs and soliton broadening effects. Dissipative Kerr solitons have now been generated in a wide variety of resonators, including those compatible with photonic integration based on silicon nitride (Si\(_3\)N\(_4\)). We will discuss the DKS regime, first discovered in crystalline resonators, and our current understanding including the observation of the breather soliton regime, the influence of avoided mode crossings on breather and the repetition rate, as well as methods to deterministically access the single soliton regime. Taken together this has enabled to reliably access single soliton states in photonic chip based resonators, in particular those utilizing the photonic damascene process. Dissipative Kerr solitons enable to obtain combs that can span more than a full octave using soliton induced Cherenkov radiation, which extends the combs bandwidth and power in the spectral wings via dispersive waves. Such DKS have been enabled to count the cycles of light, allow 2f-3f self referencing. Using such soliton Kerr optical frequency combs in a Si\(_3\)N\(_4\) microresonator we have recently demonstrated with the group of C. Koos (KIT) massively parallel coherent communication, with dual combs for both the source and as massively parallel LO for the coherent receiver\(^1\). Moreover, we have demonstrated using a pair of photonic chip based frequency combs dual comb distance measurements, with record acquisition rates due to the combs large mode spacing (100 GHz). Recent work moreover has shown that DKS can be extended to the biological imaging window at 1 micron, relevant for e.g. Raman spectral imaging or OCT. Soliton microcombs have the potential to advance timekeeping, metrology or telecommunication by providing a technology amenable to full photonic integration, low power consumption and large comb bandwidth and repetition rate.

Fano resonances in optics and microwaves: Physics and application
Tunable Fano resonances in the radiative decay rate of a dipole emitter near a graphene-coated nanowire

Abstract

We study radiative transition rates for different orientations of a dipole emitter near a graphene-coated nanowire. We show that Fano resonances appear in the Purcell factor as a function of frequency. Furthermore, the Fano line shape can be tailored and electrically tuned by varying the distance between emitter and cylinder and by modulating the graphene chemical potential. This gate-voltage-tunable Fano resonance leads to a resonant enhancement and suppression of light emission in the far-infrared range of frequencies.

1. Introduction

The modification of the spontaneous-emission rate of a quantum emitter induced by its interaction with environment is generally referred to as the Purcell effect [1]. First described in the context of cavity quantum electrodynamics [2], the Purcell effect finds applications where controlling and manipulating light emission and absorption in subwavelength structures is crucial [3], such as, e.g., high efficiency single-photon sources [4] and microcavity light-emitting devices [5]. Recently, graphene has become a promising alternative material to enhance the Purcell factor in subwavelength structures due to its unique optical properties, such as strong localized surface plasmon resonances with relatively lower losses than noble metals [6]. Furthermore, graphene exhibits strong light-matter interaction in two-dimensional atomically thin layers of carbon atoms [7], and it also offers magnetic, electrical, or chemical tunability of its conductivity from terahertz up to midinfrared frequencies [8].

Here, based on the full-wave Lorenz-Mie theory of circular cylinders, we study the spontaneous-emission rate of a point dipole emitter near a graphene-coated nanowire. By varying the distance between emitter and cylinder, the radiative decay rate associated with the dipole moment oriented orthogonal to the cylinder axis is shown to exhibit a Fano line shape as a function of the emission frequency; conversely, a dipole moment oriented parallel to the cylinder axis exhibits a Lorentzian line shape. The appearance of a Fano line shape is a signature of interference between a localized plasmon resonance at the graphene coating and a broad dipole resonance acting as a radiation background [9, 10]. More importantly, the Fano asymmetry parameter is proportional to the graphene chemical potential. This allows one to control enhancement and suppression of spontaneous emission by a gate voltage. For the interested reader, the explicit analytical connection between Fano resonances in the Lorenz-Mie theory of core-shell scatterers and radiative decay rates of a dipole emitter in the vicinity of a graphene-coated nanofiber can be found in Ref. [1].

2. Discussion and results

Let us consider a pointlike emitter located at position $r'$ in the vicinity of a uniform graphene-coated nanowire in free space, with inner radius $a$ and outer radius $b < r'$. We assume a dielectric core made of a lossless material with permittivity $\varepsilon_d = 3.3\varepsilon_0$ and radius $a = 100$ nm. Since the graphene monolayer is a two-dimensional electromagnetic material and its thickness $(b - a \approx 0.5$ nm) is much smaller than the radius of the dielectric core, we can treat it as a conducting film [11].

To simplify our discussion, let us consider the limiting case $kr' \ll 1$, i.e., the system composed by cylinder and emitter together is diameter-subwavelength, and hence can be described as a dipole-type system. With this assumption, we can simplify the expressions of the radiative decay rates normalized to free space. For each dipole moment orientation in relation to the cylindrical coordinate system $(r, \varphi, z)$, we have after some algebra

$$\Gamma_{\text{rad}}^{r}(r', \omega) \propto \frac{X(\omega) + F_{+}(r')}{[X(\omega)]^{2} + 1},$$

(1a)

$$\Gamma_{\text{rad}}^{\varphi}(r', \omega) \propto \frac{X(\omega) + F_{-}(r')}{[X(\omega)]^{2} + 1},$$

(1b)

where we have defined

$$X(\omega) = \frac{\omega - \omega_{+}}{\gamma/2},$$

$$F_{\pm}(r') \equiv \pm \frac{b^2}{r'^2} \frac{\omega_{\pm} - \omega_{\mp}}{\gamma/2},$$

$$\omega_{\pm} \equiv \sqrt{\frac{\epsilon^2 \mu_{c}}{\pi \hbar^2 b (\varepsilon_d \pm \varepsilon_0)}},$$

with $\omega_{\text{res}} = \omega_{+}$ for the resonance and $\omega_{\text{inv}} = \omega_{-}$ for the antiresonance. The quantities $\mu_{c}$ and $\gamma$ are the graphene chemical potential and the damping rate $(\gamma \ll \omega)$, respectively. Since we are interested in the frequency range where the localized surface plasmon resonance occurs, we can
consider that $\Gamma_{\text{rad}}$ has a Lorentzian line shape as a function of $\omega$: $(\Gamma_{\text{rad}} - \Gamma_0) \propto \Gamma_0 / (X^2 + 1)$. This Lorentzian line shape is related to the fact that $\Gamma_{\text{rad}}$ depends only on the transverse-magnetic mode, see Ref. [1].

The Fano asymmetry parameter given in Eq. (2) depends explicitly on the distance $\Delta r = r' - b$ between emitter and cylinder. More importantly, we see that $F_\pm(r') \propto \sqrt{\mu_c}$, which implies that both enhancement and suppression of the Purcell factor can be tuned by the chemical potential. In practice the graphene chemical potential can be dynamically controlled by an applied static electric field (gate voltage) through the graphene/dielectric interface [8].

Using the analytical expressions derived in Ref. [1], we show in Fig. 1 the plots of radiative decay rates associated with a dipole emitter at $\Delta r = 10$ nm from the graphene-coated nanowire. By increasing the chemical potential from $\mu_c = 0.1$ eV to 1.0 eV, we show that the Fano line shape is blueshifted. At the same time, the maximum enhancement of decay rates increases two orders of magnitude for $\Gamma^\text{rad}_{r}(\lambda_{\text{res}})$ and $\Gamma^\text{rad}_{\varphi}(\lambda_{\text{res}})$ [Figs. 1(a) and 1(b), respectively] and one order of magnitude for $\Gamma^\text{rad}_{z}(\lambda_{\text{res}})$ [Fig. 1(c)].

3. Conclusion

We have shown that the enhancement and suppression of the radiative decay rate of a point dipole emitter near a graphene-coated nanowire can be tuned by the graphene chemical potential monitored by a gate voltage. The Fano asymmetry parameter of radiative decay rates, which determines the degree of asymmetry of the Fano line shape, is shown to be proportional to the square root of the chemical potential and depends strongly on the distance between dipole emitter and cylinder for a dipole moment oriented along $\varphi$ direction. For a dipole moment oriented along $z$ direction, the interaction between dipole emitter and graphene is weak, leading to a Lorentzian line shape in the radiative decay rate. The strong dependence of decay rates on the graphene chemical potential can be explored to enhance or suppress the radiative decay response of a plasmonic system by dynamically controlling the Fano resonance via a gate voltage.

Abstract

Directionality properties of subwavelength High Refractive Index Dielectric particles make them good candidates for controlling the direction of the scattered radiation. Here, we show experimentally, in the microwave range, that a dimer unit made of such materials can optimize the performance of solar cells by redirecting the incident radiation to the photosensitive layer. In addition, we demonstrate its utility for building operational switching devices.

1. Introduction

Metallic particles smaller than the incident wavelength have been vastly analyzed for many different applications, like Surface Enhanced Spectroscopies (SERS or equivalent techniques), biosensing, solar energy harvesting, etc [1]. However, their inherent ohmic losses limit their performance. High Refractive Index Dielectric (HRID) particles, like silicon, germanium or other semiconductor compounds [2] in the NIR, have been proposed as an alternative to solve this issue. Their most important advantages come from their low-losses and their magnetic response in spite of being non-magnetic materials [3]. Also, the coherent effects between electric and magnetic spectral resonances give rise to directionality properties. Kerker et al. established that for a point-like particle and under certain conditions of its electric permittivity and magnetic permeability, incident radiation can be concentrated in the forward (backward) direction, being null (almost null) in the exact backward (forward) one [4,5]. This situation corresponds to the Zero-Backward (near Zero-Forward) or First Kerker condition (Second Kerker condition). In this work, we show that by means of a dimer of HRID particles and controlling the distance between them, it is possible to observe in the dipolar regime, two spectral regions where the incident radiation is mainly scattered in the forward direction. These ranges correspond to the Zero-Backward condition (also observed for either isolated particle or a particle cluster, when there is no electromagnetic interaction between its components) and to a new “near Zero-Backward” condition (originated by the interaction effects between the particles) [6]. This fact finds its major application for optimizing the performance of solar cells. For eccentric metallo-dielectric core-shell particles [7] and asymmetric dimers [8], the incident radiation can be redirected to certain directions respect to forward or backward. This effect can be used for building switching devices. Here, we analyze this by means of a symmetric homogeneous dimer of HRID spherical particles [9]. We demonstrate that the scattered intensity at 90° from the incident direction can be null or maximum by playing with the polarization of a single frequency excitation and with a dimer whose components are close enough to interact in a controlled way.

2. Results

2.1. Directionality properties

For a HRID dimer of spherical particles, it is possible to find, in the dipolar regime, two spectral regions where the incident radiation is scattered in forward. They correspond to the Zero-Backward condition and to a new “near Zero-Forward” condition. The interaction effects between the particles are responsible for the last one, which is a 180° “rotated” version of the near Zero-Forward condition. In particular, a Fano-like resonance (originated by the interference between both the sharp magnetic and the broad electric dipolar modes) gives rise to this new Scattering Directionality Condition (SDC).

Figure 1: Scattering diagrams in the scattering plane at the near Zero-Forward (NZF) condition for a HRID dimer. The radii of the particles are \( R_1 = R_2 = 9 \) mm and their dielectric permittivity is \( \varepsilon_1 = \varepsilon_2 = 15.7 + 0.3 \). The distance between both components of the dimer is \( d = 3 \) mm \( (d_0 = 1/3) \). (a-b) Longitudinal configuration. (c-d) Transverse configuration. The theoretical and experimental results are shown in left and right columns, respectively. The black arrow represents the
direction of the impinging radiation ($k$). The orange cylinders indicate the detectors positions. BWD stands for Backward Direction and FWD stands for Forward Direction.

In Fig. 1, we show the scattering diagrams at the frequencies where the near Zero-Forward condition holds for $d_0 = 1/3$ and both polarizations of the incident radiation (longitudinal ($I_{LP}$, polarization along the axis dimer) and transverse ($I_{LT}$, polarization perpendicular to the axis dimer) configurations). $d_0$ is a parameter, which takes into account the interaction effects between the particles, defined as $d_0 = d/R$, being $d$ the distance between both components of the dimer (gap) and $R$ their radius.

2.2. Switching effect

The switching effect is produced by the spectral evolution of one of the natural resonances (the dipolar magnetic) of the isolated particle to an asymmetric shape resonance (Fano-like) as the particle interaction increases. This behavior can be observed in Fig. 2, where we show the spectral evolution of the scattered intensity at 90° for longitudinal and transverse polarizations of the incident radiation. We also plot the behavior of the linear polarization degree at 90°, $P_L(90°)$ [5]. The analysis is carried out for two different distances between the particles $d_0 = 2$ (weak interaction effects between the particles) and $d_0 = 1/3$ (strong interaction effects).

In this work, we have evidenced different applications of a dimer of HRID spherical particles. In particular, we have analyzed the utility of these structures for optimizing the performance of actual photovoltaic cells. With a HRID dimer unit, it is possible to find two spectral ranges in the dipolar region, where the incident radiation is forward scattered. They correspond to the Zero-Backward condition and to a new “near Zero-Backward” condition, which is a “rotated” version of the traditional near Zero-Forward condition. We have also shown the possibility of using this scattering unit as a new block for building operational switching devices whose on/off state only depends on the polarization of the incident radiation. Both applications are a consequence of the excitation of Fano-like resonances due to electromagnetic interaction between the particles.

Trapped light states in spatially dispersive plasmonic nanostructures

Abstract

It was shown some time ago that open bi-layered plasmonic nanostructures may support trapped light states with infinite lifetimes. Counterintuitively, here we prove that spatially dispersive effects may relax the material and geometrical conditions required for the formation of embedded eigenstates in plasmonic systems.

1. Introduction

In the last years, several research groups have shown that it may be possible to have optical bound states with infinite oscillation lifetimes within the radiation continuum (embedded eigenstates) in open unbounded structures (see review [1] and references therein). However, a complete suppression of the radiation loss is typically only possible when the material structures are infinitely extended in space. In contrast, in a recent work [2], we demonstrated that the embedded eigenstates can as well be formed in compact three-dimensional (3D) nanostructures, e.g., a core-shell nanoparticle made of a dielectric core and an epsilon-near-zero (ENZ) shell [2]. Our proposal was also explored by other groups [3-4].

In [2-6] the plasmonic ENZ shell was assumed to have a local electromagnetic response, i.e., the permittivity is only frequency-dispersive and has no wave-vector dependence. However, it is known that the nonlocal effects may affect considerably the response of nanosized plasmonic particles [7]. In particular, one may heuristically expect that charge diffusion may create additional difficulties to the formation of embedded eigenstates. Surprisingly, here we prove that it is precisely the opposite, and that the spatial dispersion effects in the plasmonic shell offer new opportunities to trap light in open resonators.

2. Spatially dispersive meta-atom

Figure 1(a) depicts the meta-atom geometry: a bi-layered sphere embedded in air. The internal layer (core region) and the outer layer (shell) have respectively radii \( R_1 \) and \( R_2 \). The core material (e.g. air) has a standard dielectric response characterized by the relative permittivity \( \varepsilon_r \). The shell is made of a material with plasmonic response. To account for the nonlocal effects in the plasmonic shell, we use the hydrodynamic (drift-diffusion) model [7]. A spatially-dispersive plasma supports three plane-wave natural modes with a spatial dependence of the type \( e^{ikr} \): two transverse modes and also a longitudinal mode [7]. The transverse modes see a relative permittivity described by a standard Drude-type model \( \varepsilon_{r,1}(\omega) = \varepsilon_r - \omega_p^2 / \left[ \omega(\omega + 2i\omega_\sigma) \right] \), where \( \omega_p \) is the plasma frequency, \( \omega_\sigma \) is the collision frequency, and \( \varepsilon_r \) is the high-frequency relative permittivity (we take \( \varepsilon_r = 1 \)). On the other hand, the longitudinal mode sees a permittivity which is frequency and wave-vector dependent, described by \( \varepsilon_{r,2}(k,\omega) = \varepsilon_r - \omega_p^2 / \left[ \omega(\omega + 2i\omega_\sigma) - \beta^2 k^2 \right] \) [7], where \( \beta^2 = 3/5\varepsilon_r \omega_p^2 \) and \( \omega_\sigma \) is the Fermi velocity. Since the nanoparticle has spherical geometry (Fig. 1(a)), we can write the electromagnetic fields in all the regions of space in terms of spherical Bessel functions. In particular, we prove that the spatial dispersion effects in the plasmonic shell offer new opportunities to trap light in open resonators.

![Figure 1](image-url)

**Figure 1:** (a) Geometry of the open bi-layered spherical meta-atom. The shell is made of a plasmonic spatially dispersive material while the core material is a standard dielectric. (b) Embedded eigenstate frequency (solid red line) and optimal core radius (dashed orange line) as a function of the frequency. (c) Mie coefficient \( |a_{\text{TM}}| \) in the core region as a function of the normalized frequency \( \omega/\omega_p \) and for different values of the internal radius. The meta-atom parameters are \( \omega_p = 3 10^7 \), \( R_2 / R_{\text{opt}} = 1.1 \), \( \varepsilon_r = 1 \), and \( \omega_\sigma = 0 \).
classical boundary conditions at the interfaces. Due to the additional longitudinal mode, it is also necessary to ensure that the normal component of the electric conduction current vanishes at the interfaces of the spatially dispersive plasma [2, 7]. This procedure yields a 6×6 homogeneous linear system of the form \( M \cdot \mathbf{x} = \mathbf{0} \). The frequencies of oscillation \( \omega = \omega' + i\omega'' \ (\omega'' \leq 0) \) of the natural modes of oscillation are calculated by solving a characteristic equation \( D(\omega, R, \varepsilon_1, \varepsilon_2, \omega_p, \beta) = \det(M) = 0 \), with \( D = D' + iD'' \) complex-valued.

3. **Properties of the embedded eigenstates**

In the local limit (\( \beta = 0 \)), the embedded eigenstates can be formed only when the shell has \( \varepsilon_2 = 0 \), i.e. when \( \omega = \omega_p \) [2]. In this case, the TM waves see the ENZ shell as a PMC wall. Thus, the embedded eigenstates can emerge if and only if \( \omega = \omega_p \) coincides with one of the eigenfrequencies of the equivalent PMC cavity. The geometrical condition for the formation of an embedded eigenstate with dipolar-type symmetry (see inset of Fig. 1(b)) is

\[
R_i = R_{i,0} = 4.49\frac{\varepsilon_0}{\sqrt{\varepsilon_i}} \tag{2}
\]

In contrast, in the nonlocal case (\( \beta \neq 0 \)), the condition \( \omega = \omega_p \) does not lead to the formation of eigenstates. Remarkably, we find that the pair of equations \( D' = 0 \) and \( D'' = 0 \) always have a real-valued solution in frequency. The solution \( \omega_{\text{exp}} \) (oscillation frequency) and \( R_{i,\text{exp}} \) (optimal core radius) is associated with an embedded eigenstate characterized by the parameters \( (\varepsilon_1, R_i, \omega_p, \beta) \). The obtained results are depicted in Fig. 1(b) as a function of \( \varepsilon_1/\beta \). The results show that for small values of \( \varepsilon_1/\beta \) (i.e. for strong nonlocal effects), \( \omega_{\text{exp}} \) can be significantly different from \( \omega_p \). This means that the eigenstates may be formed for frequencies \( \omega \neq \omega_p \), for which the shell permittivity can significantly differ from zero (\( \varepsilon_1, \varepsilon_2 \neq 0 \)). Thus, nonlocal effects clearly relax the formation of the eigenstates by avoiding the need of a singular material response. Furthermore, the optimal core radius \( R_{i,\text{exp}} \) may differ considerably from the local value \( R_{i,0} \) for strongly nonlocal responses, relaxing thereby also the geometrical condition.

4. **Meta-atom response under external excitation**

Suppose now that the meta-atom is excited by a linearly polarized plane wave. The Mie coefficients that determine the fields scattered by the bi-layered nanoparticle can be calculated by solving the system of equations \( M \cdot \mathbf{x} = \mathbf{b} \), with \( \mathbf{b} \) a vector determined by the incident wave. In Fig. 1(c) we depict the variation of the first (electric-dipole) Mie coefficient in the core region \( \beta_{M}^{TM} \) with frequency for three different values of the core radius \( R_i \). The results show that for values of \( R_i \) different from the optimal \( R_{i,\text{exp}} \), the Mie coefficient has a strong resonant behavior with a Fano-type line shape. On the other hand, when \( R_i \) is exactly coincident with \( R_{i,\text{exp}} \), there is no resonance and \( \beta_{M}^{TM} = 1 \) due to a pole-zero cancellation [2]. This behavior is fully consistent with the emergence of an embedded eigenstate in the meta-atom.

5. **Conclusions**

We theoretically demonstrated that open core-shell meta-atoms may support embedded eigenstates even if diffusion effects in the plasmonic shell are fully considered. Surprisingly, the diffusion effects relax the conditions required to suppress the radiation loss, as it is no longer necessary that the permittivity of the shell vanishes as in the local case. At the conference, we will show that the same material shell can potentially trap light for multiple frequencies.

Silent enhancement of SERS signal without increasing the hot spot intensity

Mehmet Emre Tasgin

Abstract

Nanostructures enhance nonlinear response, such as surface enhanced Raman scattering (SERS), by localizing the incident field into hot spots. The localized hot spot field can be enhanced even further when linear Fano resonances (FR) take place in a double resonance scheme. On the other hand, hot spot enhancement is limited with the break-down of the molecule and the tunnelling regime. We present a method which can circumvent these limitations. Our analytical model and solutions of 3D Maxwell equations show that: enhancement due to the localization can be further multiplied by a factor of 3 orders of magnitude. Moreover, this can be performed without increasing the hot spot intensities which also avoids the modification of the Raman modes. Unlike linear Fano resonances, we create the path interference in the nonlinear response. We demonstrate on a single equation that enhancement takes place due to the cancellation in the denominator of the SERS response [1].

1. Introduction

Metal nanostructures (MNSs) can localize incident radiation in nm-size hot spots. The trapped field, as plasmon polarization, can be enhanced several orders of magnitude compared to the incident one. This yields an enhancement also in the nonlinear effects, such as surface enhanced Raman scattering (SERS) or second harmonic generation. SERS phenomenon has imaging applications in all fields of science, from chemistry to tumor targeting. This is because, SERS spectrum is material specific and can be used in identification.

There are quite recent, interesting, studies on the further enhancement of SERS. (i) A double resonance scheme, where exciting and the Raman-converted frequencies are aligned with two plasmon resonances, is shown to enhance [2] several orders of magnitude more. This is because, both the input and output hot spots localize the two fields resonantly. (ii) More recent studies cleverly combined this phenomenon with linear Fano resonances. It is well-known that Fano resonances enhance the localized field more, called as dark-hot resonances. Researchers showed that when the input and output frequencies are aligned with two linear Fano resonances in a double resonance scheme, i.e. double Fano resonance scheme, SERS signal can be enhanced even further on top of the double resonance scheme [3].

These two developments carried the SERS imaging at a new stage. Both methods, (i) and (ii), rely on the enhancement of the localized hot spot field more. On the other hand, it is experimented that strong hot spot fields can (a) modify the Raman modes of the samples, (b) burn the sample. Moreover, (c) tunneling regime in the nanogaps can avoid the further enhancement of the hot spot fields.

2. Summary

In this work [1], we present a method which can increase the SERS signal 3 order of magnitude, but can leave the hot spot intensities unchanged. That is, our method multiplies the SERS signal in a double resonance scheme by 3 orders, without heating the sample! In spite of the linear Fano resonances, we adopt the Fano resonances in the nonlinear response. Path interference takes place in the nonlinear response. On a single equation, Eq. (1), we show that this enhancement takes place due to the cancellation in the denominator of the SERS response, \( \alpha_R \), without affecting the linear response, \( \alpha \).

\[
\tilde{\alpha}_R = \frac{\beta_{ph}^*}{\beta_{ph}} \left( i \left( \Omega_R - \omega_R \right) \right) - |\beta_{ph}|^2 \left( \left( \Omega_R - \omega_R \right) \right) - |\beta_{ph}|^2 \left( \left( \Omega_R - \omega_R \right) \right) \left( \left( \Omega_R - \omega_R \right) \right)
\]

\[\omega_{eg} = \omega_R + \frac{|f|^2 y}{2(\Omega_R - \omega_R)} - \sqrt{\frac{|f|^4 |y|^2}{4(\Omega_R - \omega_R)^2} - \gamma_{eg}^2}.\]

An auxiliary quantum emitter (QE) or a MNS supporting a long-live dark plasmon mode is coupled to a metal nanoparticle (MNP)-dimer, see Fig. 1. Auxiliary QE couples only to the plasmon mode of the MNP-dimer. The choice of the level spacing for this auxiliary QE affects the SERS signal dramatically, when one chooses the level spacing \( \omega_{eg} \) as in Eq. (2), the extra term cancels the nonresonant term in the denominator of Eq. (1). We also perform 3D simulations with the exact solutions of the Maxwell equations. We observe that the enhancement, predicted by the basic model, Eq. (1), is present in Fig. 2.

Raman Active Molecule
Auxiliary QE
λL=593 nm λR=700 nm

Figure 1: Figure is from Ref. [1]. (a) The setup we use in the 3D solutions of Maxwell equations. A gold MNP dimer, of radii 90 nm and 55 nm, creates a hot spot in the 4 nm gap. A Raman-active sphere of 4 nm radius (blue) is placed close to the dimer hot spot for producing the SERS signal. We place an auxiliary QE (purple) also in the vicinity of the dimer, for enhanced interaction with the $\hat{a}_R$ plasmon mode. We move it along the z-direction when we desire to decrease the plasmon-auxiliary QE coupling, $f$. (b) Linear response of the dimer shows two plasmon peaks at $\lambda_L=530$ nm and $\lambda_R=780$ nm. System is excited by a $\lambda_L=593$ nm laser and a Stokes shifted signal emerges at $\lambda_R=700$ nm. $\lambda_L$ and $\lambda_R$ overlap with $\Lambda$ and $\Lambda_R$, respectively. The $\lambda_{eg}$ of the molecule is chosen to couple with the $\hat{a}_R$-mode, see Fig. 2a. We use parameters similar to (b) in producing an accompanying simulation within our simple model. Experimental data of gold (dimer) and a Lorentzian dielectric function (auxiliary QE), in MNPBEM [4], are used for the 3D simulations.

Figure 2: Figure is from Ref. [1]. Enhancement of the SERS signal with the presence of the auxiliary QE (purple) in Fig. 1. We plot the EFs with respect to the level spacing ($\lambda_{eg} = c/\omega_{eg}$) of the auxiliary QE interacting with the $\hat{a}_R$ plasmon mode, (Fig. 1b). Interaction of the auxiliary QE decreases with larger separations (z) to the hot spot. (a) Solutions of the 3D Maxwell equations for the system depicted in Fig. 1. EFs for SERS are calculated for three different positions of the auxiliary QE, $z=0.53, 0.55$ and $0.57$ nm. The position of optimum $\lambda_{eg}^* = c/\omega_{eg}^*$, where maximum EF appears, shifts to larger wavelengths. Optimum $\lambda_{eg}^* \approx 834$ nm, is far away from the Stokes signal (700 nm). An enhancement due to a linear FR would yield maximum enhancement at $\lambda_{eg} \approx 700$ nm. Enhancement originates from the interference in the conversion paths as predicted by Eqs.(1)-(2). Intensities of both hot spots are unchanged. (b) Simulation of the EF using our simple model with the parameters similar to Fig. 1b. Simulations are for the presence of an auxiliary QE. We observe the similar behavior in the position of optimum $\lambda_{eg}^*$, even though several complications involve in 3D simulations (a).

Abstract

We study coupled-wave model describing optical properties of diffraction gratings and rectangular ridges located on a slab waveguide. The proposed model enables obtaining simple and accurate formulas for the complex transmission and reflection coefficients of the considered structures. By analyzing these expressions, we analytically show that these structures support bound states in the continuum (BICs). We obtain simple closed-form expressions describing the positions (frequencies and wave numbers) of the BICs emerging in the considered structures.

1. Introduction

In recent years, investigation of the bound states in the continuum (BICs) has attracted considerable attention in photonics (see the review paper [1] and references therein). The BICs are eigenmodes that have an infinite lifetime though the structure supporting them has open scattering channels. The leakage into these channels is canceled either due to symmetry reasons or by means of parameter tuning [1]. Small deviation from the BIC condition makes it possible to obtain resonators with arbitrarily high quality factors. This makes the BICs promising for practical applications in laser, sensing, and filtering [1].

In the present work, we study theoretically and numerically the formation of BICs in very simple photonic structures consisting of either a single dielectric ridge or diffraction gratings located on a dielectric slab waveguide [2]. We show that such structures support high-Q resonances and bound states in the continuum. We present simple coupled-wave model that rigorously proves the existence of the BICs and predicts their spectral and angular locations. According to the derived models, the BIC formation is associated with the coupling between the different eigenmodes of the considered structures.

2. Ridge on a slab waveguide

Let us consider a rectangular ridge located on a slab waveguide [see Fig. 1(a)]. We will consider diffraction of the fundamental TE-polarized guided mode obliquely incident on the ridge. One can choose the angle of incidence in such a way that the out-of-plane scattering is completely suppressed [2]. In this case, the considered structure has only two scattering channels corresponding to the reflected and transmitted slab waveguide modes.

The ridge region [see Fig. 1(a)] can be considered as a segment of a slab waveguide having a greater thickness, thus supporting different guided modes. We will consider the case when the “thicker” waveguide supports only fundamental TE and TM modes with effective refractive indices $n_{TE}$ and $n_{TM}$. In this case, the considered structure exhibits pronounced resonant properties.

Figure 1(c) shows the reflectance of a TE-polarized mode upon diffraction by a ridge vs. the angle of incidence $\theta$ and the ridge width $w$. The spectrum, which was calculated using the aperiodic Fourier modal method, exhibits several resonant lines with their width narrowing to zero at several points. This suggests the presence of the BICs in the considered structure. Figure 1(d) showing the quality factor of the resonance vs. the ridge width $w$ proves the existence of the BICs [2, 3].

3. Coupled-wave model

To describe resonant optical properties of the considered structure, we developed the following coupled-wave model.

Let the incident wave have unit amplitude. We denote the unknown reflected mode amplitude by $R$. Inside the ridge, we consider a TE mode propagating to the right (amplitude $U_1$), a TE mode $U_2$ propagating to the left, and, similarly, two TM modes: $V_1$ and $V_2$.

The considered modes are coupled at the edges of the ridge. By equating the complex amplitudes of the modes at the edges of the ridge, we obtain the coupled-wave model of the considered structure:

\[
\begin{align*}
U_1 &= e^{i\phi} (r_1 U_2 + r_c V_2 + t) ,
V_1 &= e^{i\psi} (r_c U_2 + r_2 V_2 + t_c) ,
U_2 &= e^{i\phi} (r_1 U_1 + r_c V_1) ,
V_2 &= e^{i\psi} (r_2 U_1 + r_c V_1) ,
R &= t U_2 + t_c V_2 + r .
\end{align*}
\]

Here, $r$ and $t$ are the reflection and transmission coefficients of the incident TE mode; $r_1$ and $r_2$ denote the reflection coefficients of the $U$ and $V$ modes; $r_c$ and $t_c$ are the cross-polarization reflection and transmission coefficients. The
exponents describe the phase change of TE and TM modes acquired upon propagation between the edges of the ridge. By eliminating $U_1$, $U_2$, $V_1$, and $V_2$ from the system (1), we can represent the reflection coefficient $R$ in the form of a fraction. This fraction provides a good approximation of the reflection spectrum of the structure [Fig. 1(c)]. The BICs appear when both the numerator and denominator of this fraction vanish [2]. One can show that this happens when $\phi$ and $\psi$ take the form

$$\phi = \pi m + \arg \frac{t_c}{r_c t - r_t t_c}, \quad \psi = \pi l + \arg \frac{t}{r_c t_c - r_2 t},$$

(2)

where $m$ and $l$ are positive integers.

Having calculated the phases, one can obtain closed-form expressions for the ridge width $w$ and angle of incidence $\theta$ providing the BIC:

$$w = \frac{1}{k_0} \sqrt{\frac{\phi^2 - \psi^2}{n_{TE}^2 - n_{TM}^2}}, \quad \sin \theta = \sqrt{\frac{\phi^2 n_{TM}^2 - \psi^2 n_{TE}^2}{(\phi^2 - \psi^2)n_1^2}},$$

(3)

where $n_1$ is the effective refractive index of the incident mode, and $k_0 = \omega/c$ is the free-space wave number. The BIC positions predicted using these equations are shown with white circles in Fig. 1(c). The predicted positions are in perfect agreement with the presented simulation results. Let us note that similar equations for $\omega$ and $k_0$, providing the BIC positions for a fixed ridge width $w$ can also be obtained.

4. Grating on a slab waveguide

Let us now consider a different structure: a pair of gratings separated by a slab waveguide [see Fig. 1(b)]. We consider the diffraction of a plane wave on this structure, being interested in the amplitudes of the 0-th reflected and transmitted diffraction orders. The grating is assumed subwavelength, so that all other diffraction orders are evanescent.

In the case of oblique incidence of light one can choose the wavelength and angle of incidence in such a way that inside the slab the $-1$-st diffraction order is evanescent, whereas the $+1$-st and the 0-th diffraction orders are propagating. In this case, the model presented in the previous section can be utilized with the difference that instead of the TE and TM modes, the Fabry-Perot and the quasi-guided mode of the slab are considered. Therefore, equations similar to Eqs. (1)–(3) can be used to describe the reflection and transmission coefficients. The closed-form BIC conditions can also be derived.

5. Conclusions

We have shown that a simple couple wave model can be used to describe and predict the BICs in simple photonic structures, including a ridge on a slab waveguide and guided-mode resonant gratings. Similar models can be developed for diffraction gratings and integrated diffractive structures having different symmetries and geometries.

Abstract

We report the passive and active approaches to manipulate the properties of Fano resonances in metasurfaces. By passively tailoring the height of one arm during fabrication, double Rabi splitting caused by strong coupling of triple Fano resonances are observed in the unique 3D folded metallic resonators. Besides, by introducing the non-volatile chalcogenide phase-change material, the Fano resonances of can be actively controlled. These resonance properties are preservable, and have promising prospects in sensors, switches and modulators.

1. Introduction

Fano resonance is a common resonant scattering phenomenon of metasurfaces[1]. It can be generated in the interference between near fields of building blocks with different resonant modes. By manipulating the coupling of these modes, the properties of Fano resonances can be controlled consequently. In general, tailoring the geometrical parameters in the process of fabrication is the passive control of resonances[2], and the electromagnetic properties are fixed after fabrication. However, most of works in passive method are focus on the tuning the properties of individual resonance and neglect the control of interaction in multiple resonances. Another method is active manipulation. By introducing the functional materials, such as semiconductor, graphene and liquid crystal, the dynamic control of resonances can be achieved. However, these materials are volatile, which means once the stimulus are removed the resonance properties will return to their initial state. Here we develop the methods of passive and non-volatile active controls of Fano resonances by varying the geometric parameters in the process of fabrication and introducing the phase-change material in nano-resonators.

2. Passive control

First, we use the unique 3D folding process to tailor the geometric parameter of nano-resonators[3], achieving the passive control of the interaction in multiple Fano resonances[4]. By only varying the height of one arm of asymmetric split-ring resonators (SRRs), the resonance wavelength of one of three Fano resonances moves to and strongly interacts with the others. This interaction satisfies the strong coupling criterion, and two Rabi splittings are observed from it.

3. Non-volatile active control

Secondly, for the case of active control method, we introduce Ge2Sb2Te5 (GST) as the non-volatile functional material[5] in nano-resonators. The Fano resonances are designed at optical communication wavelength, and we modulate the properties of them simply by heating. The GST has distinct permittivity in different phase states, by which the resonance properties, such as resonance wavelength and amplitude, of resonators are controlled precisely. And the modulated properties are preservable even when the stimulus are removed. Such repeatable dynamic metasurfaces are highly promising for the applications, such as active switches and modulators.

4. Conclusion

The properties of Fano resonances in nano-resonators can be manipulated by tailoring their near field interaction passively or actively. By passive control, we demonstrate the strong coupling between multiple Fano resonances. And by introducing GST into the resonator units, the active and non-volatile active control on Fano resonances are implemented.

Interference of Multipolar Lattice Resonances in Plasmonic Crystal Excited by Structured Light

Keiji Sasaki*, Hiroki Kitajima, and Kyosuke Sakai

Research Institute for Electronic Science, Hokkaido University, Sapporo, Japan
*corresponding author, E-mail: sasaki@es.hokudai.ac.jp

Abstract

We report interference of dipolar, quadrupolar, and higher-order multipole lattice resonances in plasmonic crystal structures. We theoretically demonstrate that such bright-and dark-mode lattice resonances in finite-sized, square-lattice arrays of metal nanodisks can be excited by both vertically-incident, linearly-polarized Gaussian beam and cylindrical vector beam having orbital angular momentum. The simulation result shows that spatial distributions of the lattice resonances in the plasmonic crystal exhibit characteristic patterns with the chirality that conserve the chirality of the incident light and the excited plasmonic fields of individual nanodisks.

1. Introduction

Plasmon damping and losses limit the enhancement of the localized plasmonic field and thus represent one of the main barriers to the evolution of plasmonics into a prominent technology. It should be possible to reduce damping by controlling the material properties, whereas radiative losses can be managed by the following two approaches. The first approach is to exploit the dark modes of the localized plasmon. We have recently reported a method of exciting dark-mode multipole plasmons by using vortex beams with specific angular momentum [1-3]. The second approach to managing radiative losses is to take advantage of the lattice resonances in periodic metal nanoparticles, i.e., plasmonic crystals, in which collective resonances are mediated by the diffractive coupling of localized plasmons. In this presentation, we report a combination of the two above approaches applied to the management of radiative losses, taking advantage of multipolar dark lattice resonances, which can be excited from free space. We theoretically demonstrate that the quadrupole lattice resonances in square lattice plasmonic crystals composed of nanodisks can be excited both by vertically incident cylindrical vector (CV) beam and by a linearly polarized Gaussian beam. The spatial distributions of the lattice resonances in the plasmonic crystal exhibit characteristic patterns where the chirality of the spatial patterns conserve the chirality of the incident structured light and the excited plasmonic fields in the individual nanodisks.

2. Results and discussion

Figure 1 shows the model used in our calculations. For simplicity, we consider a square lattice plasmonic crystal in a homogeneous background with a refractive index of \( n = 1.0 \). The structure consists of 9 x 9 array of gold nanodisks with diameter of 400 nm and thickness of 30 nm, which yields localized plasmon peaks at approximately 800 nm. The lattice period \( \text{L} = 700 \text{~nm} \) is set such that normally incident light along the z direction is diffracted in the x or y directions (first-order grating) at wavelength of \( \approx 800 \text{~nm} \). A CV beam shown in the inset of Fig. 1 and a linearly polarized Gaussian beam were chosen to excite different lattice resonances. The polarization of the CV beam is linear at all points, although the direction of the electric field vector depends on the spatial position.

Figure 1. Square-lattice plasmonic crystal consisting of 9 x 9 gold nanodisks. The inset shows the cross-section of incident cylindrical vector beam. The arrows indicate the electric field vectors.

When the CV beam is used as the excitation beam (Fig. 2(a)), the near-field electric field intensity spectrum integrated over the x-y plane exhibits two clear peaks, as shown in Fig. 2(g): a narrow peak at 805 nm (quadrupole mode) and a broad peak at 1040 nm (dipole mode). The full width at half maximum (FWHM) of the quadrupole resonance is \( \approx 30 \text{~nm} \), which is much narrower than the FWHM of \( \approx 80 \text{~nm} \) for a single isolated nanodisk. This result indicates that the lattice resonance decreases the radiative...
loss even in a finite crystal with a 9 x 9 nanodisk array. The peak intensity reaches a very large value of more than 5 x 10^4. Figure 2(c) shows the near-field distribution at 805 nm, in which the single-lobed envelope function peaks at the center, even though the incident beam has a ring-shaped intensity profile. In contrast, the near-field distribution at 1040 nm shown in Fig. 2(e) exhibits a ring-shaped envelope function corresponding to a higher-order mode, with a dipole-like intensity profile on each nanodisk. The axis of the dipole on each disk is parallel to the electric field vector of the incident beam, as shown in Fig. 2(a). An inset of Fig. 2(g) shows a detailed view of the electric field profile around the central nanodisk of Fig. 2(c), thus indicating that this 805 nm lattice resonance corresponds to quadrupole mode.

The quadrupole lattice resonance is excited even using a Gaussian incident beam (Fig. 2(b)). Figure 2(h) shows the corresponding integrated intensity spectrum, in which there are two clear peaks: a narrow quadrupole peak at 805 nm and a broad dipole peak at 1040 nm. The near-field distribution at 805 nm in Fig. 2(d) shows a double-lobed higher-order envelope function along the x axis with a quadrupole profile around the nanodisks. Although it is not apparent from the figure, the phases of the left and right-hand parts are π shifted with respect to each other. As a result, the quadrupole mode is cancelled out, and only a small dipole mode can be observed in the central column. The detailed field distribution around the nanodisk indicated by the white square corresponds to quadrupole mode, as shown in the inset of Fig. 2(h). At 1040 nm, the near-field distribution exhibits dipole lattice resonances with a single-lobed fundamental envelope function, as shown in Fig. 2(f).

3. Conclusions

We showed that the quadrupole lattice resonances in a square lattice, finite-sized plasmonic crystal can be excited by vertically incident light beams. Both cylindrical vector beams and a Gaussian beam can excite dipole and quadrupole lattice resonances with broad and sharp peaks, respectively. In addition, there are considerable differences in the envelope distribution functions of the dipole and quadrupole lattice resonance fields. These results indicate that the two modes overlap and interfere with each other in space and frequency. The combination of the dark mode and lattice resonance leads to lower radiative losses than dipole localized surface plasmon resonances. Our scheme allows for the exploitation of low radiative loss plasmon resonances with many hot spots by using an incident beam from free space. This finding may pave the way for novel light-matter interactions that require a narrow spectral line width or wide field distributions.

Abstract

We propose an ultra-thin silicon metasurface supporting a high-quality quasi-bound-state-in-the-continuum (BIC) generated by the collective magnetic dipole (MD) resonance excited in the subdiffractive periodic systems. Such quasi-BIC MD state leads to a robust near-field enhancement and a significant boost of the nonlinear process, resulting in measured 500-fold enhancement of third-harmonic emission in comparison to the conventional silicon disk metasurface. We further demonstrate the highly-efficient dynamical switching experimentally over nonlinear images via polarisation and wavelength control, opening the way for various applications in highly-efficient nonlinear metadevices including tunable laser, tunable displays, nonlinear imaging.

1. Introduction

Nonlinear nanophotonics, aiming for the efficient generation and control of nonlinear properties of light in the nanoscale structures, is a rapidly developing research field benefiting applications such as chip-based light sources, nanolasers, optoelectronic devices, imaging, etc. High-index dielectric nanostructures have emerged as a promising tool to boost the nonlinear processes through efficient nanoscale light manipulation based on the control over both optically-induced electric and magnetic Mie-type resonances [1, 2], offering great potential for future on-chip applications in the nonlinear regime [3, 4]. MD resonance supported by dielectric nanostructures has been widely used to enhance the nonlinear frequency conversion due to the associated strong near-field enhancement and large mode volume. BICs, being originally predicted by von Neumann and Wigner in 1929 [5], have been extensively studied in different fields of wave physics including acoustics, microwaves and nanophotonics [6]. An ideal BIC manifests as itself via diverging Q-factor with complete suppression of the radiation of the state to the free space. By breaking the symmetry of the system which supports a symmetry-protected BIC, one can transform an ideal BIC to a quasi-BIC with finite Q-factor. It allows obtaining an energy exchange with the external modes and manifests itself as a sharp Fano resonance in the optical response spectrum [6]. Through the mechanism of BIC, one can merely control and tune the radiation damping rate and thus the width of the resonance. BIC-inspired mechanism provides a useful tool to engineer and tailor the line width and Q-factor flexibly and allows directly excite the quasi-BICs by free propagation plane waves, making it a novel platform for nanophotonics applications.

Here, by taking the advantages of both Mie resonators and BIC states, we design ultra-thin resonant silicon disk metasurface supporting high-quality quasi-BIC MD state leading to a strong near-field enhancement inside the nanoresonators. We further demonstrate highly-efficient dynamical nonlinear image tuning through designed quasi-BIC MD resonators.

2. Results and Discussions

Our designed metasurface is composed of silicon nanodisk supporting out-of-plane MD resonance which is a symmetry-protected BIC state. The thickness and period of our metasurface are 53 nm and 840 nm, respectively. We introduce an off-centred hole to open a radiation channel and transform the ideal-BIC MD state into quasi-BIC MD state which can be excited directly under normal pump irradiation. The silicon metasurface is optimised to support a quasi-BIC MD state at a near-infrared wavelength around 1345 nm with spectral full-width-at-half-maximum (FWHM) around 12 nm, which matches the spectral width of our used laser to expect maximum coupling and nonlinear signal generation. By measuring the linear transmission spectrum of the metasurface under plane wave normal incidence as shown in Figure 1a, we observed a pronounced asymmetric Fano line shape with a narrow dip around $\lambda = 1345$ nm, indicating the excitation of the quasi-BIC-MD state. We then perform the third-harmonic spec-
Figure 1: (a) Experimentally measured linear transmission spectrum. The inset shows the calculated electric near-field distribution in the x-y plane at the resonance (left) and the SEM image of the fabricated sample (right), respectively. (b) Experimentally measured THG spectra of the sample. The inset shows a photographic image of the TH emission from the sample. Nonlinear image tuning in the designed metasurfaces is demonstrated by polarisation (c-e) and wavelength tuning (f-h), respectively.

troscopy measurement as shown in Fig. 1(b). The TH signal can be dramatically enhanced in the optimised disk-hole metasurface at the quasi-BIC-MD state, resulting in more than 500-fold enhancement as compared with the silicon disk metasurface. This leads to an estimated total TH conversion efficiency in the order of $10^{-5}$ under peak pump intensity only $I_0 = 1.0 \text{ GW/cm}^2$.

Such high-quality quasi-BIC MD states provide a powerful platform to efficiently control the nonlinear emission spatially. We further encode two images into the metasurface, i.e., tuning the geometry of the nanodisks and holes to support resonances at different wavelength position or under different pump excitation polarisation conditions. Due to the spatial asymmetry of such quasi-BIC-MD states, we first encode two images of arrow $\uparrow$ and $\downarrow$ indicating the opposite directions through the metasurface for disks with x-off-centered hole and disks with y-off-centered hole, respectively. The width and length of the arrow is about 20nm and 90nm, respectively. By varying the pump from x-polarization to y-polarization, it is possible to separately excite the quasi-BIC MD states supported by the two images. Thus, one can read out the encoded image through the generated nonlinear signal (Fig. 1c-e). As the spectral position and width of such quasi-BIC MD state can be engineered effectively through geometric tuning of the nanoresonators, the nonlinear image tuning can also be achieved directly through wavelength tuning as shown in Fig. 1f-h, where the two images are encoded into the nanoresonators with quasi-BIC MD state at different spectral positions (at 1325 nm and 1355 nm).

3. Conclusions

In summary, we have demonstrated an ultra-thin resonant silicon metasurface supporting high-Q quasi-BIC MD state. Due to strong light confinement inside the nanoresonators originating from the BIC-MD nature, we have shown that such quasi-BIC MD state can significantly enhance the nonlinear process. We further demonstrated a nonlinear image switching through polarisation- and wavelength-tuning methods, respectively. Our results underpin nonlinear nanophotonics applications such as tuneable displays, tuneable nanolasing and on-chip integrated metadevices with multi-functionalities.

Abstract

High index dielectric nanostructures support both electric and magnetic multipole resonances. In real applications, it is desirable to achieve high-quality optical resonances to have a high-Q factor within a small volume of a material. Here, we demonstrate the high-Q factor resonant modes in a single nonspherical dielectric nanocavity (i.e. rectangular nanowire, cuboid, and disk) by exploring quasi-bound states in the continuum. We find that the high-Q modes only occur at a specific size aspect ratio, around which avoided crossing (or crossing) feature appears for pair modes. The Q factor can be up to 2.31×10^4 for square nanowire (n=4) with a/λ<1. Multipole analysis on the high Q eigenmode indicates that radiation is significantly suppressed in the limited eigenchannels. High Q modes are verified experimentally via scattering spectrum.

1. Introduction

Dielectric metamaterial has been promised as an alternative candidate to realise the CMOS compatible with all dielectric nanophotonics [1]. Similar to the metallic structures supporting plasmonic resonance, dielectric structures can also provide both electric and magnetic resonances (known as Mie-type resonances). The dissipative loss for dielectric materials, however, is much lower than the counterpart of plasmonic materials. Due to these two unique properties, the performance of photonic and optoelectronic devices can be significantly improved by taking advantage of dielectric materials [2]. The tremendous research effort has been conducted to study the resonant properties of a single dielectric nanocavity beyond analytical Mie theory based on finite difference time domain (FDTD) approach [3]. In our previous work [4], we clarified the resonant mode properties of a single dielectric nonspherical nanocavity from the perspective of eigenmodes and demonstrated that its optical properties are governed by the eigenvalue of the leaky modes the structures support.

Moreover, the eigenvalue of leaky modes shows a linear dependence on the size ratio of structures (i.e. rectangular nanowire (NW) or cuboid). The intuitive understanding of leaky modes may open a new door in studying the optical resonance of dielectric resonator. For example, ultrahigh Q modes are always desired to enhance light-matter interaction, which was proposed for a single dielectric cylinder recently by exploring quasi-bound state in continuum (BIC) [5]. However, how to find a high-Q mode remains unanswered in single dielectric nonspherical nanocavity.

In this work, we report the general rule of thumb to find out the high Q mode in a single nonspherical nanocavity (i.e. rectangular NW, cuboid, and disk). For rectangular NW under the transverse electric (TE) polarization with electric field parallel to the axis of NW, the supercavity modes only appear for pair modes TE(m,l) and TE(m-2,l+2) or TE(m,l) and TE(m+2,l-2) accompanied by the avoided crossing features of real part of eigenvalue between these two modes at given size ratio R (named as critical ratio). Following these general rules, we can immediately find many high-Q modes. The Q factor can be high to 2.3×10^4 for square NW while the width of NW is smaller than the resonant wavelength. The extreme good confinement of the electric field can be ascribed to the suppression of radiation in limited leaky channels or radiation quenching to a minimum from the momentum space. This conclusion can also be generalised to rectangular NW with transverse magnetic (TM) polarisation, single cylinder with finite thickness and cuboid. Moreover, we also experimentally verify high Q mode of single Si NW from scattering spectrum. Our results may find the applications in boosting the light-matter interaction, such as nonlinear optics effect and laser.

2. Results and Discussions

We start with considering the eigenmode (named leaky mode) of rectangular NW with a refractive index n=4 under the TE polarization. Assuming the width and height of nanowire are a and b, respectively. The size ratio of NW is defined as R=b/a. The leaky mode is feature by complex eigenvalue N=nωi/c=Neal+iNimag, in which ω is complex eigenfrequency of eigenmode and c is the speed of light. The Q factor can be obtained from Q=Nreal/(2×Nimag). Previously, we have demonstrated that the eigenmode supported by the dielectric nanostructure plays the dominant role in governing its optical properties. Moreover, linear dependence between Nimag and size ratio R has been shown for mode TE(m,l), in which m and l are the maximum number of electric field within the NW. In the following section, we will demonstrate that high Q and low Q modes only appear at the critical ratio of NW in the pair modes TE(m,l) and TE(m-2,l+2) or TE(m,l) and TE(m+2,l-2),
which suggests that the parity of two modes must be same? The pair modes here are divided into three categories: (1) Type I: \( m = l \pm 2 \); (2) Type II: \( m > |l| \); (3) Type III: \( m < |l| \).

Fig. 1a-b shows \( N_{\text{real}} \) and quality (Q) factor as a function of size ratio \( R \) for mode TE(3,5) and TE(5,3) which belongs to Type I. Interestingly, Q factor reaches maximum value 3300 at \( R = 1 \) for TE(3,5) while the avoided crossing occurs for real part of complex eigenvalue in these two modes. It is worth of noting that the mode TE(3,5) and TE(5,3) will interchange with each other while the size ratio larger than one based on the definition of eigenmode. Other high Q modes fallen within the category of Type I, such as TE(1,3) and TE(2,4), can be found at same critical ratio \( R = 1 \).

3. Discussion

In order to explore the physical origin of the high-Q mode, we perform multipole analysis to separate the scattering contribution of different eigenchannels [6]. Here, we consider the case of NW at oblique incidence (\( \theta = 15^\circ \)) with TE polarization to excite all the eigenmodes of NW. Fig. 1c shows scattering efficiency contributed by multipoles for square NW. Two resonant peaks can be observed at \( k_\text{a}=3.89 \) and \( k_\text{a}=3.97 \), which are related to the low Q mode TE(5,3) and high Q mode TE(3,5). The scattering efficiency around \( k_\text{a}=3.97 \) is mainly contributed by the quadrupole \((m=2)\) and weakly contributed by the multipoles \((m=6)\). Due to the interference between them, scattering efficiency contributed by \( m=2 \) displays Fano line shape. In contrast, both monopole and octupole play the major role in the scattering efficiency around \( k_\text{a}=3.89 \) for low Q mode. In addition, we also perform the multipole analysis on the eigenfield for these two modes, which is shown in Fig. 1d. Interestingly, the main radiation channels are quadrupole \((m=2)\) and multipole \((m=6)\) for TE(3,5) while they are monopole \((m=0)\) and octupole \((m=4)\), which well matches the result in the scattering spectrum. Moreover, it is also worth of noting that the monopole has large leakage rate than that of quadrupole and multipole. This also explains why TE(5,3) has much larger radiation than that of TE(3,5). In fact, high Q mode can be found in a similar way for the NW with TM polarization, cylinder with finite thickness and cuboid.

4. Conclusions

In summary, we report the upper limit of the Q factor for single dielectric nonspherical nanocavity by exploring quasi BIC. The quality factor of resonant mode can reach maximum only when avoided crossing (or crossing) features are displayed between pair modes for TE (or TM) cases in single NW, and magnetic (or electric) modes in single cuboid (disk). Such a high Q factor can be attributed to the quenching of limited radiation channels. Also, the electric (magnetic) field in momentum space is reduced to a minimum at critical size aspect ratio, indicating the limited radiating capability of the modes. This unique high Q property is experimentally demonstrated from the scattering spectrum of single Si NW. Our findings provide a general guiding principle to design extreme high Q mode with relatively small material volume and may find the applications in lasing, biosensor and enhancing light-matter interactions.

Abstract
Spin-polarized directive coupling of light is an intriguing property of topological photonic structures. Associated to the quantum spin Hall effect of light, it results from the transverse spin angular momentum density of inhomogeneous optical fields. We observed a resonantly-enhanced spin-directive coupling of light at bound states in the continuum (BICs) of nanoscale photonic crystal slabs. The application of BICs for achieving a non-plasmonic enhancement of the spontaneous emission properties and Raman scattering is also discussed.

1. Introduction
Spin-polarized directive coupling of light can be achieved with helical optical modes of photonic topological insulators and basically with inhomogeneous optical fields like surface waves manifesting spin-momentum locking [1, 2]. Herein, we discuss the experimental observation of spin-directive coupling in the Bloch’s wave components of a symmetry-protected bound state in the continuum (BIC) [3]. The waves are amplified by the the resonance and easily detected and outcoupled form the system, which consists of a photonic crystal (PhC) thin slab made of transparent silicon nitride (Si$_3$N$_4$). We show that BICs are characterized by a transverse spin angular momentum (SAM) density not only in the trivial evanescent regions of the cladding but also inside the confining dielectric material. We observe emergent surface waves propagating along the symmetry axes of the PhC at the BIC, whose intensity depends on the input polarization. Specifically, the helicity of the input circular polarization determines the intensity of the wave along a specific direction of propagation, intensity revealing a mirror-symmetry breaking despite the non chiral nature of the geometry. We interpret the phenomenon by considering the spin-momentum locking associated to the transverse SAM. Our experimental results point out the possibility of a BIC-enhanced spin-directive coupling of light. Potential multi-platform implementations are envisaged. Indeed, the near-field amplification of the BIC evanescent tail over the large PhC surface can be used in a synergistic fashion to amplify the spontaneous emission properties and Raman scattering of molecules. We discuss some results recently achieved in this direction by our group.

2. Results
2.1. Spin-directive coupling at the BIC
We studied a dielectric geometry consisting of a square lattice of cylindrical air holes etched in a thin film of Si$_3$N$_4$ between air and a supporting quartz (SiO$_2$) coverslip. Numerical modeling was carried out using a rigorous coupled wave approach (RCWA). Figure 1 shows the electromagnetic field at the BIC and input SAM dependence. Top and bottom panels refers to RCP and LCP incident radiation, respectively. The grey region reproduces the Si$_3$N$_4$ elementary volume. A BIC mode obtained for $h = 144$ nm is represented in the unit cell. The vector map of the field $E$ shows its character of surface wave with longitudinal components also inside the confining dielectric material. The colormap is associated to magnetic field intensity $|H|^2$, whose $z$-cross section is that of evanescent waves (asymmetric in the cladding). Comparing top and bottom Poynting vector maps, we can see that the propagation direction of the wave along the $x$-axis (a similar behavior occurs also along the $y$-axis) depends on the helicity of the input. The colormap is associated to the energy density. The yellow arrows are a guide to the eye. The SAM density $S = \text{Im} [\epsilon_0 E^* \times E + \mu_0 H^* \times H] / 4\omega$ associated to this BIC mode has transverse components with respect to $\Pi$ [2]. This significant transverse SAM, not only at the interfaces but also inside the nanoscale slab, is associated to the orientation of the Poynting vector, which can be seen in detail in Fig. 1e-f. From the asymmetry of the mode profile along the $z$-axis in Fig. 1 it is clear that the surface waves have different amplitude at the interfaces. Along a given direction, say $x$-axis in Fig. 1, in one way there will be more light than the way back for a given input circular polarization, with a reversed behavior for the opposite input helicity. Therefore, we can expect that the main surface wave out-coupled again in the free space at fixed direction will be characterized by a different field intensity depending on the input spin causing a breaking of the planar mirror symmetry of the system even at
Figure 1: (a, b) BIC mode profiles and electric field vector maps, Poynting vector maps (c, d) and corresponding SAM maps (e, f), respectively, for RCP and LCP input plane waves.

normal incidence, producing a macroscopic spin-polarized directive coupling. Experimental details will be given on site.

2.2. Near-field amplification at the BIC

The electromagnetic field confinement in BIC resonators occurs in the direction normal to the periodicity plane and no cavity is needed. For a transparent resonator, probe molecules or materials of interest on the PhC surface can experience a significantly amplified optical near field [4] useful in nonlinear processes and sensing applications [5, 6, 7]. However, the extremely precise alignment at normal incidence defines a stringent bottleneck limiting microscopic applications. On the other hand, for BICs based on resonance trapping mechanism the Q-factor dependence on the wavevector allows a significant amplification also with a microscopy interrogation, as our preliminary results point out. We found that BICs can be effectively used in standard microscopy for practical applications. We observed an enhancement of $10^3$ fold of both fluorescence emission and Raman scattering processes within a range of 100 nm from the PhC surface [5]. Finally, we take advantage synergistically of the BIC pre-amplification of the surface plasmon gain provided by a model plasmonic system placed on the PhC. We observed an increase of the gain of surface-enhanced Raman scattering of more than one order of magnitude by resonant matching of the localized surface plasmon resonance (LSPR) with the BIC field. Our results may open the avenue to a BIC-enhanced microscopy thanks to a simple, loss-free nanostructured glass, useful in many kind of biological investigations.

3. Discussion

In this summary, we outlined several results obtained applying large-area PhC nanoscale slabs working at the BIC point. The BIC resonator is capable of mediating the coupling to emergent surface waves having a well-defined linear momentum and transverse SAM. The asymmetry observed in the intensity of the side waves - the first four fundamental Bloch’s waves of the mode - is ascribed to transverse SAM. The advantage of the BIC mode is the resonant enhancement of the light scattered by the PhC and characterized by such a spin-polarized directive propagation. A BIC resonator may also provide a strong near-field amplification. This may lead to metasurface multiplatform applications, also favored by the large scale collective character of the BIC, which makes it robust against defects. Indeed, we studied the possibility of standard optical microscopy interrogation of a BIC-based open cavity resonator for fluorescence and Raman scattering enhancement. In contrast to plasmonic nanostructures characterized by absorption losses, the photonic crystal is a loss-free, transparent and extended dielectric platform. We foresee the possibility of versatile biological investigations for several applications.

Superchirality, circular dichroism bands and singular value resonances of a minimal dielectric metasurface

Simone Zanotto

1Istituto Nanoscienze - CNR, and Laboratorio NEST, Piazza San Silvestro 12, 56127 Pisa, Italy
*corresponding author, E-mail: simone.zanotto@nano.cnr.it

Abstract
We show that a metasurface having the simplest pattern that implements 2d-chirality shows circular dichroism band structure and superchiral near fields. These features occur in correspondence to the resonances of the singular value spectrum. In particular, Fano-like structures in the transmission spectrum are correlated with anomalies of the singular value and of the singular vector polarization states.

Electromagnetic fields which carry chirality – in their simplest form, left- and right-circularly polarized plane waves – deserve huge interest as they interact with matter chirality, enabling for instance to discriminate enantiomers in chemistry, which are ultimately connected with key features of living organisms. Indeed, many biomolecules have a specific sense of handedness, and it is not yet clear why nature has decided to go in that precise direction. From more applicative points of view, pharmaceutical industry constantly seeks for effective methods to discriminate stereoisomers, where chiral light-matter interaction could prove useful [1,2].

To date, the most common technique to prepare and analyze chiral light is to employ birefringent plates and linear polarizers that convert light to and from linear polarization, as almost no effective sources nor direct detectors of chiral light exist. Last advances in nanotechnology are however revolutionizing chiral optical devices [3,4]. Far- and near-field chiral electromagnetic responses have been indeed observed in a variety of artificially structured systems, where the shape of the machined elements must have a three-dimensional character if proper chirality has to be attained, because of the requirement of the absence of any mirror symmetry plane. While many proposed structures rely on volumetric fabrication techniques, which suffer from either scarce throughput or limited flexibility, less demanding fabrication technologies -- i.e., planar technologies -- may be also employed, as witnessed by some reports. For instance, a dielectric film with a non-centrosymmetric partially etched planar pattern was proposed as a simple gateway towards strong chiro-optical phenomena [5].

Indeed, there is a wide interest in developing subwavelength-patterned high-index dielectrics, both for applications and for fundamental research: from one side, they enable the synthesis of flat lenses, polarimeters, spectrometers, and computer-generated holograms; from another side, they exhibit a variety of intriguing phenomena such as Fano lineshapes, perfect forward scattering, geometric phase effects, and bound states in the continuum resonances.

In this work we report on the observation of photonic bands in a chiral metasurface, highlighting that the chiral response shows fingerprints of both guided wave and locally resonant phenomena. The object under investigation is an extremely simple 2d-chiral dielectric metasurface: a slab perforated with L-shaped holes. While not being 3d-chiral, it shows interesting features such as chiro-optical far-field response at normal incidence and the possibility to excite superfichiral near-fields with unpolarized light.

The objects under investigation have the layout depicted in Fig. 1. They consist of a 220 nm thick gallium arsenide membrane, patterned with L-shaped holes arranged over a square lattice. We characterized the sample by performing polarization-resolved transmission over a broad band covering the near infrared wavelength between 1 and 2 um. Fig. 1b represents such spectra. The spectra consist of a series of quite narrow dips, some of them having different shapes and depths depending on the polarization state of the incident light. From the transmittances for left (right) circularly polarized light, the transmission circular dichroism can be defined. This quantity is plotted in Fig. 1c. Here, the traces labeled front incidence and back incidence have been collected from the same sample, but illuminated from either the top surface or the bottom surface.

As it can be noticed from Fig. 1b, the transmittance spectral features are Fano resonances, arranged in multiplets whose nature becomes clearer when an angularly-resolved analysis is performed. Such an analysis revealed the presence of a photonic band structure. Curiously, such band structure also manifested itself on the circular dichroism spectrum, where intrinsic chirality fingerprints stand out.
What is more, we performed a singular-value decomposition analysis of the transmission matrix: this analysis is more suited than an eigenvalue analysis since the T-matrix of this device is not unitary. Indeed, despite the membrane does not absorb any light (at the wavelengths of interest), some light is lost in reflection.

This novel type of analysis revealed that resonant features in the singular value spectra, and in the spectra of the polarization states of the singular vectors, are strongly correlated with the features observed in the polarization-resolved transmission and in the circular dichroism. In addition, we noticed that appropriate algebraic manipulation of the SVD expressions allow to decouple the metasurface operation into a trivial one (i.e., a geometric rotation of the reference frame), and a non-trivial one, that constitutes the “core” of the metasurface operation.

Abstract

A hybrid dielectric-plasmonic waveguide grating enabling highly color-selective first order diffraction is reported. The effect is achieved by means of waveguide resonances and a Fano-like interference with the continuum formed by grating diffraction orders. This work shows the promising use of hybrid structures for taking the best features of both plasmonic and dielectric grating resonances for designing highly integrated optical devices such as spectrometers or optical security features.

1. Introduction

Plasmonic waveguides and resonant waveguide gratings have been a subject of extensive research for a few decades, showing promising optical properties relying on the Fano interference effect. In particular, filtering has been achieved thanks to the extraordinary optical transmission effect, implemented for imaging and spectral imaging devices [1]. In parallel, resonant waveguide gratings have been used for their filtering and coupling properties into thin film waveguides [2]. The search for full control of polarization, amplitude and phase of the electromagnetic field from planar surfaces remains of high interest, especially for the development of highly integrated photonic systems. Here, we report on a hybrid dielectric-plasmonic resonant waveguide grating which enables highly color-selective first order diffraction in a multimode light guide, which could be used for e.g. spectrometry or as an optical security feature.

2. Discussion

The system investigated in this work is sketched in Fig. 1a. A periodic sub-wavelength grating on glass substrate is coated with a thin silver film, followed by a coating of silica, with a thickness typically ranging up to 200nm. The silver layer alone supports a surface plasmon (SPP) mode, which is altered by the presence of the thin silica film into a hybrid dielectric waveguide-plasmon mode, named hybrid mode in the following. At a given wavelength, the incident light is diffracted by the grating and coupled into the hybrid mode with wavevector \( \mathbf{k}_w \):\

\[
\mathbf{k}_w = \mathbf{k}_{\text{in},t} + \frac{2\pi}{\Lambda}\hat{x},
\]

(1)

where \( \mathbf{k}_{\text{in},t} \) is the tangential component of the incident wavevector in the grating plane. Several optical paths are available for the hybrid mode for outcoupling. It can be outcoupled by the same grating to the zeroth order of reflection or transmission such that:

\[
\mathbf{k}_{\text{out},0,t} = \mathbf{k}_w - \frac{2\pi}{\Lambda}\hat{x} = \mathbf{k}_{\text{in},t}.
\]

(2)

Alternatively, it can be evanescently coupled into the substrate without action of the grating, with the resulting wavevector corresponds to the one of the first order of diffraction:

\[
\mathbf{k}_{\text{out},1,t} = \mathbf{k}_w = \mathbf{k}_{\text{in},t} + \frac{2\pi}{\Lambda}\hat{x}.
\]

(3)

The hybrid mode is the resonant mode in this system.
Other non-resonant optical paths include direct zeroth and first order of transmission, with tangential wavevectors equal to \( k_{in} \) and \( k_{in,t} = (2\pi/\lambda) \hat{z} \), respectively. The interaction between the SPP mode and the continuum of zeroth and first order diffraction leads to a Fano-like interference with different asymmetry parameters, as shown in the rigorous coupled wave analysis (RCWA) calculations in Fig. 1(b). The grating fabrication has been performed with electron beam lithography into a silicon wafer, which has been used as a replication template for UV-NIL on glass. After silver and silica coating, the first order diffraction efficiency in the substrate has been measured as a function of the wavelength (Fig. 2). It shows an isolated peak at the resonance wavelength with a very weak amplitude at other wavelengths, a signature of the resonance effect. In order to achieve high color purity, the coupling from free space to the waveguide should be small, which implies a low grating corrugation depth (typically in the order of 50nm and below). Overall, the grating depth and silver coating thickness are chosen to achieve the critical coupling condition, optimizing the diffraction amplitude in the first order of diffraction. Fig. 3a shows the peak wavelength and outcoupling angle obtained as a function of the silica coating thickness and period. In general a large range of design possibilities is available using this approach. Figures 3b and 3c show an example of application, in which a white light beam with large angle divergence is transformed into a set of angularly separated quasi-monochromatic light beams.

3. Conclusions

A highly color-selective diffraction and coupling into a multimode light guide has been achieved by means of waveguides resonances and a Fano-like interference with the continuum of grating diffraction orders. This work shows the promising use of hybrid structures for taking the best features of both plasmonic and dielectric grating resonances for designing highly integrated optical devices such as spectrometers or optical security features.

Acoustic topological Fano resonances

Farzad Zangeneh-Nejad, and Romain Fleury

Laboratory of Wave Engineering, School of Electrical Engineering, EPFL, Station 11, 1015
*corresponding author, E-mail: romain.fleury@epfl.ch

Abstract
We report the observation of acoustic topological Fano resonance, and demonstrate their robustness to imperfections. By going beyond the performance degradations caused by inadvertent flaws occurring during fabrication process, such topologically protected Fano resonances pave the way for a new generation of reliable wave-based devices such as ultrafast switches or modulators, efficient lasers, perfect absorbers, and highly precise interferometers.

1. Introduction
Fano resonance is a ubiquitous classical wave phenomenon, commonly found in various branches of science and engineering like atomic and solid states physics [1], electromagnetism [2], circuits [3], photonics [4], and acoustics [5]. While originally developed to explain the inelastic scattering of electrons from helium, Fano resonances have recently attracted a great deal of interest by virtue of their myriad engineering applications. As a matter of fact, the ultra-sharp spectral feature of Fano resonances has established the basis for chains of prominent technology-oriented devices such as low threshold lasers [6], low energy switches, ultrafast modulators, high quality factor filters, compact electromagnetically induced transparency (EIT) devices, ultrathin perfect absorbers, and highly accurate interferometers.

Apart from its steepness, the peculiar asymmetric line shape of Fano-type resonances is known to be excessively sensitive to environmental changes, a characteristic which has enabled the realization of highly sensitive sensors [7,8]. Such sensitivity, however, is not always desirable, when such resonances are intended for the applications other than sensing. In such cases, even slight changes in structural features such as the disorder and imperfection caused inevitably during fabrication process are highly detrimental and degrade the performance of the device severely.

The recently proposed concept of topological insulators [9], however, offers an unprecedented solution to overcome the challenges associated with inadvertent, or even deliberate, structural impurities. Topological insulators are a class of materials exhibiting insulating behavior in their bulk, yet they allow conduction along their edges. The paramount feature of topological insulators, however, relies on the fact that these conduction edge states are invulnerable to broad imperfection as they are protected by the topology of the bulk material. Here, we demonstrate how topological insulators can be leveraged to make Fano resonances robust against impurities. Towards this goal, we first investigate the unexplored physics of the topological bound states which may happen to coexist within the continuum spectrum of the edge states of a topological insulator. We then describe how such bound states can give rise to topological Fano-type resonances, protected against broad structural deformations. Such robust Fano resonances constitute a promising framework for a large variety of efficient and fabrication-insensitive Fano-type devices.

2. Results
We start with considering the topological edge states that form at the phase transition interface of the SSH array shown in Fig. 1a. The system consists of cylindrical rods embedded inside an acoustic parallel plate waveguide. Considering the symmetry of the system under study, one can categorize the corresponding edge states into two classes: the edge state stemming from the bound state in the continuum of waveguide (BIC) and those originating from the radiation modes. Fig. 3a (second and third panels) illustrate the profile of these two different types of edge states, respectively. For future references, we entitle the first and second types as dark and bright edge states, respectively. Such appellation is inspired by the fact that the dark edge state possesses much narrower resonance linewidth (or lower leakage) compared to the bright edge states [10]. We note that by scaling the lattice constant, one can readily adjust the frequency of the bright edge state [10]. Here, we have subtly chosen the lattice constant in a way that the bright edge mode occurs in the neighboring of the dark edge mode. Consequently, when performing the scattering experiment, the dark edge mode coexists in the resonance continuum of the bright edge mode, creating an ultra-sharp and asymmetric Fano resonance as observed in Fig. 3a (fourth panel). Note that if the mirror symmetry had been preserved, the dark edge mode would be hidden in the spectrum (the dashed red line), forming a topological bound state in the continuum of the bright edge mode.
Fig. 1: Topological robust Fano resonances: a, An acoustic SSH chain, consisting of a series of cylindrical rods embedded inside an acoustic parallel plate waveguide. Two types of edge states will subsequently be formed at the interface: those originating from the radiation modes (the bright edge state) and the one stemming from the BIC mode. By scaling the lattice constant, one can conveniently enforce the bright edge state occurs in the neighboring of the dark one so as to achieve the Fano-type resonance (the solid blue line). b, Same as panel a but for a largely disordered configuration. Since both the bright and the dark resonances have topological nature, the resulting Fano resonance is protected against the disorder by the topology of the bulk insulators. The interested reader in referred to [10] for more information regarding the topological nature of the system and its robustness.

We now move onto to examine the robustness of the obtained Fano resonance against structural deformation. Intuitively, since both of the bright and dark resonances have topological nature, the resulting Fano resonance is expected to be protected against disorder by the topological order of the surrounding insulators. To examine such robustness, we randomly change the positions of the obstructing circles to achieve the largely disordered system of Fig. 3b (first panel). The mode profile of the resulting dark and bright edge states are shown in Fig. 3b, second and third panels, respectively. Notice that the resonance frequencies of both bright and dark resonances are not significantly affected by the disorder owing to their topological nature. The resulting Fano resonance is therefore expected to negligibly deviate from its ideal case. This is evident from the transmission spectrum of the waveguide in Fig. 3b (fourth panel), confirming the high robustness of such kinds of Fano resonances. Such reliability offers promising perspectives for the realization of various fabrication-insensitive Fano-resonance-based devices such as low-threshold lasers, ultrafast modulators and switches, and perfect absorbers.

3. Conclusions
We introduced and the concept of topological Fano resonance. Our findings demonstrate the superior robustness of topological Fano resonances over trivial Fano resonances. Topology guarantees the peculiar Fano line shape to occur in the desired frequency range, as long as the level of disorder is not strong enough to close the surrounding topological band gaps. Remarkably, such topological Fano resonances are still sensitive to environmental changes, a characteristic which may allow for a new generation of sturdy sensors.

Our results shows that achieving a topological Fano resonance does not require tight geometrical tolerances, very different from trivial Fano resonances. We believe that the concept of topological Fano resonance can offer new perspectives in broad range of applicative fields, including, but not limited to, photonic, plasmonic, sensing, all-optical signal processing, or biomolecular detection.

Coupling regimes in a complex of two rods: from core-shell particle to dimer

Alexey A. Dmitriev\textsuperscript{1,*} and Mikhail V. Rybin\textsuperscript{1,2}

\textsuperscript{1}Department of Physics and Engineering, ITMO University, St Petersburg 197101, Russia

Abstract

We study coupling regimes in a system made of two infinite dielectric rods with the same frequency of dipole Mie resonances. We present simulated scattering spectra in three configurations: a core-shell particle, an eccentrically coated rod and a dimer. We track the evolution of spectra as the distance between the rods is varied and discuss the coupling regimes.

1. Introduction

Photonic structures operate due to resonances in their constituent elements. The strength of coupling between the resonances determines whether the corresponding mode would be local or distributed among multiple particles [1]. A core-shell particle is an example of a photonic structure operating on local resonances. Their interaction is described as a Fano resonance leading to scattering cancellation [2]. Photonic oligomers, on the contrary, support hybridized modes [3]. Each type of coupling has its own advantages and disadvantages for specific applications. Thus, it is crucial to reveal conditions for the transition between the weak and strong coupling regimes in different photonic structures.

Here we study coupling regimes in a system consisting of two infinite dielectric rods. We start with a configuration when the rods are placed coaxially forming a core-shell particle. Then we “pull” the core out of the shell by increasing the distance between the centers of the rods. We identify two possible configurations here: (i) the smaller rod is eccentrically embedded inside the bigger one, and (ii) the rods are separated by an air gap, forming a dimer.

2. Simulation of the scattering spectra

To study the coupling regimes we consider the problem of the scattering of a plane wave on a system made of two infinite dielectric rods. The rods have the radii $R$ and $r$, with $R$ being greater than $r$, and the refractive indices $n_1$ and $n_2$ with $n_1$ being less than $n_2$. We choose the refractive indices so as to tailor the dipole Mie resonance to the same frequency for both rods. The distance $d$ between the centers of the rods is varied to make one of the following configurations: (i) $d = 0$ for a core-shell particle, (ii) $0 < d \leq (R - r)$ for an eccentrically coated rod and (iii) $d \geq (R + r)$ for a dimer.

To simulate the scattering we use a rigorous coupled-multipole method also known as multiple scattering theory (MST). The method is based on rewriting each multipole of scattered field as a multipole expansion in the vicinity of another scatterer, so as to account for all subsequent scattering events. This allows us to write down a system of equations on the scattered multipole amplitudes and to solve it. We use this approach to formulate a generalized Lorentz–Mie theory for an array of rods embedded into a bigger rod. To do this, we write down the multiple scattering equations and rewrite the scattering fields as a multipole expansion around the center of the enclosing rod. By imposing field continuity conditions on the boundary between the enclosing rod and air, we can work out the scattering matrix of this complex treated as a single scatterer. Then we use the 2D optical theorem [4] to calculate the scattering cross-section from the scattered multipole amplitudes. The theorem reads

$$C_{\text{ext}} = 2\sqrt{\frac{r}{k}} \left(\text{Im}\{f(0)\} - \text{Re}\{f(0)\}\right),$$

where $f(0)$ is the forward scattering amplitude normalized to the amplitude of plane wave.
3. Results of simulation

We show the results of our simulations in Fig. 2. Solid lines correspond to the “longitudinal” configuration with the centers of rods put along the direction of incidence. We note that reversing the direction of incidence does not change the spectra. Dotted lines show the “transverse” configuration with the centers of rods put perpendicularly to the incidence direction.

At infinitely large distances (labeled $d \to \infty$ in the figure) the rods scatter light independently. Spectra in both configurations demonstrate a single peak at the size parameter of $kR = 0.25$ corresponding to two-fold degenerated dipole Mie resonances, which are tailored to the same frequency for both rods. When the distance between the rods is decreased, (see the curve labeled $d = 100 r$ in the figure) the scattering spectra start to exhibit fringes (oscillations), which correspond to Fabry–Perot-like modes appearing between the rods [4, 6]. We note that the “frequency” of the oscillations in the longitudinal configuration is two times larger than in the transverse configuration, due to the symmetry forbidding the excitation of odd modes in the latter one.

At the distance $d = 25r$ (we show $d \leq 10r$ for better clarity) the rods enter the strong coupling regime, which is characterized by splitting of the Mie resonance [5, 6]. This splitting appears due to hybridization of the eigenmodes of the rods. The lower peak corresponds to the symmetric hybridized mode, while the higher one is the antisymmetric mode. The latter peak is not observed in the spectra for the transverse configuration due to the symmetry. The splitting increases as the distance between rods is decreased.

The distance $d = 4r$ corresponds to the case of touching rods. To study the coupling at even smaller distances, we consider the eccentrically coated rod configuration with $d \leq 2r$. Here the spectra for the longitudinal configuration show the same behavior: they exhibit the peaks corresponding to the symmetric and the antisymmetric modes with the splitting increasing as the distance decreases. At the core-shell particle regime ($d = 0$) the spectra for the longitudinal and the transverse configurations coincide.

4. Conclusion

We have performed simulations of scattering spectra of two infinite dielectric rods the same dipole Mie resonance frequency and different radii in three configurations: a dimer, an eccentrically coated rod and a core-shell particle. We have compared the spectra for two scattering geometries. As the distance between the rods is decreased, the weak-to-strong coupling regime transition occurs. The strong coupling regime is characterized by splitting of the dipole peak into a duplet of a symmetric and an antisymmetric modes. After the smaller rod is embedded into the larger one to form an eccentrically coated rod configuration, the longitudinal configuration shows the same behavior.

![Figure 2: Scattering spectra of two rods in case of dimer ($d \geq 4r$), eccentrically coated rod ($0 < d \leq 2r$) and core-shell particle ($d = 0$). The spectra are shifted up along the $y$-axis.](image)

Abstract
We present a unified theory, which makes it possible to study on a unique theoretical platform diverse issues concerning resonances in complex classical as well as quantum systems including Fano resonances and exceptional points, collapse of Fano resonances and bound states in the continuum. We support the main results of our theory by numerical simulations of a real electromagnetic waveguides and discuss difference between classical and quantum description of Fano resonances.

1. Introduction
Scattered waves can exhibit either constructive or destructive interference resulting in transmission maximum (resonance) or minimum (antiresonance) correspondingly. Both types of interference phenomena take place in Fano resonances, which appear in scattering of continuum states by a (quasi) localized resonant state [1]. Fano resonances are ubiquitous in complex classical and quantum systems such as plasmonic and dielectric nanostructures, semiconductor heterostructures, photonic crystals, metamaterials and molecular conductors etc. [1,2]. Hence design and fabrication of such structures with desired resonance properties are of primary importance both for fundamental science and applications. In the present report we address this problem on the basis of a recently developed unified theory of resonances and bound states in the continuum [3]. General results of Ref. [3] are supported by means of modal plane wave expansion (PWE) and finite difference time domain (FDTD) numerical simulations.

2. Unified tight-binding theory of (anti)resonances
In Ref. [3] a scattering problem was studied for a quantum conductor or a waveguide in tight binding approximation and a universal formula for the transparency \( T \) was derived:

\[
T(\omega) = \frac{P^2(\omega)}{P^2(\omega) + Q^2(\omega)},
\]

where \( P \) and \( Q \) are some functions of photonic frequency (electron energy). It was shown that \( Q \) can be determined as the characteristic determinant of some auxiliarly non-Hermitian Hamiltonian, which can be straightforwardly deduced from Fano-Feshbach non-Hermitian Hamiltonian:

\[
Q(\omega) = \det\left( i\omega - \hat{H}_{\text{aux}} \right),
\]

Expression (1) is exact within the framework of tight-binding approximation irrespective to number of the neighbors taken into account. Real eigenvalues of \( \hat{H}_{\text{aux}} \) and roots of \( Q(2) \) exactly determine perfect transmission resonances (1). Non-Hermitian operators can possess real eigenvalues under the condition of PT-symmetry (here \( P \) – space inversion and \( T \) – time reversal operators) [4]. PT-symmetry can be broken under variation of internal system parameter at the exceptional point (EP) of the system. At EP two real eigenvalues coalesce and turn into a pair of complex conjugate. From Eq. (1) it follows that at EP two perfect resonances coalesce and turns into a single resonance with transparency less then unity.

In simply connected (linear) system \( P \) does not depend on frequency and can be written as a product of intersite couplings. Transmission (1) in this case does not possess zeroes and turns into Breit-Wigner expression near single resonance. In multiply connected systems \( P \) becomes frequency (energy) dependent and its roots determine antiresonances. Closely spaced roots of \( P \) and \( Q \) describe a typical Fano resonance. Poles of the transparency coincide with poles of scattering matrix. Therefore the compact expression (1) makes it possible to perform consistent study of bound states in the continuum (BIC) [5], which are related to the poles of scattering matrix on real axis. From Equation (1) it follows that BIC occurs if and only if \( P \) and \( Q \) share the same real root. Hence BIC emerges as a result of collapse of Fano resonance accompanied by coalescence of resonance and antiresonance. Depending on multiplicity of the \( P \) and \( Q \) roots we can also consider BIC either as a Breit-Wigner resonance or as an antiresonance with zero width.
3. Fano supernodes near exceptional points

Near EP of an auxiliary Hamiltonian transparency (1) forms a broad resonance window. As it was shown in Ref. [3] function $P$ under some conditions can be expressed as the characteristic determinant of another non-Hermitian Hamiltonian as well. This Hamiltonian can possess EP either, near which the transparency is characterized by a window of almost zero transparency – Fano supernode. It was shown that multiple transmission zeros (Fano supernodes) can provide a great enhancement in the ZT parameter of a thermoelectric transformer [6]. These supernodes can be predicted by the simplest tight-binding model with nearest neighbor approximation in transmission spectra of various molecular conductors with equal side groups placed along the conductor. Unfortunately, they are not robust against taking into account next nearest neighbors or Coulomb correlation effects [7]. Coalescence of antiresonances provides different nature of the Fano supernodes formation and they might be more robust against through-space couplings and many-body correlations. As an example consider a double-chain system with two sites in each chain (inset in Fig. 1). Taking into account next nearest neighbor couplings only shifts the supernode position rather than destructs it (Fig. 1).

4. Coalescence of Fano resonances in numerical simulations of electromagnetic waveguides

We use two techniques of electromagnetic fields simulation: FDTD and modified PWE. FDTD calculations of EM waves in a structure with sharp Fano resonances raise some difficulties such as necessity of long emitting sources due to large resonance buildup times. To avoid time consuming FDTD simulations we use a modified PWE technique for coarse estimation of the resonances positions. The PWE approach uses radiation boundary conditions and gives us realistic data for infinite long waveguides with a finite resonator. The results of numerical simulation of the simplest waveguide structure are presented in Fig. 2. We also studied temporal evolution of electromagnetic fields during BIC formation by means of FDTD technique. It should be noted that due to the difference in the conditions for the bound state existence in quantum mechanics and electromagnetic cavity modes formation the simulation of Fano resonances in quantum and classical theory possesses the essential differences.

![Figure 1: Fano supernodes. Transmission spectrum of the double chain system with two sites in each chain (inset) with next nearest neighbors couplings taken into account.](image1)

![Figure 2: Transmission spectrum demonstrating coalescence of Fano resonances in metallic waveguide with dielectric insert $n=2$, $h=1$, $L=0.5$, $1-\epsilon_1=0.46$, $2-0.60$.](image2)

5. Conclusions

In the present report we show that design rules can be formulated that makes it possible to construct electromagnetic waveguides with diverse and controllable properties of Fano resonances ranging from collapse of Fano resonances, resulting in BIC formation, to coalescence of Fano resonances accompanied by emergence of wide reflection windows.

Abstract

This work investigates the formation of bound states in the continuum (BICs) in a system of coupled plasmonic grating and a photonic waveguide. Aside from the conventional symmetry-protected BICs that appear at the band edge, the hybrid system also supports Friedrich-Wintgen BICs which form in the vicinity of the avoided crossing of strongly-coupled plasmonic and photonic modes. The radiative quality factors of the BIC states diverge to infinity which makes them perfect candidates for many applications.

1. Introduction

Since their first realization in optical systems [1], bound states in the continuum (BICs) have been achieved in a large number of loss-free optical platforms [2, 3]. However, their realization in systems with losses has been very limited [4]. In this work, we strongly-couple the plasmons modes of a silver grating and the photonic modes in a dielectric waveguide which results in an avoided crossing with Rabi frequency of 150 meV [5]. This system allows us to access different types of BICs such as symmetry-protected plasmonic BIC, and symmetry-protected photonic BIC which appear at normal incidence. Also, we can observe Friedrich-Wintgen BIC that are formed due to the destructive interference between different resonances. Besides BIC states which are dark states with theoretically infinite radiative quality factors, “near-BIC” regime is where very high quality-factors can still be attained in the vicinity of BICs is very important. Resonances in the near-BIC regime can be excited by free propagating plane waves and are generally more robust and practical to work with.

2. Discussion

In Fig. 1(a), we show the proposed hybrid system. The plasmonic grating is made of silver on top of a thick (100 nm) silver film. The periodic ridges of the grating are 30-nm high and 100-nm wide. The period of the grating is 400 nm, and the top silica layer has a refractive index of 1.45 and is 500-nm thick. The polarization of the incident light is directed along the grating wires (TM) to enable the excitation of the surface plasmon modes. Figure 2(b) shows the reflectance spectra with varying incident angles. At the normal incidence, we can notice the vanishing of the linewidth at two different wavelengths. The first is of the plasmonic resonance (upper branch ~ 700nm) which we call symmetric-protected plasmonic BIC. The second is the vanishing of the linewidth of the photonic resonance (~532 nm) which is called symmetry-protected photonic BIC. Both plasmonic and photonic symmetry-protected states disappear at the normal incidence due to the incompatibility of the symmetry of the state with the outgoing field. The second type of BICs formed in our hybrid system are the Friedrich-Wintgen BIC resulting from the strong coupling and the destructive interference of the photonic and the plasmonic modes. In Fig. 1(b), the BIC appears close to the avoided crossing at an angle of 11.4°. In all cases, photonic and plasmonic symmetry-protected BICs and the off-Friedrich-Wintgen BIC, the linewidths of the resonances disappear, and the radiative Q-factor diverges as a signature of the formation of a BIC.

Figure 1: (a) Schematic of a plasmonic grating coupled to a silica waveguide. (b) Reflectance spectra as a function of the incident angle showing the different types of BICs. At an incident angle of 0°, multiple symmetry-protected BICs are observed. The Friedrich-Wintgen BIC appears near the strong coupling point at an angle of 11.4°.

To showcase the nature of the interacting modes in the hybrid structure, the electric field distributions at 1° angle of incidence and variable wavelengths are plotted in Fig. 2. Fig. 2(a, b) show the fields at 521.3 nm and 536.3 nm wavelength, respectively, which indicated mainly photonic
nature in the 500 nm-wide slab waveguide. On the contrary, the electric field at 599.5 nm, Fig. 2(c), is purely plasmonic. Also, varying the thickness of the photonic slab waveguide changes the number of supported modes and hence dramatically alter the band diagram of the hybrid structure. This opens a multitude of opportunities for application requiring band gap engineering by controlling the dispersion of the plasmonic component, or the photonic one, or both in the hybrid design.

Moreover, we can notice from Fig. 1(b) that the system supports slow light, not only at the band edge (normal incidence), but also, at arbitrary values for the angle of incidence. More interestingly, the spectral bandwidth along which the slow light can be supported is substantially increased. As noted from Fig. 1(b), the slow light band at ~600 nm expands from -10° to 10° and that at ~560 nm from 7° to 20°. Therefore, the hybrid structure is capable of selecting the central angle at which the slow light exists, extending its angular span, and providing means to select where the slow light is supported spectrally.

3. Conclusions

In conclusion, we have explored the formation of BICs in hybrid systems with a realistic intrinsic loss. Due to the strong coupling of plasmonic and photonic modes and their destructive interference, the losses are significantly reduced due to the suppression of radiation. Two different types of BICs are accessible in the hybrid plasmonic-photonic system due to the symmetry incompatibility with the radiation as well as the destructive reactions of resonances. A distinct characteristic of the Friedrich-Wintgen BIC achieved in this study is that it originates from the interference of two resonances with different natures. Besides, we also demonstrated that the hybrid system studied exhibits strong coupling with large Rabi splitting, optical bandgap engineering and slow light with sizeable spectral robustness.

Multiple Fano Feature due to Optical Bound States in the Continuum

Dmitrii N. Maksimov* and Evgeny N Bulgakov

Reshetnev Siberian State University of Science and Technology, Krasnoyarsk, Russia
*corresponding author, E-mail: mdn@tnp.krasn.ru

Abstract
We consider light scattering by 2D arrays of dielectric spheres arranged into the triangular lattice. It is demonstrated that the scattering spectra exhibit a complicated picture of Fano resonances. The Fano features are explained as a signature of bound states in the continuum (BICs). It is found that an in-Gamma BIC induces off-Gamma BICs due to different scaling laws for real and imaginary parts of the resonant eigenfrequency, the latter being parabolic while the former form a Dirac cone.
Multipolar properties of bound states in the continuum supported in all-dielectric metasurfaces

Yi Xu

1 Department of Electronic Engineering, College of Information Science and Technology, Jinan University, Guangzhou 510632, China
*corresponding author, E-mail: yi.xu@osamember.org

Abstract

We study the multipolar properties of bound states in the continuum of all-dielectric metasurfaces which are consisted of periodic silicon nanodisks. Such bound states in the continuum can be regarded as the discrete states (subradiant modes) which involves in forming high-Q Fano resonances. By reconstructed the Fano line shape utilizing the induced multipole moments in one unit cell, we reveal the important roles of multipolar bound states in the continuum play in forming such Fano resonances.

1. Introduction

Wavelength scale dielectric nanoparticles can support Mie type resonances manifested themselves as electromagnetic multipole resonances [1]. It might even support exotic phenomena in the scattering of electromagnetic waves, such as the nonradiative anapole mode [2] and ideal magnetic dipole scattering [3]. If these Mie type resonators are arranged in a periodic way, a metasurface is formed and guide resonances can be triggered under the suitable excitation condition [4]. Such high-Q Fano resonances are attractive as they can be used in many electromagnetic applications, such as optical modulator, optical filter and optical switch [4]. In general, all of these Fano resonances are featured with sharp asymmetry line shapes, which can be easily detected in the far-field. However, less attention is paid to the near-field electromagnetic distributions of various high-Q guided resonances while they do exhibit interesting and distinct multipole features [5].

Herein, we study the multipolar properties of eigenmodes with infinite Q factors supported in an all-dielectric metasurface which is consisted of periodic arranged silicon nanodisks shown in Fig. 1 (a). Such BIC can be tuned into leaky resonances with ultrahigh Q factors. By decomposing the induced multipole moments in one unit cell, we reveal the important roles of multipolar bound states in the continuum play in forming various kinds of leaky resonances. We further discuss potentials applications, such as lasing, sensing and enhancing optical nonlinearity, by utilizing different kinds of multipolar bound states in the continuum.

2. Results

Figure 1: (a) Schematic of an all-dielectric metasurface supporting multipolar bound states in the continuum (BIC). Periodic silicon dimer nanodisks arranged in a square lattice are placed on a quartz substrate. (b) Schematic of a toroidal dipole (TD) moment. (c) Two TD BIC eigenmodes of the metasurface with their TD moments along the Y axis and Z axis, respectively. We only show the electromagnetic field inside the particles. The blue/red arrows stand for the electric/magnetic field vectors.

Without loss of generality, we show that an all-dielectric metasurface consisted of periodic silicon dimer nanodisks arranged in a square lattice supports various kinds of Bloch modes with infinite life time. Such BIC states manifest themselves as distinct electromagnetic multipolar modes in the near-field. In particular, two toroidal dipole (TD) BIC modes, which exhibit a particular localized current distribution as shown in Fig. 1 (b), can be found in this structure. Because of the special localized current distribution of the TD moment [6], these two TD BIC modes are quite unique and possess giant electric field enhancement in free space [5], i.e. on the surface and in the gap of the metasurface, as shown in Fig. 1 (c).
3. Conclusions

In conclusion, we demonstrate that all-dielectric metasurface supports BIC modes with distinct multipolar properties. By manipulating the symmetry properties of either the excitation field or the structure, we can transform these BIC modes into the leaky Fano resonances with ultrahigh-Q factors. We can further fine tune the Q factors of these BIC modes and their associated near-field enhancement. At the same time, the multipolar properties of BIC modes can find applications in many branches of physics, including, but not limited to, lasing and ultrasensitive biosensors. Our results and methods are quite general and they can be applied to a variety of areas in wave physics.

Asymmetric to symmetric line-shape transition of guided-mode resonance enabled by cross-polarization filtering

Jiaxin Lv, Jicheng Jin, Xuefan Yin, and Chao Peng*

State Key Laboratory of Advanced Optical Communication Systems and Networks, Peking University, Beijing, China
*Corresponding author, E-mail: pengchao@pku.edu.cn

Abstract

The guided-mode resonance in photonic crystal slab, also known as bound state in the continuum (BIC), usually exhibits as sharp asymmetric Fano profile owing to the interaction between the discrete localized state and the continuum state. The transition from asymmetric Fano lineshape to symmetric Lorentz lineshape could be achieved by suppressing this non-resonance continuum state. In this work, we demonstrate a measurement technique for this purpose. Nearly symmetric lineshape is observed and we utilize it as thermo-optic phase shifter.

1. Introduction

It is well-known that the guided-mode resonance (GMR) in photonic crystal (PhC) slab behaves as Fano resonance because of the interference between the directly reflected light and the radiation of resonance [1][2]. From physics point of view, the GMR is essentially a photonic bound state in the continuum (BIC), an ubiquitous phenomenon that exists in many wave systems. The reflected light only carries trivial information, and hence, usually becomes an obstruction to characterize the resonance mode itself which should be in symmetric Lorentz lineshape. In this work, we demonstrate a measurement technique that suppresses the reflections beyond from optical resonance, by applying two orthogonal aligned polarizers. Almost symmetric lineshape has been observed, showing the transition from Fano resonance to Lorentz resonance.

Further, we demonstrate a novel phase manipulation functionality based on the GMR in PhC. Specifically we adopt a pair of micro-heaters to modify the refractive index of the PhC area, and hence, the resonance peak moves thermal-optically and the phase of returned light also varies. About ~1.2π phase shift is directly observed from the shifting of fringes in the interference patterns by using Michelson interferometer.

2. Principle

The principle of lineshape transition is described as following. A normalized Fano profile can be written as:

\[
I = \frac{1}{1 + \frac{q^2}{(\varepsilon + q)^2}} \frac{(\varepsilon + q)^2}{\varepsilon^2 + 1}
\]

(1)

Where \(\varepsilon\) refers to the normalized frequency and \(q\) is a shape parameter. Fig.1 (a) shows the degree of symmetry profile changes as \(q\) varies, owing to the relative strength between the localized and the continuum state [3]. In such model, the complex amplitude is given as:

\[
A = \frac{1}{\sqrt{1 + q^2}} \frac{f(\varepsilon + q)}{j\varepsilon + 1}
\]

(2)

Considering a realistic Fano resonance in the PhC slab, the quantities \(A\) and \(q\) depend on the transmission and reflection of the slab [1], as:

\[
A = \frac{jr(\varepsilon + \frac{l}{r})}{j\varepsilon + 1}, q = \frac{r}{l}
\]

(3)

It can be noticed that the phase changes \(2\pi\) for asymmetric lineshape and \(\pi\) for symmetric lineshape, when \(\varepsilon\) changes from \(-\infty\) to \(+\infty\).

Figure 1. (a) Fano resonance with different \(q\). The profile is sharply asymmetric when \(q=1\) and becomes quite symmetric when \(q=100\) since the localized state hardly couples with the continuum state; (b) Fano resonance in PhC. S-polarized incident light \(\theta =1.14^\circ\); (c) Incident light \(\theta =1.14^\circ, \phi =0.57^\circ\).

3. Measurement setup

The measurement system for high-Q resonance observation is schematically illustrated in Fig.2. A tunable laser working at 1550 nm wavelength generates an incident light which goes through the objective lens firstly and shines on the PhC sample. The reflected light is collected by the same objective lens, transformed by a group of 4F lens systems, and then imaged onto the CCD camera. The resonance
spectrum is measured by a high-sensitive photodiode (PD) while precisely sweeping the incident wavelength [4].

Since we are expecting to observe high-Q resonance, its radiation power is quite weak and easily immersed into background noise. The optical surfaces in the measurement system, such as the lens surfaces (objective lens surface in particular), bottom surface of the SOI slab, also contribute unwanted residual reflections that deteriorate the resonance signal. Such reflections can be effectively suppressed by using a “cross-polarization-filtering” technique. Specifically, since the reflections almost keep the same polarization as the incidence while the optical resonance itself doesn’t. Two perpendicularly aligned polarizers stop most of the reflections but let part of resonance pass. An almost symmetric, Lorentz-shape-like resonance peak is observed, which represents the resonance property directly.

The phase response can also be measured by using such setup. As shown in Fig.2, the incidence is split by the beam splitter (BS1). One part is reflected by a gold mirror, regarded as “reference light”, the other part returns from the sample, and denoted as “signal light”. Obviously, those two beams form a Michelson interferometer. Interference fringes can be observed at the CCD to characterize of the phase difference.

![Figure 2. Schematic of the measurement setup.](image)

**4. Results**

We fabricate the sample as shown in Fig.3 (a). It is an one-dimensional grating lying on silicon-on-insulator (SOI) wafer and a pair of S-shape metal strips working as micro-heaters [4]. The grating contains 200 bars and in footprint of 110 μm × 300 μm. Metal micro-heaters are deposited by 25 nm of titanium and 60 nm of gold. By turning the direction of polarizers, an almost symmetric Lorentz lineshape is obtained from measurement setup and Q-factor is estimated as ~12000 (Fig.3b).

The refractive index of PhC is modified as heating. When the voltage turns from 0 V to 5.4 V, the resonance peak shifts from 1539.72 nm to 1540.66 nm, which corresponds to ~1.2π phase shift, extracted from the moving of interference fringes.

![Figure 3. (a) SEM images of PhC device; (b) Reflectivity spectrum; (c) Phase response under heating.](image)

**5. Conclusions**

We demonstrate a practically useful technique to suppress the residual reflections beyond from guided-mode resonance, and the lineshape transits from asymmetric Fano-like to symmetric Lorentz-like. A thermal-optic phase shifter based on PhC is realized. Such method characterizes the optical resonance itself, and could be useful in many related fields.

Light-Matter Interaction in Antenna-based Infrared Nanocavities

Andrea Toma*

Istituto Italiano di Tecnologia, Via Morego 30, 16163 Genova, Italy
*corresponding author, E-mail: andrea.toma@iit.it

Abstract
Antenna-based resonant nanocavities can efficiently couple to other excitations/quasi particles of similar energy, giving rise to strong signal enhancement in the infrared spectral domain. In this framework, Fano-like interferences can be successfully exploited for promoting mid-infrared and THz spectroscopic studies of molecules and/or nanomaterials at extremely low concentrations.

1. Introduction
Optical antennas are playing a fundamental role in many applications ranging from enhanced spectroscopies [1] to in vivo molecular imaging [2] and non-linear interactions. Their success relies on the strong field enhancement generated in the close proximity of the structure, when the excitation of plasmon resonances is promoted. A significant number of experimental investigations have been carried out in the last decades to completely describe the electromagnetic (EM) properties of metallic structures such as nanostars, bow-tie antennas, nanoshells etc., which are now efficiently employed to address practical questions in life sciences and nano-medicine. Within this context, infrared resonant dipole antennas coupled through nanogaps [3-5] have emerged as promising architectures for improving infrared light-matter interaction, pushing the detection limit towards the single-few units.

2. Discussion
Here we would like to report our investigations on antenna enhanced infrared spectroscopy, spanning from mid-infrared detection of medically relevant molecular species to THz sensing of nano-localized quantum dots [3,5]. In both cases, when the vibrational excitation is efficiently coupled to the nanostructure resonance, the combined system shows a clear interference feature in the extinction spectra, which can be clearly ascribed to a Fano-like hybridization.

Specifically designed nanoantenna dimers with different interparticle distances (down to the 10 nm range) were prepared by electron beam lithography and optically characterized using a Fourier-transform IR microscope, coupled to a thermal glow-bar source -for the mid-IR spectral window- or to synchrotron light (ELETTRA Trieste) in the case of THz measurements.

The efficiency of antenna-based platform in enhancing infrared spectroscopy has been further improved by decoupling the antenna structures from the underlying substrate, thus allowing a more pronounced EM field concentration and spatial overlap with the analyte/nanomaterial under investigation [6]. The advantages of a “free-standing” configuration for sensing applications have been demonstrated by monitoring the vibrational signal of test molecules, achieving a signal enhancement of an order of magnitude higher than the planar counterparts.

Finally, the conjugation between vibrational modes and confined optical resonances has been extended towards the strong coupling regime [5], where intensified light-matter interaction promotes the formation of new vibro-polariton bands, which no longer belong to light or matter in a separate way.

Abstract

The electromagnetic modes and the resonances of homogeneous, finite size, two-dimensional bodies are examined in the frequency domain by a rigorous full-wave approach. The presence of vortex current modes is demonstrated. The presence of Fano resonances in the scattering from a Si disk of size comparable to the incident wavelength is demonstrated and the interfering mode behind them are shown.

1. Introduction

In the last ten years, the rise of two-dimensional materials has attracted a great amount of interest in the field of plasmonics and photonics. In terms of electrical properties, they range from the insulating hexagonal boron nitride and semiconducting transition metal dichalcogenides, to semi metallic graphene. In this work, the electromagnetic modes and the resonances of homogeneous, finite size, two-dimensional bodies are examined in the frequency domain by a rigorous full wave approach based on an integro-differential formulation of the electromagnetic scattering problem. Open and closed surfaces are considered.

2. Formulation of the problem

We use the concept of material independent modes [1, 2]. The current modes and the corresponding eigen-conductivities are solution of a linear eigenvalue problem. The eigen-conductivity $\sigma_n$ corresponding to the current mode $J_n$ is the value that the surface conductivity of the body, normalized to the vacuum admittance $1/\zeta_0$, should have so that the current mode $J_n$ is a free source solution of the Maxwell equations. The current modes and the corresponding eigen-conductivities only depend on the geometry of the body and on the frequency, they are independent of the surface conductivity $\sigma_n$. We found that the real part of the eigen-conductivity is proportional to the radiation losses of the current mode; hence, it is always negative. The imaginary part is proportional to the difference between the time average of the magnetic energy and the time average of the electric energy of the mode hence it may be either negative or positive, depending on the shape of the 2D body and on the normalized body size $kl_c$, where $l_c$ is the characteristic length of the body and $k = 2\pi/\lambda$. The existence of vortex current modes in addition to source-sink current modes (no whirling modes), which describe plasmonic oscillations, is demonstrated.

The source-sink current modes, which in the long wavelength limit ($kl_c \to 0$) are irrotational, are characterized by a number of sources and sinks of the field lines that is conserved as the ratio between the characteristic linear dimension of the body and the wavelength $kl_c$ increases. Similarly, the vortex current modes, which in the long wavelength limit are solenoidal, are characterized by a number of vortexes of the field lines that is conserved. Important topological features of the current modes, such as the number of sources and sinks, the number of vortexes, the direction of the vortexes are preserved as the size of the body and the frequency vary. The surface current density induced on the body by an external excitation $E_{inc}$ is represented in terms of the current modes

$$J = \sum_{n=1}^{\infty} \frac{\sigma_n}{\sigma_n - \zeta_0 \sigma} (J_n^* \sigma E_{inc}) J_n$$

The expansion coefficient of each current mode is equal to $\sigma_n/(\sigma_n - \zeta_0 \sigma) < J_n^* E_{inc}>$. The resonant frequency of the mode is the frequency for which $\sigma_n/(\sigma_n - \zeta_0 \sigma)$ is maximum. This expansion reveals the important physical mechanisms involved in the electromagnetic scattering and can greatly improve the way it is understood and optimized. For instance, unlike the source-sink current modes, in open surfaces the vortex current modes can be resonantly excited only in materials with positive imaginary part of the surface conductivity. Illustrative examples for open surfaces (disk, equilateral triangle, rectangle) and a closed surface (spherical surface) will be given. The scattering efficiency and the amplitude of the near electric field of a disk with either positive or negative imaginary part of the surface conductivity will be presented and analysed, the presence of Fano resonances will be highlighted.

3. Results and Discussion

Now an example of material with positive imaginary part of the surface conductivity is considered: a dielectric thin disk with relative permittivity $\varepsilon_r = 16$ (silicon), radius $l =$
500 nm and thickness $\Delta = 19.2 \text{ nm}$. The electromagnetic field scattered by it in the wavelength range from 0.5 \( \mu \text{m} \) to 1.25 \( \mu \text{m} \) is analysed. The incident electromagnetic field is a plane wave linearly polarized, propagating normally to the disk. Since the disk thickness $t$ is much smaller than its radius and the wavelength, the thin disk may be represented as a circle with equivalent surface conductivity given by

$$\zeta_0 \sigma = x \left( \frac{\Delta}{r} \right) (\varepsilon_r - 1) i$$ \hspace{1cm} (2)$$

Fig. 1 (a) shows the scattering efficiency (black line). A very good agreement is found between the scattering cross sections obtained by using the expression 1 and the scattering cross section obtained by means of a full wave three-dimensional numerical code. This fact again validates the solution 1 and the computation of the current modes and the eigen-conductivities. Several current modes contribute to the scattered electromagnetic field. The vertical dashed lines in Fig. 1 (a) indicate the values of the resonant wavelengths of the three vortex current modes shown in Figure 1 (c), $\lambda_2 = 980 \text{ nm}$, $\lambda_6 = 696 \text{ nm}$ and $\lambda_{13} = 556 \text{ nm}$. Besides these resonant modes, the first two source-sink current modes of the disk contribute to the scattered field. These two degenerate modes are off resonance because their eigen-conductivities are bounded in the region of complex plane with the imaginary part belonging to the interval $(-2.95, 0.238)$ regardless of $l/\lambda$, while the imaginary part of $\zeta_0 \sigma$ varies between 1.45 and 3.61. Even if these modes are off resonance, their coupling amplitudes with the plane wave are very high because they have a strong electric dipole moment. To highlight the contribution of the most important current modes, Figure 1(a) also shows the partial scattering efficiencies defined as the scattering efficiency obtained by considering only one mode at a time. The partial scattering efficiencies $\sigma^{(p)}_v, \sigma^{(p)}_v, \sigma^{(p)}_v$ are relevant to the three vortex current modes shown in 1 (c); $\sigma^{(p)}_{ss,1}$ and $\sigma^{(p)}_{ss,1}$, are, instead, the partial scattering efficiency of the first source-sink current modes. The destructive interferences between the broad source-sink modes and one of the narrow vortex current mode shown in 1 (c) give rise to the Fano resonances around $\lambda = 1106 \text{ nm}$, $\lambda = 711 \text{ nm}$ and $\lambda = 563 \text{ nm}$. Figure 1 (b) shows the averaged amplitude of the electric field on the disk surface. The vertical dashed lines always indicate the values of the resonant wavelengths of the vortex current modes shown in Figure 1 (c).

Bound States and Resonances in Lattice Models

Ya Yan Lu

Department of Mathematics, City University of Hong Kong, Kowloon, Hong Kong

Abstract

In this paper, we develop a general theory for bound states and resonances in locally distorted infinite or semi-infinite tight-binding lattice models. These models can be realized as waveguide arrays. We propose a finite linear matrix eigenvalue problem for computing all bound states and resonant modes. For bound states in the continuum, we establish a necessary and sufficient condition for their existence, and study their robustness with respect to structural perturbations.

1. Introduction

There is currently a significant interest in studying optical bound states in the continuum (BICs). Strong resonances appear when system parameters are slightly perturbed from their perfect values for the existence of a BIC. Applications of the BICs are either based on enhanced local fields caused by the strong resonances or the far-field (collapsing Fano) resonance features in transmission, reflection or other spectra. Infinite or semi-infinite tight-binding lattice models with local distortions are useful discrete models for a number of physical applications. In particular, they can be realized as waveguide arrays and have been used in theoretical and experimental studies on BICs [1, 2, 3, 4]. These studies are concerned with a few specific and relatively simple configurations. To the best of our knowledge, there is no general theory about BICs on such lattice models. Although most current works on optical BICs are related to physical structures that can only be analyzed by solving Maxwell’s equations rigorously, the study of lattice models helps to gain physical insight and provides useful guidelines for analyzing more complicated structures.

2. Theory

For a locally distorted semi-infinite tight-binding lattice, the governing equation can be written as

$$Ax = \lambda x,$$  

where $x = [x_1, x_2, ...]^T$ is an infinite vector, $A = \begin{bmatrix} A_n & L \\ L^T & T \end{bmatrix}$, $A_n$ is an $n \times n$ real symmetric matrix, $L$ is an $n \times \infty$ matrix with only one nonzero entry $L_{n1} = 1$, and $T$ is an infinite tridiagonal matrix with $1$’s immediately below and above the main diagonal. That is,

$$L = \begin{bmatrix} 0 & 0 & \cdots & \cdots \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \cdots & 0 \\ 1 & 0 & \cdots & \cdots \end{bmatrix}, \quad T = \begin{bmatrix} 0 & 1 & 1 \\ 1 & 0 & 1 \\ & \ddots & \ddots \end{bmatrix}.$$

The matrix $T$ corresponds to a semi-infinite tight-binding lattice with identical hopping rates (with are normalized as 1) and identical potentials (which become 0 after a shift to $\lambda$). From Eq. (1), one gets $x_{j+2} + x_j = \lambda x_{j+1}$ for $j \geq n$. For $\lambda \in (-2, 2)$, we have propagating solutions $x_j = C_1 \mu^j + C_2 \mu^{-j}$ for a complex $\mu$ on the unit circle. If $\mu$ is chosen such that $\mu^j$ represents an incoming wave, then a scattering problem can be defined by setting $C_1 = 1$. The coefficient $C_2$ is an unknown related to the reflection coefficient. The continuous spectrum is the interval $[-2, 2]$. A general eigenmode of Eq. (1) is required to satisfy

$$x_j = C_2 \mu^{-j} = x_n \mu^{n-j}, \quad j \geq n,$$  

for any $\mu$ satisfying $\mu^2 + 1 = \lambda \mu$. A bound state is an eigenmode such that $\sum |x_j|^2 < \infty$. For the special case $x_n = 0$ (thus $x_j = 0$ for all $j \geq n$), the eigenmode is a compact bound state. If $x_n \neq 0$, a (non-compact) bound state must satisfy $|\mu| > 1$. A resonant mode is always non-compact ($x_n \neq 0$), and it corresponds to a complex $\mu$ such that $\mu^{-j}$ is an outgoing wave. It can be shown that the eigenmodes satisfy the following matrix eigenvalue problem:

$$\begin{bmatrix} A_n & -J^T \\ J & 0 \end{bmatrix} \mathbf{u} = \mu J \mathbf{u},$$  

where $J = [I_{n-1}, 0]$ is an $(n-1) \times n$ matrix and it can be obtained by adding a zero column to the $(n-1) \times (n-1)$ identity matrix. The eigenvalue problem (3) has $2n-1$ eigenvalues, since the size of the matrix in the left hand side is $(2n-1) \times (2n-1)$. A zero eigenvalue of Eq. (3) does not correspond to a “physical” eigenmode that must satisfy Eq. (2). Non-zero eigenvalues of Eq. (3) can be classified as: (1) BICs, (2) compact bound states outside the continuum (BOCs), (3) non-compact BOCs, (4) improper modes, (5) resonant modes, and (6) time-reversal of resonant modes.

Since the matrix in Eq. (3) is real, the eigenvalues $\mu$ are either real or complex conjugate pairs. A complex conjugate pair $\{\mu, \overline{\mu}\}$ on the unit circle (of the complex $\mu$ plane)
corresponds to one BIC. It has to be compact and the corresponding \( \lambda \) is in \((-2, 2)\). A complex conjugate pair inside the unit circle corresponds to a resonant mode and its time-reversal. The time-reversal of a resonant mode is an eigenmode with an incoming wave from infinity. These modes are always non-compact and the corresponding \( \lambda \) is complex. It can be proved that Eq. (3) cannot have a complex conjugate pair outside the unit circle. A real eigenvalue \( \mu \) satisfying \(|\mu| > 1\) always gives a bound state. In that case, 
\[ \lambda = \mu + 1/\mu \] 
is real and \(|\lambda| > 2\). If the corresponding eigenvector gives \( x_n \neq 0 \), the eigenmode is a non-compact BOC. If \( x_n = 0 \), it is a compact BOC. A real eigenvalue \( \mu \) in \((-1, 1)\) must be classified according to \( x_n \). If \( x_n \neq 0 \), it corresponds to an improper mode that grows exponentially as \( j \to \infty \). If \( x_n = 0 \), it is a compact BOC.

Compact eigenmodes must satisfy

\[
A_n x_n = \lambda x_n, \quad x_n = 0, 
\]

(4)

where \( x_n = [x_1, x_2, \ldots, x_n]^T \). Both BICs (which are always compact) and compact BOCs satisfy Eq. (4). If we let

\[
A_n = \begin{bmatrix} B & c \\ c^T & d \end{bmatrix}, \quad x_n = \begin{bmatrix} y \\ x_n \end{bmatrix}, \quad y = \begin{bmatrix} x_1 \\ \vdots \\ x_{n-1} \end{bmatrix}.
\]

then the compact modes satisfy

\[
By = \lambda y, \quad c^T y = 0.
\]

(5)

Using Eq. (5), the compact modes can be easily solved. If \( \lambda \in (-2, 2) \), the solution is a BIC, and if \(|\lambda| > 2\), it is a compact BOC. It is interesting to note that if the matrix \( B \) (or \( A_n \)) has a multiple eigenvalue, then compact modes always exist. Since \( B \) is symmetric, the eigenspace corresponding to a multiple eigenvalue has dimension larger than 1, and it is always possible to choose a non-zero vector \( y \) in the eigenspace such that \( c^T y = 0 \). For a multiple eigenvalue of \( A_n \), it is always possible to choose a vector in the eigenspace with zero entry at the bottom. The BICs what [2] and [4] are examples of multiple eigenvalues.

The BIC of [3] is symmetry-protected. We can use Eq. (5) to understand symmetry-protected BICs (and compact BOCs). Let \( P \) be a real \((n-1) \times (n-1)\) matrix such that \( P^2 = I \), we say the structure is symmetric if

\[
P B = B P, \quad P^T c = c.
\]

(6)

In that case, the eigenvectors of matrix \( B \) must satisfy (or can be chosen to satisfy, for multiple eigenvalues) either \( P y = y \) (symmetric) or \( P y = -y \) (anti-symmetric). An anti-symmetric mode corresponds to a symmetry-protected bound state. Since \( c^T y = c^T P y = (P^T c)^T y = -c^T y \), we have \( c^T y = 0 \). As usual, the symmetry-protected compact bound states are robust to symmetry-preserving perturbations. That means, if we perturb \( B \) and \( c \) such that Eq. (6) remains valid, then we have an anti-symmetric compact bound state with a slightly different \( \lambda \).

In general, a perturbation of the structure will turn a BIC to a resonant mode. Using Eq. (3), the complex \( \mu \) of the resonant mode can be calculated. If the strength of the perturbation is \( \delta \), the \( Q \)-factor of the resonant mode is usually \( Q(1/\delta^2) \). However, if we add one parameter depending on \( \delta \), it is possible to preserve the BIC. More precisely, assuming the structure described by matrix \( B \) and vector \( c \) has a BIC with eigenvector \( y \) and eigenvalue \( \lambda \in (-2, 2) \), and if \( B \) is perturbed to \( B + \delta B_1 \) where \( B_1 \) is a real symmetric matrix and \( y \) is not an eigenvector of \( B_1 \), \( c_1 \) is a given vector such that \( c_1^T y \neq 0 \), then for small but arbitrary \( \delta \), there is a \( \beta \), depending on \( \delta \), such that the system corresponding to \( B + \delta B_1 \) and \( c + \beta c_1 \) also has a BIC. This is quite similar to propagating BICs on periodic structures [5]. In that case, when the structure is perturbed (preserving the required symmetries), a BIC continue to exist, but only for a slightly different Bloch wavenumber.

3. Conclusion

For locally distorted tight-binding lattice models, we developed a general theory for computing and analyzing bound states (in or outside the continuum) and resonant modes. Formulated as a finite matrix eigenvalue problem, all modes can be easily calculated and BICs can be easily obtained. Based on the new formulation, we developed perturbation theories for BICs. In particular, special perturbations that preserve the BICs are obtained.

Abstract

A generic model of two antennas type dissimilar resonators coupled both via near-field and far-field coupling with active gain and/or loss media is considered. Conditions required for hitting the dark mode operation are established. It is shown that tuning the material gain level is effective in cancelling the detrimental effect of deviations from nominal values of resonant elements unavoidably caused by fabrication imperfections. The considered approach can be used for the implementation of high-contrast tunable metasurfaces.

1. Introduction

One of the most promising applications of metallic nano-resonators is their use as sensors for the detection of biological or chemical species adsorbed on their surface. The sensing detection limit and accuracy is expected to be greatly enhanced when operating at the exceptional point (EP) [1,2] or by using narrow width spectral features associated with Fano-type resonance occurring in the near vicinity of a dark mode (DM) [3]. Experimentally however, achieving operation right at the EP or DM is far from being trivial [4,5]. Unavoidable fabrication imperfections result in deviation of the geometrical size of nanoresonators and of their spatial positioning off nominal ones. Adjunction of a fine tuning mechanism in the system is then required. Conventional tuning mechanisms rely on the variation of the resonant elements refractive index, achieved either thanks to micro-mechanical actuators or through electrically addressable means such as electro-refractive effect, charge density variation and temperature change. The aim of the current contribution is to explore a different approach, where the tuning mechanism relies on the variation of the imaginary part of the refractive index that can be achieved through gain or absorption modulation in resonant nano-resonators.

2. Couple mode theory model

To this end we consider a system of two coupled antennas type resonators with resonant frequencies \( \omega_1 \) and \( \omega_2 \) and material gain or absorption rate \( g_1 \) and \( g_2 \), as well as radiation decay rates \( \gamma_1 \) and \( \gamma_2 \) [6]. The scattering matrix of such system is:

\[
S = C + iV \left[ \alpha \mathbf{l} - H_{\text{eff}} \right]^{-1} V^\dagger
\]  

where \( C \) is the background scattering which does not interact with resonator, \( V \) is the radiation-resonator coupling. The effective Hamiltonian \( H_{\text{eff}} \) can be described as:

\[
H_{\text{eff}} = \begin{pmatrix} \omega_1 & \kappa & \omega_2 \\ \kappa^* & \omega_1 & \omega_2 \\ 0 & 0 & \kappa' \end{pmatrix} + i \begin{pmatrix} \gamma_1 & \gamma_0 & \gamma_2 \\ \gamma_0^* & \gamma_1 & \gamma_2^* \\ 0 & 0 & \gamma_0 \end{pmatrix} + i \begin{pmatrix} g_1 & 0 & 0 \\ 0 & 0 & g_2 \end{pmatrix}
\]

It is assumed that the coupling coefficient \( \kappa \) related to near-field evanescent tunneling is real, while the radiative (far-field) coupling to the environment provided by \( i\gamma_0 = i\sqrt{\gamma_1 \gamma_2} \) is imaginary. The eigenvalues \( \omega_0 \) of \( H_{\text{eff}} \) are poles of the \( S \) scattering matrix and correspond to sharp features in the spectral response. While most of the parameters \( (\omega_0, \gamma_0, \kappa) \) entering in \( H_{\text{eff}} \) can be engineered by design, they can take only fixed values especially in metallic nano-resonators. Once fabricated it is not possible to adjust any more their frequency, their radiative decay rate or coupling strength between them. The only experimentally available degrees of freedom are the incident light frequency and also the material gain (loss) gain level \( g_0 \) that can be varied either by means of electrical current injection or optical pumping.

3. Results and discussion

3.1. Operation at the exceptional point

The first point of our analysis concerns examination of the requirements for attaining an EP. The real and imaginary parts of \( \omega_0 \) and \( \omega_0 \) eigenvalues coalesce at the EP when the following conditions are simultaneously fulfilled:

\[
\delta = \omega_1 - \omega_2 = -2\gamma_0 \quad \text{and} \quad \kappa = (\gamma_1 + g_1 - \gamma_2 - g_2)/2
\]

As it can be seen, the target resonators detuning \( \delta \) depends solely on the radiative coupling. Thus, \( \delta \) cannot be adjusted through gain variation to attain exactly the EP. This is at variance with the use of gain to bring the \( \kappa \)-induced splitting to zero at an EP in the PT-symmetry context. In addition, operation at the EP is also a poor option in terms of the large gain it requires. A high quality factor resonance at the EP implies \( \text{Im}(\omega_0) \rightarrow 0 \). This only occurs at the condition

\[
\gamma_1 + g_1 = \gamma_2 + g_2 = 0
\]  

In other words, the gain of each resonator should exactly compensate its radiative losses. As
will be shown below, DM operation is more favorable since it requires much less gain (temporal gain, in Haus’ theory).

3.2. DM operation without threshold gain condition

The DM condition corresponds to the cancellation of the imaginary part of antisymmetric mode [3]. It requires to simultaneously satisfy the condition for resonators detuning:

$$
\delta = \frac{\kappa \gamma_0 (Y_1 + g_1 - Y_2 - g_2)}{(\gamma_2 g_1 + g_2 g_1 + \gamma_1 g_2)}
$$

(4)

as well as either of the two conditions of Eq.(5) below:

$$
\gamma_0 g_2 + \gamma_2 g_1 + g_2 g_1 = 0 \quad (5a)
$$

$$
\kappa^2 + \gamma_1 g_1 + \gamma_2 g_2 + g_2 g_1 + g_1 g_2 = 0 \quad (5b)
$$

Eq. (5a) corresponds to the “thresholdless” gain operation for reaching the DM. Indeed, considering that \( g_1 > 0 \) is the absorption loss level in the first resonator, it directly follows from Eq. (5a) that the second resonator gain must obey:

$$
g_2 = -\frac{\gamma_2 g_1}{\gamma_1 + g_1} \quad (6a)
$$

In the limit of \( g_1 \ll \gamma_1 \), \( g_2 \rightarrow -g_1/\gamma_1 \). This means that in theory the required gain level \( g_2 \) can be arbitrary small, even much lower than the loss \( g_1 \), provided that \( \gamma_2 \ll \gamma_1 \). Another remarkable feature is that the gain condition given by Eq. (5a) is independent of the coupling strength \( \kappa \). Though detuning \( \delta \) between resonators expressed by Eq. (4) is sensitive to \( \kappa \), its deviation from nominal value can be adjusted through either variation of the gain level \( g_2 \) or loss level \( g_1 \). This is illustrated by Fig. 1a representing evolution of the real and imaginary parts of eigenvalues \( \omega_2 \) as a function of \( \omega_2 \) for a fixed \( \omega_0 \) value and three different values of \( g_2 \) [lower, equal or higher than gain \( g_1 \) given by Eq. (6a)].

3.3. DM operation with threshold gain condition

The evolution of Re(\( \omega_0 \)) and Im(\( \omega_0 \)) as a function of \( \omega_2 \) with \( \omega_0=0.5 \), \( \gamma_1=0.03 \), \( \gamma_2=0.015 \), \( \kappa=0.0175 \); \( g_1=0.01 \). Target DM indicated by bold black point. a) “thresholdless” DM regime; b) DM regime with threshold gain condition.

4. Conclusions

Tunability mechanisms based on gain or loss variation in a system of two coupled antenna-type nano-resonators were considered. Conditions corresponding to the operation in the dark mode regime were identified. It was found that the optimal configuration in terms of lowest gain to be supplied corresponds to a system composed of gain and loss resonators with highly asymmetric radiative rates (\( \gamma_2/\gamma_1 \)) and detuned resonance frequencies. The considered approach can be exploited for the implementation of tunable metasurfaces with high-contrast.

Rigorous modal analysis of photonic micro and nanoresonators

Philippe Lalanne¹, Wei Yan²

¹LP2N, Institut d’Optique Graduate School, CNRS, Univ. Bordeaux, 33400 Talence, France

Abstract

The most general motion of a system is a superposition of its normal modes, or eigenstates. For Hermitian system, classical normal mode theory applies. For non-Hermitian systems, presently a lot of progress is done to describe the response of optical micro and nanoresonators in their quasinormal mode basis. We have developed a rigorous modal analysis of electromagnetic resonators with unprecedented generality and report numerical results for the general case of 3D resonators, made of dispersive materials on substrate with guiding layers.

1. Introduction

Modes are central in physics, chemistry ... In optics, modes are self-consistent electromagnetic field distributions in waveguides, optical resonators or in free space (plane waves, Hermite–Gaussian modes ...). In waveguide and free space, they are well documented in the literature, as shown by several textbooks on Fourier optics and optical waveguide theory (Vassalo, Snyder & Love, Marcuse, Collin).

We cannot find any textbook on the modal theory of resonators, although nanoresonances play an essential role in current developments in nanophotonics, e.g., optical metasurfaces, integrated optics, optical sensing, photovoltaic devices... The reason is due to mathematical difficulties, see details in the recent review article [1], and especially to the fact that optical resonators are non-Hermitian systems; their physics is not driven by classical normal modes that can be normalized by their energy, but by quasinormal modes (QNM) with complex frequencies.

In 2013, a general method was proposed to normalize the quasinormal modes of any resonator [1], generalizing earlier works for simple 1D geometries or spheres [2-3]. From that time, the research on the modal theory of resonator has increased at a fast rate. The same year, a freeware was launched [4]. The freeware can be used by any Maxwell equation solver (surface integral methods, volume integral methods, finite element methods, other Fourier expansion, finite element methods with and without PMLs). The only exception seems to be the FDTD method. This year, the first benchmark paper [5] on the computation and normalization of quasinormal modes has been published. The publication, coauthored by 20 researchers from 9 institutions, benchmarks several methods for three geometries of wide interest in modern optics: a two-dimensional plasmonic crystal, a two-dimensional metal grating, and a three-dimensional nanopatch antenna on a metal substrate. We are close to elaborate standards for the computation of resonance modes. Presently, about 10 theoretical groups in the world are developing a modal theory for analyzing light scattering by resonators, see the recent review article published on the subject that gathers the contribution of all in a comprehensive way [6]. Progress is impressive.

Hereafter, we report on our recent work that provides a significant improvement of the state of the art, with respect to several point, the most important being the versatility and the generality of the theory and the numerical results obtained for complicated structures.

2. Main result

The theory has been reported in a recent paper [7] that we summarize hereafter. Of particular importance in the present context is the successful generalization of the auxiliary-field method, originally proposed for simulating dispersive media with finite difference time-domain simulations [8] and computing the band diagram of dispersive crystals [9], to compute the quasinormal modes of open resonators with finite element methods.

- The quasinormal modes are defined in an extended basis that comprises the electric E and magnetic H fields, like before, but which additionally comprises the polarisation P and current J fields. For the first time it is thus the whole resonance eigenstates that are computed: the modes disentangle the resonance associated to the geometry (basically associated to the E and H fields) and the resonance associated to the material (basically associated to the P and J fields).

- This allows us to successfully implement a quasinormal mode solver that efficiently computes the eigenstates of photonic and plasmonic resonators. The associated freeware QNMFig that relies on a COMSOL Multiphysics computational platform can be downloaded on the website of the group.

- On the theoretical side, another important consequence of the auxiliary-field method is a net physical interpretation of temporal dispersion, which lead us to
derive orthogonality relations in the augmented formulation for resonances made of dispersive media. Such a derivation that was not possible in earlier works with unspecified dispersion relation [6] leads to the important proposition of closed-form expressions for the eigenstate excitation coefficients.

- The following figure shows the results obtained for a silver nanobullet deposited on a Si slab and illuminated from the far-field by a plane wave. It compares the prediction of the far-field and guided-mode radiation diagrams obtained with the freeware and with classical simulations performed with COMSOL. The complexity of the present geometry, unprecedented in modal simulations performed with COMSOL, also greatly expands the capabilities of analyzing electromagnetic resonance in nanophotonics, offering increased physical insight and improved computational tools. With respect to the physics of light interaction with micro and nanoresonators, the new theory that rely on a mathematically-safe normalization of the quasinormal modes leads to a quantitative understanding of how light interact with non-hermitian systems. Many basics can be revisited, sometimes significantly, including the definition of cavity Q’s (please take for a moment a critical view on how to define the energy stored inside a photonic crystal cavity or a nanoantenna) [6] and of the mode volume [1,8], an accurate formula for the Purcell effect [1], the strong coupling of a quantum emitter and a cavity mode [6], cavity perturbation theory [1] cavity perturbation theory, Fano lineshapes.

Magnetic interactions and transport properties of parallel coupled magnetic molecules in presence of spin-orbit interactions.

S. Alwan and J. Fransson*
Department of Physics and Astronomy, Uppsala university, Uppsala, Sweden
*corresponding author: Jonas.Fransson@physics.uu.se

Abstract-Parallel coupled quantum dots embedded in a tunnel junction is a typical system that exhibits Fano resonances. Here, we consider magnetic molecules in a similar geometry and consider the electronically mediated magnetic interactions between the localized spins as function of the gate and bias voltages. In particular, we demonstrate that spin-orbit coupling enables an additional control parameter for the Fano resonances. Depending on the phase of the spin-orbit interaction, the asymmetry of the Fano resonance can be shifted from, e.g., dip-peak to peak-dip. This property leads to dramatic variations in the exchange parameters, and the anisotropic interactions are shown to be particularly sensitive to such variations.

Previous predictions of electrical and thermal control of magnetic exchange interactions between localized spin moments in, e.g., magnetic molecules have revealed the ability to fine tune gate and bias voltages in order to deliberately go between regimes of ferromagnetic and anti-ferromagnetic exchange [1–3]. These studies have been focused on serially coupled molecules in which it is well known that interference phenomena such as Fano resonances are normally not occurring. In quantum dots coupled in parallel, however, Fano resonances are known to exist and are well captured within the traditional two-path structure, see e.g., [4], which serve as a prerequisite for the effect. Here, we consider the electronically mediated magnetic interactions between the localizes spin in magnetic molecules. In particular, we address the dependence of the magnetic interactions on the gate and bias voltages between the leads. In a quite similar fashion as in the serially coupled system, we show that the exchange interaction can be controllably fine tuned between ferromagnetic and anti-ferromagnetic by means of the external control variables. In addition to this control, we also show that sudden absences of the exchange are correlated with Fano resonances and since the transport properties are deeply connected with the magnetic configuration of the spin dimer, this provides a unique way to study the Fano interference phenomena and its influence on magnetic systems.

Abstract

We provide detailed comparisons between experimental findings and numerical simulations of large cooperatively interacting, spatially disordered metamaterial arrays, consisting of asymmetrically split rings. Simulation methods fully incorporate strong field-mediated inter-meta-atom interactions between discrete resonators and statistical properties of disorder, while approximating the resonators’ internal structure. Despite the large system size, we find a qualitative agreement between the simulations and experiments, and characterize the microscopic origins of the observed disorder response. Our microscopic description of macroscopic electrodynamics reveals how the response of disordered arrays with strong field-mediated interactions is inherently linked to their cooperative response to electromagnetic waves where the multiple scattering induces strong correlations between the excitations of individual resonators. We show how the effects of disorder and cooperative interactions are mapped onto the transmission resonance in the far field spectrum. In the near field response we find substantially increased standard deviation of the Purcell-enhancement with disorder, making it increasingly likely to find collective excitation eigenmodes with very high Purcell factors that are also stronger for magnetic than electric excitations. We show that disorder can dramatically modify the cooperative response of the metamaterial even in the presence of strong dissipation losses as is the case for plasmonic systems.

1. Introduction

Disordered media and propagation of waves through them is a ubiquitous theme across physics. While metamaterials have so far been almost solely based on regularly structured resonator arrays, there is an increasing interest in extending these also to the realm of disordered systems, where disorder is introduced either in the form of inhomogeneous broadening or as random perturbations in the resonator positions. Whereas the former can affect the strength of inter-

Figure 1: Far field spectrum of microwave and optical plasmonic arrays with varying degree of disorder. The blue lines represent scattering from ordered arrays, and the red and black lines represent scattering from arrays with an increasing disorder.

Figure 2: The effects of density on the collective uniform magnetic eigenmode. Excitations of a single eigenmode with varying lattice spacing a for regular (a-c) and disordered (d-f) ASR arrays. The corresponding lattice spacings (in the units of a wavelength) are a = 0.28 (a,d), 0.83 (b,e), and 1.4 (c,f).
actions between the resonators, the latter can lead to qualitative changes in the response of the resonator array. We study the near- and far-field responses of positionally disordered metamaterial arrays consisting of asymmetrically split rings (ASRs). Our approach includes numerical simulations of the full metamaterial array, where each meta-atom is considered individually, and experimental near- and far-field measurements. We show how the response of disordered system is inherently linked to strong field-mediated interactions between the resonators that induce correlations between the excitations of different resonators and cannot be described by effective continuous medium theories of electrodynamics. We find that the dramatic difference between the responses of regular and disordered arrays manifests itself most clearly in the microscopic properties of collective radiative excitation eigenmodes. Our findings indicate that this sensitivity of the cooperative response on disorder strength depends heavily on dissipation losses. In the case of low-loss (microwave) ASR arrays, manifestations of disorder-induced collective phenomena are readily observed. On the other hand, careful engineering of the metamolecule properties allows the observation of such phenomena even in the case of plasmonic, lossy metamaterial systems operating in the optical part of the spectrum.

2. Disorder responses

In Fig. 1 we show the far field spectrum for different strengths of disorder. The reflection spectrum displays a Fano resonance that directly conveys information on the collective radiative excitation eigenmodes of the system. The cooperative response of the metamaterial array is sensitive to the density of the resonators as illustrated in Fig. 2. Numerically simulated near-field localization for different strengths of disorder is shown in Fig. 3. The effects of disorder on the Purcell factors in terms of the collective excitation eigenmodes is described in Fig. 4.

3. Conclusions

We have characterized the effects of spatial disorder in near- and far-field response in terms of collective excitation eigenmodes in strongly interacting, cooperatively radiating metamaterial arrays.

Photonic crystal structures treated by the resonant state expansion

Sam Neale and Egor A. Muljarov

School of Physics and Astronomy, Cardiff University, Cardiff CF24 3AA, United Kingdom

The resonant state expansion (RSE) is a novel rigorous method for calculating resonant states (RSs) of a photonic system [1]. These are the eigensolutions of Maxwell's wave equation (MWE) with outgoing boundary conditions. Using a complete set of RSs of a simpler system as a basis, the RSE makes a mapping of MWE onto a linear eigenvalues problem, determining the full set of the RSs of a complex system.

In addition to higher numerical efficiency [2,3] compared to other computational methods, the RSE provides an intuitive physical picture of resonant phenomena, capable of explaining features observed in optical spectra. So far the RSE has been applied to finite open optical systems of different geometry and dimensionality, as well as to homogeneous and inhomogeneous planar waveguides [3]. Very recently, the RSE was generalized to magnetic, chiral and bi-anisotropic optical systems [4], enabling its further application to metamaterials. The RSE has been also used in first perturbation order for photonic crystal (PC) structures to describe the refractive index sensing [5], and a rigorous analytic normalization of the RSs in PC structures has been presented [5,6].

Here, we develop a PC-RSE, a new rigorous approach for accurate calculation of RSs in planar PC structures using a homogeneous slab as basis system. The periodicity of PC structures mixes all possible Bragg harmonics. Therefore, the basis RSs have to be taken with different in-plane wave numbers. As a result, the Green’s function of MWE has branch cuts in the complex frequency plane, which have to be taken into account in the PC-RSE along with the RSs. This presents the major complication of the PC-RSE which we have dealt with by splitting the cuts into series of discrete, artificial cut states added for completeness to the basis of RSs [3]. Using for illustration a dielectric slab periodically modulated in one direction, we demonstrate the accuracy and efficiency of the PC-RSE for finding the RSs of photonic crystals.

We further study bound states in the continuum (BIC) of a dielectric photonic-crystal slab. We show in particular how different types of RSs of a homogeneous slab contribute to BIC and compare these contributions with other resonances of the photonic-crystal system, such as waveguide, quasi-guided [7] and Fabry-Perot modes.

Interaction between dielectric particles enhances the Q-factor

Abstract

We study behavior of resonant modes with a distance between two identical dielectric cylinders and disks. We reveal two basic scenarios of evolution of resonances with the distance between the cylinders. For larger distances and respectively weaker interaction of particles the resonances are bound around the Mie resonances and evolve by spiral way. For shorter distances and respectively stronger interaction the resonances bypass the Mie resonances. Both scenarios demonstrate considerable enhancement of the Q factor compared to the case of isolated particle.

1. Introduction

It is rather challenging for optical resonators to support resonances of simultaneous subwavelength mode volumes and high Q factors. The traditional way for increasing the Q factor of optical cavities is a suppression of leakage of resonance mode into the radiation continua. That is achieved usually by decreasing the coupling of the resonant mode with the continua by the use of metals, photonic band gap structures, or whispering-gallery-mode resonators. All of these approaches lead to reduced device efficiencies because of complex designs, inevitable metallic losses, or large cavity sizes. On the contrary, all-dielectric subwavelength nanoparticles have recently been suggested as an important pathway to enhance capabilities of traditional nanoscale resonators by exploiting the multipolar Mie resonances being limited only by radiation losses [1, 2].

The decisive breakthrough came with the paper by Friedrich and Wintgen [3] which put forward the idea of destructive interference of two neighboring resonant modes leaking into the continuum. Based on a simple generic two-level model they formulated the condition for the bound state in the continuum (BIC) as the state with zero resonant width for crossing of eigenlevels of the cavity or avoided crossing of resonances. This principle was later explored in open plane wave resonator where the BIC occurs in the vicinity of degeneracy of the closed integrable resonator [4].

However, these BICs exist provided that they embedded into a single continuum of propagating modes of a directional waveguide. In photonics the optical BICs embedded into the radiation continuum can be realized by two ways. The first way is realized in an optical cavity coupled with the continuum of 2d photonic crystal (PhC) waveguide [5] that is an optical variant of microwave system [4]. Alternatively way is the use periodic PhC systems (gratings) or arrays of dielectric particles in which resonant modes leak into a restricted number of diffraction continua [6, 7, 8, 9, 10]. Although the exact BICs can occur only in infinite periodic arrays, the finite arrays demonstrate resonant modes with the very high Q factor which grows quadratically [11] or even cubically [12] with the number of particles (quasi-BICs). Even arrays of five dielectric particles demonstrate the Q factor exceeding the Q factor of individual particle by six orders in magnitude [13].

Isolated subwavelength high-index dielectric resonators are more advantageous from an applied point of view to achieve high Q resonant modes (super cavity modes) [2, 14, 15]. Such super cavity modes originate from avoided crossing of the resonant modes, specifically the Mie-type resonant mode and the Fabry-Pérot resonant mode under variation of the aspect ratio of the dielectric disk which could result in a significant enhancement of the Q factor. It is worthy also to notice the idea of formation of long-lived, scar like modes near avoided resonance crossings in optical deformed microcavities [16]. The dramatic Q factor enhancement was predicted by Boriskina [17, 18] for avoided crossing of very highly excited whispering gallery modes in symmetrical photonic molecules of dielectric disks on a surface.

In the present paper we consider a similar way to enhance the Q factor by variation of the distance between two identical dielectric cylinders and coaxial disks as sketched in Fig. 1. As different from papers [16, 17, 18, 19, 20] we consider the avoided crossing of low excited resonant modes (monopole, dipole and quadruple) with variation of the distance between two cylinders. Because of lifting of the axial symmetry many Mie resonances contribute into the resonances of two cylinders which show two basic scenarios of evolution of the distance, bound to the Mie resonances and unbound. The same scenarios show the resonances of two coaxial dielectric disks however with those difference that for small distance between them there might be avoided crossing of different resonances of the isolated disk.
Inside the cylinders we have

$$\psi_1 = \sum_n B_{1n} H_n^{(1)}(kr_1) e^{in\theta},$$

$$\psi_2 = \sum_n B_{2n} H_n^{(1)}(kr_2) e^{in\theta}.$$  

By means of the Graf formula [24]

$$H_n^{(1)}(kr_1) e^{in\theta_1} = \sum_m i^{m-n} H_m^{(1)}(kL) J_m(kr_2) e^{im\theta_2} \tag{5}$$

$$H_n^{(1)}(kr_2) e^{im\theta_2} = \sum_m i^{m-n} H_m^{(1)}(kL) J_m(kr_1) e^{in\theta_1} \tag{6}$$

the total field $\psi = \psi_{inc} + \psi_1 + \psi_2$ can be written completely in the coordinate system of either cylinder.

Applying the boundary conditions at $r_j = a$ leads to [21, 23]

$$A_{1n} = i^n S_n(k) \sum_m i^{-m} H_{n+m}(kL) A_{2m},$$

$$A_{2n} = i^n S_n(k) \sum_m i^{-m} H_{n+m}(kL) A_{1m}, \tag{7}$$

where $S_n$ are the scattering matrix amplitudes for the isolated cylinder

$$S_n(k) = \frac{\sqrt{\epsilon} J_m(\sqrt{\epsilon}kL) J_m(kL) - J_m(kL) J_m(\sqrt{\epsilon}kL)}{H_n^{(1)}(kL) J_m(\sqrt{\epsilon}kL) - \sqrt{\epsilon} J_m(\sqrt{\epsilon}kL) H_n^{(1)}(kL)}. \tag{8}$$

The resonances are given by the complex roots of the following equation

$$\text{Det}[[\hat{M}]^2 - I] = 0 \tag{9}$$

where matrix elements $\hat{M}$ is given by Eq. (7) and equal

$$M_{mn} = S_m(k) i^{m-n} H_{n+m}(kL) \tag{10}$$

and $I$ is the unit matrix. In what follows the dimensionless complex eigenvalues $k$ are measured in terms of $c/a$ where $c$ is the light velocity and $a$ is the radius of cylinders and $L$ is measured in terms of $a$.

In general Eq. (9) has an infinite number of complex resonant frequencies $k = k_r - i k_i$. The total view of the dependence of resonant eigenvalues is shown in Fig. 3 which demonstrates complicated evolution of resonant poles against the distance between the cylinders. First of all one can see the major part of the resonances are unbound bypassing the Mie resonances of the isolated cylinder marked by crosses which are collected in Fig. 4. Second, there are a small part of resonances which are bound around the Mie resonances with smaller imaginary parts.

Let us consider the asymptotic behavior of resonances for $L \to \infty$. By use of asymptotical behavior of the Hankel functions [25] we have for matrix (10) the following

$$M_{mn} \sim \sqrt{\frac{2}{\pi kL}} e^{i(kL - \pi/4)} S_m(k)(-1)^n. \tag{11}$$

Let us take the eigenvector of matrix $\hat{M}$

$$\psi^+ = (\psi_1, \psi_2, \psi_3, \ldots).$$

Then Eq. (9) takes the following form

$$\sqrt{\frac{2}{\pi kL}} e^{ikL} S_m(k) \sum_n (-1)^n \psi_n = \pm \psi_m. \tag{12}$$
Figure 3: The behavior of resonant frequencies vs the distance between cylinders. Open green circles correspond $L = 1000a$, closed red circles correspond to minimal distance $L = 2a$, where $a$ is the radius of cylinders and black crosses are the Mie resonances shown in the next Fig. 4.

Figure 4: The Mie resonant complex eigenfrequencies (close circles) and corresponding resonant modes (the component $E_z$) of isolated cylinder.

which has the solution provided that

$$\sqrt{\frac{2}{\pi kL}} e^{ikL} \sum_n (-1)^n S_n(k) = \pm 1. \quad (13)$$

For the absolute value we have

$$\frac{2e^{\gamma_n L}}{\pi |k_n| L} \frac{1}{|\sum_n (-1)^n S_n(k)|^2} \quad (14)$$

where $\gamma_n = -2\text{Im}(k_n)$. The resonances of the isolated cylinder are given by poles of the S-matrix, i.e., by equation $\frac{1}{S_m(k)} = 0$. Therefore from (14) it follows that, first, the resonances of two cylinders do not converge to the resonances of the isolated cylinder. Second, because of finite value of right hand side of Eq. (14) the line widths and resonance positions limit to zero at $L \to \infty$. Therefore we can conclude that the resonances of two dielectric cylinders do NOT limit to the Mie resonances of the isolated cylinders at $L \to \infty$. The reason is related to to the exponential factor $\exp(\gamma_n L)$ of the resonant modes (the Gamov states) at large distances between the cylinder.

Next, we consider the behavior of some typical resonances in Fig. 4 in detail from the limiting case $L = 2a$ to $L = 1000a$. Due to the symmetry of the system relative to $x \to -x$ and $y \to -y$ the resonant modes can be classified as $\psi_{\sigma,\sigma'}$ where the indices $\sigma = s, a$ correspond to the symmetric and antisymmetric modes respectively. We start with the first two lowest symmetric and antisymmetric monopole resonant modes $\psi_{s,s/a}$. Fig. 5 (b) shows that the $Q$ factor of the antisymmetric monopole resonance exceeds the $Q$ factor of the isolated cylinder by one order in magnitude. The reason for that follows from the Mie resonances shown in Fig. 4. As seen from Fig. 5 (a) at the closest distance between the cylinders $L = 2a$ the symmetric resonant mode becomes the monopole mode with corresponding $Q$ factor close to the $Q$ factor of isolated cylinder which is rather low as marked by cross in Fig. 5 (b). At the same time the antisymmetric mode of two cylinders at $L = 2a$ becomes the dipole resonance which as seen from Fig. 4 has the $Q$ factor exceeding the $Q$ factor of the monopole Mie resonance by one order in magnitude. The next resonances illustrate that the evolution of resonances strongly
depend on interaction between the cylinders via the radiating Mie resonances. The general expressions and physical origin of the coupling of dielectric resonators was considered in Refs. [26, 27, 28]. The coupling constant can be written as [27]

$$\kappa = \int dv [\epsilon(\vec{r}) - 1] \vec{E}_1 \cdot \vec{E}_2$$

where $\vec{E}_{1,2}$ are normalized solutions by the factor $\sqrt{\int \epsilon(\vec{r})|\vec{E}_{1,2}|^2 dv}$. Here the indices 1 and 2 imply the resonant modes of the corresponding dielectric particles. The coupling constant is determined by overlapping of resonant modes which in turn depend on the distance between the particles and prevailing direction of radiation of the modes.

That conclusion is well illustrated by the Mie dipole resonant modes which are degenerate. The first dipole Mie resonant mode, symmetric relative to $x \rightarrow -x$, radiates prevalently towards the neighboring cylinder as shown in insets in Fig. 6 while the second antisymmetric dipole Mie resonant mode radiates away from the neighboring cylinder as shown in insets of Fig. 7. As a result the interaction in former case turns out stronger compared to the latter case as it follows from Eq. (15). That explains why the evolution of resonances shown in Fig. 6 (a) is similar to the case of interaction via the monopole resonant modes in Fig. 5 while the evolution of resonances in Fig. 6 is bound to the Mie dipole resonance 2 as seen from Fig. 6 (a). Respectively the gain in the $Q$ factor in the former case is smaller than in the latter case as seen from Figs. 6 (b) and 7 (b).

With further increase of the distance $L$ the resonance bypasses the Mie monopole resonance 1 of the isolated cylinder. As a result the solution of the Maxwell equations becomes close to the resonant mode $\psi_{s,s/a}$. That rule for the solutions when the resonances bypass the Mie resonances is fulfilled for all other resonances as one can see from Fig. 8. Similar evolution scenarios can be observed for the quadruple resonances shown in Fig. 9 (a). In this case the Mie resonant mode radiates from one cylinder to another that gives rise to interaction between cylinders stronger than the case of the modes $\psi_{s,s/a}$ shown in Fig. 8 (c). Both cases result in interaction weaker than the case of dipole Mie resonances. As a result in both cases one can observe that the resonances are bound around the Mie quadruple resonance 3 shown in Fig. 4 for distances from $L = 2a$ to $L = 350a$. However, in the first case of stronger interaction between the cylinders the resonances $\psi_{s,s/a}$ go away from the initial Mie resonance 3 and consequently go to zero bypassing the Mie resonance 2 as seen in Fig. 4. Meanwhile in the second case of weaker interaction the resonances $\psi_{a,s/a}$ remain bound around the quadruple Mie resonance 3 as shown in Fig. 9 (c). The dependence of the $Q$ factor on $L$ is shown in Fig. 9 (b) and (d).
Figure 8: Evolution of symmetric and antisymmetric hybridizations of higher Mie dipole resonant modes (a) and respective $Q$ factors (b) with the distance.

3. Avoided crossings in system of two coaxial disks

In the present section we consider two identical coaxial disks as sketched in Fig. 1 (b) each of them having the aspect ratio not obligatory tuned to the optimal $Q$-factor as in [14, 15]. The coaxial disks have the advantage that all resonant modes are classified by the azimuthal index $m = 0, 1, 2, \ldots$ because of the axial symmetry. Therefore one can consider subspaces with definite $m$ separately. In the present paper we follow the case $m = 0$ for which the solutions are separated by polarization with $H_z = 0$ (E modes) and $E_z = 0$ (H modes). In what follows we consider the H-modes. In general the resonant modes and their eigenfrequencies are given by solving the time-harmonic source-free Maxwell’s equations [29, 30]

$$\begin{pmatrix} 0 \\ -i\nabla \times \frac{1}{i\nabla \times} 0 \end{pmatrix} \begin{pmatrix} E_n \\ H_n \end{pmatrix} = k_n \begin{pmatrix} E_n \\ H_n \end{pmatrix} \tag{16}$$

where $E_n$ and $H_n$ are the EM field components defined in Ref. [30] as quasinormal modes which are also known as resonant states [31, 32] or leaky modes [33]. It is important that they can be normalized and the orthogonality relation can be fulfilled by the use of perfectly matched layers (PMLs) [30]. With the exception of very restricted number of symmetrical particles Eq. (16) can be solved only numerically. The eigenfrequencies are complex $k_n a = \omega_n + i\gamma_n$ where $a$ is the disk radius. In what follows the light velocity is taken unit. Fig. 10 shows resonant frequencies of the isolated disk complimented by insets with the resonant modes

Figure 9: The evolution of quadruple resonant modes under vs the distance. Crosses mark the Mie resonances shown in Fig. 4. Red closed circle marks the case of the smallest distance and open green circle marks the distance $L = 1000a$. (only the component $E_\phi$ is shown). There are modes with nodal surfaces crossing the z-axis and the modes with nodal surfaces crossing the plane $z = 0$. They correspond to the Fabry-Perot resonant modes and the radial Mie modes by the terminology introduced in paper [14].

Fig. 11 shows the solutions of Eq. (16) for the case of
two coaxial dielectric disks as dependent on the distance $L$ between the disks. The necessity to use PMLs restricts the distance between the disks which is to be considerably less than the distance between the PMLs in the $z$-direction.

In spite of an illusive complexity in Fig. 11 the zoomed pictures reveal remarkably simple behavior of resonant frequencies in the form of a spiral convergence of the eigenfrequencies to the resonant frequencies of the isolated disk marked by closed circles. However, when the disks approach close enough to each other the spiralling behavior is replaced by strong repulsion of resonant frequencies because of interaction enhancement.

In order to quantitatively evaluate this interaction we start consideration with an isolated disk for which the matrix of derivatives in Eq. (16) becomes diagonal with the complex eigenfrequencies $k_n$ in the eigenbasis presented in Fig. 10. It is reasonable to assume that for enough separation between disks the matrix is still diagonal with pairs of degenerate $k_n$ shown in Fig. 11 by blue closed circles. As the distance between the disks is reduced the interaction between the disks via the resonant modes splits the degenerate resonant modes $k_n$ giving rise to an avoided crossing. We also assume also that the value of splitting much less than the distance between the different $k_n$. These assumptions are justified numerically as shown in insets of Fig. 11, however, for only in definite domains of the frequency $k$ around the resonances of the isolated disk where spiral behavior of the resonant frequencies takes place. In the framework of these assumptions we can use two-level approximation for the Hamiltonian matrix in Eq. (16) for each resonance $k_n$ [16, 30, 15]

$$H_{eff}^{(n)} = H_{eff}^{(0)} + V = \left( \begin{array}{cc} k_n a & 0 \\ 0 & k_n a \end{array} \right) + \left( \begin{array}{cc} u_n & v_n \\ v_n & u_n \end{array} \right),$$

(17)

where $v_n$ is responsible for interaction between the disks via the resonant modes while $u_n$ is the result of the backscattering by the first disk. Therefore one can expect that $\arg(v_n) = \omega_n L/a$, $\arg(u_n) = 2\omega_n L/a$. Fig. 12 shows the behavior of the absolute value and phase both of the matrix elements. The matrix elements $v_n$ and $u_n$ can be easily found from numerically calculated resonances shown in Fig. 11

$$k_n^{(n)} a = k_n a + u_n \pm v_n,$$

(18)

as $v_n = \frac{k_n^{(n)} - k_n^{(-n)}}{2}$, $u_n = \frac{k_n^{(n)} + k_n^{(-n)}}{2} - k_n$. From Fig. 12 one can evaluate that the interaction term in (17)

$$v_n \sim e^{ik_n L} L^2, \quad u_n \sim \frac{e^{2ik_n L}}{L^3}.$$

(19)

The distance behavior (19) is observed with a good accuracy for all resonances shown in Fig. 12, however, for only spiral convergence of the resonances. Numerically calculated behavior of the matrix elements $v_n$ and $u_n$ for $n = 2$ is shown in Fig. 12. In spiraling around the resonances of the isolated disk the hybridized resonant eigenmode is given by symmetric and antisymmetric combinations of the resonant modes of the isolated disk

$$\psi_{a,s}(\vec{r}) = \psi_n(\vec{r} + \frac{1}{2} L \vec{e}_z) \pm \psi_n(\vec{r} - \frac{1}{2} L \vec{e}_z)$$

(20)

where $\vec{e}_z$ is the unit vector along the $z$-axis and $\psi_n(\vec{r})$ are the corresponding resonant modes of the isolated disk shown in the insets in Fig. 10.

At first the resonant frequencies slowly spiral away from the limiting point given by $k_n$. Respectively the $Q$ factor in Fig. 11 (c) demonstrates oscillating behavior exceeding the $Q$ factor of the isolated disk a few times. As
the disks approach each other the spiral behavior of the pair of resonances $k_{s/a}^{(n)}$ is replaced by strong repulsion as shown Fig. 11 (b), Fig. 11 (d) shows a remarkable feature caused by the avoided crossing of resonances with different $n$. To be specific there is an avoided crossing of symmetric resonances $k_{s}^{(2)}$ and $k_{s}^{(0)}$ according to enumeration in Fig. 10. Because of the same symmetry these resonances undergo typical avoided crossing with a considerable decrease of the imaginary part of the resonant frequency and correspondingly enhancement of the $Q$ factor by one order in magnitude. Respectively the two-mode approximation (17) breaks down.

It is interesting to trace the behavior of resonances and the $Q$ factors for the aspect ratio $h/a \approx 0.7$. (b) and (d) zoomed areas highlighted in (a) with symmetric (solid lines) and antisymmetric (dash lines) hybridization (20) of resonant modes of the isolated disk. (c) and (e) show behavior of the $Q$ factor vs the distance for corresponding insets at the left. Closed circles mark the eigenfrequencies of isolated disks and respectively have no enhancement of the $Q$ factor by one order in magnitude as it was achieved for the aspect ratio $a/h = 1$ (see Fig. 12 (e)).

Up to now we considered the permittivity $\epsilon = 40$ and $a = 1cm$ (ceramic disks) that enters the resonant frequencies into the THz range. Finally, we consider $\epsilon = 12$ (silica disks) and $a = h = 1\mu m$ with the resonant frequencies in the optical range. Results of computations are presented in Fig. 14 which shows that there is no qualitative difference between the ceramic disks with $\epsilon = 40$ and silica disks with $\epsilon = 12$. Similar to Fig. 11 and Fig. 13 we observe spiral behavior of the resonant frequencies for the enough distance between the disks. But what is more remarkable we also observe an avoided crossing of the resonances with different indices as shown in Fig. 14 (d) with corresponding strong enhancement of the $Q$ factor by one order in magnitude (Fig. 14 (e)).

## 4. Conclusions

For the isolated dielectric cylinder we have well known Mie resonances specified by azimuthal index $m = 0, \pm 1, \pm 2, \ldots$ (monopole, dipole, quadruple etc resonances) due to axial symmetry. Two parallel cylinders have no axial symmetry and therefore the solutions of the homogeneous Maxwell equations are given by series of the Bessel (inside) or Hankel (outside cylinders) functions in $m$. By the use of Graf formula the coefficients in series satisfy linear algebraic equations and can be easily found [21, 22, 23]. However, there were no studies on the behavior of resonances of two cylinders in dependence on the distance between them except the studies of the $Q$ factor for extremely highly excited resonances, whispering gallery modes by Boriskina [17, 18]. The study presented in this paper reveals surprisingly rich evolution of the resonances with the distance that can be described by two scenarios. In the first scenario the resonances subsequently bypass the Mie resonances. Each time when the resonance is close to a Mie resonance the resonant mode inside the cylinders takes the field profile of the corresponding Mie resonant mode. It is worthy to notify recent publication by Abdrabou...
Figure 14: (a) Behavior of resonant eigenfrequencies under variation of the distance between the disks $L$ with $\epsilon = 12$ (silica in optical range) and aspect ratio $a/h = 1$. (b) zoomed area highlighted in (a) with symmetric (solid lines) and antisymmetric (dash lines) hybridization (20) of resonant modes of the isolated disk. (c) shows behavior of the $Q$ factor vs the distance for corresponding insets at the left. Closed circles mark the eigenfrequencies of isolated disks and respectively the $Q$ factors while crosses mark the limiting case $L = a$ when two disks stick together.

and Ya Yan Lu [35] in which exceptional points for resonant states were achieved for variation of the distance between dielectric cylinders.

The evolution of resonances bound by the Mie resonances follows the second scenario and typical for the higher resonances with $m = 2, 3, \ldots$. It is interesting that the dipole resonance which leaks aside from the other cylinder bears features of the both families. When the leakage from the first cylinder is directed to the second cylinder, the overlapping (15) exceeds the coupling of the Mie dipole resonant modes which leakage aside the the cylinders. As a result in the first case the resonances consequently bypass the Mie resonances while in the second case the resonances are bound to the dipole Mie resonance of isolated cylinder. For variation of the distance the $Q$ factor shows oscillating behavior with maxima which can exceed the $Q$ factor of the isolated cylinder three times. That enhancement is typical for all types of resonances except the monopole resonance which demonstrates enhancement by one order in magnitude.

5. Discussions

The recept to enhance the $Q$ factor by means of the avoided crossing of resonances is well known. Friedrich and Wintgen [3] were the first who investigated the quantitative influence of the interference of resonances on their positions and widths. Moreover, in the framework of two-level effective Hamiltonian they found out that one of the widths can turn to zero to identify the BIC. A single isolated dielectric particle of finite dimensions can not trap light because of the infinite number of radiation continua or diffraction channels [10]. However, for sufficiently large refractive index the particle shows distinctive resonances with the $Q$-factors which can be substantially enhanced owing to the avoided crossing of the resonances under variation of the aspect ratio of the disk [14, 15]. Technologically, it might be challenging to vary the size of the disk in the optical range. In the present paper we propose to vary the distance between two coaxial disks that is preferable from the experimental viewpoint. Continuous variation of the distance gives rise to an avoided crossing of the resonances due to interaction between the disks through radiating resonant modes.

Although in the present paper we considered only dielectric cylinders and disks, it is clear that the phenomenon of the avoided crossing and respective enhancement of the $Q$ factor would occur with particles of arbitrary shape when the distance between them is varied. The case of two coaxial disks simplifies computations because the solutions with different angular momentum $m$ are independent. In the present paper we have presented only the case $m = 0$ because of a possibility to consider separately E and H polarizations.

Abstract

3-port and 4-port THz circulators are discussed. The circulators are based on graphene placed on a two-layer dielectric substrate. The circulation behaviour is defined by application of a DC magnetic field normal to the graphene plane. We discuss the choice of the physical and geometrical parameters which provide octave frequency band of these components.

1. Introduction

Nonreciprocal components are indispensable part of many microwave [1] and optical systems. The existing publications show that the bandwidth of the graphene-based circulators in THz region can be of \((10 - 20)\%\) [2]. Usually, they have rather complicated structure [3, 4]. The suggested in this work circulators have very simple design which presents the magnetized junction of three strip graphene waveguides. We discuss the principal parameters which define the bandwidth and their influence on the bandwidth. The calculations are fulfilled by a full-wave electrodynamic method. Our approach gives recipes to engineer the edge-guided circulators with octave frequency band.

2. Problem description

The geometries and coordinate system used for the analysis are shown in Fig. 1. In the 3-port circulator (Fig. 1 (a)) the device is formed by a central magnetized region and three waveguides symmetrically connected to it. Analogously, in the 4-port circulator, the four waveguides are symmetrically coupled to the central region (Fig. 1 (b)). The third device, also a 4-port circulator (Fig. 1 (c)), is equivalent to combination of two T-circulators. The width of the guides is indicated by \(w\) and \(R\) is the radius of the circumference that define the curvature of the central region of the devices. The thickness of the graphene is \(d\), of silica (\(SiO_2\)) is \(h_1\), and of silicon (\(Si\)) is \(h_2\). The permittivity of \(SiO_2\) is 2.09 and \(Si\) is 11.9. 

3. Numerical modeling of graphene

The electric conductivity tensor of graphene is modeled by using the semiclassical approach based on the Boltzmann transport equation. This model is described by simple equations and fits well in THz frequency region.

\[ [\sigma_s] = \begin{bmatrix} \sigma_{xx} & -\sigma_{xy} \\ \sigma_{xy} & \sigma_{xx} \end{bmatrix}, \]

(1)

The parameters of the conductivity tensor are given in [5]:

\[ \sigma_{xx} = \frac{q_e^2 \mu_c}{\pi \hbar^2} \frac{1}{\omega_c^2} - \frac{i \omega}{1 - \omega \omega_c^2}, \]

(2)

and

\[ \sigma_{xy} = -\frac{q_e^2 \mu_c}{\pi \hbar^2} \frac{\omega_c}{\omega_c^2} - \frac{\omega_c}{\omega_c^2}, \]

(3)

where \(q_e\) is the charge of the electron, \(\hbar\) is reduced Planck constant, \(\omega_c\) the angular cyclotron frequency, \(\tau\) relaxation time, \(w\) the angular frequency incident and \(\mu_c\) the chemical potential of graphene. The angular cyclotron frequency is defined by \(\omega_c = q_e B_0 v_F^2 / \mu_c\), where \(B_0\) represents the DC magnetic field and \(v_F\) the Fermi velocity \(v_F \approx 9.5 \times 10^5\) m/s. In this work we will use the parameter \(\tau = 0.9\) ps [6].

Similarly to that used in ferrite devices [1] we can define the graphene gyrotropy parameters, from the param-
\[ g = \frac{\text{Re}\{\sigma_{xy}\}}{\text{Im}\{\sigma_{xx}\}} = \frac{\omega_2 (\omega^2 - \omega_c^2 - (1/\tau)^2)}{\omega (\omega^2 - \omega_c^2 + (1/\tau)^2)}. \] (4)

4. Numerical Results

The numerical results were obtained by the commercial software Comsol Multiphysics [7]. Bandwidth was calculated as an intersection of frequency bands corresponding to the reflection which is less than \(-10\ \text{dB}\), the transmission which is better than \(-2\ \text{dB}\) and the isolation higher than \(-15\ \text{dB}\). From Fig. 2 one can see that, in the band of \((2.5 \div 4.5)\ \text{THz}\), the circulator has a good matching, \(S_{11}\) is better than \(-10\ \text{dB}\), in the band of \((2.65 \div 4.2)\) the level of isolation is less than \(-15\ \text{dB}\) and the insertion loss is better than \(-2\ \text{dB}\) in the band of \((2.5 \div 4.05)\). Thus, the resultant bandwidth is 42%.

![Figure 2: Transmission, reflection and isolation coefficients](image)

Figure 2: Transmission, reflection and isolation coefficients (a) for the 3-port circulator, (b) for the 4-port circulator (Fig. 1 (b)) and (c) for the 4-port circulator (Fig. 1 (c)), \(w = 2\ \mu m, R = 2.75\ \mu m, B_0 = 1.5 \ T\) and \(\mu_c = 0.15\ \text{eV}\).

In Fig. 3 we present the distribution of the electric field component \(E_z\) for the discussed circulators for the frequency \(2.85\ \text{THz}\).

![Figure 3: E_z distribution in circulators. Parameters used](image)

Figure 3: \(E_z\) distribution in circulators. Parameters used \(w = 2\ \mu m, R = 2.75\ \mu m, B_0 = 1.5 \ T\) and \(\mu_c = 0.15\ \text{eV}\).

5. Conclusions

The discussed circulators possess the record bandwidth which is twice as much as the published ones. For example, the 3-port circulator works in the 42% frequency band and even can achieve octave band. Thus, the presented components are characterized by a very high bandwidth and good characteristics of transmission and isolation. They can be used in integrated THz circuits. The presented methodology can be also used in the infrared frequency range.

Plasmon-induced inverse Faraday Effect and switchable routers and modulators in magneto-plasmonic structures

Joachim Herrmann\textsuperscript{1}, Song-Jin Im\textsuperscript{2}, Ji-Song Pae\textsuperscript{2}, Chol-Song Ri\textsuperscript{2}, Kum-Song Ho\textsuperscript{2}, Yong-Ha Han\textsuperscript{2}

\textsuperscript{1}Max-Born-Institute for Nonlinear Optics and Short Pulse Spectroscopy, Berlin, Germany
\textsuperscript{2} Kim Il Sung University, Pyongyang, Democratic People's Republic of Korea

Recently, the inverse Faraday Effect (IFE) has attracted much attention because of its potential impact for ultrafast all-optical switching of magnetization in thin magnetic films induced by ultrafast pulses \cite{1} which opens the possibility for magnetic data storage with unprecedented speed. In order to enable sub-wavelength spatial resolution for magnetic recording we study a modified version- the plasmon-induced IFE- in which instead of free space circular polarized optical pulses free running surface-plasmon-polaritons (SPP) generated by incident linearly polarized input pulses induce a quasi-static magnetic field. SPPs exhibit a longitudinal component of the electric field, therefore the vector product of \( E \) and its complex conjugate \( E^* \) do not vanishes. This means that in an opto-magnetic material quasi-static magnetic fields can also be induced by running SPPs. We present analytical and numerical results for the computation of the induced magnetic field distributions by SPPs in a metal-insulator-metal plasmonic waveguide with an isolator layer composed from a ferromagnetic dielectric and show that the magnetization of a magnetic area can be reversed within sub-ps time in such nano-confined waveguides. The magnetization can be switched back by SPPs propagating into the opposite direction. Besides we study a magneto-optical dielectric cavity side-coupled to a metal-insulator-metal (MIM) waveguide (Fig.1a). The average effective magnetic field \( H_{\text{eff}} \) denotes the average value over the magneto-optical cavity (the green part of Fig.1a). \( H_{\text{eff}} \) is sensitive to the wavelength near the resonance and perceives a sign change (the points A and C of Fig.1b). It becomes zero at the exact resonance (the point B of Fig. 1b). The sign of \( H_{\text{eff}} \) is also reversed for backward-propagating SPPs (point A$^{-}$ in Fig.1b). The cavity resonance wavelength is determined by the length of the cavity. This could open up a mechanism for multilevel 3D magnetic recording by using several layers including opto-magnetic cavities with varying resonance wavelength in every layer addressed by using multi-wavelength optical pulses.

The back-reaction of the IFE on the plasmon propagation leads to a new type of ultrafast third-order nonlinearity with a nonlinear susceptibility exceeding the optical Kerr effect of typical dielectric materials by five orders of magnitude and that of gold by two orders of magnitude \cite{3}. We derive analytical expressions for IFE-related nonlinear susceptibility for a ferromagnetic dielectric/metal interface and for a dielectric/hybrid metal-ferromagnetic interface.

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{figure1.png}
\caption{Scheme (a) and averaged effective magnetic field vs the wavelength (b).}
\end{figure}
In a second part of the talk we propose and study a magnetically controlled switchable plasmonic router with 99%-high contrast [4]. In metal films surrounded by a ferromagnetic dielectric an external magnetic field in the transverse direction can induce a significant spatial asymmetry of mode distribution. Superposition of the odd and the even asymmetric modes over a certain distance leads to a concentration of the energy on one interface which is switched to the other interface by magnetic field reversal. In Fig. 2 numerical results for the magneto-plasmonic waveguide show a high-contrast modulation and channel switching by the magnetic field reversal. We estimate the modulation contrast defined by the ratio of powers through the two channels in dependence on the gyration $g$ and the wavelength $\lambda$. The numerical results well agree with the analytically predicted results. The power splitting ratio is tunable by controlling the external magnetic field and reaches a value larger than 20 dB, which corresponds a contrast 99% over a broad wavelength range from 770nm to 820nm.

Finally, we propose and study a novel type of plasmonic resonators based on a metal-insulator-metal waveguide and above the upper thin metallic layer a side-coupled magneto-optical disk controlled by an external magnetic field [5]. The wave-number change and the transmission can be tuned by altering the magnetic field and reversible on/off switching of the running SPP modes by a reversal of the direction of the external magnetic field is demonstrated. Fig. 3(a) and 3(b) show the distribution of the magnetic field component of the SPPs at a gyration $g=-0.03$ and $g=0.03$, respectively. As seen by changing the direction of the magnetic field, the SPP transmission is switched from an off to an on state via the changed interference pattern.

Abstract

In this work we propose a new class of hyperbolic magneto-plasmonic metasurface for second harmonic generation (SHG). We discuss three possible realizations of such a metasurfaces, which based on non-linear magneto-plasmonic multilayers. Theoretical models for investigation of SHG in abovementioned realizations are performed.

1. Introduction

Nowadays, hyperbolic plasmonics attracts researchers’ attention by its exciting optical properties [1-6]. Hyperbolic metasurfaces (HMSs) support highly localized low-loss surface plasmon-polaritons (SPPs), providing drastic increase of the light-matter interactions near the surface. Moreover, HMSs allow the very effective manipulation by SPPs varying from routing them towards specific directions within the sheet, dispersion-free propagation (canalization), and to the negative refraction.

The usual realization of HMSs is constructing the surface which behaves as a dielectric (has a capacitive impedance) in one direction and as a metal (has an inductive impedance) in the orthogonal one. In the hyperbolic regime plasmons propagate as a very narrow beam along the specific direction and electromagnetic energy became localized near metasurface even stronger than for “usual” elliptic SPPs.

Recently, non-linear magnetooptical properties of rectangular array of nickel dimers featuring a nanoscale gap have been investigated [7]. Taking advantage of different periods of the investigated array in two orthogonal in-plane directions, a novel regime for the nonlinear Wood’s anomaly, when the structure exhibits grating properties exclusively at the second harmonic wavelength $\lambda/2$ but not at the fundamental wavelength $\lambda$, has been identified. In this nonlinear regime the Wood’s anomaly is characterized by an order-of-magnitude larger effect in intensity redistribution between the diffracted beams, as compared to the linear case.

The general trend of increasing light-matter interactions near the surface in hyperbolic regime allows us suppose that non-linear magneto-plasmonic effects in magneto-plasmonic HMSs should have some non-trivial features as well.

Here, we investigate a second harmonic generation (SHG) (including magneto-induced SHG) in magneto-plasmonic HMSs, when the periodicity of the metasurface is much smaller than both fundamental and second harmonic wavelengths.

2. Hyperbolic magneto-plasmonic metasurfaces

Usually HMSs are realized by deeply subwavelength grating of plasmonic (metallic) surface [1-6]. For non-linear magneto-plasmonics, metal-ferromagnet multilayer structures have a great potential [8]. Hyperbolic magneto-plasmonic metasurface may be constructed by combination of these two ideas, i.e. by subwavelength grating of magneto-plasmonic multilayers. Here, depending on the
position of ferromagnet and grating depth three variants are possible (see Figure 1 for details): noble metal covered by ferromagnetic metasurface (similar structure has been investigated recently [7], but for non-hyperbolic regime), hybrid metal-ferromagnet structure covered by noble metal based metasurface, and noble metal covered by hybrid metal-ferromagnet metasurface (similar structures have been investigated in [9], but not for hyperbolic regime as well).

Taking into account very interesting and promising properties of such kind of metasurfaces in non-hyperbolic regime, it is highly desirable to investigate the behavior of all the effects in hyperbolic regime of metasurface.

3. Discussion

In order to investigate SHG in hyperbolic magneto-plasmonic MSs, theoretical model based on effective medium approximation has been performed. In contrast to hybrid metal-ferromagnet plasmonic structure, hyperbolic magneto-plasmonic MSs will have a highly anisotropic dielectric permittivity tensor. This leads to significantly anisotropic SHG signal (with respect to SPPs propagation direction).

In directions where SPPs cannot propagate, SHG signal will have the similar behavior as for the system without the metasurface, while in directions where canalization of SPPs observed SHG signal significantly increase.

In contrast to usual hybrid metal-ferromagnet multilayers, proposed structure will have an additional surfaces for SHG signal caused by grating. For hybrid metal-ferromagnet multilayers non-magnetic SHG is caused by z-component of non-linear polarization $P_z$ at all the interfaces (z-axis is perpendicular to the interfaces, $x$- and $y$- axis lies in-plane), while magnetic SHG is caused by $P_x$. For noble metal covered by ferromagnetic metasurface and for noble metal covered by hybrid metal-ferromagnet metasurface an additional $z$-component of non-linear polarization will be induced by interfaces between magnetic metal and air in grating. In turn, for hybrid metal-ferromagnet structure covered by noble metal based metasurface, and for noble metal covered by hybrid metal-ferromagnet metasurface an additional $x$-component of non-linear polarization will be induced by interfaces between non-magnetic metal and air in grating.

4. Conclusions

We have proposed and theoretically investigated new class of hyperbolic magneto-plasmonic metasurfaces for SHG. These structures may have an increased both magnetic and non-magnetic SHG signal. Highly anisotropic properties of such structures may open the door for directional SHG and magnetic control of SHG directivity. Existence of additional grating-caused interfaces may allow geometrical tuning of the interference between magnetic and non-magnetic impact in SHG.

Abstract

Diffractive plasmonic nanostructures sustain both localized surface plasmon polaritons (LSPPs) and optical diffraction in the plane of the array, i.e., lattice plasmon. Although such structure combined with magnetic materials can largely enhance magneto-optical (MO) effects, the plasmonic material utilized for MO enhancement is limited to Au. In this study, we fabricated diffractive array composed of Al nanocylinders and succeeded in enhancement of Faraday rotation of Fe layer deposited on the array at spectrally shorter range (blue to green) of visible light.

1. Introduction

It has been demonstrated that diffractive plasmonic nanostructures can largely enhance MO effects[1-3]. Such systems include periodic one-dimensional gratings and two-dimensional nanoparticle/nanohole arrays of plasmonic metals combined with magnetic materials, which support lattice plasmons, i.e., the radiative coupling between LSPPs via light diffraction. These systems utilize two kinds of resonances for MO enhancement; not only the LSPPs that accumulate light in the vicinity of the metallic surface to enhance MO effect locally, but the light diffraction that traps light inside the MO-active region and enhances light-matter interaction. In this sense, diffractive plasmonic nanostructures possess advantages of both LSPP-based system and diffraction-based, i.e., magnetophotonic crystals [4, 5], systems. In addition, these systems enjoy advanced properties including wavelength-selective MO enhancement by the periodicity of the gratings and arrays [6, 7].

In spite of high degree of freedom in engineering the MO effect, the material used for diffractive plasmonic nanostructures has been limited to Au thus far. This restricts the tunability of enhancement to the spectral region where Au shows plasmonic behavior, typically optical wavelength \( \lambda > 600 \) nm. In this study, we fabricated Al nanocylinder array to obtain enhanced MO effect at shorter spectral regions. The array was designed to show lattice mode around \( \lambda = 500 \) nm, overlapping with LSPPs of Al nanocylinders. As a MO-active material, Fe was deposited on top of the array and Faraday effect was examined. We compared the MO enhancement to that of the Fe layer on the nanocylinder array of Si and SiO₂ with the design identical to the Al nanocylinder array.

Figure 1: SEM images of the Al nanocylinder array; (a) before and (b) after deposition with 7.5 nm Fe. Scale bar = 500 nm.

2. Experiment

2.1. Sample fabrication

Al nanocylinders arranged in a triangle lattice with a period \( p = 400 \) nm was fabricated using nanoimprint lithography in combination with reactive ion etching (RIE), as described elsewhere [8]. The designed height (\( H \)) and diameter (\( D \)) of the nanocylinder were \( H = 150 \) nm and \( D = 200 \) nm, respectively. Si nanocylinder arrays were fabricated by the combination of nanoimprint lithography and Si deep etching, from the polycrystalline Si with a 200 nm thick on silica glass substrate. SiO₂ nanocylinder arrays were fabricated by the combination of nanoimprint lithography and RIE, by directly depositing resist on the silica substrate. The same mold was used in nanoimprint process for all the fabrications so that the design of the Al, Si and SiO₂ nanocylinder arrays were identical to each other. Fe thin layer (7.5 nm thickness) was deposited on the nanocylinder arrays by electron beam deposition under 4.0 \( \times 10^{-4} \) Pa.

Zeroth-order optical transmittance was measured by UV-visible-near infrared spectrophotometer, (V770, JASCO). Wavelength-dependence of Faraday rotation angle (\( \theta_F \)) was measured at room temperature by the polarization modulation technique using a commercial measurement system (K-250, JASCO).
3. Results and Discussion

Figure 1(a) shows scanning electron microscopic (SEM) image of Al nanocylinder array prepared on silica glass substrate. Al cylinders with $D = 200$ nm are arranged in triangle lattice with $P = 400$ nm. Figure 1(b) illustrates the SEM image of Al nanocylinder array on which 7.5 nm thick Fe layer was deposited. The diameter of each cylinder becomes larger by the Fe deposition.

Figure 2 compares $\theta_F$ and transmittance of the Fe layer on the Al nanocylinder array. The transmittance of Fe layer on the array is less than that on the flat substrate because of the additional extinction by the Al nanocylinders. The vertical dotted lines denote the condition of in-plane diffraction calculated by using a refractive index of glass ($n = 1.46$). A kink is found in the optical transmission indicating the occurrence of in plane diffraction. A modulation in $\theta_F$ is found at around the in-plane diffraction condition, and the magnitude in $\theta_F$ of the Fe layer on the Al nanocylinder array is larger than that on a flat silica glass in most of the spectral range measured. In Faraday rotation spectrum, $\theta_F$ of 7.5 nm thin Fe layer on the Al nanocylinder array has two local maxima at $\lambda = 403$ and 503 nm, which are associated with SPPs and the in-plane light diffraction, respectively.

For the Fe layer on the Si nanocylinder array (Fig. 3), the value of $\theta_F$ for the Fe layer deposited on the array is similar to that on the flat substrate, and a modulation is found around the spectral range of diffraction anomaly. A comparison between Figs. 2 and 3 clearly suggests that the Al nanocylinder array possesses a higher ability to enhance Faraday rotation compared to the Si nanocylinder array.

4. Conclusions

We designed the diffractive array of Al nanocylinders and enhanced MO effect of Fe layer deposited on the top of the nanocylinders. Two local maxima appear in Faraday rotation spectrum, one is due to LSPP ($\lambda = 403$ nm) and the other is lattice mode ($\lambda = 503$ nm). A comparison with Si nanocylinder array proves that LSPPs peculiar to Al show higher ability to enhance Faraday rotation, although Si could enhance the Faraday effect under optimal designs. This work clarified the advantages of Al nanocylinder array to tune the MO effect in blue to green region of the spectrum, which cannot be achieved by Au nanostructures reported thus far.

Abstract

We demonstrate the fabrication and measurement of hybrid magnetoplasmonic Au/Tb$_{18}$Co$_{72}$ nanoantennas. Tb$_{3}$Co$_{1-x}$ alloys have been shown to exhibit all-optical switching and the merging with plasmonics could yield routes to optical switching of single nanomagnetic elements. The structures exhibit a dramatic enhancement of the Faraday effect when localized surface plasmons (LSPs) are excited. An angular dependence is observed, whereby the sign and magnitude of the Faraday effect can be tuned through the mutual combination of incidence wavelength and incidence angle.

1. Introduction

Nanoscale confinement of light with the aid of plasmonics has stimulated research towards a number of future technologies including on-chip micro- and nanosensor arrays [1], super-resolution imaging and designer flat-optics [2]. Within this field, active plasmonics, wherein the optical properties can be tuned in real time by an external stimulus are of great interest. Here, magnetoplasmonics provides a promising avenue to achieve real-time dynamic plasmonic devices with the use of an external magnetic field.

In this work, we demonstrate the incorporation of plasmonics with magnetic materials which exhibit all-optical switching [3]. Plasmonics can increase the efficiency of the all-optical switching effect whilst simultaneously allowing switching of individual nanoscopic elements. Furthermore, the use of Tb$_3$Co$_{1-x}$ alloys which have perpendicular magnetic anisotropy, reduces the magnetic field required to orient the magnetization out of the plane of the film, as is required to measure the Faraday effect.

2. Discussion

Thin films of Au(80nm)/Tb$_{18}$Co$_{72}$(20nm)/Al$_2$O$_3$(3nm) were patterned into ordered arrays of nanoantennas. We use a top-down approach to fabricate large area ordered arrays of magnetoplasmonic nanocone antennas. Using electron beam lithography a nanodisk hard-mask is patterned on the Au/Tb$_{18}$Co$_{72}$ film. After the Ar$^+$ ion milling process it is shown that the nanoantennas exhibit a conical profile. A schematic of the antenna structure is shown in the inset of Fig. 1, with the plasmonic body of Au (yellow) and Tb$_{18}$Co$_{72}$ (blue) forming the nanocone tip. The latter is ferri-magnetic at room temperature, exhibiting perpendicular magnetic anisotropy. By tuning the mask diameter, either complete or truncated nanocones are produced. The base-diameters range between 150 to 220nm.

The Faraday rotation and ellipticity was extracted as a function of wavelength, nanoantenna diameter and incidence angle. The spectral Faraday rotation measured at normal incidence is shown in Fig. 1. An enhancement of the Faraday rotation and ellipticity is observed at the LSP resonance. This LSP is very sensitive to the base-diameter of the nanostructure, shifting to longer wavelengths as the diameter increases. This behavior is confirmed by finite element simulations of both the optical and magneto-optical response using the software package COMSOL™.

![Figure 1: Spectral dependence of the Faraday rotation, demonstrating the magneto-optical plasmonic enhancement associated with the excitation of LSPs in the Au/Tb$_{18}$Co$_{72}$ nanoantennas.](image-url)
In addition, these arrays of nanoantennas show a strong angular dependence for the Faraday effect (not shown), whereby the Faraday effect can be suppressed, enhanced or even undergo a sign change by an angular rotation of the sample incidence plane of just 10 degrees. This effect is strongly dependent on the wavelength and differs between the various base-diameter nanoantennas.

3. Conclusions
We have demonstrated the integration of an amorphous transition ferri-magnetic-rare earth alloy with nanophotonics.

Abstract

We report on transverse magnetic routing of light emission (TMRLE) from excitons in a diluted-magnetic-semiconductor quantum well. The strongest directionality is achieved for a quantum well located several tens of nm apart from a metal-semiconductor interface. At such distance the quantum well is coupled to surface plasmon polaritons that carry large transverse spin and are efficiently controlled by the magnetic field direction. We observe directionality of up to 60 % for the emission detected from the grating side. When the distance between emitter and surface is large, the transverse spin is caused by the far-field interference effect and the routing is weak. The effect is studied in different geometries regarding the orientation of the plasmonic grating towards excitation and detection.

1. Introduction

Different magneto-optical phenomena such as the Faraday and Kerr effect are widely used to control the polarization and intensity of transmitted or reflected light rays. Significant enhancements of these magneto-optical effects has been achieved recently by combining magnetic and plasmonic materials[1, 2]. Additionally, gaining control over the intensity and propagation direction of emitted light is important for many domains of modern optics. We report a new class of emission phenomena where directionality is established perpendicular to an external magnetic field and show a significantly enhanced directionality of up to 60 % in hybrid plasmonic semiconductor structures.

TMRLE requires two key features to be fulfilled: first, the optical selection rules of the light source need to be modified by the magnetic field, which is an intrinsic property of any emitter in magnetic materials. In this case we use circularly polarized excitons in a magnetic quantum well as light source. Second, the emitted light should have nonzero transverse spin (angular momentum) \( S \parallel x \perp k \). This is true for a quantum well (QW) located in the vicinity of a surface because the mirror symmetry is broken, leading to spin-momentum locking. As a result a far-field effect for directionality emerges: Interference takes place between the directly emitted and reflected electromagnetic waves. The reflection occurs at the back side of the structure. The interfering beams originate from the same dipole and propagate along the same direction in free space outside the sample. The phase between interfering beams is determined by the helicity of the dipole in yz-plane, changing with the magnetic field. The result is directional emission.

The directionality can be enhanced in the near field with the QW layer being located in close proximity to a semiconductor/metal interface supporting surface plasmon polaritons (SPP). In this case the excitons emit into SPPs as shown in Fig. 1. SPPs carry transverse spin \( S_x \) with \( S_x > 0 \) for right-going and \( S_x < 0 \) for left-going waves. The spin of generated SPPs is pinned to the magnetic field \( B \) due to the modified selection rules for exciton emission, allowing magnetic control over the direction of SPP propagation and subsequent directional emission into free space by using a metallic grating. Furthermore, we show that far field effects due to superposition of electromagnetic waves diffracted at the metallic grating also contribute to the directionality of the emission.
2. Results

We measure the strength of the magnetic field induced changes in photoluminescence (PL) intensity by the quantity

$$\rho = \frac{I_+\theta - I_-\theta}{I_+\theta + I_-\theta},$$

(1)

comparing the detected light intensities $I_+ / I_-$ for magnetic fields in positive or negative $x$-direction respectively at different emission angles $\theta$. As light source we use a CdMnTe / CdMgTe quantum well structure with large Zeeman splitting and thus strong circular polarization degree in a magnetic field. On top of this structure, rectangular gold gratings with 250 nm grating period are applied for supporting SPPs. The emitted light is detected in a Fourier imaging setup with the sample being placed inside a liquid helium flow cryostat at $B_x = 520$ mT, $T = 10$ K.

Figure 2 shows an exemplary measurement of SPP-supported directional emission in $p$-polarization of up to $\rho = 5\%$ for the structure with 32 nm spacer between QW and the metallic grating. Left and right colored panels correspond to measured and calculated $\rho(h\omega, \theta)$-patterns, respectively. The side plots at the calculated pattern shows cross-sections along fixed photon energy $h\omega = 1.656$ meV (upper plot) as indicated by the dotted line or along fixed angle $\theta = 10^\circ$ (right plot) as indicated by the dash-dotted line. In these plots blue curves correspond to cross-sections of experimental data and red curves to calculation results. Yellow curves in the side plots show the absence of $\rho(\theta)$ in $s$-polarization. The measurements show that $\rho$ is an odd function with respect to emission angle ($\rho(\theta) = -\rho(-\theta)$). Thus, in our case the magnetic field-induced variation of the PL intensity is fully determined by the TMRLE with directionality $C(h\omega, \theta) = \rho(h\omega, \theta)$.

The effect is significantly enhanced by placing the sample in a bath cryostat, reaching $\rho = 60\%$ at $T = 2$ K, $B_x = \pm 1.5$ T and $\theta = 15^\circ$. This is shown in Fig. 3 where solid and dashed lines of the same colour correspond to intensity at opposite magnetic field directions. For larger spacer the effect due to SPP assisted emission disappears and far field effects with a magnitude of about $10 - 100$ times smaller take place.

Directionality of emitted light is also present for backside detection. In this case the relative contribution of SPP assisted emission is getting smaller with respect to the overall exciton signal. This results in a decrease of the TMRLE magnitude by about 5 times compared to frontside detection. At the same time the far-field effect due to interference of direct and reflected emission is getting weaker in case of backside detection.

Abstract

This work investigates theoretically nonlinear and parametric magneto-elastic interactions between surface acoustic waves and magnetization in ferromagnetic thin films and nanoparticles. Excitation of magnetic oscillations by elastic waves is calculated within a framework of a theoretical model based on the Landau-Lifshitz-Gilbert (LLG) equations dynamically driven via magneto-elastic interactions. In particular, we report on a theoretical investigation of magnetization switching in polycrystalline Ni nanoparticles induced by ultrashort pulses of surface acoustic waves.

1. Introduction

Studying the interactions of surface acoustic waves (SAWs) with magnetization in thin ferromagnetic films is motivated by beautiful physics and new principles of magnetic recording [1,2]. Nonresonant magneto-elastic switching in micrometer-sized cobalt bars using MHz-frequency SAWs has been demonstrated by Davis at al. [3]. Here we explore an alternative route of magneto-elastic switching using single broadband acoustic SAW pulses of picosecond duration. In our previous work, we have predicted the phenomenon of the acoustically induced magnetization switching in Terfenol thin films using ultrafast acoustic strain pulses characterized by the relatively large strain amplitude of 1 % [4]. Although acoustic pulses with such huge amplitude can be generated under strong excitation conditions [5], the energy barrier between the meta-stable states in Terfenol (determined by the competition of magneto-elastic, magnetocrystalline and magnetic shape anisotropies) cannot be easily tuned.

2. Main effects and equations

Let us consider a thin ferromagnetic film deposited on a nonmagnetic dielectric substrate with a constant magnetic field applied in the sample plane. Short acoustic pulses propagating at the surface of a solid can be generated by absorption of short laser pulses in a thin subsurface layer. This results in a transient and spatially inhomogeneous heating profile and subsequent generation of thermoelastic stress. This excites various acoustic modes in substrate, two of them can propagate along the surface: surface skimming longitudinal (SSLW) and Rayleigh surface acoustic wave (SAW).

Excitation of FMR precession by elastic waves has been calculated within the framework of a theoretical model taking into account the Landau-Lifshits-Gilbert (LLG) dynamics and the equations for transient elastic deformations. The effective magnetic field consists of the external DC magnetic field (with an arbitrary in-plane orientation with respect to elastic wavevectors), demagnetizing field, and a time-dependent magnetoelastic field. The latter is determined by SAW and SSLW strain elements. The equations for the magnetic oscillations induced by elastic waves have been derived by perturbation theory. The parametric interaction of elastic waves with ferromagnetic resonance leads to SAW+SSLW and SAW+SSLW harmonic generation. The magnetic precession amplitude dependences on the DC magnetic field at different angles between the DC magnetic field and the direction of acoustic k-vector were obtained.

We consider also a polycrystalline Ni nanoparticle in a shape of an ellipsoidal disc with a long axis a, short axis b and thickness c. Such structures can be routinely fabricated from thin nickel films by electron or ion beam lithography. It is important to notice that such nanoparticles, produced by lithography techniques, stick to the surface and their mechanical adhesion is the same as that of a continuous thin film. Introducing the Cartesian coordinates, we can set the y axis to be parallel to the long axis of the ellipse. The particle is placed in a permanent magnetic field H pointing along the x axis. Short acoustic transients with propagate along the x axis. The free energy density of an elliptical ferromagnetic nanoparticle consists of Zeeman, demagnetization and magneto-elastic terms. We can tune the free energy density by different means. For example, its demagnetization term depends on demagnetizing factors, therefore it can be modified by varying the aspect ratio ab/c of the nanoparticle. In the presented analysis, we use the
following particle dimensions: $a=150$ nm, $b=100$ nm, $c=20$ nm. The choice of these dimensions is arbitrary, but it fulfills certain requirements. First, such dimensions ensure that the magnetization is in a single-domain state and provide the volume of the nanoparticle to obtain the energy barrier between the metastable states. Second, the small axis of the ellipse remains much smaller than the spatial extent of the acoustic SAW pulse and justifies the assumption of spatially homogeneous strain acting on the nanoparticle. Third, as long as the lateral dimensions of the nanoparticle are large compared to its thickness, i.e. $a \ll b \ll c$, the simulations will still be valid for nanodiscs for cases with the same aspect ratio $a/b=1.5$.

Variation of the external magnetic field provides another flexible tool to change the structure of the free energy density. In the absence of the external magnetic field or for small $H$, the free energy $F$ possesses two minima corresponding to two meta-stable states of defined magnetization direction. Upon an increase of $H$, these minima merge into a single minimum, corresponding to the alignment of the magnetization along the external magnetic field. Dynamic perturbations of the bi-stable nanomagnet described above may result in magnetization switching. In this study we are particularly interested in the influence of transient elastic deformations induced by picosecond SAW pulses. Energies required for magnetization switching are expected to approach the fundamental Landauer limit of $kT \ln 2=17$ meV, i.e. the minimum energy required to record a single bit of information at $T=300$ K.

3. Conclusions

We investigated the phenomenon of magnetization excitation in films and reversal (switching) in elliptical nanomagnets induced by ultrashort pulses of surface acoustic waves. The areas of the parametric and direct excitations on the static magnetic field and amplitude of the strain were revealed. In the case of magnetization switching in nanoparticle the switching threshold between two metastable single-domain magnetization states depends on the amplitude and duration of SAW pulses, the magneto-elastic coupling efficiency and the height of the potential barrier between these states. The latter is determined by the magnetic shape anisotropy of an elliptical nanomagnet, which depends on its dimensions and the amplitude of the external magnetic field. The key point is tuning the height of the potential barrier between the metastable energy minima using weak magnetic fields easily accessible in the experiments. Our geometry, where the magnetic nanoparticle is driven by short SAW pulses, is complimentary to similar objects driven by quasi-monochromatic excitations and displaying bifurcations and chaos. Ultimate speed limits of magneto-acoustic switching can be investigated solving LLG equations driven by dynamic SAW strains. The $10^2$ SAW-switching threshold for elliptical Ni nanomagnets appears to be significantly lower as compared to highly magnetostrictive thin films of Terfenol-D switchable by ultrashort longitudinal acoustic pulses with amplitudes $10^2$ propagating in the direction perpendicular to the surface [4]. At first glance this observation may be surprising because of the 20 times larger magnetostriction coefficient in Terfenol-D. However, the much longer 300 ps duration of SAW pulses as compared to [4] and the magnetic tunability of the height of the potential barrier between the states overcompensate the lower efficiency of magneto-elastic coupling in nickel. It is quite straightforward that the SAW-induced switching threshold of Terfenol-D elliptical nanomagnets of similar dimensions should drop below $10^5$ making the investigated configuration suitable for low-power acoustic transducers.

Optical isolators based on magnetoplasmonic subwavelength gratings

Sevag Abadian, Giovanni Magno, Vy Yam, Béatrice Dagens
Centre de Nanosciences et de Nanotechnologies, CNRS, Univ. Paris-Sud, Université Paris-Saclay, C2N – 91120 Palaiseau, France

Optical isolators are one-way devices allowing light to pass only in one direction. They are elementary components to protect laser diodes against spurious back reflections or to build functions like optical circulators. Here we propose a metal-dielectric non-reciprocal waveguide that may pave the way toward the conception of compact integrated isolators. The challenge is to design integrated optical isolator with low footprint, high isolation ratio and low insertion losses. Fig. 1(a) depicts a 3D sketch of the proposed structure which includes a one dimensional (1D) subwavelength periodic gold plasmonic grating. The latter is located on one side of a magneto-optical (MO) dielectric Bismuth Iron Garnet (BIG) waveguide. These elements are placed on top of a non-MO Gallium Gadolinium Garnet (GGG) substrate and buried in SiO$_2$ superstrate. In this configuration non-reciprocal transmission of the TE fundamental mode is obtained by applying a vertical static magnetic field (inducing vertical magnetization in BIG layer).

![Fig. 1](image)

**Fig. 1:** (a) A gold grating on one side of a MO dielectric BIG waveguide placed on a non-magnetic substrate GGG and buried in SiO$_2$. Magnetization $M_z$ is applied vertically in the BIG layer and a TE source is used. (b) represents the Isolation ratio in dB versus the grating slit width and the wavelength for a device length of 3µm for a grating width of 0.13µm. Red and blue areas underline the resonances.

In this work, the enhancement of the TMOKE (Transverse MO Kerr Effect), arising from the coupling of grating and plasmonic resonances with guided modes, is studied in order to achieve efficient isolation. The numerical investigation has been performed by means of FDTD simulations. In non-guided configuration it has been observed that, when extraordinary optical transmission (EOT) occurs in deep-subwavelength plasmonic gratings placed on top of a MO substrate, a giant enhancement of the MO effect is achieved [1,2]. Here, in the case of integrated guided device, Fig. 1(b) shows the blueshift of the isolation curve peaks (defined as the difference in transmission in the forward and backward directions) as the slit widths increases from 0.03µm to 0.07µm, when a structure with ten gold gratings having a thickness of 0.13 µm is considered. To account for the losses, crucial in isolators, we define a figure of merit (FoM) as the ratio of isolation to insertion losses. The figure of merit calculated for the same structure shows a maximum value of 1.9dB, at $\lambda=1373$ nm.

To further investigate the behavior of our structure, hereinafter we consider larger grating thicknesses in order to exploit the existence of both the horizontal and the vertical Fabry Perot modes within the grating slits. To unveil the different optical mechanisms occurring in this structure a set of bandstructure simulations were performed on a unitary cell (with periodic boundary condition) [3].

![Fig. 2](image)

**Fig. 2(a)** represents the band diagram of the proposed structure when $p=0.3\mu m$, $s=0.04\mu m$ and $h=0.9\mu m$. Dashed white lines correspond to SiO$_2$, GGG and BIG lightlines. We can distinguish a set of propagating modes, identified as the TE waveguide mode (see label ‘1’), and a SPP mode (see label ‘2’), as well as a third, second and first order horizontal Fabry Perot flat bands (labels ‘3’, ‘4’ and ‘5’, respectively).
Fig. 2. (a) Bandstructure for $+M_3^{\text{flat}}$ for period 0.3µm, slit width of 0.04µm and gold width of 0.9µm. Inset: superimposed band structures for $+M_3^{\text{flat}}$ and $-M_3^{\text{flat}}$ at the vicinity of the interaction of the SPP with the third order FP mode. (b) Transmission (red, blue) and Isolation ratio (black) in dB versus wavelength for a device length of 3µm.

By inspecting the bandstructure in Fig. 2(a), we can see that the SPP mode interacts with the flat band near the third order horizontal Fabry Perot mode. This reflects on the amplitude of the isolation curve shown in Fig. 2(b) at $f=180$THz. Finally, the inset in Fig. 2(a) depicts the superimposed band structures for $+$ and $-$. We clearly observe the existence of a difference between the wave vectors for waves propagating in forward and backward directions, at the vicinity of the interaction between the guided TE mode, SPP mode and the Fabry Perot resonance housed inside the slit.

The spectral position of the slit resonances can be predicted by considering the response of an equivalent FP-like slab resonator: a layer with an index $n_{\text{eff}}$, the same thickness as the gold grating and sandwiched between SiO$_2$ and the BIG waveguide. The effective index $n_{\text{eff}}$ is given by the fundamental TE mode of the whole transverse structure which is represented in Fig. 3(a).

Fig. 3: (a) Transverse structure consisting of gold/SiO$_2$/gold waveguide and its extension into a resonant cavity by introduction of the garnet and SiO$_2$ media is shown schematically. (b) and (c) respectively represent the vertical and horizontal electric field profiles of the third Fabry Perot mode confined in the cavity with the SiO$_2$ gap set to 0.04µm, frequency 180 THz.

The location of the cavity resonances is then found by expressing round-trip resonance [4]:

$$2k_0n_{\text{eff}}h_1 + \varphi_{r_1} + \varphi_{r_2} = 2n\pi, \quad n \in Z$$

Where $h_1$ is the length of the Fabry Perot cavity, in this case it is the width of the gold grating and $\varphi_{r_1}$ is the reflection phase shift of the slit mode at both ends of the cavity.

As preliminary result we have identified that vertical Fabry Perot modes seem to have stronger impact than the horizontal ones on the device isolation ratio.

In this work, we have numerically shown that when a MO-BIG waveguide is coupled to a gold grating adjacent to it, surface plasmon polaritons may strongly enhance transverse magnetic-optical Kerr effect especially when guided TE modes interact with slit FP modes. The TMOKE effect can be tuned by optimization of grating geometry and opens the prospect of achieving an integrated isolator for TE mode.

Abstract
We investigate four-port circulators for THz region which present two parallel graphene waveguides with SPP modes and a magnetized resonator of elliptic form. The waveguides and the resonator are placed on a two-layer dielectric substrate. The working principle of the device is based on the rotating dipole resonance of the magnetized graphene resonator. Numerical simulations demonstrate good parameters of the circulators.

1. Introduction
Circulators are nonreciprocal components frequently used in microwave and optical systems for different purposes [1]. One of their main applications is protection of vulnerable sources from parasitic reflections in other circuit elements. Usually, they are based on different physical effects in waveguides with magneto-optical materials (one of such circulators in the photonic crystal technology is described in [2]). In this work, we investigate four-port circulators for THz region which present two parallel graphene waveguides with SPP modes and a magnetized disk or ring graphene resonator of elliptic form.

2. Circulator Description
The geometries of the circulators are presented schematically in Fig. 1 for the graphene resonators in the form of elliptic disk and ring. A magnetized resonator is placed between two identical parallel graphene waveguides with surface plasmon-polariton (SPP) modes. In the resonator for a given external DC magnetic field, two rotating modes can exist. The wave with the central frequency in port 1 propagates in waveguide 2 and excites the anticlockwise rotation mode in the resonator. This rotating mode, in its turn, excites the waveguide 1. The SPP mode in this waveguide appears in port 2. The wave entering in port 2, passes directly to port 3 without excitation of the resonator. Due to two-fold rotational symmetry, the physical processes in port 3 and in port 4 run their course analogously. Thus, the device provides the circulation 1→2→3→4→1. In our analysis, we start with a circular geometry and then make small changes to come to elliptic one.

3. Optical Conductivity Tensor
With applied DC magnetic field \( B_0 \), the 2D tensor of conductivity is as follows:
\[
\begin{pmatrix}
\sigma_{xx} & -\sigma_{xy} \\
\sigma_{xy} & \sigma_{yy}
\end{pmatrix}
\]
where \( \sigma_{yy} = \sigma_{xx} \), \( \sigma_{yx} = -\sigma_{xy} \). The components of the tensor are:
\[
\sigma_{xx} = \frac{2D}{\pi} \frac{1/\tau - i\omega}{\omega^2 - (\omega + i/\tau)^2},
\]
\[
\sigma_{xy} = \frac{2D}{\pi} \frac{\omega_0}{\omega^2 - (\omega + i/\tau)^2},
\]
where \( \sigma_{xy} \) is the conductivity of graphene, \( D = 2\sigma_{xx} / \hbar \) is the Drude weight, \( \hbar \) is the reduced Planck’s constant, \( \omega_0 = eB_0 \sqrt{\varepsilon_f} / \varepsilon_f \) is the cyclotron frequency, \( \varepsilon_f \) is related to chemical potential of graphene, \( e \) is the electron charge, \( \tau \)}
is the relaxation time, $\omega$ is the frequency of incident wave, $v_F$ is the Fermi velocity, $B_0$ is the magnetic field and $i = \sqrt{-1}$.

We consider the graphene monolayer with a finite thickness $\Delta$ and the conductivity tensor given by $\sigma = (\sigma_x, \sigma_y) / \Delta$, where $[\sigma]$ are tensor components (2) and (3). In our simulations, we use $\Delta = 1$ nm. The artificial parameter $\Delta$ is used only for calculation purposes and the numerical calculations were made for the following data: $\mu_c = 0.15$ eV, $B = 0.8$ T and $\tau = 0.9$ ps [3].

4. Numerical Results

The device in Fig. 1 (a) consists of the disk graphene resonator with radius $R=600$ nm and two symmetrical parallel graphene waveguides with the width $w=200$ nm and the length $L=4210$ nm. The resonator is magnetized by a magnetic field of normal direction to the graphene resonator along the $z$-axis, the waveguides are coupled laterally to the resonator with the gap $g = 2.5$ nm. In Fig. 1(b) a similar device with ring resonator is shown. The relation of internal and external radius in the circular ring is $s = R/R_0$. In the example below, $R_0 = 600$ nm and $R = 150$ nm, $s = 0.25$. The graphene elements are placed on a dielectric substrate composed of SiO$_2$ and Si layers with $h_1 = h_2$, thicknesses equal to 5000 nm and relative permittivity 2.09 and 11.9, respectively.

The numerical results were obtained using the commercial software Comsol Multiphysics [4]. We consider the resonators with a small eccentricity. The frequency characteristics of the disk circulator are shown in Fig. 2. Fig. 3 demonstrates the frequency responses for the ring case. The field distributions of the electric field with the disk structure are shown in Fig. 4(a) and Fig. 4(b), and for the ring one in Fig. 4(c) and Fig. 4(d) for the cases with excitation of different ports. The central frequency of the disk circulator is 5.09 THz, and 4.61 THz for the ring one. In the disk structure, we used the ellipse with eccentricity of 3% of the value of $R$ and for the ring one of 7% of the value of $R$.

The device based on disk resonator has the transmission coefficient around -4.0 dB, the isolation of port 4 -8.7 dB, isolation of port 3 of -29.7 dB and reflection coefficient of -40.3 dB for excitation at port 1. DC magnetic field is $B = 0.8$ T.

4. Numerical Results

The device based on ring resonator has the transmission coefficient around -4.0 dB, the isolation of port 4 -8.7 dB, isolation of port 3 of -29.7 dB and reflection coefficient of -40.3 dB for excitation at port 1. DC magnetic field is $B = 0.8$ T.

Figure 2: Frequency responses of ring circulator for excitation at port 1 and 2.

Figure 3: Frequency responses of ring circulator for excitation at port 1 and 2.

Figure 4: $E_z$ field distribution for disk and ring circulators.

5. Conclusions

We analyzed two types of four-port graphene circulators operating in THz region. These devices have a very simple structure composed of graphene elements placed on a dielectric substrate, with resonators of different geometries. The simulations of the devices demonstrated that the circulators possess good isolation and matching. The insertion losses can be reduced by optimization of the physical and geometrical parameters.

Magnetoplasmonic Modulators for Integrated Optics

C. J. Firby* and A. Y. Elezzabi

Abstract
Incorporating magnetic materials into plasmonic devices facilitates unique nonreciprocal phenomenon and highly nonlinear temporal dynamics in integrated nanoplasmonic circuitry. In this work, we review some of our recent advances in the development of magnetoplasmonic waveguide devices. Specifically, we demonstrate that integrating magnetic garnets as the core of plasmonic waveguide platforms allows for the development of unique optical phase and intensity modulators which are vital for integrated plasmonic networks.

1. Introduction
Nonreciprocal elements are crucial for integrated optical networks, as they be used to manipulate the flow of light in a circuit, provide unique mechanisms through which modal properties can be tailored, or facilitate unique modulator designs. As such, it is imperative to develop such components in the plasmonic regime. In optics, nonreciprocity is typically introduced by incorporating magnetooptical materials. Since plasmonic waveguide devices are inherently limited by the propagation losses of their metallic constituents, employing ferromagnetic metals, which are exceptionally lossy, only exacerbates these issues. Thus, a promising solution involves incorporating magneto-optical (MO) garnets, such as yttrium iron garnet or its derivatives (e.g., bismuth-substituted yttrium iron garnet or Bi:YIG, and cerium–substituted yttrium iron garnet, or Ce:YIG), into plasmonic structures. Such materials are dielectrics that are characterized by low absorption around the telecom wavelength of 1550nm, high magneto-optical parameters, and low saturation magnetizations, making them ideal candidates for plasmonic integration.

In this work, we review some of our recent designs for novel integrated magnetoplasmonic devices. By integrating magneto-optic garnets into plasmonic waveguide architectures, unique functionalities can be realized. Specifically, we design and numerically analyze devices such as a plasmonic phase shifters, isolators, and unique modulators such as a magnetoplasmonic analog to the electrical clock-multiplier, and an RF mixer.

2. Background
Incorporating magnetic garnets into waveguide architectures and subsequently magnetizing them via static external magnetic fields ($H_{static}$) can generate a number of unique effects on a propagating optical mode. If the magnetic garnet is magnetized transverse to the direction of propagation, a nonreciprocal phase shift will be imparted onto the optical mode. This implies that the propagation constant will differ for both forward and backward propagating modes. These unique effects can be modeled by considering the fully asymmetric permittivity tensor of the magnetic garnet [1]:

$$\varepsilon = \begin{bmatrix} n_{YIG}^2 & -ig_z & ig_y \\ ig_z & n_{YIG}^2 & -ig_x \\ -ig_y & ig_x & n_{YIG}^2 \end{bmatrix}$$ (1)

where $n_{YIG}$ is the refractive index of the garnet, and $g(M) = (g_x, g_y, g_z)$ is the gyration vector of the material, and $M$ is the magnetization vector.

Furthermore, the magnetization of a material, and thus the magneto-optic phenomena, can be actively modulated via the application of time varying magnetic fields, $h(t)$. In such scenarios, the magnetization will evolve in accordance with the Landau-Lifshitz-Gilbert model of magnetization dynamics [2]:

$$\frac{dM}{dt} = -\frac{\mu_0\gamma_0}{1 + \alpha^2} [M \times (H_{static} + h(t))] - \frac{\mu_0\gamma_0\alpha}{M_S(1 + \alpha^2)} [M \times (H_{static} + h(t))]$$ (2)

where $\mu_0$ is the permeability of free space, $\gamma_0$ is the gyromagnetic ratio, $M_S$ is the saturation magnetization, and $\alpha$ is the Gilbert damping constant. As such, a variety of novel structures are investigated via fully vectorial 3D finite-difference-time-domain (FDTD) simulations.

3. Results and discussion
3.1. Phase shifter
First, we examine the simplest structure to incorporate magneto-optical effects into a plasmonic platform: the dielectric-loaded plasmonic waveguide [3]. By incorporating a rectangular ridge of Bi:YIG onto an Ag transmission line, we show that the NRPS can be tailored to be as high as 6.99 rad/mm. Furthermore, by passing transient current pulses through the underlying transmission line, the corresponding magnetic field pulses can modulate the magnetization, and hence the NRPS within the device. We show...
that the device is capable of providing dynamic phase shifts up to 0.33rad within the propagation length of 49\(\mu m\).

3.2. Isolator

The inherent limitation on the attainable phase shift in the previous dielectric loaded plasmonic waveguide device is the short propagation length of the magnetoplasmonic mode. As such, the waveguide architecture can be modified to produce a device that can provide a useful \(\pi/2\) NRPS within its propagation length. Specifically, we consider the popular long-range dielectric-loaded plasmonic waveguide geometry, with a core of Ce:YIG, thin film of Ag, and buffer layers of Si\(_3\)N\(_4\) and Al\(_2\)O\(_3\) on a SiO\(_2\) substrate. We demonstrate that this waveguide architecture can provide a NRPS of 3.11rad/mm, which can impart a useful \(\pi/2\) phase shift within only 505.6\(\mu m\), which is far less than the 3.14mm propagation length of the mode. This waveguide architecture can be used within a Mach-Zehnder interferometer (MZI) configuration, biased by buried SmCo permanent magnets, to develop a magnetoplasmonic optical isolator [4]. We show that this isolator design produces isolation ratios of 22.82dB with low insertion losses of only 2.51dB.

3.3. Clock multiplier

The aforementioned MZI configuration can lead to the development of unique modulator geometries as well. Specifically, we show that one can construct the plasmonic equivalent of an electrical clock multiplier by employing Bi:YIG in a long-range dielectric loaded plasmonic waveguide MZI, in conjunction with two adjacent Ag transmission lines to apply transient magnetic fields [5]. In such a device, the applied fields can be tailored to excite resonant precession of the magnetization within the MZI arms, and thus, correspondingly excites a continuous oscillation of both the NRPS, and the MZI output. Tuning the magnetic field parameters can yield continuous optical intensity oscillations between 279.9MHz and 5.6GHz with 16.26dB modulation depth, and can multiply the exciting electrical pulse frequency up to \(2.1 \times 10^5\) times.

3.4. RF mixer

While previous applications considered transient electrical pulses driving the NRPS in magnetoplasmonic devices, driving the same MZI geometry with continuous RF signals can modulate the output intensity in a highly nonlinear manner. This is due to the nonlinear dynamics prescribed by Eqn. 2. By examining the frequency spectrum of the modulated transmission signal, we observe that RF mixing and nonlinear frequency generation occur [6]. Specifically, driving the Bi:YIG magnetization with a single sinusoidal signal can generate harmonics of the driving frequency, as well as frequency splitting into sidebands and down-conversion. Furthermore, by exciting the magnetoplasmonic MZI with two RF signals, the nonlinear behavior produces various mixed frequencies of the inputs.

4. Conclusions

In conclusion, we have reviewed a number of novel magnetoplasmonic devices. By incorporating Bi:YIG and Ce:YIG into magnetoplasmonic waveguides, we have shown that active phase shifters can be formed, and furthermore, these nonreciprocal phase shifters can be incorporated into MZI geometries to produce a plasmonic isolator, an analog to an electrical clock multiplier, or a nonlinear RF mixer. These devices are envisioned as critical building blocks in future nanoplasmonic networks.

Abstract

We propose and experimentally demonstrate a novel approach for all-optical control and switching of magnetization states of individual layers in the multilayered GdFeCo structures utilizing the excitation of the surface plasmon polaritons. Surface plasmon polaritons provide us an efficient tool to tailor light energy distribution inside the multilayered structure with GdFeCo layers, and thus for addressed magnetization reversal in the particular layer of the whole structure without any impact on the other layers.

1. Introduction

GdFeCo is a ferrimagnetic material which magnetization state can be all-optically controlled by laser pulses [1]. Moreover, it is a unique material since its magnetization could be switched by means of femtosecond laser pulses in the absence of the external magnetic field [2]. The effect originates from the peculiar ultrafast dynamics of the exchange coupled Gd and Fe sub-lattices having different relaxation times [3]. The important thing found is that all-optical magnetization reversal depends on the laser pulse energy density absorbed by the layer and has a threshold below which the layer does not switch magnetization [4]. Among the most fascinating effects observed in GdFeCo is all-optical helicity-dependent switching which is a difference of the threshold fluence required for magnetization reversal for opposite circular polarization states of the pump. The phenomenon of circular magnetic dichroism explains the observed effect, thus confirming the principal role of the absorption in the all-optical magnetization reversal [4]. Due to this helicity-dependence, one can switch the domains of one magnetization direction without any impact on the domains with the opposite direction.

As the all-optical magnetization switching takes place at picosecond time scale, it is very promising for the data storage applications at ultrafast recording rates. GdFeCo film could be as thin as a few nanometers, the most serious limitations of record density are imposed by the size of the optical laser spot. Therefore, for practical applications it is crucial to find the methods of increase the record density for such films. Multilayered GdFeCo structure could open the door for the multifold record density increase. However, up to nowadays, there was no way how to perform magnetization reversal in only one particular layer without making impact to the other ones.

In this work we present the method of layer-selective all-optical switching in GdFeCo multilayered structure utilizing the excitation of the surface plasmon polaritons (SPPs). The energy of the SPPs is concentrated locally near the metal/dielectric interface where they are excited [5]. Therefore, SPPs present an efficient tool to tailor light energy distribution inside the multilayered structure, and thus for addressed magnetization reversal in the particular layer of the whole structure.

2. Layer-selective magnetization reversal in bilayer structure

We demonstrate the proposed approach in the following bilayer GdFeCo SPP-supporting structure: (glass substrate)-Si\textsubscript{3}N\textsubscript{4}(5nm)-Gd\textsubscript{26}Fe\textsubscript{64}Co\textsubscript{9}(10 nm)-Si\textsubscript{3}N\textsubscript{4}(80 nm)-Gd\textsubscript{27}Fe\textsubscript{63}Co\textsubscript{9}(10 nm)-Si\textsubscript{3}N\textsubscript{4}(10 nm). For the SPP excitation, we use Kretschmann scheme with a 60-deg. SiO\textsubscript{2} prism attached to the glass substrate. The absence of exchange interaction between the two GdFeCo layers is achieved via the inclusion of the middle Si\textsubscript{3}N\textsubscript{4}(80 nm) layer, which width was tuned to achieve the significant difference in absorption of the top and bottom GdFeCo layers.

SPP excitation (at GdFeCo/air interface) and localization near the bottom GdFeCo layer is observed for p-polarized incident light, causing p-polarized femtosecond pulse being absorbed predominantly in this bottom layer. However, for the same angle of incidence of 60 deg. inside of the prism, and the same 800 nm wavelength of the pump, electromagnetic field distribution s- polarization is almost...
the contrary. S-polarized incident pulse cannot excite SPP and is mostly absorbed in the top GdFeCo layer. Therefore, for the pump fluence exceeding the threshold value required for magnetization reversal, polarization is responsible for targeting of the certain layer where the magnetization would switch, without any impact on the other layer.

We have performed experimental investigation of the plasmonic-enabled layer-selective GdFeCo switching. Observation of magnetooptical state of each layer was possible due to the different contribution of each layer to polar magnetooptical Kerr effect (PMOKE) of the whole structure. The PMOKE hysteresis loop measured as the dependence on the external magnetic field showed four distinct PMOKE values corresponding to the four possible magnetization states of the bilayered GdFeCo structure. It made possible magnetooptical imaging of the pump impact on the magnetization state of each layer. Obtained magnetooptical images (Fig. 1) clearly show the difference in the targeting layer for p- and s- polarizations of light.

Figure 1: Magnetooptical image of GdFeCo structure after exposure to p- and s-polarized pump.

Explicit description of the experimental results on layer-selective switching in the bilayered structure could be found in Ref. [6]

3. Layer-selective magnetization reversal in multilayered GdFeCo structures

The demonstrated approach might be easily extended to the multilayered structures where the SPP resonances for different layers take place at different pump wavelengths or incidence angles. The most straightforward way to detune SPP resonances in the spectral range is to select the GdFeCo-surrounding dielectrics with different refractive indices for each GdFeCo layer of the multilayered structure. However, the broadness of the SPP resonances as well as high nonlinearity of the dielectrics with high refractive indices prevents from practical use this approach. Way that is more efficient might be etching of GdFeCo layers to achieve gratings of different periods. Each grating period \( P \) in this case is responsible for the SPP resonance position determined as: \( k_0 \sin \theta + 2 \pi / P m = k_{0,\text{SPP}} \), where \( k_0 \) is the wavenumber in free space, \( \theta \) is the angle of incidence, \( m \) is the grating diffraction order (integer number), and \( n_{\text{SPP}} \) is the effective SPP mode index. Therefore, variation of the GdFeCo grating period \( P \) makes the SPP resonances to be spectrally diverged, both in wavelength and angular spectra. This allows one to achieve all-optical layer-selective magnetization reversal using pump of different wavelengths (or angles) in multilayered GdFeCo structures.

4. Conclusions

We have proposed and demonstrated a novel concept of layer-selective all-optical magnetization reversal in bilayer GdFeCo structure based on the controllable accumulation of energy in a particular layer due to the SPP excitation. We have shown experimentally, that using a single shot of the femtosecond laser pulse one can all-optically reverse the magnetization state of only one layer determined by the polarization of the pump. This approach of all-optical layer targeting and magnetization reversal in GdFeCo could be easily extended to the layered structures with multiple GdFeCo layers where the SPP resonances are detuned from one another.

Abstract

The magnetic circular dichroism and the Faraday rotation are the fundamental phenomena of great practical importance arising from the breaking of the time reversal symmetry by a magnetic field. In graphene those non-reciprocal phenomena are linked to the cyclotron resonance, and as such appear at very low frequency [1], therefore limiting their potential for applications. In this work we studied both theoretically and experimentally the possibilities that graphene based metasurfaces offer for the control of the Faraday rotation and MCD. We studied various metasurfaces, both plasmonic [2] and photonic [3] and observed strong enhancement of the Faraday rotation at selected frequencies independently of the cyclotron resonance. We went further by showing that, depending on its design, each metasurface allows specific control over the frequency, amplitude and/or broadening of the non-reciprocal optical response of graphene [4], possibly forming the building blocks for future non-reciprocal optical elements from Terahertz up to the mid infrared.

Abstract

Since the middle of the 1970s, thin films with perpendicular magnetic anisotropy (PMA) have been widely studied for recording media applications [1,2]. These systems can be designed with high thermal stability to avoid superparamagnetic behavior and with good writability [1], but this may raise the switching field above that which can be produced by currently available write heads. In order to overcome this limitation, other alternatives, such as perpendicular exchange coupled composite or exchange spring media, have been explored [3,4]. Perpendicular exchange spring systems consist of exchange-coupled hard and soft magnetic layers with respectively out-of-plane and in-plane easy magnetization axes. While the magnetically hard film provides thermal stability, the soft layer reduces the reversal field.

In this work, we studied [CoFeB/Pd] multilayer thin films as well as [CoFeB/Pd]/Co exchange spring structures by comparing time-resolved magneto-optical Kerr effect (TR-MOKE) measurements [5] with ferromagnetic resonance analysis (VNA-FMR). TR-MOKE measurements show a sudden drop within the first picosecond and a fast recovery (remagnetization) within a few picoseconds. This is followed by a clear oscillation or precession during a slower magnetization recovery (Figure 1 a). From the analysis of the precession behavior, we determined both the ferromagnetic resonance frequency \(\omega_{\text{FMR}}\) and the effective Gilbert damping parameter \(\alpha_{\text{eff}}\) (Figure 1 b). Both parameters have been compared with the results obtained from the VNA-FMR measurements.

Finally, the ultrafast demagnetization and the fast remagnetization processes within the initial 5 picoseconds have been analyzed. Measurements of the laser-induced demagnetization revealed a minimum at \(t \approx 320\) fs for the [CoFeB/Pd]5/Pd/Co(7Å) sample (Figure 1 c).

Abstract

Grating offer a solution towards integrated optical isolation by coupling optic fibers to on-chip waveguides. In this context, we study the interplay between diffraction and plasmons in magnetoplasmonic gratings, where broken time-reversal symmetry induces frequency shifts in energy and angular spectra of plasmon resonances. As a result, exceptionally large magneto-optic responses are seen in diffracted modes. Our results can be generalized to complex diffractive elements, such as metasurfaces, where they could find use in designing tunable nonreciprocal devices.

1. Introduction

Photonic or hybrid electronic/photonic circuits are considered to be a promising perspective for the next-generation of integrated devices [1]. This brings up the need for integrated nonreciprocal devices that could find use for optical isolation at small scales. Facing this need, there is an emergent activity that aims at achieving unidirectional light propagation along integrated optical waveguides. Additionally, optoelectronic devices are investigated, in which modulation and switching capabilities can be accomplished by electric control of the amplitude and phase of electromagnetic waves, using architectures based either on Mach-Zehnder interferometers or microring resonators. Therefore, the control of the properties of devices by electric fields is an active research field in nanophotonics.

Optical nonreciprocity is usually achieved by magneto-optic materials. However, as the relevant device length is reduced to very small scales in integrated devices, the magneto-optic activity—which is proportional to the amount of material—is drastically reduced. It is therefore necessary to compensate the large reduction in size and magneto-optic activity with a large enhancement of the intrinsic response. Facing this challenge, a substantial research has been devoted to boost the intrinsic magneto-optical magnetoplasmonic devices [2]. Along these lines, metallic diffraction gratings have been studied in the context of magnetoplasmonic crystals where control on surface plasmon polaritons (SPPs) is exerted by external magnetic fields. Yet, the mutual interplay of plasmonics, magneto-optics and diffraction has not been addressed so far. Facing this challenge, we have been primarily concerned with the study of this interplay using the grating coupler structure as the basic device where to analyze the effect of diffraction and plasmonics on magneto-optic responses. Indeed, grating couplers are important devices in the perspective of integrated photonic applications, as they enable efficient coupling between light from optic fibers to on-chip waveguides offering easy integration on wafers and enabling communication with external units via optical links.

2. Angle-resolved reflectance Fourier spectroscopy

We studied the optical properties of magnetoplasmonic gratings using Fourier optics microscopy [3], which provides access to the band structure of photonic crystals. The working principles of the Fourier optics are based on the collimation of the light coming from a point source, so that a plane wave is projected into the detector, which is placed in the Fourier plane, in which the reflected light projects the reciprocal space response, providing the band structure of photonic structures. This way, the angular information can be recovered through a space-angular conversion, providing angle-resolved reflectance (ARR) maps. The Fourier spectroscopy approach can be adapted to the study of magnetoplasmonic gratings by reducing the beam spot size in the objective back aperture, so that diffracted modes can be analyzed independently, enabling the exploration of the interplay between plasmonic resonances and diffracted light. We used this approach to study selectively surface plasmon polaritons propagating along backward or forward directions, enabling us to easily assess their non-reciprocal magnetic modulation.

2.1.1. Magneto-optic response of individual SPP excitations

To assess the magneto-optic response, we measured the transverse magneto-optic Kerr effect (TMOKE) amplitude of Au/Co magnetoplasmonic gratings, measured from the ARR maps, obtained through the expression

$$\tau = \frac{1(\mathbf{H}_z) - i(\mathbf{H}_x)}{1(\mathbf{H}_{\text{avg}})}$$  \hspace{1cm} (1)
where \( I(H_+) \), \( I(H_-) \) are the reflected or diffracted intensity detected at opposite saturated magnetizations of Co (taken at \( H_{sat} = \pm 150 \text{ Oe} \)), and \( I(H_{avg}) \) is defined as the average of the absolute value of \( I(H_+) \) and \( I(H_-) \) over many hysteretic cycles. In our study we demonstrate that that large TMOKE signals are associated with individual forward- and backward- SPP propagating modes. Interestingly, we found remarkably large TMOKE responses (above 4%) enhanced by selectively excited propagating plasmons. This observation opens up interesting perspectives in nanophotonics, as it might be exploited in on-chip grating couplers to external optical links, eventually enabling one-way propagation in integrated photonic circuits.

![Figure 1](image1.png)

Figure 1: Panels (a) and (b) show, respectively, the reflectance and TMOKE angular resolved plots from off-angle excitations, in which the light beams arise from the specular reflection and diffraction modes, corresponding to a grating with periodicity of \( \Delta = 1000 \text{ nm} \).

2.1.2. Magneto-optic response of SPP excitations under electric fields

In addition to magnetism, we also analyzed plasmon propagation and magnetooptic responses under the effects of electric fields after incorporation of ferroelectric materials into the magnetoplasmonic structures. For that purpose, we measured ARR maps under applied electric fields (Figure 2). We studied the particular case of Au/Co magnetoplasmonic gratings grown in combination with ferroelectric BaTiO\(_3\) layers.

In line with our previous results, large magneto-optic signals – two orders of magnitude larger than intrinsic responses– arise from the SPP excitation. We show that, due to the presence of the ferroelectric layer, plasmon propagation can be modulated by electric fields enabling reversing the sign of magneto-optic signals. Thus, the combined integration of magneto-optical and ferroelectric materials enables control over non-reciprocal device properties by application of external electric fields, rather than magnetic fields, which could greatly simplify their integration into multifunctional nanophotonic devices.

![Figure 2](image2.png)

Figure 2: Panels (a)-(c) display the normalized average intensity in the Fourier plane for three polarization states. Plasmon resonances are visible in (a) and (b). Panel (a) shows an orange square, from which the normalized average intensity as a function of field is calculated. Panel (d) shows a zoom of the region where the plasmonic effects are extracted.

3. Conclusions

Large enhancements of the magneto-optic response are found in magnetoplasticmonic grating couplers. This enhancement is due to magnetically-induced frequency shifts in the energy and angular spectra of plasmon resonances. Interestingly, these shifts can be modulated by electric fields via the control of the electric polarization of magnetoplasmonic gratings that incorporate ferroelectrics. The concepts presented here can be used to develop non-reciprocal devices that exploit diffraction in order to achieve tailored electromagnetic responses, opening up new avenues for active integrated nanophotonic devices.

Abstract

The optical properties of antiferromagnets and cavity magnonics of ferromagnets are discussed. The antiferromagnetic system displays phenomena analogous to non-ferroic hyperbolic materials and meta-materials, with interesting possibilities for optical spintronics. The ferromagnet cavity system shows mode attraction and may also support an analogy to opto-mechanical cavity response.

Natural hyperbolic magnetic media exist in which optical effects such as Goos-Hanchen shifts [1] and negative reflection [2] can be tuned by simply applying external magnetic fields. We discuss how this occurs in antiferromagnets and show that by rotating the easy axis of the crystal, the hyperbolic dispersion is rotated and the angle of refraction is modified and cannot be defined as simply negative and positive as is done in conventional hyperbolic media. The optical properties derived from the hyperbolic behaviour are also modified, and can result in slab focusing with a magnetic field dependence.

An example is shown below in Figure 1, where negative refraction is predicted for light propagation through an antiferromagnet with frequency chosen such that there is competition between elements of the permeability tensor. [2]

![Figure 1. Illustration of negative refraction through an antiferromagnetic film for different applied magnetic field strengths (after Ref. 2).](image)

Magnetic polaritons in antiferromagnets are electromagnetic excitations coupled with spin degrees of freedom. Antiferromagnetic spin excitations can have properties that arise from a feature associated with their spin ordering that provides an analogy to right and left circular polarisation of optical radiation. This allows us to explore possibilities for unique coupling between optics and spintronics. [4,5] As first demonstrated by Tang and Cohen in chiral optics, the asymmetry in the rate of electromagnetic energy absorption between left and right enantiomers is determined by an optical chirality density. Here, we demonstrate that this effect can exist in magnetic spin systems. By constructing a formal analogy with electrodynamics, we show that in antiferromagnets with broken chiral symmetry, the asymmetry in local spin-wave energy absorption is proportional to a spin-wave chirality density, which is a direct counterpart of optical zilch. [4] We propose that injection of a pure spin current into an antiferromagnet may serve as a chiral symmetry breaking mechanism, since its effect in the spin-wave approximation can be expressed in terms of additional Lifshitz invariants. We use linear response theory to show that the spin current induces a nonequilibrium spin-wave chirality density.

Cavity electrodynamics can also be realised in the context of magnetic spin systems. [6-7] In contrast to the THz frequency excitations typical of antiferromagnets, we consider instead the microwave frequency properties of ferromagnets. In ferromagnetic resonance, the zero wavevector resonance mode can be driven by fields within a microwave cavity. The cavity modes can hybridize with the resonance modes and create level splitting that is tuned by an applied magnetic field. An example of an experimental geometry is shown below in Figure 2 along with example results for mode hybridisation. [7]
Figure 2. An example cavity geometry is shown in (a), (b) and (c), and examples of cavity and ferromagnetic resonance hybridization is shown in (d) and (e). An interesting feature is the possibility of mode attraction, as observed in Ref. 7. We examine also possibilities for creating an analogy to optomechanical cavities using a topological excitation that can exist in magnetic spin systems. Topological soliton 'twists' can respond to optical pressure with natural frequencies determined by either structure or pinning. We predict mode repulsion and attraction processes, tunable with applied magnetic field, should exist for these systems also.

Abstract

We present results on ultrafast magnetization dynamics induced by the surface plasmon-polariton electric field in Au/iron-garnet magnetoplasmonic crystals [1]. The spin precession excited through the inverse Faraday effect demonstrates strong localization and efficiency enhancement by two orders of magnitude at the surface plasmon resonance. The mechanisms of the observed effect are discussed both analytically and numerically.

1. Introduction

Ultrafast spin dynamics is a research field of constantly growing interest. By coherently controlling the magnetic order of the solids, one can open possibilities for terahertz speed recording of information [2]. As new optical mechanisms for spin control are being developed [3], the problem of spatial localization still remains unsolved. At the same time, by using magnetoplasmonic structures one can excite surface plasmons in magnetic systems [4, 5, 6]. High spatial confinement and short lifetime of these excitations [7, 8] may help overcoming the localization problem [9].

One of the mechanisms for coherent spin control via optical fields is the inverse Faraday effect (IFE), when the light electric field induces a static magnetic field in a gyrotropic medium [10]:

\[
H_{k}^{IFE} = \chi_{ijk}^{m} E_{i} E_{j} \sin \varphi,
\]

where \(\chi_{ijk}^{m}\) is the magneto-optical susceptibility, \(E_{i}, E_{j}\) the electric field components and \(\varphi\) the phase delay between them. \(H_{k}^{IFE}\) is maximal for circularly polarized light and zero for linear polarization. Interestingly, the field structure of the surface plasmon polariton (SPP) is such, that it should produce strongly localized static IFE magnetic field on the timescale of the SPP lifetime. In this study we aim to utilize this unique combination of spatial and temporal localization of the magnetic field to control the spin dynamics in a transparent ferrimagnetic dielectric.

2. Experiment

For the experiment we fabricated an Au/garnet magnetoplasmonic crystal consisting of the 380 µm thick Gd-Yb-doped bismuth iron garnet single crystal (Gd₄/₃Yb₂/₃BiFe₅O₁₂, GdYbBIG)) covered with 50 nm Au grating with the period of 800 nm (Fig. 1). GdYbBIG is a ferrimagnetic dielectric, in which the exchange precession mode can be efficiently excited via the IFE (precession frequency is 0.41 THz) [11]. The sample was studied using a pump-probe setup with 800 nm probe and near-IR pump. The pump wavelength was tuned across the resonance for the SPP excitation at the Au/GdYbBIG interface. As schematically shown in Fig. 1, the SPP electric field rotates in the incidence plane as the SPP propagates along the Au/GdYbBIG interface and induces a static transversal IFE magnetic field localized on the scale of 100 nm.

By measuring the probe pulse Faraday rotation variation with respect to the time delay between the pump and probe, we were able to extract the amplitude and phase of the exchange precession mode for different pump pulse wavelengths. Spectrum of the exchange mode amplitude is shown in Fig. 2 for circular and linear pump polarizations.

Figure 1: Illustration of the Au/GdYbBIG magnetoplasmonic crystal and the IFE mechanism for the SPP field.
### 3. Discussion

The precession amplitude spectrum for circularly polarized pump does not show any features, since no SPPs are excited and the precession is homogeneously induced in the bulk of the GdYbBIG crystal due to the helicity of the pump pulse. At the same time, for the linearly polarized pump the bulk IFE effect should be zero, while the SPP excitation should induce the static IFE magnetic field localized at the Au/GdYbBIG interface. Indeed, the precession amplitude spectrum in this case shows strong feature centered at 1400 nm (Au/GdYbBIG SPP excitation in the first diffraction order) and changes the sign (phase) of the precession.

We also confirm our findings with numerical simulations and demonstrate high localization of the SPP-induced IFE magnetic field on the scale of 100 nm. Using the precession amplitudes and the characteristic dimensions of the regions, where the probe pulse experiences rotation, we calculate the ratio between the precession excitation efficiencies for resonant (SPP excitation) and non-resonant (circularly polarized pump) cases. The SPP-induced IFE magnetic field turns out to be $10^2$ times larger than that induced by the circularly polarized pulses in the bulk of the crystal.

### 4. Conclusions

Our findings demonstrate that the electric field of the SPP can induce a highly localized static magnetic field in gyrotropic medium that allows for efficient precession excitation in ferrimagnetic dielectrics.

Abstract

We demonstrate the anomalous enhancement of the longitudinal magneto-optic Kerr effect of bismuth-substituted yttrium iron garnet films, induced by localized surface plasmons in embedded gold nanoparticles. We reveal the underlying mesoscopic near-field mechanism by quantifying the result of the mixing of the two localized plasmonic resonant modes on the magneto-optic response in the far-field. Our results pave the way to the design on demand of the magneto-optic response of similar hybrid structures.

1. Introduction

The field of magneto-plasmonics allows to explore the influence of the strong localization of light, enabled by resonant plasmonic structures, on the response of magneto-optically active adjacent materials [1,2,3]. Nowadays, it is generally accepted that the strong confinement of light in plasmonic structures results in large local field enhancements, which increase enormously the interaction of light with the magnetic material. However, no conclusive quantification of the effect has been discussed. Recently, first steps in this direction were taken by showing the correlation of near- and far-field effects to design the magneto-optic response of a magneto-plasmonic material [4]. Here, we focus on the origin of the magneto-optical/plasmonic interaction using nanoparticles that support localized surface plasmons (gold nanoparticles-AuNPs) embedded in ferri-magnetic dielectric layers composed of bismuth substituted yttrium iron garnet (Bi:YIG).

2. Results

For our study, the AuNPs are randomly distributed on the interface of the Bi:YIG and gadolinium gallium garnet (GGG) layers. The optical properties of this sort of system are mainly determined by Localized Surface Plasmon resonances (LSPs), rather than by geometrical-lattice resonances. The Au/Bi:YIG system has already attracted numerous theoretical and experimental [5, 6, 7] studies based on the Faraday and Polar Kerr Effect (P-MOKE) enhancement. However, the underlying near-field mechanism is not clarified while there is lack of studies on the anomalous longitudinal MOKE response (L-MOKE) induced by LSPs. The L-MOKE geometry, used in our study, is easy to be implemented and therefore quite attractive for technological applications. The samples consist of AuNPs fabricated on top of a single crystalline GGG (111) substrate by post heating of a thin continuous Au film. On top of the AuNPs layer, the BiY2Fe5O12film is grown. The Kerr rotation spectra measured with the aid of a spectroscopic Kerr effect setup operating in the longitudinal mode, by means of a Wollaston prism, combined with a balanced photodiode setup, mounted on a motorized rotational stage. The setup is fully automated and, with proper calibration, it can provide the Kerr rotation in absolute values.

Numerical calculations were based on the Finite Integration Technique (FIT) method, by using the CST Microwave Studio. The Kerr rotation as a function of the light wavelength is shown in Fig. 1 for a reference Bi:YIG sample without AuNPs and for a Bi:YIG film containing AuNPs. The magneto-optical response of Bi:YIG in the optical and near-infrared region is attributed to the wings of the optical transitions occurring at photon energies of 2.8 and 3.3 eV (442 and 378 nm correspondingly). The main contribution is coming from the 3.3 eV transition band, which is largely affected by the Bi substitution, and less from the 2.8 eV band. Bi substitution increases both the oscillator strengths, as well as the splittings of the electronic transition bands. The Kerr rotation curves corresponding to both samples increases to high positive values for the low-wavelength spectral region, verifying the aforementioned points. For both samples exists a certain spectral region for which the Kerr rotation sign inverts. The spectral position of the zero-crossing is highly sensitive to the stoichiometry and the thickness of the film. For the sample containing AuNPs, the magneto-optical response of the Bi:YIG layer is strongly modified in the very broad optical region where the resonant localized surface plasmon phenomena take place. One sharp feature is located close to 625 nm, and a moderately broad one with an opposite sign at ∼700 nm.
As a generic conclusion, the experiment clearly shows a large anomalous modification of the magneto-optical response of Bi:YIG originating from LSPs.

2.1. Simulated Kerr rotation

In order to gain insight into the deeper mechanism of the observed anomalous magneto-optic activity, we need to answer the following question: Is the magneto-optic behavior of the hybrid Bi:YIG/AuNPs attributed to a possible modification of the off-diagonal elements of the dielectric tensor of Bi:YIG, caused by the intensified electric field of the LSPs, or is it simply attributed to the modification of the light scattering / absorption close to the resonant wavelength of the AuNPs?

For this, we calculated the reflectivity for s- and p-polarized light R_s and R_p respectively, as well as the polarization conversion efficiency R_sp and R_pp in the L-MOKE geometry. We furthermore studied the electric near-field components and attempt to correlate the magneto-optical far-filed spectral features with the magneto-optically induced near-fields. From the simulated data we can conclude that the sign of Kerr rotation in the far-field, as well as its absolute value in the LMOKE geometry, is an interplay between the main oscillating field resonances and the magneto-optically induced resonances. The Kerr rotation in the far-field is generated by the landscape of the near-field modifications of the magneto-optically induced fields.

3. Conclusions

We make a step towards engineering the magneto-optical response of noble metal/magneto-optically active dielectric structures, by addressing the key question of how the localization of the electromagnetic field defines the magneto-optical enhancement in these structures. We achieve the latter by mapping the enhancement of the magneto-optically induced near-fields. Furthermore, we show how the magneto-optic behaviour of the hybrid Bi:YIG/AuNPs system can be reproduced computationally. Near-field simulations show that the far-field MOKE features are attributed to more than one LSP resonant mode. The different modes have different field orientations and signs, and this effectively alters the dielectric tensor elements of the magnetic material.

Abstract

We report on the transverse magneto-optical Kerr effect in a two-dimensional magnetoplasmonic quasicrystal and compare it to the case of magnetoplasmonic crystals with different basic angles. The quasicrystalline structure provides resonant response with increased bandwidth.

1. Introduction

Quasicrystalline structures were experimentally discovered by Shechtman et al. [1], for which he was awarded the Nobel Prize in Chemistry in 2011. Quasicrystals are non-periodic but ordered structures [2]. Contrary to the periodic crystalline structures, they do not possess translational symmetry but have long-range ordering. For periodic structures the reciprocal lattice is given by an equidistant set of reciprocal vectors. Unlike periodic structures, the quasiperiodic ones are characterized by discrete but non-equidistant reciprocal lattices and corresponding unusual diffraction patterns.

Two-dimensional quasicrystalline structures can possess rotational symmetry \( C_n \) of orders, that are prohibited for periodic structures, such as \( n = 5, 7 \) and higher orders. An example of that is Penrose tiling that possesses \( C_5 \) rotational symmetry. Quasicrystalline substances are usually metallic alloys and they provide high hardness, low coefficient of friction, low thermal conductivity and wide optical absorption bands. Quasicrystals, like two-phase materials containing steel, have potential application as materials having high strength and plasticity at high temperatures and also as coatings, for example, for frying pans, solar energy absorbers and reflectors [2].

The concept of quasicrystals has been implemented in plasmonics as well. Plasmonic quasicrystals in the form of metal-dielectric nanostructures with quasicrystalline pattern that support excitation of surface plasmon-polaritons (SPP) were designed. Due to the discrete non-equidistant reciprocal space and the rotational symmetry of quasicrystals, a larger number of resonances associated with SPP modes appear and therefore such structures demonstrate a broadband optical response. Moreover, it is polarization-independent for the 2D structures [3]. The advantage of quasicrystalline structures over periodic and non-periodic ones is that they possess rich and designable reciprocal lattice that governs the optical diffraction and dispersion of the eigenmodes, and therefore offer designable broadband optical response. It comes from the fact that the reciprocal lattice is strongly dependent on the geometrical parameters of the structure, while for the periodic structures it is defined solely by the period.

The study of magnetoplasmonic quasicrystalline structures is also performed. In particular, the transverse magneto-optical Kerr effect (TMOKE) was shown to demonstrate multiband response in one-dimensional magneto-plasmonic crystals [4].

In the present work we present theoretical and experimental study of the TMOKE in a two-dimensional magnetoplasmonic quasicrystal as well as two-dimensional periodic structures.

2. Considered structures

The considered structures consist of metallic grating of these patterns and a smooth magnetic dielectric film. The periodic structures are formed by circle holes in metallic films with rombohedral lattice with different basic angles of 30, 36, 45, 60, 72 and 90 degrees. The quasi-crystalline structure is formed by superposition of five periodic lattices with basic angles 72 deg. rotated by 72 deg. with respect to each other. Such structure obviously possesses 10-fold rotational symmetry. The quasi-crystalline pattern is shown in Fig. 1.

The metal grating is made of gold with the thickness of 100 nm. The magnetic dielectric is a bismuth substituted iron-garnet film of composition Bi₁₋ₓGdₓFe₁₋₅Al₆O₁₂ with the width of 80 nm, so that waveguide modes are not excited.

The light is TM-polarized and hits the sample from the metal side of the structure. The TMOKE in transmission is measured as \( \delta = |T(M)−T(−M)|/T(0) \), where \( T(M) \) is transmittance at magnetization equal to \( M \).
3. Results and discussion

Fig.2 shows the TMOKE for the quasicrystalline structure and for the plasmonic crystal with the basic angle of 72 degrees. The spectral position of the resonances are the same, which corresponds to theoretical consideration, as the quasicrystal is formed by superposition of similar crystalline structures. The width and the strength of the resonances are different because the quasicrystalline structure supports the greater number of plasmonic modes propagating in different directions. Experiments also reveal that the resonance position changes when the basic angle changes.

Experimental Realization of Tunable Microwave Coherent Perfect Absorber in Graphene-based Sandwich Structure

Jin Zhang and Weiren Zhu*

Department of Electronic Engineering, Shanghai Jiao Tong University, Shanghai, China

Abstract

We exploit experimentally a graphene-based sandwich structure for the realization of tunable microwave coherent absorption. It is demonstrated that the coherent absorption can be tuned from 65% to 100% via changing the Fermi energy of graphene, in good accordance with numerical simulations and equivalent circuit model analysis.

1. Introduction

Coherent perfect absorption is a time-reversed process of lasing at threshold, where a pair of coherent waves could be totally absorbed in a medium/device, named as a coherent perfect absorber (CPA) [1]. The exclusive features of complete absorption of electromagnetic radiations in CPAs are of great interest for a wide range of applications, including radar cloaking, sensing, and molecular detection. Various types of CPAs have been realized in several platforms, including ultrathin metasurfaces, plasmonic surfaces and waveguides. Recently, another feasible method to realize CPAs is using graphene as the absorbing medium. The static CPA in graphene for microwave and visible spectra has been demonstrated experimentally [2-3]. Recent study also show that graphene would yield tunable absorption for terahertz radiation [4]. However, due to the limitation of conventional doping method, graphene-based tunable CPA has not been experimentally achieved in microwave yet.

In this paper, we realize the tunable perfect absorption of gigahertz radiations by exploiting the concept of coherent absorption within a graphene-based sandwich structure (GSS). Owing to the unique tunable characteristics of the GSS, experimental results show that the coherent absorption could be tuned from 65% to 100% by changing Fermi energy of the graphene film. This method provides additional degree of freedom in designing graphene based coherent absorber.

2. Structure and Analysis

Figure 1(a) gives a schematic representation of the GSS. Two graphene layers are separated by an electrolyte medium, where \( h_e = 50 \mu m \) is the distance between the two graphene layers. Applying a voltage bias between the top and bottom monolayer graphene polarizes the electrolyte and thus generates different polarities concentrating beside the graphene layers. In such a way, the graphene layers are electrostatically doped and the Fermi energy could be dynamically adjusted. In a coherent system as shown in Fig. 1(a), the complex output beams \( (O_k) \) from the GSS are related to the two input beams \( (I_\pm) \) through an S parameters matrix,

\[
\begin{bmatrix}
O_+ \\
O_-
\end{bmatrix} = \begin{bmatrix}
S_{11} & S_{21} \\
S_{12} & S_{22}
\end{bmatrix} \begin{bmatrix}
I_+ \\
I_-
\end{bmatrix}.
\]

(1)

For simplicity, the scattering matrix can be simplified with \( S_{11} = S_{22} \) and \( S_{12} = S_{21} \), since the proposed CPA is a reciprocal structure with spatial symmetry. The equivalent circuit model of this graphene-based CPA is shown in Fig. 1(b). \( C_e \) represents the electrostatic capacitance of the electrolyte and \( Z_e \) represents the characteristic impedance of the electrolyte medium. The doping level of graphene layers defines graphene’s surface resistance, \( Z_g \), which could be expressed as

\[
Z_g = \frac{\pi h^2}{-j2e^2k_BT}\log^{-1}\left[\frac{2\cosh\left(\frac{E_F}{2k_BT}\right)}\right],
\]

(2)

where \( e \) is the electron charge, \( k_B \) is the Boltzmann constant, and \( h \) is the reduced Plank constant. \( \tau \) and \( T \) represent the scattering rate and temperature. It is easy to know that the increase of the Fermi level \( E_F \) in graphene will lead to the decrease of surface resistance \( Z_g \). For example, the surface resistances of graphene are roughly \( 3000 \Omega/\text{sq} \) and \( 80 \Omega/\text{sq} \) for \( E_F = 0 \) eV and \( 1 \) eV, respectively. According to transmission line theory, the \( S \) parameters for this system can be calculated as:

\[
S_{11} = \frac{Z_{in} - \eta_0}{Z_{in} + \eta_0}, \quad S_{12} = \frac{2Z_{in}}{Z_{in} + \eta_0},
\]

(3)
where $Z_{in}$ and $\eta_0$ represent the input impedance and wave impedance of free space. Considering two coherent waves with identical amplitude normally incident on the two sides of GSS, the coherent absorption $A_{co}$ can be written as [5]

$$A_{co} = 1 - 2 \left| S_{11} \right| \left| S_{12} \right| \left( 1 + \cos \Delta \phi \cos \Delta \varphi \right) - (\left| S_{12} \right| - \left| S_{11} \right|)^2$$

(4)

where $\Delta \phi$ is the phase difference between $S_{11}$ and $S_{12}$, $\Delta \varphi$ is the phase difference of the beams $I_+$ and $I_-$. The large-area monolayer graphene is synthesized by chemical vapor deposition on copper foil and then transferred onto a polyvinyl chloride substrate. The membrane soaked with ionic liquid is severed as electrolyte medium, which has a large electrochemical window that yields tunable Fermi energy on graphene. When a bias voltage is applied, the Fermi energy of graphene can be significantly changed. Two-layers GSS are used in our experiment that enables $Z_{in}$ to match the wave impedance of free space.

Figure 3 shows the measured tunable coherent absorption spectra with variable Fermi energies. It is assumed that the phase modulation is fixed at $\Delta \varphi = 0$ for all the cases. It is seen that when the Fermi energy of graphene increasing from 0.04 to 0.2 eV, the coherent absorption increases correspondingly from about 65% to 100%. In particular, the coherent perfect absorption is realized when the Fermi energy is 0.2 eV.

4. Conclusion

In summary, we have shown that graphene sandwich structure can be employed for perfectly suppressing scattering of coherent microwave radiations. Furthermore, it is experimentally demonstrated that the coherent absorption of the GSS could be dynamically manipulated via changing the Fermi energy of graphene.

Abstract
Recently the performances of radar absorbing materials have been extended by designing new thin structures with wideband properties and large angles of incidence [1]. In this paper, the design and performances of such ultra-wideband microwave absorber of low thickness material developed within the framework of the SAFAS project (self-complementary surface with low signature) are confirmed with complementary quasi monostatic measurements and finite array simulations using Finite Element Tearing and Interconnecting domain decomposition methods (FETI).

1. Introduction
The innovative nature of the SAFAS project is based on the combined use of a self-complementary chessboard-like structure, a metasurface, and a WAIM layer, to make possible a dual polarized self-complementary connected array antenna [2] and, also, an ultra-wideband and wide-angle metamaterial absorber. The architecture of the absorber material that has been optimized in [3] is presented in Figure 1 and Figure 2. The lower part is the self-complementary structure (checkerboard) which inherently has a wideband behavior. The elementary cell of the absorber is given in Figure 2, where the metallic parts are drawn in grey. To achieve the absorption of the structure, resistive deposits were placed between each conducting patch of the checkerboard. This self-complementary structure is placed above a ground plane. To increase the bandwidth of the structure, a metasurface also using resistive deposit has been optimized and is located above the checkerboard. Finally, to minimize the impedance discontinuity between the absorber and free space and to provide wide angle and wideband frequency matching, a WAIM layer has been added at the top of the structure.

In this paper, additional simulations results of the absorber performances for several finite sizes of the array are presented. The simulations using the FACTOPO code developed at ONERA and equipped with a FETI-2LM solver ([4]) are carried out on High Performance Computer (HPC) provided by the GENCI consortium in France (Grand Equipement National en Calcul Intensif). New measurement results obtained with CAMERA@ONERA measurement facility are also presented to confirm the simulated predictions.

Figure 1: Multilayer absorber description (unit cell).

Figure 2: Nomenclature of each layer of the ultra-wideband absorber

2. Results and discussion
The absorber is composed with Copper as ground plane, Epoxy FR4 (glass-reinforced epoxy laminate, $\varepsilon_r = 4.7$, tan $\delta=0.02$), RO4003 (woven glass reinforced hydrocarbon/ceramics, $\varepsilon_r = 3.38$ and tan $\delta = 0.0027$) from Rogers, MY360 (woven glass PTFE, $\varepsilon_r = 2.33$ and tan $\delta = 0.0011$) from Neltec and Diclad 880 (fiberglass reinforced
PTFE-based composites, \( \varepsilon_r = 2.2 \) and \( \tan \delta = 0.0009 \) from Rogers. The checkerboard is constituted by metallic patches etched on RO4003 material and connected at their corners with Resistor Foil NiCr (100 ohms per square) from Ticer Technologies. The metasurface is composed with the same Resistor Foil NiCr (100 ohms per square) etched on the second RO4003 material. The total thickness of the absorber is 11.5 mm. Other material choices were possible but not reachable in the time line of the SAFAS project. It is therefore not an optimum but a compromise to validate a proof of concept.

The prototypes having the following dimensions (20 cm\(^2\)) and composed of 1600 cells were manufactured by CIRETEC (Figure 3). The simulations results presented in Figure 4 are obtained with ONERA’s FACTOPO, fem-feti domain decomposition code [4]. The exact size of the array prototype 20 cm\(^2\) fabricated with 1600 unit cells is simulated as well as virtual prototypes of 10 cm\(^2\) (400 cells) and 30 cm\(^2\) (3600 cells). These parametric studies on the size of the array show that the performances of the absorber are already obtained with a limited size of 10 cm\(^2\). It is also observed a convergence of the RCS reduction in terms of bandwidth and magnitude starting from a prototype of size 20 cm\(^2\).

![Figure 3: Prototype of the manufactured absorber.](image)

![Figure 4: Finite array simulation results and measurements of the checkerboard-like absorber.](image)

Similar to what has been observed in previous works [1], at normal incidence (Figure 4) the FACTOPO@ONERA finite arrays simulation results give a bandwidth (-10dB) of 3.5-18 GHz while the CAMERA@ONERA measurement results give 3.7-17.5 GHz. These results seem different from each other but the behavior of the absorber is well observed on a very large bandwidth. The level of the two characteristic minima appearing at 5 GHz and 14 GHz in simulation is shifted around 4.9 GHz and 12.5 GHz in measurements. This frequency shift can be explained mainly by the cause of a poor estimation of the dielectric constants. The FR4 material is a low cost material and the dielectric constant is subject to significant fluctuations. This work seems to exclude the influence of the finite dimensions of the absorber in these frequency shifts. The level of the magnitude of the reflection coefficient between these two minima is higher in measurements than in simulations, and a poor estimation of the dielectric constant can also be the cause. Finally, it should be noted that these differences occur between -14 dB and -18 dB which are intrinsically low values.

3. Conclusions

New simulation results and complementary measurements of the SAFAS prototype presented in this paper confirm the overall performances of the absorber. These works are actually transposed to the domain of composite materials in the framework of the SAFASNAV project.

Abstract

The phase distribution required along a metasurface in order to converge the energy to any desired spatial position is calculated. In order to dynamically control this convergence point, a planar reconfigurable metasurface has been developed. This structure is composed of meta-atoms that incorporate voltage-controlled varactor diodes. The dispersion responses of each unit cell are individually tailored for the reconfigurability mechanism. Experimental verifications performed on an active metasurface agree with theoretical calculations and validate the proposed concept.

1. Introduction

Electromagnetic (EM) wave control has become possible today thanks to metamaterials. In addition, in recent years a planar version of metamaterials called metasurfaces has been developed. These new structures present the main advantage of having reduced profile and therefore reduced losses [1]. By controlling the reflection and/or transmission characteristics of metasurfaces, they have been successfully implemented to generate anomalous reflection and refraction [2-3], to control the polarization [4], generation of vortex beams [5] and holograms [6].

2. Manipulating spatial energy distribution

In order to manipulate the spatial energy distribution of an EM wave, a general theoretical model has been developed recently [7]. This model allows calculating the phase distribution that should be applied along a metasurface in order to converge energy to any desired spatial position. This theoretical approach is based on a holography imaging technique. For that, we start by imposing a desired spatial distribution of the energy, and then we extract the phase profile that allows obtaining such desired configuration. In this work, we aim to design a reconfigurable converging mirror that allows controlling the focal point position. In this case, we define an elementary point source on the desired focal points (F = 50 and 120 mm in our case).

3. Results

The calculated phase profiles, shown in Fig. 2, are applied to a reconfigurable metasurface that is composed of resonant meta-atoms. Each individual meta-atom incorporates a varactor diode that can be controlled by a DC voltage. By varying the applied bias voltage, the reflection phase response of each unit cell can be tuned and in this way, the calculated phase profiles can be applied to the whole structure. An electric field mapping distribution along xoz plane is then reconstructed and presented in Fig. 3(a). Energy spots are respectively obtained at the positions of 50 mm and 120 mm in calculations.

Figure 1: Schematic view of the design principle process for the manipulation of the spatial energy distribution.
profile. Measurements are performed and the experimental near-field distributions show the reconfigurability of the focal point, as presented in Fig. 3(b).

Figure 2: Calculated phase profiles for two different focal points $F = 50$ and 120 mm.

Figure 3: Mapping of intensity of the electric field for the two focal point along $xoz$ plane. (a) Calculations. (b) Experimental.

4. Conclusions

To summarize, a phase distribution that allows to converge an EM wave to any desired spatial position has been calculated. In order to dynamically control this convergence point, a planar reconfigurable metasurface that incorporate voltage-controlled varactor diodes has been developed. Two focal points ($F = 50$ mm and 120 mm) have been tested and near-field measurements have been performed to validate the concept.

Metasurface Surface-Wave Dispersion Analysis and Synthesis Technique

Karim Achouri¹, and Olivier J. F. Martin¹

¹Nanophotonics and Metrology Laboratory, Department of Microengineering, École Polytechnique Fédérale de Lausanne, Route Cantonale, 1015 Lausanne, Switzerland
*corresponding author, E-mail: karim.achouri@a3.epfl.ch

Abstract

The proposed technique allows one to efficiently and quickly retrieve the dispersion diagram of a metasurface from its numerically simulated scattering parameters without resorting to a time-consuming numerical eigensolver. It may also be used to find the metasurface structure corresponding to desired surface-wave propagation characteristics.

1. Introduction

This work aims at relating the susceptibilities of a metasurface to its ability of supporting the propagation of surface-wave modes. To do so, an eigenvalue equation is formulated using the geometry depicted in Fig. 1, where the metasurface is modelled based on the generalized sheet transition conditions (GSTC) [1–4]. While several surface-wave analysis techniques have already been developed, such as in [5–8], most of them are limited to impenetrable and anisotropic surfaces. The proposed technique alleviates these limitations as it may be applied to penetrable, impenetrable, anisotropic and bianisotropic structures.

2. Eigenvalue Problem

For a general bianisotropic metasurface lying in the xy-plane at z = 0, the GSTC read [1, 9]

\[ \mathbf{z} \times \Delta \mathbf{H} = j \omega \mathbf{\varepsilon}_{ee} \mathbf{E}_{av} + j k \mathbf{\varepsilon}_{em} \cdot \mathbf{H}_{av}, \]  
\[ \mathbf{z} \times \Delta \mathbf{E} = - j \omega \mu \mathbf{\varepsilon}_{mm} \cdot \mathbf{H}_{av} - j k \mathbf{\varepsilon}_{me} \cdot \mathbf{E}_{av}, \]  
(1a)

\[ \mathbf{z} \times \mathbf{H} = j \omega \mathbf{\varepsilon}_{ee} \mathbf{E}_{av} + j k \mathbf{\varepsilon}_{em} \cdot \mathbf{H}_{av}, \]  
\[ \mathbf{z} \times \mathbf{E} = - j \omega \mu \mathbf{\varepsilon}_{mm} \cdot \mathbf{H}_{av} - j k \mathbf{\varepsilon}_{me} \cdot \mathbf{E}_{av}, \]  
(1b)

where \( \mathbf{\varepsilon}_{ee}, \mathbf{\varepsilon}_{mm}, \mathbf{\varepsilon}_{em}, \) and \( \mathbf{\varepsilon}_{me} \) are respectively the electric, magnetic, magnetic-to-electric and electric-to-magnetic susceptibility tensors, the operator \( \Delta \) refers to the difference of the fields between both sides of the metasurface while the subscript "av" refers to their arithmetic average.

A surface-wave eigenvalue problem may be formulated from (1) by defining the fields at \( z = 0^+ \) and \( z = 0^- \) as that of TE and TM surface waves [4]. After substantial algebraic manipulations, we arrive at the eigenvalue problem defined by

\[ \mathbf{M} \cdot \mathbf{x} = k_z \mathbf{x}, \]  
(2)

where \( \mathbf{M} \) is a matrix (provided in [4]) containing the metasurface susceptibilities and the media parameters, the eigenvalue \( k_z \) is the normal propagation constant of the surface wave and the eigenvector \( \mathbf{x}^T = (A^T_{TE}, A^T_{TM}, A^+_{TE}, A^+_{TM}) \) contains the amplitude of the TE and TM surface waves on the top and bottom sides of the metasurface.

Table 1: Dispersion relations of anisotropic metasurfaces.

</tbody>
</table>

From (2), one may obtain the dispersion diagram of a metasurface using \( k_x = \pm \sqrt{k^2 - k_z^2} \), where \( k_x \) is the eigenvalue of the problem and \( k \) is the propagation constant in the medium of interest. In this case, the susceptibilities in \( \mathbf{M} \) may be found from numerically simulated scattering parameters [3, 4]. Alternatively, the metasurface susceptibilities required to achieve a specified surface-wave propagation may be obtained by specifying \( k_z \) and \( \mathbf{x} \), and solving (2) for the susceptibilities.

The case of anisotropic (birefringent) metasurfaces is of particular interest as it corresponds to most surface-wave guiding structures (it includes isotropic structures but excludes gyrotropic ones). Assuming that such an anisotropic
metasurface is surrounded by the same medium on both sides, the system (2) may be easily solved and yields the 4 solutions provided in Table 1 corresponding to TE and TM, symmetric and asymmetric surface-wave modes.

Figure 2 compares the dispersion curves of a 60 nm thick gold slab obtained from the TM solutions in Table 1 and the exact solutions from Maxwell equations. Similarly, Fig. 3 compares the dispersion curves of the three first surface-wave modes propagating on the microwave metasurface structure discussed in [4] obtained using Table 1 and the eigenmode solver of CST MWS. Both figures show good agreements.

We also have considered the case of bianisotropic (omega-type) metasurfaces. The solutions of (2) for this type of structures are given in Table 2. The main advantage of bianisotropic metasurfaces over anisotropic ones is their ability to independently control the amplitude of the surface waves on the top and bottom sides of the structure, as evidenced by the dependence of the eigenvectors on the susceptibilities.

Abstract

In this paper, transmissive-type metasurfaces is proposed to independently refract the orthogonal circularly polarized wave in microwave region. Based on the combination of propagation phase and geometry phase principles, the opposite circularly polarized transmitted wave can be deflected into independent and arbitrary directions. Experimental measurement are conducted and effectively verified the feasibility of the proposed theory for artificial manipulation of circular polarization manipulation in microwave region.

1. Introduction

Polarization is one of the intrinsic attributes of planar electromagnetic (EM) wave \cite{1}. Traditional methods of polarization manipulation are birefringence \cite{2}, photonic crystals \cite{3}, metasurfaces \cite{4} and so on. The geometric phase also known as Pancharatnam-Berry phase can be employed to convert the left-/right-handed circular polarized (LHCP/RHCP) incident wave into its opposite circular handedness with totally symmetrical characteristics \cite{5}. However, the inherent restrictions of this symmetry characteristic have limited the applications in wireless systems \cite{6}. Various works have been proposed to figure out the symmetry limitation in orthogonal polarization manipulation of EM wave \cite{7}.

In this paper, transmissive meta-lens is proposed to realize polarization-independent refraction at microwave frequencies. Based on the library of unit cells for the full phase coverage, the meta-lens is composed of 8 unit cells with different constructions. The simulation and measurement results demonstrate that the desired polarization-independent refraction can be achieved in a wide frequency band, suggesting promising applications in wireless communication systems.

2. Principles and results

The schematic of polarization-independent refraction is shown in Fig. 1. Under the orthogonal circularly polarized incident waves, the transmitted wave can be refracted into different and independent directions by elaborately designed meta-lens.

![Figure 1: Schematic of proposed meta-lens for generating polarization-independent refracted wave with the illumination of orthogonal circularly polarized incident waves.](image)

In this paper, transmissive-type metasurfaces is proposed to independently refract the orthogonal circularly polarized wave in microwave region. Based on the combination of propagation phase and geometry phase principles, the opposite circularly polarized transmitted wave can be deflected into independent and arbitrary directions. Experimental measurement are conducted and effectively verified the feasibility of the proposed theory for artificial manipulation of circular polarization manipulation in microwave region.

In this paper, the phase gradients for circularly polarized incident waves are set as $\alpha = 0.5k_0$ and $\beta = 0.25k_0$, where $k_0$ is the wave number ($k_0 = 2\pi/\lambda_0$, $\lambda_0 = 30$ mm). According
to the generalized refraction laws, the transmitted refraction angle can be obtained as -30° and -14.5° with the illumination of LHCP and RHCP waves.

The constructed meta-lens is exhibited in Fig. 2(a) and the unit cell is composed of two metallic layers separated by a dielectric substrate. One of the utilized unit cells are simulated and analyzed shown in Fig. 2(b) and 2(c). It can be seen that the magnitude responses under orthogonal linearly polarized incidences are equal and higher than 0.9 at 10 GHz, while the difference of phase delays along x- and y-directions maintains π during the bandwidth, which guarantees the effective conversion of circular polarization at working frequency.

Figure 2: (a) The schematic of unit cell and proposed meta-lens. Simulated (a) magnitude responses and (b) phase responses under x- and y-linearly polarized incident waves.

Figure 3: Simulated phase front distributions of cross-polarized transmitted wave under (a) RHCP and (b) LHCP incident waves, respectively.

In order to verify the performances of the designed meta-deflectors, full-wave simulations based on the finite difference time-domain technique (FDTD) are conducted at 10 GHz. The simulation results of asymmetrical refractions are shown in Fig. 3. It can be observed that under different circularly polarized incident wave, the transmitted wave are refracted into -30° and -14.5°, which are in accordance with the theoretical design.

The measured normalized far-field intensity distributions of the cross-polarized component under incidence with different polarizations are presented in Figs. 4(a) and 4(b). It can be observed that the operation bandwidth of proposed meta-lens is about 2.5 GHz with a relative band width of 25%, where the LHCP and RHCP components in transmitted field are deflected into required directions.

Figure 4: Measured normalized far-field distributions of cross-polarized transmitted wave under (a) RHCP and (b) LHCP incident waves, respectively.

3. Conclusions

To summarize, a general scheme to design broadband ultra-thin metasurface for polarization-independent manipulation of EM wave is presented in this paper. The simulated and measured results verify the designed meta-lens has ability to deflect transmitted waves into desired directions independently within a wide frequency range. The design method proposed in this paper shows great potential to meet various requirements of microwave wireless communication systems.

Abstract

The high intrinsic loss of graphene severely obstructs us from achieving high-quality resonance in various graphene metamaterials and metasurfaces. Here, we demonstrate that the photoexcited graphene, in which the quasi-Fermi energy of graphene changes corresponding to optical pumping, can boost the originally extremely weak plasmonic resonances in a graphene metasurface, showing remarkable modulations in the transmission. And it is also found the loss compensation in graphene is helpful in realizing long-range plasmonic waveguiding. Our work pioneers the possibilities of optically pumped graphene metasurfaces for significant enhancement of light-graphene interactions for various active meta-devices.

1. Introduction

Graphene is also promising for applications in photonics and optoelectronics. Much stronger confinement of surface plasmons at the atomic scale [1], implying that graphene is a novel platform for boosting light–matter interactions [2]. More importantly, the sensitivity of Fermi energy to the carrier density in the Dirac fermions results in ultrawide tunable space in responding external light fields, which makes it a feasible and outstanding platform for actively controllable plasmonics [3]. Graphene metasurfaces [4–7] were proposed to realize various tailorable functionalities. However, the optical loss of graphene hinders many practical applications of the 2D plasmonic excitations. The large real part of surface conductivity (i.e., the intrinsic loss) makes the propagating plasma decay fast and the local resonant plasmonic modes weakly excited, especially the magnetic dipolar mode in graphene-based plasmonic metasurfaces.

Fortunately, the unique band structure of graphene offers the possibility of a new mechanism for loss compensation. The gapless and linear dispersion of the 2D Dirac fermions could lead to negative dynamic conductivity in an ultrawide frequency range under optical pumping [8–10], which is significant for active photonics in 2D. The stimulated emission at the terahertz and near-infrared region has been experimentally demonstrated in graphene with inverted Dirac fermion population through time-resolved spectroscopy of fast nonequilibrium carrier relaxation dynamics. These findings support the significance of graphene in active photonics applications.

In this work, we theoretically study the loss compensation of resonant plasmonic excitations in photoexcited graphene metasurface and graphene plasmonic waveguide. It is well known that the coupling of magnetic dipoles of natural atoms to the external light field is much weaker compared to electric dipoles especially at optical frequencies. It is shown in the scattering spectra and local-field distributions that photoexcitation is a promising route to compensate the resonantly enhanced energy dissipation in graphene metasurfaces. It is found that the difficultly excited magnetic resonance in passive graphene can be boosted in a photoexcited graphene metasurface with proper quasi-Fermi energy, and significant modulations in the transmission and absorption in the photoexcited graphene metasurfaces can be achieved. We also find the photoexcitation in graphene is helpful in realizing extended graphene plasmon propagation. Our work pioneers the way toward various practical applications based on the active and dynamic plasmonic excitations in graphene microstructures due to strong light–graphene interactions [11].

2. Results and Discussion

We first studied a magnetic metasurface in which the photoexcited monolayer graphene is patterned into a periodic array of split-ring resonators. We performed full-wave numerical simulations with a finite-element-method (FEM)-based electromagnetic package (COMSOL Multiphysics) to calculate the terahertz response of graphene metasurfaces. We first consider the resonant behavior of a photoexcited graphene metasurface at a temperature of 77 K. The transmission and absorption spectra of an unpumped graphene metasurface were studied in FEM simulations. It was found that the magnetic resonance of the photoexcited graphene metasurface is continuously strengthened as the pump beam is on, or the quasi-Fermi level increases from 0 meV to about 10 meV. Especially when the quasi-Fermi is 10.3 meV, a pronounced dip is observed from the transmission spectrum. The corresponding absorption and transmission are 39% and 8%, respectively, indicating that we can achieve a strong
modulation in the transmission through the photoexcited magnetic metasurface. The modulation depth is over 90% (the transmission changes from 99% to 8%). The evolution of the loss compensation in different photoexcited graphene metasurfaces at 77 K is investigated by studying the on-resonance transmission and absorption (transmission and absorption at resonant frequencies). The on-resonance transmission and absorption are plotted as a function of the quasi-Fermi levels in Figure 1. As the excitation power of the pump beam is increased with the quasi-Fermi level changing from 0 to 10.3 meV, the on-resonance transmission undergoes a strong modulation from nearly unity to the minimum 8%, and the on-resonance absorption also undergoes a dramatic increment to the maximum 50% at the quasi-Fermi level of 10.2 meV. When the quasi-Fermi energy is further increased, the on-resonance transmission undergoes an increment reversely, and the photoexcited graphene metasurface becomes lasing with an amplified beam propagating through the SRRs. The on-resonance absorption becomes negative regarding the loss compensation in the magnetic resonant structure.

Then we further studied the photoexcitation in a graphene plasmonic waveguide, we found that the loss-gain in graphene forms plasmonic cavities for enhancing the propagating length of graphene plasmons.

3. Conclusions
In summary, we studied the boosting the originally weak plasmonic resonances in graphene metasurfaces and plasmons in graphene waveguide via photoexcitation-induced inverted Dirac fermion population for intrinsic loss compensation. The proposed mechanism may also apply to all other 2D conductive materials in the format of various micro- and nanostructures. Our work therefore paves the way toward more efficient control of light with many potential applications.

Holographically-modulated metasurface leaky-wave antennas for multiple near-field focused spots manipulation

José Luis Gómez-Tornero*, and Miguel Poveda-García

Dep. Information and Communications Technologies, Technical University of Cartagena (UPCT), Spain

Abstract
This work describes a synthesis technique to generate multiple near-field focused beams in the microwave regime, using single-fed thin metasurface antennas. Using spatially-modulated leaky-wave theory and holographic principles, it is demonstrated how one can tailor the equivalent amplitude and phase aperture distributions of the waves emerging from the metasurface, so to precisely locate several independent near-field focused spots in the Fresnel region.

1. Introduction
Holographic surface antennas transform a reference surface wave which is bounded inside the thin patterned substrate, into a leaky wave which produces directive space radiation [1]. This relation between radio-frequency holography and modulated leaky-wave antennas (MLWAs), -also referred to as metasurfing-, has been applied for far-field focusing [1], and also for near-field (NF) focusing in the Fresnel zone. This type of MLWAs offering NF focusing, also known as leaky-wave lenses (LWL), were initially proposed for 1D [2]-[4] and later for 2D [5]-[8] metasurface antennas. As demonstrated, the engineered metasurface must be properly patterned by modulating the constitutive unit-cell dimensions along the antenna aperture, so to obtain the desired NF focused spot specifications: namely the focal point location and the half-power focal region size (depth of focus and focal width).

This design is even more challenging for the case of simultaneous multiple-focus synthesis, as recently pursued by some authors [9]-[13]. Phased-array antennas designs [9]-[12] need a beam-forming network to feed each individual radiators with optimum amplitude and phase for the multi-focusing synthesis. In [13], a reflective metasurface was proposed for multi-feed and multi-focus. Compared to these phased-arrays [9]-[12] and reflectarrays [13] designs, LWLs offer much simpler and integrated solutions which dispenses from beam forming networks and external feeders. As shown in Fig.1, a planar LWL uses a single integrated port to launch a travelling surface-wave, which is manipulated by the thin metasurface to create several independently controllable focal regions in the desired locations. Here we demonstrate for the first time the capability to synthesize several focused spots in the NF from a single-fed holographic LWL.

Figure 1: Scheme of a 1D LWL with a single feeding, creating three different focused spots in the Fresnel region.

2. Results
The basic theory to synthesize a single focused NF spot located at the position \( F_l = \{ y_{Fl} , z_{Fl} \} \), using a LWL was described in [2]. The modulated LW must create a given phase and amplitude field distribution along the aperture length \( L \). Fig.2 shows results for an aperture length \( L = 10\lambda_0 \) (where \( \lambda_0 \) is the free-space wavelength), and for three different focal positions \( F_1 = \{ 1\lambda_0 , 5\lambda_0 \} \), \( F_2 = \{ 5\lambda_0 , 10\lambda_0 \} \), and \( F_3 = \{ 9\lambda_0 , 8\lambda_0 \} \). Using the holographic principle, we can superimpose the complex field distributions for \( N \) focused spots at the antenna aperture. The resulting holographic interference created by the complex addition of the three modulated LWs is plotted with thick black line in Fig.2.
Then, this total holographic field at the LWL aperture can be generated by a single modulated LW, which local scanning angle and leakage rates, $\theta(y)$ and $\alpha(y)$, must be properly tapered along the LWL aperture as explained in [2] and shown in Fig.3. The last design step involves the translation of this LW electromagnetic modulation into geometrical modulation of a practical MLWA, as it was done in [3] for a holographic LWA in planar Substrate Integrated Waveguide (SIW) technology. The theoretical fields created by such MLWA are plotted in Fig.4, demonstrating the successful synthesis of three simultaneous focused spots at the prescribed focal points (indicated with red stars), located in the Fresnel region of the metasurface.

Figure 3: Modulation of the leaky-wave (LW) local leakage rate $\alpha(y)$ and scanning angle $\theta(y)$ to create the interference holographic complex field in Fig.2.

Figure 4: Simulated near-field intensity (in dB) created by the modulated leaky-wave in Fig.3.

3. Conclusions

It has been demonstrated for the first time that a single leaky wave modulated by a metasurface can radiate a holographic field which synthesizes several simultaneous focused spots in the Fresnel zone. Compared to more complex designs, the holographic leaky-wave lens (LWL) dispenses for more complex and bulky feeding network, since a single port can be used to launch the surface wave propagating through the hosting waveguide. More detailed results will be given in the full paper and the oral presentation.

Abstract

Curved reflective mirrors with inevitably bulky size play an indispensable role in widely-employed Cassegrain-type optical devices. Through substituting geometric phase based flat reflective metasurfaces for curved mirrors, here planar Cassegrain-type Schwarzschild objectives are obtained experimentally, with their achromatic focusing and imaging functionalities. The planar reflective objectives achieved are intrinsically free of residual light. Our designs can potentially reshape and simplify the core components of many microscope and telescope systems working over broadband spectral regimes.

1. Introduction

Optical mirrors are probably the most ubiquitous optical elements in both everyday infrastructures and scientific apparatus. The Cassegrain family of two-mirror configurations are employed in all conventional Cassegrain-type Schwarzschild objectives. The efficient phase tuning and beam redirections rely on the continuous geometric curvatures of the consisting elements, which inevitably result in cumbersome and costly optical devices.

The paradigm has been totally shifted with the explosively developing field of optical metasurfaces, which are composed of spatially variant meta-atoms on a planar interface and show unprecedented flexibility for optical wave manipulations. Among all the metasurface-based optical components, probably the most attractive and promising example is the planarized refractive objective lenses, which could consist of an individual metalens, metalens doublets, and other more sophisticated designs.

Here we investigate the simplest and most widely employed two-mirror reflective configuration and realize planar Cassegrain-type Schwarzschild objectives, of which both the functionalities of focusing and imaging with high efficiencies are experimentally demonstrated. The curved concave and convex primary and secondary mirrors in the conventional Schwarzschild objective are replaced by a pair of conjugated planar metasurfaces. The wavefront shaping and beam routing within the metasurface objective are achieved by the efficient tuning of the geometric Pancharatnam-Berry (PB) phase, which is inherent to a cascaded process of circular polarization transformations. Compared to the refractive metalenses based on geometric PB phase metasurfaces, our reflective design is intrinsically free of residual light. Moreover, the achromatic focusing property has been achieved by optimizing the phase profiles of the metasurface mirrors. It is expected that our work here can trigger an avalanche of investigations into reflective optical components, which can potentially set off the trend to reconstruct and refine many optical devices including microscopes, spectrometers, telescopes.

2. Designs of the Planar Schwarzschild Objective

The conventional Cassegrain-type Schwarzschild objective is shown schematically in Fig. 1a. The objective consists of one concave primary mirror and one convex secondary mirror. A judicious combination of designed geometry and spatial parameters for the two mirrors leads to a reflective Schwarzschild objective. A planar version of the Cassegrain-type Schwarzschild objective is shown in Fig. 1b, where the curved mirrors are replaced by two metamirrors made of flat metasurfaces with correspondingly converging and diverging optical functions. The required phase distributions upon reflections by the metamirrors are made possible by the geometric PB phase. To be more specific, upon each reflection, the originally left-/right-circularly polarized (LCP/RCP) light is converted to RCP/LCP light. As a result, upon the two successive rounds of reflections by the metamirrors, at the opposite sides of the metasurface objective the optical wave is of the same circular polarization [Fig. 1b]. In both the conventional and planar designs there is an aperture throughout the primary mirror. Figures 1c and 1d show the two-dimensional cross-section views of Figs. 1a and 1b for further clarity.
The intensity distributions in Fig. 2 are shown in false-color, which are captured by a monochrome CCD camera.

Figure 2. Focusing properties of the planar Cassegrain-type Schwarzschild Objectives. N. A. = 0.1. (a, d) The measured intensity profiles at the focal plane (scale bar: 3µm). (b, e) The corresponding cross-sections of the focal spots along y direction, with FWHM of 3.15 µm, 2.83 µm, respectively. (c, f) The intensity profiles along the propagating axial plane. The wavelength of incident light is 780 nm in (a-c), and 633 nm in (d-f).

4. Conclusions

We have successfully incorporated flat optical elements made of plasmonic metasurfaces into classical Cassegrain-type reflective systems and demonstrate highly efficient planar Schwarzschild objectives that can be applied for achromatic focusing. We believe our work opens the door to metasurface-based revolutionary refinements and miniaturizations for not only refractive but also reflective optical systems. The fusion of refractive optical elements and planar meta-optics paves new avenues for manufacturing and reconstructing new types of microscopes, telescopes and other optical devices over much broader spectral regimes.

Abstract

While plasmons in noble metal nanostructures facilitate strong nanoscale light-matter interactions, the overabundance of free electrons in these systems inhibits their tunability by weak external stimuli. Countering this limitation, the linear electronic dispersion in graphene endows the two-dimensional material with an enhanced sensitivity to doping electron density, enabling active tunability of its highly-confined plasmon resonances, and a low electronic heat capacity with a large thermo-optical response. Here we show that these properties combined enable significant optical modulation in isolated graphene nanostructures from the energy associated with just one of their supported plasmons. Our analysis is based on realistic, complimentary classical and quantum mechanical simulations, revealing that the energy associated with a single plasmon, absorbed in a small, lightly-doped graphene nanoisland, can sufficiently modify its electronic temperature and chemical potential to produce unity-order modulation of the optical response within sub-picosecond timescales, effectively shifting or damping the original plasmon absorption peak and thereby blockading subsequent excitation of a second plasmon. We further demonstrate that the proposed thermo-optical single-plasmon blockade consists in a viable ultra-low power all-optical switching mechanism for actively-tunable metasurfaces consisting of periodically-arranged doped graphene nanoislands, while their combination with quantum emitters could yield applications in biological sensing and quantum nano-optics.

1. Introduction

The ability of plasmons, the collective oscillations of conduction electrons, to intensify the electromagnetic fields upon which nonlinear optical phenomena superlinearly depend motivates fertile research efforts in nonlinear plasmonics to control light by light on the nanoscale [1]. In this context, engineered plasmonic near field enhancement from noble metal nanostructures has been enormously successful in bolstering the weak susceptibilities associated with coherent nonlinear processes while reducing the intensity threshold for optical switching [2], with engineered nonlinear plasmonic metasurfaces enabling a large nonlinear response from optically-thin structures [3]. However, despite impressive plasmonic enhancement, the realization of strong nonlinear optical interactions at ultra-low powers, ultimately down to the few- or single photon regime, remains elusive.

Here we propose that the combined large thermo-optical response and very low heat capacity originating from the unique conical dispersion of graphene can enable single plasmons strongly modulate the optical response. In particular, we explore scenarios where the energy of a single plasmon quanta ($\hbar \omega_p$, where $\omega_p$ is the plasmon resonance frequency), distributed among a finite number of electrons, can modify the local equilibrium temperature and chemical potential of a graphene nanoisland enough to produce observable changes in its supported plasmon resonances [4, 5]. Remarkably, in small graphene nanoislands doped with only a few electrons, we predict unity-order modulation of the optical response through single-plasmon absorption on ultrafast timescales, during the transfer of electronic energy to lattice vibrations. This phenomenon consists in an incoherent plasmon blockade, whereby the decay of a single excited plasmon suppresses the probability of exciting additional plasmons. We further demonstrate that this phenomenon enables ultra-low power optical modulation in nanopatterned graphene metasurfaces.

2. Results and Discussion

Optimal single-plasmon thermo-optical switching is achieved in small graphene nanoislands doped with a few electrons, necessitating a quantum-mechanical treatment of their electronic states and optical response [5]. Indeed, for nanohexagons containing $\sim 1000$ or fewer carbon atoms, the Fermi energy does not well-describe the initial charging state in the presence of large energy gaps between discrete electronic states. We consider in Fig. 1 situations where an integral number of electrons $N_e$ are added to a graphene nanohexagon, down to doping with only a few additional electrons. The absorption spectra shown in the upper row of Fig. 1 are dominated by quantum-finite size effects, where peaks associated with the HOMO-LUMO transition appear in the spectra even for undoped ($N_e = 0$) structures. The excitation and decay of a single plasmon quantum at the frequency of this high-energy peak at various charging states results in even higher obtained electronic temperatures (see lower row of Fig. 1), which manifest prominently in the shift of the lower-energy plasmonic peak appearing for $N_e > 0$ that dominates the response when $N_e \gg 0$. 

A grand goal of nonlinear optics is the realization of an all-optical switch to produce light modulations in which the modulated light is phase-locked with the light gate signal. Our proposed switch does not preserve gate-signal phase coherence, but in exchange, it produces order-unity modulations with a single photon in a robust, integrable, solid-state platform (nanostructured graphene). The single-plasmon thermo-optical switching mechanism in nanostructured graphene is made possible by the intrinsically-low heat capacity of the 2D material and strong light-matter coupling of its electrically-tunable plasmon resonances, the latter enabling significant absorption even in very small structures containing only a few doping electrons. These properties are essential to achieve significant modifications in the optical response, which relies on the distribution of a finite plasmon energy among a small number of electrons to produce dramatic changes in the electronic temperature and the chemical potential. The change in optical response associated with single-plasmon absorption consists in ultralow power all-optical switching for atomically-thin metasurfaces, which in combination with proximal dipole emitters could open new avenues in optical sensing and quantum nano-optics.

Figure 1: Thermo-optical switching by molecular plasmons. For graphene nanohexagons shown in the upper row containing $N$ carbon atoms, with lateral sizes of 7.1 nm (left column), 4.5 nm (center column), and 2.0 nm (right column), we show in the center row the absorption spectra when the corresponding hexagon is doped with integral numbers of electrons $N_e$, plotting in each case the spectrum before (solid curves) and after (dashed curves) the absorption of a single plasmon. For each hexagon we show in the lower row the chemical potential shift $E_F - \mu$ (blue squares) and the electronic temperature (red circles) obtained upon absorption of energy $Q = \hbar \omega_p$, associated with the dominant plasmon absorption peak in the $T = 0$ case for the considered doping charge.

Abstract

Metamaterial absorbers have drawn lots of attentions due to their higher degree of freedom in geometry design for some specific applications compared with conventional multilayer absorbers. Recently, we have reported meta-surface optical solar reflectors (OSRs) based on metamaterial absorber, which can provide cost-effective high performance alternative to conventional OSRs in spaceship applications. However, the design and optimization of meta-reflectors unsurprisingly involve numerical simulations with wide range of multiple design variables and leads to a low computational efficiency. In this work, we adopted a deep learning technique to speed up the computational efficiency and demonstrated that the optical response of meta-reflectors can be directly predicted through machine deep learning for a given set of design parameter. In addition, an inverse design of meta-reflector can also be obtained for desired optical properties, which could provide a complete novel design strategy in the optical design. The proposed deep learning design technique is found to be promising for ultracompact nanophotonics device design.

1. Introduction

Meta-reflector is a flexible optical solar reflector with high reflection in visible range and broadband absorption (high emissivity) in the infrared based on meta-surface nanostructures, which can be used for the radiation cooling of spacecraft [1]. Compared with conventional multilayer optical solar reflectors, meta-reflectors could achieve an improved performance due to the excitation of plasmonic resonance [2-3]. The conventional way of designing meta-reflector is based on simulating a serial of different geometries [4], through solving the Maxwell’s equation using commercial numerical software (COMSOL and FDTD). Recently, with the advance of computational techniques, Deep Learning (DL) becomes a powerful computational tool to solve problems and boost the developments, e.g. face recognition [5] and optical information storage [6]. Therefore, it is of interest to investigate deep learning capability on nanophotonic device design. Here, we present an innovative deep learning technique, which can predict the optical response of meta-reflectors with given design parameters and also predict design parameters for a given spectral response (inverse design).

2. Results and Discussion

2.1. Design of metareflector and training for neural networks

Figure 1 shows the schematic of a meta-reflector. The metareflector is designed using the Salisbury screen and consist of three layers, the bottom Al mirror layer as back-reflector, the middle dielectric layer of SiO2 and the top patterned layer of Aluminum-doped Zinc Oxide (AZO), AZO is a Transparent Conductive Oxide (TCO) with a dielectric response in visible range and metallic response in infrared range. The device optimizations were done through varying three parameters, AZO feature gap (g), AZO feature width (w) and SiO2 thickness (t). Using numerical simulations, 2000 datasets were generated with different gap (g), width (w) and thickness (t) to train the neural networks (deep learning).

Figure 1: Schematic of a meta-reflector
2.2. Forward problem: Predict the reflectance spectrum

Initially, the neural network was trained to solve the forward problem, predicting the reflectance spectrum for a set of given parameters t, w, g, as shown in Figure 2. The reflectance generated by the trained neural network well agrees with that generated from FDTD numerical method over a wide range of wavelength for a given structure. Unlike numerical method through finite element method by solving Maxwell equation, deep learning method can obtain the response through a direct calculation using trained neural networks and this is highly advantageous in computational efficiency.

Figure 2: Meta-reflector reflection spectra of generated from the trained neural network and FDTD numerical method for a given design.

2.3 Inverse problem: Predict design parameters for a desired spectral response

In many cases, it would be more important to achieve a design with a desirable optical response and this makes an inverse design even more attractive than the forward design given by a numerical method. The trained neural network is therefore tested for it capability in finding the structure for a desirable response. Figure 3 shows reflectance comparison of the predicted structure through the trained neural network and the given arbitrary structure. Reflectance spectra of some random structures are also plotted for comparisons. The predicated parameter from the trained neural network shows the best fitting parameter with a thinner (800 nm) thickness than the preset one. This discrepancy provides an insight that similar performance can be achieved with a further compact design, which is essential to reduce fabrication costs and spaceship’s launch costs.

Figure 3: Meta-reflector reflection comparison between the trained neutral network predicted structure and the preset structure.

3. Conclusions

In conclusion, we have demonstrated that the deep learning can be used to predict the reflectance spectrum of a meta-reflector. The deep learning technique is highly advantageous over the conventional numerical method for its significantly improved computational efficiency and multi variable handling. Moreover, the deep learning neural network can also provide an inverse design capability to directly get the design structure for the desired optical response.

Abstract
We show that resonant subwavelength media illuminated by a circularly polarized beam produce optical vortices of order two in the opposite circularly polarized components of the reflected and transmitted fields as a consequence of enhanced spin-orbit interaction of light. Our theoretical predictions indicate that graphene and near-zero index media hold great potential as miniaturized active devices for the optical control of light orbital angular momentum.

1. Introduction
The exploitation and control of light orbital angular momentum (OAM) constitutes a novel and potentially disruptive technology for increasing the bandwidth of current telecommunication systems. Indeed, with respect to other mode division multiplexing schemes, OAM has the advantage of ease detection through phase-only optical elements along with a reported Tbit/s transmission capacity over both free space and optical fibers. In this context, spin-orbit interaction (SOI) of light is a very important research topic since it provides a tool for manipulating the spatial degrees of freedom of radiation by acting on its circular polarization state. As an example, reflected and refracted beams at a planar medium discontinuity experience a lateral shift which depends on the circular polarization state of the incident beam (spin-Hall effect). Another remarkable SOI effect is the generation of optical vortices from circularly polarized beams, a process accompanied by spin to orbital angular momentum conversion. Standard procedures to achieve vortex generation are focusing by high-numerical aperture lens, scattering by small particles, propagation along the optical axis of a uniaxial crystal, and propagation through semiconductor microcavities. Similar SOI effects involving Bessel beams have been considered in uniaxial crystals and at reflection and transmission by a planar interface between two homogeneous media. The advent of metamaterials has further increased the SOI research effort, mostly in the use of ultra-thin metasurfaces for manipulating the angular momentum of light and for vortex generation [1, 2, 3].

Near-zero index (NZI) media are nowadays attracting an increasing research interest owing to the very unconventional way they affect the electromagnetic radiation. The effective wavelength in NZI media is much larger than the vacuum wavelength and this entails a regime quite opposite to geometrical optics where the field is slowly-varying over relatively large portions of the bulk. Such feature has been exploited for squeezing electromagnetic waves at will, for tailoring the antenna radiation pattern and for enhancing nonlinear response of matter.

2. Discussion
Here we show that two-dimensional materials and near-zero index thin films can support vortex generation [4, 5]. We prove that such genuine SOI effect is physically due to the mutual difference between the dynamics of transverse magnetic and transverse electric fields upon reflection and transmission. As the majority of radiation SOI phenomena, the slab vortex generation is mainly a nonparaxial effect. On the other hand, we prove that vortex generation in the NZI regime is remarkably efficient even for incident paraxial beams in spite of the very small film thickness. Such phenomenology is unprecedented since paraxial vortex generation occurs only in uniaxial crystal and its efficiency requires very long samples whose thickness is comparable with the beam diffraction length (millimeters). Here, the crucial role is played by the physical ability of a NZI slab to turn a paraxial wave, incoming from vacuum, into a nonparaxial one within the bulk, its nonparaxiality triggering the predicted slab vortex generation. In addition we provide a first-principle theoretical approach able to describe the scattering of arbitrary tightly confined fields impinging on a generic two-dimensional medium. Our framework, which does not resort to any approximation on the vectorial electromagnetic field, is very similar in its kinematical traits to the description of a spin one quantum particle living in the atomically thin medium, whose orbital, spin and total angular momenta are the basic quantities allowing us to elucidate the physics of radiation matter interaction in the presence of two-dimensional materials. Rotational invariance is the key ingredient of our analysis and accordingly we find that the ensuing total angular momentum conservation rules radiation scattering. Indeed, the rotationally invariant electromagnetic coupling provided by the two-dimensional material, triggers photon transitions accompanied by an exchange between the orbital and spin angular momenta which is quantified by suitable selection rules. We further specialize our calculations to doped extended graphene, demonstrating that thanks to plasmon-enhanced SOI such an atomically-thin medium can generate efficiently optical vortices of order $m = \pm 2$ and actively...
manipulate the mixing of different OAM states by means of the external gate voltage, thus enabling fast electrical processing of information stored in OAM states. In addition, we demonstrate that such a tunable mixing of OAM vortices of different order can be exploited to devise subwavelength arrays of optical traps in the near field able to pin cold atoms into desired patterns, thus enabling the engineering of artificial materials at will.

3. Conclusions

In conclusion we show that resonant subwavelength materials like graphene and NZI media enable the generation of optical vortices at the nanoscale with unprecedentedly high efficiency and deep-subwavelength spatial features. We show that extended graphene is ideal since it hosts plasmons with long lifetime and high quality factor, increasing the vortex generation efficiency. Furthermore, thanks to the mixing and interference of distinct vortices, we demonstrate the ability of graphene to generate deep subwavelength optical lattices of arbitrary shape and pace of few nanometers, enabling to devise artificial media at will. Although future work is required to extend our results to the quantum regime, we envisage that they will constitute a solid theoretical ground for the development of nano-scaled active elements and logic gates for enhanced quantum computation based on hyper-entangled photon states.

Hiding a QR code in a Vector Light Beam

Chunmei Zhang, Yuttana Intaravanne, Wei Wang, Xianzhong Chen*

School of Engineering and Physical Sciences, Heriot-Watt University, Edinburgh, UK

Abstract

As one of the important properties of light, polarization profile can be utilized to carry information. Metasurfaces have shown great potentials in manipulating the light propagation. In this paper we experimentally demonstrate a metasurface device which can encode a quick response (QR) code into the space-variant polarization profile of a laser beam. A linear polarizer is used to reveal the hidden QR code. This technology has potential application in anti-counterfeiting, security and so on.

1. Introduction

In the recent years, optical metasurfaces have been adopted to generate the vector beams with typical or even arbitrary polarization states [1-3]. Quick response (QR) code is two-dimensional barcode which has been widely used in the daily life. QR code usually consists black and white patterns with spatially varying intensity profile, which can be processed by a QR code reader. To further explore the capability and feasibility of the optical metasurfaces, we experimentally demonstrate a metasurface device upon which a QR code can be encoded into the spatially-variant polarization profile of the light beam.

2. Results

In our design, the vector beam that can be used to hide the QR code is generated by a reflective metasurface (Fig.1b), illuminated by a linearly polarized light beam at normal incidence. The polarization profile are space variant after the incident light is reflected by the metasurface. If adding an analyzer before the CCD camera, the hidden QR code can be revealed which is impossible without this analyzer. The standard electron-beam lithography is used to fabricate the designed metasurface, then followed by the lift-off process. The size of finished sample is 300 µm by 300 µm. The SEM image of part of the fabricated sample is shown in Fig.1a. Since the sign of the geometric phase generated at the interface of metasurface depends on the helicity of the incident light, upon the illumination of the linearly polarized light which can be decomposed to two circularly polarized light beams with opposite helicity which will meet and interfere with each other, generating the desired polarization profile which is space variant. The simulation and experimental results with and without the analyzing polarizer are shown in Fig.1c and Fig.1d, for incidence wavelengths of 650nm and 540nm, respectively. The slight difference between experiment and simulation is due to the imperfection of the sample and measurement error. The QR code contains the information of our group website (http://nanophotonicslab.eps.hw.ac.uk/), which can be accessed by using a QR code reader such as a smart phone.

![Figure 1. Simulation and experimental results. (a) SEM image of the fabricated sample. The scale bar is 1 µm. The size of fabricated sample is 300 µm by 300 µm. Each unit cell is 300 nm by 300 nm. (b) Schematic of experimental setup. QWP: quarter waveplate. Simulation and experimental results (c) with and (d) without the analyser.

We further characterize the device by studying the relationship between the obtained QR code images and the transmission axis of the analyzer. In the original design, the transmission axes of the polarizer (before the sample) and the analyser (after sample) are designed to be along the horizontal and vertical directions, respectively. Various QR codes are obtained by rotating the transmission axis of the analyser, while that of the polarizer is fixed along the horizontal direction. Fig.2 shows the simulation and experimental results when the rotation angles of the analyser (away from the designed direction) are 0, π/4, and π/2, respectively. It is interesting to find that those two QR codes for the analyser with orthogonal directions of transmission axis (0 and π/2) are complementary images, i.e., the brightest area becomes the darkest area and vice versa. This phenomenon can be explained from the point of Malus’ law.

3. Discussion

The uniqueness of this multichannel metasurface device is that the black and white image the integration of totally
different functionalities onto a single device by the independent control of phase and polarization profile. In our demonstration the reconstructed holographic image is dependent on the polarization state of the incident light, while the hidden image is embedded in the inhomogeneous polarization distribution of the generated laser beam and can be revealed by using a linear polarizer.

![Figure 2](image)

Figure 2. The dependence of experimental results on the rotation angles of the transmission axis of the analyser away from the vertical direction. The incident light is linearly polarized along the horizontal direction.

The demonstration of this new device will possess a unique advantage over traditional security holograms due to the combination of image-switchable functionality and the hidden image in the laser beam.

4. Conclusions

Optical metasurfaces provide the capability to generate inhomogeneous polarization states, providing a powerful tool to develop compact and novel device with unusual functionalities. We experimentally demonstrate a metasurface device which can generate space variant polarization distribution which is used here to hide a QR code into it. This study of the multichannel device based on the independent control of polarization makes this technique very attractive for compact optical devices with high density of functionalities.

Abstract

We report on the use of optical metasurfaces for the development of the concept of surface normal mapping to achieve the representation of 3D objects and shading effects. As a proof of principle, a flat diffuse metasurface imitating lighting and shading effects of a 3D cube was fabricated and characterised under incoherent illumination. The metasurface performs in a broad range of the visible spectrum, including the three main RGB wavelengths. Applications of these metasurfaces span from 3D security features and anti-counterfeiting to efficient optical diffusers.

1. Introduction

Dielectric and plasmonic metasurfaces provide excellent control over the shaping of optical wavefronts via the manipulation of polarisation, phase and amplitude of the light. Taking advantage of their subwavelength thicknesses, metasurfaces have shown to be a very promising technology in a variety of applications including beam steering and focusing, polarisation and angular momentum control, enhancement of nonlinear effects, as well as holographic information encoding for 3D displays [1-3]. Recently, the emergence of virtual reality and augmented reality technologies have led to the constant demand of effective techniques for the 2D visualisation of 3D objects. Normal mapping [4], for example, is widely used in computer graphics to create shading effects and recreate 3D-like features of surface textures, such as regular patterns, bumps or ripples. Normal maps are typically overlaid onto low resolution models to add fine geometric surface features, in order to increase the rendering speed of a 3D image. In this way, the brightness of different parts of the 3D object varies accordingly to the normal map, providing adequate shading to the object.

In this work, we designed an optical metasurface implementing diffuse reflection and using the concept of normal mapping to control its scattering properties. The metasurface, imitating the shading of a 3D cube, is designed so the “3D image” is displayed directly on the illuminated metasurface and its shading varies in response to the change in illumination angle.

2. Discussion

In order to transpose the computer graphics approach to the metasurface, the normal map of the 3D cube is created by controlling the phase distribution of the metasurface. To do so, a reflective metasurface design based on the Pancharatnam-Berry principle [5,6] was used. The phase controlling elements are aluminium nanorods placed above an aluminium film and separated from it by a MgF₂ dielectric spacer (Fig. 1). A superstrate of MgF₂ is used to prevent oxidation.

Figure 1: Schematic illustration of a metasurface unit cell.

In the experiments, the structure is illuminated by circularly polarised white light and the observation is performed in cross-polarised configuration. Images of the 3D object created are recorded for different illumination angles of the sample as well as different rotation angles. The metasurface is shown to exhibit a high scattering efficiency in a broad spectral range, including the main RGB wavelengths, and performs well for a wide range of illumination angles. Figure 2 shows images of different metasurface patterns for three different angles of rotation of the sample, observed at a normal to the metasurface pattern as the light source rotates
about the sample. The metasurface is illuminated at an angle of 30° with incoherent white light. It is shown that the metasurface behaves as a real 3D object when during rotation, the cube faces facing the light become brighter.

Figure 2: Images of different metasurface patterns under incoherent white light illumination. The rotation angles of the sample are 0° (a), 120° (b), and 240° (c). The structures are illuminated at the angle of incidence of 30°.

3. Conclusions

We have developed the concept of surface normal mapping for the visualisation of 3D objects and shading effects with optical metasurfaces. The designed metasurface, which provides an efficient control of diffuse scattering, performs under broadband incoherent illumination, including the main RGB wavelengths. The 3D images created via normal mapping based on optical metasurfaces provide an effective technology for 3D security features and anti-counterfeiting. This type of metasurfaces can also be useful in the design of efficient optical diffusers for display technology and etalons for metrology. Combination of metasurfaces with complex polarisation light states may provide additional degrees of freedom for multiplexing and active manipulation of images and optical information [7-9].

Abstract

We present a bottom up coupled-mode-model from first principles (Maxwell's equations) to study the plasmonic open systems, where, all coupling parameters can be calculated by a directly integration of different optical modes. Based on this theory, we establish phase diagrams to systematically study the whole picture of optical response of interested systems. For example, designing meta-surface to realize wide-band optical transparent window (OTW) with diminished transmittance fluctuations.

1. Introduction

Over the past decades, many efforts were devoted to studying plasmonic open systems, particularly those consisting of multiple plasmonic resonators coupled in different ways. The latter can generate fascinating effects such as Fano resonance, Rabi oscillations, and plasmonic-induced transparency in different scenarios, which can have plenty of applications in practice. However, understanding the profound physics underlying these intriguing phenomena is far from satisfactory. While full wave simulations can numerically repeat experimental findings in most cases, they can offer very little physics, not mentioning the huge computing costs required. Meanwhile, many models (e.g., coupled-mode-theory (CMT)[1], Fano’s formula[2], or effective circuit models[3], etc.) are intuitive enough to explain the underlying physics, they unfortunately require model parameters obtained from fitting with available experimental/simulation results, implying that they are empirical models which cannot predict unknown phenomena before performing simulations or experiments. The difficulties behind the slow theoretical development in such a field are ultimately due to the fact that the plasmonic coupled systems are complex open systems, in which not only different resonators are coupled with each other via near-field effect but also they can couple with external free space via far-field interactions.

Here, we present a bottom up coupled-mode-model from first principles (Maxwell's equations) to study the plasmonic open systems. Here, direct and indirect coupling parameters can be calculated by a directly integration of different optical modes. Our theory is fully justified by both full wave simulations and infrared experiments. Based on this theory, we establish phase diagrams to systematically study the whole picture of optical response of interested systems. For example, we can predict and design the complex meta-atoms with optimized local field enhancement or optimized quantum yield, which can be used in metasurface enabled fluorescence enhancement or other light mater interactions enhancement. Such a theoretical approach can be also used to design structures to realize wide-band optical transparent window (OTW) with diminished transmittance fluctuations. As an illustration, we design a 4-layer structure (with a total thickness 36 mm) through solving the proposed criterion, and experimentally demonstrate that it exhibits a flat OTW within 3.7 - 5 GHz with transmittance fluctuations smaller than 10%.

2. Theoretical framework of plasmonic open systems

![Figure 1 Comparison between experiment results (solid circle lines), FEM simulation results (open circle lines) and theoretical prediction (red lines) on two different plasmonic open systems.](image)

Before the presenting the analytical model, we briefly review the Hamiltonian form of Maxwell’s equations for nanoparticles systems[4,5]. In analogy to the Schrödinger equation, the full-vector Maxwell’s equations coupled with equation of motion for electron can be rewritten in a Hamiltonian form \( \hat{H}\ket{\psi} = \omega \ket{\psi} \), where the wave function is defined as \( \ket{\psi} = [H, E, P, V]^T \) and the Hamiltonian operator is defined

\[
\hat{H} = \begin{pmatrix}
0 & -\frac{i}{\mu} \nabla \times & 0 & 0 \\
\frac{i}{\epsilon_\infty} \nabla \times & 0 & 0 & -\frac{i}{\epsilon_\infty} \\
0 & 0 & 0 & i \\
0 & i\omega_0^2 \epsilon_\infty & i\omega_0^2 & -i\Gamma_e
\end{pmatrix}
\]
Here $E$ is the electric field, $H$ is the magnetic field, $P = [\varepsilon(\omega) - e_3]E$ is the polarization field, $V = dP/dt$ is the polarization field. We also note that the inner product is defined as $\langle \psi_1 | \psi_2 \rangle = \frac{1}{\sqrt{\Omega}} \int d\tau [\mu H_1 \cdot H_2 + \varepsilon_\omega E_1 \cdot E_2 + \omega_0^2 (\omega_0^2 \varepsilon_\omega)^{-1} P_1 \cdot P_2 + (\omega_0^2 \varepsilon_\omega)^{-1} V_1 \cdot V_2]$. Based on this Hamiltonian, the coupled mode model of plasmonic systems can be expressed by

$$-\imath \omega a_m = -i(\omega_m + t_m)a_m - \Gamma_m a_m + \sum_{n \neq m} (-\imath \gamma_{mn}) a_n + \sum_n X_{mn} a_n$$

$$+ \sum_k \kappa_k S_k$$

(2)

Where $a_m$, $t_m$ and $\Gamma_m$ is the amplitude, on-site correction, and radiation damping of the $m$-th plasmonic mode, $X_{mn}$ and $t_{mn}$ describes the far field and near field coupling, $\kappa_m$ denotes the coupling efficiency between $m$-th mode and $k$-th port. In order to verify our analytical model, we design and fabricated inferred nano-particles, we can see that the measured and theoretical calculation are in good agreement with each other, [see Fig. 1]. Such nice agreement unambiguously justified our validated model analysis.

3. Application: mechanism and realization for flat optical transparent window

We now employ the CMT model to study the multilayer metasurfaces for the realization of flat optical transparent window. Solid lines in Fig. 1(d) depict the FDTD simulated transmittance/phase spectra of a slab formed by stacking $N=4$ such layers (N denotes the number of layers) with equal interlayer distance, where the building block of metasurface the a metallic “H” shape inserted in subwavelength size metallic mesh. While the coupling between these layers indeed enlarges the total transmission band, strong fluctuations on both amplitude and phase exist inside the transmission band, especially at the high-frequency edge of the OTW [7].

![Figure 2](image_url)

Figure 2. (a) Modes diagram depicting the collective modes for the $N=4$ stacked metasurface. (b) Photography of microwave samples. (c) Measured (symbols) and numerical-simulated (curves) transmittance and phase spectra of designed metasurface with flat transparent window.

We find that the peaks in the transmission spectrum of a coupled multilayer metasurface are closely related to the “collective” resonant modes supported by the system, which can be well controlled by the inter-layer couplings [Fig. 2(a)]. Such inherent link enables us to efficiently manipulate the shape of transmission spectrum via varying the inter-layer distances of the coupled multilayer system. As an illustration of our general theory, we applied it to design and fabricate a metasurface [Fig. 2(b)] exhibiting an optical transparency window with 3.7–5 GHz with diminished transmittance fluctuations, and demonstrated the idea by microwave experiments [Fig. 2(c)]. Our design approach is robust, intuitive, fast, and can have many applications in practice.

4. Conclusions

To summarize, we have established a highly efficient approach to study the plasmonic open systems. As an illustration of our general theory, we applied it to the design of a structure exhibiting an optical transparency window with a 3.7–5 GHz range with diminished transmittance fluctuations, and demonstrated the idea by microwave experiments. Our approach can have many applications in practice.

Abstract

Optical fiber is an excellent platform in guiding light, which has been widely employed for optical communication, imaging/sensing, and fiber lasers. Although a dielectric optical fiber is efficient for transmitting light, its functionality is limited by the geometry and dielectric material of fiber (Ge-doped silica for core and silica glasses for cladding). The mode size is limited by the diffraction limit of the dielectric core, and the numerical aperture is determined by the refractive index of the fiber materials. Meanwhile, the spot size right after the fiber is divergent and the intensity decreases dramatically with distance. However, the emergency of metasurfaces provides the opportunity of a variety of optical fiber innovations. In this presentation, we report an ultrathin optical metalens cascaded on the facet of a photonic crystal optical fiber that enables light focusing in the telecommunication regime (Fig. 1). In-fiber metalenses with designed focal lengths at the wavelength of 1550 nm are demonstrated [1]. The integration of an ultrathin metalens and optical fiber will pave the way of ultracompact in-fiber optical devices for optical imaging, sensing and fiber laser applications.

We also experimentally demonstrate a novel optical waveguide of side-polished optical fiber nano-coated with an ultrathin aluminum-doped zinc oxide (AZO) epsilon-near-zero film by atomic layer deposition technique. The AZO thin film with thickness of ~73 nm and ENZ wavelength of 1577 nm (real part of permittivity of the material crosses zero) is fabricated onto the D-shaped platform. Due to the evanescent field between the core mode and the mode supported by the AZO nano-layer, a highly confined ENZ mode in the AZO nano-film on the fiber could be excited (Fig. 2). We observed a resonant dip at the wavelength of ~1700 nm with strength of 8.2 dB in the measured transmission of 1.7 cm long ENZ-fiber, showing a good agreement with the phase matching condition from the full-wave numerical simulation by considering the measured dispersion of the AZO thin film. Our results show the first experimental demonstration on the excitation of highly confined ENZ mode on optical fibers. These hybrid ENZ-optical fibers could be applied in zero-index photonic applications for studying enhanced ENZ nonlinear in fiber, quantum emission in ENZ media, and subwavelength mode enhanced in-fiber optical and bio-sensing.

Abstract

We discuss our recent work on condensation phenomena on plasmonic lattices as well as K-point lasing in honeycomb lattices.

1. Experiment on Bose-Einstein condensation

A metal nanoparticle array gives rise to quasi-particles called surface plasmon polaritons (SSPs) which are a mixture of light and electron movement in metal. We demonstrate a Bose-Einstein condensate (BEC) of SSPs in a lattice of metallic nanoparticles [1]. Interaction of the SSPs with organic dye molecules induces thermalization by subsequent absorption and re-emission processes. With suitable lattice periodicity this interaction leads to condensation, which occurs at room temperature and in a picosecond timescale. The dynamics are studied in an experiment that utilizes the propagation of the modes and the open cavity character of the system, see Fig 1. Linewidth narrowing and increase of the spatial coherence of the mode is observed in response to onset of condensation. Transition from BEC to lasing is observed when the periodicity of the lattice is varied. We also discuss our more recent progress in this topic.

2. K-point lasing

We also study lasing at the high-symmetry points of the Brillouin zone in a honeycomb plasmonic lattice[2] with IR-792 dye as gain material. We demonstrate lasing, Fig.2, at the K points. By comparing polarization properties to T-matrix simulations, we identify the lasing mode as one of the singlets with an energy minimum at the K-point enabling feedback.

Functional all-dielectric nanophotonic: from colloidal synthesis to transition metal dichalcogenides nanoantennas

Ruggero Verre1,*, Nils Odebo-Länk1, Denis Baranov1, Timur Shegai1 and Mikael Käll1

1Chalmers University of Technology, Physics Department, Göteborg, 41264, Sweden

Abstract
We present the first techniques able to fabricate solutions of all-dielectric nanoparticles with predefined shape and demonstrate that multilayer WS2 nanodisks support geometrical Mie resonances and new light-matter regimes not attainable by standard materials.

1. Introduction

Electromagnetic (EM) metasurfaces are structured material layers with subwavelength thickness that appears smooth to an impinging EM field because the feature spacing is small compared to the incident wavelength. In particular, the use of high-index dielectric (HID) nanoparticles as metasurface building blocks, or meta-atoms, allows for extremely flexible control of the optical properties by engineering their morphology. Similar to their metallic counterparts, HID nanoparticles support multiple resonances[1] and are able to efficiently convert propagating fields into sub-wavelength volumes. HID nanoparticles also have additional advantages, such as thermal stability, reduced Ohmic losses and CMOS fabrication compatibility. These features render HID metasurfaces highly interesting for applications like wavefront manipulation, light management, directional antennas, light harvesting, ultra-fast optical switching and molecular sensing, to name a few.[2]

The diverse pool of potential applications highlights the need for flexible and cost-effective fabrication methods that would enable realization of large-scale nanostructured HID materials with well-defined physical and optical properties. Many of the available techniques have their limitation: lithographic methods cannot cover large areas and the features are generally planar. On the other hand, wet chemistry synthesis of HID nanoparticles is far from being as mature as for metal nanoparticles, several methods are capable of producing high quality spherical silicon particles with a range of sizes have been recently reported.

In this document, we first demonstrate a method for large-scale fabrication of different silicon nanostructures using a modified version of the hole-mask colloidal lithography (HCL) technique. Afterwards, we present a method for removing such Si particles from a supporting substrate and used it to realize colloidal HID solutions. We show that this methodology can be used to detach and dissolve nanoparticles of diverse shapes ranging from disks to chiral particles. In the final part of the document, we will discuss some applications of the different fabricated systems. It is important to note that this is the very first technique able to fabricate shaped high index dielectric nanoparticles in solutions and these can be used for optical trapping fundamental studies or to realize new type of systems.

Finally, it is demonstrated that patterned multilayer transition metal dichalcogenides are nanoparticles which support geometrical Mie resonance like standard high index materials. In addition, thanks to their excitonic response and optical anisotropy, this materials support novel light matter interactions not encountered with standard materials.

2. Metasurface fabrication

Figure 1a shows the basic principle for the fabrication of HID metasurfaces [1-2]. A sacrificial layer, for example a resist or a SiO2 film, is formed by spin coating or deposition, on top of a deposited Si film. Polystyrene beads are then dispersed on the substrate. After a thin metal film evaporation and tape stripping, a hole mask is formed. The sacrificial layer is then etched through the holes in the mask, followed by evaporation of hard mask (Ni or Cr) nanoparticles of a chosen shape. These hard mask particles can be transferred to the poly-Si film underneath by anisotropic etching.
The method described can be used to produce homogeneous metasurfaces over 4-inch wafers, as shown in Figure 1b. Most importantly, it is also highly versatile and capable of fabrication of nanoparticles of different shapes simply by changing the conditions for deposition of the Ni mask.

3. Colloidal solutions

The fabricated nanoparticles can be removed from the substrate to realize colloidal [2-3]. The as-fabricated metasurface is first dipped into a HF solution (5%) to selectively etch the substrate. Subsequently, diluted HF (0.1%) is drop-casted on the metasurface until the particles disperse into the solution. The HF solution is then left to evaporate. Finally, the particles are dispersed by sonication in an aqueous solution of cetyltrimonium bromide (CTAB, typically 1-5mM). The colloidal solution is stable for several months. Note that this method can in principle be adapted to substrates prepared by any large-scale fabrication method. The optical extinction measurements of the metasurface (b) and colloidal solution (d) composed of nanodisks, reveal the presence of tunable multiple resonances, typical of HID nanostructures.

Finally, we have recently discovered and demonstrated that nanoparticles made of multilayers WS₂, a Van der Vaal’s crystal typically used as a 2D material, also supports Mie resonances like standard high dielectric materials [4]. However, thanks to the rich exciton physics, the possibility of simple flake transfer on any host transfer and their anisotropic dielectric function, this material can be used as a platform capable of realizing new light-matter interaction regimes and whose potential still needs to be completely unveiled.

Abstract

Plasmonics has proven to be a powerful tool to improve the performance of optical devices. The possibility of modulating the emission, propagation and/or detection of radiation constitutes a promising aspect to expand the limits of the currently used technologies. In this sense, fast and contactless actuation on plasmon resonances via the Magneto-Optical (MO) effect has been put forward by the inclusion of ferromagnetic components into noble metal layers and nanostructures, yet up to now restricted to the visible and near-infrared ranges.

Recently it has been shown that this magnetic field modulation can be extended to the mid-IR and THz region by the use of the Magneto-Refractive (MR) effect, i.e., a change in the optical properties of the system by magnetic field controlled electrical resistivity¹,²,³. In this talk we will review the effect that a magnetic field has on the plasmon properties and in particular this new alternative for magnetic modulation in the mid and far IR range using different plasmonic metasurfaces.

Abstract

Inspired by frustrated magnetic systems, the effect of geometric frustration in the optical response of plasmonic arrays of Au nanoelements is studied. In particular, we show how the symmetry of the lattice can hamper the excitation of near-field dipolar modes among the nanoelements, favoring in turn the excitation of lattice collective modes. Both simulations and experimental results demonstrate that these systems behave as perfect absorbers in the visible and/or the near infrared and they exhibit a relatively extended time response.

1. Introduction

Geometric frustration has largely been studied in magnetism where the term refers to situations in which spins in one or more of the magnetic sub-lattices do not find a proper orientation to fully satisfy the interactions with the neighboring spins due to the actual geometry of the structure itself. This yields slow dynamics caused by an intricate energy landscape with lots of quasi-degenerate states. We introduced this concept in the field of plasmonics referring to situations in which the symmetry of the array does not favor a complete ferroelectric polarization of the gaps between neighboring elements \cite{1}. Our goal is to favor the excitation of collective modes at the expense of the near-field interactions with prevailing dipolar character. We show that the key ingredients in settling the degree of geometric frustration of these lattices depend on the complexity of the system, that is, the number of sub-lattices of gaps with different spatial orientations (see Fig. 1(b)), together with the strength of the interactions among them. The former is related to the symmetry of both the lattice and the elements of the array. Furthermore, since the strength of the interactions among neighboring gaps depends on their areal density and inter-distances, the effect on the optical response of the array can also be modulated by changing both the size of the nanoelements and the pitch of the array.

Studies on the geometric dependence of the plasmonic response of arrays have already been reported \cite{2,3}, most of them exploiting the coupling through the gaps between close-lying structures. However, few works studied the dependence of the system’s response on the lattice symmetry, and in particular, the interplay between low energy and high energy modes within those lattices \cite{3}. Here, we go one step further and exploit multiple coupling in various hexagonal arrays of Au nanoelements to yield extended time response with echoed excitation of lattice modes at significantly longer times than in systems without frustration.

2. Results and discussion

We present experimental and numerical results for the optical response of three cases of hexagonal lattices of plasmonic nanoelements.

2.1. Design

We studied a hexagonal array of Au disks, a honeycomb array of Au bars, and a hexagonal array of Au asterisks (see Fig. 1 for a scheme of the latter). Our structures are arranged in such a way that the elements strongly interact via near-field coupling thanks to the small gap between them. Also, we studied structures with metal-insulator-metal (MIM) configuration where the spacer was set to a quarter-wavelength thickness to achieve maximum absorption around the plasmon resonance for normal incidence (Fig. 1(a)).
2.2. FDTD simulations

Finite-Difference Time Domain (FDTD) simulations using the Lumerical FDTD Solutions package were carried out to calculate the absorption spectrum, the near-field intensity, the charge distribution, and the time evolution of the optical response.

Figure 2: Absorption spectrum for a hexagonal array of asterisks. The two panels at the right-hand side show the electric field distribution corresponding to the peaks labeled as II and III in the figure.

The absorption spectra for the three lattices have common features [1,4]: All of them show a broadband in the near-infrared region (NIR) attributed to the dipolar excitation of the gaps, and higher order modes lying around the visible, which are associated with collective modes and correspond to sharp and high absorption peaks that in some cases can reach almost perfect absorbance. While the electric field associated with the NIR modes is mainly concentrated within the gaps, the high-energy modes exhibit electric field distributions around the whole nanoelements. These modes are also enhanced because of the cavity formed by the MIM stack. Figure 2 shows an example of this general behavior for a hexagonal array of asterisks.

Figure 3: Spectral distribution and time evolution of the intensity of the electrical field at the point indicated in the inset for a hexagonal array of asterisks.

Figure 3 shows the time evolution of the magnitude of the electric field at a certain point of the lattice for the asterisk array [1]. Remarkably, the system remains active for over 70 fs after a pulse excitation of 8 fs and the main contributions to the spectral distribution are in the visible region corresponding to lattice excitations that are still shining after relatively long times. We also evidence that this general behavior is shared too by other arrangements without triangular symmetry such as a square array of bars.

2.3. Experimental results

A set of samples with triangular symmetry were manufactured by electron beam lithography. Scanning Electron Microscopy (SEM) images are shown in Fig. 4(a-c) together with their corresponding extinction spectra (Fig. 4(d-f)) which are in qualitative agreement with the simulated ones.

Figure 4: SEM images of three samples and the corresponding extinction spectra.

3. Conclusions

We show arrays of Au nanoelements with various lattice symmetries, all of them exhibiting high absorption sharp peaks in the visible and/or the NIR, as well as an extended time response of the collective modes due to the frustrated dipolar polarization of the gaps between the nanoelements [4]. This behavior, together with the fact that the electric field enhancement in these plasmonic arrays extends over very large areas, makes them suitable as enhancers for spectroscopies such as Raman and fluorescence that benefit from increased light absorption.

Abstract
Graphene has offered a new paradigm for extremely fast and active optoelectronic devices. Here we present novel integrated graphene plasmonic devices for on-chip light modulating and detecting. The graphene plasmonic modulator shows high modulation depth and low insertion loss, and the graphene plasmonic waveguide photodetector has the bandwidth beyond 110 GHz and intrinsic responsivity of 360 mA/W.

1. Introduction
Graphene, a unique two-dimensional material, provides great potential in the realization of high-performance optoelectronic devices. In particular, significant efforts have been devoted to graphene modulators and photodetectors [1-6]. The distinct properties of graphene in terms of ultrahigh carrier mobility, zero bandgap property that enables wavelength-independent light absorption over a very wide spectral range, and tunable optoelectronic properties give rise to realize graphene devices with large spectral bandwidth and high speed. However, their performance is still limited by weak light-graphene interaction and large resistance-capacitance product. Here we present our recent results on graphene plasmonic hybrid platforms for on-chip light modulating and detecting, giving a promising way to realize on-chip interconnects with graphene plasmonic devices.

2. Results
Figure 1(a) shows the SEM image of our proposed graphene plasmonic waveguide modulator [7], where the plasmonic slot waveguide is coupled in/out by silicon waveguides with inverse tapering tips. The plasmonic waveguide can confine modes beyond diffraction limit, while at the same time suffering large propagation loss. Here we propose plasmonic slot waveguides relying on the concept of leaky mode, giving us extremely low loss of 0.25dB/μm. The good alignment of the coupling part (between the silicon and plasmonic waveguide) leads to high in/out coupling efficiency of 1.45 dB.

Transmissions of the light at 1.55 μm through 20 μm-long leaky-mode graphene-plasmonic waveguides at different bias voltages are presented in Fig. 1(b) for two slot widths of 120 nm and 145 nm. One can find that the transmission through the graphene-plasmonic hybrid waveguides is
effectively tuned by applying bias voltages on the graphene. An efficient attenuation tunability of 0.13 dB/μm is achieved for the plasmonic slot width of 120 nm at low gating voltages. The modulation depth of 0.13 dB/μm achieved here exceeds that for reported graphene-plasmonic hybrid device [8].

Figure 2 shows our proposed ultra-compact, on-chip, and high-speed graphene photodetector based on a plasmonic slot waveguide [9]. The subwavelength confinement of the plasmonic mode gives rise to the enhanced light-graphene interactions, and the narrow plasmonic slot of 120 nm enables short drift paths for photogenerated carriers. The schematic of the proposed graphene plasmonic hybrid photodetector is shown in Fig. 2(A), where the light from a fiber is first coupled to a silicon waveguide through a grating coupler and further to the plasmonic slot waveguide by a short taper structure. Fig. 2(B) shows a fabricated graphene-plasmonic photodetector, where the dashed lines represent the graphene coverage boundary, and the corresponding optical bandwidth measured by VNA, impulse response, and frequency beating with ESA is presented at the bias voltage of 1.6 V, showing that the bandwidth is over 110GHz. Moreover, the use of chemical-vapour deposition (CVD)-growth graphene here allows for the scalable fabrication and we believe that our work greatly pushes the 2D material towards practical applications, e.g. in optical interconnects, high-speed optical communications, and so on.

3. Conclusions

We present novel integrated graphene plasmonic devices for on-chip light modulating and detecting, which shows a promising way to realize ultra-compact and high-speed optoelectronic devices for potential applications in on-chip interconnects.

4. Acknowledgements

Abstract

In the past decade, the scientific community could obtain the in-vitro recording of intracellular action potentials from large networks of electrogenic cells by exploiting 3D vertical nanostructures, such as nanopillars. Despite the high quality of the recordings, these techniques were not implemented in commercial products due to difficulties in the mass production of 3D nanostructures. Here, we show that intracellular action potentials can be acquired also with laser excitation of planar nanoporous metamaterials used as meta-electrodes of multi-electrode arrays. The fabrication of the meta-electrodes is extremely cost-effective and is compatible with large production, allowing for the fast and easy integration on commercial devices.

1. Introduction

The in-vitro characterization of electrogenic cells is a fundamental step to understand the functioning mechanisms of neuronal and cardiac cell cultures\textsuperscript{[1]}. These data are acquired with multi-electrode arrays (MEA) that record extracellular action potentials from hundreds to thousands of cells simultaneously. However, the extracellular action potentials do not provide comprehensive details on the cell activity. In fact, to improve the quality of the obtainable information, the scientific community has developed new methodologies to achieve recordings of intracellular action potentials, which are significantly richer of information on the electrogenic activity of the cell and on its ion channels’ status. For instance, the recording of intracellular action potentials allows for detecting changes in the functioning of ion channels due to the effects of drugs. Almost all in-vitro intracellular recording techniques exploit 3D vertical nanopillars fabricated on the MEA electrodes to enhance the coupling with cells and to achieve intracellular access\textsuperscript{[2,3]}. However, 3D nanostructures are not easily implemented on commercial devices because of difficulties in combining them with large and cost-effective production processes. Here, we show that plasmonic nanoporous metamaterials can replace 3D nanopillars as efficient tools to porate the cellular membrane and to record intracellular action potentials, while preserving compatibility with large production processes. The membrane poration process exploits the fast-pulsed laser excitation of the metamaterial to produce plasmonic hot spots, which locally disrupts the cellular membrane and allows for accessing the intracellular compartment\textsuperscript{[4]}.

2. Discussion

Nanoporous metamaterials present several interesting properties for biological applications. On the one hand, they can efficiently absorb light radiation in the visible/near-infrared region and can concentrate it in plasmonic hot spots located in the nanogaps of the material. On the other hand, porous materials strongly promote cell adhesion due to the very high surface roughness. At the interface with such materials, the cellular membrane conforms to the rough surface and infiltrates the nanogaps in the nanoporous material. When exploited together, these features make it possible to porate the cellular membrane by exciting the porous metamaterial at the interface with cells. In fact, the cellular membrane is in tight adhesion in the nanogaps where the impinging radiation is concentrated and thus where the plasmonic enhancement is highest.

In figure 1a and 1b, we report SEM images of MEA electrodes coated with nanoporous platinum and nanoporous gold respectively. The electrodes do not present protruding vertical structures and show a planar configuration at the microscale. However, at the nanoscale, the materials present bumps and gaps with sizes down to 10-20 nm. The use of a fast-pulsed laser in the near-infrared (NIR) region allows achieving cell poration without heating the biological sample\textsuperscript{[4]}. In our experiments, we use a 1064 nm pulsed laser source with pulse duration of 8 picoseconds.
In figure 1c, we show superimposed intracellular action potentials of a HL-1 cardiac cell after the administration of 500 nM dofetilide, a known compound that slows down the repolarization phase and thus prolongs the action potential duration. The signals were recorded with a commercial MEA device and using plasmonic optoacoustic poration to enable intracellular recording. The traces show a high signal-to-noise ratio that allows for the precise characterization of the action potential shape.

Figure 1: a) SEM image of a meta-electrode on a MEA commercial device based on CMOS technology. b) Close-up view of planar gold meta-electrodes with nanoporous surface. c) Superimposed intracellular action potentials of HL-1 cardiac cells after the administration of 500 nM dofetilide.

3. Conclusions

Here, we have shown that nanoporous metamaterials can be very effective tools in the field of in vitro electrophysiology. By means of fast-pulsed laser NIR radiation, the plasmonic properties of the metamaterials allow for disrupting the cellular membrane of cells cultured in tight adhesion on them. When the metamaterials are fabricated onto the electrodes of multi-electrode arrays, they provide a cost-effective and non-invasive tool for recording high-quality intracellular action potentials from large cultures of electrogenic cells.

Abstract

We report recent breakthroughs in nanomechanical metamaterials including (i) a giant acousto-optical effect, (ii) on/off switching of metasurfaces, (iii) selective electrical and optical actuation of metamaterials elements with sub-wavelength spatial resolution, (iv) phase-change metasurfaces with bistable optical and mechanical properties and (v) metamaterials tuned by electrostriction.

1. Introduction

The optical properties of metamaterials, and indeed any other material, depend strongly on the spatial arrangement of their components. This has enabled giant thermo-optical, electro-optical, magneto-electro-optical and nonlinear optical phenomena in photonic metamaterials fabricated on dielectric membranes of nanoscale thickness, where the nanostructure is rearranged by thermal, electrical, magnetic and optical forces [1]. Here we provide an overview focusing on recent advances.

2. Results

High-contrast modulation of light is of great practical importance. We observe giant acousto-optical modulation in a nanomechanical metamaterial that is actuated by ultrasound frequency vibrations. Such modulation exhibits strong nonlinearities and reaches relative reflectivity changes of up to 75\% in a structure of only 100 nm thickness.

Exploiting electrostatic forces in nanomechanical metamaterial structures, we demonstrate novel approaches to electro-optical modulation based on (i) MEMS modulation of the interaction of light with a metasurface, essentially switching the metasurface on and off [2], and (ii) electrostriction in a nanomechanical metamaterial [3].

Dynamic control over optical properties at any point in space and time is arguably the ultimate metamaterials vision. We demonstrate both electrical and optical methods that enable selective actuation of nanomechanical metamaterial elements with sub-wavelength spatial resolution [4, 5].

Phase transitions enable bistable nanomechanical actuation associated with bistable optical properties. Exploiting phase change materials such as shape memory alloys [6] and chalcogenide glasses, we demonstrate nanomechanical metamaterials with optical memory functionalities.

3. Conclusions

In summary, we report recent advances in nanomechanical metamaterials, including light modulation based on acousto-optical, coherent electro-optical and electrostriction effects, optical and mechanical bistability based on phase transitions, and electric as well as optical nanomechanical actuation with sub-wavelength resolution.

Abstract

We demonstrate, theoretically and experimentally, the achievement of broadly customizable Epsilon-Near-Zero response in the whole visible range by using Metal/Insulator/Metal nano-cavities. The optical response of the proposed structures is modelled in both a classic and a quantum framework, elucidating the resonant tunneling nature of the Epsilon-Near-Zero (ENZ) response occurring at the cavity modes, clarifying the reason why they can be excited without any momentum matching. We also investigate the hybridization of the ENZ modes in multiple cavity systems, achieving broadly tailorable ENZ bands. As remarkable applications, we demonstrate how the proposed systems can be used as tunable superabsorbers, refractive index sensor and to enhance the photophysical performances of weakly coupled fluorophores.

1. Introduction

Metal/Insulator/Metal (MIM) waveguides constitute a versatile platform for light confinement at the nanoscale. Their optical response has been widely investigated in the past, since these structures revealed outstanding properties as plasmonic waveguides, color filter and superabsorbers. Recently, it has been demonstrated that these MIM nanocavities support ENZ response at their resonances. In this work we explore this scenario, investigating the occurrence of their ENZ response by means of a quantum approach. This new point of view provides great insight in the physics governing the optical response of MIM structures, elucidating that the MIM’s resonances correspond to resonant tunneling modes occurring due to the zero wavevector inside the MIM, due to its effective ENZ permittivity.

2. Single MIM

The optical response of a Metal/Insulator/Metal (MIM) nanocavity is ellipsometrically detected, and its homogenized refractive index is calculated via a direct fitting of the ellipsometrical angles Ψ and Δ, demonstrating the occurrence of a vanishing effective dielectric permittivity in correspondence of the absorbance maxima (1-Transmittance-Reflectance), corresponding to the modes of the cavity. The MIM system is modeled in a classic framework as a simple harmonic oscillator. Such an approach allows a quick and accurate calculation of the effective permittivity of the MIM, demonstrating the low-loss ENZ nature of the modes of the cavity. The optical response of the MIM nanocavity is then modeled in a quantum framework as a finite quantum well. This analogy provides deep physical insight in the behavior of the MIM system, demonstrating that the modes of the cavity correspond to resonant tunneling frequencies occurring thanks to the zero wavevector inside the MIM, due to its effective ENZ permittivity.

3. MIMIM and multicavity systems

A second MIM cavity is then fabricated on the top of the first one, to form a MIMIM system. Sharing the common central metal, the two cavities can exchange energy very efficiently, so that the hybridization and splitting of their resonance occurs, as shown in Figure 2.
The MIMIM system is modeled as double quantum well, in analogy with many two level systems, so that an accurate analytical description of the dispersion of the MIMIM structure is provided. Ellipsometrical measures carried out over this system reveal the ENZ nature of the hybridized modes as well. The splitting of the two modes can be finely engineered by acting on the geometrical parameters of the resonators, in order to position the two resonances where desired within the complete visible range. The resonances of the MIMIM are tuned to match the absorbance and the emission of a CsPbBr$_3$ perovskite placed in proximity of the MIMIM, demonstrating remarkable Purcell effect with consequent enhancement of its photophysical properties (photoluminescence, decay lifetime and quantum yield), as shown in Figure 3. Multicavity systems made of several stacked MIMs are then analyzed to demonstrate how to engineer complete ENZ bands.

4. Conclusions

In conclusion, we investigated the optical response of metal/insulator multilayers in a quantum framework, revealing that the cavity modes correspond to resonant tunneling ENZ modes, occurring due to the vanishing wavevector inside the cavity. This approach allows to finely determine the dispersion of these structures, providing at the same time new insight on very well-studied systems. We demonstrate how such an approach can be extended towards the design of artificial metals with engineered ENZ bands. As remarkable applications, we demonstrate the possibility of using these structures as completely tailorable superabsorbers, refractive index sensors and as innovative platforms for the enhancement of the photophysical properties of fluorophores.

Ultrafast Laser-Induced Control of Interface-Induced Magnetic Anisotropy in Ferromagnetic Thin Films

Alexandra Kalashnikova

Ioffe Institute, 194021 St. Petersburg, Russia
E-mail: kalashnikova@mail.ioffe.ru

Abstract
Ultrafast laser-induced changes of magnetic anisotropy is the phenomenon allowing to excite and control dynamics of magnetization in a bulk, thin films, and nanostructures. We present our recent results on studies of ultrafast laser-induced thermal changes of magnetic anisotropy with emphasis put on contributions defining properties of thin and ultrathin films. We consider the laser-induced manipulation of perpendicular magnetic anisotropy in magnetic tunnel junctions, and of magneto-elastic domains in composite strain-mediated multiferroics.

1. Introduction
Excitation of magnetic media by femtosecond laser pulses yields a broad variety of ultrafast spin phenomena [1], from subpicosecond demagnetization [2] and full magnetization reversal [3] in metals to opto-magnetic effects in transparent dielectrics [4]. Recently, a particular interest arose to laser-induced thermal changes of magnetic anisotropy. Such mechanisms rely on a rapid laser-induced increase of temperatures of various subsystems of a medium and, therefore, can be realized in different materials, metallic [5, 6], semiconducting [7], and dielectric [8]. It has been shown, that such changes of magnetic anisotropy enable novel pathways for laser-induced switching of magnetization [9, 10, 11], launching spin pumping in spin-valve structure [12], driving multiple spin-wave modes in thin films [13], etc.

Here we present a review of our recent works on ultrafast laser-induced control of magnetic anisotropy in thin films of a ferromagnetic CoFeB alloy with emphasis put on contributions to the magnetic anisotropy related to the interfacial phenomena. In particular, we discuss how laser excitation can affect the strain-induced anisotropy and perpendicular anisotropy in thin and ultrathin CoFeB films.

2. Results and discussion
When a magnetic metallic film is excited by a femtosecond laser pulse, the energy is transferred to an electronic subsystem, and, upon electron-phonon relaxation, to a lattice. Increase of the temperatures of these two subsystems reach hundreds degrees, and a following cooling down can proceed on various timescales, from picoseconds for electrons to nanoseconds for a lattice. This, in particular, leads to an ultrafast demagnetization, i.e. decrease of the saturation magnetization $M_s$, and variations of magnetic anisotropy parameters $K_{1, u,...}$. When the external field is applied to a magnetic film, the total effective field setting the magnetization orientation is determined by the balance between the anisotropy $\sim K_{1, u,...}$ and the Zeeman $\sim HM_s$ energies. Therefore, laser-induced changes of $K_{1, u,...}/M_s$ lead to abrupt reorientation of this field, thus triggering a magnetization precession. Angle by which the total effective field reorients determines the amplitude of the excited magnetization precession, while the strength of the changes and their relaxation times may affect the precession frequency. This simple macroscopic picture captures the main features of the process of ultrafast changes of magnetic anisotropy and of the related excitation of magnetization precession. Therefore, in experiments, by studying the properties of the laser-driven precession, one can extract a valuable information about microscopic mechanisms underlying ultrafast laser-induced anisotropy changes.

2.1. Laser-induced changes of perpendicular magnetic anisotropy
In thin and ultrathin magnetic films, in particular in metallic films grown on oxide substrates, interfacial contribution to magnetic anisotropy may play a decisive role and, in particular, stabilize perpendicular magnetic anisotropy (PMA) [14]. In order to investigate a possible impact of ultrafast laser pulses on such structures, we studied the laser-induced excitation of magnetic tunnel junction structure formed by two layers of amorphous CoFeB separated by a 1.2-nm thick layer of MgO. The important feature of the studied structure is that one of the magnetic layers with a thickness of 1.2 nm is in a vicinity of the thickness-induced spin reorientation transition (SRT) due to the subtle balance between shape- and PMA-contributions to the magnetic anisotropy [15]. Upon excitation of such structure by a femtosecond laser pulses, the magnetization precession is observed. The precession excitation can be unambiguously ascribed to the laser-induced suppression of the PMA-contribution to the anisotropy. Owing to the proximity of SRT, the laser-induced changes of PMA are found to be very pronounced and affect not only the excitation of precession, but also the frequency of the latter. As a result, the laser-induced suppression of PMA enables tuning the precession frequency in a wide range, e.g. from 3 upto 6 GHz by changing the
pulse pulses fluence at a fixed applied field.

2.2. Laser-induced changes of magneto-elastic anisotropy

Amorphous CoFeB is a model material to investigate a laser-induced dynamics of another type of magnetic anisotropy – magnetoelastic one. We studied the structure consisting of a 50-nm thick layer of CoFeB deposited on a ferroelectric substrate BaTiO$_3$. Strain transfer from the ferroelectric domains in BaTiO$_3$ to the CoFeB layer imprints in the latter magnetic domains with anisotropy axes defined solely by magneto-elastic interactions [16]. Such system represents a composite multiferroic in which the magnetization can be controlled by applying electric voltage to a ferroelectric layer. We demonstrate excitation of the magnetization precession by femtosecond laser pulses in individual magnetic domains in the CoFeB layer of such the multiferroic structure. By analyzing the dependence of the excited precession on the orientation of external magnetic field relatively to the magneto-elastic anisotropy axis of a particular domain, we show that the precession is launched by the ultrafast laser-induced thermal changes of the magnetoelastic parameters. We suggest that such an approach paves a way for controlling magnetization in multiferroic micro- and nanostructures with high spatial and temporal resolutions provided by electric and optical stimuli, respectively.

3. Conclusions

We have demonstrated ultrafast laser-induced changes of magnetic anisotropy in thin-film structures based on CoFeB ferromagnetic alloys. We showed that in the ultrathin CoFeB/MgO layers with PMA, the latter can be efficiently suppressed due to laser-induced picosecond heating. Such an effect, in particular, allows realizing laser-driven tuning of the magnetization precession frequency. In multiferroic structures CoFeB/BaTiO$_3$ we have realized laser-induced excitation of magnetization precession in individual micrometer-sized magnetic domains. We show that this is enabled by the ultrafast laser-induced thermal changes of magneto-elastic anisotropy.

Abstract
We designed a class of spiral thin-film antennas for enhancing, in the near field, the incident terahertz (THz) magnetic field. Indeed, using existing laser-based THz sources, our metamaterial geometry allows generating magnetic fields of the order of 2 T over a time scale of few picoseconds, enabling the investigation of nonlinear ultrafast spin dynamics in table-top experiments.

1. Introduction
In the last three decades, the development of high-power ultrafast table-top lasers represented a great experimental advance, as emphasized by the 2018 Nobel Prize in Physics. Indeed, these tools allow studying non-equilibrium dynamics in several systems on a sub-ps time scale, directly unveiling the foundations of the involved physical processes. In particular, ultrafast magnetism proved to be an exciting field of research after the groundbreaking experiments that showed the possibility of achieving sub-ps demagnetization of ferromagnetic materials by ultrafast optical excitation[1]. The use of visible radiation involves three main systems in the process: the electrons, the spins and the lattice[2]. Besides the clarity and the relevance of the experimental evidences, the interplay between these three systems makes the interpretation of the phenomenon quite complicate and highly debated[3].

Hence, to shed light on ultrafast demagnetization, a recent and successful approach consisted in the use of single-cycle THz radiation for triggering magnetization dynamics[4, 5]. Indeed, the magnetic field component of the THz radiation can couple directly to the spin degree of freedom, reducing the number of systems involved in the process. Through this capability, it is even possible to induce coherent precessional magnetization reversal (“ballistic switching”) in metallic ferromagnets[6], which constitutes the fastest and most efficient switching method to be used, e.g., in magneto-recording media[7]. However, the peak THz magnetic field needed for ballistic switching is of the order of 1 T, whereas only about 0.33 T can be reached nowadays through optical rectification in table-top setups.

2. Discussion
For this purpose, we designed a class of thin-film metamaterials that can be patterned on top of the target sample for enhancing, in the near field, the incident THz magnetic field[8, 9]. Through finite element simulations, the asymmetric spiral geometry[9] resulted to be the best compromise between magnetic field uniformity and enhancement factor. Indeed, this metamaterial acts as a RLC circuit whose resonance frequency can be precisely defined by varying the characteristic geometrical parameters and the number of turns, so allowing the design to be adapted to the THz radiation to be used. Figs. 1(a)-(b) show the electric and magnetic field enhancements of an asymmetric spiral antenna tuned to have a resonance frequency of 1 THz, a typical value in THz pump-probe experiments[5]. The magnetic field enhancement, which is quite uniform in the central region of the spiral, can reach a factor of 40.

However, when performing time-resolved measurements with single-cycle pulses, the antenna bandwidth plays a major role, and the total enhancement results in a factor of 6, as shown in Fig. 1(c). This is not a drawback, since the balance between resonant enhancement and antenna bandwidth actually provides an effective design: the peak magnetic field of the amplified pulse is high enough for, e.g., testing ballistic switching in ferromagnetic materials, whereas the antenna bandwidth can be properly tuned to obtain a table-top near-field source of multicycle THz radiation driven by broadband THz pulses.

3. Conclusions
In conclusion, the asymmetric spiral antenna proved to be a flexible and effective design for obtaining THz magnetic field enhancement in table-top experiments. Not only our metamaterial can provide uniform enhancement of THz single-cycle pulses, but also constitutes a source of intense multicycle THz radiation.
Figure 1: (a) Electric and (b) magnetic field enhancements for an asymmetric spiral antenna (100 thick Au) at the resonance frequency of 1 THz, as obtained from frequency-domain simulations. The incident radiation is linearly polarized along the direction of the spiral arm (horizontal in the figure). (c) Magnetic field profile ($H_z$) at the center of the spiral antenna, as obtained from time-domain simulations. The incident magnetic field $H_{\text{incident}}$ is visible in semi-transparent color between 0 and 3 ps. Adapted from Ref. [9].

Abstract

The computing landscape has been dramatically perturbed due to the slowing to a halt of Moore’s law, favoring the advancement of several non-VonNeuman architectures. Analog memory devices [1], neuromorphic photonics for deep learning applications [2–4], optical coprocessors for high speed convolutions [5,6] and quantum analog computers [7] are just some examples of currently used analog architectures which can tackle complex tasks more efficiently than a regular digital processor. The main advantage of analog computers is the ability to perform algebraic and integro-differential operations upon continuous signals, without a temporization, enabling efficient processing for specific operations. One of the mathematical tasks that can exploit these paradigms and could greatly benefit from using analog co-processor is solving Partial differential equation (PDE). In the past, analog processors, consisting of grids of resistive or reactive elements, were used to model the spatial distribution of physical quantities, in a speculative way to a finite difference approach. However, the complexities of an effective integration of a high speed programmable and concurrently energy efficient static-like analog mesh significantly reduced the advancement of this technology. Here, we demonstrate the realization of a nano-optic co-processor able to instantaneously solve partial differential equation. The proposed PDE processor is based on air grooves meshes, engraved in an Indium Tin oxide (ITO) substrate at epsilon-near-zero condition locally excited by the near field generated by a dipole. We show that this platform behaves as a lumped circuit [8–10], similarly to a resistive mesh, and can be configured to map a finite difference problem, thus providing a discretized solution of a PDE. Thanks to an unprecedented control of the ENZ position and material losses over ITO [11], we are able to provide a top-down approach for a monolithic integration of nano-optics circuits based only on opportunely processed ITO films. In details, we are able to obtain ITO films with tailored values of real and imaginary part of the dielectric constant, mimicking resistors and reactivities in our nano-optic circuit, which operates in the IR telecommunication wavelength. Moreover, the elements of the circuit can be electrostatically tuned, by altering the carriers in a capacitor configuration [12–14] and therefore reprogrammed, aiming to solve a great variety of PDEs with different boundary conditions including Poisson Equation, Diffusion Equation and the Wave Equation. We further investigate the performance of our nano-optic processor by comparing the accuracy of the solution of PDE representing a heat transfer problem with the results obtained with finite difference approaches, demonstrating physical limit of the technology in terms of mesh density and size. We also prove that the circuit dimensions, contrary to a lumped circuit model, can be of the same size or exceed the dimension of the impinging radiation wavelength, while elements of the circuit being still locally coupled. We also show that, unlike resistive network, the operating bandwidth at which the circuit can be reprogrammed is decoupled from the physical dimensions of the circuit, thus obtaining high speed reconfiguration without trading off with solution accuracy. Ultimately, power consumption and footprint of the proposed metatronic circuit are evaluated and compared to those required by the state-of-the-art PDE analog co-processors, demonstrating orders of magnitude improvement with respect of speed, power, and size, while providing an accurate solution. Our results open a significant pathway towards the realization of nano-optics reprogrammable co-processor able to efficiently solve complex problem, in particular for those systems where only small amounts of energy is available, while still demanding for high computation speed.

Metamaterials are artificial materials with an engineered periodic structure aiming in properties which cannot be found in nature. Lithographically nano-patterned magnetic materials can result in fascinating behaviour exploiting the magnetic dipolar interactions between individual elements. The emergent properties in such systems are distinctly different from those of their constituent components, driven by the collective dynamics of the interacting elements and respond to external stimuli such as magnetic fields or temperature. Further enhanced functionality can be realised exploiting the fact that the periodicity and element size in such nano-patterned magnetic arrays matches well the wavelengths of visible light, thus providing an ideal setting for the investigation of the interaction of light with magnetic metamaterials. I will present approaches for the fabrication of magnetic metamaterials using thin films. Recent works have demonstrated the creation of reconfigurable magnetic structures which undergo phase transitions and exhibit dynamics on adjustable length- and energy-scales [1-8]. The interaction of visible light with such structures also reveals the opportunity of “steering” light and altering optical properties using such magnetically reconfigurable metasurfaces [9-11].

Abstract
Optical control of the magnetization at ultrashort time scales attracts much attention in context of the data processing and spintronic applications. In this work we demonstrate the optical confinement in photonic microcavity that results in the significant increase of the inverse Faraday effect (IFE) within the magnetic layer. Along with that we show the light localization inside the dielectric sub-wavelength gratings in iron-garnet films that gives rise to the enhancement of the photo-magnetic effects.

1. Introduction

Optical manipulation of the magnetization at ultrashort time scales is of prime interest in context of the data processing and spintronic applications. Excitation with femtosecond laser pulses provides a new way for efficient control of spins at GHz and THz rates. Light localization is the additional way to enhance the light-matter interaction and also to manipulate the magnetic properties at sub-wavelength scales. All-dielectric structures in many aspects are more advantageous for the light localization since they provide optical resonances with high optical quality factors and allow excluding the thermal effects.

In this work, we investigate the influence of the optical confinement in two systems: magnetophotonic microstructures and dielectric sub-wavelength gratings, where in both the magnetic layer is iron-garnet film.

2. Experimental

The magnetophotonic microcavity consists of the magnetic film and two non-magnetic dielectric Bragg mirrors. The iron-garnet magnetic film includes two layers M1 and M2: the auxiliary 72-nm-thick Bi11.0Lu0.5Gd1.3Fe42Al12O42 layer and the main 210-nm-thick Bi2,5Gd0.5Fe1.8Al1.2O12 layer. Each Bragg mirror consists of four pairs of alternating 76-nm-thick TiO2 and 117-nm-thick SiO2 layers grown on the fused quartz substrate.

The all-dielectric iron-garnet 1D gratings have been formed on the films by ion etching. The height and width of the pillars is around 200 nm, while the underneath film was left 75 nm thick, the period is around 450 nm. Magnetic film and the formed gratings are located on the GGG substrate.

To investigate the magnetization precession we used the pump-probe experimental technique. The laser system (Newport Mai Tai HP Ti:Sapphire laser and Spectra-Physics Inspire Auto 100 optical parametric oscillator) emits at 80.54 MHz repetition rate pairs of 150-fs-pulses that are tunable in wavelength. The weaker probe pulse is used for observation of the magnetization dynamics through the direct Faraday effect, i.e. by measuring variation of the Faraday rotation angle, Ψ, caused by the magnetization precession. The average pump light energy fluence was set to 0.66 mJ/cm². An external magnetic field, H, was applied in-plane to saturate the magnetization.

3. Discussion

We first turn to the discussion of the magnetophotonic microcavity sample. The optical confinement of the cavity was used as a tool for enhancement of inverse magneto-optical effect. Basing on the approach of the optical excitation of magnetization precession by femtosecond laser pulses [1–4], we excite the magnetic layer inside the magnetophotonic microcavity and detect the significant increase of the IFE due to the concentration of the optical energy and angular momentum. The cavity mode is excited in the photonic band gap center at λ0 = 642 nm (Fig. 1). Spectral dependence of the IFE on the laser pulse wavelength in the band gap of the magnetophotonic microcavity has a sharp peak that results in a significant enhancement of the IFE (Fig. 1 bottom). Localization of light inside the microcavity leads to the 3D IFE enhancement in depth within the cylindrical regions with diameter of the laser spot and height as small as 30 nm inside of the magnetic layer. These excited volumes can be shifted along the sample depth via e.g. changing the frequency of the laser pulses.
Two systems, namely magnetophotonic microcavity and 1D gratings, both containing the iron-garnet as the magnetic material, have been used to demonstrate the enhancement of the inverse magneto-optical and photo-magnetic effects. In the case of the microcavity we show the 5-times IFE enhancement and the light localization of femtosecond laser pulses in 30 nm cylinder areas in depth of the magnetic layer. While in the all-dielectric sub-wavelength 1D gratings we detect the significant enhancement of the photo-magnetic effects with local light impact across the film thickness and in the transverse direction. For both systems excitation wavelength and polarization of the laser pulses determines the intensity of the effects and leads to the light localization that enhances the light-matter interaction. The obtained results can be a path for the new applications in magnonics.

Abstract
Photo-doping of low dimensional materials with plasmonic hot carriers is a promising route for fast all-optical modulation of optoelectronic devices\textsuperscript{1,2}. Hence understanding the fundamental processes involved in hot-electron generation, transport and thermalization is of crucial importance. Theoretical analysis of the quantum decay of surface plasmon polaritons, with and without phonons, showed that the prompt distribution of generated carriers is extremely sensitive to the band structure of the plasmonic material. In particular, the onset of interband transitions, occurring in the visible regime (around 2 eV) for most common plasmonic metals (Au, Cu, Ag), is expected to significantly modify the hot-carrier distributions\textsuperscript{3}. Also, upon interband excitation of d-band metals such as Au and Cu, a high probability of very hot holes has been predicted\textsuperscript{3}. In our work, we first focused on elucidating the role of plasmon excitation and metal band structure on the internal quantum efficiency of plasmonic photodetectors\textsuperscript{4}. Next, we utilized ultrafast visible transient absorption spectroscopy to understand the effect of hot-hole removal on the thermalization process of hot electrons\textsuperscript{5}. The choice of an appropriate experimental platform (Au/GaN heterostructures) combined with advanced theoretical methods enables unprecedented insight into the dynamics of plasmonic hot electrons.

Abstract

We show that chemically prepared cobalt ferrite nanoparticles can be selectively assembled on plasmonic gold nanodisks, thus forming a hybrid magnetic-plasmonic platform. Spectroscopic and field-dependent magneto-optical studies show an interesting behavior around the plasmon resonance frequency: the magneto-optical response of the gold disks is influenced quantitatively by the local magnetic field induced by the surrounding nanoparticles. We thus propose the idea of using plasmonic nanoantennas as optical local magnetic field sensors.

1. Introduction

Magnetoplasmonics is the research field dedicated to studying the effect of a static magnetic field on plasmon resonance \cite{1}. In this paper we show how magnetoplasmonic effects can be used to gain information on the local magnetic fields generated by nanometric magnetic objects placed around plasmonic nanoantennas. This has been achieved by selectively assembling chemically prepared colloidal nanoparticles on the gold surface of plasmonic nanodisks. Ligand-passivated cobalt ferrite nanoparticles (average diameter \(\sim 15\) nm) were prepared by thermal decomposition of organometallic precursors \cite{2}. This method affords highly crystalline, monodisperse spherical nanoparticles which can be efficiently dispersed in organic solvents. Gold nanodisks (diameter x height \(\sim 150x25\) nm) were prepared by hole-mask colloidal lithography \cite{3}. This highly parallel procedure yields gold nanostructures supported on glass over macroscopic areas. Hydrophobic interactions between the alkyl chains passivating the nanoparticle surface promote binding to the polarizable gold disks. On average, around 15-20 particles are attached to each nanodisk (Figure 1).

Figure 1: Scanning electron micrograph of magnetic nanoparticles assembled on plasmonic nanoantennas.

Magnetic circular dichroism (MCD) spectroscopy was used to characterize the hybrid system. Tuning both incoming light wavelength and applied field magnitude, a full map of this bidimensional parameter space can be investigated (Figure 2).

Figure 2: Magnetic circular dichroism (\(\Delta A\)) intensity map of the magnetic nanoparticle-plasmonic nanoantenna hybrid system as a function of light wavelength and applied magnetic field.
2. Discussion

Two regimes in the low and high magnetic field can be seen in the plasmon resonance wavelength range, centered at 670 nm. This peculiar behavior arises from the different field dependence of the magnetic and plasmonic components of the hybrid: cobalt ferrite nanoparticles exhibit a saturating behavior with respect to an external magnetic field. Gold nanoantennas, on the other hand, show a linear field dependence of their magneto-optical signal [4,5], which becomes dominant at high field values. Taking advantage of this different behavior of the two components, it is possible to separate the their respective spectroscopic footprints, as shown in Figure 3.

![Figure 3: Sketch of the dipolar fields generated by magnetized particles around the nanoantenna.](image)

The linear contribution shows the derivative-like magnetoplasmonic signal arising from magnetic field modulation of plasmon resonance [4]. The saturating (i.e. magnetic) contribution shows a direct footprint of the magnetic nanoparticles in the 350−450 nm range, which is related to charge transfer processes of cobalt ferrite. A second, inverted derivative-like signal is found in the plasmon resonance range: this is not related to direct magneto-optical transitions of cobalt ferrite, but rather to an effect induced by them on plasmon resonance. Considering the assembly geometry of the nanoparticles around the disk, they can be divided into two populations: those standing around the disk and those lying on top of them. We assume that the latter population does not affect strongly plasmon resonance, since most of the near field localization of light is concentrated at the base of the disk (calculations not shown). Considering the nanoparticles adsorbed at the sides of the disks, we observe that their generated dipolar magnetic field is of opposite direction to that of the applied (magnetizing) field (Figure 4). We hypothesize that this opposite field component causes an inverted magnetoplasmonic response in the nanoantennas. Since the magnetoplasmonic signal scales linearly with the field, we can calculate the average magnetic field generated by the nanoparticles around each disk (~ 0.6 T).

3. Conclusions

We observed an anomalous behavior in the magneto-optical response of gold nanodisks when magnetic nanoparticles are adsorbed on their surface. We ascribe this behavior to dipolar fields generated by the particles, to which the plasmonic antenna responds locally.

We believe that, with proper optimization, this principle could be used to design (magneto-)optical readout systems for magnetic fields at the nanoscale.

Tunable and nonlinear metamaterials for circular polarization control

Kuniaki Konishi

Institute for Photon Science and Technology, The University of Tokyo, Tokyo, Japan
E-mail: kkonishi@ipst.s.u-tokyo.ac.jp

Abstract

Symmetry of material plays a crucial role in the polarization sensitive optical phenomena; thus it is important to design and control shapes of artificial nanostructures for developing devices for active polarization control. We have been developing methods of circularly polarized light control by using them. In this presentation, I introduce the recent progress of our study for controls of active THz polarization by active chiral metamaterials and second-harmonic generation with nonlinear metasurfaces with rotational symmetries.

1. Introduction

Circularly polarized light (CPL) sources are important for a variety of applications, such as circular dichroism spectroscopy, spin state control in materials, ultrafast magnetization control and so on. Metamaterials are promising candidates for ultra-small devices with a lot of flexibility in their design for CPL control. The symmetry of a material plays an especially crucial role in polarization sensitive optical phenomena; therefore it is necessary to employ metamaterials with appropriate symmetries to achieve circular polarization control. We have studied the effect of circular polarization in planar metamaterials. We demonstrated that chiral metamaterials which exhibit strong optical activity and found that active control of the structure can be used for THz polarization control with dynamic chirality switching. We also demonstrated that triangle-arrayed metamaterials, which have threefold rotational symmetries, exhibit a unique polarization effect in a second-order nonlinear process: a circularly polarized fundamental beam produces a counter-circularly polarized second-harmonic beam. In this presentation, the recent progress of our research related to these topics is shown.

2. Active Handedness-Switchable Metamaterial for THz Polarization Control

Active modulation of the polarized state of light is important for polarization-sensitive spectroscopy. In the THz frequency region, practical polarization-modulation devices for such purposes have been in demand. Active metamaterials are attracting attention [1], and especially, tunable chiral metamaterials are promising candidates. We present a new type of active chiral metamaterials whose optical activity is controlled by vertical deformation of a three-dimensional structure, engineered by micro electro mechanical system (MEMS) technology [2, 3].

The working schematic and a scanning electron microscope (SEM) image are shown in Figure 1(a). When a planar Archimedean spiral is actuated in the upward vertical direction, the spiral becomes left handed (LH) (Fig. 1a). A reversal of the direction provides a right-handed (RH) spiral, a mirror image of the LH spiral. This reversal achieves chirality switching while maintaining the enantiomeric symmetry. The spiral deformation modulates the polarization state of THz wave passing through it (Fig. 1b).

To enhance the spatial dispersion, we employed a unique pneumatic force actuation, which provides a significantly larger deformation.

Planar Archimedean spirals are fabricated by gold thin film deposited on Si membrane, and direction of deformation is selected by the direction of N₂ pressure supply [3]. The microscopic images of the fabricated spiral metamaterial are shown in fig. 1(c).

Figure 1: (a) Principle of enantiomeric chirality switching of the spiral structures (b) Configuration of spiral structures arrayed to form a chirality-switchable metamaterial. (c) Microscope images of the MEMS spirals in the pre-actuation and on-actuation states. The scale bar corresponds to 100 μm. [3]

The optical activity of the device was investigated using THz time-domain spectroscopy. We observed that the amplitude of optical activity depends on the amplitude of
vertical defamation. Moreover, enantiomeric switching is realized by selecting the deformation direction, where the polarity of the optical activity is altered while maintaining the spectral shape. A polarization rotation as high as 28° is experimentally observed, thus providing a practical and compact polarization modulator for the terahertz range. In the THz regime where polarization devices are still lacking, the presented device can for example be used to create a simple and practical polarization-modulated THz imaging system when combined with other new types of THz devices, such as the THz camera [4].

3. Polarization-Controlled Circular Second-Harmonic Generation from Metamaterials with three-fold rotational symmetry

Nonlinear processes forbidden in homogeneous media can be allowed in metamaterials, thereby offering a unique opportunity to study the interplay between the shapes and mutual arrangements of individual nanostructures. This is especially important for second-order nonlinear optical phenomena and second-harmonic generation (SHG) in arrays of metal nanoparticles and has accordingly been investigated extensively [5].

It is attractive to handle the polarization state of the SH beam arbitrary by controlling that of the fundamental beam in properly designed metamaterials. It was known that circularly polarized SHG occurs from a counter-circularly polarized fundamental beam which propagates along a threefold rotational axis of a nonlinear optical crystal [6]. If the same relation holds between the polarization states of the fundamental and SH beams in nonlinear metamaterials, these materials will be an attractive solution for controlling SHG polarization. Therefore, we investigate SHG in a nonlinear metamaterial with threefold rotational symmetry [7].

Figure 2: (a) SEM image of the sample with three-fold rotational symmetry [7] (b) Schematics of circularly-polarized second-harmonic generation in metallic meta surface with threefold rotational symmetry.

Figure 2(a) shows a SEM image of a fabricated metal nanostructure with triangular-hole arrays, which possesses a threefold rotational symmetry axis. We measured the polarization properties of the SH beam generated by laser pulses with various polarization states and found that the SH beam was predominantly right circularly polarized when the fundamental was left circularly polarized, and vice versa, indicating that the helicity of the SH beam was opposite to that of the fundamental beam (schematics is shown in Fig. 2(b)). Such metallic nanostructures are recently attracting attention as a useful tool to control polarization in nonlinear processes referred as nonlinear photonics metasurface [8].

The presented relationships between polarization selection rules and rotational symmetries of nanostructures are of practical importance for developing wavelength-conversion devices that function in wavelength regions in which other methods of polarization control are unavailable. In the presentation, I would like to also introduce our recent progress on this point if possible.

Abstract

For arbitrarily programmable metasurfaces, a local change of the optical properties of each individual meta-atom is needed. We employ and compare different non-volatile phase-change materials (PCMs) as switchable dielectric environment for meta-atoms. We show the fine-tuning of individual elements of a metasurface covered with a PCM by locally addressing them with laser pulses. Our materials and concepts can be applied to a multitude of already present metasurface designs.

1. Introduction

Despite their nanometer thickness, metasurfaces consisting of resonant metallic or dielectric nanostructures offer comprehensive control over light fields and allow for the creation, detection and transformation of light. Often, their optical functionality is only obtained at a fixed wavelength, determined by the geometric design and the material properties. For optimal functionality, they need to be freely programmable and have low optical losses.

Phase-change materials (PCMs) provide a switchable dielectric environment for resonant nanostructures, altering their resonance frequencies in a non-volatile, reversible way. PCMs have a high optical contrast between their amorphous and crystalline phases (Fig. 1a), while only exhibiting low optical losses in the infrared [1,2].

Active metasurfaces based on PCMs are thus promising building blocks for compact photonic components because they offer adjustable, designed functionality for the manipulation and control of light [2]. Among recent examples are polarization filters [3], beam steerers and lenses [4-6]. Conventionally, they feature multiple operation states by switching the whole phase-change material partially or fully between two states of drastically different optical properties via short electrical or optical pulses (Fig 1b). Here, we take a different approach by using a visible light switching laser to crystallize sub-wavelength regions in an infrared (IR) metasurface (Fig. 1c). By varying the pulse parameters of the laser, we can control the size of the switched phase-change spot inside of each meta-atom. Thus, it will be possible to tune the amplitude and phase of the light everywhere on the metasurface and impart multiple complex functionalities onto the same metasurface.

2. Results

As proof of principle, we investigated an Al nanorod antenna array on a Si substrate covered by a thin film of the PCM Ge₅Sb₂Te₆ (GST-326) a protective capping layer of (ZnS)₈0₋(SiO₂)₂₀, similar to the sketches in Figure 1. These linear nanoantennas is used as a simple model system for
various kinds of meta-atoms. Upon phase change from the amorphous to the crystalline state, the real part of the GST-326 refractive index changes from $n_\text{a} = 3.5$ to $n_\text{c} = 6.1$ at 2000 cm$^{-1}$[1].

To demonstrate the effect of the position and size of crystalline volume inside of one meta-atom, we varied the size of elliptical crystalline spots centered on the antennas. Simulated relative reflection spectra of infinite periodic arrays with different C-spot sizes all show clear resonant behavior (Figure 2a). Depending on the size of the C-spots (color coded for the long spot axis $l$), the resonance frequencies shift from $f_{\text{res}} = 2028$ cm$^{-1}$ in the amorphous case to 1692 cm$^{-1}$ in the fully crystalline case. The larger the C-spot, the lower the resonance frequency $f_{\text{res}}$. The measured relative reflectance spectra of differently switched 6x6 antenna arrays are shown in Figure 2b. The C-spot size has been controlled by adjusting the laser power employed to switch the material. The resonance frequency decreases with increasing spot size, from $f_{\text{res}} = 2006$ cm$^{-1}$ in the fully amorphous case down to $f_{\text{res}} = 1711$ cm$^{-1}$ for the largest spots.

Figure 2: Simulated (a) and experimentally obtained reflectance spectra of identical linear nanoantennas which are differently addressed by switching a certain spot size (elliptical spot with long axis $l$) of the PCM.

3. Discussion

While the experimental spot-size dependent resonance shifting behavior qualitatively matches the predicted one, the total achieved shift at the maximum spot size is considerably smaller than simulated. Only after fully crystallizing the sample by annealing it in an oven at 180°C for 30 min, a comparable resonance shift was achieved. In order to understand this apparent difference, we have to investigate the three-dimensional nature of the optically induced crystallization and its consequences for the metasurface resonance tuning [7].

4. Conclusions

We show how we can fine-tune individual metallic infrared nanoantennas covered with the phase-change material Ge$_2$Sb$_2$Te$_5$ by locally addressing them with single visible laser pulses. Our work represents an advance towards actively programmable metasurfaces and the concept can be applied to a multitude of already present metasurface designs.

Exploiting the polarization of nanoparticles near surfaces: position sensing, recoil optical forces, and full angular spectrum engineering

Lei Wei, Jack Kingsley-Smith, Michela F. Picardi, Anatoly V. Zayats, and Francisco J. Rodríguez-Fortuño

Abstract
Small polarized nanoparticles exhibit remarkable electromagnetic properties even in the dipolar regime. The superposition of electric and magnetic dipoles on illuminated nanoparticles may result in far-field destructive interference and in near-field directionality, with applications on ultra-sensitive position sensing, optical forces due to recoil, and polarization control of the amplitude and phase of modal excitation in nearby waveguides. We describe our recent theoretical works on these applications.

1. Introduction
A small illuminated nanoparticle is polarized and scatters light. In general, this scattering can be studied via an expansion of electric and magnetic multipoles. If the particle is small compared to the wavelength, the lowest order electric and magnetic dipoles dominate the scattering fields. We conventionally describe dipolar modes as having the familiar toroidal radiation diagram; however, this description is naive as it assumes a single linear dipole component. In general, six different dipole components ($p_{0}$, $p_{r}$, $p_{0}$, $m_{0}$, $m_{r}$, $m_{0}$) may interfere coherently with each other, resulting in remarkable directionality properties of the nanoparticle. Much interest has surrounded the combination of electric and magnetic dipoles to create the so-called Huygens dipole, which exhibits far-field directionality with applications on metasurfaces. The use of circularly polarized dipoles as polarization-controlled directional sources of guided modes in nearby waveguides spurred huge interest with applications in light nanorouting, polarimetry and optical isolators. Recently, we showed that the combination of electric and magnetic dipoles can also be exploited for near-field directionality [1], [2]. Practical ways of exciting all these dipoles may be: via engineering of the particle’s polarizabilities, which enables controlling amplitude and phase of the different dipolar components, or by using structured illumination, which allows great control on the incident amplitude and phase of the electric and magnetic fields. In this work we summarize our recent research efforts in exploiting the properties of these particles for practical applications.

Figure 1: Illumination of a magnetoelectric particle with evanescent wave interference for position sensing. (a) Schematic of the proposed setup. (b) Map of interfering evanescent waves’ Poynting vector (purely imaginary), with positions C and D separated by a distance $\lambda/20$. (c-d) Far-field radiation diagrams of the particle at locations C and D, respectively (showing YZ cut-plane and full half-space radiation diagram in the inset).

2. Far-field interference for position sensing
The interference of two evanescent waves, easily achieved by dual plane wave illumination in a total internal reflection setup (Fig 1a), gives rise to a remarkable interference pattern in which the Poynting vector may become purely imaginary [3] and changes rapidly its orientation with position along
the surface (Fig 1b). An engineered particle with electric and magnetic polarizabilities 90 degrees out of phase can be placed in this interference pattern to achieve perfect destructive interference in a specific far-field direction, whose angle is extremely sensitive to variations in the particle’s position (Fig 1c), resulting in a practical method for position sensing [4].

3. Dipolar interference for optical forces

The far-field and near-field directional excitation enabled by dipole interference implies an imbalance in the net outgoing optical linear momentum, which necessarily requires the existence of recoil optical forces on the particles [5], such as that on a Huygens dipole near a surface (Fig 2).

![Figure 2: Optical forces of a Huygens dipole radiating near a plasmonic surface. (a) Electromagnetic fields of a Huygens dipole ($m_s = k_{app} c n_s$) at a distance $0.15\lambda$ over a surface of a metallic material ($\epsilon_{m}=12+3i$), exciting surface plasmons directionally due to near-field interference. (b) Resulting time-averaged lateral force $F_L$ in the x-direction (normalized to the power radiated by the dipole) calculated analytically (line) and confirmed via Maxwell Stress Tensor integration (circles).](image)

4. Engineering the full angular spectrum

Beyond simple dipoles such as circular, Huygens or Janus dipoles, we have endless possibilities. Fully exploiting the six degrees of freedom in dipolar sources enables a full control of their angular spectra, which can be applied for the directional excitation of modes with arbitrary amplitude, phases and even multimode control in nearby waveguides (Fig 3).

![Figure 3: Dipolar angular spectrum engineering for full control of the excitation of nearby waveguided modes in terms of amplitude, phase and mode excited. (Top) Schematic of the idea, the angular spectrum can be designed in relation to the dispersion relation of the waveguide. (Bottom) Numerical simulation of designed dipole exciting different modes on different directions.](image)

5. Conclusions

We have outlined several applications that arise from the deceptively simple system of a small particle near a surface or waveguide, from position sensing to optical forces. The advantage of using the dipole polarization is that these effects can be tuned via the illumination, potentially at ultrafast speeds.

Abstract
In this work we present a new strategy to actively enhance the magneto optical activity beyond its current limits by the excitation of a hybrid dark-bright modes in a magnetic-disk/metallc-ring plasmonic nanocavity.

1. Introduction
Magneto-plasmonic structures composed by arrangements of magnetic nanoantennas can be used for the active control of light polarization. Their unique optical properties arise from combining strong local enhancements of electromagnetic fields in surface plasmon excitations with the magneto-optical (MO) activity inherent to ferromagnetic materials that can be controlled by external magnetic fields.

Up to now, most studies exploiting metal magneto-plasmonic nanostructures focused on the effects of the scattered electromagnetic field due to the excitation of localized dipolar plasmonic resonances (LPRs). Indeed, dimeric and multilayered hybrid noble/ferromagnetic metals structures as well as purely ferromagnetic nanoantennas have demonstrated the possibility to control and amplify the MO properties via plasmonic excitations [1-3]. For a circular disk-like magneto-plasmonic nanoantenna, incident radiation of proper wavelength excites a LPR. When the nanoantenna is magnetic-field (H) activated, a second LPR is induced by the inherent MO activity. The MO-induced LPR (MOLPR) is driven by the LPR in a direction orthogonal to both H and the LPR. The ratio between the MOLPR and the LPR corresponds to the ratio between the response of orthogonal radiating electric dipoles that determine the magnetic-field induced polarization change of scattered light [4]. For typical metallic constituents, the electric dipole per unit volume associated to the MOLPR is about 2-orders of magnitude larger than that in a film or bulk magnetic material counterparts. This remarkable value represents the theoretical limit for the maximum achievable MO activity amplification. However, the MOLPR amplification results from a parallel enhancement of the electric dipole per unit volume associated to the LPR by typically 1-order of magnitude with respect to film or bulk counterparts. This simultaneous excitation of the LPR and MOLPR limits the maximum achievable enhancement of magnetic-field activated change in polarization to only 1-order of magnitude, as observed experimentally [1-3]. Thereby, using bright dipolar LPRs this 1-order of magnitude enhancement of MO activity represents a sort of fundamental upper limit that cannot be overcome, hindering the applications of magneto-plasmonics to active nanophotonics and flat-optics.

Here, we propose and demonstrate a strategy to overcome the aforementioned limitation based on a hybridization with high order multi-polar dark modes as a viable and powerful mean to amplify the magneto-optical activity of magneto-plasmonic nanoantennas and achieve an unprecedented active control of the light polarization under a magnetic field. Symmetry broken non-concentric magneto-plasmonic-disk/plasmonic-ring nanostructures are designed to enable the free-space light excitation of dark modes in the plasmonic-ring as well as their hybridization with the dipolar plasmonic resonance of the magneto-plasmonic disk.

2. Discussion
The magneto-optical response of a hybridized system composed by a non-concentrating Nickel (permalloy) disk inside a gold (labeled as NCRD in Fig. 1) is drastically modified by the excitation of a hybrid dark-bright mode
resulting in an extraordinary amplification of the magneto-optical activity.

Figure 1: a) Schematic and b) realistic NCRD hybrid structure. c) and e) show the experimental results and simulation of the Kerr rotation and ellipticity, respectively. d) and f) show the magneto-optical (MOA) for the bare permalloy disk (Py) and the hybrid non-concentric ring-disk (NCRD)

This far more efficient magnetic field control of the polarization of light is explained by a large enhancement of the radiant magnetic-field activated magneto-optical bright dipole in the magneto-plasmonic nanoantenna driven by the low-radiant hybrid dark-bright mode. The subradiance of the hybrid mode arises from an overall reduction of the total dipole moment due to the antisymmetric coupling of the parent plasmons. While bare magneto-plasmonic nanoantennas enhance the magneto-optical response typically by 1 order of magnitude with respect to the corresponding film counterpart, in the present case the peculiar resonant mechanism leads to an observed enhancement approaching the theoretical limit of 2 orders of magnitude.

The experimental results showed in Fig 1. were complemented with a detailed study of the surface charge density maps and the strength of optical and magneto-optical electric dipoles using the Finite Element Method (FEM) implemented in the commercial COMSOL Multiphysics software in order to explain the mechanism behind. Simulations show that the MOA features are a consequence of the subradiant character of the hybrid mode that leads to an overall reduction of the total optical dipole moment.

3. Conclusions

High-order multi-polar dark plasmon resonances in magnetoplasmic nanocavities can be used to achieve unprecedented enhancement of the magneto-activated optical response, beyond the present limitations of magnetoplasmic nanoantennas, enabling a far more efficient active control of the light polarization under weak magnetic fields. The novel concept showed in this work opens a new path towards applications of magnetoplasmics to a variety of fields ranging from active nanophotonics to sensing. This mechanism might have a huge impact on forthcoming photonic nanotechnologies based on plasmon-mediated local enhanced manipulation of electronic spin-currents opening excellent perspectives in disclosing novel opto-electronic phenomena.

Ultrafast dynamics at fs-laser-excited magnetic meta-surfaces

Alexandr Alekhin and Vasily Temnov

Institut des Molecules et Materiaux du Mans, UMR CNRS 6283, Le Mans Universite, Le Mans, France
vasily.temnov@univ-lemans.fr

Interactions of femtosecond laser pulses with magnetic materials result in a large variety of physical phenomena from different fields of physics: nonlinear optics, magnetism, ultrafast spintronics, acoustics, shock waves and/or laser-induced phase transitions. From a metrological perspective different time scales associated with those transient phenomena can be measured with femtosecond temporal resolution in conventional all-optical pump-probe experiments utilizing linear and non-linear magneto-optical techniques. However, in a typical pump-probe experiment, absorption of ultrashort femtosecond laser pulse by an opaque magnetic material may trigger very complex dynamics including coherent and incoherent excitations of electronic, phononic and magnetic subsystems. Different underlying processes evolve on several time scales, and their characteristic time constants can be close to each other rendering the identification of the underlying mechanisms extremely challenging.

One of the ways to reduce the complexity of ultrafast optical measurements is to study the experimentally accessible monochromatic excitations and their interactions. To be more specific, here we are talking about the periodic oscillations of electromagnetic fields at the (fundamental, second harmonic, third harmonic etc.) optical frequencies, elastic deformations (surface acoustic waves) at MHz-THz frequencies and time-dependent perturbations of the magnetic order (ferromagnetic resonance, magneto-static or exchange-coupled magnon modes) oscillating at GHz-THz frequencies.

Apart from a trivial case of oscillating optical fields, the temporal periodicity of fs-laser-induced magnetic and acoustic dynamics is not granted. For example, the absorption of an ultrashort optical pulse in a magnetic material results in a famous phenomenon of ultrafast demagnetization [1]. However, under specific conditions dictated by the orientation of an external magnetic field, ultrafast demagnetization can trigger ferromagnetic resonance (FMR) precession and oscillating spin-wave resonances at elevated frequencies in ferromagnetic thin films [2,3].

At the same time, fs-laser excitation of opaque materials is signified by the thermo-elastic generation of single-cycle acoustic pulses with picosecond time duration [4], which may reach giant strain amplitudes up to 1%, strong enough to induce the nonlinear lattice dynamics at the nano-scale [5] or even switch magnetization in magnetostrictive thin films [6] and ferromagnetic nanostructures [7].

Monochromatic acoustic waves can be generated by fs-laser excitation of periodic gratings, either in the so-called transient grating geometry [8-9] or using permanent gratings [10]. The characteristic feature in these experiments is the possibility to excite monochromatic surface acoustic waves (SAWs) with frequencies determined by the grating periodicity and going up to a few tens of GHz when using deeply sub-wavelength periodic structures with periods of the order of 100 nm. This sub-wavelength spatial periodicity for magneto-acoustic studies represents the link between ultrafast magneto-acoustics and (magneto-)optics of meta-surfaces. The intrinsic possibility to bring the FMR-frequency in resonance with acoustic waves, for example using a proper combination of grating periodicity and the magnitude of an external magnetic field, can result in the resonant enhancement of the FMR precession [8-10], with the onset of parametric instabilities [9]. Whereas the experimental conditions to obtain large-amplitude FMR precession through the fs-laser mediated resonant magneto-elastic interactions have not yet been optimized, such technique would provide new possibility to modulate the optical properties of magnetic meta-surfaces. Given that the static nonlinear magneto-optical and/or magneto-plasmonic effects are more pronounced than the linear ones [11-14], it makes sense to go beyond the time-resolved measurements based on linear magneto-optical effects and probe dynamics of resonant magneto-acoustic interactions [8-10] with nonlinear magneto-optical detection schemes [11-14], hoping to develop real-life applications with magnetic meta-surfaces modulated on ultrafast time scales.

Abstract

We experimentally investigate how the process of deterministic all-optical switching in GdFeCo alloys depend on the properties of the optical pulse i.e. photon energy and pulse duration. We reveal that the switching of magnetization can be achieved using photons in the mid-infrared spectral range, and there exists a composition-dependent pulse-duration threshold above (below) which the switching fails (succeeds). To explain our findings, we develop a simple but elegant phenomenological theory of longitudinal magnetization dynamics.

1. Introduction

Ultrafast reversal of magnetization can generally be achieved through modifying the magnetic properties (such as magnetic anisotropy[1]) or the magnetization length (i.e. demagnetization). Despite the fact that deterministic all-optical switching of GdFeCo was discovered more than half a decade ago[2], deep physical understanding of the process is still lacking. To date, GdFeCo is the only material known to exhibit ultrafast deterministic all-optical switching, whereby its net magnetization can be reversed upon exposure to a single femtosecond laser pulse in the absence of any bias magnetic field. Experimentally, it has been revealed[3] that the process evolves in the ferrimagnet GdFeCo via the simultaneous optically-induced demagnetization of both sublattices (gadolinium and iron-cobalt), giving rise to a transient ferromagnetic state on the picosecond timescale. Subsequently the magnetization of both sublattices reverse.

While this description has been supported by experimental measurements[2] and atomistic simulations[2], several recent findings have suggested that this description is incomplete. In particular, experiments shown in Ref. [4] have demonstrated that an ultrafast laser pulse is not a prerequisite for deterministic all-optical switching. Using a single pulse of duration 15 ps, for example, the authors in Ref. [4] were able to switch the magnetization of a particular alloy of GdFeCo. In addition, it is still an open question as to whether the photon energy represents an important constraint on the material process.

In this work, we experimentally investigate how the process of ultrafast helicity-independent all-optical switching evolves as a function of both the photon energy, the pulse duration and the chemical composition of GdFeCo. To explain our results, we expand on a simple but elegant mean-field theory. This model not only successfully reproduces our experimental findings, but provides a general formalism which should be able to predict and explain ultrafast all-optical switching in a wider array of materials.

![State map showing how the process of all-optical switching in GdFeCo evolves as function of both the photon energy and the pulse duration.](image)

Figure 1: State map showing how the process of all-optical switching in GdFeCo evolves as function of both the photon energy and the pulse duration.

2. Experimental measurements

We perform experiments using optical pulses sourced from FELIX Laboratory in the mid-infrared spectral range.
Through magneto-optically imaging the effect of exposing different Gd(FeCo)\(_{100-x}\) alloys to multiple pulses, we were able to identify that all-optical switching was largely unaffected by the photon energy (Figure 1). Moreover, we identified the existence of a composition-dependent pulse-duration threshold. For example, a pulse of duration 6 ps is capable of switching the magnetization in Gd(FeCo)\(_{8}\), but incapable of doing the same in Gd(FeCo)\(_{7}\). In the latter case, only demagnetization is observed.

3. Modelling deterministic all-optical switching

To explain our experimental results, we improve upon the phenomenological mean-field approach presented in Ref. [5]. Specifically, we solve the coupled equations of motion

\[
\frac{dS_{\text{Gd}}}{dt} = \tilde{\lambda}_{G}(H_{\text{Gd}} - H_{F}) + \tilde{\lambda}_{\text{in}}H_{\text{in}},
\]

\[
\frac{dS_{\text{Fe}}}{dt} = -\tilde{\lambda}_{G}(H_{\text{Gd}} - H_{F}) + \tilde{\lambda}_{F}H_{F},
\]

Where \(S_{\text{Gd}}\) and \(S_{\text{Fe}}\) are the temperature-dependent angular momenta of the gadolinium and iron sublattices respectively, and damping terms of different origin are represented by \(\tilde{\lambda}\). The effective fields acting on the indicated gadolinium and iron site are given by a combination of the time-dependent heating and the composition-dependent inter- and intra-sublattice exchange interactions. The thermal load delivered by the optical pulse is essentially captured by a simple form of the two-temperature model, given by a rise time of \(\tau\) and a subsequent exponential decay.

Using our mean-field approach, we successfully demonstrate that as one increases \(x\), the pulse duration \(\tau\) capable of achieving single-shot switching of magnetization increases monotonically. When using an ultrashort pulse, both sublattices demagnetize at substantially different rates, giving rise to switching via the formation of a transient ferromagnetic state. If the pulse instead has a duration on the order of picoseconds, the sublattices demagnetize at similar rates, predominantly exchanging angular momentum between each other. If the duration is too long however, we identify a peculiar evolutionary trajectory whereby the gadolinium sublattice actually becomes first to demagnetize fully[6]. This gives rise to a transient ferromagnetic state, with the magnetization Gd becoming parallel to the still-demagnetizing Fe sublattice. In this form, switching is forbidden. Using these trends, we are able to fully explain our experimental findings.

4. Conclusions

In summary, we have demonstrated that the photon energy plays no significant role in the process of deterministic all-optical switching of magnetization in GdFeCo. Rather, the key criterion lies in the pulse duration, whereby there exists an alloy-dependent threshold below/above which the ultrafast toggling succeeds/fails. We have expanded upon a phenomenological mean-field theory to successfully predict and explain this compositional dependence. Our results and explanatory model not only resolve fundamental questions concerning the origin and mechanism of all-optical toggle-switching, but could also potentially be used to predict and explain all-optical toggle-switching effects in a broader class of ferrimagnetic alloys.

Abstract
This talk will overview a new direction of research based on self-assembly of plasmonic nanoparticles at electrochemical liquid-liquid or solid-liquid interfaces. Optical properties of such systems can be varied in real time via voltage-control over the structure and density of the nanoparticle assemblies. Potential applications involve switchable mirror-windows, tunable color mirrors, optical cavities, and pixels.

1. Introduction
Progress in photonic metamaterials was made possible by advances in nanotechnology. Many of such materials, however, can only perform a single target function. Not surprisingly, already Meta-2014 was opened with a provocative statement: “The time of metamaterials is over… It is the time of tuneable metamaterials” (N. Zheludev). Realization of such platforms would allow properties of such functional metamaterials to be tuned in real-time, with major implications for absorbers in solar cells, antennae, super-lenses, cloaking, sensors – amongst others. Tunability can be reached by utilization of fine electrodynamic effects, controlling light by light, etc, but also via changing the structure of metamaterials in real time. To make the latter kind of tuning and switching fast, is a challenge, but not an unsolvable one. Our team pursued this direction of research, and its current status is summarised below.

2. Chemical tuning of nanoplasmonic meta-arrays
We responded to this challenge first with developing the ‘nanotechnology-free’ concept of chemically tunable self-assembly of plasmonic nanoparticles (NPs), such as quasi-2D arrays NPs at a liquid|liquid (LLI) and solid|liquid (SLI) interfaces [1,2]. We have demonstrated that such arrays could be used for ultrasensitive SERS detection of trace analytes – e.g. proxies for pollutants, illegal substances, terror agents – that get into ‘hot spots’ between NP’s [3].

The array structure was controlled by tuning the composition of the solutions (electrolyte concentration or pH). Indeed, NPs are functionalized by ligands that dissociate, in the aqueous phase, leaving negative charges at their terminal groups. This is necessary to prevent NPs to agglomerate in the bulk of the solution, otherwise driven by Vand-der-Walls attraction. pH and electrolyte concentration control the repulsion between NPs. More basic pH will increase dissociation of ligands and thereby increase the charge. Increase of electrolyte concentration will decrease the Debye length and will weaken the repulsion. Starting with arbitrary conditions that do not allow NPs’ agglomeration in the bulk, we cannot expect them to come too close to each other at the surface. Still, they come much closer to each other there, than in the bulk: because of the strong driving force for them to be at the interface, they have to tolerate the proximity of each other. For instance, at an oil|water interface each individual NP strongly adsorbs, to block the energetically unfavorable contact between water and oil; the effect called ‘capillary attraction’. One can obtain denser quasi-2D monolayers of NPs by minimizing their charges down to and maximizing the electrolyte concentration up to the values that yet do not allow their agglomeration in the bulk. We have been able to establish the conditions of this fine balance.

We performed a complex study of the structure and optical properties of such NP arrays at DCE|water interface. Within the same setup, we performed a combination of grazing incidence, small angle X-ray scattering and in situ optical reflectivity. From the X-ray and optical data, we could determine (from a combination of experimental [4] and original theoretical [5] results) the average distance between NPs, the long-range order, and reflectivity – all as a function of concentration electrolytes, either of inorganic electrolyte in water, or organic electrolyte in oil. Incorporating the obtained values of array’s ‘lattice constants’ into the theory of optical reflectance from such arrays [5], we could calculate the reflectance spectra for each electrolyte concentration and compare them with those measured in the same system [4]. The excellent match between the theory and experiments demonstrated that the physics worked exactly as expected! These studies gave us confidence that we could control these novel nanoplasmonic platforms by smart ‘physical chemistry, i.e. generate tunable self-assembled metamaterials. But it was not a real-time reversible control.
3. Voltage-controlled tuning of meta-arrays and switching dynamics in electrochemical cells

A sketch of a self-assembled voltage-controlled of negatively charged Au NPs at electrified interface of two immiscible electrolytic solutions (ITIES), in reflecting mode (left) and transmitting mode (right). Switching on- and off- reflection or modification of the reflection spectra can be achieved by controlling the density of charged nanoparticle arrays adsorbed at the interface through the variation of applied voltage.

It was clear to us, that electrochemistry will be the game changer here. At electrochemical interfaces, with tiny voltage variation, one can create localised electric fields that may dramatically change the structures of adsorbed NP arrays and their optical properties. We demonstrated this by creating the first electrically switchable mirror based on voltage controlled self-assembly of functionalized gold NPs at the interface of two immiscible electrolytic solutions [see video at https://youtu.be/6t8J0yLvrvJE] [6]. We have shown that it is possible to transition between a mirror and window and back again using a mere 0.5 V - voltage variation through its effect on the density of the NP arrays and their resulting optical response.

The reflectivity spectrum, the maximum of which is centered near the frequency of coupled localized plasmon resonances in NPs, gradually shifts to the blue and its intensity gradually vanishes with reduction of the density of the NP array, making the interface transparent. This process is controlled by the voltage drop across the interface: polarizing water positively, we invite negatively charged NPs to leave the potential wells at the interface and move to the aqueous bulk; polarizing water negatively we stimulate adsorption of NPs.

A switch of a different kind, based on voltage-controlled adsorption/desorption of NPs on a metal substrate, described earlier in detail theoretically [7], was reported in Ref. [8]. The difference of this system from the LLI case is as follows. Metallic electrode (in our study – silver, covered by thin protective film of titanium nitride) reflects light itself, but when covered by a dense array of plasmonic NPs (Au, in our case), an effect of resonance quenching of reflection by increased absorption of light in the NP-array/metallic substrate system turns on. These causes a dip in reflectivity spectrum, centered near the frequency of localized plasmons in NP. The latter shifts to the red, with denser population of the surface by NPs. All-in-all, some range of frequencies are get reflected less, and the mirror becomes colored. The density of NP arrays is again controlled by voltage: positively polarized electrode will cause stronger adsorption (‘electrosorption’) of negatively charged NPs, decreasing the average inter-NP distance. Through affecting this distance, voltage controls the color of the mirror.

Both for LLI and SLI, studying the evolution of the spectra with time, we learn about the kinetics of voltage-controlled adsorption/desorption of NP, by fitting the spectra to the theory that relates the latter with the density of NP arrays at the interface. Generally, reproduction by the theory [5,7] of the experimental data both for the LLI and SLI systems [6,8] is amazing; the theory itself, systematically tested against COMSOL simulations, shows excellent correspondence with the latter.

A set of other interesting scenarios have been also considered (see e.g. [9,10]). Several other papers are submitted for publication, whereas the disclosure of some other results awaits patenting.

Abstract

Next-generation flat optics require dynamic control over optical functionalities. We demonstrate actively-tunable and atomically-thin optical lenses by carving them directly out of monolayer WS₂. Using ion-liquid gating to dynamically manipulate the material’s exciton resonance we show actively modulation of the focal intensity.

1. Introduction

Since the development of diffractive optical elements in the 1970s research has focused on replacing bulky optical elements such as lenses and grating by thin counterparts. Over the last decade, nanophotonic metasurfaces rapidly advanced the development of flat optical elements based on the realization that resonant optical antenna elements enable local phase control. Present applications of metasurface flat optical elements include lenses, polarization control, and beam steering. Next-generation applications of flat optics require dynamic control over optical functionalities, e.g. the focal position or efficiency of optical elements. However, most nanophotonic structures are static after design and fabrication. Current approaches for dynamic control like electrical gating exhibit limited tunability due to the finite few-nm extend of the depletion and accumulation layers as result of Coulombic screening.

2. Results

Here, we demonstrate actively-tunable and atomically-thin optical lenses by carving them directly out of monolayer transition-metal dichalcogenides (TMDCs) like WS₂ with a strong excitonic resonance in the visible spectral range. This turns the 2D material into the antenna or metamaterial and incorporation of active materials into larger antenna structures will no longer be needed. Due to their sub-nm thickness, these materials are highly tunable through external control. We demonstrate dynamic electrical tuning of the focusing efficiency through manipulation of the excitonic material resonance properties as opposed to tuning of antenna resonances.

Large-area monolayer WS₂ on sapphire is obtained commercially and covered by a monolayer of graphene (Gr) through large-area manual wet-transfer. The graphene functions as a transparent conducting electrode to provide homogeneous gating of the WS₂. Next, Au electrodes and reference pads are fabricated using optical lithography, metal deposition and lift-off. The Gr/WS₂ bi-layer is then patterned into Fresnel zone plates through e-beam lithography and reactive-ion etching. The lens has a 1 mm diameter with a focal length $f = 2$ mm. Finally, an electro-chemical cell is fabricated on top of the sample and filled with ionic liquid (DEME-TFSI) to facilitate gating of the WS₂.

Using confocal microscopy, we characterize the focus that is formed above the surface in transmission (illuminated through substrate), and demonstrate active modulation of the focal intensity.

3. Summary

We demonstrate actively-tunable and atomically-thin optical lenses by carving them directly out of monolayer WS₂. Using confocal microscopy we characterize the focusing efficiency spectrum and identify the role of excitonic light scattering in the efficiency spectrum. Next, we employ ion-liquid gating to actively manipulate the excitonic materials resonance and use this to demonstrate active intensity modulation in the focus of the lens.
Beyond plasmonic functional materials: the challenge of magneto-plasmonics towards single molecule detection

Abstract
The research activity developed by our group in the ambit of magneto plasmonic metal nanostructures and their functional characterization as chemical sensors with improved performances is here reviewed. Novel insights towards plasmon-molecule interactions studies are opened up.

1. Introduction
The resonant coupling of electromagnetic waves to collective oscillations of free electrons in metals, known as surface plasmon resonances (SPRs), has been exploited largely because of the possible control of light properties at the nanometer scale. Whether they are excited as guided modes propagating along flat planar or grating metal/dielectric interfaces (under the phase-matching with light) or as localized modes in metallic nanostructures with dimensions comparable to or smaller than the exciting light wavelength, high level of light confinement and of electromagnetic (EM) field enhancement can be achieved. New routes for integrated nanophotonics and miniaturized optoelectronic devices can be thus opened up [1].

Magneto-optical (MO) effects are also of prime interest to photonic control, as they allow fast modulation of light polarization and intensity via external magnetic fields [2]. They can be greatly affected by the huge EM enhancement occurring upon Surface Plasmon (SP) modes excitations in metal nanomaterials. Magnetic field induced modifications of the optical properties of materials were first observed by M. Faraday (1845) and J. Kerr (1877).

In the last decades, the possibility offered by the variety of nanofabrication tools, has started a race to develop even better nanomaterials where magnetic and plasmonic properties are intertwined, allowing for example plasmonic properties to become tunable upon the application of a magnetic field or the MO effects to be largely increased by plasmon resonance excitation [3]. Nanomaterials with large MO activity, low losses, and compatible with the fabrication processes are demanding in order to tailor optical and MO responses for improving the performance of components and devices such as isolators, modulators, or sensors.

The activity developed by our research group in this Active Plasmonics field is here reviewed and discussed. Our interest is the study on the effects that plasmon excitation (either localized or propagating) have on the MO activity of different kinds of nanostructures supported on glass substrates as a consequence of the EM field enhancement in the MO active component of the investigated structure. The final aim is the realization of novel transducers able to achieve higher sensing performances towards refractive index changes at the metal-dielectric interface with respect to traditional plasmonic passive transducing platforms.

2. Plasmonic and Magneto-Plasmonic Nanomaterials
First steps have been moved with metal multilayers supporting Propagating Surface Plasmon modes. Sustained by numerical simulation tools, a proper combination of noble metal and ferromagnetic thin films with suitable thickness has been proposed. When SPR conditions are satisfied, an enhancement of the MO activity due to the combined action of the intense decrease of the reflectivity of the system and the enhanced electromagnetic field inside the MO active layer can be observed. This amplification was highly dependent on the plasmon excitation, thus on the particular choice of the metals and on their optical properties as well as on the refractive index of the dielectric (in gas or liquid phase) in contact with them. These investigated multilayer structures can act as proper transducer components in a new SPR configuration, the so called magneto-optic surface plasmon resonance (MO-SPR) probe. MO activity is demonstrated by using metal heterostructures in Transversal MO Kerr geometry (T-MOKE) upon SPR excitation achieved by traditional prism coupling. These studies demonstrated in a fascinating way the possibility of modulating the optical response by means of an external agent, namely a magnetic field, and the exploitation of this phenomenon as a new probe for the development of innovative magneto-plasmonic sensing devices[4].
A great part of our recent research activity has been focused also on the realization and optical characterization of metal nanostructures on planar substrates. Metallic nanostructures supporting Localized Surface Plasmon Resonances (LSPR) are characterized by their unique ability to control and manipulate light at the nanoscale. Moreover, they have demonstrated to exhibit MO activity in the presence of modulated magnetic field of relatively low intensity in transversal configuration (T-MOKE). In these kinds of nanostructures where strong nanoantenna effects take place, the influence of the MO part become peculiar. Metal nanostructures of different diameters and thickness have been realized by proper combination of template-mediated nanofabrication tool and thermal evaporation techniques. Interparticles distanced in a long and short-range order have been taken into account as well. SPR excitations with spectral position tuned in the VIS-NIR range are thus obtained depending on the nanodisks size and distribution. Correlation between Kerr effects and the metal nanostructure polarizabilities allows a better understanding of MO response, thus tailoring the nanomaterials geometry to the functional needs [5].

Validation of experimental findings was achieved by numerical simulations based on Finite Element Method (FEM) techniques. The developed numerical models allowed studying the combination of the T-MOKE effect with the LSPR resonance of metal nanoparticles. Numerical optical and magneto-optical spectra provided a deep insight on the physical aspects behind the MO activity of metal nanostructures strictly related to the direction of oscillations electrical dipoles generated in resonance conditions.

3. Functional characterization in gas or liquid ambient

The ability of SP modes to sense even small refractive index changes occurring at the metal-dielectric interface where they are excited is well known. These properties make plasmonic platforms suitable for low-cost diagnostic devices, owing to their integration into microfluidic systems and sensitivity to changes of dielectric properties at the interface.

In spite of the extensive research efforts on SPR biosensing, detection of small analytes at very low concentrations remains still challenging. One of the strategies that can be used to amplify the SPR signal is using MO structures as active transducer elements. Through modulation of the intensity of reflected light, light localization associated with SPRs can be used for resonant enhancement of TMOKE. The enhanced EM field along the plasmonic surface is distributed inside the MO layer, thus increasing the MO activity. In contrast to the broad SPRs, TMOKE exhibits very sharp resonances, which are highly sensitive to the surrounding dielectric properties. This feature of TMOKE allows an increase of the device’s resolution thus lowering the detection limits by up to 3 orders of magnitude. As a proof of concept, different sensing schemes have been tested by our research group. A proper choice of sensing layers deposited as thin film by physical and chemical methods on to the MO transducing platform allows the detection of chemical compounds in gas or liquid phase. Both organic and inorganic sensing layers have been investigated for application in food and environmental control. Research activity in this field is going with the aim of exploring also the effects of plasmon and molecular energy coupling with respect to the optical and MO behavior as well as on their functional aspects. A proper choice of organic sensing layers whose molecular resonances can be tuned across the plasmonic resonance energies allows for a deep investigation into the critical research field of plasmon-molecule interactions. This would introduce magneto-optics to the so-called field of molecular plasmonics.

Figure 1: Schematic representation of the investigated plasmonic and magneto-plasmonic heterostructures and related optical and MO signals exploited as refractive index transducing probes.

Abstract

In this work, the magneto-optical activity of noble metal nanostructures in Kretschmann configuration has been investigated. The possible effect of an increasing order in their spatial distribution has been theoretically and experimentally investigated, by considering purely disordered, short-range and long-range ordered gold nanostructures. A sizable MO activity can be recognized by using an external magnetic field of low intensity. Modelling tools are used to predict and realize a proper design of the investigated materials tailored on the nanoscale.

1. Introduction

Plasmonic nanostructures provide new ways of manipulating the flow of light, with nanostructures and nanoparticles exhibiting optical properties never before seen in the macro-world. Therefore, researchers are constantly pushed towards the design and fabrication of innovative plasmonic systems characterized by novel functionalities and better performances. Recently, considerable activities have been performed for the development of new kinds of small, fast, and reliable plasmonic sensors, looking for the improvement of traditional Surface Plasmon Resonance (SPR) and Localized Surface Plasmon Resonance (LSPR) sensor performances. Various approaches have been proposed to enhance the sensitivity of traditional SPR based sensors. These include, for example, phase-sensitive detection schemes, use of highly ordered metallic nanostructures or hole arrays in metal films and several active modulation techniques that can be used to improve the signal to noise ratio (SNR) and enhance the limit of detection [1–3]. The design and implementation of configurations where an external agent, such as temperature4,5, electric6,7 or magnetic fields8, can control surface plasmons is actually known as Active Plasmonics9, and constitutes the basis for the development of innovative optoelectronic components. Among different routes that have been proposed so far, the use of a magnetic field seems a very promising one. Taking advantage of the Magneto-Optical (MO) effect, the magnetic field provides an interesting way to actively control the resonant behavior of these structures, opening new perspectives in device applications. In order to ensure a sufficient plasmonic modulation inside metals nanoparticles, a promising approach is the incorporation of a ferromagnetic component into the plasmonic systems, thus forming innovative magneto-plasmonic (MP) nanostructures. However, as recently demonstrated [4], the MO effect might also be detected in Au nanostructures. The MO activity of bulk gold originates from the activation of the Lorentz force: light drives electrons to oscillate at the optical frequency, the presence of external magnetic field results in a rotation of the light polarization or in the intensity of the reflected light, depending on the relative position of the magnetic field with respect to the oscillating dipoles. This effect is normally smaller than that of ferromagnetic substitutes. However, when the LSPR conditions are satisfied, it is possible to observe an enhancement of the MO activity, which can be exploited as a new probe for the development of innovative magneto-plasmonic sensing devices [5,6]. Reflectance experiments in polar configuration can be found in literature as well as magnetic circular dichroism examples [7,8]. In this work, Au nanostructures characterized by different planar distribution on glass substrates are investigated in a Transverse MO configuration by prism coupling; a sizable MO activity can be recognized by using an external magnetic field of low intensity. The possible effect of an increasing order in their spatial distribution has been theoretically and experimentally investigated, by considering purely disordered, short-range and long-range ordered noble metal nanostructures. Modelling tools are used to predict and realize a proper design of the investigated materials tailored on the nanoscale. Optical and morphological properties will be correlated with functional properties of the realized Au nanostructures deposited on glass substrates showing that the recorded MO signal can be used as a novel transducer probe for refractive index sensing.

2. From disordered to periodic plasmonic nanostructures

In this work, three different fabrication technique have been implemented to fabricate planar distributions of metal nanoparticles (NPs), characterized by an increasing order in their spatial distribution. Thermal de-wetting, Colloidal Lithography and Nano Sphere Lithography have been exploited to fabricate purely disordered, short-range ordered and long-range ordered Au NPs, respectively. In the case of thermal de-wetting, gold nanoparticles were prepared by a physical methodology consisting in electron beam
evaporation of a thin Au film onto corning glass substrates followed by a rapid thermal annealing treatment. This process allows the Au thin film to coarse into a dense and uniform array of metal nanoparticles characterized by disordered distribution as reported in Fig. 1a. In the case of CL, short-range ordered gold nano-disk arrays onto glass substrates were fabricated by electrostatically-driven self-assembly of negatively charged colloids onto a polydiallyldimethylammonium (PDDA) monolayer, as can be noticed in Fig. 1b. Finally, a modified NSL based technique was developed to fabricate highly ordered arrays of gold NPs distributed in hexagonal lattice onto glass substrates. These nano-structures were fabricated by a simple and reproducible approach based on the self-assembling of close-packed polystyrene particles at air/water interface. After the transfer onto a solid substrate, exploiting the interstitial geometry of the colloidal mask, periodic array of plasmonic nanostructures can be easily prepared. Also a simple but versatile approach for inducing shape modifications of metal nano-particles fabricated by NSL, while preserving their highly periodic distribution was developed. Based on the application of suitable thermal treatment, this approach enables to modify the size and morphology of nano-particles, from their original triangular geometry to more symmetric and spherical nano-structures, as reported in Fig. 1c.

3. Magneto-Optical Properties of Au NPs

The fabricated Au nanostructures have been investigated in Total internal Reflection configuration, in order to demonstrate a magneto-optical activity in TMOKE configuration, when their resonance conditions are satisfied. In order to optimize the structure of the plasmonic transducers and obtain further insight of the physical mechanism underlying these effects, numerical simulations have been performed for each kind of plasmonic transducer. Unlike traditional LSPR sensors, based on optical measurements (Reflectivity, Transmission, Absorption, ECS, etc.), the magneto-plasmonic sensors are based on the measurement of the TMOKE signal when plasmonic events are excited. As can be noticed in Fig. 1d, this magnitude is also very sensitive to changes of the refractive index of the dielectric environment allowing the development of a new kind of chemical sensor.

Abstract

By designing the electron temperature distribution in hyperbolic metamaterials, induced by control light illumination, we demonstrate the efficient control of the metamaterial’s resultant optical dynamics, creating tuneable switching state durations of 200-500 fs. This is shown to be due to the overlap between the signal light mode and the evolving electron temperature distribution.

1. Introduction

Plasmonic metamaterials are known for their effectiveness at enhancing light matter interactions. This field enhancement has led to the investigation of plasmonic nanostructures to provide dynamic control of optical signals utilizing the free-electron nonlinearity of metals. While this Kerr-type nonlinearity responds to ultrafast excitation with changes to the refractive index on fs time scales, the typical relaxation mechanisms occur over several ps. The spatial distribution of the electron temperature, induced by a control light pulse and the source of permittivity changes in the metal, is often taken to be homogeneous to simplify the description of the system. However, this simplification can leave out important features in the optical dynamics at short timescales \cite{1}.

In this work, we demonstrate tailoring of the optical dynamics of a gold nanorod metamaterial through the spatial engineering of the electron temperature distribution. From pump-probe spectroscopy measurements, we find a sub-300 fs switching state dependent upon the induced hot electron distribution in the nanostructure, which can be modified by changing the control-signal mode overlap \cite{2}. The design of electron temperature environments not only has consequences for switching rates, with the metamaterial proving to be an effective intensity and polarization modulator \cite{3, 4}, but also for efficient local control of hot carrier generation and extraction for use in photocatalytic processes \cite{5}.

2. Results

2.1. Sub-picosecond switching state

Pump-probe spectroscopy measurements were carried out on a nanorod metamaterial sample. The self-assembled nanorod metamaterial consists of an array of periodic gold rods oriented perpendicular to a glass substrate and embedded in an alumina matrix. The geometric parameters of the metamaterial are tuned to produce a resonance for TM polarized light at around 700 nm. On illumination with a control light pulse, this resonance red shifts due to induced electron temperature heating, which is probed by a signal light pulse delayed in time (fig. 1a).

If one monitors the transmitted intensity at the wavelength indicated by the grey line in fig. 1a, a ~300 fs switching state is observed as the resonance red-shifts across this wavelength (fig. 1b). The resonance then returns to its original position over 200 ps as the energy is dissipated in the system. One will note however that the point of maximum red-shift (orange dot in fig. 1) is not coincident with the maximum average electron temperature (indicated by the dashed line in fig. 1b). In fact, the maximum red shift is achieved 200 fs after the maximum average electron temperature \( T_e \) is reached. This points to the importance of considering inhomogeneous electron dynamics (i.e. electron temperature diffusion) and the overlap between...
the induced permittivity distribution and signal light mode in the nanorod.

2.2. Considering inhomogeneous electron temperature.

In the transient experiments, the absorbed control light induces an initial distribution of the electron temperature in the nanorods. This inhomogeneous distribution then diffuses across the structure, whilst energy is also coupled to phonons in the system. Therefore, at short times, the overlap between this electron temperature distribution and the spatial distribution of the signal light mode will be important for the optical dynamics. To show this, the weighted average electron temperature $\overline{WAV}(T_e)$ was calculated for electron temperature distributions set up by different control light wavelengths. $\overline{WAV}(T_e)$ is calculated as,

$$
\overline{WAV}(T_e, t = t_0) = \frac{\int |E_s(x,y,z)|^2 T_e(x,y,z,t=t_0) dV}{\int |E_s(x,y,z)|^2 dV}
$$

(1)

Where, $E_s$ is the electric field of the signal light mode. When we compare $\overline{WAV}(T_e)$ with $T_e$, which is spatially averaged across the structure, we see large differences in the initial electron temperature dynamics.

The effect of changing the control mode on dynamics was experimentally investigated by transient optical measurements multiple control wavelengths. The fastest change in optical density is seen for the distribution with the greatest overlap with the signal mode. The control light distributions with less overlap have longer switching times, providing the ability to tune switching state times with proper design of electron temperature distributions.

3. Conclusion

In conclusion this work shows the ability to tune the optical dynamics of a system by designing initial electron temperature distributions and considering their overlap with signal light modes. The dynamic spatial control of permittivity in nanostructures has implications for direct tailoring of Kerr-type nonlinearities, allowing tuneable switching states for all-optical devices. Furthermore, this approach allows for the design of local electromagnetic environment affecting both spontaneous emission rates and second harmonic generation, useful in the design of nanoscale light sources and display technology.

Abstract

The optical properties of any material are strongly related to the temperature of their surrounding environment as well as by any temperature-carrying-source, such as laser light, impinging on the material [1,2]. In this regard, it is well known that in bulky metals the reflectivity monotonically decreases upon increase of the temperature [3]. Here we will show that when the nano-patterning of a metallic substrate in form of nano-antennas is instead considered, the situation changes drastically with respect to the aforementioned bulk behavior. Indeed, upon temperature increase of the substrate, we can achieve either a reflectivity decrease (as for bulky metal) or the opposite behavior, namely a reflectivity increase. We will demonstrate that it is uniquely related to the aspect ratio of the antenna which determines a shift of the antenna absorption efficiency. The underneath mechanism is related to the possibility to increase or decrease the light-to-heat conversion rate depending on the temperature of the system. Furthermore, we shall demonstrate how the temperature sets a maximum value for the absorption efficiency and how this quantity can be geometrically tuned, thus leading to a temperature-controlled optical heat dissipation. In

This scenario can be related to the temperature-matched description of the classical antenna theory. Our results, experimentally demonstrated and numerically/analytically explained, open the route towards the design of nanostructures capable of providing temperature controlled optical heat dissipation [4].

Abstract

At terahertz (THz) frequencies, superconducting metamaterials offer a promising avenue for low loss and tunable THz functional devices. Using superconducting (SC) NbN film, we realized the THz wave modulation by biasing different voltage. The modulation speed is up to 1 MHz and is mainly limited by the slow thermal diffusion in metamaterials. To improve the performance of modulators, we further proposed a type of NbN-Au hybrid metamaterials. The THz modulator shows good prospect in cryogenic THz systems.

1. Introduction

In the last decades, terahertz (THz) technology has experienced fast growth and is promising for applications such as wireless communication, radio astronomy and biomedical imaging etc.[1]. The THz modulators with high modulation speed and modulation depth is highly demanding for various THz application. The devices that combines artificial subwavelength resonant structures tunable materials in THz band provides a good way to develop high performance THz modulators.

For THz metamaterials, superconductor is not only used to deal with the loss issue, but also is widely used for tunable THz devices because the optical properties of superconductor can be altered by applying electric bias, laser illumination or magnetic field[2][3]. In this paper, we reviewed our work on the active modulation of THz wave based on superconducting niobium nitride (NbN) metamaterials. The applied voltage on the NbN resonators leads to the switching from superconducting state and normal state, so the THz transmission can be modulated dynamically[4][5]. The thermal effects of these modulators were investigated using low temperature scanning laser microscope(LTLSM) [6]. In order to improve the switching speed, we proposed a NbN-Au hybrid structure and the spectral response was studied by simulation. This study will be beneficial for developing high performance THz modulators.

2. Results and discussions

Figure 1 displays the diagram of the superconductor THz modulators. Each unit cell, made from 200 nm-thick NbN film, includes a split ring resonator and an outer square ring resonator. The NbN wire is connected to the gold electrode on the two sides of sample for voltage bias. The sample is fabricated onto a MgO substrate. We used low temperature THz time domain spectroscopy to characterize their spectral responses. When the NbN resonators are in superconducting state, we observed electromagnetic induced transparency-like spectral response in the measured THz transmission spectra. With the increase of applied bias voltage, the superconducting carriers are broken and THz transmission amplitude at transparency window gradually decreased. The highest modulation depth is nearly 80%. When the alternating voltage signal is applied, the THz transmission can be tuned dynamically. Using continuous wave measurement system, we found the modulation depth gradually falls down with the increase of frequency and the maximum modulation speed is 1 MHz.

![Figure 1](image.png)

Figure 1 The diagram of THz superconducting NbN metamaterial-based modulator

In order to clarify the mechanism of devices, the LTSLM is used to study the Joule power distribution in cryogenic environment. The transition process from superconducting state to normal state at different voltage bias was recorded by the scanning images. We found that the state switching across the unit cell does not occur simultaneously. The hotspots first appear at the regions connecting the
neighboring unit cells and the transmission spectra experience obvious changes after the hotspots show up. Based on both experimental and theoretic study, we found that the thermal effects play an important role in THz wave modulation and the hotspots is of great help for increasing the modulation speed.

![THz Transmission Spectra](image)

Figure 2 The simulated THz transmission spectra of proposed hybrid metamaterials at a variety of temperatures. The inset shows the unit cell structure of Au-NbN hybrid metamaterials.

In order to improve the performance of THz modulators, we proposed a new design in which the NbN-Au hybrid structure is used. As shown in the inset of Figure 2, the two gold split ring resonators are connected by a NbN microbridge. The thickness of NbN film is only 5 nm so as to speed up the thermal diffusion. The THz transmission spectra of this device was simulated using electromagnetic full wave simulation software and plotted in Figure 2. Though the simulation is done with the variation of temperature, the tuning behavior of the transmission spectra under electric bias is quite similar[4]. When the temperature exceeds the superconductor critical temperature of NbN (15 K), there is a remarkable change of the microbridge resistance. As a result, the two resonant modes merge into one mode after NbN goes into normal state. The resonant mode switching brings in a modulation depth as high as 98.7% around 0.27 THz. Compared with the design in Figure 1, the film thickness is decreased from 50 nm to 5 nm. In that case, the thermal capacitance can reduce at least one order. It is expected the modulation speed can reach to 10 MHz.

Besides that, the kinetic inductance of superconducting film is prominent and temperature-dependent, especially for the 5 nm-thick film. In our work, we found the resonance frequency red-shifts obviously as temperature increases. As shown in the Figure 2, the resonance frequency at low frequency regions decreases from 0.274 THz at 4 K to 0.227 THz at 12 K, the frequency shift is more than 17%. It suggests that we can use this hybrid metamaterials to realize the active control of resonance frequency shift.

3. Conclusions

Using the unique capability of metamaterials in manipulate electromagnetic wave and superconducting NbN film, we realized dynamic THz wave modulation with a modulation speed up to 1 MHz. By scanning the thermal distribution of superconducting modulators, we found that the thermal effects are essential for the THz wave modulation. We proposed a new type of superconductor-metal hybrid metamaterials and they potentially have a higher modulation speed compared with the present superconducting modulator. These compact THz modulators will be of great benefit for THz systems working at cryogenic environment.

Abstract
We study the thermomechanical behavior of a bimaterial cantilever made of a metal-insulator and a dielectric layer clamped on one of its ends to a wall at a fixed temperature and which interacts radiatively with two further reservoirs at two different temperatures. We show that with an appropriate choice of the three temperatures the cantilever has several stable stationary solutions, between which it can evolve by means of a local thermal excitation.

1. Introduction
The physics of cantilevers (i.e. beams fixed at one end and with no support at the other one) is relevant in many branches of physics, since they represent a key element in several experimental techniques. As a matter of fact, their deflection typically allows to infer the value of other physical quantities with a remarkable sensitivity. For example, this feature has been used in one of the very first measurements of radiative heat transfer at sub-micron distances [1]. A proper knowledge of their static and dynamical properties is thus relevant and interesting for numerous applications.

We discuss here the thermo-mechanical behavior of a cantilever in the presence of a radiative heat exchange with a structured environment. Radiative heat transfer is the photon-mediated energy exchange taking place between any couple of bodies kept at different temperatures, even when separated by vacuum. While it has been known for a long time that this energy flux is limited at large distances by Stefan-Boltzmann’s law, the pioneering works of Polder, van Hove [2] and Rytov [3] showed more recently that it can overcome this limit even by several orders of magnitude when the two bodies are placed in the so-called near-field regime (i.e. at distances much closer than the thermal wavelength \( \lambda_T = \hbar c/k_B T \), of the order of \( 10 \mu m \) at ambient temperature). This heat-flux amplification can be particularly pronounced when the two interacting bodies support resonant surface modes [4].

In this work, we exploit the properties of vanadium dioxide (VO\(_2\)), a material which undergoes a first-order transition [5, 6] from a low-temperature insulating phase to a high-temperature metallic phase close to room temperature (\( T_c = 340 \) K). This peculiar optical response has allowed to highlight several effects in the domain of far- and near-field radiative heat transfer [7, 8, 9], ranging from bistability to the design of the thermal analogue of electrical components. By studying the mechanical and thermal properties of a cantilever induced by radiative heat transfer in the presence of VO\(_2\), we highlight several interesting features, including a bi- multistable behavior.

2. Physical system and theoretical approach
The system we consider is depicted in Fig. 1. A beam is attached to a wall maintained at temperature \( T_w \), whereas its right end is free. The beam is described in terms of its displacement \( u(x, t) \) from the \( x \) axis, while \( T(x, t) \) represents its temperature profile. Moreover, the beam exchanges heat radiatively with two reservoirs at temperature \( T_1 \) (top in Fig. 1) and \( T_2 \) (bottom in Fig. 1), respectively. The beam has height \( h \), length \( L \), width \( \delta \) and is made of two different materials having thicknesses \( h_1 \) and \( h_2 \), such that \( h = h_1 + h_2 \).

The radiative heat flux is described here by means of a fluctuation-electrodynamics approach, where the statistical properties of the charges fluctuating inside each body are accounted for by means of the fluctuation-dissipation theorem [4], which correctly describes the heat exchange both...
in the far and in the near field. In this framework, the heat flux per unit surface between two identical planar substrates at distance \(d\) and temperatures \(T_1\) and \(T_2\) can be written as a sum over all the frequencies \(\omega\), wavevectors \(\mathbf{k}\) and polarizations \(p\) of the electromagnetic field as

\[
\Phi = \int_0^\infty \frac{d\omega}{2\pi} \left[ \Theta(\omega, T_1) - \Theta(\omega, T_2) \right] \sum_j \int_0^\infty \frac{d^2k}{(2\pi)^2} T_p(\omega, k, d),
\]

where \(T_p(\omega, k, d)\) is the energy transmission coefficient and can be expressed in terms of the usual Fresnel coefficients as

\[
T_p(\omega, k, d) = \begin{cases} 
(1 - |r_p|^2)^2 / |D_p|^2, & k < \omega/c, \\
4 \text{Im} (r_p)^2 e^{-2i[k_d x]/|D_p|^2}, & k > \omega/c,
\end{cases}
\]

and \(D_p = 1 - r_p^2 e^{2ik_d x}\) is a Fabry-Pérot denominator.

Concerning the \(x\)- and \(t\)-dependent temperature profile of the cantilever, it is solution of the following second-order differential equation

\[
\rho C \frac{\partial T(x, t)}{\partial t} = \hbar \frac{\partial^2 T(x, t)}{\partial x^2} + \Phi(u(x, t), T(x, t)),
\]

where \(\rho\) is the beam effective density, \(C\) its effective thermal capacity, while \(\Phi \partial \phi dx\) is the energy received per unit time by the infinitesimal element of the beam located between \(x\) and \(x + dx\). Finally, the profile \(u(x, t)\) of the beam is the solution of the fourth-order Euler-Bernoulli [10] differential equation

\[
EI \frac{\partial^4 u(x, t)}{\partial x^4} = -\mu \frac{\partial^2 u(x, t)}{\partial t^2} + q(x, t),
\]

where \(EI\) is the effective flexural rigidity of the beam, \(\mu\) its effective linear mass density and \(q(x, t)\) is a load term describing the presence of a radiative heat flux, which can be expressed explicitly as a function of the temperature profile \(T(x, t)\).

3. Results

We study the coupled system of Eqs. (3) and (4) for different temperature configurations \((T_w, T_1, T_2)\). By performing this investigation both statically and dynamically, we show that the first-order transition of VO\(_2\) induces the appearance of a bistable or multistable behavior, i.e., two or more stationary solutions.

We discuss how this depends on the choice of the three external temperatures. Moreover, we prove that the injection of a controlled amount of power at the contact between the cantilever and the wall can be used to switch between the different stationary solutions. This can be exploited to produce, e.g., an oscillatory mechanical motion at the frequency of our externally-injected flux.

Our findings could be relevant for the modeling of the thermo-mechanical coupling in micro- and nano-electromechanical systems, and could be promising for piezoelectric applications.

Coupled resonances of Surface Plasmon Polaritons and Localized Surface Plasmons in Ferromagnetic Nanoparticle Arrays

Francisco Freire-Fernández¹, Mikko Kataja², and Sebastiaan van Dijken¹

Abstract

Surface lattice resonances are coupled resonances in periodic arrays of noble metal nanoparticles that circumvent optical losses and enable surface plasmons resonances with linewidths below 5 nm. However, the excitation of such ultra-narrow modes in magneto-optical systems remains elusive. We investigate coupled resonances in a Ni nanodisk array placed on top of a continuous SiO₂/Au bilayer where the near-field of surface plasmon polaritons in Au induces an intense and spectrally narrow localized surface plasmon resonance in the Ni nanodisks.

1. Introduction

Ordered ensembles of noble metal nanostructures can support ultra-narrow surface lattice resonances (SLRs). These modes circumvent optical losses in noble metals and are able to produce resonances with linewidths below 5 nm [1,2]. The locally enhanced electric field intensities near the plasmon resonances offer interesting prospects to enhance light-matter interactions. Therefore, it is appealing to integrate plasmonic antennas with materials that have externally controllable properties, such as magneto- or electro-optically active materials. Indeed, arrays of ferromagnetic Ni nanoparticles have been shown to support similar resonant modes, despite their larger intrinsic ohmic damping [3,4]. The magnetization of the particles combined with their plasmon resonances was shown to result in enhanced magneto-optical activity at resonant frequencies. However, the ohmic damping of nickel limits the linewidth of the SLR modes to ~100 nm and accordingly reduces the intensity of the resonant modes present in the optical and magneto-optical spectra. Here, we demonstrate that narrow linewidth and intense magneto-optical resonances can be attained by placing Ni nanodisk arrays within the optical near field of surface plasmon polaritons (SPPs) that propagate along a SiO₂/Au interface.

2. Results

Ni nanodisks with a diameter of 190 nm and a thickness of 40 nm were patterned on top of 5 – 60 nm SiO₂/150 nm Au bilayers by e-beam lithography. The nanodisks were ordered into square arrays with periodicities ranging from 350 nm to 500 nm. The geometry of the system is depicted in Figure 1(a). For comparison, identical Ni nanoparticle arrays without the SiO₂/Au bilayer were fabricated on glass substrates. A SEM image of a nanodisk array is shown in Figure 1(b). Due to the periodic corrugation provided by the Ni nanodisks, SPPs are excited at the SiO₂/Au interface if the SPP condition for normal incidence radiation is met:

\[ \lambda = \frac{d}{m \sqrt{\varepsilon_1 \varepsilon_2}} \]

Here, \(d\) is the periodicity of the nanoparticle array, \(m\) is an integer denoting the order of the diffracted order and \(\varepsilon_1\) and \(\varepsilon_2\) are the permittivities of the Au and SiO₂ layers. Due to their proximity to the Au film, the electric field of the SPPs extends to the Ni nanodisks where it induces a spectrally narrow localized surface plasmon resonance (LSPR). This resonance manifests as an extinction maximum indicated by the downward arrow in the extinction spectrum of Figure 1 (c). This intense SPP mode at \(\lambda_1 \approx 710\) nm has a FWHM of ~30 nm. A broader and less intense resonance is measured at \(\lambda_2 > 1000\) nm. This mode can be identified as the SLR of the Ni nanodisk array.

Figure 1: (a) Schematic of the hybrid magnetoplasmonic system. (b) SEM image of a Ni nanodisk array on a SiO₂/Au bilayer. (c) Extinction of the \(d = 450\) nm Ni nanodisk array with and without the Au/(10 nm)SiO₂ underlayer. Due to the reflective underlayer, extinction for the bilayer sample was measured in reflection geometry and defined as inverse of reflection E = 1-R. The sample without the underlayer was measured in transmission where the extinction is given by E = 1-T.

The calculated wavelength for the SPP mode using equation 1 and \(d = 450\) nm is 706 nm, which is in good agreement with our experimental observation. In Figure 1(c), we compare the
extinction spectrum of the Ni nanodisk array on the SiO$_2$/Au bilayer to the extinction spectrum of the same nanodisk array on glass. In the latter, a broad SLR with a maximum centered at $\lambda = 850$ nm is measured. Figure 2(a) shows the magneto-optical Kerr spectrum of the same two samples. In the Ni nanodisk array on glass, the relatively broad SLR mode produces a Kerr angle of about 5 mrad at 870 nm. For Ni nanodisks patterned onto the SiO$_2$/Au bilayer, we measure a narrow (FWHM = 30 nm) and three times more intense magneto-optical resonance at $\lambda_1 = 710$ nm that arises from the SPP-induced LSPR resonance. In addition, we observe a second peak in the magneto-optical spectrum that is associated with the SLR mode at $\lambda_2 = 955$ nm.

3. Discussion

As previously demonstrated for noble metal nanodisk arrays [5,6], a propagating SPP mode can induce intense electric dipoles on the nanodisks over a narrow wavelength range. In our Ni nanodisks, this effect produces a strong magneto-optical Kerr effect via the spin-orbit coupling [7]. To gain further insight into the character of plasmon modes in our hybrid magnetoplasticmonic system, we performed finite-difference time-domain (FDTD) simulations of the electric field distributions at $\lambda_1$ and $\lambda_2$ using Lumerical software. The results are shown in Figures 2(b) and 2(c). The simulations clearly confirm that the narrow SPP mode at $\lambda_1$ induces much stronger LSPRs on the Ni nanodisks than the broader SLR mode at $\lambda_2$ and thus results in a much stronger resonant enhancement of the magneto-optical signal.

Figure 2 (a) Magneto-optical Kerr angle spectrum of a Ni nanodisk array with $d = 450$ nm on a glass substrate (red data) and on a 10 nm SiO$_2$/150 nm Au bilayer (violet data). (b,c) Electric field distribution (EFD) at $\lambda_1$ and $\lambda_2$ of the Ni nanodisk array on SiO$_2$/Au. The XY monitor in the simulations is located on top of the Ni nanodisks.

4. Conclusions

We have experimentally shown that propagating SPPs in combination with ferromagnetic plasmonic nanodisks produce narrow and intense resonances in optical and magneto-optical spectra. A control sample of an identical nanodisk array on glass enabled us to compare two distinct coupling mechanisms between the Ni nanodisks, i.e., far-field radiative (SLR) and near-field (SPP) coupling. The larger electric-field intensity of the SPP mode induces more intense electric dipoles in the Ni nanodisks, giving rise to a stronger magneto-optical response. Our results reveal a new configuration where plasmonics can be used to further enhance the magneto-optical activity of ferromagnetic nanostructures, which could find applications in biosensing, non-reciprocal optoelectronic devices, nonlinear optics, and localized all-optical magnetic switching [8].

Transformation optics concept and applications
Designing devices for sub-wavelength imaging using a transformation-optics approach

Mircea Giloan*, Robert Gutt and Gavril Saplacan

Company for Applied Informatics, Cluj-Napoca, Romania
*Corresponding author, E-mail: mircea_giloan@cianet.ro

Abstract
Transformation-optics inspired flat lenses are used to build up optical systems capable to transpose a sub-wavelength sized area surrounding the object focal point of the system into a magnified area surrounding the image focal point of the system. The anisotropic and inhomogeneous media constituting the lenses enable the processing of the high spatial frequencies waves without converting them in evanescent waves. Numerical simulations show the capability of the proposed devices to perform magnified discernible images of the sub-wavelength details.

Projective imaging systems based on lenses are the best option for high-speed optical microscopy. The resolution of these optical devices is limited due to the fact that sub-wavelength information from an object is carried by high spatial frequency waves which become evanescent inside of conventional optical lenses. Transformation-optics approach opened a path for designing anisotropic and inhomogeneous media, capable to manipulate not only the wave paths but also the wave vectors [1]. Recently, a general method was proposed for designing both converging and diverging flat lenses made of media derived from specific coordinate transformations [2].

The concept of the proposed optical system is schematically represented in figure 1. The $(y-z)$-plane view of two identical converging flat lenses, object lens (left) and image lens (right), embedded in the free space (green rectangles) is depicted in figure 1(a). The lenses have a thickness $(d)$ to focal distance $(\varphi)$ ratio equal to four $(\rho = 4)$. The permittivity and permeability tensors of a converging lens of thickness $d$ and focal distance $\varphi$, embedded in an isotropic and homogeneous medium having $\varepsilon = \mu = m$, is generated by the following transformation function applied to $z$ coordinate $(z' = z/h(x, y))$:

$$h(x, y) = m \left[ \delta - \gamma (\varphi^2 + x^2 + y^2)^{1/2} \right], \quad (1)$$

where $\delta = 1 + \varphi/d$ and $\gamma = 1/d$. When $m = 1$ the lens is embedded in the free space $\varepsilon = \mu = 1$. The cases when parameter $m$ is supra-unitary $(m > 1)$ or sub-unitary $(m < 1)$ can be viewed as an additional transformation of the space like a compression or dilation, respectively. The object and image lenses are depicted by red and blue rectangles and correspond to negative and positive values of $z$-coordinate, respectively. The curves of constant transformed $z$ coordinate are depicted by red and blue lines inside the area of the object and image lenses respectively.

Figure 1(b) depicts the setup of the studied optical devices. The object lens and its adjacent space are dilated by a factor of 4 $(m = 1/4$ in Eq. (1) and $\varepsilon = \mu = 1/4$ for the object area). The curves of constant transformed $z$
coordinate are depicted rarefied inside the area of the image lens in order to suggest the transformation by dilation of this lens area. Since the proposed device is confined to positive optical parameters of the constituent lenses the depicted area is limited on y-axis by the singularity point \( y_S = \varphi(\rho(\rho + 2))^{1/2} \) derived from Eq. (1). An optical ray leaving the object focal point under an angle \( \alpha \) with the \( z \)-axis will arrive into the image focal point under the same angle \( \alpha \) with the \( z \)-axis (see orange straight lines in Fig. 1(b)). The electromagnetic wave following this path, from \( F_o \) to \( F_i \), will be affected by reflection/transmission at the input \( (P_o) \) and output \( (P_i) \) interfaces of the device (see Fig. 1(b)) In order to withdraw the dependence on \( \alpha \) angle of the system transmission, an additional layer which introduce an absorption given by:

\[
\tau(\alpha) = \frac{\rho + 1}{(\rho + 2)^2} \left( 1 + \cos \alpha \right)^2 \cos \alpha,
\]

is placed between the object and image lenses (yellow vertical strip in Fig. 1(b)).

The electromagnetic behavior of the proposed optical system is investigated using numerical simulations. For simplicity, the response of the designed optical device is analyzed in a two-dimensional simulation setup which reduces the computations to the field components \( \{E_x, H_y, H_z\} \). The numerical simulations are performed using a two-dimensional finite-difference-time-domain (FDTD) algorithm. Two electric dipole sources generated by electric currents parallel to \( x \)-axis, are placed symmetrically with respect to \( z \)-axis and object focal point \( (F_o) \) at a distance equal to \( 3\lambda/4 \), where \( \lambda \) is the free space wavelength of the sources. The sources are generated coherently, i.e. in phase. Figure 2(a) shows the intensity inside a square area of side length \( 8\lambda \) surrounding the object focal point. The dipole sources are clearly observed as the points with the highest intensity. They are placed symmetrically with respect to \( z \)-axis and the distance between them is \( 3\lambda/4 \).

Figure 2(b) shows the intensity inside a square area of side length \( 8\lambda \) surrounding the image focal point \( (F_i) \). The image of the dipole sources are clearly observed as two areas of high intensity placed symmetrically with respect to \( z \)-axis. The increased distance between the image spots compared with the distance between the dipole sources shows the magnification ability of the proposed optical device for sub-wavelength features. Two additional spots of significantly high intensity can be observed along the \( z \)-axis without disturbing the image of the dipole sources [3].

Abstract

Here, we demonstrate that by extending the common two-dimensional (2D) transformation optics (TO) to the third dimension in an engineered fashion, it is possible to eliminate unwanted reflections from the device boundaries in cases where the compression or expansion of the space makes the ideal transmission of the power impossible in the common formulation. The feasibility of the proposed idea is demonstrated by an example simulated in COMSOL.

1. Introduction

Ever since the two pioneering papers by Pendry and Leonhardt got published in 2006 putting forward the idea of TO, researchers have adopted the method to propose various new devices [1, 2]. What makes TO interesting is the freedom to create marvelous practical devices just by proposing a mapping between two spaces. The most well-known device is the cloak of invisibility where an incoming wave is guided around a concealment area by a cylindrical or spherical metamaterial shell. The idea of cloak was soon followed by several new devices like polarization splitters [3, 4], flat and bespoke lenses [5, 6] and couplers [7, 8, 9].

TO relates the electromagnetic quantities between two spaces namely virtual and physical spaces. Based on TO, the physical space \((x', y', z')\) coordinates medium is related to the virtual \((x, y, z)\) coordinates medium through the well-known TO formula:

\[
\varepsilon = \mu = \frac{JJ^T}{\det(J)}, \tag{1}
\]

where \(J = \partial (x', y', z')/\partial (x, y, z)\) is the Jacobian matrix which defines the coordinate transformation between two spaces. Equation 1 leads to two similar tensors for the permittivity and permeability tensors. It is shown by following Maxwell equations that \((E_z, H_x, H_y)\) and TM \((H_z, E_x, E_y)\) polarizations are affected by \((\mu_{xx}, \mu_{xy}, \mu_{yz}, \mu_{yy}, \varepsilon_{zz})\) and \((\varepsilon_{xx}, \varepsilon_{xy}, \varepsilon_{yx}, \varepsilon_{yy}, \mu_{zz})\) parameters, respectively. Here, we consider TE polarization and TM case can be treated similarly. The dispersion equation and the functionality of the device is maintained as long as the multiplication of \((\mu_{xx}, \mu_{xy}, \mu_{yx}, \mu_{yy})\) and \(\varepsilon_{zz}\) is not changed for TE polarization.

Since the reflection suppression is meant to be achieved, the Brewster angle \(\beta\) for an interface along \(y\)-axis between the vacuum and an anisotropic material is derived and presented as follows:

\[
\cos^2 \beta = \frac{(\mu_{xx}\varepsilon_{zz} - 1)}{(\mu_{xx}\mu_{yy} - \mu_{xy}\mu_{yx}) - 1}. \tag{2}
\]

A 2D TO is defined in the most general form as \(x' = f(x, y), y' = g(x, y), z' = z\), where \(f(x, y)\) and \(g(x, y)\) are the two functions that map the spaces to realize a desired functionality. In such definition, it is assumed that the medium and fields do not alter with respect to the \(z\) coordinate and the material defined in the \(x-y\) plane is stretched along \(z\) axis to the infinity. Following Eq. 1, it is understood that for all 2D TO designs, the in-plane tensor elements of the permeability tensor \(\mu_{x-y} = (\mu_{xx}, \mu_{xy}, \mu_{yx}, \mu_{yy})\) intrinsically satisfy \(\mu_{xx}\mu_{yy} - \mu_{xy}\mu_{yx} = 1\), meaning that the eigenvalues multiplication of \(\mu_{x-y}\) is unity. This is a crucial property for the omnidirectional reflectionless feature which has been previously observed in the case of invisibility cloaks [10]. However, many TO based devices do not require the reflectionless property to be omnidirectional since the wave interact with a certain boundary of the device from a known angle. The unity eigenvalues multiplication causes unwanted reflections for devices where a boundary in the virtual space is expanded, squeezed or flattened.

2. Extended 2D Transformation

Now, consider the extended 2D TO described as \(x' = f(x, y), y' = g(x, y), z' = h(x, y)z\) where \(h(x, y)\) is added to eliminate the boundary reflections. Using Eq. 1, the transformation will lead to a three-dimensional (3D) medium which changes along the \(z\) coordinate. However, if we take the resulting medium at \(z = 0\) plane and stretch it along \(z\)-axis, an intrusting property is achieved. Using Eq. 1, it is seen that for the resulting medium, the eigenvalues multiplication of \(\mu_{x-y}\) is no longer unity and equals \(\mu_{xx}\mu_{yy} - \mu_{xy}\mu_{yx} = h^2(x, y)\). Also, introducing \(h(x, y)\) does not change the dispersion equation.

3. Simulation Results

Here, we apply the idea to the design of a cylindrical-to-plane-wave converter used inside a horn antenna. Inspired by the original idea of Jiang et al., such device has a trans-
formation formula as follows [5]:
\[ r' = \frac{(c - a)r^2(x - a)}{x(bx - ar)} + \frac{ar}{x}, \varphi' = \varphi, z' = z, \quad (3) \]
where \( x = a \) is mapped to \( x' = a \) and the transformation is continuous, leading to an omnidirectional reflectionless property. Also, \( r = b \) is mapped to \( x' = c \). Since a circular phase front \( r = b \) in the virtual space is flattened to a planar one \( x' = c \) in the physical space, reflections are produced at this boundary.

The waves at \( x' = c \) boundary are perpendicular to it, hence if only one can satisfy the Brewster angle for normal incident at this boundary, the reflections will be suppressed. Considering Eq. 2, condition \( \mu_{xx} \mu_{yy} - \mu_{xy}^2 = h^{-2}(x, y) = \mu_{xx} \varepsilon_{zz} \) should be met at the output boundary. Hence we define a smooth function for \( h(x, y) \) to have a value of 1 at \( x = a \) and the value of \( (\mu_{xx} \varepsilon_{zz})^{-2} \) at \( r = b \).

This technique is used to flatten the phase front of a horn with flare angle of \( \pi/4 \). Simulations were carried out at 9 GHz where design parameters in Eq. 3 are \( a = 0.1m \), \( b = 0.21m \) and \( c = 0.15m \). Results for the common 2D and extended 2D TO cases are illustrated in Fig. 1. The reflections of the 2D TO are 13% and the extended TO suppressed reflections, being less than 1%.

4. Conclusions

A extended 2D transformation is proposed that suppresses the reflection from the boundary of TO-based devices. The formulation is specially useful for devices where one stretches, compresses or flattens a boundary of virtual space to achieve a certain functionality. The validity of the method is verified by an example from the literature.

Abstract
A novel generation method for OAM with different topological charges using the concept of space transformation is presented. The whole device is equally divided into 8 modules which represent the 2π phase range. Designed modules with different phase values can be judiciously arranged to generate beams carrying OAM with different modes. Three-dimensional full-wave simulations validate the spiral-shaped phase fronts of the emitted vortex wave. The proposed method illustrates the practicality of space transformation to achieve a new class of optical devices.

1. Introduction
An electromagnetic wave carrying OAM modes is referred to as a vortex electromagnetic wave, presenting a phase quantified by \( \exp (i\ell \varphi) \) \((\ell = 0, \pm 1, \pm 2, \pm 3\ldots)\) in its wave front, where \( \ell \) is the intrinsic value of orbital angular momentum and \( \varphi \) is the transverse azimuthal angle. OAM vortex waves with different topological modes are mutually orthogonal to each other. The main methods used to generate orbital angular momentum vortex beams include antenna arrays, metasurfaces, and spiral phase plates (SPPs) [1-2]. However, most of them can only generate OAM waves with single-mode. Therefore, it is necessary to put forward a technology able to generate multi-modes OAM beams.

Space transformation is well known in controlling electromagnetic fields in unprecedented ways through the use of judiciously engineered materials with parameters that vary spatially. This concept offers a technique to manipulate electromagnetic fields into desired spatial patterns, providing applications in engineering and applied sciences, such as invisibility cloaking, focusing devices, and so on [3]. In this paper, based on the concept of space transformation, we present a design methodology of an all-dielectric reflection lens, which can generate OAM waves with different modes. Eight sectors representing different phase variation are obtained, which can cover a total range of 2π.

Each sector presents the same physical size but different relative permittivity distribution. Adjusting the arrangement of each sector allows OAM waves with modes \( |l| = 1 \) and \( \pm 2 \) to be generated. The proposed all-dielectric lens is designed and simulated to validate the proposed design.

2. Design of the OAM generation device
A piece of metal parabolic with central angle of \( \theta = \pi/4 \) is shown in Fig. 1(a). When a beam is incident on the surface, the different regions of the wave-front will produce relative phase delays due to the non-planar spiral structure of the metallic parabola, thus achieving the effect of wave-front twisting.

![Figure 1: Representation of the space transformation from virtual space to physical space, the curved metal reflector is transformed into a sector of the proposed lens.](image)

Based on the concept of space transformation, a flat shaped lens which has the same function as the reflector is designed, as shown in Fig. 1(b). The physical and virtual space coordinates are respectively denoted by \( (r, \theta, z) \) and \( (r', \theta', z') \). Three-dimensional space \( ABCDEF \) represents the metallic parabola with air-filled virtual space and the desired physical space is formed by space \( A'B'C'D'E'F' \). The curved surface \( DEF \) and plane \( D'E'F' \) are perfect electric conductor boundaries. Note that the thickness of physical space is a constant \( L \). The Neumann-Dirichlet
sliding boundary condition is set at the edge of the microwave lens as follows:

\[
\begin{align*}
\hat{n} \cdot \nabla f_{r',z',r'z'} & = r', \\
\hat{n} \cdot \nabla f_{z',z} & = 0,
\end{align*}
\]

(1)

\[
\begin{align*}
\hat{n} \cdot \nabla f_{z',z} & = 0, \\
\hat{n} \cdot \nabla f_{z',z} & = M K (r')^2 - (K + M), \\
\hat{n} \cdot \nabla f_{z',z} & = 0
\end{align*}
\]

(2)

where \( \hat{n} \) is the vector normal to the boundaries of the surface. Through simulations and optimization of variable \( K \), eight sectors with different permittivity distribution are utilized. The distribution of calculated permittivity of the physical domain is presented. The permittivity of each sector shares similar distribution but different range and the phase variation between two adjacent sectors is \( \pi/4 \). With different combinations of such sectors, the transformed media corresponding to different modes of OAM waves are shown in Fig. 2.

In summary, based on the concept of space transformation, we propose a universal method to generate electromagnetic waves carrying different OAM modes respectively in an effective manner. By arranging the sectors which represent different phase variations, the OAM vortex wave with different modes can be feasibly realized. In order to validate the OAM characteristics, different configurations of the device generating vortex waves with topological charge \( l = \pm 1, \pm 2 \) were simulated at 12 GHz. The phase profiles simulated from the vortex beam generators are consistent with the theoretical distributions. Such space transformation based design method is an efficient way to tailor electromagnetic waves with any desired property.

Figure 3: Numerical simulation results for four different generation lenses of mode \( l = \pm 1, \pm 2 \) at 12 GHz.

### 3. Simulation of all-dielectric lens

Three-dimensional simulations are performed to verify the functionalities of the OAM generation lenses at 12 GHz using the finite element method based software HFSS. A regular wave port emitting spherical waves located along the central axis of the microwave device is utilized as feeding source and is placed at 50 mm (2\( \lambda \)) at 12 GHz, with \( \lambda \) being the wavelength) away from the upper surface of the transformed medium, which is backed by a circular reflecting metallic plate. From the phase profiles of the electric near-field distributions at 12 GHz (Fig. 3), it can be clearly observed that vortex waves with topological charge \( l = \pm 1, \pm 2 \) are indeed respectively generated by the different permittivity distribution configurations in the device. The helical transverse phase distribution of an electromagnetic wave carrying an OAM mode can be obviously observed from Fig. 3.

Abstract
Using the tools of transformation optics, we show how spatially modulated wire media can be treated as if they (instead) had a spatially modulated plasma frequency, in agreement with intensive 3D numerical simulation results.

1. Introduction
Wire media [1] are a type of metamaterial which can be used to directly design the electromagnetic field profile within a structure. Analysis is usually [2, 3, 4, 5] based on a straightforward multi-step procedure where numerical results from uniform wires (see fig. 1) are combined to generate modulated wire designs with the desired properties. This process turns out to be unexpectedly simple, but why it works so well is less clear. Here I take a transformation optics (TO) approach to explain the mechanisms involved.

Figure 1: Part of a wire medium formed from a rectangular array of parallel dielectric rods.

2. Mathieu’s equation
Mathieu’s equation [6] is a well established differential equation with a set of known solutions, and is

$$\partial^2_t Y + [a - 2q \cos(2\sigma)] Y = 0. \quad (1)$$

where the free parameters $q$ and $a$ control the properties of the solution. For a given $q$ there always exists a discrete spectrum of $a$ values such that the solutions $Y(\sigma)$ are periodic over 2$\pi$. In the simplest case where $q = 0$, $a$ has the set of possible values $\{0, 1, 4, 9, \ldots\}$. Mathieu solutions have a wide range of possible profiles, but for the purposes here we note only several possibilities, i.e. those that are quasi-sinusoidal, but have either flat-tops or that are strongly peaked. Our challenge here is to show how field profiles might be generated directly by a TO scheme, whether based on Mathieu functions or some other scheme.

If Mathieu’s equation above were adapted with $\omega = \sqrt{a}$ and a Fourier transform into the time domain, giving us

$$\partial^2_t Y - \partial^2_\sigma Y + 2q \cos(2\sigma) Y = 0, \quad (2)$$

which is essentially the same as a scalar wave equation for a plasma-like system, but with a scaling $\sigma = z/L$, where $L$ is the unit-cell length; and an extra oscillating potential-like term proportional to $q$. We will use this similarity below.

3. Wire Media
Wire media metamaterials consisting of a lattice of parallel wires of small radius. One of the useful features of these structures is that they support purely electric longitudinal modes which have a simple dispersion relation.
