Of course, real wire media are complex, three-dimensional, and inhomogeneous, which makes them difficult to study in detail without recourse to numerics [2, 3, 4, 5]. Consequently, here we only investigate the longitudinal modes, which have a plasma-like dispersion relation, and which exhibit spatial dispersion. Leaving aside the detailed physics, the dispersion relation for these modes is

$$\omega^2 - \beta \epsilon c^2 k^2 + (\omega_0^2 - \omega_p^2) = 0, \quad (3)$$

where $\beta \epsilon$ is an effective wave speed (polariton velocity), $\omega_0$ is the polariton resonance frequency, and $\omega_p$ is the plasma frequency parameter. We can immediately see that this is compatible with the Mathieu equation above, if we can match

$$[a - 2q \cos(2\sigma)] \propto [\omega^2 + \omega_p^2 - \omega_0^2]. \quad (4)$$

The point to note here is that one or both of $\omega_0$ or $\omega_p$ need to provide the spatial variation matching the $\cos(2\sigma)$ term.

In existing work [2, 3, 4] this variation has been shown numerically to be achievable by means of a modulation of the wire radius. This is because if a suitable set of full-wave 3D reference simulations are available, a modulation can be designed that gives the desired effective $a$ and $q$ parameters.

However the proposal for radius modulation is based largely on expected fabrication constraints, it should also be possible to achieve the necessary variations in $\omega_0^2 + \omega_p^2$ by means of a permittivity variation instead; this has been verified numerically. A familiarity with the machinery of TO then leads to the concept used in the next section, where the permittivity variation is designed by an appropriate stretching and contraction of the actual longitudinal coordinate $z'$. 
onto a reference one \( z \), where the reference situation has a uniform wire radius and uniform permittivity.

In the transformation calculation below, we need a dynamic model that matches the dispersion relation. We get this with Fourier transforms in \( \omega \) and \( k \), so that

\[
\partial_t^2 E - \partial_z^2 c_E^2 \partial_z E + \omega_E^2 E = 0, \tag{5}
\]

which, with \( c_E^2 = 1/\epsilon \mu \), can be deconstructed \[7\] into

\[
\partial_t D = \partial_t (\epsilon E) = (\partial_z + \kappa_E) H \tag{6}
\]

\[
\partial_t B = \partial_t (\mu H) = (\partial_z - \kappa_E) E. \tag{7}
\]

In this form \( \omega_D^2 \) and \( \omega_B^2 \) have been combined into a single \( \omega_E \), which appears above as the \( \kappa_E \) terms; the polaron velocity \( \beta c \) has been merged into \( \epsilon \). We will focus on the non-magnetic case, with \( \mu = \mu_0 \) in line with fabrication constraints and experimental proposals \[5\].

4. Transformation Design

The machinery of TO and other forms of transformation design is most simply – but not strictly accurately \[8\] – expressed as a coordinate transformation. In dielectric wire media, we can make a very good approximation that the net effect of that modulation in the wire radius is simply the effect on the resonance term \( \kappa_E \).

Now, in the 1+1D case (i.e. only \( t \) and \( z \)) we allow both a \( \kappa_E(z) \) and a transformation between standard space \( z \) and transformed space \( z' \) where \( z = f(z') \) such that

\[
\frac{dz'}{dz} = \left[ \frac{df(z')}{dz} \right]^{-1} = \Gamma(z'). \tag{8}
\]

After applying this transformation, we can define either speed \( c_E = 1/\epsilon \mu_0 \), or speed \( c_B = \Gamma^2/\epsilon \mu_0 = \Gamma^2 c_E \), which then gives us two versions of \( (5) \) to choose from, namely

\[
\partial_t^2 E = \Gamma^2 c_E^2 \partial_z^2 E - c_B \kappa E^2 + \Gamma^2 c_E^2 X, \tag{9}
\]

or

\[
\partial_t^2 E = \ c_B \partial_z^2 E - \frac{c_B \kappa^2}{\Gamma^2} E + \ c_B^2 X. \tag{10}
\]

Here \( X \) combines a range of \( z' \) derivative terms involving \( \Gamma, \kappa, \) and \( E \). Whilst it is not obvious that \( X \) can always be neglected, note that such approximations are relatively routine in TO, where the necessity for matched electric and magnetic responses is ignored in return for the simplicity of an dielectric-only design. In this summary, we simply assume these terms are negligible.

Examining \( (9) \), we see that if the transform \( f \) gives a \( \Gamma \), which is matched to (and cancels) the variation in \( c_E^2 \) (i.e. \( \epsilon \)), this in turn adds a compensating modulation to \( \kappa \). Thus an oscillation in \( \epsilon \) transformed by a suitable \( \Gamma \) can be converted into an effectively unvarying wire with a varying resonance parameter \( \kappa \).

Likewise, examining \( (10) \), we see that if the transform \( f \) gives a \( \Gamma \), which is matched to (and cancels) the variation in \( \kappa \), this in turn (via \( c_B^2 \)) adds a compensating modulation to \( \epsilon \). Hence although we might start with a modulated wire media with an (effective) oscillating resonance parameter \( \kappa \); we can use an appropriate transformation \( \Gamma \) to cancel that oscillation in \( \kappa \), whilst inducing an oscillation in \( \epsilon \).

5. Conclusions

The work summarized here shows how transformation design techniques explain why a spatially modulated wire medium can be treated as if it acted as a plasma-like medium with a modulated plasma frequency. This helps us understand why the numerical approach for modelling such wire media \[4\] works so well, making the design process for customized EM field profiles remarkably efficient.

In the conference presentation, more theoretical detail will be shown, along with numerical results.

Abstract

During this presentation, we will review the recent developments realized at CRHEA on the fabrication and design of 2D metasurfaces in the passive and active regime. Passive GaN metasurfaces for beam steering and orbital angular momentum holography will be discussed. We will also present tunable gate-voltage controlled light emission at hybridized MoS2/Metasurfaces. The concluding remarks will be devoted to the works on conformal metasurfaces.

1. Introduction

A new class of planar, wavelength-thick optical components exhibiting exceptional optical properties have emerged in recent years[1-3]. These artificial interfaces, known as metasurfaces, rely on the scattering properties of the subwavelength structures patterned at interfaces to mold the wavefront of light in almost any desired manner. To further develop this technology towards dynamic tuning, broadband application and industrial production, new materials and new fabrication methods are required.

2. Presentation summary

In the first part we will discuss the realization of GaN based metasurfaces for visible applications. In particular, we demonstrate basic metalens fabrication and further utilize these GaN metasurface [4] for the demonstration of an entirely new concept of metasurface OAM holography [5]. The latter are capable of reconstructing a range of distinctive OAM-dependent holographic images from a single meta-hologram.

The remarkable control over the electromagnetic fields offered by the metasurface technology can be further extended to the active regime in order to manipulate the light characteristics in real-time. In this presentation we will begin by discussing the hybridization of atomic-thin MoS2 flakes material with gap-surface-plasmon(GSP) metasurfaces[6]. By doing this, the light emission polarization of the MoS2 flake can be effectively controlled. Furthermore, applying gate voltage directly on the metasurface could is performed to control the trapping charges density at interface, leading to gate-tunable polarized photoluminescence into GSP mode.

Figure 1: (a) The schematic of the gap plasmon metasurfaces which comprises an array of Au metallic stripe and Au substrate, separated by a 100nm thick insulating SiO2 dielectric layer and a monolayer MoS2 flakes (b) The SEM image of the fabricated hybrid MoS2 gap-mode metasurface. (c) Schematic representation of the fabricated tunable devices. (d) Photoluminescence spectra of gated MoS2-gap plasmon metasurfaces for different applied voltages, indicating strong voltage tunable light emissions. This structure shows extraordinary advantages of controlling the light emitting characteristics such as polarization control, and selective enhancement of emission, benefitting from its unique resonant coupling between the excitonic resonance and the gap plasmon resonance.

In the second part of the discussion, we will address the problem of conformal metasurface design. The discontinuous variation of these electromagnetic fields across traditional planar metasurfaces can be modelled by considering specific boundary conditions called generalised sheet transition conditions (GSTCs). In this framework,
metasurfaces are described as a 2D interface with abrupt
surface susceptibilities, corresponding to complex reflection
and transmission coefficients. To go beyond planar
metasurfaces, getting into the regime of metasurfaces with
arbitrarily curved shapes, the design of free-form
metasurface optical elements turns out to be remarkably
complex and requires careful consideration of the substrate
gometry. Recently, we have proposed a new theoretical
framework called ‘conformal boundary optics’ to describe
the electromagnetic boundary conditions at the boundaries
of arbitrary geometries. Given input and output field
distributions, conformal boundary optics addresses the
inverse engineering problems of calculating the interface
response at interfaces with arbitrarily curved shapes. This
model applies the concept of transformation optics at the
level of the boundary conditions, transforming the
electromagnetic fields expressed in the laboratory
coordinate to their expression in the coordinate system
conformal to the interface. As a result, it is possible to
obtain designer reflection or refraction of light from objects
with unconventional shapes[7].

Figure 2: Top: 2D planar metasurface of subwavelength
thickness. For planar interfaces, generalized sheet boundary
conditions readily apply, and the surface susceptibility
tensors can be calculated. (b) The local coordinate system
of the surface follows its local curvature, changing with the
position along the interface. Boundary conditions of the
fields are obtained in the coordinate system of the interface
and are therefore position dependent. To produce an effect
equivalent to that in (a), the surface susceptibilities of the
optical interface have to be engineered to account for the
effect of the physical distortion. The dashed blue lines
denote the equiphase fronts of the electromagnetic fields.
Bottom: Results of numerical simulation showing the
magnetic field intensity distribution of beam deflector
designed, according to the generalized Snell laws, to refract
light to an angle of rad. In the calculations, the incident
light is a TM polarized plane wave propagating along the
direction. (a) and (b) Gray intensity distributions of planar
and sinusoidal beam deflector.

3. Conclusions

The research on metasurface holds tremendous potential to
discover some exotic new physical phenomena and could
eventually lead to some unprecedented optical components,
but there is still a long journey to implement these advanced
ccepts.
In this presentation, we report on some of our research
efforts to achieve semiconductor-based metasurfaces in the
passive (GaN based metasurfaces) and active regimes as
well as free-form metasurfaces design for interfaces of
arbitrary shapes and functionalities.

Transformation optics with “invisible” loss and gain

Yun Lai1 and Jie Luo1

1School of Physics, Nanjing University, Nanjing, China
*corresponding author, E-mail: laiyun@nju.edu.cn

Abstract

We introduce balanced loss and gain into a general class of non-Hermitian systems by using transformation optics. We demonstrate that loss and gain turn “invisible” in such systems, and provides a perfect way of energy transportation in open systems.

1. Introduction

Since the proposal of transformation optics [1, 2], this fascinating theory has led to numerous intriguing concepts and applications such as invisibility cloaks [1, 2] and illusion optics [3]. In this talk, I will discuss some interesting effects when loss and gain are introduced into transformation optics. We show that through transformation optics, loss and gain can be perfectly balanced, bestowing the non-Hermitian system with passive responses for arbitrary external waves. Therefore, loss and gain become “invisible” [5]. Energy is perfectly transported between loss and gain internally. We will also discuss the potential application and advantage of this system, such as wireless charging.

2. Main results

We demonstrate some examples of transformation optics involving balanced loss and gain. For instance, such a system can be realized by using space folding operation, which has led to intriguing effects such as cloaking at a distance [4] and illusion optics [3]. We find that when loss and gain are balanced, the response of the system is always passive despite that the system itself is inherently non-Hermitian. By designing practical metamaterials, we have demonstrated such an intriguing phenomenon. However, it should be noticed that much of the energy transportation is mediated by evanescent waves instead of propagating waves. Therefore, it also imposes a high requirement on metamaterials. We have analyzed the quality of such an effect by using different types of metamaterials and even photonics crystals [6]

3. Discussion

This non-Hermitian system designed by transformation optics is especially valuable for realizing perfect transportation of energy between loss and gain, e.g. wireless charging. Traditionally, energy transportation in open systems has a low efficiency because of radiation loss. In this open system, we show that the radiation loss tends to zero. Therefore, it provides a perfect approach for the application of wireless charging [5].

4. Conclusions

We have demonstrated that transformation optics can be applied to establish non-Hermitian systems with perfectly balanced “invisible” loss and gain, with significant potential applications for energy transportation in open systems such as wireless charging.

Numerical Design of Bio-Resonator with Filtering Effect

N. Raeis-Hosseini* and C. Papvassiliou

1Department of Electrical and Electronic Engineering, Imperial College London
*corresponding author: n.raeishosseini@imperial.ac.uk

Abstract- A bioinspired resonator based on a polysaccharide material for biodegradable nano-optics is designed and simulated. The device has a simple structure with a sandwiched spacer between two metal layers, which represents resonating effect. Due to biodegradability of the utilized material and its natural abundance it has potential to be fabricated in large area. Base on the simulation results, the proposed resonant optical device exhibits a narrow bandwidth absorber absorption and filtering effect.

Utilization of light at subwavelength with extraordinary optical properties is achieved by nanophotonic materials.[1, 2] Particularly, supranatural transmission and absorption filters based on localized/delocalized resonances have been triumphed by plasmonic metamaterials.[3] However, attainment of large area superior optical filters built on nanoplasmonics under visible wavelength is defying because of high-cost lithography techniques and deficiencies of nanofabrication.[4] We report a planar optical resonator built on a Fabry-Perot (FP) etalon with a lithography-less fabrication[5] process, which is extremely cost-effective.

Multi-layered optical devices have earned research attentions owing to their unique performance and lucrative fabrication in employing of light. The conventional planar resonators encounter deficiencies in sensing abilities due to the inconvenient impact of analytes on the physical variables of the insulator film.[5] We exploited the advantage of a natural biomaterial (NBM) as a bio-inspired material to fabricate an optical device with M-I-M structure, which is capable of being utilized in bio-sensing.

We employ NBM as insulator layer or spacer of the suggested device with biocompatibility, non-toxicity, and biodegradability. The utilized NBM offers exceptional features of the homogeneity, transparency, and hydrogel properties, which makes it a proper material for an absorber and color filter. Through reaction of the insulator thin film with humidified environment, it tunes the resonance wavelengths by swelling. The proposed NBM is sandwiched between two Ag layers, while the substrate is made of NBM (Figure 1a). The NBM, which serves as insulator layer or the spacer of the color filter reacts with the environmental liquids (water) and swells (Figure 1b, c). The resonance mode is altered due to a shift of refractive index (RI) causing an increase in the volume of the spacer.[5] The FP resonances can get tuned by liquid absorption of NBM spacer. During the experiment and measurement, the amount of swelling is governed by changing the liquid type and its pH.
In summary, we designed and simulated a super absorber and color filter based on NBMs. Our suggested super absorber shows similar properties of nanostructured plasmonic materials.

New materials for photonics (Graphene, MoS2, WS2, etc)
Synthesis and Plasmon Responses of Sodium Tungsten Bronze Nanoparticles

Levi Tegg¹, Dylan Cuskelley², and Vicki J. Keast¹

¹School of Mathematical and Physical Sciences, University of Newcastle, Callaghan 2308, NSW, Australia
²School of Engineering, University of Newcastle, Callaghan 2308, NSW, Australia

Abstract

The sodium tungsten bronzes are sub-stoichiometric metal oxides with interesting electrical and optical properties which vary with the sodium content. We have developed a synthesis technique which makes high-purity sodium tungsten bronze nanoparticles across a wide composition range. Results from electron energy-loss spectroscopy reveal that these materials support high-quality localised surface plasmons, with resonance frequencies which are tunable across visible and near-infrared frequencies by varying the sodium content.

1. Introduction

To date, Au and Ag have been the materials-of-choice for most plasmonic applications. Au has high chemical stability, but plasmon resonances are damped due to interband transitions. In contrast, Ag supports very strong plasmon resonances, but corrosion in air is a significant issue. The ideal material for plasmonics should be an inexpensive metal with high chemical stability, simple nanofabrication techniques, and low intrinsic damping losses [1].

The sodium tungsten bronzes (NaₓWO₃, 0 ≤ x ≤ 1) are sub-stoichiometric metal oxides with properties which vary with the Na content, x [2]. For x > 0.4, Na is inserted into a perovskite-like framework of corner-sharing WO₆ octahedra, forming a solid solution with a Na:W ratio of x. The inserted Na donates its 3s electron to the WO₃ conduction band. This gives NaₓWO₃ metallic optical properties, with a plasma frequency which approximately varies with ω_p ∝ 1/√x [2]. In this presentation, we show that NaₓWO₃ is a promising new plasmonic material due to its simple nanoparticle synthesis and tunable, low-loss nanoparticle plasmon responses.

2. Methods

For a detailed description of the synthesis and characterisation techniques, see reference [3]. Briefly, NaₓWO₃ nanoparticles were synthesised using a modified furnace-assisted method [4]. Sample composition was determined using X-ray diffraction and Rietveld refinement. Particle morphology was investigated using scanning electron microscopy (SEM). To map localised surface plasmon resonances (LSPRs), electron energy-loss spectroscopy (EELS) in the scanning transmission electron microscope (STEM) was performed on nanoparticles deposited on Si₃N₄ membranes. The boundary element method (BEM), as implemented in the MNPBEM toolbox [5], was used to simulate the optical properties and EELS responses of NaₓWO₃ nanoparticles. Dielectric function data for NaₓWO₃ was calculated previously using density functional theory [2].

3. Results

Figure 1 shows SEM micrographs of (a) Na₀.₆₁WO₃ and (b) Na₀.₈₃WO₃ nanoparticles. This synthesis method produces nanocubes when x > 0.5, and quasispheres mixed with rods when x ≈ 0.2 – 0.6, with particle sizes around d ≈ 150 – 300 nm. We have found that the ratio of quasispheres to rods varies with the sintering temperature [3]. Although these nanoparticles are large compared to those typically used in plasmonics, NaₓWO₃ has a lower ω_p than typical plasmonic materials, so low-order modes still dominate the near-infrared and visible optical properties.

![SEM images of NaₓWO₃ nanoparticles](image)

Figure 1: (a) SEM images of (a) Na₀.₆₁WO₃ and (b) Na₀.₈₃WO₃.

Fig. 2 (a) shows experimental EEL spectra from a prolate Na₀.₆₁WO₃ nanoparticle. The three spectra shown are taken from the corresponding coloured points in (b), a high-angle annular dark-field (HAADF) image of the nanoparticle. After subtracting the Si₃N₄ spectrum and the zero-loss peak (ZLP), three Gaussians were fit to the spectra at the frequencies indicated by the vertical lines in (a). (c–e) map the magnitude of these Gaussians at each frequency. LSPR modes similar to those of spheroids are observed [6], with a longitudinal mode at ħω₁ = 1.35 eV and a transverse mode at ħω₂ = 1.65 eV. The bulk plasmon is observed at ħω_BP = 2.06 eV, consistent with previous studies [2].
As the particle morphology varies with $x$, quantitative comparison of the plasmon responses between different samples is challenging. Since BEM simulations accurately reproduce experimental results [3], they have been used to predict how resonance frequencies change as $x$ is varied. Fig. 3 shows the calculated change in plasmon frequencies with $x$ for nanospheres (low $x$) and nanocubes (high $x$). Similar to the variation in $\omega_p \propto \sqrt{x}$, the LSPRs dramatically redshift with decreasing $x$ from visible to near-infrared frequencies.

4. Discussion and conclusions

Our straightforward synthesis technique produces bulk quantities ($\approx 2.5$ g) of plasmonic Na$_x$WO$_3$ nanoparticles using inexpensive reagents. Although work is continuing to reduce particle sizes further, we have started exploring applications in plasmonic photocatalysis and solar-control filtering. Over the course of this project ($\approx 2$ years), we have observed little change in the composition or optical properties of our nanoparticle samples, suggesting a high corrosion resistance. EELS studies, supplemented with BEM simulations, show that Na$_x$WO$_3$ supports high-quality bulk and nanoparticle plasmon resonances which blueshift from the near-infrared to the visible with increasing $x$. The variation in LSPR frequency with composition is additional to the standard tunability by particle size, shape and dielectric environment, and represents a great strength of Na$_x$WO$_3$ as a plasmonic material.

Optoelectronic Mixers Based on Graphene Photodetectors

Chuantong Cheng\(^1\), Beiju Huang\(^1,2\), Huan Zhang\(^1\), Hengjie Zhang\(^1\), Hongda Chen\(^1,2\)

\(^1\) State Key Laboratory on Integrated Optoelectronics, Institute of Semiconductors, Chinese Academy of Sciences, Beijing, China

Abstract

We demonstrated a novel optoelectronic mixer based on graphene photodetector in this work. Considering the ultrahigh carrier mobility and the CMOS compatible fabrication routing, graphene material is a potential candidate for the next generation radio frequency applications.

1. Introduction

Signal mixers are essential devices in radio frequency (RF) applications. The available mixers can only mix two electric signals and additional photodetectors are needed to convert the optical signals to electric signals. Hence, if both the photodetection and mixing functions can be achieved in a single device, a compact system can be obtained.

Graphene, the first discovered two-dimension monolayer material, is a potential candidate for future RF applications because of its ultrahigh carrier mobility and saturation velocity \[1\]. However, graphene field effect transistor (GFET) is hard to be turn off due to its zero band gap, which means it is suitable for analog circuit rather than digital application. Up to now, several promising RF devices such as voltage amplifier \[2\], frequency multiplier \[3\] and signal mixer \[4\] have been achieved with GFETs. Drain current saturation is essential for a high performance analog amplifier. However, a GFET with traditional structure just exhibits weak current saturation due to the absence of a band gap \[5\]. And some methods to obtain current saturation in GFET are at the cost of the performance or reliability degradation of the devices. On the other hand, signal mixers based on GFETs have attracted much interest because of the superior electrical properties of graphene. At the same time, graphene’s linear output characteristic makes it particularly suitable for resistive mixer applications \[6\]. Lots of discrete RF mixers and wafer scale integrated circuits (ICs) operating as RF mixers have been reported successfully \[6\]-\[8\].

Therefore, to compete with tradition IC technologies based on silicon, requires that all high performance graphene based active and passive components be monolithically integrated onto single chip. In our case, to obtain signal mixer with high performances is extremely urgent. Here, we will show a novel work about graphene RF devices of our group. An optoelectronic mixer (OEM) based on graphene photodetectors (GPDs) have been achieved in our group and will be demonstrated in details here.

2. Results

Frequency upconversion is essential in high-speed communication systems nowadays. For example, before being radiated by antennas to the end customers, the baseband signal in radio-over fiber systems is upconverted to RF signal at first. The upconversion functions is commonly performed using mixers that modulate base-band to RF carriers by multiplying the base-band signal with a local oscillator (LO) signal. In traditional mixer, the mixing is performed through two electronic signals. However, a more compact alternative is based on OEMs, where both the photodetection and mixing functions are achieved in a single device. More clearly, OEMs are devices that mix two intensity-modulated optical signals and generate two electrical signals at frequencies \(f_{\text{up}} = f_{\text{opt1}} + f_{\text{opt2}}\) (upconversion) and at \(f_{\text{down}} = |f_{\text{opt1}} - f_{\text{opt2}}|\) (down-conversion). Here we report the first graphene based OEMs which can mix two RF optical signals.

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{fig1.png}
\caption{(a) The three-dimensional schematic of the basic device structure and its operation principle are shown. Two optical signals with different frequency (\(f_1\) and \(f_2\)) are absorbed by graphene and mixing electronic signals (\(f_1 \neq f_2\)) are obtained. (b) The optical micrograph of the fabricated GPD based OEM is displayed. The white dotted frame shows the location of the graphene and the scale bar is 3 μm.}
\end{figure}

Fig. 1(a) shows the three-dimensional schematic of the basic device structure and operation principle and Fig. 1(b) displays the optical micrograph of the fabricated GPD based OEM. The width and the length of the graphene channel is 20 μm and 3 μm, respectively. Fig. 2 shows the mixing
spectrum of a 3 GHz optical signal with wavelength of 1530 nm and 80 MHz optical signal with wavelength of 1570 nm. This GPD upconverts the 80 MHz signal to 3000 ± 80 MHz. And the conversion loss is 23 dB.

![Fig. 6. The mixing spectrum of a 3 GHz optical signal with wavelength of 1530 nm and 80 MHz optical signal with wavelength of 1570 nm.](image)

3. Discussion

As the channel length in all our GPD based RF devices are defined by photolithography processes, the operation bandwidths are limited by the device sizes. In consideration of graphene’s potential ultrahigh carrier mobility and high saturation velocity, the bandwidth of graphene device is not limited by the carrier transit time, but mainly limited by the RC time constant of the device structure. With recent developments in GPDs, an intrinsic unity current gain frequencies higher than 400 GHz have been achieved [9], which makes graphene a promising material in future RF applications. Therefore, the reported novel RF devices here will see their importance in the graphene based RF optoelectronic applications in the near future.

4. Conclusions

In this paper, we have proposed a novel RF device based on GPDs. An OEM that can mix two optical signals effectively is also reported for the first time. The finished graphene based novel RF devices may have a far-reaching significance for the realization of graphene based IC for RF applications.

Abstract

By combining high-quality graphene with a narrow-gap antenna structure, we demonstrate a very fast and highly sensitive terahertz (THz) detector. The detector is based on the efficient heating of graphene carriers induced by THz absorption and photocurrent generation through the photo-thermoelectric effect, where carrier heat leads to a photoresponse at a junction between two graphene regions with different carrier density, typically a pn-junction. Crucially, the metallic antenna structure leads to strong field enhancement exactly at the location of this junction.

1. Introduction

The detection of THz light is highly interesting for applications in fields such as sensing, security and quality control. However, currently there are no room-temperature THz detectors that are simultaneously sensitive, fast, and broadband. Since a few years, graphene has been suggested as a promising material that could overcome these limitations. However, there seems to be no consensus regarding the exact physical material that leads to a THz-induced photoresponse in graphene. Here [1], we have developed a THz detector based on high-quality graphene, where we optimize the response generated by the photothermoelectric (PTE) effect, where THz-induced carrier heating [2] at a pn-junction leads to a large photoresponse.

2. Detector design

A crucial challenge for our THz detectors based on the PTE effect is the large mismatch between the geometry that maximizes the PTE response, which is a graphene channel of typical size ~1 micron, and the THz wavelength of ~100 microns. To overcome this challenge, we used a dipolar antenna with a narrow gap (~100 nm), in order to funnel the incoming THz light into a very small volume around the antenna gap. In our design, the two branches of the antenna simultaneously serve as gates that create the pn-junction in the graphene channel situated just above the antenna, separated by hexagonal BN of ~15 nm thick. This junction is created by applying appropriate (opposite) voltages to the two antenna branches. Thus, the pn-junction coincides – by design – with the area where the incoming THz radiation is focused, optimizing the PTE response of the hybrid graphene-antenna structure.

Figure 1: Schematic overview of the center part of the hybrid graphene-antenna structure, showing an H-shaped graphene channel above the antenna gap. The color scale indicates the intensity enhancement $|E/E_d|^2$ due to the antenna structure (in the plane of the graphene sheet), reaching a maximum of almost $10^3$.

3. Results

We have characterized the sensitivity of our hybrid graphene-antenna THz detectors based on the PTE effect by measuring the photoresponse as a function of the voltages on the two split gates, i.e. the two antenna branches. We observe the characteristic sixfold pattern corresponding to a PTE photoreponse [3], with the maximum photoresponse for pn and np configurations. We also measured the noise of our device, which is given by Johnson noise, since the device is passive (no applied bias voltage), thus finding a noise-equivalent power of NEP <100 pW/Hz$^{1/2}$. This is a very good number for being a room-temperature detector.

The speed of the detector was determined by modulating in time the output of a THz quantum cascade laser, and measuring the photoresponse with an oscilloscope. We find that the response is faster than 30 ns, limited by our preamplifier with a bandwidth of 5 MHz. The intrinsic response is as fast as 10 ps, considering the RC-time of the device.
Finally, we measured the photoresponse over a large range of incident THz powers, finding a linear response over three orders of magnitude, and over a range of frequencies between 2 and 4 THz. Thus the detectors have a large dynamic range and are sensitive for a broad range of THz frequencies. The spectral sensitivity is determined by the antenna response and could therefore be extended by using more broadband antenna designs with a similar narrow gap.

4. Discussion

Since our hybrid graphene-antenna THz detectors show the characteristic sixfold pattern corresponding to a PTE response [3], we have developed a simple analytical model to describe the response. As input for this model we have used numerical simulations of the graphene-antenna structure to characterize how much of the incident THz radiation is absorbed in the graphene sheet. Based on this input, we find good agreement between our experimental results and the results of the analytical model. This agreement is highly valuable for understanding and optimizing PTE-based hybrid graphene-antenna THz photodetectors in particular, and PTE-based detectors in general.

5. Conclusions

In conclusion, we have developed [1] a hybrid graphene-antenna structure for THz detection, exploiting the strong field confinement around the gap of the narrow-gap antenna. The THz detector works at room temperature, is very sensitive (NEP <100 pW/Hz^{1/2}), fast (<30 ns, setup-limited), has a large dynamic range (3 orders of magnitude) and broad spectral sensitivity (2-4 THz, antenna-limited).

Abstract.

This paper shows the obtention of thick titania sol-gel films and their technological processing to metallic films of TiO$_x$N$_y$ by ammonolysis process. The aim of this process is the realization of subwavelength TiO$_x$N$_y$ micro-structured surface for application in resonant plasmonic gratings in the Near-InfraRed range (NIR).

1. Introduction.

New metamaterials have been the subject of a lot of researches for plasmonic materials [1,2]. Among them, transition-metal nitrides, in particular titanium nitride (TiN), offer interesting properties for plasmonic applications in the Near-InfraRed (NIR) range [3,4]. Usually the TiN layer is deposited by means of expensive techniques such as PVD and CVD. Due to their intrinsic properties (hardness and chemical stability), their microstructuration such as gratings components is very difficult. Some technologies like lift-off lithography and/or physical or chemical etching process is used for this purpose [5] but their realization is time-consuming and expensive.

Another way to elaborate TiN layer is possible, using the ammonolysis process of TiO$_2$ films [6] and it allows to obtain a non-stoichiometric TiN or TiO$_x$N$_y$ material. This technique is often used in a way to implement from low to a high level of nitrogen that it can be used to improve the photocatalytic activity [7].

Now, this technique deserves a new interest, because TiO$_2$ can support a high degree of nitridation and also it can be deposited by sol-gel method offering new interests and new fields of applications.

In this paper, the authors present an original approach and an experimental demonstration of a TiO$_x$N$_y$ plasmonic grating fabrication using ammonolysis of titanium oxide from direct microstructuration of a photopatternable sol-gel layer, which acts like a negative photoresist [8]. The aim is the obtention of a TiO$_2$ grating by the direct photo-patterning of a sol-gel layer and their tranformation in a TiO$_x$N$_y$ based grating, using the ammonolysis process.

2. Experimental procedure.

2.1 Sol-gel method.

The films used in this work were elaborated from a specific photo-patternable sol-gel prepared from titanium isopropoxide orthotitanate (TIPT) complexed by benzoyl acetone (BzAc) in methanol and butanol using a previous procedure published [8–10]. After it was deposited by spin-coating on a silicon substrate, the sol-gel layer was first dried at room temperature and then heated at 110°C, leading at an inorganic polymer film constituted of Ti-O-Ti chains with organic chain-end groups arising from the sol formulation, mainly TIPT-BzAc complexed species. The main interest of this protocol relies on the properties of BzAc, which makes the film soluble in a solvent while being sensitive to UVA light. Indeed under UVA illumination, the TIPT-BzAc complex is partially degraded in insoluble species such as carbonates and/or carboxylates. Therefore, it will create a contrast of solubility between illuminated and non-illuminated areas.

2.2 Sol-gel films microstructuring.

The pattern to be printed on the samples is obtained by UV illumination through a chromium photomask of 1 μm period during 10 min under a 365 nm wavelength collimated light with an irradiance of 400 mW.cm$^{-2}$. Then a short baking step of 8 min at 110°C is performed in order to increase solubility contrast between insolated and non-insolated areas. The photo-chemical or thermo-chemical effects of this three step process have been described in [8]. The development of samples was optimized by washing in ethanol that dissolves easily the non-insolated layer, leading to a grating whose period is the same as that of the photomask, i.e. a TiO$_2$ grating of 1μm period. Finally the sample was baked at 300°C for (15 min).

2.3 Nitridation process.

The Nitridation of TiO$_2$ sol-gel was realized by ammonolysis. The films were heat under Ar gas (100 sccm) in a SiO$_2$ glass tube furnace up to 800°C, 900°C or 1000°C.
Then, the temperature was kept constant and NH\textsubscript{3} flow (100 sccm) was applied during 30 min to achieve nitridation.

3. Results and discussion.

In order to prove the ability of the fabricated TiO\textsubscript{x}N\textsubscript{y} grating to be used as a plasmonic component, measurements were performed with an experimental set-up. A collimated and linear polarized (TE or TM) polychromatic wave is incident onto the grating. This source is a halogen lamp, which emits on the desired bandwidth in the very near IR. A spectrometer measures the wavelength spectrum of the 0\textsuperscript{th} reflected order. The spectrometer is adapted to the NIR range and is able to detect the signal in the 900-2000 nm bandwidth. The angle of incidence \( \alpha \) is fixed at three values: 25°, 30° or 35°. The figure 1 shows the 0\textsuperscript{th} reflected order of the TiO\textsubscript{x}N\textsubscript{y} grating in the 1300 - 1700 nm bandwidth and for the three chosen angles of incidence. One can observe in this figure a nice SPR depicted by a minimum of the 0\textsuperscript{th} reflected signal in TM polarization which appears at 1440 nm, 1515 nm and 1590 nm for incident angles of 25°, 30° and 35°, respectively. The TE mode exhibits a constant reflection close to 60% with no particular change whatever the incidence angle.

![Figure 1: Experimental measurement in 0\textsuperscript{th} reflected order of the TiO\textsubscript{x}N\textsubscript{y} grating for incidence angles of 25°, 30° and 35° for TE or TM](image)

The structure of TiO\textsubscript{x}N\textsubscript{y} films was analysed by X-ray diffraction (XRD) and SEM images (figure 2). The results of XRD patterns indicate the presence of a single fcc crystallographic phase that may correspond to the TiN phase. Ammonolysis at 900°C leads to the crystallization of TiO\textsubscript{x}N\textsubscript{y} grains of around 30 nm in diameter. Even if so small grains cannot precisely be observed in the SEM image of Fig. 2(b) owing to resolution limitations, this image clearly depicts the granular morphology of the ammonolyzed grating. Thermo-mechanical stress occurring at the film-substrate interface during the pre-heating and post-cooling ammonolysis steps may also cause the formation of localized micro-cracks. Moreover, grain boundary and localized microcrack features are likely to induce the roughness depicted by AFM profiles after ammonolysis. These features can also reduce the conduction and optical performances of the fabricated grating, leading to losses for plasmonic applications. In other words, a same TiO\textsubscript{x}N\textsubscript{y} layer free of grain boundary and micro-crack features should exhibit better conduction and optical performances closer to that of stoichiometric TiN.

![Figure 2: a) X-ray diffraction patterns for pre-treatment at 300°C and ammonolysis at a = 800°C, b = 900°C and c = 1000°C. b) SEM image of the TiO\textsubscript{x}N\textsubscript{y} grating in cross section view.](image)

3 Conclusions.

A process for the ammonolysis of a TiO\textsubscript{2} grating involving a directly photopatternable sol-gel thin film layer has been demonstrated, with the aim to use the derived grating as a plasmonic component. The characteristics of the nitried grating led to the experimental demonstration of the plasmonic resonance at the metal-air interface in the NIR range. The grating elaborated from the TiO\textsubscript{2} nitridation does not lead to a pure TiN and induces roughness due to the ammonolysis treatment but the derived plasmonic component is easy to realize and excitation of the plasmon is directly achieved by coupling the incident wave by a quasi-sinusoidal grating. From these promising results and despite the no perfect stoichiometry of the TiO\textsubscript{x}N\textsubscript{y} layer and its roughness, the authors are currently working on further understanding of the plasmon mode excitation on such TiO\textsubscript{x}N\textsubscript{y} and further developments to reduce losses to be used in different applications such as optical sensors [11], biosensors [12] and photovoltaics [13].

Abstract

Photoluminescence (PL) control in suspended 2D transition metal dichalcogenides (TMDC) monolayers is explored as a pathway for novel optoelectronic devices. By engineering the dielectric surrounding of TMDC layers one can significantly enhance both light absorption and PL emission. Nanostructured buried microcavities facilitate the enhancement of in- and out-coupled fields in both vertical and horizontal direction. Here, we demonstrate near-field nano-imaging as a tool for characterizing the in-coupled light on a WS$_2$ monolayer suspended above a circular Bragg microcavity designed for exciton PL enhancement.

1. Introduction

Transition metal dichalcogenide monolayers are 2D semiconductors that are studied due to their extraordinarily strong light-matter interaction. Thinning down TMDCs to 2D monolayers with sub-nanometer thickness leads to an indirect-to-direct energy gap transition and allows for increased photoluminescence [2]. Out of these materials, WS$_2$ is particularly promising for nanophotonic applications due to comparatively easy exfoliation and a narrow and strong A-exciton photoluminescence peak [3] with high quantum yield [4].

Light interacting with the TMDC monolayers is subject to multiple reflection in the surrounding dielectrics and substrate. The arising interferences can be exploited to engineer enhancement and attenuation of the incident and emitted light by tuning the thickness and refractive indices of the surrounding media. It has been shown, that by taking into account multiple reflections in vertical and horizontal direction laser light in-coupling into and PL out-coupling from a TMDC monolayer flake can be optimized by structuring the substrate underneath the monolayer flake [5, 6].

Here, we examine a suspended WS$_2$ monolayer flake where the substrate underneath has been engineered and structured in vertical and horizontal direction with the aim of facilitating both in-coupling and out-coupling enhancement of light. Scattering-type near-field optical microscopy (s-SNOM) is applied as a tool to characterize the in-coupling engineering of incident light onto the WS$_2$ monolayer. We demonstrate that s-SNOM can resolve the near-field profile on a nanostructured microcavity, including the case where the cavity is covered by a suspended monolayer flake. In the scope of optimizing the PL enhancement, nano-resolved near-field mapping complements (multiple reflection) modelling to distinguish between the two effects of improved in-coupling and out-coupling enhancement.

2. Experiment and Results

We study here a hBN-buffered WS$_2$ monolayer flake on top of nanostructured GaP substrate using scattering-type near-field microscopy. The PL enhancement of the WS$_2$ flake is achieved through a buried circular Bragg microcavity which was embedded in the patterned substrate using FIB etching. The thin hBN buffer layer serves to avoid quenching effects. The trench height of 70 nm of the Bragg microcavity was optimized considering incident light at 532 nm and emitted light at the A-exciton wavelength of 615 nm using a multiple reflection model [6]. Figure 1(a) and

Figure 1: Topography and near-field measurements of monolayer-covered and open microcavity structure. (a-c) Topography and near-field maps at 532 nm and 850 nm, respectively, of covered cavity. (d-f) Topography and near-field maps at 532 nm and 850 nm, respectively, of open cavity.
Figure 2: Horizontal line-outs taken from the AFM and s-SNOM measurement. a) Dashed vertical lines mark the edges and center of the microcavity structure. While the field maxima at 850 nm coincide with the topographical maxima of the Bragg cavity, the field distribution at 532 nm shows a different behavior. One can observe clear field maxima in the center of the cavity for both measurements taken at 532 nm.

To assess the effectiveness of the cavity, we investigate the local field distribution of the pump light using s-SNOM. The s-SNOM uses a metallized AFM tip oscillating at 260 kHz. Its apex is illuminated by a laser beam at the excitation wavelength 532 nm or at the off-resonant out-of-stopband wavelength 850 nm for reference. While the tip is kept at a constant time-averaged distance of 20 nm from the surface the sample is translated for raster-scanning. Meanwhile, the probe tip acts as a nano-antenna, scattering part of the near-field wave into the far-field revealing the near-field signature. The technique is sensitive to buried spectroscopic information and has a spatial resolution of 20-50 nm. It is thus feasible to resolve the wavelength-dependent in-coupling enhancement of the monolayer-covered Bragg microcavity. Figures 1(b-c) show the near-field map of the WS$_2$-covered cavity at the excitation wavelength of 532 nm and at 850 nm for reference, respectively. Figures 1(e-f) show the same near-field maps for the open microcavity at both wavelengths. For clarity, Figure 2 shows horizontal lineouts through the center for each panel presented in Figure 1. Vertical dashed lines indicate borders and center of the cavity.

3. Discussion

In both figures the in-coupling spatial enhancement of the in-coupled green light is prominent as a central peak in the cavity at 532 nm. On the other hand, the field distribution for excitation at the off-resonant out-of-stopband wavelength 850 nm shows opposite behavior and a minimum in the center. The same observation holds for the measurements on the open microcavity. This suggests that the spatial enhancement of in-coupling can be assigned to the lateral grating structure, while the vertical resonant behavior affects primarily the out-coupling enhancement of the WS$_2$ exciton PL. One may further note that while the near-field map at 850 nm matches the topographical profile, the signal at 532 nm shows field enhancement in the gaps of the microcavity for both the uncovered and covered sample. This may be attributed to the fact that s-SNOM measures two effects simultaneously: local electric fields and differences of material properties [38]. We follow that the signal at 532 nm resolves the strong field distribution with its maxima in the gaps. The signal at 850 nm, however, incorporates a rather strong spectroscopic material-dependent contribution.

4. Conclusions

We have demonstrated near-field maps of buried microcavities for PL enhancement of WS$_2$ monolayers. s-SNOM nano-imaging serves to assess the effectiveness of previously engineered substrate patterning and to distinguish between in- and out-coupling enhancement. Depending on the structure, material-dependent measurement artifacts must be taken into account. Finally, we confirm that the PL of the WS$_2$ is additionally locally enhanced by the Bragg microcavity through an increased resonant in-coupling efficiency of the exciting light.

Abstract

In this work we demonstrate that a variety of J-aggregates can be used to make organic materials that confine light on the nanoscale. J-aggregate thin films were prepared by spin-coating a mixture of J-aggregate and a polymer matrix. A selection of J-aggregate thin films were chosen with metal-like optical properties from green to red wavelengths. The potential of these films for nanoscale light-confinement was then tested by coupling to the surface-exciton-polariton (SEP) mode of each film, using Fourier imaging spectroscopy.

1. Introduction

The field of plasmonics is primarily concerned with nanoscale light-confinement by metals. Metals are able to confine light due to their free electrons, which allow the bulk medium to become highly polarised in the presence of an electric field. However, free electrons are not the only possible origin of these optical properties. Large excitons, delocalised electron-hole pairs, can allow fundamentally different kinds of materials to reach similar values of electric permittivity, and hence such materials can confine light on the nanoscale [1]. Thin films of J-aggregate in a polymer matrix are observed to have metal-like properties in a narrow wavelength range, due to delocalised excitons in the constituent J-aggregates. Here we will demonstrate light-confinement using these organic materials based on J-aggregates, by coupling to the surface-exciton-polariton (SEP) mode of these materials.

J-aggregates are large, organic dye molecules that self-assemble in solution under specific conditions. When monomers are assembled into J-aggregates, the electronic orbitals of individual monomers are coupled together, so that the aggregates support large excitons that are delocalised across many monomer units. These delocalised ex-
citons interact strongly with light [2].

In this work we produce polymer films doped with J-aggregates. Aqueous solutions of J-aggregate and poly(vinyl alcohol) (PVA) are mixed. The resulting solution can then be spin-coated onto hydrophillic substrates to yield films around 30nm thick. These films have metal-like electric permittivity in a narrow wavelength range due to the excitation of delocalised excitons close to the J-aggregate absorption. This gives these J-aggregate and polymer films a metal-like reflectance, coloured according to the wavelength of the absorption of the J-aggregate used to make the film (Fig. 1).

3. Optical measurement: exciting surface-exciton-polaritons in organic films

The aim of this work is to show that J-aggregates can be used as the building blocks for organic materials that confine light on the nanoscale. To do this we demonstrate coupling to the SEP mode of a J-aggregate thin film. The SEP mode is analogous to the surface-plasmon-polariton (SPP) mode in metals, and can be measured in a similar way. SPPs are traditionally observed in reflectance, using a metal film deposited on a prism, with light incident on the film from the glass side [3]. This is necessary to give the incoming light a large enough wavevector to match the dispersion of the SPP. By controlling the angle of incidence, the dispersion of the incoming light and the SPP are matched, and incoming light is coupled into the SPP resulting in a dip in reflectance. This only occurs for p-polarised light above the critical angle, which matches the polarisation of the SPP and exceeds the maximum possible wavevector in air.

The same measurement protocol as described above applies to SEPs. We implemented a prism-coupling configuration using an oil-immersion objective lens with a high numerical aperture. This was used to view J-aggregate and PVA films deposited on glass coverslips, with the objective lens contacting the glass side of the sample. This configuration was used to perform Fourier imaging spectroscopy, which measures the reflected spectrum at specific angles.

In a metal below the plasma frequency, SPPs can occur at a wide range of wavelengths and hence the dip in the reflectance of p-polarised light corresponding to an SPP is broad in wavelength. Contrastingly, a J-aggregate film only has metal-like optical properties for a narrow range of wavelengths, and hence, the measured dip in reflectance corresponding to an SEP is narrow in wavelength (Fig. 2). The metal-like region in which SEPs propagate is close to the J-aggregate absorption, on the short-wavelength side: therefore different J-aggregates yield SEP dips at different wavelengths. Surrounding these SEP dips, the reflectance is close to one: at these wavelengths, the J-aggregate film is a dielectric and we observe total internal reflection. Several J-aggregate and polymer films were tested and all supported SEPs, showing that J-aggregates can be used as the building blocks of an organic platform for plasmonics.

4. Conclusions

In this work we have demonstrated the ‘plasmonic’ capabilities of a new family of organic materials. This novel organic platform can exploit the fabrication tools of supramolecular chemistry, to control and design J-aggregates which give access to light-confinement at desirable new wavelengths across the visible and near infrared; extending plasmonics beyond the fixed properties of metals by a new means.

Abstract
Plasmonics and metamaterials have been a driven force for nanotechnology applications allowing concentrate the light right down to the nanoscale. Metals such as gold or silver have been the material platforms for the plasmonic revolution. In this work we show that organic materials can be the key to confine light at nanoscale and enhance light matter interactions with a plastic. Moreover, we will show that it is possible to define colloid chemistry routes to build up organic building blocks which can establish the fundamentals towards fully plastic metamaterials.

1. Introduction
Noble metals have been traditionally used as the materials palette for building blocks at nanoscale. However, some applications require crossing the visible range and obtaining plasmon-like response at infrared or ultraviolet wavelengths. A variety of alternative materials have been explored, including doped semiconductors, graphene or transparent conducting oxides. In 2014, Nunez-Sanchez and colleagues demonstrated that densely packed molecular thin films doped by J-aggregates can exhibit inherent metal-like properties being able to confine the field in at nanoscale as metals (see Figure 1).[1] More recently, in 2016, they shown that this metal-like behavior could be used in photonic design to define new types of optical modes.[2] Now, in this work, we will go further in the application of these molecular materials as building blocks at nanoscale exploring new chemistry routes for the preparation of molecular doped nanoparticles with plasmon-like response.

2. Excitonic materials with metal-like response
Decades ago, molecular crystals shown metallic reflection associated with strong interactions between neighbouring molecular excitons.[3] In these organic materials the individual molecules are spatially distributed in the crystal lattice and can be considered as small local dipoles that can be excited collectively under specific conditions. This behaviour is responsible for the optical properties of the material for which the real part of the permittivity can achieve negative values resembling metallic behavior in a restricted wavelength range (see Figure 1). This negative values of the permittivity can be also achieved by heavily J-aggregates doped polymers, where the polar molecules are randomly spatially distributed.[1] In this work we will study how we can control this metal-like band at nanoscale as a function of the loading of molecules in our excitonic core-shell nanoparticles establishing a relation with the optical properties of the bulk.

Figure 1.- Picture of a J-aggregate thin film deposited on top of a glass and located on top of a white (left) and black (right) paper. The reflected color shows a strong metal-like band in the orange.

3. Localized Surface Exciton Resonances (LSER) in Silica-J-aggregate core-shell nanoparticles
In this work, we have synthesized and studied stable colloidal dispersions of excitonic core-shell nanoparticles. These core-shell nanoparticles are formed by a core of silica and a shell of densely packed J-aggregates (see figure 2). The role of the silica nanoparticles is being the inorganic scaffold or template for molecular J-aggregates whom will provide the plasmon-like properties to the colloids.

Figure 2.- Sketch with a graphical description of the core-shell nanoparticles with plasmon-like response synthetized by colloidal chemistry methods.

The first step was the synthesis of silica nanoparticles with
size control following the method proposed by Bogush et al.[4] In the next step, J-aggregates were deposited through electrostatics on the silica surface using the Layer-by-Layer technique. In order to stabilize the J-aggregates on the silica surface, polyelectrolytes were used after each J-aggregate layer. The deposition of the organic layer on the nanoparticle surface has been confirmed by Transmission Electron Microscopy (TEM), Zeta potential and UV-Vis spectroscopy.

![Figure 3](image_url)

**Figure 3.** Mie simulations of extinction cross sections of the excitonic core-shell nanoparticles. For low levels of molecular loading (f=0.20) a small peak associated to the absorption of the J-aggregates (TDBC) is observed on top of the silica core response. As the loading of molecules is increased (f=0.45) a second peak appears associated to the local surface exciton resonance.

The optical response of the hybrid nanoparticles was studied as a function of the number of J-aggregate layers deposited at the surface of the silica nanoparticles. For low molecular loaded samples, an absorption peak is observed on top of the silica core optical response due to the inherent absorption of J-aggregates. As the loading of J-aggregates increases a new excitonic resonance appears which can be only justified by a plasmon-like resonance (localized surface exciton resonance-LSER). These experimental results have been confirmed by numerical simulations revealing the potential use of J-aggregate materials as an excitonic alternative to plasmonics at nanoscale (see Figure 3) and corroborating their relation with the optical properties in the bulk.

### 4. Conclusions

In this work we have shown how J-aggregate doped polymers can establish a novel molecular route for plastic building blocks at nanoscale. Starting from excitonic thin films with metal-like optical response we have been build up core-shell nanoparticles by colloid chemistry methods. These Silica-J-aggregate core-shell nanoparticles shown LSER similar to localized surface plasmon resonances in metals corroborated by numerical simulations. In our knowledge this is the first experimental evidence than excitonic plastics can show plasmon-like response in nanostructures opening a new fully plastic era in metamaterials.

Abstract

We consider a hybrid structure formed by graphene and an insulating antiferromagnet, separated by a dielectric of thickness up to \( d \approx 500 \text{ nm} \). When uncoupled, both graphene and the antiferromagnetic surface host their own polariton modes coupling the electromagnetic field with plasmons in the case of graphene, and with magnons in the case of the antiferromagnet. We show that the hybrid structure can host two new types of hybrid polariton modes. First, a surface magnon-plasmon polariton whose dispersion is radically changed by the carrier density of the graphene layer, including a change of sign in the group velocity. Second, a surface plasmon-magnon polariton formed as a linear superposition of graphene surface plasmon and the antiferromagnetic bare magnon. This polariton has a dispersion with two branches, formed by the anticrossing between the dispersive surface plasmon and the magnon. We discuss the potential these new modes have for combining photons, magnons, and plasmons to reach new functionalities.

1. Introduction

It is known, that an uniaxial antiferromagnet (AF) can exhibit negative permeability in certain frequency range \([1, 2]\). As a consequence, surface of AF is able to support surface magnon-polaritons (SMPs) \([3]\) – a special kind of electromagnetic waves coupled to the surface magnons of an antiferromagnet.

The fabrication of nanostructures offers a new arena to explore hybrid systems with collective modes in the spin and charge sectors, that could result in a new type of polariton, mixing spin and charge collective modes. In this paper we explore this possibility in a system that seems easy to fabricate with state of the art techniques. We consider the coupling of SMPs supported by AF to surface plasmon polaritons (SPPs) in graphene.

The main objective of this paper is to investigate how the presence of graphene in the vicinity of an AF influences the spectrum of SMPs, and vice versa, how the SPPs in graphene are affected by the AF. Thus, we consider the semi-infinite AF, and graphene monolayer, arranged at distance \( d \) parallel to the AF surface.

2. TE-polarized modes, propagating perpendicularly to the staggered magnetization

In this case the spectrum of SMPs is strongly modified owing to the influence of free charges in graphene on the electromagnetic field of the SMP, supported by the surface of the AF. As a result, hybrid surface magnon-plasmon-polariton (SMPP) mode is formed. The SMPP spectrum for relatively small distance \( d = 500 \text{ nm} \) is depicted in Fig. 1(a) for different values of the Fermi energy. Thus, for finite doping of the graphene, SMPP spectrum has a starting-point with the frequency \( \omega_i > \Omega_0 \) (where \( \Omega_0 \) is the frequency of the antiferromagnetic resonance), lying on the light line. An increase of the Fermi energy \( E_F \) results into the shift of the starting-point of the spectrum towards higher frequencies.

In the \( k \to \infty \) limit, the spectrum tends to \( \omega = \sqrt{\Omega_0^2 + \Omega_s^2} \) (horizontal dash-and-dotted line, where \( \Omega_s \) stands for the saturation frequency). Therefore, as \( E_F \) is ramped up and the spectrum is pushed up in frequency at the smallest allowed values of \( k \), so that the starting SMPP’s frequency becomes larger than that limiting frequency \( \omega_i > \sqrt{\Omega_0^2 + \Omega_s^2} \), their group velocity \( v_g = \frac{d\omega}{dk} \) has to be negative. This happens at experimentally attainable dopings of the graphene. For \( E_F = 0.01 \text{ eV} \) and \( E_F = 0.03 \text{ eV} \), orange and green lines in Fig. 1(c), respectively, \( v_g < 0 \) in a range of high values of \( k \). For higher values of \( E_F \) \( v_g < 0 \) for all values of \( k \).

This result is distinct from the zero Fermi energy case, where SMP’s group velocity [slope of the dispersion curve, \( \omega(k) \), depicted by solid blue line in Fig. 1(a)] is positive in all range of frequencies and wavevectors. It is possible to see, that the group velocity is much smaller than the speed of light in vacuum, \( c \). Even more, in short-wavelength limit \( ck/\Omega_0 \gtrsim 30 \) the group velocity is less than \( 10^{-5}c \), i.e. SMPPs are slow waves.
Figure 1: (a) Surface magnon–plasmon–polariton (SMPP) spectrum in the AF/graphene structure for Fermi energy values $E_F = 0$ (solid blue line), 0.01 eV (solid orange line), 0.03 eV (solid green line), and 0.4 eV (solid red line). Black dashed line stands for the light line in vacuum, $c = ck$; (b) Spatial distributions of the SMPP electric field for the modes with $ck/\Omega_0 = 1.46$ and 0.01 eV (orange line A), 0.03 eV (green line B), and 0.4 eV (red line C). These modes are indicated in panel (a) by the respective letters A, B and C. The region occupied by the AF is shadowed in panel (b) and the position of graphene is shown by vertical bold black solid line; (c) Group velocity, $v_g = d\omega/dk$ (in dimensionless units $v_g/c$) of the SMPP modes with $E_F = 0.01$ eV (orange line), 0.03 eV (green line), and 0.4 eV (red line). In all panels the fields and magnetization of AF are $\mu_0H_A = 0.787$ T, $\mu_0H_e = 55.3$ T, and $\mu_0M_s = 0.756$ T, for the antiferromagnet MnF$_2$. The spacer between the AF and graphene has thickness $d = 500$ nm. The magnitude of the fields was chosen arbitrarily for convenient visualization of their profiles.

Examples of spatial profiles of SMPP modes are shown in Fig. 1(b). As can be seen from the figure, in the case of TE-polarized wave $E_y(0) > E_y(d)$, so the field is mainly concentrated nearby of the AF surface.

3. TM-polarized modes, propagating parallel to the staggered magnetization

We now consider the case of TM-polarization, for which the graphene layer is able to sustain SPPs. In the AF-graphene coupled structure, the graphene SPP is hybridized with the AF magnon, resulting in a polariton spectrum with 2 branches, that reflects the emergence of a hybrid collective mode that combines graphene plasmons with AF magnons. We shall call these hybrid excitations surface plasmon–magnon–polaritons (SPMPs). These two branches of SPMP are characterized by the anticrossing in the vicinity of AF resonance frequency. The electromagnetic field is, for all modes, predominantly concentrated nearby the graphene layer.

4. Conclusions

In this work we have investigated the electromagnetic properties of an antiferromagnetic insulator in the proximity of a graphene sheet. We have found two new types of hybrid polaritons (SMPP and SPMP) that combine the electromagnetic field with the magnetization in the magnetic material and the free carrier response of Dirac electrons in graphene. In both cases, a quantized theory of this new polaritons implies a new type of hybrid collective modes that combine of surface plasmons in graphene, magnons in the AF and the photon field. Their properties can be tuned by changing the carrier density in graphene.

Abstract

We propose and numerically analyze a mid-infrared electrically controllable plasmonic waveguide directional coupler that is composed of two parallel identical straight dielectric loaded graphene plasmonic waveguide. By varying the Fermi energy level of the graphene sheet, the maximum power coupled from the input waveguide to the cross-waveguide and the corresponding coupling length could be effectively tuned. This directional coupler could serve as an electrically controlled optical switch or a 3-dB splitter around the wavelength of 10.5μm.

1. Introduction

Graphene is a promising candidate for mid-infrared to terahertz surface plasmons (SP) waveguide, due to its extraordinary properties. Here, we propose dielectric loaded graphene plasmon waveguide (DLGPW) [1], which is not influenced by the edge shape of graphene and could be produced in a straightforward way by, for example, standard processes of lithography. Moreover, the mode propagation characteristics of the DLGPW could be controlled by varying the Fermi energy level of graphene sheet through electrostatic gating. And the coupling between two DLGPWs could be electrically controlled accordingly. Based on this study electrically controllable optical switch and 3-dB splitter is proposed.

2. Structure and results

Figure 1 shows the schematic of the directional coupler (DC) based on dielectric loaded graphene plasmon waveguide. Two parallel identical straight DLGPWs with edge-to-edge separation d constitute the coupling region. The coupling region with a length of L is connected to the output waveguides (Ps and Pc) by two S-shaped waveguide bends. SiO₂ dielectric layer with a thickness of hs is used to separate the graphene sheet and the back-gated metal film. By applying a voltage between the graphene sheet and the back-gated metal film, the carrier concentration and thus the Fermi energy level of graphene can be electrically tuned. Then the coupling between the two DLGPWs could be tuned. [2]

![Image of schematic](image)

Figure 1: Schematic of the electrically tunable directional coupler based on dielectric loaded graphene plasmon waveguide.

Figure 2(a) shows the transmission of the proposed DC at different Fermi level energy of graphene, which indicates the output could be effectively tuned by varying the Fermi energy level. These results enable an electrically controllable optical switch, with E_F = 0.7 eV as switch on state and E_F = 0.5 eV as switch off state. The switch on-off extinction ratio is larger than 16 dB. Moreover, when E_F = 0.82eV, without changing the structure, the DC could serve as a 3-dB splitter. Figure 2(b) shows the power flow...
distributions at different Fermi energy level for the wavelength of 10.5μm.

Figure 2: (a) Transmission rate of the proposed DC at different Fermi energy level with a coupling length of 2.6 μm. (b) Power flow distributions at different Fermi energy level for the wavelength of 10.5 μm.

3. Conclusions

In summary, we have studied the coupling characters of a directional coupler (DC) consisting of two parallel identical straight DLGPWs in the mid-infrared regime. The maximal power coupled from the input waveguide to the cross-waveguide and the corresponding coupling length could be manipulated by changing the Fermi energy level of the graphene sheet, which enables electrically controlled functional devices. Based on this DC electrically controlled optical switch operating around the wavelength of 10.5 μm is proposed and simulated. The switch on-off extinction ratio is larger than 16 dB. Moreover, without changing the structure, by varying the Fermi energy level, the function of the DC could be changed from an optical switch to a 3-dB splitter, making this DC a multifunction device. At the same time, the size of the entire device is only around 6 μm × 3 μm. This DC-based electrically controlled device may find potential applications in high-density integrated active plasmonic circuits.

Abstract

We proposed a tunable terahertz half-wave plate composed of a periodic array of graphene nanodisk dimers supported on a dielectric spacer backed by a planar gold layer. The polarization conversion phenomena are attributed to the hybridization effect caused by coupling interactions between plasmonic resonances in the graphene nanodisk dimers. By varying the distance between graphene nanodisks, the polarization conversion performance can be controlled. Further, the polarization conversion can be dynamically tuned at different frequencies via electrostatic doping of graphene.

1. Introduction

Manipulating the polarization state of light is useful for practical applications. Conventional methods of manipulating the polarization include using natural anisotropic crystals or employing subwavelength gratings. Researchers have recently found that metamaterials and surface plasmon polarization structures can be used as alternative routes to controlling the polarization state of light at the nanoscale. Various polarization converters based on metamaterial structures have been achieved, such as metallic nanoparticles and metallic nanoslots. However, the operating frequencies of these reported polarization converters are fixed and cannot be electrically tuned, which limits their uses in practice. Graphene, a single-layer carbon atom arranged in a honeycomb lattice, appears to be a good candidate for designing tunable devices operating in the terahertz (THz) spectral range because of its tunable conductivity. In this paper, we focus on the polarization conversion properties of coupled graphene nanostructures. We confirm that using a periodic array of coupled isotropic graphene nanostructures is an alternative route to achieving polarization conversion. The proposed structure can convert linearly polarized light to its orthogonal polarization in the reflection mode simultaneously at two frequencies.

2. Structure and results

Figures 1(a) and 1(b) show a schematic illustration and the designed geometry of the proposed nanostructure. It consists of a periodic array of CGNs and a 150-nm-thick planar gold layer, separated by a 1250-nm-thick dielectric spacer. An ion gel layer is used to electrically dope the CGNs. Doped graphene nanostructures have been predicted to support strong plasmonic resonance.

Figure 1: (a) Arrays of CGNs. (b) Unit cell of CGN

The polarized reflectances \( R_{xx} \) and \( R_{yy} \) (\( R_{lm} \) represent the complex amplitude of the reflected wave and denote the \( l \)-polarized reflectance from \( m \)-polarized excitation) as a function of frequency are shown in Figure 2(a). We can observe two reflection peaks in \( R_{xx} \), at about 47 and 51 THz, with corresponding dips in \( R_{yy} \), indicating that the structure can realize energy transfer from \( x \) to \( y \) polarization after reflection. One key parameter of a wave plate is the polarization conversion rate (PCR), which is defined as \( \text{PCR} = R_{xx}^2/(R_{xx}^2 + R_{yy}^2) \). As shown in Figure 2(b), the local maximum PCRs reach high values of 0.997 and 0.995 at about 47 and 51 THz, respectively, whereas the corresponding reflection phase differences approach 0 and 180°, indicating that a linear polarization state can be realized. The polarization conversion can be dynamically tuned on and off or tuned for activity at different frequencies via electrostatic doping of graphene. To demonstrate the tunability, we calculated the PCRs as a function of frequency when the Fermi energy of graphene varies from 0.7 to 1.0 eV, as shown in Figure 2(c). It can be seen that the local maximum of the PCR is still close to 1. The local PCR maximum is blue-shifted as \( E_F \) increases, which can be interpreted as indicating the graphene resonance condition. The local maximum frequency of the PCR corresponds to the resonance frequency of graphene surface plasmons, which is proportional to square root of the Fermi energy level of
graphene. Hence, the proposed half-wave plate can be controlled by changing the Fermi energy of graphene in lieu of redesigning the structure.

![Graph showing calculated reflectance and polarization conversion rate](image)

Figure 2: (a) Calculated reflectance $R_{xx}$ and $R_{xy}$. (b) Polarization conversion rate (PCR) and the reflection phase difference. (c) PCRs of the CGN structure at different Fermi energy levels.

### 3. Conclusions

In conclusion, we proposed a tunable half-wave plate in the THz region based on a hybridization effect caused by coupling interactions between plasmonic resonances in graphene nanodisk dimers. We also demonstrated that using a periodic array of coupled isotropic graphene nanostructures instead of uncoupled anisotropic graphene nanostructures is another route to achieving polarization conversion. The polarization conversion properties hinge mainly on the distance between graphene nanostructures. The method of using coupled graphene nanostructures can be expanded to obtain other novel phenomena and interesting applications.

Graphene-based Perfect Absorption in the Near Infrared

Hanyu Wang ¹, Wei Xu ¹, Chao Li ¹, Jianfa Zhang ¹, Chucai Guo ¹, Ken Liu ¹, Xiaodong Yuan ¹, Zhihong Zhu ¹, and Shiqiao Qin ¹

¹National University of Defense Technology, Changsha, China

Abstract
In this work, we propose a kind of monolayer graphene based absorption structures which comprise dielectric materials with low refractive index contrast, and we directly verify the complete optical absorption in experiment for monolayer graphene based subwavelength structures in the near-infrared. Peak absorptions over 99% at wavelength around 1.5 μm with full-width at half maximum (FWHM) about 20 nm are demonstrated from monolayer graphene coupled with different subwavelength gratings on top of a back gold mirror.

1. Introduction
As a novel 2D material, graphene has been studied intensively due to its outstanding optical and electronic properties. However, the absorption efficiency of suspended monolayer graphene toward the normal incident light is only 2.3%, which limits its optoelectronic applications. In the visible and near-infrared, the absorption of graphene was normally enhanced by coupling graphene with dielectric or metallic resonant structures. And complete absorptions of monolayer graphene were numerically demonstrated by using critical coupling and guided mode resonance. However, the experimentally realization of complete absorption for monolayer graphene based structures in the optical range is still a great challenge.

2. Structure and results
The schematic image of the absorption structure under investigation in this work is demonstrated in Figure 1a. The structure comprises a monolayer graphene which is sandwiched between a 1D polymethyl-1-methacrylate (PMMA) grating and a silica layer, and a gold layer is coated in the back side of the silica layer. The absorption structure shown in Figure 1a supports several resonant modes which could be excited by outside incident waves under phase matching conditions. When the incident wave is coupled with a resonant mode, the absorption of the structure could be enhanced due to the field enhancement in the structure. And complete absorption can be obtained when the reflection wave is canceled by the emission wave of the resonant mode since the transmission of the structure is blocked by the gold layer.

Figure 1: (a) Schematic image of the monolayer graphene based absorption structure. (b) Optical image of the fabricated sample. (c) Top SEM image of a fabricated pattern.

Figure 2(a) shows the reflection (R) and absorption (A) spectra of a fabricated structure with grating period d = 1254 nm for transverse-electric (TE) polarization, where the reflection spectrum was normalized by the reflected light of the 200 nm thick gold layer in the sample (assume the reflectivity of the gold layer R Au = 98.8% at the wavelength around 1500 nm according to the simulation result) and the absorption spectrum was derived based on the equation A = 1 − R since the transmission was blocked by the thick gold layer. As shown in Figure 2(a), peak absorption over 98% with absorption FWHM of 19 nm for TE polarization was measured. Figure 2(b) shows the measured absorption spectra of different fabricated monolayer graphene based absorption structures for TE polarization. Measurement results show that the peak absorptions of the structures with d = 1230 and 1254 nm are over 98% and the peak absorption of the structure with d = 1270 nm is over 97%.
Figure 2: (a) Measured (solid line) and simulated (dot line) reflection and absorption spectra of a fabricated monolayer graphene based absorption structure with $d = 1254$ nm. (b) Measured (solid line) and simulated (dot line) reflection and absorption spectra of a fabricated monolayer graphene based absorption structure with different grating periods.

3. Conclusions

In conclusion, peak absorptions over 99% with FWHM about 20 nm in the near-infrared were measured for monolayer graphene coupled with subwavelength gratings on top of a back gold mirror. The demonstrated absorption structures with total thickness less than 1.0μm are very compact, and the absorption peak wavelength of the structure can be easily controlled by changing the geometric parameters of the structure. Because of their high absorption efficiency and loose fabrication requirements, the demonstrated structures may provide practical applications for graphene and other 2D material based optoelectronics devices, such as high efficiency photodetectors and high extinction ratio modulators.

Optical antennas and plasmonics-based devices
Multiband Antennas for Si-based Terahertz Detectors

Ke Wang, Fangfang Ren, Yi Yang, Ping Han, and Xiaoli Ji

School of Electronic Science and Engineering, Nanjing University, Nanjing, China
*corresponding author, E-mail: xji@nju.edu.cn

Abstract
The authors demonstrate a Si-based multiband terahertz antenna which can be fully integrated with MOSFET-based terahertz detectors in standard Si technologies. It consists of semicircular nesting rings and slots. For an optimized antenna structure with a size of 160μm×160μm, four separated bands can be achieved in the range of 0.1~1.2 THz with the central one located at 0.5THz with a bandwidth of 30GHz.

1. Introduction
MOSFET-based terahertz (THz) detectors are generally integrated with an on-chip antenna for collecting THz signals. Single-band RF antennas had already been widely designed with metals in standard CMOS process [1,2], possessing the advantages including low profile, light weight and easy fabrication. However, multiband and wideband antenna design remains challenges because of the mismatching of the input impedance of FET device with the multiband antennas. To overcome the difficulties, we propose a semicircular nesting ring antenna used for the application of silicon (Si)-based multiband THz detectors. It can be fabricated with standard CMOS technologies.

2. Semicircular nested antenna
When THz signal is incident upon a semiconductor material, surface plasmon resonances (SPRs) can be excited at the interface of metal/dielectric. Many semiconductor materials have been proposed to work as the plasmonic materials in THz because their free carrier concentrations can be steadily and easily controlled by doping, thermal, electrical or optical excitations. Through the employment of unique resonance structures, strong THz wave enhancement can be realized by poly-Si due to the plasmonic effect. The dielectric constant can be obtained by Drude model [3].

Figure 1 (a) shows the 3D schematic of the multiband antenna. It was designed based on the gate material of MOSFETs. Following the typical standard 0.18μm CMOS technology, the gate material is the poly-Si doping with density of 1×10^20 cm^-3 and thickness of 0.2μm. The structure of the multi-frequency antenna is completely symmetrical, consisting of two semicircular receiving faces and two rod mixing structures. The semicircle radius, inner ring radius, outer ring radius, rod length, rod width, slot width, gap width and the shortest distance of the end face from the rod are denoted as R, d, w, a, g, b, respectively. Figure 1(b) shows the cross-sectional view of antenna embedded Si FET detector. The MOSFET is located at the center of the antenna. We fabricate the antenna above the shallow trench isolation structure, below which is a Si substrate. The slots and surroundings of the antenna are filled with SiO₂, and the thickness of SiO₂ above the antenna is about 10.7μm.

3. Simulation results and analysis
During the simulation for the antenna design, the excitation THz source is located above the SPR antenna and a TM mode plane wave is radiated with frequencies in the range from 0.1 to 1.2 THz where the electric field direction is parallel to the rod and the electric field strength E₀ is set to 1V/m. The dielectric constants of Si and SiO₂ are roughly set to be 11.9 and 4, respectively. Figure 2 (a) shows the simulated frequency dependence of the center-position of the poly-Si antenna. It can be seen that the plasmon resonances of the antenna surface are effectively excited. When the geometric parameters of antenna are optimized as R₁=12μm, R₂=34μm, R₃=66μm, d=13μm, w=1μm, a=2μm, g=2μm, b=1μm, the electric field gain E/E₀ is up to 150 times at the resonant frequencies of 0.4, 0.71 and 1.11THz, respectively, with a bandwidth above 30 GHz. The fourth resonance peak at 0.96 THz has a peak gain of about 100 times with more advantages in terms of narrower bandwidth. Figure 2 (b) shows the typical electric field distributions on the antenna surface at four response peaks with the optimized geometric parameters. It can be seen that the resonance modes I and IV around 0.4 and 1.11 THz might be induced along the semicircular slots with radius of R₃ and R₁, respectively. The modes II and III around 0.71 and 0.96 THz might be owing to the LC-type resonances based on electric dipoles. It also can be seen that the circular rings provide a discrete current path along the edges of the
ring. For the ring slot, the current path is well defined, similar to the operation of a circular disk antenna operating at its lowest or “fundamental” resonance.

Figure 2: (a) The frequency dependence of the center-position response of the Si antenna; (b) The electric field distributions of the antenna surface at 0.4, 0.71, 0.96, and 1.11THz.

In order to accurately understand the mechanisms of the resonance modes, the frequency dependence of the center-position poly-Si antenna on the geometric parameters has been studied. As shown in Fig. 3(a), when \( R_1 \) is increased from 11 to 14μm, mode IV is redshifted from 1.17 to 1.01 THz, indicating that this resonance is strongly dependent on the length of the semicircular slot ( \( \approx \pi R_1 \)). Similarly, the size of the outer slot \( R_2 \) also has an important effect on the resonance modes of the multi-frequency antenna. As shown in Fig. 3(b), when the value of \( R_2 \) is modified from 24 to 44μm, the mode I is redshifted from 0.52 to 0.32 THz. As compared, the slight shift of mode IV can be negligible if considering the limited simulation accuracy. In summary, \( R_1 \) and \( R_2 \) have a decisive effect on the resonance modes of the antenna, and their values should be appropriate in order to reduce its effect on adjacent peaks, which is because the slot structure might change the current path on the antenna surface. On the basis of discussion in [4], the radius of \( R_1 \) or \( R_2 \) determines the length of inner or outer slot. When \( h = 200 \) nm and \( R_1=12 \)μm, we can calculate the resonance frequency \( f = 1.12 \)THz, which matches the simulation results very well. It also fits well for \( R_2 \). Figure 3(c) shows the frequency response of the center-position poly-Si antenna dependent on the varied value of \( R_3 \). As \( R_3 \) increases from 56 to 76μm, mode II is redshifted from 0.73 to 0.67THz and mode III is redshifted from 1.03 to 0.9THz. As discussed in Fig. 2(b), these two modes can be regarded as LC-type resonances occurring along the direction of rods by considering the fact that the strong near fields are concentrated at the center of antenna. It is therefore, the redshift of mode frequency can be attributed to the increase of capacitance with \( R_3 \) increasing, which is in consistent with the behavior of a traditional dipole SPR antenna.

4. Conclusions

In this work, we proposed a novel SPR antenna for multi-frequency THz detector. As compared to conventional one-frequency antenna, our design is demonstrated with a broader response frequency regime, and also promising for an improved performance with smaller area size and higher responsivity.

Abstract

The switching mechanism of valence change memories involves the migration, accumulation and rearrangement of oxygen vacancies within a dielectric medium to change the electrical conductivity, and is triggered by an external applied potential. Here, resistive switches are constructed to exploit the high sensitivity to morphology at tightly-confined plasmonic hotspots within the switching material. This gives a non-destructive technique to detect oxygen vacancy motion with nm-scale sensitivity using visible light.

1. Introduction

Resistive switches (RRAMs) are one of the most promising emerging devices for memory-inlogic operations, attracting great attention due to their high scalability, ultra-fast access times and ease of fabrication [1]. The ability to look deep inside materials to unveil how morphological changes characterize the functioning of active devices has triggered the interest of a wide scientific community. However, current technologies often result in destructive and invasive techniques. In this work, we adopt a new fully-optical non-destructive technique to observe the valence change mechanism (VCM), i.e. the motion of oxygen vacancies within a switching material, otherwise invisible to typical electron microscopy techniques.

2. Results

Resistive switches arranged in a nanoparticle-on-mirror geometry (Fig. 1a) are developed. Combining resistive switches and large field enhancements in nanoplasmonic systems has proven a powerful approach to understand the dynamics involved in the switching process of the closely related system of electrochemical metallization cells (ECM) [2]. In this previous pioneering study, we implemented optically-accessible ECM switches and monitored in real time the scattering signal coming from the plasmonic field which is tightly confined to the nanometer-sized switching gap.

In this talk we will show how it is possible to monitor in real time the scattering signal coming from VCM systems (Fig. 2b) enabling the observation of migration, accumulation and rearrangement of oxygen vacancies within a dielectric medium (Fig. 2c) [3].

Figure 1: (a) Nanoparticle-on-mirror geometry in VCM cells and its (b) scattering signal correlated to (c) oxygen vacancies motion within the switching material.

3. Conclusions

We present an innovative technique able to follow in real time the drift (I) and accumulation (II) of oxygen vacancies and the subsequent creation (III) and dissolution (IV) of a conductive bridge triggered by an external applied field. This is a non-destructive and non-invasive technique able to detect oxygen vacancy migration in ambient conditions, leading to the investigation of the mechanism that underpins this new generation of ultra-low-energy memory nano-devices and their integration into fast, logic-in-memory architectures opening up new routes to sustainable future IT.

Abstract

Fabry-Perot (FP) like resonances have been widely described in nanoantennas. In the original Fabry-Perot resonator, a third mirror can be added, resulting in a multimirror interferometer. However, in the case of combination of nanoresonator, it has been reported that each cavity behaves independently. Here, we evidence the interference between two FP absorbing nanoantennas through a common mirror, which has a strong impact on the optical behavior. While the resonance wavelength is only slightly shifted, the level of absorption reaches nearly 100 %. Moreover, the quality factor increases up to factor 7 and can be chosen by geometric design over a range from 11 to 75. We first demonstrate thanks to a simple analytical model that this coupling can be ascribed to a double FP cavity resonance, with the unique feature that each cavity is separately coupled to the outer medium. Based on this principle, we experimentally illustrate the existence of a high-Q factor resonance originating from the interference between two under-coupled ribbon-shaped nano Fabry-Perot.

1. Introduction

The Fabry-Perot (FP) interferometer was invented in 1899, and consisted of two parallel highly reflecting mirrors, the resonance behavior being characterized by peaks or dips in the transmission and reflection spectra [1]. It has been used in a variety of devices among which optical cavities for lasers or filters [2]. Since this seminal work, various evolutions of the FP interferometer have been introduced among which multi-mirror FP that give birth to a coherent superposition of all the beams [3]. Noteworthy, in most configurations, the mirrors are placed in series. In the past two decades, the development of nanophotonics has given birth to FP-like resonators [4]–[7], in which a guided mode in a metallic cavity has a behavior that is well described by the FP formalism. The advantages of these nanoresonators are their compactness, and the possibility to combine them to design broadband or multiband resonances. It is well accepted that, since these metallic cavities are the siege of localized resonances, they have negligible influences on each other when they are combined [8]–[12].

The two most common plasmonic nanostructures with a FP behavior are the metal-insulator-metal patch nanoantennas (horizontal resonance), and the high aspect ratio nanogrooves (vertical resonance). Both of these resonators are promising for applications ranging from thermal emission [12],[13], or infrared detection [14] to biosensing [15]. Yet, they suffer from their low quality factor.

In this letter, we introduce double cavity Fabry-Perot like nanoresonator in both vertical and horizontal configurations. It departs from previous works on multimirror FP resonators, as the mirrors are in an hybrid configuration between series and parallel. It gives birth to a spectacular effect where critical coupling, i.e. a zero of reflectivity, is obtained while, independently, each of the two cavities is loosely-coupled to free space. Moreover, the quality factor of the double cavity resonators is increased from 11 to 50, well beyond the limit for FP plasmonic nanoresonator [10].

We developed an analytical model that confirms the multimirror FP behavior. Last, but not least, we experimentally demonstrate the coupled Fabry-Perot resonance on a horizontal nanoresonator.

2. Analytical model of the coupled nano Fabry-Perot resonator

We study a periodic double-groove resonator whose period contains two grooves of different heights. While the reflectivity of the periodic single-groove resonators does not go below 85%, the resonance of the double-groove presents a zero of reflectivity and a quality factor of 50 (See Figure 1).

Figure 1 Comparison between the reflectivity of two loosely-coupled single-nanogroove resonators and the reflectivity of a critically coupled resonator composed of the two aforementioned cavities. The geometrical parameters of the cavities, described in the insets, are $d=1 \mu m$, $w=0.3 \mu m$, $h_1=0.62 \mu m$, $h_2=0.55 \mu m$.
We demonstrate thanks to an analytical model that this coupling can be ascribed to a double FP cavity resonance, with the unique feature that the cavities are coupled to one another through a common mirror.

Using the reflection, transmission and propagations coefficients represented on the figure 2, we can write the reflectivity of the resonator as a sum of three terms:

\[
RT = T_{TBA} + T_{TBA} R_{BA} + T_{TBA} R_{BA} T_{TBA},
\]

Where \( G_1 \) and \( G_2 \) represent the loop inside the first and second groove and can be written, in the steady state as:

\[
\begin{align*}
G_1 &= \rho P_1^2 \left[ (T_{BB} - P_{BB} P_{BB}^*) (T_{BB} - P_{BB} P_{BB}^*) (T_{BB} - P_{BB} P_{BB}^*) \right], \\
G_2 &= \rho P_2^2 \left[ (T_{BB} - P_{BB} P_{BB}^*) (T_{BB} - P_{BB} P_{BB}^*) (T_{BB} - P_{BB} P_{BB}^*) \right].
\end{align*}
\]

The critical coupling (zero of reflectivity) is then achieved through a three wave destructive interference dictated by the coupling parameter \( \Gamma_{BB} \).

3. Experimental demonstration of the coupled nano Fabry-Perot resonance

For this experimental demonstration, we consider horizontal nano FP cavities. An analogy has been demonstrated between the vertical and horizontal nano FP cavities, providing a simple geometry transformation whose principal parameters are summarized in figure 3. The resulting horizontal coupled FP nanostructures studied in this letter are made of three layers as illustrated in the inset of the figure 4.b. A top periodic nanostructure composed of one or several gold ribbons of the same height (t=50 nm) but different width denoted by capital letters \( (W_A=400 \text{ nm and } W_B=495 \text{ nm}) \) is deposited on two continuous layers, a SiC insulating layer of 280 nm thickness and a gold mirror.

4. Conclusions

The description of the double-groove resonator paves the way to the manipulation and the engineering of the equivalent mirror coupling the two nanocavities, in order to reach multimirror interferences predictions. This structure is also very promising for many practical applications. For example, the wide dielectric layer is needed for nanostructured photodetectors or a high Q-factor resonance is useful for gas detection.

Abstract
We present a combined experimental and numerical study that utilizes optical antennas to convert a carbon nanotube as a model system for 1D emitters into a single photon source by localization and efficient exciton-exciton annihilation (EEA).

1. Introduction
Since its first report in 2008 \cite{1}, photon antibunching in the photoluminescence (PL) from semiconducting single-walled carbon nanotubes (SWCNTs) attracted considerable attention because of potential applications of SWCNTs as single-photon-sources. Known for single point-like quantum systems, the observed antibunching from a 1D nano-material also raised fundamental questions regarding the underlying mechanism. In general, antibunching is thought to require the efficient localization of the excited state energy at local minima in the exciton energy landscape or at chemical dopant sites and was reported for different nanotube materials and configurations upon optical as well as electrical excitation \cite{2, 3, 4, 5}.

2. Antenna-enhanced exciton-exciton annihilation for single photon emission
For SWCNTs it was found that high exciton mobility and EEA can lead to significant antibunching with reported values ranging from $g^{(2)}(0) \approx 0.3$ to 0.9 \cite{2, 4}. In numerical simulations, the exciton density and the diffusion length of mobile excitons were found to be key parameters in controlling $g^{(2)}(0)$. Moreover, Ishii et al.\cite{4} suggested that the former could be minimized using near-field optical techniques. To proof the feasibility of the approach, we used a Hanbury-Brown-Twiss interferometer and measured the second-order correlation function $g^{(2)}(\tau)$ of the PL emission from individual carbon nanotubes. The SWCNTs were deposited on a glass substrate and excited with a pulsed laser, either with or without a sharp gold tip acting as optical antenna, the principle of which is shown in Figure 1a. Starting at a low excitation rate with less than one absorbed photons per pulse on average, there is still a sizable chance to create two or more excitons at the same time since the number of photons in a laser pulse follows a Poisson distribution. The nearfield of a nanoantenna then acts as a funnel for the excitons, with the idea that by efficient exciton-exciton annihilation only one exciton per pulse will survive to later emit a photon. Figure 1b presents an optical nearfield image of an individual (6,5) SWCNT recorded with the setup at a resolution of around 20 nm. Figure 1c presents the normalized second order correlation function $g^{(2)}(\tau)$ of the PL emission of a (6,5) SWCNT, measured with and without an optical antenna. Antenna-controlled antibunching is seen as a reduction of $g^{(2)}(0)$ by around 0.2. We further employed a Monte-Carlo scheme to model and understand the physics of exciton diffusion, annihilation and decay at a nanotube \cite{4, 6} in interaction with an optical antenna. Figure 1d presents the resulting magnitude of the three decay channels at an increasing field enhancement factor $f$ for the situation of 4 initially created excitons. High field enhancement leads to a significantly amplified EEA channel, which in return controls and reduces the exciton number on the nanotube. From repeated simulation runs, the normalized second order correlation function can be calculated. The resulting values for $g^{(2)}(0)$ from numerous simulations are in good agreement with the findings from our measurements, if the typical parameters of an electrochemically etched gold tip antenna are estimated as $f \approx 2 - 5$ and $d \approx 20$ nm. Higher field enhancement factors, a longer diffusion length or lower quantum yield leads to even higher degrees of photon antibunching.

3. Conclusions
Nanoscale optical antennas can be used to control the photon emission statistics of one-dimensional emitters and turn them into single photon sources. Our Monte-Carlo simulations show that the degree of antibunching $g^{(2)}(0)$ can be reduced to below 0.3 for realistic parameter sets. Key for this behavior is the nearfield of the tip that leads to a locally enhanced exciton density, which increases EEA. Together with the enhanced radiative decay rate, single photon emission is favoured. Proof-of-concept experiments on SWCNTs show a reduction of $g^{(2)}(0)$ by about 0.2 in good agreement with the calculated results. Since the mechanism of antibunching does not rely on the used material here, the concept can be extended to other 1D materials that show EEA.
Figure 1: **a** Schematic of the approach for antenna-controlled photon antibunching. The presence of an optical antenna concentrates the excitons and leads to an increase in the exciton-exciton annihilation rate. **b** Antenna-enhanced near-field optical PL image of a (6,5) carbon nanotube. **c** Antenna-controlled antibunching: The normalized second order correlation function $g^{(2)}(\tau)$ of the PL of a (6,5) SWCNT with and without optical antenna, recorded after pulsed laser excitation. **d** Monte-Carlo simulations show the control of the relative decay rates by the local field enhancement factor $f$.

Abstract

By using DNA nanotechnology it is now possible to build complex nanostructures and hybrid materials. We used three dimensional DNA origami structures to design plasmonic nanoantennas containing a fluorescent dye or molecular assays that are placed in a controlled way into the hotspot of two metallic nanoparticles which are connected to the DNA origami. With these nanoantennas, we were able to optically detect Zika-virus related nucleic acids. The fluorescence enhancement enables detection of fluorescence signals of single dyes on low-tech devices such as smartphones.

1. DNA Origami Folding

To assemble DNA origamis\textsuperscript{[1]}, a long scaffold DNA strand of roughly 8000 nucleotides is folded into the desired shape by hybridizing about 200 short oligonucleotides. In this way, the short staple strands connect different parts of the scaffold strand and therefore predefine the structures. This can be programmed by choosing the right sequences of the staple strands. The principle of DNA origami is shown in Fig. 1 and has enabled several different structures in two and three dimensions. AFM images of a rectangular DNA origami with dimensions of 70 nm x 100 nm is exemplarily shown in Fig. 1b.

In addition to the structural control, it is possible to place functional groups at distinct positions on the origami during the folding process by using modified staple strands for certain positions. In a first example, DNA origamis were thus equipped with several fluorescent dyes to create dye patterns that could be resolved with a super-resolution fluorescence microscope\textsuperscript{[2, 3]}.

2. Single molecule diagnostics using DNA Origami Nanoantennas

Figure 1: a) DNA origami nanostructures that are self-assembled from a single stranded circular DNA scaffold (black) by addition of multiple short staple strands (colored). Fluorescent dyes on staple strands are indicated as red shiny spheres in the upper left and lower right corner. The designed structure provides nanometer control for positioning e.g. fluorescent dyes, nanoparticles and proteins; b) AFM images of rectangular DNA origamis (edge lengths: 70 nm x 100 nm).

Here, DNA origami nanostructures were used to arrange different components for nanophotonics applications\textsuperscript{[4]}. One example is shown in Fig. 2 where two silver nanoparticles were arranged to build an antenna with a gap of 15-20 nm. These gold nanoparticles (diameter about 80-100 nm) create a plasmonic hotspot between the particles where the local electric field of the incident laser light is enhanced by hundred- to thousandfold\textsuperscript{[5]}. It was already stated that the emitter or even larger biomolecular assays can be placed in the hotspot in a stoichiometrically controlled manner. This is unique compared to optical antennas produced by nano-lithography.

To bind the nanoparticles to the DNA origami, they first have to be modified with thiolated DNA strands that are complementary to DNA strands protruding from the DNA origami. Additionally, the DNA origami structure is equipped with biotin modifications at the bottom for
selective immobilization on BSA-biotin-neutravidin passivated surfaces and a green fluorophore is placed near the bottom of the DNA origami pillar for visualization of bound nanostructures. In the example shown in Fig. 2, a DNA hairpin assay is placed in the plasmonic hotspot created by two silver nanoparticles with a diameter of 80nm. The hairpin assay is modified by one ATTO647N dye and a Blackberry650 (BBQ-650) quencher. The fluorescence of the dye is therefore quenched when the hairpin is closed. Upon opening of the hairpin, the distance between quencher and dye is enlarged, and in turn the emerging weak fluorescence is enhanced in the hotspot and can be detected [6, 7].

The idea of a single-molecule diagnostic assay is illustrated in Fig. 2b. In the original structure (without target), the hairpin is closed and the red fluorescence is quenched. Therefore, only green spots indicating the presence of the DNA origami structures are visible in false color fluorescence images (upper panel). After incubation with the target, the hairpin opens and the red fluorescence of ATTO647N is released. This leads to the appearance of yellow spots in the false color image (lower panel) indicating the co-localization of red and green fluorescence. The panels of Fig. 2c,d show the fluorescence enhancement and the fluorescence lifetime that was measured with such an assay. Fluorescence enhancements of up to several hundred fold were achieved while at the same time the fluorescence lifetimes were drastically shortened. This indicates that the presence of the nanoparticles not only increases the excitation intensity but also radiative and non-radiative decay rates are increased strongly.

The high fluorescence enhancement factors presented in this work encourage us to think that in the future it might be possible to detect the enhanced fluorescence intensity of single molecules on low-cost devices such as smartphone cameras. As a first approach to this vision it was already shown that a smartphone camera is able to image fluorescence beads with a low number of fluorophores [8]. Combining the smartphone-based microscope with DNA origami nanoantennas will be a breakthrough in future diagnostics procedures.

Figure 2: a) Sketch of three dimensional DNA origami with fluorescence quenching hairpin (ATTO647N, BBQ 650 quencher) and 80 nm silver nanoparticles; b) Illustration of the DNA detection assay. Upper panel: without target only green spots indicating the presence of the DNA origami should be visible. Lower panel: After binding the target sequence, the dye is removed from the quencher and fluorescence is released indicated by the yellow spots in the false color images; c) Histogram of fluorescence enhancement factors of the opened hairpin relative to an ATTO647N dye bound to DNA; d) Fluorescence intensity versus fluorescence lifetime scatter plots. Three spots show a fluorescence lifetime of around 4 ns without fluorescence enhancement. This behavior is the expected for ATTO647N on DNA origami without silver nanoparticles in the vicinity. All remaining DNA origami structures carry the silver nanoparticles as visible by the shortened fluorescence lifetime and increased fluorescence intensity.

Abstract

This paper presents simulated fluorescence enhancement results for large area gold dipole nanoantenna arrays. Each array element consists of two circular gold nanodots with a small gap between their outer-edges. The hexagonal arrays can be formed by ‘Double’ Displacement Talbot Lithography via a lift-off process to pattern large area substrates. Intensity enhancement of ~2249 at \(\lambda=1371\)nm is simulated when an analyte of \(n=1.333\) flows over the nanoantenna array.

1. Introduction

In-vitro fluorescence-based optical imaging of tissues and cells in the NIR-I (~700-900nm) spectral region is well established [1,2]. Simultaneous observation of several proteins in live cells via multicolor fluorescence has been achieved in this window, but imaging multiplicity is limited by the number of fluorescent channels with non-overlapping emission. Extending the spectral range into the second NIR optical window (NIR-II; 1000-1700nm) has several advantages including increased image multiplexing capability. There has been much recent progress in this NIR-II window using Organic NIR fluorophores [3] and Carbon Nanotubes [4], and by coupling these emitters with an array of nanooantennas that can drastically enhance emission could yield a new era for biosensing applications.

These optical antennas, as with conventional RF antennas, can extract more energy from an electromagnetic source, an effect known as Purcell Enhancement, enabling increased sensitivity or reduced costs. Using conventional Electron-Beam Lithography (EBL) would prove expensive to write large area arrays into resist so an alternative, lower cost method using Displacement Talbot Lithography (DTL) [5,6] is explored in this work. In DTL a periodic mask produces a diffraction pattern that can expose an entire wafer in a single dose when moved vertically through one Talbot length.

The mechanisms for Purcell enhancement are described in our previous paper [7], where cross dipole nanoantennas were modelled and shown to enhance both absorption and emission in the antenna gap. Due to the proximity of the each nanocell, in an array it is important to consider array effects in terms of directional emission [8].

2. Fabrication

A Eulitha PhableR 100 DTL machine is used for exposing the resist. The technique has the advantage of a theoretically infinite depth of field but has the disadvantage of the low contrast between exposed and unexposed regions on the sample due to the mixing of the self-image and other secondary constructive interference features. Also, there is a restriction to simple periodic features. Nevertheless, the illumination process will not be sensitive to surface roughness, or imperfect parallelism between the mask and the sample, or the depth of field; all important parameters in conventional photolithography. By combining the system with a nano-positioning stage a new, high-throughput and rapid tool that allows the fabrication of complex periodic nano- to micron patterns over a large area is proposed – ‘Double’ Displacement Talbot Lithography (D2TL) [9]. By moving the wafer perpendicular to the axis of illumination, much more complex features are possible. One of which being a dual exposure, when combined with metal deposition and lift-off process, allows the fabrication of dual nanodots of metal separated by a small gap as shown in fig. 1, where dots of diameter ~300nm are separated by gaps of 30-50nm.

Figure 1: A scanning electron microscope image of a hexagonal array of gold nanodot antennas fabricated on a silicon substrate using D2TL.
3. Discussion

Intensity enhancement of a two-arm dipole nanoantenna is determined by several parameters. In this work, we have utilized Lumerical Finite-Difference Time-Domain simulation tools where a plane-wave source, polarized across the dipole gap, is incident onto an infinite hexagonal array of gold nanodot dipole nanoantennas. In this model, the individual nanodots have diameter 200nm and are 30nm thick, and the dipole gap is constant at 30nm. They are in a hexagonal array which is modelled as a unit cell with periodic boundary conditions. Fig. 2 shows the $E_x$ intensity enhancement at the central position between the antenna nanodots normalized to the field for the free space simulation.

The resonance is a result of localized surface plasmon resonance (LSPR). LSPR can be understood as a plasmonic standing wave on the surface of the antenna arms – Fig. 3 shows the $|E|$-field through the vertical centre of the arms. This wavelength is highly dependent on the characteristics of the antenna—such as size, shape, and material properties of both the antenna itself and analyte flowing above [10].

The fundamental LSPR resonance shown in fig. 3(b) has an intensity enhancement of ~3.4x higher for the array as compared to the single antenna. In contrast the higher-order LSPR resonance shown in fig. 3(a) is only ~1.2x higher for the array. It is planned to place these arrays within a microfluidic channel, an example of one fabricated in Bristol is shown in fig 4.

![Figure 2: Intensity enhancement for various hexagonal array periods on a glass substrate with an analyte of $n=1.333$ flowing over the surface. The single antenna case is also shown.](image)

![Figure 3: $|E|$-field snapshots at (a) $\lambda=716$nm, and (b) $\lambda=1371$nm for an 1µm spaced hexagonal array where intensity enhancement of ~366 and ~2249 was observed respectively.](image)

4. Conclusions

This paper shows the design and fabrication of gold nanodot dipole nanoantenna arrays for plasmonic, fluorescence-based sensing. Keeping the nanodot geometry constant, the array spacing has been explored showing an enhancement of up to ~2249 at the NIR $\lambda=1371$nm. In future, fluorescent nanoparticles will interact with these arrays within microfluidic channels in order to study their use in low cost biosensing applications.

Abstract

In this work, we have designed and fabricated an array of plasmonic nanodisks to investigate their interaction with different types of quantum emitters (QEs) in visible wavelength. We consider embedded fluorescent dye molecules in PMMA polymer as a potential QE for our investigation. The interaction between the strong subwavelength localized field at the edges of the gold nanodisks and QEs enhances the Purcell factor towards the modification of spontaneous emission and decay rate of QEs.

1. Introduction

Nano-scaled hybrid plasmonic–excitonic systems are offering promising features in light–matter interactions to achieve light amplification via enhancement in emission or absorption rates [1,2]. In addition, these hybrid nanostructures provide the opportunity of loss mitigation in plasmonic metamaterials through non-radiative energy transfer process from quantum emitters (QEs) to plasmonic absorber [3,4]. The Förster like dipole-dipole interaction between plasmonic and QEs modes is highly sensitive to donor-acceptor inter-distance, dipole-dipole orientation, donor and acceptor dipole moment strength, as well as, the spectral overlap between the emission band of the QE and the plasmon band of the nanostructure [5]. These are necessary conditions for both photoluminescence (PL) enhancement and quenching regimes. In the PL enhancement regime, due to the energy transfer from the QE to bright plasmonic modes, plasmonic structure operates as a transmitting nano-antenna and consequently, the quantum efficiency of the system enhances. While in quenching regime, this energy transfer is occurring to dark plasmonic modes, resulting in quenching of the emission and fluorescence lifetime of the QE [6].

In this regards, we have designed and fabricated an array of plasmonic nano-disks in order to study their interactions with different types of QEs in visible spectral range. The LDS 750 fluorescent dye molecules with three different concentrations are embedded in PMMA polymer as the host medium. The designed nano-antennas are fabricated with different periods and diameters in order to investigate how the spectral overlap between nanodisks absorption and QEs emission spectra affects the efficiency of the PL enhancement process. Alongside creating an efficient spectral overlap, a thin layer of the dielectric layer between the plasmonic structures and the gain medium layer provides an effective spatial overlap. The interaction between the strong subwavelength localized field at the edges of the gold nano-disks and QEs enhances Purcell factor towards the modification of the fluorescence and decay time of QEs.

The performed comprehensive study can lead the scientific community to understand deeper the details of the exciton-plasmon interactions in hybrid systems. Moreover, this study opens an avenue towards practical applications for novel light sources such as core-shell quantum dots (QDs), diamond nitrogen vacancy (NV) centers and 2D hexagonal boron nitrite (h-BN) [7], which are the vital components of future quantum technologies.

2. Discussion

We designed 3×3 matrices of gold plasmonic nanostructures with three different periods of 340 nm, 380 nm, 420 nm and three different diameters of 140nm, 160 nm and 180 nm by using FDTD simulation method. Later we fabricated the designed nanodisks by applying standard EBL (electron beam lithography) method. As an example, a SEM image of one fabricated array of Au nano-disks is shown in Fig. 1.

Figure 1: A SEM image of the fabricated nanodisks on fused silica substrate with period of 420 nm and diameter of 140 nm.

The applied alteration in period and diameter creates the opportunity of sweeping the nano-antennas reflection/absorption spectra (Fig. 2). This provides us the opportunity for achieving the spectral overlaps with different efficiencies between the fluorescent dye molecules emission and the plasmonic nanostructures reflectance spectra. As it is evident from Fig. 2, the increase in diameter of nano-disks
and decrease in their periodicity lead to the shift of reflectance spectrum to the longer wavelengths and the enhancement of the reflection intensity.

Figure 2: The measured reflectance spectra of 3×3 matrices of gold plasmonic nanostructures with different periods and diameters.

The PL spectrum of embedded LDS 750 QEs in PMMA A2 dielectric medium appears around 680 nm. The homogeneously dispersed dye molecules in PMMA polymer with three different concentrations are spin-coated over the nano-antennas, creating a thin gain layer of 60 nm. The emission spectrum of the gain medium overlaps with different percentages with the reflectance spectra of the fabricated nano-antennas. Such varied spectral overlaps change the efficiency of the RET (Resonance Energy Transfer) process from gain material to plasmonic nano-antennas and consequently, alters the Purcell factor enhancement. We observe an effective spontaneous emission enhancement for those better spectral overlap cases, because of a strong RET between gain medium and plasmonic nano-disks. Fig. 3 presents the maximum spontaneous emission intensity of the LDS 750 dye molecules with concentration of 0.005% in the presence and the absence of the nano-disks with a particular period and diameter. The slope modification of the curves is the signature of the non-radiative RET occurring in hybrid system.

Figure 3: The maximum spontaneous emission intensity of the LDS 750 dye molecules with the concentration of 0.005% in the presence and the absence of the nano-disks with period and diameter of 420 nm and 140 nm, respectively.

The acquired decay time data, accompanied by the fluorescent lifetime imaging microscopy (FLIM) results are providing another evidences for the occurrence of the RET process among dye molecules and plasmonic nano-disks.

The existence of the emitter in close proximity of plasmonic nanostructure increases the optical density of states. According to Purcell effect, the radiative decay rate of the emitter increases because of the decrease in the modal volume, that is, the effective cavity where the mode is confined within [8]. The increase in radiative decay rate leads to a net increase in the emission intensity. Another definition for the observed PL enhancement is to consider metallic nano-disks as efficient antennas that out-couples the plasmons to the far field in a more efficient way, resulting in the boosting of the hybrid system emission.

3. Conclusions

Our experimental investigation proves the functionality of the designed nano-disks for spontaneous emission enhancement as a result of RET process between these nanostructures and fluorescent dye molecules. Such design has the potential for light boosting and lasing purposes by using other types of QEs such as QDs and 2D h-BNs layers and their flakes. Our comprehensive study assists us to design an efficient hybrid system towards PL enhancement applications in practical systems.

Abstract

In this work, a 10 $\mu$m × 10 $\mu$m infrared imaging pixel is proposed based on electrically small resonators. The novel pixel configuration is composed of eight split ring resonators electromagnetically coupled to two tapered transmission lines that are purposed to deliver the coupled electromagnetic power to a resistive sheet, representing a microbolometer. The proposed structure is simulated and the power absorption efficiency in the longwave infrared (8-12 $\mu$m) band is analyzed.

1. Introduction

An electrically small resonator-coupled detector configuration has been proposed for longwave infrared (8-12 $\mu$m) sensing in [1]. The proposed detector configuration advocated the possibility of using electrically small resonator-coupled sensors as alternatives to antenna-coupled detectors [2]-[4] for longwave infrared detection. Electrically small resonators are small-sized electromagnetic structures; they have achieved high absorption efficiencies in the microwave and terahertz bands [5, 6] when used in array configurations. Electrically small resonators, thus, can possibly achieve high absorption efficiencies in the infrared band; in addition, they can eventually be configured to be wavelength tunable and polarization agile, all of which supports their use as infrared imaging elements.

In this paper, a novel configuration of a 10 $\mu$m × 10 $\mu$m infrared imaging pixel is presented, based on electrically small resonator structures. The proposed pixel size is commensurate with current state of the art commercial infrared imaging pixel sizes. The pixel is made of eight metallic (gold, Au) split ring resonators (SRRs) suspended on a silicon dioxide ($SiO_2$) film having an underlying Au ground plane. The SRRs are purposed to absorb the incident infrared electromagnetic radiation and couple the absorbed power to two tapered transmission lines which in turn deliver the coupled power to a resistive sheet. The proposed configuration is simulated and optimized for maximum power absorption.

2. Geometrical Configuration

We propose a square shape arrangement composed of eight SRRs where they circulate two tapered transmission lines as seen in Fig. 1. The transmission lines have a very sharp tip directed inwardly to leaving a very narrow gap sets in the middle of the arrangement. Since the metallic materials in infrared frequency range are very lossy, choosing a proper metal is critical for device performance. We chose Au for the metallic structures and $SiO_2$ layer as a dielectric material. The gold layer has a conductivity $\sigma = 2.8 \times 10^9$ S/m, as measured in [7] and a thickness of 150 nm, while the silicon dioxide has a thickness $h = 1.5 \mu$m and dielectric constant $\epsilon_r = 4.84 + j0.097$. We intentionally maintain a square-like shape with a square side length = 8 $\mu$m to have an accurate pixel configuration. The outer ($l_1$) and inner ($l_2$) arm lengths of the SRR are 2 $\mu$m and 1.45 $\mu$m, respectively. The gap opening dimension ($g$) is 0.6 $\mu$m while the spacing between two SRRs in y-direction ($s$) is 0.65 $\mu$m.

The resistance of the resistive sheet can be varied during the simulation to determine the optimum resistance where impedance matching between the structure and the resistive sheet is achieved.
3. Discussion and Results

The structure basic mechanism is to expose it to a perpendicular direct infrared wave allowing the eight SRRs to be in excitation mode with a high build up voltage across their gaps. Each gap can virtually be presented as a voltage source, while the TMS lines, set in the middle of the arrangement, couple and focus the collected energy from each SRR to a centric focal point. The structure is designed to operate from 20-25 THz. We simulate the proposed configuration using ANSYS® HFSS™ numerical full-wave simulation tool.

To gain more insights about the structure mechanism, we simulated the electric field distribution on the metallic inclusions in resonance state as depicted in Fig. 2. The image shows that the excited electric fields intensify around the SRRs gaps and at the edges of the TMS lines alike. The aforementioned comparatively high electric fields indicate to energy transition from the SRRs to the TMS lines without any physical connection. The less-connectivity feature will allow more pixel arrangements without compromising a metallic loss in the structure.

The next step then to examine the structure performance was to numerically calculate the structure reflection and transmission coefficients as seen in Fig. 3. The plots apparently indicate that both transmission and reflection power are suppressed within the structure. More precisely, 73% of power impinging the structure dwell in the structure, which results in reasonably good power confinement. Afterwards, Equation 1 in [5] was applied to calculate the power absorption efficiency:

\[
\eta = \frac{P_{\text{received}}}{P_{\text{incident}}} \quad (1)
\]

where \( P_{\text{incident}} \) is defined as the available power at the surface of the structure and \( P_{\text{received}} \) is the power absorbed across the resistive sheet. Fig. 4 shows that the proposed geometry can absorb approximately 36% of the incident power at such high and lossy frequency. Different resistive load values were varied to check which resistance yields the highest absorption efficiency. One can say that the achieved efficiency is relatively small; however, better absorption efficiency can be realized by changing the structure’s orientation and its topology. Improving efficiency will be further studied in future research.

4. Conclusion

Special arrangement of eight electrically small resonators and two tapered microstrip lines are placed together to function as energy collector. The structure is designed and numerically simulated to examine its ability of infrared detection. An initial power absorption efficiency of 36% is achieved utilizing the proposed structure. The relatively low efficiency is attributed to the metallic losses and the gold low conductivity at such high frequency. Dramatic absorption efficiency improvement will be presented during the conference.

Abstract

The thermal behavior of a thermophotovoltaic system composed of a metallodielectric spectrally selective radiator at 1500 K and a GaSb photovoltaic cell is investigated. Using a coupled radiative, electrical and thermal model, we highlight that without a large convective heat transfer coefficient applied to the cell, the raise in temperature of the PV cell induces dramatic efficiency losses. We then investigate radiative cooling as a potential passive cooling solution.

1. Introduction

Thermophotovoltaics (TPV) is a promising technology for converting heat into electricity using a radiator emitting thermal radiation toward a low-bandgap photovoltaic (PV) cell. During the past years, many studies focused on tailoring the spectral emission of the radiator such that the energy of the emitted photons matches with the bandgap of the PV cell [1], in order to maximize conversion of photons into electron-hole pairs. However, the point of view of the PV cell was often neglected. In particular, the raise in temperature of the PV cell due to thermalization of high energy photons, absorption of photons with subbandgap energy and recombination losses inside the PV device can lead to dramatic losses in efficiency, as the performances of the junction decreases with the cell temperature. These thermal effects are a common issue in standard solar PV [2], where the incident solar radiative power is much lower than in thermophotovoltaics. This means that thermal losses in TPV can be expected to be extremely large. To highlight this, we simulate the behavior of a TPV system consisting of a 1D multilayer selective emitter made of W and HfO\textsubscript{2} and a p-on-n GaSb junction. Radiative heat transfer from the emitter to the cell, transport of electrical charges and recombinations inside the PV cell and variations of the cell temperature are accounted for. We also investigate radiative cooling as a potential cooling solution for TPV cells.

2. Modeling of the TPV system

Radiative heat transfer between the radiator and the PV cell is computed within the frame of fluctuational electrodynamics in conjunction with the S-matrix approach. The radiative power absorbed by the PV cell is then used to compute the local generation rate of electron-hole pairs, which is required to solve the minority carrier diffusion equation. The maximum electrical power output $P_{\text{max}}$ and the efficiency $\eta$ of the PV cell can then be calculated. The heat sources inside the PV cell $Q_{\text{PV}}$ are then calculated as

$$Q_{\text{PV}} = Q_{\text{abs}} - P_{\text{max}},$$

where $Q_{\text{abs}}$ is the radiative power absorbed by the PV cell. Convective heat transfer is considered to cool the PV device, and its power $Q_{c}$ is calculated as

$$Q_{c} = h_{c}(T_{c} - T_{\infty}).$$

Here, $h_{c}$ is a convective heat transfer coefficient, $T_{c}$ is the operating cell temperature and $T_{\infty}$ is the temperature of the cooling fluid (set at 300 K in this study). As an addition to the cooling system, we also consider radiative cooling as a passive thermal management solution. To evaluate the limits of the impact of radiative cooling on the system performances, we consider that the thermal emission of the radiative cooler $Q_{\text{rad}}$ is the one of a blackbody at the cell temperature, given by Stefan-Boltzmann law:

$$Q_{\text{rad}} = \sigma T_{c}^{4}.$$  

By solving a thermal balance equation, the temperature of the PV cell can be calculated. The calculation is then performed again with updated temperature-dependent properties of the PV cell until convergence of the temperature of the PV device. The outputs of the calculations are the system efficiency, maximum power-output and operating cell temperature.

3. Thermal behavior of the TPV system

The system under consideration is depicted in Fig. 1(a). A 1D multilayer W-HfO\textsubscript{2} spectrally selective radiator at 1500 K (similar to [3]) radiates thermal energy toward a GaSb pn-junction. At the rear of the junction, a gold layer is used as a backside reflector to recycle photons that have not been absorbed by the PV cell by reflecting them back to the radiator. A black surface is considered to act as a radiative cooler at the back of the cell, next to the gold layer. In Fig. 1(b), the spectral hemispherical emissivity and spectral emissive power of the selective radiator radiator are plotted. The designed radiator has high emissivity for photons with energy above the bandgap of the PV device, and low emissivity for subbandgap photons.

The spectral emissivity for subbandgap photons.
Using the model discussed in the previous section, the efficiency of the system and the operating cell temperature are calculated as a function of the heat transfer coefficient applied to the PV cell. The results are displayed in Fig. 2, when considering radiative cooling or not. It is observed that to maintain the cell temperature near the ambient, a large heat transfer coefficient must be applied to the PV cell. These values are much larger than what can be obtained with passive convection. For values of $h_c$ below 100 $\text{W.m}^{-2}.\text{K}^{-1}$, due to the extremely large values of the cell temperature, the efficiency of the TPV system reaches values close to 0. As expected, due to the large heat flux emitted by the radiator at 1500 K, thermal effect arises as a major issue in TPV. The impact of radiative cooling can be observed by comparing the results for the two cases, with and without radiative cooling. At high values of $h_c$, radiative cooling has no significant impact on the system efficiency, because the convective heat power is much larger than the radiative one. However, when the values of $h_c$ get lower, radiative cooling can decrease the cell temperature and therefore increase the system efficiency [4]. However, this occurs in the regime where the efficiency has already dropped significantly from its value at 300 K. Therefore, even if radiative cooling has a positive impact on the system performances, it is not a suitable solution to reach the optimal efficiency of the TPV system.

4. Conclusions

We have investigated the performances of a TPV system composed of a spectrally selective radiator and a GaSb PV cell. Results have highlighted that even a spectrally selective radiator has a large emissive power that induce high cell temperatures and low efficiencies if passive cooling system are considered. Radiative cooling is not a suitable solution to reach the optimal system efficiency. Therefore, thermal management of TPV devices should be issued in the design of TPV systems.

Abstract
This paper presents fabrication results showing large area laser patterning of molybdenum for use as a solar thermal absorber. Measured solar absorptance results show good performance and the temperature measurements of the samples show promise for solar thermal applications.

1. Introduction
Solar energy converters based on thermal processes require the maximum incident solar energy to be absorbed and converted into heat. Ideal solar absorbers therefore need to have excellent selective surface properties, absorbing all incident electromagnetic energy whilst minimising re-radiation[1]. It has been shown through electromagnetic modelling that surface nanopatterning can dramatically alter the optical response of an interface and that it can be tailored to enhance broadband absorption across the solar spectrum[2][3]. This paper looks at 2D Molybdenum microstructures that can be achieved over large areas using low cost laser processing and measure the reflectance and subsequent temperature rise achieved using a solar simulator both in air and simulated under vacuum conditions.

2. Fabrication and Optical characterization
As shown in Table 1, 10x10mm, 0.25mm thickness molybdenum samples have been produced by single pulse laser firing with different periods (10, 20 and 30µm) and at different laser energy (20%=28.6 µJ/pulse, 30%=38.3 µJ/pulse, 40%=48.1 µJ/pulse). Figure 1 shows an SEM of the surface the molybdenum sample laser milled at 28.6 µJ/pulse with a period of 30µm. Figure 2 shows the measured absorptivity for samples with the same period but produced at different laser powers.

3. Thermal Measurements
Samples were illuminated using a focused solar simulator and temperature recorded over time using a thermocouple acting as the sample stage where samples were fixed on two glass slides. Figure 3 shows the temperature rise of both COMSOL modelled data and measurement for one of the samples. Figure 4 shows the measurement of the highest temperatures reached by ten different samples under 500s solar simulator illumination. The samples produced at higher laser energy (larger and deeper holes) show higher absorptivity in the visible and near IR range.
Figure 3: Simulated and measured temperature rise of 1x1cm, 0.25mm thick molybdenum square with patterning (30μm period and 40% laser energy) and without patterning under 500s solar illumination.

Figure 4: Measurement of the highest temperatures reached by ten different samples under 500s solar simulator illumination.

In order to minimise the thermal conduction and convection loss of the sample, we designed a vacuum device for mounting the sample as shown in Figure 5. The sample is fixed on a round quartz holder with a cut-out in the centre. The conduction loss is minimised since quartz glass is an excellent thermal insulator. A K-type bare wire thermocouple is attached to the back side of the sample and its two ends connect to two copper tube terminals. The device is pumped into vacuum through one copper tube. Figure 6 shows the comsol model for sample heating.

Figure 5: Vacuum device fixed on an aluminium base.

Figure 6: Quartz holder for mounting the sample.

Figure 7: Simulated temperature rises of patterned molybdenum sample in air and vacuum.

Figure 7 shows the Comsol simulated temperature rises of patterned molybdenum sample in air and under vacuum conditions. It shows that the achieved temperature in vacuum is predicted to be nearly double to the temperature in air.

4. Conclusions

This paper has presented the optical absorption of micro-patterned molybdenum produced by laser etching. It is shown that this technique dramatically increases the absorptivity of molybdenum across 400-1000 nm which is ideal for solar thermal applications. Simulation results of the sample under vacuum condition shows that much higher temperatures can be achieved. We will verify these results with measurements and further increase the light intensity on the sample. This is very promising for solar thermal applications which operates at >500 degC.

Optical properties of self-assembled, thin-walled nanotube TiO$_2$ arrays

Christin David

Madrid Institute for Advanced Studies in Nanoscience (IMDEA Nanoscience), Madrid, Spain
E-mail: christin.david@imdea.org

Abstract
Optical properties of two-dimensional arrays of hollow TiO$_2$ nanotubes are investigated. Their straightforward fabrication via electrochemical anodization allows precise tailoring of geometry and material properties. We calculate achievable field enhancement, including under additional charge doping occurring during fabrication, and the short circuit current for a range of configurations. For our simulations, we employ the Rigorous Coupled Wave Analysis to perform field enhancement studies of the optical response of arrays of thin-walled nanotubes relative to the bare Ti foil substrate.

1. Introduction
Two-dimensional arrays of hollow nanotubes (NTs) made of TiO$_2$ are a promising platform for sensing [1], spectroscopy [2, 3], nanosized test tubes in biomedicine [4] and light harvesting applications. The electrochemical growth TiO$_2$ nanotubes from a Ti foil allows studying self-assembled nanotube arrays [5, 6]. Annealed crystalline TiO$_2$ NTs show an increased doping level allowing to further improve electron transfer efficiency for bi-electrochemistry applications [3]. It was demonstrated that the additional charge carriers can yield high field enhancement in densely packed, thin-walled TiO$_2$ NT arrays, independent from the chemical environment [2].

We take a detailed look at the optical properties of regular TiO$_2$ NT arrays with an emphasis on achievable field enhancement and photocurrent gain in semiconductor substrates including additional charge carrier doping that occurs during fabrication. [2]. For our calculations, we employ the Rigorous Coupled Wave Analysis (RCWA) to perform field enhancement studies of the optical response of arrays of thin-walled nanotubes relative to the bare Ti foil substrate.

From an optical perspective, the nanotubular geometry adds directionality improving photon scattering towards a photo-active region [1]. Self-assembled nanostructures are favourable with view to their fabrication costs, in particular, in highly competitive industries such as solar cell technology. [7]

2. Discussion
The possible enhancement of reaction or transport rates due to a large surface area, see Fig. 1, strong electron confinement and short diffusion paths makes these structures highly interesting for (photo-) catalysis [8, 9, 10] and photovoltaics (PV) [11, 12, 1, 13, 14]. In addition, the high refractive index (RI) of TiO$_2$ makes this an interesting material for a broad range of further photonic and hybrid applications, i.e. exploiting plasmon-assisted enhancement effects by combining with metal nanoparticles [15]. These are typically used to enhance intrinsically low quantum efficiencies, e.g. in rare earth transition rates [14], and to sensitize the UV-active TiO$_2$ towards visible light [9]. The nanotubular geometry adds directionality to incoming light improving charge transfer towards an electrode or photon scattering towards a photo-active region [1, 13]. Self-assembled nanostructures are favourable with view to their fabrication costs, in particular, in a highly competitive industry such as solar cell technology. [7]

3. Conclusions
Fabricated NT arrays can show a high degree of order and regularity which allows studying and optimizing their properties in direct comparison with available modeling tools which this work contributes to. While typically grown on Ti substrates or alloys, TiO$_2$ NTs can be produced as membranes through a lift-off process [6]. This technique allows em-
employing them on different substrates such as Si or GaAs for solar cells. A further advantage for use in bionanotechnology, photocatalysis and related fields is the biocompatibility of the material [3, 2], which makes an additional coating of the obtained oxide unnecessary.

Abstract

We report on the possibility of enhancing the energy transfer from colloidal single up-converting NaYF4 nanocrystals doped with rare-earth ions to poly(3-hexylthiophene) (P3HT) polymer by plasmon excitation in a single silver nanowire. Based on such an approach we want to demonstrate how to sensitize organic solar cells to the infrared optical spectrum.

1. Introduction

Up-converting nanomaterials are promising candidates for sensitizing solar cells to infrared radiation [1]. Rare-earth doped materials, due to up-conversion process, absorb infrared radiation and convert into visible. It has been demonstrated that the presence of up-converting nanoparticles increases the efficiency of photovoltaic devices [2]. Additionally, relatively low efficiency of the up-conversion process can be improved by plasmonic excitation localized within metallic nanoparticles [3]. For enhancing the infrared optical response of organic polymer we use a single silver nanowire.

2. Materials & methods

Hybrid nanostructure studied in this work contains a single silver nanowire surrounded with Er and Yb doped 20-nm-large up-converting nanocrystals located in its vicinity. On top of such a structure a drop of P3HT polymer was applied in a controlled manner. Up-converted emission of nanocrystals excited at 980 nm (Fig. 1, black line) spectrally overlaps with the absorption of P3HT (Fig. 1, blue line), and with the broad extinction spectrum of silver nanowires (Fig. 1, green line).

To examine the optical properties of the hybrid nanostructure, we used a confocal up-conversion fluorescence microscope with a sample mounted on a piezoelectric stage. Emission of the nanocrystals was extracted using appropriate bandpass filters (540/40 nm, 650/30 nm, Chroma), while the emergence of the P3HT fluorescence was probed with a 720/10 nm bandpass filter.

![Fig. 1](image1.png)

**Fig. 1** Comparison of optical spectra of: NaYF4:Er3+/Yb3+ nanocrystals (black line), emission of P3HT polymer for excitation 532 nm (orange line), absorbance of the P3HT polymer (blue line) and excitation of AgNWs (green line).

3. Results

A unique micro-deposition system allowed to place a glass capillary with P3HT polymer over the selected single nanowire, as shown in Fig. 2(a)-(b). To control the volume of P3HT polymer, the tip of capillary was elongated and had an outlet with a diameter of approximately 500 nm. Backscattered light intensity map of the selected single nanowire is shown in Fig. 2(c).

![Fig. 2](image2.png)

**Fig. 2** P3HT polymer solution in a capillary (a), picture of the selected single nanowire (b), the silver nanowire imaged using backscattered laser light (c).
By probing both steady-state and time-resolved properties of individual up-converting nanocrystals excited with infra-red laser and located in vicinity of single nanowire, before (Fig. 3(a)) and after (Fig. 3(b)) drop-casting P3HT polymer, we demonstrated that upon up-conversion to the visible spectral range the energy is not only efficiently transferred from the nanocrystals to P3HT polymer, but this effect is also enhanced by the plasmon excitations in the single silver nanowire.

Fig. 3 Maps of luminescence intensities for the hybrid nanostructures: NaYF₄:Er³⁺/Yb³⁺ + AgNW and NaYF₄: Er³⁺/Yb³⁺ + AgNW + P3HT obtained for 980 nm excitation, (a)-(b) – green emission of nanocrystals (540/40 nm).

Time-resolved measurement shows significant shortening of the luminescence lifetime of selected nanocrystal (green circle, Fig. 3) in the vicinity of the single nanowire and far from nanowire (blue circle, Fig. 3) after drop-casting P3HT polymer, what is presented in Fig. 4.

Fig. 4 Normalized luminescence decays for 540 nm emission for the single placed close to the nanowire (green) and for the reference (blue). Black line – emission transient measured for the same nanocrystals as green before covering the sample with a drop of P3HT polymer.

4. Conclusions

The obtained results prove that by proper fabrication of a hybrid nanostructure, where the interaction can be optimized, it is possible to sensitize the conductive polymers to the infrared radiation. These results are important for improving the spectral response of organic bulk heterojunction solar cells towards infrared region.

Abstract

We describe the fabrication of TiO$_2$-plasmonic hybrid nanocapsules with photocatalytic features. These hybrid structures hold a number of outstanding properties that make them valuable photocatalysts in biological media: (i) they can be excited with NIR radiation given the plasmon-induced activation of the semiconductor; (ii) the mesoporous nature of the silica shell surrounding the active species endows them with size selective capabilities and (iii) the production of ROS is limited to the inner space within the capsules, avoiding therefore any damage to the surrounding biological tissues.

1. Introduction

Titanium dioxide (TiO$_2$) stands out among the inorganic semiconductors due to its high abundance, low cost, chemical stability and unique photochemical and photoelectrochemical properties.1 Actually, the development of TiO$_2$-based photocatalysts has recently experienced an important growth, expanding the applicability of these materials in fields such as the production of renewable fuels [1], water remediation [2], or the formation of self-cleaning surfaces [3], among others. The major drawback limiting the applicability of TiO$_2$ in a biological context comes from its wide bandgap (3.2 eV), feature that restricts the impressive characteristics of this material to the ultraviolet (UV) segment of the solar radiation spectrum. Along these lines, the use of highly energetic photons is known to produce adverse effects to biological tissues due to the formation of reactive oxygen species (ROS) such as O$_2^\cdot$-, H$_2$O$_2$ or HO$^\cdot$, small molecules that produce oxidative stress-related phenomena like lipid peroxidation, enzymatic deactivation or DNA damage that may disrupt important intracellular processes and eventually lead to cell apoptosis [4,5]. Thus, the development of TiO$_2$-based nanomaterials capable of holding a high photocatalytic activities in biological environments while presenting low cytotoxicity under irradiation remains a task of paramount importance. In that sense, near-infrared (NIR) light-responsive systems are especially attractive from a biological point of view, owing to their deep penetration capabilities. In this manner, the use of anisotropic plasmonic nanoparticles as photosensitizing agents would ensure that the main absorption contribution of the hybrid is kept in the first biological transparency window (650-950 nm) of the NIR range, where low scattering and energy absorption provide with optimal tissue transmission and maximum radiation penetration [6]. In this vein, the development of TiO$_2$-plasmonic hybrids that could provide controlled responses in real biological settings would represent a very significant scientific advance. Moreover, and in opposition to those studies in which TiO$_2$ is combined with upconverting (UC) materials [7,8], the aforementioned composites do not lead to the formation of UV photons throughout the photosensitization process, thus excluding any possible cytotoxicity issues.

2. Discussion

The work is focused in the development of a novel nanoreactor capable of overcoming the limitations that hamper the study and application of TiO$_2$-based photocatalysts in a biological context. In this manner, hollow mesoporous silica nanocapsules whose internal walls have been functionalized with TiO$_2$ nanoparticles and Au nanorods (Au-TiO$_2$NCs) have been synthesized (figure 1), creating a novel architecture that presents a number of characteristics that make it an ideal candidate for the applications mentioned above. The morphology of the hybrid nanostructure and the chemical composition of its outermost shell are two characteristics of major importance for the correct design of a final composite with the desired properties and functionalities. In a first set of experiments, it has been demonstrated the ability of these composites to selectively target specific molecules depending on their size. The different degradation obtained show that the molecular diffusion through the mesoporous silica shell is essential for an efficient degradation of the chosen molecule.
On the other hand, it has been studied the photocatalytic activity of the Au-TiO\(_2\)NCs under NIR irradiation. This experiment also excludes the direct photosensitization of TiO\(_2\) by RhB as a possible photodegradation mechanism under visible light that could interfere with the plasmon induced photosensitization of the semiconductor.

A preliminary study on the photocatalytic features of the Au-TiO\(_2\)NCs in a biological context has been performed. In order to do this the intracellular degradation of RhB in Vero cell culture and in the presence of the hybrid capsules has been studied under irradiation with a NIR laser (785 nm). In this manner, we have observed RhB molecules that had diffused within the internal cavity of the nanocapsules can be degraded given their interaction with the ROS created during the photoexcitation process.

### 3. Conclusions

In summary, we have successfully fabricated a novel TiO\(_2\)-plasmonic hybrid nanocapsule where the porosity of silica shell endows this nanoreactor with an unprecedented control over the reactivity of the photoactive components while providing them with an improved stability. Moreover, preliminary results show the ability of these nanohybrids to remain catalytically active in biological environments. Interestingly, no sign of cell degradation could be observed for short irradiation times, highlighting the possible suitability of this material as a valuable theranostic agent.

Abstract

Transmission characteristics of a mid-infrared spectral filter are presented for a device based on metal films with resonant nano-cavities filled with high-index dielectrics. These resonances resemble those in Fabry-Perot resonators and can yield high transmission with a narrow bandwidth. Importantly, the cavity slit resonance is decoupled from the plasmonic grating resonance, resulting in angular insensitivity for polarized light up to 60 degree incidence.

1. Introduction

Optical transmission filters operating in the mid-infrared are useful for hyperspectral imaging, remote chemical sensing, infrared countermeasures, and high sensitivity detectors. A desirable filter would be easy to integrate with existing photonic devices and offer a wide field of view, requiring angular insensitivity. Sharp resonances have been achieved through metal-dielectric layered coatings, as well as structures involving coupling to surface plasmon-polaritons [1]. While these structures provide great flexibility in designing the transmission characteristics, they can be difficult to integrate with photonic devices and are inherently angle-dependent. Metallic grating-based slit structures show Fabry-Perot resonances associated with modes propagating in the film voids in the direction orthogonal to the plane of the film [2], which can be angle-independent if no surface excitations are involved [3]. If these gratings are designed with a sufficiently small period, the angle-dependent grating resonance will be decoupled from the slit resonance, resulting in an angular independent transmission filter. Such a filter has been proposed for the visible spectrum which has transmission peaks narrow enough to act as a color filter for LCD displays [4].

Here we investigate a one-dimensional array of metallic nano-cavities optimized for mid-infrared transmission. The cavities are filled with a high-index medium to enhance light confinement and keep the thickness small. The cavities can be arranged periodically to cover a large area, although the periodicity is decoupled from the slit resonance; each individual cavity is a filter of its own. For TM polarized light, these filters have been configured to produce a sharp resonance around 8.6 $\mu$m and are angle independent up to 60\degree. The angular independence is desirable for display and imaging applications requiring a wide field of view.

2. Design and Fabrication

The structure consists of a metal grating whose cavities are filled with a high index material (see Figure 1). The substrate is low index and highly transparent in the mid-IR and long wave-IR. The cavities must be filled completely, and the surface must have a small roughness to achieve a high Q factor of the resonance. This structure is polarization-dependent; TM polarized light will resonate in the dielectric-filled cavity. This acts like a plasmonic gap resonance, with the system being the subwavelength dielectric core between metallic reflectors. The modal index, determined by the optical constants of the materials, will affect the resonance position. Optical losses in the metal will limit the resonant transmission. However, the origin of these resonances is not plasmonic in nature--in the case of a perfect conductor the plasmonic gap mode turns into a transmission line mode in a slit.

Figure 1. (a) Diagram of the device structure, (b) SEM cross sectional image taken after etch and metal evaporation.

The structure has been designed for mid-IR resonance and is 1 $\mu$m thick with a slit width of 0.5 $\mu$m and a periodicity of 2 $\mu$m. Barium fluoride is the chosen substrate, which is 90% transparent up to 12 $\mu$m and has an index of $n=1.4$. The metal chosen is silver and the dielectric is germanium, which has an index of about 4.
The sequence of processing is actually the opposite of the prior explanation; dielectric gratings are fabricated first and subsequently filled in with metal. Germanium is deposited onto a barium fluoride substrate, and is patterned with the grating structure via deep-UV photolithography. An anisotropic reactive ion etch (RIE) leaves only the germanium grating with nearly vertical sidewalls. Silver is deposited by e-beam evaporation in a tilted configuration to fill in the space between the dielectric gratings. Figure 1b shows a cross-sectional scanning electron microscope (SEM) image of the fabricated grating structure. The transmission spectra for the filters were measured using a Bruker FTIR with a reflecting microscope objective to narrow the incident beam to a small section of the patterned material. Consequently, the incident light on the sample is not parallel but has a light cone of about 24° which excludes normal incidence. The sample is tilted with respect to normal incidence of this light cone, and for simplicity the sample tilt angles are reported. Transmittance is reported into the barium fluoride substrate; therefore a bare BaF₂ substrate is used as the reference material.

3. Results

Figure 2 shows results for the proposed design. Simulations locate the fundamental TM mode at 8.6 μm, while the second harmonic is much smaller around 4.3 μm. Hence, the fundamental mode is largely isolated, providing a clean transmission line. There is little change in the transmitted intensity and resonant wavelength between light at normal incidence up to 60° incidence.

Experimental data show a resonance with over 90% transmittance which is angle invariant up to 60° angle of incidence. The resonance deviates from the simulation in a large blue shift down to 6.1 μm. The full width half maximum of this resonance is extrapolated to be approximately 0.7 μm, similar to the simulation results; however the apparent transmission width is artificially higher due to overlapping resonances at 6.6 μm, which appears as a shoulder on the fundamental peak, and a broad feature around 7.3 μm. The change in resonant wavelength, as well as the additional resonant peaks, is likely caused by insufficient filling of the gaps between the germanium pillars by the deposited silver. The SEM image of the structure in Figure 1b shows that the metal is not completely rectangular but rather slightly trapezoidal, which produces small voids between the metal and dielectric. The dielectric therefore is no longer simply germanium but rather an effective medium of germanium and air, which has a reduced permittivity. Furthermore, the size of this air gap is inconsistent across multiple lines of the grating, producing an array of slightly different effective media. Altering the simulated structure to include an air gap of only 10 nm on either side of the metal produces a 1 μm blue-shift, while an air gap of 50 nm on either side produces a blue-shift of almost 3 μm from the fundamental 8.6 μm resonance. Refining the fabrication process to reduce the air gap and increase uniformity should result in transmission resonances closer to the design.

4. Conclusions

The experimental results show angular insensitive narrow band transmission similar to that suggested by the simulation. Multiple resonances were observed outside the reported spectral range for both TM and TE polarizations which also closely resembles the simulation results. Importantly, the location of the fundamental resonance does not shift with increased angle of incidence, and the resonance remains strong. Transmission characteristics should improve with a more consistent fabrication process that addresses the air gap between the metal and dielectric.

Abstract

We investigate, both experimentally and with computational modeling, the coupling of gap plasmon modes and lattice plasmon modes in metal-dielectric-metal structures in the mid-wave infrared. Coupling between these modes is observed due to the asymmetric Fano-like lineshape at the resonant crossings both in finite-difference time-domain simulations and angle dependent spectra.

1. Introduction

Metal-dielectric-metal (MDM) structures have been developed for enhancement of single emitters \[1,2\] and for perfect absorbers for sensing \[3\] utilizing the gap plasmon mode. Recently, by integrating epsilon-near-zero (ENZ) films a flat-top, wideband perfect absorber has been demonstrated \[4\] as well as strong coupling between the gap plasmon mode and the ENZ mode \[5\]. The lattice plasmon resonance has been investigated in 1D nanogratings recently for the possibilities of light emission modification \[6\]. Lattice plasmon resonances have also been utilized in plasmonic all-optical modulation \[7\]. In this work the coupling between the lattice plasmon mode and the gap plasmon mode of a MDM structure is investigated in the mid-wave infrared (MWIR).

2. Modeling, Fabrication, and Measurement

The nominal design of the MDM structure consists of a gold ground plane, a 50nm SiO\textsubscript{2} dielectric spacer layer, and a gold grating with width (period) of 1270nm (3330nm) and a height of 60nm as depicted in Fig. 1.

2.1. Computational Modeling

The MDM structure is modeled using two-dimensional finite-difference time-domain (FDTD) technique implemented in a commercial software package (Lumerical FDTD). A mesh override in the dielectric region of the structure is used to achieve 5nm (10nm) meshing in directions parallel (orthogonal) to the surface normal of the structure. The broadband fixed angle source technique (BFAST) and corresponding boundary conditions are used requiring only a parameter sweep over the angle of incidence, \(\theta\), with transverse magnetic (TM) polarization. Permittivities built-in the software are used for the materials in the structure. The dispersion of the lattice plasmon and gap plasmon modes as modeled are shown in Fig. 2 with the gap plasmon displaying a small angle dependence while the lattice plasmon mode shifts from \(\lambda \sim 3.3\mu m\) at \(\theta = 0^\circ\) to \(\lambda \sim 5.9\mu m\) at \(\theta = 60^\circ\). The coupling between the modes occurs at \(\lambda \sim 5.5\mu m\) at \(\theta \sim 40^\circ\).

Figure 1: (Top) Diagram of TM polarized light on MDM grating structure. (Bottom Left) Cross-section of MDM structure and (Bottom Right) plan-view SEM image of fabricated structure, 10,000X.

Figure 2: Simulated dispersion profile of the gap and lattice plasmon resonance of the MDM structure. (Inset) Spectral profile at the resonant crossing.
2.2. Sample Fabrication

The 380nm gold ground plane with 20nm titanium for adhesion is deposited by electron beam deposition on a silicon wafer. Subsequently PECVD is used to deposit the SiO₂ dielectric spacer layer. Using a standard lift-off technique, electron beam lithography (EBL), and electron beam deposition the 8x8mm metallic grating structure was fabricated. The EBL of a pattern this size required stitching of 500x500µm patterned regions. A scanning electron microscope (SEM) image in Fig. 1 bottom right shows a plan-view of a fabricated structure at 10kX magnification.

2.3. Experimental Measurements

Spectral scans at a constant angle of incidence as well as angle scans at a constant wavelength were done using a dual-angle goniometer and a tunable quantum cascade laser (QCL) module housing four QCLs (Daylight Solutions MIRCat). The wavelength range covered by this module is 3.96 to 5.96µm. The module is pulsed at a 100kHz frequency with 500ns pulses. Detection of the specular reflection from the sample is with a HgCdTe detector and a high-frequency lock-in amplifier (Zurich Instruments UHFLI). Sample spectra are normalized by a protected gold mirror. Normal incidence spectra are collected with a FTIR microscope (Bruker Vertex 80v and Hyperion microscope).

Figure 3: Simulated (solid) and experimental (open) spectral resonance locations of MDM structure relative to the gap plasmon resonance.

3. Discussion

Both computational modeling and experimental measurements display the resonant crossing of the lattice plasmon and gap plasmon modes. Due to fabrication imperfections the resonant wavelengths are about 0.4µm off. However, if we look at the spectral positions of the lattice plasmon relative to the gap plasmon mode, Fig. 3, the observed behavior is in good agreement for simulation and experiment. Both show resonant crossing between 35° and 40°, minimal gap plasmon angular dependence, comparable lattice plasmon dispersion, and exhibit Fano-like lineshapes at the resonant crossing. The role additional parameters play in controlling the coupling between these resonances will be discussed. This will include the dielectric complex permittivity, grating height, and role of a dielectric superstrate. The resonant coupling between the gap and lattice plasmon could have applications in emission enhancement and sensing techniques.

4. Conclusions

Resonant crossing and asymmetric Fano-like lineshapes due to the coupling of the gap plasmon and lattice plasmon resonances of the MDM structure are observed both in FDTD simulations and experimentally.

Abstract

We investigate two kinds of electromagnetically-induced-transparency-like (EIT-like) effect induced by hybrid state of Tamm and localized Plasmon-Polaritons in the region of infrared. The EIT-like effects are corresponding to two mechanism, which induced by near-field coupling and standing-wave-field coupling, respectively.

Keywords—Plasmonics, Electromagnetically induced transparency, metamaterials

1. Introduction

Electromagnetically induced transparency (EIT) is a quantum coherence effect observed in three-level atomic systems in which a beam of light can find its way through the medium with almost no absorption [1]. Recently, some studies have shown that the EIT-like effect can be achieved using classical structures, such as waveguide system [2], multi-layer fish scales [3], coupled metal-stripe antennas [4], and planar metamaterials [5]. In those structures, EIT-like effect arises from the coupling effects in the near field interaction between “bright” and “dark” states. The EIT-like effect as a novel way of optical quantum control has a profound influence on the field of optics. More interestingly, in 2012, R’ohlsberger et al. proposed a new mechanism to realize an EIT-like effect by using two ensembles of identical two-level nuclei embedded in a resonant cavity [6].

In this scheme, the EIT-like effect is induced by coupling between the bright and dark nuclei via standing wave field in a cavity. Above all, EIT-like effect can be generated based on the near-field coupling or standing-wave-field coupling. Theoretical and experimental studies on these two kinds of EIT-like phenomena have been done in microwave, terahertz, as well as infrared spectra. For example, very recently, the EIT-like effect induced by standing wave field in cavity has been experimentally demonstrated in microwave region [7].

In this work, two different EIT-like effects induced by hybrid state of Tamm Plasmon-Polaritons (TPPs) and LPPs in the region of infrared are investigated, simultaneously. Here, we use metal nanowire pairs that support Localized Plasmon-Polaritons(LPPs) as two levels “atoms”, which can couple to TPPs field. Interestingly, the hybrid state of TPPs and LPPs can induce EIT-like effect, which strongly dependent on the sequence of the “dark atom” and “bright atom”. In addition, we obtain the other EIT-like effect induced by near-field interaction.

2. Two kinds of EIT-like effect

2.1. EIT-like effect induced by standing -wave-field coupling

Fig. 1. Simulated reflectance spectra and electric field distribution for EIT-like effect induced by standing -wave-field coupling.

Figures 1 shows the simulated reflectance spectra and electric field distribution of different hybrid configurations. The result revealed the peculiar feature that EIT occurs only if the two “atoms” are arranged in a sequence in which the probing electromagnetic wave first reaches the “dark atom” and then the “bright atom”. In contrast, the EIT cannot occur if the “atoms” are placed in reverse order (bright, dark). In Figs. 1(b), the field distribution at the resonance frequency 196.8THz shows that the LPPs is not excited because of the very small amplitude of the standing wave at this site, and it can be described as a dark atom. Figures 1(c) present the spectra and field distribution for the situation where the nanowire is placed at an antinode where the E field reaches a maximum for the TPPs field. We find that the reflection spectrum splits into two dips. In Figs. 1(d), the
two nanowires are arranged in the sequence node-antinode. In this case, an EIT-like reflection dip appears at the resonance frequency. The EIT-like effect disappears in the case of Figs. 1(e), where the two nanowires are arranged in the reverse sequence antinode-node. From the field distribution in Figs. 1(b)-(d), we can see that the electromagnetic energy transfers from “bright state” to “dark state”. That is, the “bright” and “dark” atoms can change energy through the standing-wave-field. This is a distinct feature of the EIT effect.

Interestingly, the simulation result revealed the peculiar feature that EIT occurs only when the two “atoms” are arranged in a sequence in which the electromagnetic wave first reaches the “dark atom” and then “bright atom”. In contrast, if the “atoms” are placed in reverse order (bright, dark), no EIT-effect is observed. That is, the hybrid state of TPPs and LPPs can induce EIT-like effect, which strongly dependent on the sequence of the “dark atom” and “bright atom”.

2.2. EIT-like effect induced by near-field coupling

Figures 2 shows the simulated reflectance spectra and field distribution of different hybrid configurations, which demonstrate the EIT-like effect induced by near-field coupling. The configurations of EIT-like reflectance spectra vary gradually as the distance between “bright state” and “dark state” changed. In Figs. 2(a), the field distribution at the resonance frequency 196.8 THz shows that the LPPs is not excited at the node of the standing wave, and it can be described as a “dark atom”. Figures 2(b) present the spectra and field distribution for the situation where the nanowire is placed at a non-node for the TPPs field. We also find that the reflectance spectrum splits into two dips, and it can be described as a “bright atom”. As shown in Figs. 2(c)-(e), we can clearly see that coupling is strengthened and EIT-like effect is increasingly apparent. In short, we have achieved two EIT-like effects based on the hybrid state of TPPs and LPPs in the region of infrared.

3. Conclusions

In summary, we numerically investigated the EIT-like effect induced by hybrid state of TPPs nd LPPs in the region of Infrared. The EIT-like effects are corresponding to two mechanisms, which induced by near-field coupling and standing-wave-field coupling, respectively. The “bright” and “dark” states are excited by adjusting the position of the nanowire pair in the Bragg reflector.

Abstract
Implementation of resonant plasmonic semiconductor-based detectors of terahertz (THz) radiation represents a major challenge due to high requirements on carrier mobility. We demonstrate the resonant plasmon-assisted THz detection in bilayer graphene/boron nitride heterostructures. Due to gate-voltage tuning of plasmon resonance, the reported devices can be used as on-chip THz spectrometers. We show that photovoltage spectroscopy offers a convenient tool to study plasmon spectra and damping in 2d channels, and use it to uncover novel plasmon modes in graphene Moiré superlattices.

1. Introduction
Graphene-based photodetectors offer ultrafast response but suffer from weak absorption of electromagnetic radiation by a single carbon sheet. This problem can be circumvented with excitation of graphene plasmons offering voltage tuning of resonance in a broad range of frequencies. Extending the graphene plasmonics down to terahertz (THz) range represents a significant challenge as the quality factor of plasma resonance scales linearly with frequency. For this reason, efficient excitation of THz plasmons requires ultra-long electron momentum relaxation time, and all previous attempts of plasmon-aided THz detection in graphene were unsuccessful [1-3].

2. Resonant terahertz detection in graphene transistor
In this paper, we demonstrate the long sought-for resonant plasmon assisted detection of terahertz radiation in graphene field-effect transistors (FETs) [4]. The FET channel was made of graphene bilayer encapsulated between boron nitride crystals, its source and gate terminals were connected to a broadband THz antenna, while the rectified photovoltage was read out between source and drain. In contrast to the previous studies where the photovoltage was proportional to the FET transconductance, our measurements reveal a strong oscillatory modulation of photovoltage vs. gate-controlled carrier density (Fig. 1a). We argue that the FET channel acts as a Fabry-Perot cavity for graphene plasmons, and the maxima of photoresponse occur once the cavity hosts an odd number of plasmon quarter-wavelengths [5].

Figure 1: (a) Measured gate voltage dependence of detector responsivity at \( T = 10 \) K anf \( f = 2 \) THz. Top inset: magnified view of plasmon resonances for electron channel doping. Bottom inset: responsivity at 77 K (b) Positions of plasmon resonances on the voltage scale vs order number of plasmon modes (dots) compared with theory of gated 2d plasmons (lines). No fitting parameters are used. Inset: photograph of THz antenna with FET channel in its focus. Scale bar is 10 mkm.
We show that, independent of microscopic terahertz rectification mechanism, the responsivity $R_v$ can be presented by the Fabry-Perot-type equation

$$R_v = \frac{R_0(\omega, V_G)}{1 - r_s r_d e^{2i(\omega, V_G) L}},$$

(1)

where $R_0(\omega, V_G)$ is a smooth (non-resonant) function of frequency $\omega$ and gate voltage $V_G$, while the resonant denominator is responsible for enhancement of responsivity under plasmonic resonance. Above, $q(\omega, V_G)$ is the plasmon wave vector, $L$ is the source-to-drain distance, $r_s$ and $r_d$ are the reflection coefficients of plasma wave from source and drain terminals, respectively. For input signal fed at the source and output signal read at the drain, the reflection coefficients satisfy $r_s r_d = -1$, and the responsivity maxima occur at

$$L = \frac{\lambda_p}{4} (2k + 1),$$

(2)

where $\lambda_p$ is the plasmon wavelength and $k$ is an integer.

The comparison of resonance positions with the theory of gated two-dimensional plasmons supports the plasmonic origin of enhanced responsivity (Fig. 1b). We find the fingerprints of plasmons in photoresponse up to liquid nitrogen temperature at 2 THz frequency, and down to 400 GHz frequency at $T = 10$ K.

3. Photovoltage-based spectroscopy of 2d plasmons

Most previous studies of plasmons in 2d systems were performed using scanning near-field microscopy [6] and transmission spectroscopy of patterned 2d layers [7]. We show that spectroscopy of photovoltage in graphene-based FET offers an alternative and simpler tool to study the dispersion and damping of plasmons.

Indeed, known the ‘quantization rule’ for plasmons (2), one readily extracts the density-dependent plasmon wavelength. By performing the Lorentz fit to each individual resonant peak, one extracts the density-dependent plasmon lifetime. The extracted wavelength and lifetime are shown in Fig. 2. Analysis of resonance width indicates on extra plasmon damping channels, in addition to carrier scattering by impurities and phonons. We argue that the observed extra damping can be attributed to re-radiation of waves by antenna.

Finally, we managed to observe extra plasmon modes not described by conventional models in devices aligned with boron nitride substrates. These modes appear simultaneously with extra peaks in resistivity previously ascribed to clonning of Dirac fermions in graphene-boron nitride superlattices [8]. This fact allows us to interpret these modes as collective oscillations of second-generation Dirac electrons.

Abstract
We have numerically investigated the degradation of the nano-focusing/confinement performance of plasmonic metal-insulator-metal waveguides due to quantum effects at nanometer gap sizes. We demonstrate that Landau damping is the dominant effect for gaps larger than 0.5 nm but below ~5 nm, decreasing the propagation length but not affecting the mode length. Below 0.5 nm, quantum tunneling significantly increases the losses, setting a practical limit of 0.5 nm for the minimum gap size.

1. Introduction
Waveguides based on surface plasmon polarization (SPP) are of significant interest for future integrated nanophotonic information processing technologies due to their ability to achieve confinement well below the diffraction limit [1]. The metal-insulator-metal (MIM) waveguide (Fig 1) is of interest due to its ability to achieve huge confinement through shrinking the inner dielectric gap [2, 3].

![Figure 1. Diagram of MIM waveguide structure.](image)

Figure 1. Diagram of MIM waveguide structure. The silver material is a metal (Ag) and the material in the gap is an insulator (air). Plasmon modes confine the energy in the gap.

Despite the interest in MIM waveguides, the limits to the achievable confinement and performance at small gap sizes are not well understood. Under the classical model, the MIM waveguide could achieve arbitrarily small confinement [2]. However, this model does not consider quantum effects that appear as the gap approaches atomic proportions [2].

Previous work has established two major effects in plasmonic structures with single and sub nanometer gaps, quantum tunneling and nonlocal effects. When plasmonic structures are separated by ~0.5 nm, electrons tunnel across the gap, changing the plasmonic modes [4-6]. For larger gap sizes below 5 nm, shifts in the modes are seen that have been phenomenologically modeled as nonlocal effects [7]. Recently, theoretical work has shown nonlocal effects can be attributed to Landau damping (LD), the absorption of high wavevector light leading to an effective increase in the damping constant of the metal [8, 9].

In this work, we numerically investigated the effect of Landau damping and quantum tunneling on the performance of MIM waveguides. The propagation length and mode length are analyzed to understand the losses and confinement respectively. It was found that in the 0.5 to 5 nm gap regime, quantum tunneling has negligible effects on the performance of the waveguide. Landau damping, however, significantly decreases the propagation length as the gap is shrunk but has a negligible effect on the mode length. Below 0.5 nm, quantum tunneling dominates and significantly increases the losses, thus providing a practical limit on the gap size. This will have significant ramifications for the future development of highly miniaturized MIM waveguides in integrated nanophotonic technologies.

2. Results
Simulations of the mode profile of Ag-air-Ag MIM waveguides (Fig 1a) were performed using FEM software. The effects of Landau damping on the waveguides were calculated using the approach in Ref. 9, whereby the LD induced damping rate is iteratively calculated.

The gap was varied from 0.5 to 5 nm with an excitation wavelength of 833 nm. Then the excitation wavelength was varied from 700 to 1500 nm with the gap fixed at 1 nm. The magnitude of the LD induced damping rate increases with decreasing gap size and wavelength (Fig 2). However, even at ~2 nm the induced damping rate is already close in magnitude to the intrinsic damping rate of Ag.

![Figure 2. LD Induced Damping Rates.](image)

Figure 2. LD Induced Damping Rates. LD induced damping rate in the MIM structure for different gaps (left) and excitation wavelengths (right). For comparison, red dotted line indicates the intrinsic damping rate of Ag.
The propagation length of the waveguide was calculated (Figure 3A). A significant decrease in the propagation length due to Landau damping is observed. To understand the ramifications of this, an MIM waveguide made up of an ideal metal with no intrinsic loss was considered. Under classical models this lossless waveguide would have an infinite propagation length. However, with Landau damping considered, the propagation length is below a micron at a gap size of 1 nm. This indicates that Landau damping provides a limit on the maximum propagation length achievable with MIM waveguides that is not significantly better than what can be achieved using Ag.

To understanding Landau damping’s effects on confinement, the mode length was calculated (Figure 3B). Landau damping does not significantly change the mode length. This indicates there is no limit to the confinement achievable with bulk metal MIM structures down to 0.5 nm.

**Figure 3. Effects of LD on MIM performance.** (Left) Propagation length (PL) of the MIM waveguide mode versus gap size for LD and classical models. The PL of a lossless metal under the LD model is also present for comparison. (Right) Mode length versus gap size for LD and classical models. There is no significant difference between the two.

Finally, the effects of quantum tunneling were simulated through implementation of the Quantum-Corrected Model (QCM) [6]. The model changes the refractive index of the dielectric gap as a function of the gap size. The simulations showed no significant change for gaps down to 0.5 nm (Figure 4A), thus indicating that Landau damping is the dominant effect in that regime. Further calculations demonstrated that below ~0.5 nm, the tunneling induced loss tangent of the dielectric gap approaches that of Ag (Figure 4B), thus becoming dominantly lossy and practically limiting the minimum gap size for MIM waveguides [6].

**Figure 4. Effect of Tunneling on MIM Performance.** (Left) Mode length of MIM structures under classical and tunneling (QCM) models. No significant change is seen. (Right) Calculated dielectric loss tangent of the inner dielectric from the QCM tunneling model. The red dashed line is the loss tangent for Ag.

### 3. Conclusion

From the above simulations, we have identified two regimes. The first is when the gap size is between 0.5 and 5 nm and Landau damping is the dominant effect. This is the more technologically relevant region, particularly for integrated nanophotonic applications. In this region, Landau damping caps the maximum achievable propagation length to below 1 µm for 1 nm gap sizes. This limits the potential applicability of highly compact MIM waveguides for data transfer in integrated photonic applications. This limitation can potentially be overcome through pursuing hybrid plasmonic-dielectric or plasmonic-electronic devices, or through using 2D materials [10]. In addition, the lack of effect on mode length ensures the ability of bulk MIM waveguides to confine energy to nanoscale lengths, allowing them to be packed tightly together for integrated nanophotonic technology and optically probe individual molecules.

Below 0.5 nm, quantum tunneling dominates and the induced loss becomes considerable, practically limiting the minimum MIM gap size to ~0.5 nm and thus limiting the maximum energy confinement (mode length) to ~1 nm.

Abstract

Microtubular cavities, which are self-assembled from prestrained nanomembranes, can support optical whispering-gallery mode (WGM) resonances via light circulating in the tube wall. By coating plasmonic nanostructures onto the microcavity surfaces, photon-plasmon coupling were investigated relying on the interaction of WGM resonant modes and surface plasmon resonances, which leads to many novel phenomena on optical tuning and potential applications. As a novel platform, our microtubular cavities imply promising applications for enhanced light-matter interactions, optical tuning, photonic integration and quantum optics.

1. Introduction

Plasmonic nanostructures integrated onto dielectric whispering-gallery mode (WGM) microcavities have been shown as a novel platform for the study of photon-plasmon coupling and enhanced light-matter interaction.\cite{1,2} The combination of a dielectric WGM microcavity and plasmonic nanostructures leads to the benefits of maintaining relatively high Q factor, small modal volume, and the extremely enhanced electric field at a localized area (also called as “hotspot”), which are crucial for light-matter interactions and related applications. In recent years, novel phenomena of photon-plasmon coupling in a rolled-up microtube integrated with metal nanostructures have also been reported.\cite{3-6} Microtubular cavities, which are self-assembled from prestrained nanomembranes, can support whispering-gallery mode (WGM) resonances in the rolled-up dielectric nanomembranes. Owing to the ultra-thin cavity wall, optical evanescent field greatly extend out of cavity surfaces, allowing for efficient interactions with the surrounding media. By designing the cavity structure and the gradient of refractive index, axial potential wells can be formed for the generation of higher order axial modes with promoted optical confinement. By combining metal nanostructures onto the dielectric microcavity surfaces, the interaction between photonic modes and plasmonic modes were studied both theoretically and experimentally, showing a unique platform for the study of photon-plasmon coupling.

2. Results and discussion

Figure 1(a) shows photon-plasmon mode hybridization in a silver nanocap coated microtube cavity. The silver nanocap was fabricated by physical vapor deposition on top of a rolled-up microtube. In previous reports, uniformly distributed hybrid modes were explored, which in turn exhibit only monotonous fields with fixed polarization in the opto-plasmonic WGM cavities. Here, we design and fabricate silver nanogaps coated on microtubular microcavities. In contrast to previous reports, angle-dependent non-uniform hybrid modes were realized in a single microcavity due to the varying coupling strength and shielding effect enabled by the metal nanocap. As such, not only the coupling strength but also the optical field polarizations can be tuned depending on the azimuthal angle. More interestingly, the intensity ratio of strongly hybridized transverse magnetic (TM) mode and transverse electric (TE) mode is extremely sensitive to nano-perturbations at the metal nanocap surface, thus providing a novel scheme for label-free sensing. This work reveals a metal nanocap capable of tuning the photon-plasmon coupling, and exhibits a novel scheme for manipulating light-matter interactions in a versatile nanotechnology platform.

For the study of light-matter interactions, the size mismatch between the optical wavelength and any interacting nano-objects is bridged by cavity quantum electrodynamics or plasmonic nanostructures integrated within the cavities. We designed a plasmonic nano-gap in microtubular cavities to demonstrate efficient coupling of localized surface plasmons (LSPs) and resonant light, as shown in Fig. 1(b). Moreover, selective coupling of LSPs and resonant modes are achieved, exhibiting spatial dependence of the plasmonic nanogap on the microcavities.

To combine metal nanoparticles onto optical microcavities, delicate nano-manipulations are required to transfer metal nanoparticles onto microcavities. However, in practical work it is of high interest to get mechanically more stable metal nanoparticles grown on dielectric microcavities in a reproducible and location-selective fashion which is limited in previous reports. To address this issue, we introduce an in-situ fabrication of silver nanoparticles on optical microtube cavities for the manipulation of photon-plasmon coupling, as schematically shown in Fig. 1(c). Moreover, by creating multiple plasmonic-nanoparticle spots on the
optical microcavity, optical modes are freely tuned due to multi-coupling between localized surface plasmon resonances supported by the metal nanoparticles and whispering-gallery-modes supported by the microtube cavity.

As a hot research field, the plasmonic resonances in metallic nanostructures mainly concern the structure size, geometry and symmetry, where the topology was excluded in the previous reports. In our group, we demonstrated topology induced anomalous plasmon modes in metallic Möbius nanorings, as shown in Fig. 1(d). Due to the occurrence of an extra phase (Berry phase) in the topological Möbius configuration, half-integer plasmon modes were observed which cannot exist in conventional plasmonic rings. Due to symmetry breaking, the higher-order plasmon modes turn into bright ones in the Möbius nanorings, which are supposed to be dark in conventional cylindrical rings. The feature of half-integer numbers of plasmon modes as well as the corresponding resonant frequencies is robust to the variation of the surface-charge distribution on the Möbius nanoring due to the non-trivial topology.

3. Conclusions

Self-assembled microtube cavities have been used to integrate plasmonic nanostructures for the study of photon-plasmon coupling. By tuning the coupling strength, site of localized surface plasmon resonances, and topology of the plasmonic structures, several phenomena have been revealed ranging from far-field directional emission, mode profile tuning, to anomalous plasmon modes, which show a versatile platform to manipulate photon-plasmon coupling for potential applications.

Abstract

The far field spectrum of plasmonic metasurface with sharp features is very sensitive to nonlocality in the metal such that the microscopic nonlocal effects can be unveiled from far field measurements.

1. Introduction

Singular metasurfaces have a strong field enhancement, because of their ability to compress the wavelength of surface plasmons [1]. However, if the length scale of the singularity is smaller than the screening length of metal, nonlocal effects must be considered. In view of this, the hydrodynamic model is considered which takes into account the interaction between electrons. In this model, the longitudinal mode of plasmon becomes $k$-dependent and couples with transverse mode.

2. Results

Fig. 1(a) depicts our singular metasurface. In the presence of nonlocality, the surface charge becomes a volume charge, see the purple layer on top of the metasurface. The thickness of this layer is scaled by the nonlocal parameter $\beta$. To study this structure, a conformal mapping is employed to transform this singular metasurface into a slab array, shown in Fig. 1(b). As the longitudinal permittivity is $k$-dependent, the decay length in the transformed frame is not uniform such that the thickness of electron layer is thinner near the origin and increase when $x \to \pm \infty$ in the slab frame shown in Fig. 1(b). Then our analytical calculation is carried out in the slab frame, where the boundary matching is easier.

Using the method we have developed in a previous paper [2], the reflection spectrum is obtained and shown in Fig. 2(a). In this figure, the reflection spectrum with and without nonlocality are compared. From this comparison, we conclude that the introduction of nonlocality makes the spectrum discrete [3]. When the nonlocal parameter $\beta \to 0$, the discrete spectrum transits into a continuous one. Thus, nonlocality introduces a significant change in the spectrum and has to be considered for the real purpose. For the near field profile shown in Fig. 2(b), we see the electric field becomes continuous across the metal interface when the nonlocality is introduced. This is because of the absence of surface charge in the hydrodynamic description. Besides, the field in the nonlocal case oscillates much less rapidly than the local case, which results in a weaker compression of the field.

We also studied the dependence of the spectrum on period of the metasurface, which is a length scale parameter that competes with nonlocal parameter. We show that increasing the period is equivalent to reducing $\beta$ in the quasi-static limit. For large periods, the radiation loss comes into play which broadens the width of the peaks. However, we
show that this broadening is limited in our structure, especially for the high order peaks.

Abstract

Water, ethanol, and isopropyl alcohol are general solvents and dispersing media for different suspensions. We estimate the resonance properties of SPP modes excited at interfaces between silver and these solvents using Fano approximations in the ultraviolet, visible and infrared regions. The obtained results suggest potential applications of planar plasmonic structures in nanotechnology and biosensing in the near- and mid-infrared regions.

1. Introduction

Optical characterization of materials is important for a variety of applications in nanotechnology, sensing, and spectroscopies. In such fields as biosensing and nanofabrication of nanoparticles, a liquid environment for the dispersed particles is generally employed [1]. Responses of optical resonant structures to changes in the optical characteristics of environment are widely used in optical sensing. It is well known that an interface between a metal and a dielectric supports propagation of surface plasmon-polaritons (SPP) modes [2]. The resonance characteristics of planar SPP structures in aqueous environment were obtained in the ultraviolet (UV), visible and near-IR regions using exact electromagnetic (EM) theory, which required heavy data processing [3, 4]. Recently, we analytically obtained Fano approximations for asymmetric resonance line shapes in spatial spectra of planar plasmonic structures [5]. In the present work, we analyze the resonance characteristics of SPP modes at solvent-metal interfaces for water, ethanol, and isopropyl alcohol (IPA) using our Fano approximations.

2. SPP resonances at dielectric-metal interfaces

Let us consider an interface between a dielectric and a metal with permittivities \( \varepsilon_1 = \varepsilon'_1 + i\varepsilon''_1 \) and \( \varepsilon_2 = \varepsilon'_2 + i\varepsilon''_2 \), respectively, where \( \varepsilon'_1 > 0 \) and \( \varepsilon'_2 < 0 \). SPP modes propagate along the interface provided that \( \varepsilon'_1 + \varepsilon'_2 < 0 \), \( \varepsilon'_1 \varepsilon'_2 < 0 \), \( |\varepsilon'_1| |\varepsilon'_2| \ll |\varepsilon''_1| |\varepsilon''_2| \) [2]. The complex propagation constant \( \gamma_{\text{SPP}} = \gamma'_{\text{SPP}} + i\gamma''_{\text{SPP}} \) of SPP mode is found as [2]

\[ \gamma_{\text{SPP}} = \sqrt{\varepsilon_1 \varepsilon_2 / (\varepsilon_1 + \varepsilon_2)}. \]  

At the interface, the field of an external evanescent wave non-resonantly generates a secondary evanescent field and interacts with the SPP mode. If the in-plane wavevector of the external exciting wave approaches the wavevector of the SPP mode, the energy of the wave is partly transferred to the SPP mode that leads to the resonant increase of the SPP mode amplitude and near field enhancement. We demonstrated that interference of the secondary field and resonant response from the SPP mode results in asymmetric SPP resonances in spectra of near field enhancement that can be approximated by the Fano formula [5]:

\[ |r(\alpha)|^2 = |r'(\alpha)|^2 \frac{\alpha - \gamma'_2 + \gamma''_2}{\alpha - \gamma'_p + \gamma''_p}. \]  

where \( \alpha \) is the in-plane propagation constant of the external wave; \( \gamma' = \gamma'_2 + i\gamma''_2 = \gamma_{\text{SPP}} + 2\gamma''_{\text{SPP}} / [(\varepsilon'_2 - \varepsilon_e)] \) is the zero and \( \gamma_p = \gamma'_p + i\gamma''_p \) is pole of function (2);

\[ r'(\alpha) = (\varepsilon_e - \varepsilon) (\varepsilon'_p + \varepsilon'_2)^{-1} + (\varepsilon'_2 + \varepsilon_e) \gamma_{\text{SPP}} (\varepsilon'_2 - \varepsilon_e)^{-1} \alpha^2 \]  

is the non-resonantly slowly changing near field enhancement component. The maximum near field enhancement can be estimated as \( |r(\gamma'_2)|_{\text{max}}^2 = |r'(\gamma'_2)|^2 (|\gamma'_2 - \gamma'_p|^2 + \gamma''_2^2 / \gamma''_p) \). The resonance width in the spatial spectrum is determined as \( \Gamma = 2\gamma''_{\text{SPP}} \gamma''_p \) [5].

3. Numerical results and discussion

The refractive indices for silver (Ag) [6, 7], ethanol and IPA [1], and water [8] were used for calculation of resonance characteristics of SPP modes, which are excited at interfaces between silver and the set of solvents. The propagation constant \( \gamma_{\text{SPP}}(\lambda) \) calculated by Eq. (1) decrease with wavelength as demonstrated in Fig. 1. The difference in \( \gamma_{\text{SPP}}(\lambda) \) between different solvents is maximal in the 1.0 – 2.8 \( \mu \)m region. The width \( \Gamma \) of the SPP resonance line shape takes its lowest values in the 1.0 – 2.4 \( \mu \)m region for all the considered solvents as shown in Fig. 2. The
maximum near field enhancement $|r_{max}|^2$ reaches its maximal values in the 0.5 – 1.6 μm region in all cases. The regions of SPP modes excitation are above 350 nm in all cases, respectively, and in the IR region up to 4.1 μm. In the case of ethanol and IPA, SPP mode can be excited also in the 3.6 – 6 μm region. The near field enhancement and resonance width degrade in the mid-IR region due to the increasing water absorption.

4. Conclusions

According to the data obtained by the Fano approximation, water can be used as a solvent for spectral measurements based on SPP resonances in the 0.4 - 2.65 μm and 3.55 - 4.05 μm regions, ethanol – in the 0.35 – 2.8 μm and 3.7 – 5.8 μm regions, and IPA – in the 0.35 – 2.8 μm, 3.2 – 3.3 μm, and 3.57 - 6.2 μm regions. The theoretical results can be used for engineering of the line shapes of SPP resonances in solutions and concentration measurements.

Abstract

In this article, we present a diffraction-free Bloch Surface Wave in an aqueous environment sustained on all-dielectric multilayers with two crossed gratings or silver nanowires. It can propagate in a straight line for distances longer than 110 μm at a wavelength of 633 nm and could be applied as an in-plane optical virtual probe. Its robustness and long diffraction-free distance to multiple obstacles make this wave ideal for certain applications in bio-photonics and chip-level optical interconnections.

1. Introduction

Recent development of photonic integrated circuits meet high demand for light confinement and manipulation at subwavelength scale [1]. Compared with the candidates such as Surface Plasmon Polaritons (SPPs) [2], the Bloch Surface Waves (BSWs) which are excited between a truncated periodic dielectric multilayer with a photonic band gap (PBG) and its surrounding medium is competitive for its lower loss as well as consequent longer propagation lengths. Both SPPs and BSWs undergo diffraction in the plane of the interface, which will induce coupling losses between the on-chip components as the wave packet spreads laterally during propagation. In recent years, many methods have been proposed to construct diffraction-free SPPs[3,4]. However, little effort had been devoted to constructing diffraction-free surface waves in an aqueous environment and in the visible light band, which is more favorable for biological applications. In the present report, we demonstrate both experimentally and theoretically that diffraction-free BSWs (DF-BSWs) can be generated on an all-dielectric multilayer with simple dielectric gratings or silver nanowires. Owing to the low loss of BSWs, it can propagate in a straight line for distances longer than 110 μm in an aqueous environment at a wavelength of 633 nm, which had not been demonstrated experimentally for any diffraction-free SPPs.

2. Results and Discussion

Figure 1b and 1c shows the experimental and numerical results of diffraction-free BSW with dielectric gratings. Both images have a significant main lobe and several parallel side lobes that appear and propagate toward the right side. The diffraction-free distance approaches 110μm, illustrating that the BSW can propagate much further than SPP. Another important advantage of this low-loss dielectric system is that the diffraction-free property can be preserved even after passing several obstacles. Figure 1e and 1f clearly show that the main lobe of the BSWs keep collimation after passing three separate obstacles. To the best of our knowledge, there is no previous report of diffraction-free SPPs that can pass through three obstacles.

Silver nanowires with crystalline structure can be synthesized with chemical approach, which is a convenient and low-cost method for practical applications. In figure 2, we demonstrate that two crossed silver nanowires instead of gratings can also be used for excitation of the diffraction-free BSW. Figure 2(a, c, e, g) show white light images of the two contacted Ag nanowires with different cross angles. The experimental results show that the non-diffracting distance and the full width at half maximum of the main lobe decreases as the cross angle of the two nanowires increases in Figure 2(b, d, f, h). Thus the DF-BSW can be regarded as an in-plane optical virtual probe since the width and the length can be tuned.

3. Conclusions

In summary, the crossed gratings and silver nanowires are used to generate the DF-BSW in water environment at visible light frequency, respectively. The low loss property of the dielectric multilayer configuration compared with a metal film, especially in the visible spectrum, makes BSWs more favorable than SPPs for the formation of diffraction-free surface waves. As it has longer diffraction-free propagation distance and robustness against disorder in the propagating path, DF-BSWs have potential prospect in areas such as on-chip optical interconnections, where the signal may encounter obstacles as the devices become more complex. Besides, the tunable capability by changing of the width and length of the DF-BSWs may also find applications in optical nano-manipulation of molecules in liquids.

Abstract

In this work we demonstrate that Surface Plasmon Polaritons (SPPs), propagating in a single silver nanowire, can be used for remote (bi-directional) communication with up-converting nanocrystals (UCNPs), which are anti-Stokes emitters. In particular, SPPs activated at one end of the nanowire induce emission of single UCNPs deposited at the opposite end of the nanowire. We show using spectrally- and time-resolved luminescence microscopy that range of this communication depends on light polarization, SPPs mode, and functionalization of the nanocrystals.

1. Introduction

Surface Plasmon Polaritons (SPPs) can be activated by light at the metal-dielectric interface. Apart from metallic layers, SPPs can propagate in silver nanowires, which behave like waveguides, routing the energy for quite long distances reaching many microns [1]. Due to small lateral dimensions of the nanowires (~100 nm), plasmonic waveguides allow construction and further miniaturization of optoelectronic circuits, far beyond diffraction limit for light. For this reason, metallic nanostructures attract great attention as promising candidates for new generation of on-chip optoelectronic devices.

It has been experimentally demonstrated that SPPs can transport the energy between spatially distant parts of the nanowire what can leads to activation of photoluminescence or Raman scattering [2]. As it has been shown, SPPs typically support only one-way (excitation/detection) communication channel, whereas complementary detection/excitation process requires far field optical microscope. For this reason, SPP-mediated processes have found rather limited number of applications despite their unique optical properties.

In this work we demonstrate that both excitation and detection processes, followed by spectrally- and time-resolved analysis, can be realized exclusively by SPPs propagating in a single silver nanowire. The results show that even ineffective two-photon up-conversion luminescence can be successfully activated and detected utilizing SPPs, propagating one way and back in a nanowire. The efficiency of such a “boomerang” effect strictly depends on the orientation of nanocrystals (dipoles) with respect to the nanowire, as well as particular configuration of the SPPs mode. Other non-local optical processes like polariton-mediated absorption are discussed and experimentally verified.

Fig. 1: Microscopic image of a single silver nanowire, decorated by small population of nanocrystals, visualized by (a) transmission and (b) photoluminescence microscopy (λdet = 650 nm). (c) Photoluminescence map demonstrating emission of light from free (lower) end of the nanowire. (d) Experimental configuration used to investigate polariton-mediated excitation and emission processes.
2. Materials and methods

In the experiment we used single silver nanowires featuring diameters of about 100 nm and lengths about 10-20 μm. The nanowires were coupled with small population of anti-Stokes emitters, represented by α-NaYF₄:Er³⁺/Yb³⁺ upconversion nanocrystals. Small volume of the nanocrystals (~fL) was precisely deposited on one end of single silver nanowire using microinjection capillary tip. Such a sample was investigated using anti-Stokes confocal and wide-field photoluminescence (PL) microscopes, equipped with a high numerical aperture oil immersion objective (NA=1.49). For excitation we applied a single-mode infrared CW/pulsed laser operating at 980 nm. For detection we used a single photon counting unit, connected to the counter card (PL imaging) or to the multiscaler card (time-resolved imaging). Detailed topography of the sample, including arrangement of the nanocrystals near the nanowire tip were realized using Atomic Force Microscopy and Scanning Electron Microscopy techniques.

3. Results and discussion

The results of optical studies of the nanowire decorated with nanocrystals on one end are displayed in Fig. 1. The microscopic image of the nanowire, including a small disturbance at the top end of the nanowire, which we attribute to the nanocrystals, is presented in Fig. 1a. The luminescence (λ₀= 650 nm) intensity map obtained for the same nanowire (Fig. 1b) using confocal luminescence microscopy proves that the most of the emission originates from the top end of the nanowire, where the nanocrystals were deposited. However, one can see weak but a very well defined emission spot emerging at the lower end of the nanowire, where no nanocrystals were deposited (Fig. 1c). This observation means that when the nanowire is excited at this very end, as the result of interactions that are taking place at the interface between the nanowire and nanocrystals (at the other end), it itself becomes a light emitter [3].

To explain this effect it is required to consider and analyze the experimental conditions, in particular the locality and non-locality of both excitation and emission processes, what is illustrated in Fig. 1d. Excitation of the end of the nanowire where no nanocrystals are present must launch SPPsexc, which propagate towards the second end of the nanowire, i.e. the one where the nanocrystals are present. It should be noted that the SPPsexc not only are capable of reaching the second end of the nanowire, but can also provide sufficient energy to activate the up-conversion process in these nanocrystals. In the final step, remotely excited nanocrystals convert the energy and launch SPPsrem corresponding to their emission lines. Eventually, they propagate back to the excitation spot, where radiation is released. The whole process has strong non-local character, since the excitation/detection spot is spatially distant from the optically active area of the nanocrystals.

Quite different functionality of the plasmonic nanostructure can be achieved through change of the sample geometry. For instance, when nanocrystals are positioned more in the middle of the nanowire, polaritons propagating through the wire can “probe” optical properties of surrounding nanocrystals. We will demonstrate that sensitivity of such polariton-mediated process is high enough to map absorption lines, assigned to the optical transitions in the rare-earth doped nanocrystal. In addition, we will demonstrate that efficiency of polariton-nanocrystal interaction strongly depends on orientation of the dipole moments in the nanocrystals.

4. Conclusions

The central observation described in this work is the ability for a single silver nanowire to act (at the same time) as an energy transmitter and a remote activator of up-converted emission in nanocrystals. By developing a simple method of local deposition of nanocrystal solution on one of the nanowire ends and the ability to excite exclusively the second end of the nanowire, we demonstrate efficient remote activation and detection of the emission via surface plasmon polaritons. As the studied experimental configuration is diffraction-free in an optical manner, the results open rarely addressed facets of miniaturization of optoelectronic circuits further below the diffraction limit for light.

Abstract

In this work we present the results regarding interaction between single emitters (nanocrystals) and metallic nanoparticles (silver nanowires). In the experiment we use Photoluminescence (PL) microscopy together with Fluorescence-Lifetime Imaging Microscopy (FLIM) to investigate radiative emission rates of the nanocrystals localized close to the nanowire. We use polarized laser beam to control orientation of the dipole moments of the nanocrystals to show that radiative rate enhancement strongly depends on orientation of the dipoles with respect to the nanowire, giving new insight into nature of the metal enhanced fluorescence process.

1. Introduction

Metal Enhanced Fluorescence (MEF) is one of the most interesting and widely investigated phenomenon in the last years. The most significant advantage regarding MEF is that quantum efficiency of a particular emitter can be controlled and frequently improved by positioning it close to a metallic nanoparticle.

There are several parameters that have to be optimized in order to activate MEF. Very important in this regard is the distance between the emitter and the metallic nanoparticle. It was showed that maximal enhancement can be observed for distances between 10 to 15 nm [1]. When the distance is too large, the metal-emitter interaction decreases and the enhancement disappears. On the other hand, when the distance is too small, the luminescence is strongly quenched by non-radiative transfer of the energy from the emitter to the metallic nanoparticle.

Additionally, optimal spectral matching between elements of the system has to be assured. To improve the efficiency of absorption, the plasmon resonance should overlap with the absorption of the emitter. This quite intuitive condition guarantees effective absorption of the excitation energy by the whole nanostructure. On the other hand, to increase spontaneous emission rates, a rather different spectral optimization is required. According to the experimental results, the largest enhancement of the radiative emission rates is usually observed for a system, where spectral position of the emission line is red-shifted with respect to the maximum of the extinction of metallic nanoparticles [2].

It should be noted that efficiency of interaction that takes place between the emitter and metallic nanoparticles depends also on mutual orientation of their dipolar moments. In this work we focus on understanding a microscopic image of the MEF processes. In the experiment we used a system, consisting of single silver nanowires and nanocrystals without permanent dipole moments. Instead, the nanocrystals feature induced dipole moments, which can be freely reoriented using external laser light with respect to the nanowire, giving new insights into nature of the MEF.

Figure 1. Nanostructure consisting of single nanowires and nanocrystals, deposited on glass, imaged using: (a) elastically scattered laser light, (b) up-conversion photoluminescence microscopy and (c) fluorescence-lifetime imaging microscopy.
2. Materials and methods

The nanostructure studied in this work consists of silver nanowires (NWs) and dielectric NaYF$_4$ nanocrystals (NCs) doped with Er$^{3+}$/Yb$^{3+}$ ions. Components were spin-coated on a glass substrate layer by layer. In contrast to organic dyes or semiconductor quantum dots, the emission of the NCs is very stable, it neither features blinking nor photobleaches under laser illumination. Furthermore, the infrared laser excitation generates no background in the visible spectral range, enabling straightforward observation of the emission of individual nanocrystals.

Samples were investigated using anti-Stokes confocal luminescence microscope, equipped with a high numerical aperture oil immersion objective (NA=1.49). For excitation we applied a single-mode infrared CW/pulsed laser operating at 980 nm. For detection we used a single photon counting unit, connected to the counter card (PL imaging) or to the multiscaler card for time-resolved imaging (FLIM). Luminescence transients were collected with 1 μs time resolution in a time window of 0-1 ms. Detailed topography of the sample was realized using AFM and SEM.

3. Results and discussion

The exemplary results of optical studies of the nanostructures are displayed in Fig. 1. All presented maps were measured over the same sample area, as evidenced by identical positions of the silver nanowires. The elastic scattering image (Fig. 1a) features two randomly oriented silver nanowires with lengths of about 4 and 10 μm. An up-conversion luminescence intensity map (Fig. 1b), acquired for the detection wavelength of 650 nm, corresponding to red emission of Er$^{3+}$, features two qualitatively different subsets of emitters. First, round and diffraction-limited spots attributed to the emission from individual or few close lying NCs (the reference), and the second – consisting of very bright stripes, whose positions correlate with the positions of the nanowires. These nanocrystals feature shorter luminescence decay times (~60 μs) than the reference ones (~100 μs), what can be seen on the FLIM map (Fig. 1c). We attribute this emission to the nanocrystals coupled with nanowires, and featuring the MEF effect [3].

Interestingly, efficiency of the luminescence enhancement strongly depends on the polarization of the excitation beam. We demonstrated previously that absorption of light by NCs coupled with NWs is the most efficient when the excitation beam is polarized parallel to the nanowire [3,4]. In this work, however, we demonstrate that NCs emission rates are also sensitive to the laser polarization [5]. We performed FLIM imaging using unpolarized (Fig. 2a) and polarized laser beam oriented parallel (Fig. 2b) and perpendicular (Fig. 2c) to the nanowire. We noticed that for the parallel polarization emission decays are significantly longer than for the perpendicular one. We attribute this effect to different orientation of dipole moments of the NCs, which can be controlled by the excitation laser. Our results will be discussed and confronted with theoretical simulations.

4. Conclusions

In this work we demonstrated very efficient coupling between up-converting nanocrystals and silver nanowires. In the vicinity of a single NW the up-conversion process is strongly enhanced. By using FLIM microscopy we proved the effect of plasmon excitations in silver nanowires on radiative transition rates of NCs placed in their vicinity. We noticed that the highest emission rates enhancement is observed for dipole moments oriented perpendicular to the nanowire. This observation gives a new insight into the MEF phenomenon.

Abstract

We investigate a hybrid nanostructure consisting of a single silver nanowire placed on graphene, and with one end being locally decorated by a small amount of colloidal nanocrystals. We show how the propagation length of SPPs can be controlled by a graphene substrate and affects the up-conversion process in nanocrystals coupled with the metallic nanowire. Such structures are of particular interest because they can provide a platform for new applications in photovoltaic devices and various sensor architectures \cite{1}.

1. Introduction

Silver nanowires can effectively support surface plasmon polaritons (SPPs). They can operate as nanoscopic waveguides, capable of routing SPPs for quite long distances approaching tens of microns \cite{2}. Recently, SPPs were used for remote activation of fluorescence, Raman scattering or catalysis of the chemical reactions \cite{3}. Quite recently we have demonstrated that surface plasmon polaritons, propagating in a single silver nanowire, can remotely activate two-photon up-conversion luminescence \cite{4}.

In the last years, graphene has attracted much attention as an interesting component for new optoelectronic devices. Due to exceptional physicochemical and optical properties like flat absorption spectrum or perfect electrical conductivity, it became a platform for many sensoric applications. Despite this fact, there are some disadvantages associated with the use of graphene. In this work we present our results regarding the influence of the graphene substrates on SPPs. Of particular interest is potential graphene-induced SPPs quenching, which can translate to limited SPPs propagation range.

2. Materials and methods

In this work we investigate a nanostructure consisting of a long, single silver nanowire decorated with a small drop of nanocrystals (~fL), deposited precisely at one of its ends (Fig. 1). The nanowires feature lengths of about 10-15 microns. The extinction spectrum of colloidal nanowires ranges from about 400 nm to 1000 nm and is presented in Fig. 2.

NaYF\textsubscript{4} nanocrystals used in this work, are doped with erbium and ytterbium ions, and they have sizes of approximately 20 nm in diameter. Rare-earth ions are responsible for anti-Stokes luminescence (550 and 650 nm), which is activated by near-infrared radiation at 980 nm. Emission lines of nanocrystals are presented in Fig. 3. They overlap with the extinction of nanowires (Fig. 2), thus the interaction between them (under specific circumstances, such as optimal distance) can be very efficient and can lead to new effects.

Figure 1: Schematic illustration of silver nanowire deposited on a graphene substrate with a droplet of nanocrystals at one end. Plasmon modes are induced by the infrared laser operating at 980 nm.
Graphene is a monolayer of carbon atoms, tightly packed into two-dimensional hexagonal lattice. Monolayer graphene is a semimetal with a zero bandgap and can be considered also as plasmonic material. The most outstanding advantages of graphene are high electron mobility and high mechanical strength. From the optical point of view, single graphene layer shows about 2.3% absorption of incident light, that occurs in a broad spectral range.

Our samples were investigated using anti-Stokes confocal photoluminescence microscope, equipped with a high numerical aperture oil immersion objective (NA=1.49). For excitation we applied a single-mode infrared CW/pulsed laser operating at 980 nm. For detection we used a single photon counting unit, connected to the counter card (PL imaging). Detailed topography of the sample, including arrangement of the nanocrystals near the nanowire end were realized using Atomic Force Microscopy and Scanning Electron Microscopy techniques.

3. Results and discussion

We used high numerical aperture objective to launch the SPPs by a laser beam focused at the free end of the nanowire (without nanocrystals). The SPPs propagate towards the other end, and activate luminescence of the nanocrystals deposited locally on the nanowire. Next, excited nanocrystals can induce polaritons, which propagate back to the starting excitation spot. This polaritons feature frequencies corresponding to the emission of nanocrystals, what is observed as a characteristic SPPs mode. The propagation of the energy in a silver nanowire is strongly substrate-dependent and is less efficient on graphene, mostly due to energy transfer from SPPs to graphene. Additionally, the efficiency of this process strongly depends on the polarization of the laser, diameter and length of the nanowire [5]. The key issue of our work was to introduce a spacer, limiting SPPs quenching, but conserving measurable coupling between nanocrystals, nanowires and graphene.

4. Conclusions

In this study, we proposed a complex hybrid nanostructure consists of up-conversion nanocrystals, silver nanowires and graphene, as an new interesting platform for optoelectronic application. We investigated and optimized efficiency of mutual interactions in order to obtain a structure featuring new functionality and best properties of its components.

Abstract

CdO is an n-type semiconductor with excellent transport properties, gaining attention in recent years for the study of strong light-matter interaction phenomena. Here we show the conductivity of the MOCVD-grown CdO can be improved by alloying it with ZnO, reducing the losses in the mid-IR and enhancing its performance as a plasmonic material. Here we combine infrared reflectance and ultraviolet-visible absorption spectroscopies together with Hall effect, to determine its optical and electrical transport characteristics for increasing Zn contents.

1. Introduction

The field of plasmonics was widely studied during the last decades, by using noble metals as Au and Ag, on which the plasma resonance falls in the visible region of the electromagnetic spectrum. Although metals have very high conductivities and behave as perfect reflectors at far infrared (IR) frequencies, in the mid-IR region they have very large optical losses due to the excitation of interband transitions. Thus, alternative compounds are needed for the mid-IR range and CdO fulfils the requirements for becoming a low-loss plasmonic material:¹ a high and tunable plasma frequency ($\omega_p$) as well as a high electron mobility ($\mu$) is attainable in as-grown material.

Some studies suggest the free electron concentration, and therefore $\omega_p$, can be increased in CdO by alloying it with ZnO,² allowing to modulate the plasmonic resonance over a range of frequencies. However, in polycrystalline materials, grain boundary scattering limits the enhancement of electron mobility, a key parameter for reducing the optical losses. Here we present the results³ of the transport and optical properties of single-oriented CdZnO thin films grown on r-plane sapphire in rock-salt phase. Thanks to the high crystal quality achieved in the films, an enhancement in the electron mobility with Zn was found, which, combined with the rise in the free electron concentration, makes CdZnO an excellent candidate for IR plasmonics and leads to the lowest reported resistivity values for the rock-salt CdZnO ternary.

In addition, as a consequence of the bandstructure modification and the band filling, the incorporation of Zn to the rock-salt crystalline structure of CdO induces a blueshift of the optical bandgap, widening the transmission window of the material and therefore improving its performance as a transparent conductive oxide (TCO).

2. Samples and characterization techniques

The CdZnO films were grown by metal organic chemical vapor deposition (MOCVD) on r-plane sapphire substrates. Nominal Zn contents range from 0 to 25 % and the thickness is approximately 150 nm.

The optical properties of the films in the mid-IR were studied by means of infrared reflectance (R) spectroscopy with a Fourier Transform Infrared Spectrometer (FTIR). The R spectra were fitted using a dielectric function model, which accounts for the interaction between light and free electrons with a Drude term, as

$$\varepsilon(\omega) = \varepsilon_\infty^{CdZnO} - \frac{\omega_p^2}{\omega^2 + i\omega\gamma_p}$$  (1)

where $\varepsilon_\infty^{CdZnO}$ is the background dielectric constant of the alloy, $\omega_p$ is the plasma frequency and $\gamma_p$ its broadening. The plasma frequency is related to the optical electron concentration ($n_{opt}$) and the electron effective mass ($m^*_e$) by

$$\omega_p^2 = \frac{n_{opt}}{m^*_e\varepsilon_0}$$  (2)

and the broadening of the plasma resonance is related to the optical mobility ($\mu_{opt}$) by $\mu_{opt} = e/m^*_e\gamma_p$, where $e$ is the speed of light and $e$ the electron charge.

The electrical properties of the CdZnO films were analyzed at room temperature with Hall effect in the Van der Pauw configuration. From Hall effect measurements, the Hall electron concentration ($n_{Hall}$), the Hall mobility ($\mu_{Hall}$), and the electrical resistivity ($\rho$) was determined for each Zn content.

Finally, the optical bandgap, one of the fundamental parameters of TCOs, was determined from ultraviolet-visible transmission spectroscopy. Since CdO is a degenerate semiconductor, in order to derive the real bandgap of the material at the Γ point, band filling should be taken into account together with the conduction band (CB) nonparabolicity, as

$$E_{BM} = \left(\frac{\hbar^2}{2m^*_e}\right)\left(3\pi^2n\right)^{2/3},$$  (3)

where $m^*_e$ of each film was derived from Eq. (2) considering $n_{opt} = n_{Hall}$.
3. Results and discussion

From the R measurements performed with the FTIR, the plasma frequency and its broadening are obtained and are shown in Figure 1.

![Figure 1. Plasma frequency and its broadening as a function of Zn content in the CdZnO films.](image)

As the Zn content is increased, the plasma frequency shifts to higher energies, reaching a value of 10250 cm$^{-1}$ for a Zn content of 25 %, indicating a rise of the optical electron concentration. On the other hand, the broadening is reduced from 577 cm$^{-1}$ to 420 cm$^{-1}$ as 5 % Zn is added to CdO, whereas for larger Zn contents it increases monotonically, although is maintained below 600 cm$^{-1}$ for Zn contents up to 15 %. Only for the largest Zn contents a clear drop of $\gamma_p$ is observed, indicating a degradation of the crystal quality of the alloy.

From the point of view of CdZnO as a plasmonic material, we want to highlight the plasma frequency can be tuned from 7000 cm$^{-1}$ to 9000 cm$^{-1}$ while maintaining or even reducing the optical losses.

![Figure 2. Dependence of the Hall electron concentration, Hall mobility and resistivity on the Zn content.](image)

Regarding the Hall results showed in Figure 2, the trends observed of $\mu_{Hall}$ and $n_{Hall}$ are similar than for the optical values. Free electron concentration values are above $10^{20}$ cm$^{-3}$, with a maximum value of 3.9$x10^{20}$ cm$^{-3}$ for 20 % Zn. The Hall mobility values are the highest for Zn contents of about 5 – 10 %. Combining both parameters, resistivity values are always below 6$x10^{-4}$ cm$^2$/Vs, with a minimum value of 2$x10^{-4}$ cm$^2$/Vs, which correspond to the lowest reported values for the CdZnO alloy.

4. Conclusions

In summary, we have identified the rock-salt CdZnO ternary as an excellent candidate for IR plasmonics. The high crystal quality achieved in the CdZnO films reduces the plasma broadening and its frequency can be tuned with the Zn content. Indeed, the optical and electrical mobilities obtained correspond to the best reported values for the CdZnO alloy. Besides, the incorporation of Zn yields a simultaneous decrease of the electrical resistivity and a widening of the transmission window of the material, key parameters for TCOs.

Abstract

CdZnO is a promising candidate to substitute metals in future IR plasmonic devices. As an approximation to these plasmonic phenomena, we have studied the plasmonic modes present in a double-interface asymmetric system. For this purpose, reflectance of thin CdZnO layers grown on r-sapphire substrate were measured in Otto configuration. In thick samples, modes appeared to be asymptotically pinned to the single-interface plasmon frequency. In contrast, the thinnest layers showed an important coupling between both interfaces, with a strongly confined ENZ mode at high energies and a hybrid Surface Plasmon-Phonon mode at lower frequencies.

1. Introduction

This study continues our previous work [1] about the electro-optical properties of CdZnO as a Transparent Conductive Oxide (TCO). We have previously shown that percentages of around 10 % Zn made the alloy a perfect candidate for plasmonic applications. This ternary showed a high plasma frequency (over 9000 cm\(^{-1}\)) with a relatively high mobility (110 cm\(^2\)/V·s), values fully compatible with a plasmonic behavior in the IR.

In this work, we study the Surface Plasmon Resonance (SPR) in thin layers of CdZnO (10 % Zn) with an asymmetric air-TCO-sapphire system, and their coupling to surface phonons producing a hybrid Surface Phonon-Plasmon Resonance (SPhPR). TCO layers with different thicknesses were used, ranging from a thin 25 nm, close to the air-sapphire non-plasmonic limit, to 460 nm, where the air-CdZnO interaction domines. According to theory [2], a thin metal layer (or TCO in our case) sandwiched between two dielectric semi-infinite media is able to stablish two different surface plasmon modes, a high energy one with symmetric distribution of the electric field across both interfaces, and a lower energy mode for an antisymmetric pattern. In our case, this symmetry will be broken by the use of different dielectric materials, but similar modes are expected.

For thin TCO layers, it has been theoretically [3] and experimentally [4] shown that the high amplification of the field across both interfaces can drive the higher energy mode to overpass its own single-interface frequency limit. The effect appears for layers thinner than \(\lambda_p/5\pi\), with \(\lambda_p\) being the wavelength associated with the plasma frequency [4]. This is a low dispersive mode usually called epsilon near zero (ENZ), where the field is heavily amplified and confined in the TCO and the SPR almost reaches the plasma frequency of the material. In the same range of small TCO thickness, the lower energy SPR is expected to reach frequencies small enough to interact with the substrate phononic modes. These Surface Phonon Resonances (SPhRs) are surface modes, analogous to SPR, where light couples phonons as elementary oscillation instead of plasmons. While being formally similar to SPR, they have a much more restricted dispersion, with a range of frequencies limited to the reststrahlen band defined by transversal and longitudinal phononic modes [5].

2. Materials and methods

The CdZnO samples were grown by Chemical Vapor Deposition (CVD) on r-plane sapphire substrates at 330°C. Their reflectance spectra were measured with a Fourier Transform Infrared (FTIR) spectrometer and fitted with a computational software based on the Transfer Matrix Method (TMM). Values of TCO thickness (\(d\)), high frequency dielectric constant (\(\varepsilon_\infty\)), plasma frequency (\(\omega_p\)), and damping (\(\gamma\)) were extracted from the fits.

For the study of the SPR, an Attenuated Total Reflection (ATR) configuration with a ZnSe prism was used in conjunction with the FTIR. P-reflectance of the samples was measured as a function of the angle of incidence and compared with theoretical reflectivity simulations where the previously fitted parameters were used.

3. Results and discussion

As shown in Figure 1, the two expected SPR modes were found in each reflectance experiment as absorbing minima in reflectivity maps. Hence, they can be associated with the symmetric and antisymmetric distributions of the electric field we previously discussed.

Regarding the upper branch, this is consistently under $\omega_{sp,air}$, the single-interface air-CdZnO SP frequency in thick samples, acting as an asymptote. The case is indistinguishable from a simple air-CdZnO system, so this mode can be considered decoupled from the interface with sapphire. As the thickness decreases, this limit is clearly overpassed and the resonance almost reaches the plasma frequency of the TCO. Thus, we are clearly in the ENZ regime expected for such small thicknesses.

In contrast with the upper branch, the lower minima range is more intensely affected by changes in the TCO thickness. In thick samples, while the asymptotic decoupled limit ($\omega_{sp, sapphire}$) is not reached in our experiment, the computational extension of the angle of incidence pins the minimum to the expected value. Thinner samples restrict the decrease in frequency to the SPhR limit measured in absence of plasmonic layer. Consequently, the lower branch in our system could be considered a hybrid Surface Phonon-Plasmon Resonance, preserving some of the desirable properties associated to both types of light interactions. From the SPR, it maintains the wide range of tunability via thickness control and doping. From the SPhR, the low widening of the absorption minima, especially at lower energies.

4. Conclusions

We show here that the CdZnO effectively supports surface plasmonic modes that can be conveniently tuned by a fine control of the thickness. For thin TCO layers, the strong interaction of the electric field across both interfaces leads to two strongly coupled modes that include a low dispersion ENZ mode and a highly tunable hybrid SPhPR. Thicker CdZnO layers decouple the interaction and those modes are expected to be indistinguishable from single-interface systems. Accordingly, a versatile plasmonic behavior of CdZnO has been proven, with the advantages associated to this ternary compound: high plasma frequency and mobility with a relatively low growth temperature.

Abstract

Biexcitons, which can be excited in semiconductor quantum dots (QD), cause the multiphoton emission effect. However the photoluminescence quantum yield (QY) of biexcitons is low due to the Auger process. In this study we demonstrate the biexciton QY enhancement in single QDs due to their coupling with gold nanorods (GNRs). Measuring the photoluminescence properties of the same single QD before and after coupling with GNRs, we obtained a confirmation of the biexciton QY increase due to the Purcell effect.

1. Introduction

Semiconductor quantum dots (QDs) are known for their unique photophysical properties and, in particular, their ability to multiphoton emission caused by recombination of biexcitons that is practically simultaneous emission of two photons from single QD as a result of a biexciton / exciton cascade [1]. The latter phenomenon has an important implication for quantum technologies, since photons emitted by the biexciton and exciton can be entangled in polarization steaming from the spin of biexciton [2]. However, the luminescence quantum yield (QY) of biexciton states is relatively low due to the fast Auger non-radiative process, which limits the applicability of this effect in practice. Plasmonic nanoparticles (PNPs) can significantly modify the optical properties of nearby QDs [3, 4]. An important condition for plasmon-exciton coupling is the resonant overlapping of the plasmon modes and QD photoluminescence (PL) spectra. Particularly, PNP may acts as a near-field resonator, leading to an acceleration of the radiative recombination in QDs due to the change in the density of photon states, i.e., Purcell effect. If the rates of nonradiative processes remain unchanged, this should lead to the increase in PL QY. However in real systems, the change in the QY depends on the trade-off between the acceleration of the radiative process due to the Purcell effect and the acceleration of nonradiative losses due to resonant energy transfer. The purpose of our study was to create a composite thin-film material from QDs and gold PNPs with controlled distance between them, and during the fabrication of the material observe the same QD before and after deposition of PNPs to directly measure the changes in the PL properties of excitons and biexcitons [5].

2. Experimental

In this study we used the CdSe/ZnS/CdS/ZnS QDs in hexane solution with 90% QY and 5 nm diameter. The PL and extinction spectra of QDs are shown in Figure 1a. We used PNPs in the form of gold nanorods (GNRs) with $39.1 \pm 1.3$ nm length and $20.5 \pm 0.5$ nm diameter. Their extinction spectrum is presented in Figure 1a. To prepare thin-film hybrid structure the hexane solution of QDs was spin-coated on the thin (~5 nm) film of PMMA on glass so that, as a result, there is no more than one QD per 1 $\mu$m$^2$. Then the one or two PMMA layers were spin-coated on the top of QDs to control the distance between QDs and GNRs. To study the emission properties of the same single QD before and after GNRs deposition, we used the following procedure. At first, the objective was fixed on the single QD and its time-resolved PL intensity, PL decay kinetics and second-order cross correlation function were measured. Then GNRs were dropped on the top of the structure and left to dry completely. After that the PL properties of the same QD were studied again (Figure 1b). To measure the PL properties a confocal time-resolved fluorescent microscope Micro Time 200 (PicoQuant) was used. For excitation, we used 485 nm diode laser working at a pulse regime with 5 MHz repetition rate and ~100 ps duration. The biexciton QY was estimated by comparison of central and side parts of cross-correlation function $g^{(2)}$ [1]:
where $\Phi_{XX} = \Phi_X \frac{\int_{0}^{\infty} g^{(2)}(t) dt}{\tau} = \Phi_X \frac{\text{central peak}}{\text{average side peak}}$

Figure 1. (a) PL (red line) and extinction (black line) spectra of QDs and also extinction spectra of GNRs (blue line). (b) Schematics of the hybrid QD-GNR structure during PL experiments on a single QD.

3. Results and discussion

We prepared a series of samples in which the QDs layer was separated from the GNRs by a PMMA spacer (from 5 to 170 nm). Then, time-resolved, time-correlated and photon correlation spectroscopy measurements were performed. In all samples the central part of $g^{(2)}$ did not exceed 30% of side parts (17.5% in Figure 2a). After the GNRs deposition in all samples the central part of $g^{(2)}$ increased to the values of 70–120% of side parts (77% in Figure 2b) and the increase was the greater, the smaller the thickness of PMMA spacer. This situation may indicate an increase in the biexciton QY. Therefore, we measured the PL lifetime to prove the Purcell effect.

After GNRs deposition the PL lifetime shortened for all samples. For sample with 30 nm PMMA spacer this shortening was from 22.8 to 1.5 ns (Figure 2c). To show that this shortening is predominantly due to the Purcell effect, and not the plasmon-induced PL quenching, we measured the PL time trace before and after GNRs deposition. In all samples the average PL signal decreased in the presence of GNRs, but this decrease was much lower than PL lifetime shortening. For sample with 30 nm PMMA spacer this decrease was only 2.3 times (Figure 2d). This indicates an increase in the radiation rate due to the change in the density of the photon states, i.e. Purcell effect.

4. Conclusions

In this study we directly demonstrate the distance-controlled enhancement of the biexciton emission of single CdSe/ZnS/CdS/ZnS QDs due to their coupling with GNRs. Specifically, using photon correlation spectroscopy, accompanied by time-resolved luminescence studies of the same single QD before and after coupling with GNRs, we obtained an confirmation of the plasmon-mediated increase in the QY of biexciton states. By changing the separation between the QD and GNRs, we have demonstrated that the enhancement of the biexciton emission decreases monotonically with increasing distance. We explain this enhancement by the efficient coupling between the biexcitons in QDs and the GNRs plasmons, which leads to the predominant influence of the Purcell effect. Our findings constitute a reliable approach to managing the efficiency of multiphoton emission over a wide span of distances and can be used for the development of new materials, structures and devices with applications the fields of optoelectronics, optical computing and quantum technologies.

Ultrafast response of a plasmonic distributed feedback laser in large-signal modulation regime

Abstract

The time response to an external signal is the main characteristic of optoelectronic devices which determines their maximum modulation speed. The use of plasmonic structures can significantly reduce the response time. In this paper, we show that the response time of a two-dimensional plasmonic DFB laser in the large-signal modulation regime strongly depends on the size of the pump beam. There is an optimal size of beam for which the modulation speed is a maximum, and can achieve 1 THz.

1. Introduction

For many optoelectronic applications, such as the modulation of optical signals and sensing, lasers with an ultrafast modulation response are required [1, 2]. Such devices often operate in a large-signal modulation scheme where a pumping pulse switches the laser between the subthreshold regime and the above-threshold regime. The maximal modulation frequency of surface emitting lasers based on dielectric structures is limited to several tens of GHz [3]. This frequency can be significantly increased if one use metallic plasmonic structures. In our paper, we study the dynamics in the large-signal modulation regime of a plasmonic distributed feedback (DFB) laser that consists of a gold film perforated by a periodic array of holes, and is coated with a layer of an active medium. We examine the behavior of the laser for different sizes of the pump beam. Combining numerical simulations of the laser dynamics within the framework developed in Ref. [4, 5] with an analytical evaluation, we show that the response time strongly depends on the size of the pump beam. We demonstrate that there is an optimal size of the pump beam, for which the response time reaches a minimum. For typical experimental parameters, the optimal size of the pump beam is \(15 \mu\text{m}\) and the minimal response time is \(1 \text{ ps}\). The obtained value of the response time is in agreement with a recent experiment [1] where it has been shown that plasmonic lasers have a modulation frequency exceeding several hundred GHz in the large-signal modulation regime.

2. The time response of a plasmonic DFB laser

To describe the multimode dynamics of the plasmonic DFB laser we use an approach for considering ultrafast phenomena in dispersive dissipative media. This approach is based on the following equations:

\[
\frac{dn_{jk}}{dt} = -(\gamma_j + \gamma_k) n_{jk} + i \left( \omega_j - \omega_k \right) n_{jk} + \sum_{m=1}^{N_{\text{atom}}} \left( \Omega_{km} \varphi_{jm} + \Omega_{jm}^* \varphi_{km}^* \right)
\]

\[
\frac{dD_m}{dt} = -\gamma_D (1 + D_m) - 2 \sum_{j=1}^{N_{\text{mode}}} \left( \Omega_{jm} \varphi_{jm} + \Omega_{jm}^* \varphi_{jm}^* \right)
\]

\[
\frac{d\varphi_{jm}}{dt} = -\gamma_{jm} \varphi_{jm} + i \left( \omega_j^0 - \omega_m \right) \varphi_{jm} + \Omega_{jm}^* \left( D_m + 1 \right) + \sum_{l=1}^{N_{\text{mode}}} \Omega_{lm} n_{jl} D_m,
\]

Here, \(n_{jj}\) is the photon number in the \(j\)th Bloch mode, \(n_{jk}\) is an interference term responsible for the flow of photons from the \(j\)th to the \(k\)th mode, when \(j \neq k\). \(D_m\) is the population inversion of the \(m\)th atom and \(\varphi_{jm}\) describes the energy flow between the \(m\)th atom and \(j\)th mode. The parameters \(\omega_j, \gamma_j\) correspond to the real and imaginary parts of the eigenfrequencies of the modes; \(\omega_j^0\) and \(\gamma_D\) are the atom transition frequency and the relaxation rate of the population inversion of the atoms, \(\gamma_{jm} = \gamma_j + \gamma + \gamma_D/2\), \(\gamma_D\) is the relaxation rate of the phase of the atom polarization. \(\Omega_{jm}\) is the Rabi constant of coupling between the \(j\)th mode and the \(m\)th atom.

In Fig. 1 the dependence of the photon number on time is shown. There are three stages of the response of the system [6]. In the first stage, the response of the system is determined by the spontaneous emission in the active medium. The photon number in the plasmonic DFB laser is small. For the system under consideration, the duration of this stage, i.e., the delay time, turns out to be less than a picosecond.

\[
t_{\text{delay}} = \gamma \ln \left( \frac{N_{\text{at}}}{2} \right) / 4N_{\text{at}} \Omega_r^2.
\]
In the second stage, the photon number in the plasmonic laser rapidly increases due to stimulated emission in the active medium. This growth ceases with the saturation of the population inversion in the active medium. In the third stage, the photon number in the system decreases exponentially with time. We identify the total response time with the time when the number of photons in the system has decreased by a factor of ten from its maximum value. This time is about one picosecond.

Figure 1: The dependence of the total photon number on the time at the different diameters of the pump beam. The diameters are equal to 20 µm (red line), 10 µm (blue line), and 5 µm (purple line).

Figure 2: The dependence of the modulation times on the diameters of the pump beam. The blue line depicts the delay time; the purple line depicts the time of the end of the second stage; the red line depicts the total response time.

The dependence of the total photon number on time is qualitatively the same for different diameters of the pump beam. However, the response times manifest a non-monotonic dependence on the size of the pump beam, see Fig. 2. It can be seen that there is an optimal size of the pump beam at which the response time is a minimum. For the considered plasmonic DFB laser the optimal diameter of the pump beam is about 15 µm. As the pump beam diameter decreases, the response time increases rapidly. With an increase in the diameter of the pump beam, the response time changes slowly. This kind of behavior of the plasmonic DFB laser takes place at different initial values of the population inversion of the active atoms.

3. Conclusions

We have shown that the response time of such a laser for typical experimental parameters can be decreased to one picosecond, which corresponds to a modulation frequency of 1 THz. This value is close to the upper limit for plasmonic lasers (the total response time can not be shorter than the time of the third stage, which is determined by the losses in the cavity, and is ~ 1 ps).

It has been shown that the laser’s response time can be shortened by optimizing the size of the pump beam, as a result of the consequent reduction of the delay time. The dependence of the response time on the size of the pump beam is for following reason. The interaction of the laser modes with the pumped active medium results in the emergence of a single collective mode. If the size of the pump beam exceeds the propagation length of the EM waves, this collective mode is located in the pumped area. The response time then grows logarithmically with increasing pump beam diameter. In contrast, when the mode is outside the pumped region, the response time is approximately inversely proportional to the square of the pump beam diameter, and so increases rapidly as this diameter decreases from its critical value. Thus, there is an optimal size of the pump beam, for which the response time is a minimum.

Superradiant molecular aggregates on dielectric surfaces interacting with plasmonic structures

A. Eisfeld

1Max Planck Institute for the Physics of Complex Systems, Nöthnitzer Strasse 38, 01187 Dresden, Germany

Abstract

Molecular aggregates formed on dielectric surfaces can show strong collective effects which can result in eigenstates which exhibit super- or sub-radiant emission. Here we discuss how nearby nano-structures influence these eigenstates of the aggregate and the resulting optical properties.

1. Introduction

Organic molecules can self-assemble on dielectric surfaces into regular structures, such as one-dimensional chains or two dimensional arrays. Because of strong resonant interaction between the transition dipoles of the individual molecules, collective eigenstates are formed where an electronic excitation is coherently shared by a large number of molecules. The optical properties of these states differ extremely from those of the individual molecules. In previous work on the organic semiconductor PTCDA on a potassium chloride surface we have created two-dimensional arrays consisting of hundreds of molecules [1]. As a result of the collective eigenstates we observed super-radiant and sub-radiant behavior [1, 2]. This formation of collective states also leads to coherent transfer of a localized excitation along the aggregate. One way of creating such localized excitation is via a metallic nanotip [3].

2. Coupling between tip and aggregate

Our basic setup is sketched in Fig. 1. A metallic tip is placed at nanometer distance above a molecular aggregate formed on a dielectric surface. In Ref. [4] we have shown that in this way one can create a localized excitation which can be used for near-field spectroscopy, circumventing the far-field selection rules. In the present contribution we focus on the interaction between the metallic nanotip and the aggregate, which can be quite strong depending on the size of the nanotip and its distance from the aggregate. One example is shown in the two panels at the bottom of Fig. 1. In the absorption the coupling to the nanotip leads to a broad background on which peaks stemming from the aggregate eigenstates are imprinted.

3. Conclusions

In conclusion, we have considered strong interaction of a metallic nano-tip with a molecular aggregate formed on a dielectric surface. This study is a further step in understanding and designing hybrid systems of molecular aggregates and metallic nanostructures for optical and energy transfer applications.

Abstract

Propagation of a hybrid mode formed by mixing of a dielectric waveguide mode with several plasmonic modes, is studied numerically in 3D. Edge plasmons are used to maintain coupling between states with different polarisations. Proposed waveguide structures allow to reach a strong light-matter interaction regime and balance plasmonic losses, providing a convenient basis for various compact and efficient photonic devices, including electro-optical modulators and polarisation converters.

1. Introduction

Surface plasmon polariton (SPP) modes provide good optical confinement of light and play a significant role in nanophotonics. One well-known drawback of these modes is connected with losses. On the other hand, dielectric nanowaveguides provide a loss-free way to transmit light, but the confinement is poor, to compare, for example, with the typical sizes of modern electronic components. The idea of hybrid plasmonic waveguides (HPWG) is to mix both concepts and obtain a compromise solution with a desired proportion between losses and confinement \cite{1}. Strong optical confinement of SPP modes is accompanied by enhanced field intensity and strong light-matter interaction (via the oscillations of surface electrons plasma). This property is extremely useful in photonics and allows to construct small and efficient devices. For example, it is used in combination with epsilon-near-zero (ENZ) effect to produce compact waveguide based optical modulators \cite{2}.

In classical hybrid waveguides \cite{3} a layer of metal, separated by a thin dielectric, is placed on top of an ordinary waveguide. In this case at least two hybrid modes are formed (for a single mode waveguide) and participate in the evolution of the mixture. The strength of hybridisation can be controlled via the thickness of the insulating layer. There is at least one principle limitation of this structure connected with a polarisation of plasmons. They interacts only with waveguide modes polarised perpendicular to the metallic surface. Applications which assume a delicate polarisation processing require HPWG with more sophisticated structure.

Propagation of hybrid modes (even in the simplest case) is usually accompanied by a periodic oscillation of populations in different components of the mixture. There is a certain analogy between the behaviour of HPWG and directional couplers, where the optical signal travels back and forth between two waveguides, placed close to each other. Nevertheless, the theory of coupled waves, well developed for directional couplers is not efficient for HPWG, because of a strong interaction \cite{1}. To study the propagation of strongly coupled plasmonic modes numerical calculations are necessary.

In our work we construct HPWG where the waveguide mode is hybridised with several SPP modes. Edge plasmons with a mixed polarisation state are used in our design to couple otherwise orthogonal states to each other. During the propagation of the mixture, polarisation oscillates between horizontal and vertical directions. It is discussed how to use the proposed principle for the construction of compact polarisation converters \cite{4} and expand the idea of a waveguide based plasmonic modulator to remove polarisation restrictions typical for this class of devices. Numerically heavy 3D calculations are performed to model the proposed HPWG.

2. Discussion

One of the proposed HPWG (see Fig. 1 (a) where the transverse cross-section is shown) consists of a single mode silicon waveguide with dimensions 600 nm \times 200 nm. At the telecom wavelength of 1550 nm it supports one \textit{y}-polarised propagating mode. On top of the waveguide there is a 10 nm layer of high quality dielectric HfO$_2$ and 15 nm layer of transparent conductive oxide ITO. In the absence of external fields the refractive indices of two materials (real parts) are close to each other and the boundary between them is almost optically homogeneous. The HfO$_2$/ITO junction is useful for applications, where the switching behaviour is required (like, for example, modulators). Applying the voltage one may initiate ENZ effect in ITO which leads to the strong attenuation of the signal. Above the ITO layer we place an additional block of ITO with dimensions 80 nm \times 65 nm, which we call a geometrical defect or an impurity. The golden electrode placed at the top of the structure forms two golden edges at the Au/ITO boundary, which support edge plasmonic modes with mixed polarisation states. The existence of the geometrical defect thus allows to couple the \textit{y}-polarised waveguide mode and two \textit{z}-polarised plasmonic modes via edges. At the same time
3. Conclusion

In our work we analyse the propagation of hybrid modes with several plasmonic components (including edge plasmons) in different regimes. Influence of the geometry and materials properties on the mixed state evolution is studied. Numerically expensive 3D computations are employed in the analysis. Plasmonic losses are evaluated and structural advantages of the presented models for practical applications are studied. We discuss how to use proposed HPWG to produce efficient waveguide based electro-optical modulators, which work with $y$-polarised signals, and compact polarisation converters.

References

The propagation of light in the described structure is accompanied by the periodic oscillation of populations in the waveguide mode and plasmonic modes. The period depends significantly on coupling and thus the geometry of the defect. One period (which is close to 7 µm in our example) is shown in details in Fig. 1, where the absolute value of the electric field is plotted. To compute the field distribution, Maxwell equations are solved numerically in the frequency domain. Four different cross-sections of the 3D model are shown. In Fig. 1 (a) (b) cross-sections transverse to the direction of the propagation are plotted. In (a) the waveguide mode is maximally populated and in (b) most of the field is transmitted into plasmonic modes. In Fig. 1 (c) and (d) two other cross sections are shown: vertical (c) and horizontal (d) which can be considered as 'side view' and 'top view' respectively. In the first case the plane is fixed at the middle of the waveguide which allows to see mainly the waveguide mode. In the second case the plane passes through the center of the gap between the waveguide and the metal and allows to see the plasmon. In the last case the field is divided by 2.5 for the better visualisation.
Near-field phase imaging using phase-shifting digital holography

Abstract
We propose a novel method for the phase distribution measurement of the near electric field based on the principles of phase-shifting digital holography. The holographic interference occurs already in the near field and the phase distribution can be determined purely from the scanning near-field optical microscopy measurements. We demonstrate the capabilities of the proposed method by reconstruction of the phase difference between interfering surface plasmon waves and by imaging the phase of a single surface plasmon wave.

1. Introduction
The surface plasmon polaritons (SPPs) are evanescent electromagnetic surface waves coupled to the collective longitudinal oscillations of the free-electron gas in a metal propagating along a metal-dielectric interface. Spatial confinement of the electromagnetic field at the interface and smaller wavelength compared to the excitation light, corresponding enhancement of electromagnetic energy density at this interface, and the sensitivity of SPPs to dielectric functions of both material constituents forming the interface make SPPs attractive for many applications. Scanning near-field optical microscopy (SNOM) in combination with plasmonic interference structures is a powerful tool for imaging and analysis of SPPs [1].

2. Results and discussion
The correct interpretation of SNOM images requires profound understanding of principles behind their formation. To study fundamental principles of SNOM imaging in detail, we performed spectroscopic measurements by an aperture-type SNOM setup equipped with a supercontinuum laser and a polarizer, which gave us all the degrees of freedom necessary for our investigation. The series of wavelength- and polarization-resolved measurements, together with results of numerical simulations, then allowed us to identify the role of individual near-field components in formation of SNOM images, and to show that the out-of-plane component generally dominates within a broad range of parameters explored in our study [2]. Our results challenge the widespread notion that this component does not couple to the aperture-type SNOM probe and indicate that the issue of SNOM probe sensitivity towards the in-plane and out-of-plane near-field components — one of the most challenging tasks of near field interference SNOM measurements — is not yet fully resolved.

Moreover, we present a novel experimental method of plasmonic phase-shifting digital holography (PPDH) and demonstrate its potential for pure-near-field measurements of the surface plasmon polariton (SPP) phase distribution [3]. The experimental set-up for PPDH is shown in Fig. 1. The core of the proposed method is an on-chip interferometer which works with co-propagating or counter-propagating SPPs representing the analogy of signal and reference wave. The SPPs and consequently their interference patterns can be controlled by a Spatial Light Modulator (SLM) implemented in the far-field illumination path of an optical setup equipped with an aperture-type Scanning Near-Field Optical Microscope (a-SNOM) for SPP detection (collection mode) [1]. In this way, phase-controlled excitation of SPPs can be studied. By adopting the principles of the phase-shifting holography, we generate four slightly modified SPP interference patterns, allowing the numerical reconstruction of the SPP phase distribution in the pattern [4]. These four interference patterns differ in the mutual phase shifts between the individual SPPs (set by the SLM). An example of the measurement of the phase of plasmon standing wave created by a circular slit with the diameter of 0.01 mm is shown in Fig. 2. Since all information is collected in the near-field, our method provides a purely near-field measurement and it advantageously avoids the use of a far-field interferometer. Applying the SLM, this method can be directly used in a variety of techniques capa-
Figure 2: SPP phase reconstruction realized by numerical processing of the experimental and simulated interference patterns: Four measured interference patterns with the 4 distinct phase-shifts 0, $\pi/2$, $\pi$, and $3\pi/2$ introduced between the interfering SPPs by the SLM followed by the SPP phase difference reconstructed by numerical processing of the experimental data. To compare the experiment with the theory, the SPP phase difference image reconstructed by numerical processing of the FDTD simulated interference pattern is presented excluding and including the noise which disrupts the measured data. The profiles show cross-sections along the dashed lines in the central parts of the phase images.

3. Conclusions

In summary, we have presented a new method for near-field phase imaging based on the principles of phase-shifting digital holography. We have demonstrated the capabilities of our method by reconstructing the phase difference between counter-propagating SPP waves excited inside a circular slit structure. The strength of this method lies in its compatibility with experimental techniques suitable for ultrafast SPP imaging, e.g. photoemission electron microscopy. This method presents an important step towards the development of 2D plasmonic holography for imaging of phase contrasts of objects (e.g. biological cells, plasmonic nanoantennas) bound to surfaces.

1. Introduction

Localized surface plasmons (LSP) are self-sustained collective oscillations of free electrons in metal nano- and microstructures, often called plasmonic antennas, coupled to the local electromagnetic field. LSP resonances can be characterized by electron energy loss spectroscopy (EELS) and cathodoluminescence (CL). Both techniques utilize an electron beam that interacts with the metallic nanoparticle and excites the LSP resonances. EELS measures the energy transferred from electrons to the LSP. CL deals with the light which the LSP emit during their decay. Both techniques are sensitive to the electric near field of LSP.

Babinet’s principle, originating in the wave theory of light and analysis of diffraction, relates the properties of a planar plasmonic antenna (particle) and a complementary aperture in a thin metal film of the same size and shape [1]. In particular, the energies of LSP resonances in both antennas shall be identical and the corresponding near fields shall be complementary with the electric field distribution of the solid antenna corresponding to the magnetic field distribution of the complementary aperture. This link allows studying the magnetic near field, for example, by measuring the electric near field by EELS in the complementary structure.

We present a study of Babinet’s principle of complementarity in plasmonics focused on elementary disc-shaped plasmonic antennas followed by a theoretical and an experimental study of plasmonic antennas with electric and magnetic hot spots based on Babinet’s principle [3, 4].

2. Results and discussion

We have studied a set of gold plasmonic antennas fabricated in the form of particles and apertures in a gold layer by focused ion beam lithography to investigate the basic properties of complementary structures and describe similarities and differences. Focused ion beam lithography is a suitable technique for fabrication of a small series of plasmonic antennas [5] allowing to fabricate easily both types of antennas (particles and apertures) on the same sample.

2.1. Disc-shaped plasmonic antennas

While the qualitative validity of Babinet’s principle has been confirmed, quantitative differences have been found. As it is found by comparing the experimental data with a theoretical model, differences originate both from the limited theoretical validity of the Babinet’s principle and from different operational conditions. In particular, apertures were found to exhibit stronger plasmonic response than solid antennas, which makes them a remarkable alternative of the usual plasmonic antennas design [2]. We have also examined magnetic near field imaging based on the Babinet’s principle. Figure 1 shows dark field micrographs of a gold disc and aperture with the diameters of 100 nm together with intensity maps measured by EELS presenting the spatial distribution of the dipole LSP resonance at 1.75 eV for the particle and 1.5 eV for the aperture.

2.2. Bow-tie and diabolo antennas

We have studied plasmonic antennas featuring areas of extremely concentrated electric or magnetic field, known as hot spots. We combined two types of electric-magnetic complementarity to increase the degree of freedom for the design of the antennas: bow-tie and diabolo duality and Babinet’s principle. The role of Babinet’s principle in interchanging electric and magnetic field hot spots and its consequences for practical antenna design are discussed.

In particular, diabolo antennas exhibit slightly better performance than bow-ties in terms of larger field enhancement and larger Q factor. For specific resonance frequency, diabolo antennas are considerably smaller than bow-ties which makes them favourable for the integration into more
complex devices but also makes their fabrication more demanding in terms of spatial resolution [3].

Moreover, we have revisited plasmonic modes in nanoparticle dimers with conductive (diabolo or inverted bow-tie antennas) or insulating (bow-tie or inverted diabolo antennas) junction. In our study combining EELS, optical spectroscopy, and numerical simulations we show coexistence of strongly and weakly hybridized modes [4]. We show that Babinet’s principle allows to engineer the near field of plasmonic modes independent of their energy. Finally, we show that combined EELS imaging of a plasmonic antenna and its Babinet-complementary counterpart allows to reconstruct the distribution of both electric and magnetic near fields of LSP resonances supported by the antenna as well as charge and current antinodes of related charge oscillations as shown in Figure 2 for the transversal dipole (TD) mode in the diabolo antenna.

3. Conclusions

We have studied a set of gold plasmonic antennas in the form of particles and apertures. By comparing the experimental data with a theoretical model we found differences originating both from the limited theoretical validity of the Babinet’s principle and from different operational conditions for elementary disc-shaped plasmonic antennas. Further we have studied engineering of plasmonic antennas with electric and magnetic hot spots based on Babinet’s principle and from different operational conditions for elementary disc-shaped plasmonic antennas. Further we have studied engineering of plasmonic antennas with electric and magnetic hot spots based on Babinet’s principle and from different operational conditions for elementary disc-shaped plasmonic antennas.

Abstract

In the fully quantum mechanical framework of Time-Dependent Density Functional Theory (TD-DFT), we investigate the interactions between a localized surface plasmon excitable in a silver tetrahedral cluster and a molecular exciton optically active in the same energy range. We show that the optical response of the system, for an ultra-near-field regime of interaction, is marked by the appearance of a two-peak structure. We propose a plasmon-exciton electromagnetic interaction model as explanation of the spectra of this kind of hybrid systems of interest for molecular plasmonics.

1. State of the art

Fully atomistic approaches can offer important insights in the study of metal-molecule systems of interest in Nanophotonics and Plasmonics.

In fact, if on the experimental level, fabrication and characterization techniques can manage light-matter interaction at sub-nanometer scales, on the theoretical level application of computational methods from classical electrodynamics to these kind of systems breaks down [1]. In this context, TD-DFT [2] represents, nowadays, an established opportunity to study the electrodynamic coupling between molecules and metallic nanoantennas without neglecting intrinsic quantum effects and thus able to overcome the limits of the classical vision.

2. System and method

Using TD-DFT we studied the system depicted in the panel a of Fig. 1, which consists of a tetrahedral cluster of Ag₂₀ and a molecule of trans,trans-1,4-diphenyl-1,3-butadiene (t,t-DPB) [3], a molecular emitter belonging to the class of photo-switches and for this reason interesting for promising applications in molecular plasmonics.

We computed the absorption spectra in an ultra-near-field regime of interaction with the aim to study how the optical response of the plasmonic cluster is influenced by the functionalization with the molecule. The physics underlying the absorption spectra has been well investigated in terms of transition densities, the results showing a plasmon-exciton electromagnetic interaction. All the calculations have been performed with the TURBOMOLE program [4].

3. Results and discussion

As the panel b of Fig. 1 illustrates, the absorption spectrum is marked by the presence of two well distinguishable peaks.

Reasoning in terms of two-coupled oscillators model, the absorption spectrum can be explained in the manner sketched in Fig. 2.

When the cluster and the molecule are close enough to allow a coupling between their transition dipole moments, the formation of two states becomes possible: B (bonding) at energy ω₋ and A (anti-bonding) at energy ω₊.

The bonding state B originates from the aligning along the z axis of the two transition dipoles of the interacting components and, thus, it emits and absorbs far-field radiation and assumes an optically active or bright behavior. The anti-bonding state A originates from an anti-parallel align-
Figure 2: A pictorial scheme of the coupling between a plasmon and an exciton. The black thick lines indicate the excitation energies of the isolated molecule and cluster. When the counterparts are close enough to allow a coupling between their transition dipole moments, this interaction permits the formation of two states: the bright or bonding one $B$ at energy $\omega_-$ represented by the green thick line and the dark or anti-bonding one $A$ at energy $\omega_+$ represented by the orange dashed line.

The interaction along the $z$ axis of the transition dipole moments of the two components and, consequently, it is characterized by a small total transition dipole and it results to be optically inactive or dark. Between the bonding and anti-bonding excitations, there is the plasmonic peak of the cluster, due to the allowed states $P_x$ and $P_y$ which do not interact with the molecule.

This interaction scheme was confirmed by the results obtained from the transition densities analysis computed for the bright, plasmonic and dark peaks characterizing the absorption spectra in the distance range going from 2 to 4.5 Å. A scheme of this kind of analysis is reported in the panel $c$ of Fig.1 for the distance of 2 Å, in which it clearly appears that both the excitations at energy $\omega_-$ and $\omega_+$ are hybrid, while, the excitation at energy $\omega_0$ is localized on the cluster.

Moreover, in order to investigate about the possible presence of charge transfer effects, we quantified the transition densities computing the integral over $x$-$y$ plane of the three-dimensional transition densities for all the bright excitations in the distance range from 2 to 4.5 Å and we found that a small fraction of electronic charge ($0.13$ e for the distance of 2 Å) passes from the molecule to the cluster. Nevertheless, this contribution is so small that the coupling mechanism can be substantially explained in terms of a plasmon-exciton electromagnetic interaction model.

4. Conclusion

In conclusion, we have presented a TD-DFT analysis on the plasmon-exciton interactions characterizing a model system composed of a $t,t$-DPB molecule and a tetrahedral cluster of $Ag_{20}$, treating both the metallic and molecular counterparts atomistically. We have shown that, for ultra-near field regime of interaction, the optical response of the system is characterized by a double peak structure. We have analyzed the transition densities for the peaks energies and proposed a plasmon-exciton electromagnetic interaction model to explain the origin of the lower-energy resonance and the physics underlying the electrodynamic coupling in such hybrid systems.

This fully atomistic approach represents thus a complete theoretical scheme which, considering both the electronic and optical effects taking part to the interaction, can shed light on the mechanisms involving a plasmonic system interacting with a molecular switch.

Moreover, such hybrid configurations could result very appealing for applications in Nanophotonics, going from bio-sensing to quantum computing.

Slender-body theory for localized-surface-plasmon resonance

Matias Ruiz\(^1\)*, Ory Schnitzer\(^1\)

*corresponding author, E-mail: matias.ruiz@imperial.ac.uk

Abstract

We propose a slender-body theory for calculating the surface-plasmon eigenvalues and eigenmodes of smooth high-aspect-ratio metallic nanoparticles (of otherwise arbitrary shape) and their resonant excitation by incident electromagnetic radiation. Using matched asymptotic expansions, we develop an equivalent one-dimensional model which is straightforward to solve numerically and in special cases furnishes closed form solutions.

1. Introduction

Elongated metallic nanoparticles are frequently used in nanoplasmics, as nano-antennas and bio-sensors, enabling wide tunability and strong field enhancements \([1]\). We are accordingly motivated to consider the problem of a slender metallic nanoparticle subjected to either incident radiation or a time-harmonic current density \(J(x)\) in its external vicinity. Assuming that the particle is deeply subwavelength, we adopt the quasi-static approximation of Maxwell’s equations:

\[
\nabla \cdot (\varepsilon(x)E) = -\frac{i}{c\omega} \nabla \cdot J, \tag{1}
\]

\[
E \to E_\infty \quad \text{as} \quad |x| \to \infty, \tag{2}
\]

where \(E(x)\) is the electric field, \(E_\infty\) is a constant forcing term representing a possible incident plane wave and \(\varepsilon(x)\) is the electrical permittivity relative to its value \(\varepsilon_0\) in free space; we adopt the usual convention for time-harmonic fields at angular frequencies \(\omega\). The relative permittivity \(\varepsilon(x)\) takes the constant positive value \(\varepsilon_m\) outside the particle and the complex-valued and frequency dependent constant \(\varepsilon_c(\omega)\) inside it.

The induced field \(E(x)\) can be expanded in terms of the solutions of the so-called plasmonic eigenvalue problem, which, in this context, consists of finding the values (eigenvalues) of the ratio between the inclusion permittivity and the medium permittivity, for which there exist non-trivial solutions to (1) and (2) when both \(J(x)\) and \(E_\infty\) are set to zero. In the case of a smooth inclusion, the eigenvalues are discrete, real, negative and accumulate at -1. We denote the \(n\)-th eigenvalue (counting multiplicities) and eigenmode as \(\mathcal{E}^{(n)}\) and \(E^{(n)}\), respectively. Thus, assuming that the eigenvalue problem has been solved and that the eigenmodes have been properly normalised, we have [2]

\[
E(x) = F(x) + \sum_{n=0}^{\infty} \frac{\varepsilon_c/\varepsilon_m - 1}{\varepsilon_c/\varepsilon_m - \mathcal{E}^{(n)}} \beta_n E^{(n)}(x), \tag{3}
\]

where \(F(x)\) corresponds to the induced field in the absence of the particle and \(\beta_n\) represents an overlap integral depending solely on \(F(x)\) and \(E^{(n)}\) within the particle.

In the visible regime and when the metal is small compared to the operating wavelength, the real part of the inclusion’s permittivity is negative while the imaginary part, which accounts for ohmic losses, is often relatively small. It follows that the \(n\)-th mode will be greatly enhanced if the frequency \(\omega\) is such that \(\Re(\varepsilon_c(\omega)/\varepsilon_m)/\mathcal{E}^{(n)} \approx 1\) and \(\Im(\varepsilon_c(\omega)/\varepsilon_m)/\mathcal{E}^{(n)} \ll 1\), where \(\Re\) and \(\Im\) denote the real and imaginary parts respectively. Such resonant behaviour can therefore by captured by virtually a single term in the eigenfunction expansion (3).

In this work we use singular perturbation techniques, namely matched asymptotic expansions in the spirit of slender-body theory [3], to develop asymptotic solutions to the plasmonic eigenvalue problem in the limit where the slenderness of the particle vanishes. The asymptotic eigen-solutions are subsequently used, in conjunction with (3), in order to obtain approximations for the induced field and optical cross sections in the case of plane-wave illumination.

Applications involving slender particles usually rely on lower-order modes that vary mainly in the longitudinal direction, as these efficiently couple with incident radiation and allow tuning the surface-plasmon frequencies down to the IR regime. Accordingly, it is convenient to focus here on axisymmetric particles, for which the longitudinal modes are easily identified with axisymmetry. We further assume that the particle is smooth, having locally paraboloidal tips, though otherwise its shape profile remains arbitrary.

2. Slender-body theory

2.1. Geometry

We introduce the cylindrical co-ordinates system \((ar, az, \theta)\), where \(2a\) is the dimensional length of the major axis of the particle. The surface of the particle is described by the thickness profile \(r = hf(z)\) \((-1 \leq z \leq 1\) where \(h > 0\) is a slenderness parameter and \(f(z)\) is a positive real-valued smooth function such that \(f = O(|z + 1|^1/2)\) as \(z \to \pm 1\). Given the axial symmetry of the geometry, the modes can be sought as functions of \((r, z)\) times \(\cos(m\theta)\) or \(\sin(m\theta)\), where \(m = 0, 1, 2, \ldots\)
2.2. Eigenvalue scaling

Let $E$ denote some plasmonic eigenvalue. Using scaling arguments, it can be shown that for non-axisymmetric modes $(m \neq 0)$ the limit $E \rightarrow -1$ as $h \rightarrow 0$ holds, whereas for axisymmetric modes $(m = 0)$:

$$E \sim -\frac{\alpha}{h^2} \text{ as } h \rightarrow 0,$$

where the pre-factor $0 < \alpha$ depends on the thickness profile and mode number; and as we shall see, the dependence of $\alpha$ upon $h$ is strictly logarithmic.

2.3. Effective eigenvalue problem ($m = 0$)

Using the method of matched asymptotic expansions in the limit $h \ll 1$ we find the following effective eigenvalue problem for the reduced eigenvalue $\alpha$ and the corresponding leading-order voltage inside the inclusion $v(z)$ (coupled with the leading order surface charge per unit length $m(z)$),

$$m(z) + \pi \alpha \frac{d}{dz} \left( f^2 \frac{d}{dz} v(z) \right) = 0,$$

$$v(z) = \frac{m(z)}{2\pi} \log \frac{2\sqrt{1-z^2}}{f'(z)} + \frac{1}{4\pi} \int_{-1}^{1} \frac{m(\zeta) - m(z)}{|\zeta - z|} d\zeta. \quad (6)$$

2.4. Solutions to the effective eigenvalue problem

In the case of a prolate spheroid, for which $f(z) = (1 - z^2)^{1/2}$, analytical solutions to the effective eigenvalue problem can be found as

$$\alpha^{(n)} = \frac{1}{n(n+1) \log(2/h)} - \sum_{k=1}^{\infty} \frac{1}{k} \log(1/k), \quad (7)$$

where $n = 1, 2, \ldots$, with $v^{(n)}$ and $m^{(n)}$ proportional to the $n$'th Legendre polynomial. Fig. 1 shows excellent agreement between (7) and the exact eigenvalues of a prolate spheroid.

In the case of an arbitrary thickness profile, the eigenfunctions $v$ and $m$ can be expanded in terms of Legendre polynomials yielding, through controlled truncation, a generalised eigenvalue (matrix) problem whose solution can be found at a negligible computational cost. Fig. 2 compares the calculated first mode of a prolate spheroid and a deformed slender shape lacking fore-aft symmetry.

3. Plane-wave illumination

In the scenario where the metallic nanoparticle is subjected to an incident plane wave, the above eigen-solutions together with (3) can be used to obtain asymptotic approximations to all quantities of interest. For example, Fig. 3 shows the angle-averaged extinction cross-section per unit volume in the case of a spheroid and a slender shape lacking fore-aft symmetry. We note the excitation of multiple resonances in the asymmetric case.

Abstract

State-of-the-art fabrication and characterization techniques are to date able to experimentally control light-matter interaction at sub-nanometer scales where computational methods from classical electrodynamics fail. In this work we analyze the effects of the metal-molecule distance on the lower-energy peak appearing in the absorption spectra of hybrid plasmonic nanosystems underlying the importance of a fully quantum mechanical approach to take into account all the phenomena playing a role in such kind of electro-optical interactions.

1. Introduction

Classical electrodynamics has been until now largely applied to study the optical properties of many plasmonic systems. However, in the last few years, thanks to the development of fabrication and characterization techniques and to their capabilities to manage light-matter interaction at the sub-nanometer scale, a growing interest toward the quantum nature of matter is appearing in the scientific community dealing with plasmonics and above all molecular plasmonics. The goal is that to fully control the physics of interaction between plasmons and molecular emitters by considering at the same time electronic and optical effects. Differently from what happens in the regime of classical interactions, where extended systems far from each other are considered, non classical effects, such as the nonlocality or the spill-out of the electronic density, must be taken into account to manage the physics of multi-scale plasmonic systems - including subnanometers features - or sub-nanometer gaps configurations in which phenomena of resonant electron transfer of tunneling can emerge [1].

In this work we shed light on the role of these effects on the absorption response of hybrid metal-molecule nanosystems which could result very promising for applications in ultra-sensitive and selective biosensing as well to realize logic gates for quantum computing.

2. Method

In this work we focus on a system consisting of a molecular emitter, trans,trans-1,4-diphenyl-1,3-butadiene (t,t-DPB), and a tetrahedral cluster of Ag20.

The molecule belongs to the important and vastly studied class of molecular photoswitches which can be converted from one configuration to one another via photoisomerization processes while the cluster is among the smallest ones having a plasmon-like excitation in the same spectral region of the above mentioned molecular emitter.

The system is treated at three different levels of approximation: (i) Time-Dependent Density Functional Theory (TD-DFT) [2], (ii) Finite Element Method (FEM) [5] and (iii) dipole-dipole model.

For what concerns the most rigorous approach (i), both the optical antenna and the quantum emitter are treated atomistically (see the sketch in Figure 1). All the DFT simulations on geometry relaxation, ground state and excited states have been performed with the TURBOMOLE program [3]. Regarding the structure relaxation, it was performed with a B3LYP functional for the exchange-correlation energy and a def2-SVP basis set for the molecular part and a PBE/def2-SVP prescription for the metallic nanocluster [4]. The DFT relaxed geometries of the isolated systems were, then, considered as a starting point for the TD-DFT analysis of the optical behavior of both the isolated components and the total system in which the photoswitch was rigidly shifted away from the silver nanoparticle in order to explore all the different distances ($d_{DFT}$). The distance considered for this approach was, thus, the difference between the $z$ coordinates of the $H$-atom closest to the cluster and the top Ag atom of Ag20, as indicated in Figure 1.

Regarding the FEM study, the absorption cross section spectra were simulated by using COMSOL Multiphysics [5]. In particular the tetrahedral cluster was modelled as an ideal tetrahedron of 1.8 nm side with rounded-corners, i.e. curvature radius of 0.269 nm. The used dielectric function was the one tabulated by Palik for Ag [6]. The molecule was instead approximated as a small nanosphere (radius of 0.28 nm) with an ad-hoc dielectric function engineered in order to exactly give the TD-DFT absorption spectrum. The distance in this case was assumed as $d_{DFT} + L_{mol}$, where $L_{mol}$ is the distance between the outer H-atoms and the molecule center (0.66 nm). Finally, the system was studied within a classical dipole-dipole model in which the transition dipole moments of the two systems at the resonant energies were considered to estimate the
\( d_1 \) and \( d_2 \) values. The distance was, then, assumed to be \( d_{DFT} + L_{mol} + L_{cluster} \), where \( L_{cluster} \) was fixed to 0.3 nm (distance of a vertex from the Ag\(_{20}\) center).

### 3. Results

We analyzed the TD-DFT absorption spectra for several distances, going from 0.2 nm to 6 nm. We noted that, in the distance range going from 0.2 nm to 0.45 nm, each spectrum is characterized by the presence of two peaks, while, starting from the distance of 0.5 nm, the splitting gradually disappears, as long as, the single peak progressively becomes the sum of the absorption spectra of the two separated constituents, at 3.28 eV and 3.29 eV respectively for the cluster and the molecule.

In Figure 1 we report the effects of the metal-molecule distance, \( d_{DFT} \), on the spectral position of the lower-energy peak. What is evident is that this state importantly depends on the cluster-molecule distance, as it is evident from the red-shift of the absorption peak reducing the metal-molecule distance and that also the TD-DFT trend seems to follow a dipole-dipole interaction law.

Reasoning in terms of two-coupled dipoles model, the two peaks in the absorption spectra found out for the distances range 0.2-0.45 nm, can be explained as the bonding dipole due to the hybridization of the \( z \)-components of the surface charge of the two oscillators (lower-energy distance-dependent resonant peak) and the uncoupled \( x \)- and \( y \)- modes of the three-fold degenerate plasmon excited inside the metallic cluster (fixed reference peak).

In more details, the molecule is characterized by a transition dipole moment oriented along the \( z \)-direction and this state interacts only with the \( z \) component of the cluster transition dipole. This creates two hybrid states: a bonding state at an energy lower with respect to the reference one and anti-bonding at an higher energy (with null oscillator strength and thus not visible or dark).

What is interesting is that, even if the dipole-dipole interaction model seems to work well in terms of trend for distance larger that 0.5 nm, the effects as the charge transfer was proved to be negligible with respect to the electromagnetic contribution, the interaction among the two charge distributions at excitation results to be much larger in the quantum mechanical scheme, this attesting the necessity to take into account the real dislocation of the charge all over the systems and the atomistic nature of the quantum emitter. Classical models fail, thus, in reproducing TD-DFT results for the ultra-near-field regime of interaction, i.e. separation distance smaller that 0.5 nm.

### 4. Conclusion

In this work we use the TD-DFT framework to analyze the interactions in an ultra-near-field regime, between a localized surface plasmon excitable in a silver tetrahedral clus-

ter and a molecular exciton with a resonant excitation energy. We report that, for metal-molecule distances below 0.5 nm, the optical response of the system presents the onset of a double peak structure which can be explained within a dipole-dipole interaction scheme.

However, the comparison among classical and quantum mechanical models shows that a pure classical description of the two nanosystems seems to be inappropriate to predict the right position of the hybrid peaks in the absorption spectra of such kind of hybrid configurations which could result very promising for applications in bio-sensing as well as in quantum computing.

Angular momentum transfer from a swift electron to a small nanoparticle

José Ángel Castellanos-Reyes* and Alejandro Reyes-Coronado

Departamento de Física,
Facultad de Ciencias, Universidad Nacional Autónoma de México, Ciudad de México, México

Abstract

In this work we present a study of the angular momentum transfer from a fast electron, like those typically used in Transmission Electron Microscopes, to a spherical nanoparticle using a classical electrodynamics approach within the small particle limit. We show preliminar results obtained for an aluminum-like nanoparticle modelled with a Drude dielectric function.

1. Introduction

Electron microscopy has been widely used to study physical and chemical properties of materials [1–3]. In particular, Transmission Electron Microscopes (TEMs) have reached, in recent times, unique capabilities such as a spatial resolution up to 0.5 Å, an energy resolution of 10 meV, the possibility to perform Electron Energy Loss Spectroscopy (EELS) in the low-energy regime ~ 10 meV with a probe size less than 1 nm, and the possibility to inspect the momentum transfer dependence (hν) of vibrational modes with a momentum transfer resolution of Δν = ±0.5 Å⁻¹ and spatial resolution < 2 nm [4,5].

It has been shown that high-energy electron beams in TEMs, achieving energies up to 400 keV [3], may alter the samples under study. In particular, while operating in scanning mode (STEMs), it has been observed that the electron beam can induce movements on metallic nanoparticles [6], giving rise to the implementation of TEMs’ electron beams to control and manipulate nanometric particles at will, a technology now called electronic tweezers [7].

Although important efforts have been made in the past to describe the linear momentum transfer from a swift electron to a spherical nanoparticle characterized by a dielectric function ε(ω) [3,6,8–14], there is still a lot of work to do in order to fully understand the underlying physics. Precisely, for the angular momentum transfer study, there is still the need of a theoretical model that fully explains the dynamics of the nanoparticles induced by the swift electrons to completely understand the capabilities of electronic tweezers and exploit their technological potential.

In this work we present a model for the angular momentum transfer from a swift electron to a spherical nanoparticle, in the small particle limit approximation using the classical electrodynamics approach, as a function of the relevant parameters of the problem: radius of the nanoparticle, electron’s speed and impact parameter. We show preliminar results for an aluminum-like spherical nanoparticle modelled with a Drude dielectric response.

Figure 1: Sketch of the system under study: An electron (yellow spot) travels with constant speed v in a straight line at a distance b from the center of a spherical nanoparticle (grey sphere) with electromagnetic response ε(ω). The electron transfers angular momentum to the nanoparticle inducing a rotation (orange arrow).

2. Theoretical model

For the calculation of the angular momentum transferred from a swift electron to a spherical nanoparticle, modelled with a Drude dielectric function and under the small particle limit, we consider that the electron is traveling with constant speed v in a straight line, at a distance b from the center of the nanoparticle, as illustrated in Fig. 1.

In the frame of classical electrodynamics and under the small particle limit, the response of a nanoparticle is mainly due to both the electric (p) and a magnetic (m) dipole moments induced by the external radiation [15]. For an isotropic nonmagnetic (μ = μ₀) sphere, immersed in vacuum, the electric and magnetic polarizabilities, αE and αM, respectively, can be obtained from Mie theory [16] (in S.I. units):

\[ α_E(ω) = \frac{6πi}{k^3} a_1(ω), \]  
\[ α_M(ω) = \frac{6πi}{k^3} b_1(ω), \]

where \( a_1(ω) \) and \( b_1(ω) \) are the first Mie coefficients [16], \( k \) is the wavenumber and \( i = \sqrt{-1} \). The dipole moments are given by \( p(ω) = ε_0 α_E(ω) \mathbf{E}^{ext}(ω) \) and \( m(ω) = α_M(ω) \mathbf{H}^{ext}(ω) \) [17], where \( \mathbf{E}^{ext}(ω) \) and \( \mathbf{H}^{ext}(ω) \) are the electromagnetic fields produced by the bare electron [18].
evaluated at the center of the nanoparticle. The torque performed by the electromagnetic fields produced by the electron is

$$\mathbf{\tau} = p \times \mathbf{E}_{\text{ext}} + m \times \mathbf{H}_{\text{ext}}.$$  \hspace{1cm} (3)

Expressing the electromagnetic fields by means of their Fourier transforms in Eq. (3), the total angular momentum transferred can be written as

$$\Delta L = \int_{0}^{\infty} L(\omega) \, d\omega,$$ \hspace{1cm} (4)

i.e., as the integral of a spectral contribution $L(\omega)$.

### 2.1. Aluminum-like nanoparticle

We consider the case of a spherical nanoparticle with a dielectric response given by the Drude model, with parameters mimicking the aluminum, and numerically study the angular momentum transfer from an electron traveling with different speeds and impact parameters. As a preliminary result, we show in Fig. 2 the angular momentum transfer $\Delta L$ (in atomic units) for a nanoparticle with radius of 5 nm, as a function of both the impact parameter $b$ and the electron’s speed $v$, being $\beta = v/c$, where $c$ is the speed of light, considering only the electric induced dipole moment $p$.

Abstract

Following a classical electrodynamics approach, we present an analysis of the linear momentum transfer from swift electrons to nanoparticles as a function of the relevant parameters: particle’s radius, speed of the electron and its impact parameter. Since the momentum transfer is given in terms of the Maxwell stress tensor, we split the contribution to the momentum transfer in electric and magnetic components, and discuss their contribution to both attractive and repulsive regimes, previously found.

1. Introduction

Electrons have been widely used since many decades ago to gather information about electronic structure of materials. Nowadays, the use of scanning transmission electron microscope (STEM) machines is extensively spread in several areas besides physics, proving to be a fundamental tool, in particular for plasmonics. \textsuperscript{[1, 2]} We have studied the interaction between swift electrons, likes those typically used in STEMs, and plasmonic nanoparticles (NPs), and we have shown that it is possible to induce forces on a small metallic NP (2-3 nanometers in radius). \textsuperscript{[3–7]} Depending on the relevant parameters such as impact parameter and electron velocity, it is possible to move the NP towards the electron beam or away from it, opening the possibility of moving plasmonic NPs in a controllable way, technology named as electronic tweezers. \textsuperscript{[8]}

For electrons traveling in the nearby of a neutral metallic NP, what is intuitively expected is an attractive interaction between the electron and the positive induced charge in the closest region of the NP respect to the electron trajectory. This is the case for large enough impact parameters, where the localised surface dipolar plasmon is mainly excited. However, for small enough impact parameters the higher-energy multipolar modes play a predominant role. \textsuperscript{[9, 10]} Under this scenario, we showed that the interaction between the electron and the NP turns out to be repulsive, that is, the electron beam expels the NP away. \textsuperscript{[3]} Thus, by controlling the impact parameter of the electron beam respect to the NPs, it is possible to induce attractive forces that triggers coalescence between pairs of particles, as it has been observed and studied experimentally, \textsuperscript{[11]} or avoid that two NPs approach to each other.

2. Theoretical model

The linear momentum transferred from a swift electron, traveling with constant speed in a straight line, to a nanoparticle characterized by a dielectric function $\epsilon(\omega)$ [see Fig. 1], can be calculated from the momentum conservation equation. \textsuperscript{[3]} integrated along the whole electron trajectory

$$\Delta \mathbf{\bar{P}}_{\text{mec}} = \int_{-\infty}^{\infty} \frac{d}{dt} \mathbf{\bar{P}}_{\text{mec}}(t) \, dt = \int_{-\infty}^{\infty} \oint_{S} \mathbf{T}(\mathbf{r}; t) \cdot d\mathbf{a} \, dt,$$

where $\mathbf{T}$ is the Maxwell stress tensor, given by (cgs units system) \textsuperscript{[12]}

$$\mathbf{T}(\mathbf{r}; t) = \frac{1}{4\pi} \left[ \mathbf{\tilde{E}}(\mathbf{r}; t) \mathbf{\tilde{E}}(\mathbf{r}; t) - \frac{1}{2} \mathbf{\tilde{T}} \mathbf{\tilde{E}}(\mathbf{r}; t) \cdot \mathbf{\tilde{E}}(\mathbf{r}; t) + \mathbf{\tilde{B}}(\mathbf{r}; t) \mathbf{\tilde{B}}(\mathbf{r}; t) - \frac{1}{2} \mathbf{\tilde{T}} \mathbf{\tilde{B}}(\mathbf{r}; t) \cdot \mathbf{\tilde{B}}(\mathbf{r}; t) \right].$$

By performing a Fourier transform of each electric and magnetic fields appearing in the Maxwell stress tensor, the total linear momentum transfer can be written as

$$\Delta \mathbf{\bar{P}}_{\text{mec}} = \frac{1}{4\pi^2} \int_{0}^{\infty} \frac{d\mathbf{P}}{d\omega} \, d\omega.$$

with

$$\frac{d\mathbf{P}}{d\omega} = \Re \left\{ \oint_{S} \left[ \mathbf{\tilde{E}}(\mathbf{r}; \omega) \mathbf{\tilde{E}}^*(\mathbf{r}; \omega) - \frac{1}{2} \mathbf{\tilde{T}} \mathbf{\tilde{E}}(\mathbf{r}; \omega) \cdot \mathbf{\tilde{E}}^*(\mathbf{r}; \omega) + \mathbf{\tilde{B}}(\mathbf{r}; \omega) \mathbf{\tilde{B}}^*(\mathbf{r}; \omega) - \frac{1}{2} \mathbf{\tilde{T}} \mathbf{\tilde{B}}(\mathbf{r}; \omega) \cdot \mathbf{\tilde{B}}^*(\mathbf{r}; \omega) \right] \cdot d\mathbf{a} \right\},$$

and $\Re$ stands for the real part. The closed-surface integral is performed in a spherical grid concentric to the nanoparticle, with radius slightly larger than the particle’s radius. 

Figure 1: Sketch of the system: An electron (blue spot) travels with constant velocity $\mathbf{v}$ at a distance $b$ from the center of a spherical nanoparticle (yellow sphere) with dielectric response function $\epsilon(\omega)$. 
The electric $\vec{E}$ and magnetic $\vec{B}$ fields are the total fields: each of them is the sum of the electromagnetic fields produced by the bare electron, called external fields, and the fields produced by the nanoparticle (due to induced currents within the particle), called scattered field, that is

$$\vec{E} = \vec{E}_{\text{ext}} + \vec{E}_{\text{scat}} \quad \text{and} \quad \vec{B} = \vec{B}_{\text{ext}} + \vec{B}_{\text{scat}}.$$  

The electromagnetic fields produced by the bare electron are closed expressions given in [13], while the ones generated by the nanoparticle are written in terms of a multipolar expansion. [3]

### 3. Results and remarks

The Maxwell stress tensor can be divided in two parts, electric and magnetic contributions. Even more, in each part of the Maxwell stress tensor, say the electric field part, appears the product of the electric field with itself, giving rise to three terms: one related to the product between the external electric field only, a second term related to the product of the scattered field only, and a third mixed term related to the product between the external and the scattered field. In this work we study the contribution of each of the six terms to the total linear momentum transfer. Actually, we already showed that the external-external term for both electric and magnetic contributions is zero. Additionally, since the scattered field is given as a multipolar expansion, we also present an analysis of the contribution of each multipole to each of the six terms.

For the detailed analysis, which is currently in process, we are considering different materials for the nanoparticle: the simplest dielectric function given by the Drude model (mimicking Al), more realistic metallic materials such as Au and Ag, and also MgO and SiC as dielectric materials. It is worth to mention that in this work we are incorporating new numerical methods, such as Gauss-Kronrod and exp-sinh quadratures, [14, 15] to get good convergence in several integrations steps. It is also remarkable that this is the first time we manage to consider nanoparticles with radius larger than 1 nm, and we are in position to study the linear momentum transfer as a function of the particle’s radius.

As a preliminary result, we observed that the electric contribution to the linear momentum transfer is out of phase respect to the magnetic contribution, that is, whilst the electric contribution gives one sign, the magnetic counterpart gives the opposite sign. At the end, the attractive/repulsive regime for specific set of parameters depends on a delicate balance between both contributions.

Abstract

A tightly focused, radially polarised cylindrical vector beam in conjunction with a plane wave has been applied to launches toroidal dipole moment while suppressing electric dipole moment in a silicon nanodisk. The nanodisk was illuminated in z-axis by the cylindrical vector beam while the plane wave exposed the disk in a 45° direction relative to the beam. In a given configuration we were able to achieve the strongest toroidal dipole moment excitation.

Introduction

Properties of electromagnetic media are traditionally described by electric and magnetic dipoles and a set of their combinations called multipoles. Although the typical set of multipoles consists of two families of electric and magnetic multipoles, there is another type of electromagnetic sources named as toroidal multipoles. Toroidal modes are complementary terms for standard multipole expansion and show the scattering contribution of poloidal currents. They can be used to describe unusual electromagnetic properties of metamaterials and subwavelength structures. Toroidal dipole, which is the lowest order of toroidal family, is associated with surface currents, \( \mathbf{J} \), that flow along the meridians of a virtual toroid. Toroidal dipole moment is along the torus axis and given by [1]:

\[
\mathbf{T} = \frac{1}{10c} \left( \mathbf{r} \times \left( \mathbf{r} \times \mathbf{J} \right) - 2r^2 \mathbf{J} \right),
\]

where \( c \) is referred to as light speed. In spite of distinction between the electric and toroidal dipoles nature, their radiated fields have the same parity and angular momentum and therefore, they are indistinguishable in long distance. Consequently, a specific superposition of moments of toroidal and electric dipoles can lead to a destructive interference [2].

In this paper, a radially polarised cylindrical vector beam (CVB) in conjunction with a plane wave is used to illuminate a silicon nanodisk to excite toroidal dipole moment while suppressing electric dipole moment. An applied CVB excites both toroidal and electric dipole moments in nanodisk. Importantly, the electric dipole moment can be suppressed via appropriately following CVB with a plane wave. The proposed scheme of simulation is illustrated in Fig.1 where a tightly focused, radially polarised CVB exposes nanodisk along the z-axis and a plane wave is applied at an angle relative to CVB. For a radially polarized CVB, electric field around focus is described by two components of longitudinal and radial as bellow while azimuthal component is zero [3].
\[
\begin{align*}
\mathbf{E}_p^{(c)}(\rho, z) &= \frac{A}{5} \cos^{1/2} \Theta \sin 2\Theta \, l_0(\Theta) J_1(\kappa \rho) \cos \phi \\
\mathbf{E}_t^{(c)}(\rho, z) &= 2\frac{A}{5} \cos^{1/2} \Theta \sin^2 \Theta \, l_0(\Theta) J_1(\kappa \rho) \sin \phi 
\end{align*}
\]

where \( r = (\rho, \phi, z) \) represents cylindrical coordinates, \( l_0 \) shows relative amplitude of the filed, and \( J \) is Bessel function.

1. Results and discussion

Simulations have been conducted based on the setup illustrated in Fig.1. Both light sources have the same amplitude of 6032.7 V cm\(^{-1}\). Silicon disk of 100 nm radius and 108 nm height is placed in a medium with a refractive index of 3.5. Furthermore, the numerical aperture of the lens and beam waist are considered to be 0.86 and 1 \( \mu \text{m} \).

While it is expected that efficient suppression of electric dipole moment is more effective at \( \theta = 90^\circ \), the best outcome is achieved at \( \theta = 45^\circ \). The electric and toroidal dipole moments of the nanodisk are indicated in Fig.2 as a function of light wavelength for two angles 45\(^\circ\) and 90\(^\circ\). The ratio of the toroidal moment to the electric moment is also shown in the figure. As can be seen, the values of electric dipole moment at two angles are almost equal, although the angle of 45\(^\circ\) shows smaller moments. The maximal value of toroidal moment/electric moment ratio is 27.042 and achieved at wavelength 463.5 nm.

2. Conclusions

Excitation of the electric and toroidal dipole moments in a silicon nanodisk using a plane wave and radially polarised cylindrically vector beam has been studied numerically. We found that when the angle between the cylindrical vector beam and the plane wave is 45\(^\circ\), the strength of the electric dipole moment is reduced while the toroidal dipole moment is increased. As a next step, we are planning to conduct experimental studies to verify these results. The outcomes of such research can be applied in various areas of optical communication.

Abstract
Localized surface plasmon resonances (LSPR) of metal nanostructures exhibit peculiar resonance spectra depending on their size, shape and composition. We focus on Au nanorings supported by Pd nanosheets for possible applications in catalysts. In this study, we have prepared Au double nanorings by chemical synthesis in the liquid phase and investigated their optical properties.

1. Introduction
Ultrathin nanosheets of transition metal Pd have high catalytic activity because of their large surface areas. On the other hand, nanostructures of noble metals such as gold and silver are applied to surface-enhanced Raman spectroscopy and biosensing because of the enhanced electric field of LSPR. The fabrication of complicated nanostructures requires expensive equipment such as an electron beam lithography facility and complex processes. Therefore, it is desirable to establish a chemical synthesis method that can control the shapes of metal nanoparticles in large quantities at low cost. In this research, we synthesized chemically Au double nanorings supported by Pd cyclic nanosheets. We investigated the size control and optical properties of Au double nanorings.

2. Experimental Section
2.1. Synthesis of Au double nanorings supported by Pd cyclic nanosheets
Pd nanosheets were synthesized by reducing the Pd precursor in a DMF solution. By oxidatively etching the Pd nanosheets in the presence of halide ions, a central portion of the sheets were perforated to produce Pd cyclic nanosheets. By injecting chloroauric acid into the Pd cyclic nanosheet solution at a constant speed and selectively depositing Au along the inner and outer edges of the nanosheets, we synthesized Au double nanorings supported by Pd cyclic nanosheets. The outer diameter of the Au double nanorings were controlled by the diameter of the Pd nanosheet support. Pd nanosheets with large diameters were synthesized with varying amounts of citric acid and protective agent.

2.2. Structural and Optical properties
Transmission electron microscopy (TEM) images were obtained using a JEOL JEM-200EX II microscope at an acceleration voltage of 100 kV. The Au nanorings were dispersed in an ethanol solution, and the absorption spectra were measured with an ultraviolet-visible spectrophotometer.

3. Results and Discussion
3.1. Au double nanorings supported Pd cyclic nanosheets
Fig. 1 shows a TEM image of an Au double nanoring of 60 nm in diameter. It is seen that the ring structures were formed by growth and aggregation of the Au particles along the outer and the inner peripheries of the Pd cyclic nanosheet. The widths of the gold rings were less than about 10 nm.

![Figure 1: TEM image of an Au double nanoring supported by a Pd cyclic nanosheet.](image)

3.2. Optical properties of the Au double nanorings
Fig. 2 shows the absorption spectra of the Au nanorings of 60 nm in diameter supported by Pd nanosheet without an opening in the center and the Au double nanorings with the same outer diameter supported by a cyclic Pd nanosheet.
In both cases, two LSPR peaks derived from Au were observed. The broad peak at around 1100 nm is attributable to an in-plane resonance mode parallel to the ring plane, and the relatively sharp peak at around 550 nm to the out-of-plane resonance mode perpendicular to the ring plane [3]. It should be noted that, due to the influence of the inner Au nanoring, the out-of-plane mode peak of the Au double nanorings is relatively more pronounced and red-shifted compared to that of the Au single nanorings.

The absorption spectrum of Au double nanorings of 40 nm in diameter synthesized using smaller Pd cyclic nanosheets is compared with the Au nanoring 60 nm in diameter in Fig. 3. The peak of the in-plane resonance mode is blue shifted by about 220 nm from 1050 nm to 835 nm. This suggests that the peak wavelength of the plasmon resonance in the near infrared region can be controlled by changing the outer diameter of the Pd cyclic nanosheet support.

4. Conclusions

We synthesized Au double nanorings supported by Pd cyclic nanosheets using a seed-mediated growth approach. The LSPR characteristics of the gold double nanorings can be adjusted by varying the diameter of the supporting Pd cyclic nanosheets.

Abstract

The optical properties in active double SiO₂-Si wire system have been investigated by using Four-Level Two-Electron model with the Finite-Difference Time-Domain(FDTD) solutions. The super resonance occurs with appropriate dimensions of the width of the Si wires and the gap between them. Furthermore, with increasing the separation between two Si wires, the peak value decreases in the beginning and then increases when the optical path difference is exactly equal to the emission wavelength of the gain material.

1. Introduction

In recent years, the active coated has drawn great attention of many researchers for the reason that the gain molecules embedded in nanostructures can provide large gain coefficients to compensate the loss of surface plasmons (SPs) of metallic nanostructures and amplify the desired SP response. Considering a series of inherent defects in metal, nanostructures consisted of semiconductor nanoparticle has been started to research.

In this paper, we adopted Four-Level Two-Electron model to calculate the spectra of silicon nanostructure combined with a specific gain material, an organic dye Oregon Green 488 (OG-488, Invitrogen, Thermo Fisher Scientific). This model is more practical because it presents parameters of material which can be found or made in reality.

2. Calculation

We use FDTD solutions to calculate the double silicon wire systems with doped silica shells placed on the top of a SiO₂ layer.

2.1. Parameters of Four-Level Two-Electron model

According to absorption and emission spectra provided by the gain material provider and approximate life time measured in ref.6, we estimated the parameters of Four-Level Two-Electron model in FDTD solutions by fitting to the full set of rate equations for the four-level system. And the gain material of these parameters was considered in the later calculations.

2.2. Simulation

As showed in Figure 1, an active double Si wires system is comprised of two silicon nanowires, which are coated with dye-doped silica shell, supported on silica capped silicon substrate.

Figure 1: Schematic of double Si wires and experimental configuration with FDTD.

The width, height and the period of the double Si wires system are 306nm, 150nm and 3um respectively. The incident light (linearly polarized plane wave) was gradually increased until the inverted gain medium inside the silica shell reach a sufficient amount to observe a significant laser phenomenon.

3. Discussion

3.1. Results

We explored the relationship of simulated emission spectra and the gap between the two Si wires (Figure 2). The center frequency of the emission spectrum stayed almost the same with the gap below 200 nm. And the value of the peak point of emission spectrum reached maximum when the gap is 30 nm which means the coupling occurred between the two wires. The center frequency of the spectrum has a red shift phenomenon with the increase of the gap above 300 nm. Furthermore, the peak value is greatly enhanced again with the gap above 400 nm. Because these gaps are much larger than near-field on the surface of Si wires, the twice enhancement of the peak with gaps of these dimensions do not due to the coupling between the two wires. The optical path difference between the two Si wires is exactly at the emission wavelength of the gain material. So the interference of light between the two wires may be the reason for the twice enhancement of measured emission spectrum.
Figure 2: stimulated emission spectra of double Si/silica/dye systems.

Fig. 3 is the stimulated emission spectrum of double Si-SiO2 system with the gap of 30nm. The width of the spectrum is 2.1 nm and the Q-factor is 253 which calculated by the equation

\[ Q = \frac{\lambda_0}{\Delta \lambda}, \]  

where \( \lambda_0 \) is the center frequency of the emission spectra and \( \Delta \lambda \) is the full width at half maxima of the spectrum.

Figure 3: stimulated emission spectrum of double Si/silica/dye nanostructures with gap of 30 nm.

4. Conclusions

The super resonance properties of the active double Si wires system have been investigated by the use of Four-Level Two-Electron model and FDTD solutions. At the appropriate dimensions of Si wire and the gap, the width of emission spectrum can reach minimum value which means super resonance. At the peak of the emission spectrum, the peak value of active emission spectrum is enhanced compared to passive structures. And the peak value at 526nm extremely enhanced because of optical interference when the optical path difference between the two Si wires is exactly near the peak wavelength of the gain material emission spectrum when the gap is above 300nm.

Abstract

Quantum states in different molecules can be hybridized by strong light-matter interaction. Here we present strategies that employ such coupling to enable photochemistry involving remotely separated species. First, we show how polariton-assisted remote energy transfer (PARET) across hundreds of nanometers occurs when surface plasmons strongly interact with both donor and acceptor chromophores. We then propose a remote control of chemistry whereby photoexcitation of molecules in one optical microcavity influences the photoinduced reactivity of molecules in another microcavity.

1. Introduction

In the limit where a molecular transition strongly interacts with light, the coupled species hybridize into quantum states called polaritons. Compared to the original (or bare) matter states, the polaritons are significantly photonic in character and shifted in energy. These properties themselves have important consequences for molecular processes [1]. However, polaritonic setups typically employ a macroscopic chemical sample. As a result, almost all superpositions of the coupled transition in each molecule are not coupled to light. These linear combinations are known as dark states, which remain in energy at the bare transition. Nevertheless, this dense reservoir of states also affects chemical dynamics under strong light-matter coupling [1], namely by acting as an energy sink for polaritons [2]. Given the above phenomena, it would be interesting to explore what novel chemical opportunities are available by strongly coupling transitions of several compounds to light. In this work, we theoretically demonstrate how polariton photochemistry involving spatially separated compounds. We first discuss polariton-assisted remote energy transfer (PARET) between donor and acceptor chromophores both strongly coupled to surface plasmons [3]. Then, we introduce a polaritonic device that supports remote control of chemistry [4].

2. Results and discussion

2.1. Polariton-assisted remote energy transfer (PARET)

In typical samples of donor and acceptor chromophores (without the presence of surface plasmons), electronic photoexcitation of the former species is followed by energy transfer, of the Förster type, to the latter. The second process is Coulombic in nature and occurs only when interchromophoric separation lies within ~1 – 10 nm. To extend the range of energy exchange, we consider strongly coupling a surface plasmon mode to the first electronic transition of each dye.

Figure 1: (a) Schematic energy-level diagram depicting polariton-assisted remote energy transfer (PARET) transitions among polariton (upper, UP; middle, MP; lower, LP) and dark states for both donor (D) and acceptor (A) chromophores strongly coupled to donor-resonant surface plasmon (SP). (b) Rates γ for selected energetically downhill transitions as a function of separation Δz between slabs of each chromophore. Adapted from [3].
Therefore, upon excitation of either of the higher-energy polaritons, vibrational relaxation to the lowest-energy polariton occurs through a series (Fig. 1a) of ultrafast (Fig. 1b) transitions to and from dark states. Such decay processes occur for interal slit distances of up to ~400 nm (Fig. 1b) and are induced by the vibronic coupling inherent to molecules in general. Notice that the higher-energy polaritons have molecular character of mostly donor while the lowest-energy polariton has that mostly of acceptor. It follows that PARET from donor-like state to acceptor-like state is achieved. In fact, our theory is in good agreement (Table 2 of [3]) with experiment [5].

2.2. Remote control of chemistry

Figure 2: (a) Scheme illustrating remote control of chemistry using optical microcavities. ‘Pump’-pulse excitation of a polariton whose character is mostly ‘remote catalyst’ glyoxylic acid (trans-cis conformer) and its cavity enables the ‘probe’ pulse to efficiently excite a polariton whose character is mostly reactant cis-HONO and its cavity; subsequently, the reactant isomerizes into product trans-HONO. (b) Enhancement $\eta_{\text{ON}}/\eta_{\text{OFF}}$ of reaction efficiency (compared to $f_{\text{pump}} = 0$, probe excitation only) as a function of fraction $f_{\text{pump}}$ of pump-excited remote catalyst. Adapted from [4].

Conventionally, a catalyst binds its reactant to accelerate the conversion to product. Given the ability for strong light-matter interaction to hybridize molecular species separated well beyond chemical length scales, we design a device where acting on a ‘remote catalyst’ (RC) affects the reaction of a spatially separated reactant. This device consists of trans-cis conformer of glyoxylic acid as RC in one optical microcavity and cis-nitrous acid (HONO) as reactant in another optical microcavity (Fig. 2a). Suppose that the OH stretch vibration of each compound interacts strongly with the corresponding host cavity. The cavities themselves also experience strong coupling. Thus, both molecular species and their respective cavities hybridize into four polaritons. Due to the anharmonicity of the RC OH stretch mode, exciting the highest, RC-like polariton modifies the energy and mixing fraction of each polariton [6]. Consequently, this ‘pumping’ of an RC-like polariton modifies the reactivity induced by exciting the lowest, reactant-like polariton with a near-resonant ‘probe’ pulse. Indeed, increasing the population of excited RC enhances the efficiency of cis $\rightarrow$ trans isomerization of HONO by an order of magnitude (Fig. 2b). Hence, we establish remote control of chemistry.

3. Conclusions

In summary, we first find that when both donor and acceptor dyes are strongly coupled to a surface plasmon mode, energy transfer from donor-like polariton to acceptor-like polariton occurs via vibrational relaxation for interchromophoric separations up to hundreds of nanometers. We next reveal remote control of chemistry: raising the excitation of a ‘remote catalyst’-like polariton in one optical microcavity enhances the infrared-induced conformational isomerization of a cis-HONO-like polariton in another optical microcavity by an order of magnitude.

Abstract

Silver amalgam represents the most suitable alternative electrode material to a metallic mercury in electroanalytical chemistry. Nanostructuring the amalgam promises improved electrochemical performance and brings along the prospect of plasmonic activity. Here, we present a detailed study of plasmonic properties of silver amalgam nano- and microparticles with plasmon resonance wavelengths spanning from ultraviolet to the mid-infrared region depending on the particle size. This combined electrochemical and plasmonic functionality renders the system as a very promising electrode material for spectroelectrochemical studies.

1. Introduction

Silver amalgam was found to be one of the most suitable solid electrode materials in electroanalysis of various reducible organic and inorganic compounds including heavy metals, agrochemicals, colorants, drugs, environmental pollutants, or biologically important compounds such as DNA and proteins [1, 2]. Recently, similarly to other research areas, electrochemistry has benefited from the emergence of nanomaterials such as gold nanoparticles and carbon nanotubes [3]. When such materials are applied to the conventional electrodes, they help to increase its active surface area, charge transfer efficiency and overall sensitivity, though it also introduces additional complexity to the system. Synthesizing the nanoparticles directly from the silver amalgam can, therefore, bring along the benefits of the nanostructured electrodes without complicating the system structure by the presence of additional materials. However, currently there is a lack of knowledge about the optical properties of nanostructured or even bulk silver amalgam which prevents its use in spectroelectrochemical and photochemical studies.

Here, we present a detailed study of optical properties of silver amalgam and we demonstrate the plasmonic nature of its nano- and microparticles using optical and electron beam spectroscopy.

2. Results and discussion

Silver amalgam nano- and microparticles were prepared by controlled electrodeposition on a conductive indium tin oxide (ITO) support from a mixed solution of silver and mercury ions [4]. Their optical response was obtained using Fourier-transform infrared spectrometer which confirmed the plasmon resonance of sufficient quality for spectroelectrochemistry ranging from ultraviolet to mid-infrared region depending on the particle size. To support our findings, numerical simulations were performed employing the dielectric function of a thick silver amalgam layer which was obtained by spectroscopic ellipsometry.

To understand the nature of plasmonic modes in amalgam particles, focus was brought from the ensemble response down to a single-particle level utilizing the scanning transmission electron microscopy (STEM) combined with electron energy loss spectroscopy (EELS). In order to prepare the samples for EELS, amalgam nanoparticles were washed off the ITO into a demineralized water in an ultrasonic bath and the resulting solution was dropped and dried on a silicon nitride membrane. A typical rod-shaped nanoparticle with the length of 170 nm, width of 120 nm and the thickness of 80 nm is shown in Figure 1. The chemical composition of this amalgam nanoparticle measured by energy dispersive X-ray spectroscopy (EDS) in STEM is homogeneous and in weight percent corresponds to (67 ± 6)% of Ag and (33 ± 6)% of Hg. The rod-shaped amalgam nanoparticle exhibits three different resonant modes which were also complemented by the numerical simulations using boundary element method (BEM). The first peak that is at 1.77 eV in the experiment (1.60 eV in BEM simulation) corresponds to the longitudinal dipole mode, which has the maximum in the middle of nanoparticle’s short edge. The second peak at around 2.8 eV in the experiment (2.84 eV in BEM simulation) indicates a transversal dipole mode, which has the maximum in the middle of nanoparticle’s long edge. The third peak around 3.2 eV in the experiment (3.15 eV in BEM simulation) corresponds to a quadrupole mode. The results of the simulations show reasonable qualitative and quantitative agreement with the experiment giving us better understanding of experimentally observed plasmonic peaks.
3. Conclusions

To conclude, we have demonstrated that silver amalgam, apart from its proven usefulness in electroanalytic chemistry, can also be regarded as novel plasmonic material with promising optical properties. We have synthesized silver amalgam nano- and microparticles which exhibit strong plasmon resonances in ultraviolet to mid-infrared regions depending on the particle size, while in single nanoparticle studies we have also identified individual plasmonic modes. These findings will help in designing a unique spectroelectrochemical platform, where the synergy between its plasmonic and electrochemical qualities can be fully utilized.

Coupling a single carbon-nanotube to a plasmonic “hotpots-patch” antenna.

Abstract

We report on the coupling of single carbon-nanotubes to plasmonic “hotspots-patch” antennas made by a random collection of metallic scatterers. Preliminarily to luminescence experiments, we have characterized the quenching of a single carbon-nanotube due to the metallic plane. We highlight that the experimental results fit well with the power radiated by a dipole parallel to the metallic plane. Finally we show that the hotspots lead to luminescence enhancement. Interestingly we report on plasmonic modes with quality factor of the order of $Q \sim 80$ up to $Q \sim 200$.

1. Introduction

With the adequate chirality, semiconducting carbon nanotubes can radiate in the near-infrared window range $[900\ nm, 1600\ nm]$, more specifically in the telecom window range. Despite this very interesting wavelengths range, carbon nanotubes suffer from very low quantum yields because of their unidimensional geometry. As a consequence they are poorly light emitting sources. We investigate the possibility of luminescence enhancement thanks to plasmonic nanostructures.

Plasmonic nanostructures are known to enhance luminescence due to an increase of energy extraction from the emitter to the far-field because of a high density of electromagnetic states as compared to the vacuum. Luminescence enhancement also arises because of radiation redirection due to antenna effects. A possible geometry for the plasmonic structure is a patch antenna made by a small metallic particle separated from a metallic plane by a dielectric layer (see Fig:2-a) for illustration). The metallic patch supports surface plasmon-polariton resonances and luminescence is enhanced as compared to its value in the vacuum[1]. This geometry is attractive because of its simplicity, because of its ease of implementation and because light emission is redirected in only one half-space. This geometry has shown quantum-dots luminescence enhancement[2]. Unfortunately luminescence enhancement in this geometry is highly dependent on the orientation of the emitter dipole[1]. Indeed, Purcell-factor on the order of 70 are predicted for dipoles perpendicular to the metallic plane whereas the Purcell-factor value saturated at 5 in the case of a parallel dipole[1]. Because of the unidimensional character of carbon nanotubes, their emitting dipole is parallel to the metallic plane. So the patch-antenna geometry is not really suitable to get a large enhancement of luminescence in the case of carbon nanotubes. We have tried to circumvent this difficulty by implementing a “patch” exhibiting electromagnetic hotspots. Electromagnetic hotspots result from lightning-rod effects leading to large values of the electric-field. Hotspots generally appears on semicontinuous metallic films. The ref.[3] have demonstrated luminescence enhancement for carbon nanotubes above a gold semicontinuous film. In our sample the “hotspots-patch” antennas are made by a random collection of metallic scatterers separated from metallic plane by a dielectric layer. The geometry under study is depicted on Fig:2-a). On a 200 nm thick gold mirror, the dielectric layer is deposited. The spacer thickness has been varied from $d=0$ nm up to $d=200$ nm. It is made on a PFO polymer except for the $d=200$ nm thickness for which the polymer is PMMA. Then a 5 nm thick layer of PFO enriched with carbon nanotubes is deposited on top of the dielectric spacer. Finally, the metallic scatterers are spread over the sample. They are gold nanorods with radius 10 nm and length 80 nm. Their resonant-wavelength is around $\lambda_{r} \approx 1280 nm$. Some nanorods aggregate to form a patch.

2. Quenching of the luminescence of a carbon nanotube due to a gold mirror

First we measure the quenching of the carbon nanotubes luminescence as a function of the spacer thickness. Indeed, because gold films support surface plasmon-polariton, which are non-radiative electromagnetic modes, the luminescence intensity decreases when the distance between the
gold plane and the emitter decreases. In order to quantify this decrease, we have measured the intensity of carbon nanotubes luminescence as a function of the dielectric layer thickness (PFO polymer). The results are presented on Fig (2) where we have plotted the logarithm of spontaneous decay rate as a function of the carbon nanotubes height above the gold plane. The data have been normalized in reference to the luminescence intensity for the height \(d = 200\,nm\) above the gold film.

![Figure 2: Logarithm of the normalized Decay rate for a single carbon-nanotube luminescence as a function of the distance from the gold plane. The normalization is done with the decay-rate value at 200 nm, \(\Gamma_0\), as a reference. The insert is a zoom on the distance range \([0, 30\,nm]\).](image)

Our measurements (circles with error-bars in Fig 2) are well reproduced by the spontaneous decay of an electric dipole parallel to the gold film (red dashed curve in Fig 2). These measurements confirm that the dipole of the carbon nanotubes is parallel to gold mirror.

### 3. Luminescence enhancement thanks to electromagnetic hotspots

We now present the experimental results for the "hotspots-patch" antenna. Only results with spacer thickness \(d = 0\,nm\) are presented on Fig 3. Figure 3-b is the spectrum for an ensemble of carbon nanotubes in PFO (no plasmonic antenna for this result). Our sample of carbon nanotubes contains 5 chiralities that can emit light in the experiment. Each chirality gives rise to one single peak in the spectrum. Inhomogeneous broadening being quite small, the width of the luminescence peak due to a single carbon nanotube is similar to the width of the peaks in Fig. 3-b. Coupling carbon nanotubes to a "hotspots-patch" antenna leads to spectra plotted on Fig. 3-c, Fig. 3-d and Fig. 3-e. In Fig. 3-c, the peak corresponding to the chirality emitting near \(1.2\,eV\) is enhanced as compared to the other chirality. Moreover the luminescence peak is split in two narrow peaks. Finally, only the luminescence peak of one chirality is enhanced in Fig. 3-e but the peak width is very small as compared to the peak of the corresponding chirality with the "hotspots-patch" antenna. We explain these features from the existence of electromagnetic hotspots on the patch. Some of them have a large quality factor leading to the narrow peaks in Fig. 3. The quality factor of these modes is larger than the quality factor of a single gold-nanorod as it can be seen on Fig. 3-a, which is the scattering spectrum of a single nanorod on a gold plane.

![Figure 3: a) Scattering spectrum of a single gold-nanorod. b) Luminescence spectrum of an ensemble of carbon nanotubes in PFO exhibiting the five chiralities that emit light in the experiment. c,d,e) Spectra for the coupled systems: carbon nanotubes and "hotspots-patch" antenna. The maximum of all curves has been normalized to one. The curves have been shifted for clarity.](image)

### 4. Conclusions

To conclude, we have shown that a patch antenna exhibiting hotspots can enhance the luminescence of carbon nanotubes despite that their dipole is parallel to the metallic mirror. The orientation of the emitting-dipole has been confirmed from the evolution of the radiative rate with the distance from the gold plane. "Hotspots-patch" antenna has also the interesting feature of exhibiting high quality-factor modes. The quality factor of these modes (\(Q \sim 80\)) is larger than both the quality factor of a single gold nanorod (\(Q \sim 15\)) or the quality factor of the luminescence peak of a single carbon nanotube (\(Q \sim 40\)).

Abstract

Unidirectional light scattering by a nanoantenna, placed in homogeneous medium or on a substrate is studied in this paper. A fully intelligent method, combining Bayesian optimization algorithm and commercial electromagnetic solver, is utilized to optimize the parameters of the nanoantenna to realize unidirectional scattering. With the aid of the machine learning method, a strong forward or backward scattering by the designed nanoantenna at arbitrary wavelength can be effectively achieved.

1. Introduction

Due to its profound implications and vast applicability, scattering of light by nanoantenna has gained great attention in recent years. Generally, the unidirectional scattering can be achieved in two distinct ways: detuned electric dipoles approach and the excitation of electric and magnetic multipole (ED and MD) resonance simultaneously. While for the first approach, it is difficult to realize miniaturization and integration since the separation of the constitutive nanoantenna is about a quarter-wavelength. And the later one is the physical theme of our design nanoantenna in this work. Often, numerical simulations are used for obtaining suitable structures. While due to the complexity of nanoantenna that can support ED and MD resonance simultaneously [1], the parameters spaces are mostly high-dimensional and naïve optimization strategy fail to provide fast and reliable result.

In this work, we describe a mechanism based on geometric parameter optimization to realize superior unidirectional scattering at one or two wavelengths. We show that by combining a computational electromagnetic solver and the Bayesian optimization method, a strong forward or backward scattering for nanoantenna, placed in homogeneous surroundings or on a substrate, can be automatically achieved, in commonly affordable time and cost.

2. Design Method

Figure 1 depicts the flow of the unidirectional scattering nanoantenna design, which has four basic ingredients: candidate set, evaluator, calculator and optimization method. Firstly, we set the parameters to be optimized and then construct the candidate sets. It should be noted that all full wave electromagnetic calculations are performed using commercial simulation package COMSOL Multiphysics based on the finite element method (FEM). For the evaluator, the directivity \( G_{FB} = 10 \log_{10}(S_F / S_B) \) is chosen to quantitatively evaluate the performance of each configuration, where \( S_F \) and \( S_B \) are the radiated powers evaluated at the forward (\( z = +\infty \)) and the backward (\( z = -\infty \)) directions, respectively. After confirming the candidate set and evaluator, a bridge between the COMSOL and Bayesian optimization has been built up. Bayesian optimization, an experimental design algorithm is utilized to achieve the optimal size of the structure that has strong asymmetric scattering. And Gaussian processes [2] have been adopted as surrogate models for the Bayesian optimization due to their flexibility and tractability.

Figure 1 The flowchart for the optimal design of unidirectional scattering nanoantenna. In the Comsol module, schematic figure of the nanoantenna consisting of three gold nanodisk with diameter \( d \) and thickness \( t \) and they are...
separated by two different layers of thickness \( t_1 \) and \( t_2 \), respectively. The FS (forward scattering) are along the wave vector of the incident light \( \mathbf{k} \), and it is opposite for the BS (backward scattering).

3. Nanoantenna placed in homogeneous medium or on a substrate

For the case of nanoantenna placed in an homogeneous surrounding (for example vacuum) The optimized result is shown in Fig. 2. we can clearly see that all optimizations process with different initial training set can be quickly converge to the same minimum or maximum within 900 interactions (comparing with the total number of candidate set), as shown in Fig. 2(a). And the optimal parameters are given in Table 1 and the corresponding \( G_{FB} \) of the two

<table>

nanoantenna are plotted in figure 2(b). Figure 2(c) and 2(d) show the far-field radiation pattern of the two nanoantennas at \( \lambda = 670 \) nm, respectively. It is clearly seen that a nearly complete cancellation of BS or FS is present. Note that I respects the structure for BS and II corresponds to the structure for FS. Three-dimensional (3D) radiation patterns for nanoantenna-I (c) and nanoantenna-II (d) at \( \lambda = 670 \) nm.

Figure 2. FS and BS structure optimization for wavelength \( \lambda = 670 \) nm. (a) 5 optimization runs with different initial choices of candidate sets for the case of forward and backward unidirectional scattering, respectively. (b) Far-field directivity \( G_{FB} \) of the two nanoantennas. Three-dimensional (3D) radiation patterns for nanoantenna-I (c) and nanoantenna-II (d) at \( \lambda = 670 \) nm.

This method is also adapted to design unidirectional scattering in opposite direction at different wavelengths for the case of the nanoantenna placed on a substrate. Figure 3 shows the optimized result of nanoantenna placed on a glass substrate. We can see that the strong FS and BS are separately occurred at the \( \lambda = 650 \) nm and \( \lambda = 670 \) nm, which is confirmed by the scattering patterns (see Fig. 3(b) and 3(c)).

4. Conclusions

Combining a well established electromagnetic solver and a home-made Bayesian optimization implementation, we can quickly design nanoantennas placed in homogeneous surroundings or on a substrate (metal or dielectric), with unidirectional scattering at one wavelength or unidirectional scattering in opposite directions at different wavelengths.

Abstract

Using our fluorescence microscope setup, with confocal excitation and wide-field fluorescence detection, we were able to excite Surface Plasmon Polaritons (SPP) in a silver nanowire (AgNW) structure, which we demonstrate for several excitation wavelengths. We want to combine the capabilities of our optical setup and experience in chemical synthesis of long AgNWs [1] to achieve long distance SPP propagation. We intend to first determine experimentally the influence of different dimensions and surface functionality on SPP propagation.

1. Introduction

Silver nanowires have a dual functionality of an optical antenna, capable of capturing energy of incoming light and focusing electric field near the structure’s surface [2], [3], and of plasmonic waveguides [4] able to deliver this excitation, through SPPs, to a distant location along the wire. The chemical methods of AgNWs synthesis [5] provide an advantage over lithographic methods by yielding single-crystalline structures and good control over morphology, they do not however give good control over dimensions of nanowires. Hydrothermal methods commonly produce AgNWs with lengths exceeding 100 µm [6], [7]. A high numerical aperture (NA) objective lens [8] enables light coupling into bound, rather than leaky SPP modes, which can deliver excitation to more distant locations. Millimeters long propagation lengths have been demonstrated for metal stripe waveguides, embedded in homogeneous dielectric medium when SPP modes were excited using end-fire technique [9], however use of nanowires in sensing applications will require less favorable conditions, close contact with probes and surface functionalization, that will influence refractive index of surrounding medium and disturb SPP propagation. Furthermore while longer wavelength can excite SPPs that propagate further, they may not couple with energy levels of the probes as well. In our work we used a fluorescent probe to study SPP propagation. We show how different excitation wavelengths influence SPP propagation and present results of hydrothermal synthesis of long AgNWs

2. Materials and Methods

2.1. Fluorescence microscopy

To effectively excite SPP modes in AgNWs we deliver laser light through single mode optical fibers, an achromatic collimating lens and a high NA objective. We can focus the excitation light to a <1µm in diameter spot for each of the excitation wavelengths used: 635, 532, 488 and, 405 nm. Detection in wide-field mode allows for observation of fluorescence excited at a distance from the excitation spot, along the entire nanowire length and at the distal end. Set of optical filters is used to prevent, as much as possible, laser radiation from reaching the camera detector. Water soluble, CdTe (QDs) were used as a fluorescent probe with maximum emission wavelength of 720 nm. AgNWs and QDs are embedded in PVA polymer to reduce scattering which would otherwise arise at the glass-air interface.

2.2. Long AgNWs

The silver nanowires we studied were synthesized using a hydrothermal method with peroxide used as a reducing agent [1]. We were able to achieve AgNWs nearly 800 µm long, with 10 % of the structures reaching at least 400 µm. Their diameter is in the range of 40-180 nm. Silver nanowires acquired in this method are covered by a PVP polymer cap, which stabilizes the wire in solution, but also likely influences SPP propagation, as its morphology can change over time.

3. Results and Discussion

For our experiments we have taken water dispersed AgNWs prepared using the hydrothermal synthesis method, mixed them with QDs and PVA polymer and spin-coated the solution on a glass coverslip. The resultant sample is a thin polymer layer that has QDs and AgNWs embedded in it. For a few of the AgNWs sequences of fluorescence images were taken when one of the nanowires was illuminated with a laser beam of wavelengths 635, 532, 488 and 405 nm, in this specific order, and power of around 10 µW. One
set of such measurements is shown in Fig. 1. It is worth noting that though the fluorophore is present in the entire polymer film, unless the beam is positioned at the nanowire’s end, the fluorescence is only observed coming from the position of excitation spot. When beam points at one of the AgNW’s ends, then the fluorescence is also visible along the AgNW and at its other end. The fluorescence intensity profiles differ as a function of excitation wavelength with excitation at 635 nm producing the slowest and excitation at 405 nm the fastest decrease in fluorescence intensity as the excitation travels along the wire. In all cases fluorescence is excited at the other end of the nanowire as well.

![Figure 1: QDs fluorescence along a single AgNW excited at 635, 532, 488 and 405 nm.](image)

We want to use this technique to study SPP propagation in AgNWs, specifically influence of structure diameter and surface functionality on SPP propagation, and eventually obtain long range SPP propagation in surface modified structures. At the same time we work to obtain very long AgNW, like those shown in Fig. 2 with the intention of achieving SPP propagation that would span the entire structure length – few hundred micrometers. At such distances we would expect only bound modes to propagate efficiently, so surface functionality will likely have great impact on the process.

![Figure 2: Bright-field reflection image of AgNWs dispersed on glass.](image)

### 4. Conclusions

For a single silver nanowire surrounded with fluorescent CdTe QDs, we demonstrated wavelength-dependent SPP propagation. We want to further extend our research to correlate structure diameter or surface functionality and SPP propagation. In parallel we work on fabricating AgNWs that would enable long range SPP propagation.

Abstract—Experimental and theoretical investigations of promising metamaterial flat lens have been carried out. Unique optical properties are detected of the polymer film PVA/PVP with nanoparticles of gold displaying independence of polarization of incident radiation and low losses in absorption.

One of the most interesting applications of metamaterials is the light focusing by flat lenses with subwavelength resolution. The phase profile, which determines the possibility of focusing, transfer function and spatial resolution of lenses based on metal-dielectric (MD) structures have been calculated for the wavelengths of the visible and ultraviolet ranges.¹ Measurements with modified walk-off interferometer have shown that investigated MD-structure (Ag/SiO₂) possesses necessary phase characteristic of flat lens only for $p$-polarized light.² The generalization of this result to the variant of real three-dimensional beams allows one to assert that the flat MD-structure focuses radially polarized beams. The second disadvantage is high enough loss in wave propagation when there is no impedance matched to air. The aim of our paper is to propose and investigate a metamaterial flat lens with low losses in absorption and properties independent of polarization of incident light.

In order to form coatings based on gold nanoparticles (NPs) in a dielectric polymer complex matrix of polyvinylpyrrolidone (PVP) and polyvinyl alcohol (PVA) we used PVA “Mowiol 28-99” (Hoechst Akiengesellschaft, Germany) and PVP M = 100000-150000 g/mol (AppliChem, Germany). We prepared two aqueous polymer solution: 15 wt% PVA and 10 wt% PVP, which are then mixed in different proportions so that the total polymer content of the composition was 10 wt% Then, after thorough mixing, was introduced a sample of HAuCl₄, dissolved in water. The solution was dispersed in an ultrasonic bath for 1h at 60°C. Then film was deposited on a glass substrate using spin-coating and further drying at T = 65 ± 5°C for 1-3 hours. Samples were annealed at 250°C for 2 hours to decrease the thickness of PVA/PVP-Au films and removal of the polymer matrix. Investigations with SEM and AFM have shown that less than 20 nm gold NPs and almost smooth surface were observed after annealing of PVA/PVP-Au films.

In our investigation we used direct measurement of the phase shift produced by a film inclined to incident laser beam at specified angles. During the experiment in the modified walk-off interferometer there was used the radiation of single-mode He-Ne laser with the radiation wavelength of $\lambda = 632.8$ nm. According to the technique used in the walk-off interferometer the film under investigation has been deposited on the part of surface of plane-parallel glass substrate of high optical quality. When changing the beam incident angle $\theta_a$, we measured the angular dependence of phase shift $\Delta\phi(\theta_a)$ passing through the sample radiation. Fig. 1 shows experimentally measured optical path difference $\Delta p$ (phase shift $\Delta\phi$ in arc degrees $\Delta\phi = 360\Delta p/\lambda$) of light beam passed through the sample. Investigated film is characterized by high homogeneity. At the light wavelength of $\lambda = 632.8$ nm film possesses small losses in absorption and scattering less than 5%.
Figure 1. Optical path difference $\Delta p$ and phase shift $\Delta \phi$ versus angle of incidence $\theta_{in}$.

The polymer film PVA/PVP with nanoparticles of gold possesses the necessary phase feature for creation on its base of flat lens with properties independent of polarization of incident radiation. The figure of merit of flat lens based on similar structure can achieve large values due to low losses on absorption.

Numerical simulation of propagation of plane wave through dielectric film with randomly distributed golden nanoparticles was performed. Phase of transmitted wave was calculated for different angles of incidence, film thicknesses and particle concentration. Increase of metal concentration up to 1.0% for film thickness about 100 nm and increase of film thickness for lower concentrations lead to similar angular phase dependences as ones observed in experiment.

Abstract

Plasmonic films with concave shapes are known to enhance Raman scattering. Herein, we present monoparticulate films that are formed via self-assembly of gold nanoparticles (NPs) at the air-water interface, upon heating to 80 degrees C a solution containing the NPs. Molecular analytes present in the water can be adsorbed on the metal NPs and be concentrated at the surface, allowing a higher sensitivity for analysis of aliphatic molecules by surface-enhanced Raman Spectroscopy (SERS).

1. Introduction

Nanostructures with complex shapes can be used for many applications, such as (meta)optical devices [1], sensing [2] or catalysis [3], and they can be synthesized by different techniques, such as gas-phase methods [4] or colloidal approaches [5]. An example of these colloidal techniques are films directly formed in solution at the interface of two immiscible liquids. This process is driven by the decreased interfacial energy when NPs are trapped at the interface [6]. Although some of these processes have been shown to occur spontaneously, most of them require the covalent functionalization of the NPs [7], hindering the applications where close plasmonics, SERS and catalysis [8]. The synthesis of complex interconnected refracted nanoscale geometries presents many advantages for these applications due to the strong enhancement of electromagnetic field in concave nanostructures, although it is limited by their inherent thermodynamic instability. These nanostructures formed at the interfaces would be greatly beneficial for SERS measurements, since in this way the plasmonic films are more accessible to phonons and analytes alike [9]. Herein, plasmonic films presenting optical homogeneity and high reproducibility are prepared based on the self-organization of NPs at the air-water interface (Figure 1).

2. Discussion

The synthesis of the initial gold NPs (AuNPs) [10] consists on the reduction of gold(III) in the presence of tetrakis-(hydroxymethyl)phosphonium chloride (THPC) in an alkaline aqueous medium. AuNPs of about 3 nm diameter, weakly stabilized with THPC, are obtained. These NPs are stable at room temperature, but when they are placed in a closed reactor at 80 °C, a plasmonic monolayer at the air-water interface is obtained. Figure 2 shows TEM images of the cold-welded films transferred to TEM grids at different assembly times.

In most cases, the plasmonic NPs form discrete unconnected films at the interface [11,12]. However, in this case the preparation of dendritic structures with a homogeneous character is carried out. The formation of these chains is favored by the positive balance between repulsive and attractive forces [13], in addition to the low affinity of THPC for the gold surface. It was observed that the NP merger proceeds only to a certain point (24 h), without major changes when increasing the heating time. On the other hand, the obtained plasmonic films can be easily transferred to different substrates: glass, cellulose filters or silicon wafers, among others.
Different techniques for the characterization of these films have been carried out. In their optical characterization, it was observed that the films present a localized surface plasmon resonance (LSPR) band that slowly redshifts and increases in intensity as the incubation time increases. For the SERS characterization, 4-mercaptobenzoic acid (4-MBA) has been used as molecular probe. SERS intensities are considerably larger for the cold-welded films as compared with other conventional substrates. This is due to the fact that, in this case, the analyte is adsorbed and concentrated onto the AuNPs that subsequently migrate to the interface to form the films, which considerably increases the local concentration of the analyte at the point of measurement. Both SERS intensity and intensity homogeneity suggest that the cold-welded films can serve as optimal substrates for SERS quantification. This is tested using thiram, which is an aliphatic fungicide with a small SERS cross-section, and its vibrational pattern is clearly recognized for concentrations less than nM. Therefore, the applicability of the films for the ultraquantitative determination of aliphatic molecules in aqueous media was demonstrated.

3. Conclusions

The synthesis of gold nanostructures with metastabled concave geometries has been carried out through self-assembly of AuNPs at the air-water interface. The weakly-bonded THPC surface ligands facilitate the assembly and merging of the plasmonic NP into nanostructures with refracted geometries. The characterization of the films shows a homogeneous structure with a high density of hot spots. These properties allow the use of these films for the ultrasensitive quantification of aliphatic molecules in aqueous medium by SERS.

Abstract

Optical absorber is achieved by employing moth-eye nanostructure covered by a single-layer of non-noble metallic film. The architecture provides uniform, broadband, omnidirectional absorption for both the front- and back-sided incidence by taking advantage of the strong photon manipulation capability of the structure to couple and trap electromagnetic wave. Experimental results show that the absorber yields an average absorption of 90.0\% and 89.3\% at normal incidence, 79.8\% and 81.5\% at tilt 60° incidence in spectrum of 400–800 nm for front- and back-sided incidence, respectively.

1. Introduction

After millions years of evolution, biological systems exhibit many amazing functionalities due to their unique morphologies and physico-chemical properties, such as the adhesive performance of gecko foots, the self-cleaning ability of lotus leaves, and the anti-fogging property of fly-eye. Similarly, the optical architectures of the cellular structures in the biological surface have been refined to control and manipulate light and span diverse array of applications such as sensitivity improvement, temperature control and mate attraction by making use of a wealth of optical physics.

Here we demonstrate a double-sided, omnidirectional broadband absorber based on a bio-inspired moth-eye nanostructure covered by a single-layer non-noble metal. It shows the capability of absorbing incident light a low sensitivity to the angle of incidence, which exceeds the structured bulk metallic surfaces as black-body performance. The value of the proposed device as excellent absorber needs more attention due to several facts: (i) It has much simple device configuration compared with other types of optical absorber, such as plane film stack relied on Fabry-Perot cavity, metamaterial-based surfaces, and metallic nanostructures employing surface plasmonic phenomenon. (ii) It is easy to be fabricated by a combination of soft-nanoimprinting and metal deposition techniques. Only one single layer of non-noble metal material is contained. There needs no complicated fabrication procedure, such as the time-consuming and costly fabrication technology of electron beam lithography or focused ion beam milling. (iii) Capable of absorbing and trapping light from both the front- and back-sided incidence, the proposed absorber can contribute to enhancing the efficiency of new exciting perspectives, especially for thermophotovoltaics, thermal emitters, and other light-trapping optoelectronic devices. (iv) For its nonresonant absorption in nature, the absorber is characterized by high absorption for a broad range of incident angles over broadband. In this paper, we demonstrate experimentally that two-dimensional arrays of tapered moth-eye nanostructure ensure efficient, broadband and wide-angle absorption of unpolarized light over a large range of incident angles. It has potential applications in a wide range of passive and active photonic devices, including inkless printing, harvesting solar energy, as well as thermal emitter and optical detectors.

2. Discussion

2.1. Design and simulations

Independently absorptive properties of the wavelength, angle, and polarization of the incident radiation are of primary interest for fulfilling the fundamental requirements of harvesting more photons. A number of device configurations based on different working principles have been reported to achieve such purpose, but they suffer from unlimited fabrication complexity or are only capable of absorbing light from one incident side, which inevitably involve high cost and limit their utility for energy harvesting. The model of the optical absorber composed of moth-eye nanostructure with one single-layer non-noble metal is constructed through schematic diagrams in Fig. 1a. Ellipsoid-shaped moth-eye nanostructure with parameters of a 400 nm separation and a 1 μm height is used for simulation. The base diameter of the motheye is 350 nm. The shape profile of the moth-eye is fitted with the equation and a 50nm-thick chromium is deposited on the surface. The refractive index of the substrate and the UV resin is assumed to be 1.5. The optical absorption (A) is calculated by 1−T−R, where T is transmission, R is reflection and both can be obtained directly from the simulation. For the periodic boundary condition is applied in x-y plane, the absorptive property is independent of the polarization orientation of the incident light. Fig. 1c - 1d show the contour plots of
absorption variation as a function of wavelength and incident angle for the double-sided incidence. The simulation results indicate that the absorber functions very well in both cases, thus demonstrating excellent broadband absorption feature at very large incident angle (up to 70°) in the visible wavelength range.

![Figure 1](image1.png)

Figure 1. (a) Calculated incidence-angle dependence of absorption. (b) Simulated reflection (•••) and transmission (- - -) and absorption (-) spectrum calculated by 1-R-T from both the front and back incidence. Contour plots of the absorption as a function of wavelength from (c) front- and (d) back-sided incidence.

2.2. Experimental Results and Discussions

To experimentally verify and demonstrate the absorption property the process comprises the fabrication of an AAO template with high order pore array, replication of the nanostructure, and sputtering coating deposition (shown in Fig. 2a). There is no need for the fussy fabrication of discrete metallic gratings. In order to create high-order tapered nano-pore array, the aluminina anode oxide (AAO) template is fabricated by using a well-known two-step anodization process. Then, the AAO template is fluoroisilane-treated to obtain an easier demolding condition, which is a critical issue in high aspect ratio nanostructure replication. Figure 2b shows the corresponding goniometer images for 1 μL droplets with apparent contact angles of before (top, 61°) and after (bottom, 117°) surface treatment, respectively. Larger contact angle means weaker adhesion of the treated AAO mold to the UV resin. After the soft lithography process, a thin layer of metal (Cr, Al, etc.) is deposited on the moth-eye nanostructure by successive ion sputtering to obtain the semi-directional absorber. Figure 2c shows the top and side-view of the AAO template. The period of the nanopore array with high-filling factor is 400 nm. The height of the tapered hole is about 1 μm, and the diameter of the nanopores is 350 nm at the top and 40 nm at the bottom. Figure 2d - e show, respectively, the top and side-view of the replicated nanostructures. It can be clearly seen that, although the perfect ellipsoid-shape structure is difficult to fabricate, the tapered nanostructure in the mold has been well replicated to the UV resin with high fidelity, high filling factor and high aspect ratio, which is useful for promoting optical performance.

![Figure 2](image2.png)

Figure 2. (a) Schematic of the steps involved in the fabrication of moth-eye nanostructure based absorber by using soft lithographic approach. The original AAO template is fabricated by a well-known two-step anodization process. Then the tapered nanonipple structure was obtained from the AAO template and metal Cr of 50 nm thickness is sputtered on the front surface. (b) Goniometer images for 1 μL droplets with apparent contact angles of PUA on the surface of the AAO template before surface treatment (top) and after surface treatment (bottom). SEM images in top and side views of the AAO template (c), the replicated moth-eye nanostructure before (d), and after Cr sputtering (e).

3. Conclusions

In conclusions, the proposed architecture provide great potential for manipulating light, because of the strong coupling between electromagnetic fields and surface charges. Theoretical and experimental characterizations clearly demonstrating that the biomimetic light absorber proposed here yields seductive double-sided omnidirectional absorption over the entire visible spectrum. It has potential applications in a wide range of passive and active photonic devices, including inkless printing, harvesting solar energy, as well as thermal emitter and optical detectors.

Abstract

This work reports a design of a narrowband and full-angle refractive index sensor based on Tamm plasmon resonance (TPR) by introducing a distributed Bragg reflector (DBR) integrated with a non-adjacent metal layer. The analyte flows into the cavity comprising of the DBR and the non-adjacent metal layer. Simulated results show that the incident light can be strongly confined in the specially designed cavity. The sharp reflection dip within the forbidden band of the isolated DBR indicates the excitation of Tamm mode, and the spectral characteristics were monitored upon exposure to various analytes with different refractive indices. The optimally designed system shows the sensitivity (S) and full width at half-maximum (FWHM) can be up to 860 nm/RIU (refractive index unit) and ~2.2 nm with a figure of merit (FOM) of 391. Furthermore, the highly-sensitive characteristic can be sustained in a wide angle range of 0° to almost 90°under both TM- and TE-polarized lights.

1. Introduction

Recently, optical sensors based on surface plasmon resonance (SPR) have experienced an unprecedented growth for chemical, biomedical and environment monitoring over the last two decades due to the possibility of high-sensitivity and label-free detection [1–3]. In terms of the SPR shift driven by the environment-plasmon interaction, SPR sensors based on various types of metal nanoparticles have attracted a great deal of attention [4–5]. Nevertheless, the trigger of SPR requires stringent injection conditions (e.g., polarization and incident angle) due to the momentum mismatch between light and SPR at the same frequency [9]. Besides, almost all of the existing SPR-based sensors employ metal/dielectric hybrid systems with delicately designed nanostructures, which normally have in-plane subwavelength (or deep-subwavelength) patterns and require complicated/costly fabrication. Therefore, part of the attention goes back to the planar scenarios for cost-effective strategies. Unfortunately, the poor optical performance in light trapping remains one of the major hurdles of the planar architectures. As a result, some carefully designed planar structures emerge. Studies on Tamm Plasmon resonance (TPR), proposed by A. V. Kavokin et al. in 2005, are flourishing [6-7]. In this work, we propose a refractive index sensor based on TPR, which is comprised of planar multilayer structure, with the advantages of easy-fabrication and cost-effectiveness relative to these devices using nanostructured films or periodical nanostructures. To explore the sensing potential of our proposed structure, we bound the Au layer to a flow cell sealed with the inverse DBR atop of a transparent superstrate. Through numerical simulation, we found that the sensor performance is highly dependent on the cavity height and the DBR parameters. By optimally tuning the TPR, the sensitivity of the proposed multilayer structure can be up to 860 nm/RIU (refractive index unit) and the full width at half-maximum (FWHM) can be 2.2 nm in the infrared range, therefore the figure of merit (FOM) can be up to 391.

2. Structure design and analysis

The proposed TPR sensor is based on a planar multilayer structure comprising of a DBR in the front side, a non-adjacent Au layer in the rear side, and a cavity consisting of the upper DBR and the lower Au layer, as shown in Fig. 1(a). The analyte flows into the cavity with a width (W) far larger than the wavelength of incident light. The height of the cavity and the thickness of the Au layer are labelled as $H$ and $d_{Au}$, respectively. When the wavelength of incident light coincides with the excitation of TPR, electromagnetic energy accumulates within the cavity closed to the Au interface and thus enables optical monitoring of the analytes’ refractive index. Rigorous numerical simulations were conducted throughout the design to illustrate how the electromagnetic field is confined by TPR and tailor the structural parameters to the desired optical response. For all the employed materials, the optical constants are from Palik. Rigorous coupled-wave analysis (RCWA) is firstly employed to calculate the optical dispersion characteristics to properly configure the device for the excitation of TPR. Fig. 1(b) plots the reflection spectra $R(\lambda)$ of the isolated DBR under normal incidence and the proposed device illustrated in Fig. 1(a), where the pair number of Al$_2$O$_3$/TiO$_2$ ($N_{DBR}$) is 7, $H = 450$ nm, and $d_{Au} = 200$ nm. It is clear that there exists a reflection dip for
different analytes with varying refractive indices \( (n) \) in the forbidden band of the isolated DBR, which indicates the excitation of TPR. Note that for most fluids, the refractive index is in the range of 1.32–1.45, while that of gas is around or a little larger than 1. In Fig. 1(b), the reflection dip for \( n = 1.0 \) is relatively gentle compared to those for the other two cases, which can be ascribed to the un-optimized height of the cavity, and the small and narrowband reflection for \( n \) around 1 can also be obtained by adjusting the sizes of the cavity. These results suggest the proposed structure may be used for sensing the refractive index for both the gas and the liquid.

Figure 1: (a) Schematic diagram of the proposed planar multilayer structure comprising a distributed Bragg reflector (DBR), separating walls with various heights \( (H) \), and an Au layer atop of a SiO\(_2\) substrate. (b) Reflection spectra of the isolated DBR (black line) and the proposed structure with various analytes (blue line for \( n=1.32 \), red line for \( n=1.42 \) and pink line for \( n=1 \)).

3. Discussion

The optimally designed system shows the sensitivity \( (S) \) and full width at half-maximum (FWHM) can be up to 860 nm/RIU (refractive index unit) and \( \sim 2.2 \) nm with a figure of merit \( (FOM) \) of 391. Furthermore, the highly-sensitive characteristic can be sustained in a wide angle range of \( 0^\circ \) to almost \( 90^\circ \) under both TM- and TE-polarized lights.

4. Conclusions

In summary, we present a planar multilayer structure without the conventional highly nanostructured components for the refractive index sensing. The planar multilayer structure is designed to be composed of DBR, Au layer, and the formed cavity for analyte flowing. Such device structure can excite a very strong TPR, which confines the incident photon energy in the cavity. With varying the analyte index, the deep reflectance dip can be sustained with the sensitivity \( (FOM) \) close to 860 nm/RIU (391). The angular sensitivity is demonstrated to be sustained with the incident angle closed to \( 90^\circ \). This work sheds light on the achievement of the high-performance and low-cost refractive index sensing.

Abstract

We design chains of triangular and circular nanostructures and optimize their size, shape, and inter-distance for efficient plasmon propagation. Directional plasmon propagation is achieved by an elongated triangular shape, and by implementing a gradual change in size of the elements within a chain. The coupling between neighboring elements is optimized by carefully tuning the gap, or respectively the overlap, of the nanostructure elements. We analyze the optical nearfield of such self-similar chains by finite element simulations, and fabricate the waveguides from Au elements on Si substrates. The size and shape of the nanostructures is characterized by scanning electron microscopy (SEM), and the optical properties of the self-similar nanostructure chains are investigated by scattering near-field optical microscopy (SNOM).

1. Introduction

Plasmonics of metal nanostructures represent a highly versatile approach for the manipulation and localization of light in the visible and near-infrared spectral range.[1] Localized surface plasmon resonances (LSPRs) in metallic nanostructures are capable to confine light to a volume of nanoscale size that is much smaller than that given by the optical diffraction limit. The plasmon resonance depends on the size of the metallic elements, and the gap between neighboring elements can play a crucial role in the coupling.[2] However, the short decay length of plasmons in metallic waveguides remains an obstacle.[3] Tapered arrays of metallic nanostructures have demonstrated strong coupling and efficient plasmon propagation, and therefore represent an interesting alternative for plasmonic waveguiding. [4, 5]

2. Results and Discussion

Chains of Au nanostructure elements are fabricated by electron-beam lithography and metal evaporation. An example an isosceles triangle with an aspect ratio of around 2 is shown in Figure 1, together with an image of a chain of such triangles separated by a nanoscale gap. We systematically varied the distance of the neighboring elements in the chains from nanometer separation to a small overlap. Using finite element method simulations, we calculated the electrical nearfield distribution for excitation with a plane wave at different wavelength, and with parallel and perpendicular polarization to the long axis of the triangles.

Figure 1: Scanning electron microscopy (SEM) images of the triangular elements in a chain. The curvature at the edges is evaluated by the radius of a circle.

Furthermore, we evaluated the coupling and the signal propagation along the chains. Figure 2 shows the field distribution (a) and the signal propagation (b) when the left end of the chain is illuminated with a Gaussian beam with a beam waist of 0.8 µm. Experimentally realized chains of triangles that manifest an overlap (top) or a gap (bottom) depicted in Figure 2c. Here also a gradual reduction in element size was introduced that increases the coupling of the larger element to the slightly smaller one on its right side, which enhances the unidirectional coupling and signal propagation in the chain. By comparing simulations of chains with gapped and overlapping elements, we find that the coupling and the signal propagation along the chain is enhanced when the triangular elements have a small overlap.

Figure 2: ...
We investigated the optical nearfield resonances in the chain-like waveguides by scattering scanning nearfield optical microscopy (s-SNOM) with a microscope from Neaspec. The samples were illuminated with a laser beam at 785 nm that was focused by a parabolic mirror, and the 3rd harmonic of the optical signal, together with its phase, was detected by a metal coated atomic force microscopy tip. Figure 3 shows the topography of a section of a tapered triangular chain, together with the optical nearfield signal and phase.

3. Conclusions

Nanostructuring of plasmonic waveguides can be an efficient means to enhance the plasmon propagation length. The design of the shape and inter-distance of the elements in chain-type waveguides allows to optimize the nearfield coupling and thereby the propagation length. Unidirectional propagation can be obtained by asymmetric elements and by introducing a gradient in element size in the chains.

Abstract

This article proposes a star gap quadrupole nano-antennas that can operate for both linear and circular polarizations. We have achieved the electric field enhancement of 27 and 37 for linear- and circular-polarized pump, respectively. The antenna is characterized using Raman spectroscopy which produce surface enhanced Raman scattering enhancement of \(4.18 \times 10^6\) line for methanol.

1. Introduction

Plasmonic nano-antennas are capable of localizing light in a sub-wavelength region below the diffraction limit [1], leading to the generation of high electric fields by exploiting localized surface-plasmon resonance (LSPRs)[2]. Due to their large electric field enhancement, they have been used as probes in Surface Enhanced Raman Scattering (SERS)[3] to enhance the intensity of Raman signal, enabling single-molecule detection[4].

Many antennas reported in the literature (e.g. dipole antenna) work with linear polarization. A few antennas such as patch antennas[5] can work with circular polarized waves but they do not produce high electric field. Circularly polarized light is important, for example, in the study of chiral organic molecules. In this work, we design a star gap quadrupole antenna which has nearly 1.4 times stronger electric field enhancement factor for circular polarization than for linear polarization, has a larger footprint than bowtie antennas and a high electric field enhancement.

2. General description of the structures and theoretical analysis

To obtain a high electric field intensity with strong resonance and multiple resonance responses, we have designed a star gap circular nano-antenna as shown in Figure 1.

The device is fabricated with a FEI Helios 600 focused ion beam (FIB) system. A scanning electron microscopy (SEM) image of single structure is shown in Figure 3. Since the performance of nano-antennas are hard to measure directly; we can indirectly assess the theoretical results by using SERS. We have used a Renishaw in Via 2 spectrometer to analyze the spectrum of methanol with a concentra-

\[ F = \left| \frac{E_{\text{gap,peak}}}{E_{\text{inc,peak}}} \right| \]
Figure 2: Spectral response of our designed device for both linear and circular polarization.

Figure 3: SEM image of single quadrupole nano-antenna with splitted circular ring.

tion of 17 mol/l in the presence of nano-antenna and only using glass slide. Firstly, we placed the methanol solution on the top of a quartz surface, which is used as a reference. Later, to get the intensity of methanol with structure, methanol is dropped from top using pipette on the sample and a glass plate is placed on the top of methanol drop to ensure methanol molecules attached well to the surface of the device. The Raman intensity of structure with methanol solution averaged over 20 spectra with an acquisition time of 32s and compared with the quartz surface. we got the intensity for methanol is 38279.50 counts and only quartz substrate is 3231 counts. The measured SERS EF of our periodic structure in the presence of methanol at 2943 cm$^{-1}$ is $4.18 \times 10^6$, which is higher than the theoretical value $5.31 \times 10^5$ (considering the SERS enhancement is proportional to the fourth order of local electric field enhancement factor). Since, chemical factors for the total SERS EF is in the range between 10 and 100, therefore-the measured SERS enhancement factor is approximately 10 times higher than the theoretical value.

4. Conclusions

In summary, we have studied a star gap quadrupole nano-antenna that can boost the electric field by a factor of 27 for linearly-polarized pump and 37 for circularly-polarized pump, respectively. The performance of the fabricated nano-antenna is validated for linear polarization with Raman experiments, which shows that the SERS enhancement is $4.18 \times 10^6$ for the 2943 cm$^{-1}$ line of methanol.

Abstract

For explaining the physics puzzle, we discover a new physics of self-beating without nonlinearity, together with plasma effects. While a portion of the light pulse transmits through the slit as a sub-pulse, the rest is reflected at the exit, propagates a round-trip, and then reaches the exit again. These linear processes repeat. The superposition of sub-pulses with a phase delay in-between produces a periodic light that beats its original light frequency. Analytical models proposed agree well with simulations.

1. Introduction

Beating involves two waves of different frequencies and is a key mechanism of nonlinear science, besides the high order response of nonlinear materials to large wave amplitude. When light pulses are transmitted through a subwavelength plasmonic aperture, a few phenomena [1, 2] have been observed experimentally. Besides extended second half pulse duration [1], the transmitted spectrum can become flatter [2]. Different theoretical explanations are proposed. In the Fabry-Perot like mechanism, the light spectrum transmitted through a perfect electric conductor (PEC) are calculated and the results show that the spectrum becomes slightly narrower [3] or that the pulse widths are broadened [4], while the shapes remain about the same. But, the physics proposed for PEC [3] cannot be applied to explain what observed for plasmonic metal film [5, 6]. Surface plasmon [5] and nonlinear beating [6] are phenomenologically proposed for complicated phenomena observed in FDTD simulations. Considering only linear materials and processes, we discover a new physics of self-beating when a Gaussian light pulse transmits through a subwavelength plasmonic slit. Together with the plasma effects of non-uniform dispersion and sub-pulse spreading, self-beating can explain many phenomena observed. Analytical models are proposed and the modeling results agree well with simulations.

2. Gaussian pulse transmitting through a PEC slit

The magnetic field of Gaussian pulse light at the source is

\[
H_1 = H_0 e^{-\alpha(t - \tau_s)^2} \sin[\omega_0 (t - \tau_s)],
\]

where \(\alpha = \ln 2 / [2(\Delta / 2)^2]\), \(\Delta\) is the FWHM of the intensity, and \(\tau_s\) is the time of the source peak. The magnetic field transmitted without reflection can be written as

\[
H_0 = H_0 e^{-\alpha(t - \tau_0)^2} \sin[\omega_0 (t - \tau_0)],
\]

where \(\tau_0\) is the time of the peak to exit the slit. The roundtrip reflections produce sub-pulses as

\[
H_j = H_0 r^j e^{-\alpha(t - \tau_0 - j\tau_r)^2} \sin[\omega_0 (t - \tau_0) - j\phi],
\]

where \(j\) is the roundtrip number and \(\phi\) is the phase delay. The superposition principle gives the transmitted magnetic field up to \(n\) times of the roundtrip can be expressed as

\[
H_n = \sum_{j=0}^{\infty} r^j H_j \quad \text{so that} \quad H_n = \left[\sum_{j=0}^{\infty} r^j \cos(j\phi) e^{-\alpha(t - \tau_0 - j\tau_r)^2} \sin(\omega_0 t)\right].
\]

Figure 1 shows the transmitted wave functions. As shown in Fig. 1(a) for the case of \(\phi = 2.5 \times 2\pi\), the off phase effect causes the cancellation of the field so that the resultant pulse width is significantly shortened. In contrast, for the \(\phi = 6\pi\) case as shown in Fig. 1(b), the in phase effect enhances the pulse amplitude and significantly extends the pulse length so as to form a long tail. Note that a small change in the phase delay can be so critical to determine the resultant pulse. When the phase delay is twice the original pulse FWHM, the resultant wave function is modulated as shown in Fig. 1(c). For an even longer phase delay, as shown in Fig. 1(d), the sub-pulses do not overlap and a pulse train is observed. The resultant wave functions can be quite different with the original light pulse. All the FDTD simulation results agree well with their corresponding modeling results.

![Figure 1](image-url)
becomes a flat valley. In contrast, for a slightly larger phase delay of 6 periods, the spectrum peaks at the central frequency as other in-phase cases while the spectral width decreases and two weak side bands appear. As the phase delay is doubled, these two side bands grow higher and move closer to the central frequency, and two more side bands appear, as shown in Fig. 2(b). The number of the spectral peaks for the out-of-phase and in-phase cases are even and odd, respectively. Again, all the simulation results agree well with their corresponding modeling results.

Figure 2: Spectrums from the modeling (color), the simulation (gray), and the incident pulse (black) (a) $\phi = 7\pi$, $\phi = 11\pi$, $\phi = 12\pi$, and (b) $\phi = 24\pi$.

3. Gaussian pulse transmitting through a plasmonic metallic slit

The dispersion relation of the wave in the slit is given as [7]

$$\tanh(a\sqrt{k^2 - k_0^2}) = -\sqrt{k^2 - \varepsilon_m k_0^2}/\varepsilon_m \sqrt{k^2 - k_0^2},$$

where $k$ is the wave number, $\varepsilon_m = 1 - \omega_p^2/\omega^2$, and $\omega_p$ is the plasma frequency. In the frequency domain, a component of the incident pulse at the entrance is expressed as

$$H_i(\omega) = H_i \int_0^R e^{-a(t - \tau_s - \tau_d)^2} \times \sin\omega_0(t - \tau_s - \tau_d) \exp(j\omega_0\tau_s) dt.$$  

(6)

The magnetic field transmitted without reflection becomes

$$H_0(\omega) = H_i(\omega) r_s(\omega) e^{jk(\omega) h},$$

(7)

where $t_s$ and $r_s$ is the frequency domain. The magnetic field transmitted after the $jth$ roundtrip is

$$H_j(\omega) = H_0(\omega) r_s^{j} e^{jk(\omega) h}.$$  

(8)

In the time domain, the $jth$ sub-pulse can be obtained by inverse Fourier transform.

Figure 3 shows the results of the pulse transmission through a slit in a plasmonic metal film. The transmitting pulse inside the slit of the plasmonic metal film of $\omega_0/\omega_0 = 4.0$ shows that the wavelength is shorter and the peak arrives to the center later because of the plasma dispersion. The peak amplitude is lower due to the excitation of surface plasmon and the field energy penetrating into the metal. For $\omega_0/\omega_0 = 2.0$, the wavelength reduces more at the peak and, in fact, even shorter (longer) at the rear (front) part, while the peak amplitude is further lower. The group velocity of the peak is $v_g = 0.14c$ while the front (rear) propagates faster (slower) and thus the pulse disperses during propagation. From the transmitted sub-pulses, we find the transmission and reflection coefficients depend on the wave frequency. For $\omega_0/\omega_0 = 4.0$, the transmitted field history is similar to that of Fig. 1(c), as shown on Fig. 3(a). As for the $\omega_0/\omega_0 = 2.0$ case, the sub-pulses are elongated as shown on Fig. 3(b). The more roundtrips, the longer elongation. For both cases, the simulation and modeling results agree well.

Figure 3: The histories of the magnetic field measured at the slit exit from the model (orange) and the simulation (black) for a $h = 660$ nm film of (a) $\omega_0/\omega_0 = 4.0$ and (b) $\omega_0/\omega_0 = 2.0$.

4. Discussion

From the viewpoint of cause, what we find is the new physics of self-beating without nonlinearity. From that of effect, the consequence is the same as nonlinear beating so that we may also consider it as meta-nonlinearity. It is a spectrum beating with the original frequency.

5. Conclusions

We have revealed the new physics of self-beating and, together with plasma effects, explained various phenomena occurs during pulsed lights transmit through a plasmonic metallic slit. Although our study is in the time domain, the concepts, mathematics, physics and results may be generalized to multi-dimensional spatial domain, including free space. Besides nonlinear sciences, physics, materials and photonics, this study may be applied to other areas of wave mechanics from classical to quantum.

Bridging Classical and Quantum Plasmons via an FDTD-TDDFT Hybrid Model

Jian Wei You and Nicolae C. Panoiu

Department of Electronic and Electrical Engineering, University College London, London, United Kingdom
*corresponding author, E-mail: jvyou@ucl.ac.uk

Abstract

The interaction between classical plasmons of a gold bowtie nanoantenna and quantum plasmons of graphene nanoflakes (GNF) placed in the narrow gap of the nanoantenna is studied by a proposed FDTD-TDDFT hybrid numerical method. Our analysis shows that the quantum plasmon response of a molecular-scale GNF can be enhanced by more than two orders of magnitude in this hybrid system. This finding can be particularly useful for applications to molecular sensors and quantum optics.

1. Introduction

Recently, plasmons in two-dimensional (2D) materials, such as graphene, have attracted increasing research interest, primarily because of the new rich physics characterizing these materials. However, when the geometrical size of plasmonic nanoparticles is less than about 10 nm, the description of their optical properties becomes more challenging because quantum effects begin to play an important role. At this scale, plasmon resonances become more sensitive to the quantum nature of the conduction electrons [1], thus the theoretical predictions of classical approaches based entirely on the Maxwell equations are less successful in describing experimental results [2]. The shortcomings of the classical theory stem chiefly from neglecting three quantum effects: i) spill-out of electrons at medium boundaries, ii) surface-enabled electron-hole pair creation, and iii) nonlocal effects of electron wavefunction. These quantum effects can significantly change the features of plasmon spectra predicted by the classical theory [3]. To overcome these shortcomings of the classical theory, a new research area that combines plasmonics with quantum mechanics, known as quantum plasmonics, has recently emerged [4]. In this paper, we apply an FDTD-TDDFT hybrid numerical method [5] to study the classical-quantum plasmon interaction of a multiphysics system in the weak-coupling regime.

2. Physical System

The physical system used to illustrate the main features of our numerical method is shown in Fig. 1. It consists of a gold bowtie nanoantenna placed on a silica substrate and a molecular-scale GNF located in the narrow gap of the nanoantenna. The nanoantenna is made of two triangular gold plates with angle, \( \alpha \), length, \( L \), and thickness, \( t \), the separation distance between the tips of the gold plates being \( \Delta \). In all our simulations \( \alpha=12^\circ \), \( \Delta=10 \) nm, and \( t=30 \) nm, but \( L \) will be varied. Moreover, the GNF has a triangular shape, too, with side length, \( a=1.23 \) nm, namely there are six carbon atoms along each side of the triangle. It should be noted that triangular GNFS is one of the stable configurations in which they exist [6]. The GNF is positioned in such a way that its symmetry axis coincides with the longitudinal axis of the nanoantenna. The bowtie nanoantenna has plasmon resonances associated with the triangular plates and strongly localized (hot-spot) plasmons generated in the narrow gap of the nanoantenna.

3. Results and Discussion

3.1. Quantum plasmons of graphene nanoflakes

We considered first the GNFS described in the preceding section and used the TDDFT method to investigate their optical spectra. More specifically, we used the Octopus code package [7]. The GNF is freestanding and it only interacts with an external time-dependent and spatially constant electric field. We assumed that the time dependence of the field was described by a delta-function. In the right-side inset of Fig. 2, we have performed a calculation for a GNF with charge doping concentration of 15%. Here, the charge doping concentration is defined as the ratio of the number of excess charges to the number of carbon atoms in the GNF. The quantum response of the GNF is quantified by the dipole strength function \( S(\omega) \). It can be seen in this figure that the main resonance peak of this GNF is located in the infra-red region. Moreover, we have also calculated the distribution of the net charge density at the resonance frequencies, as compared to that in the ground state. The blue and red colors correspond to the negative and positive net charge density, respectively. This net charge distribution does prove that this resonance peak corresponds to collective electron density oscillations, i.e. it can be viewed as a quantum plasmon.

Abstract
We investigate the evolution of localized surface phonon polariton (SPhP) resonances supported by L-shaped nanoresonators for a range of geometries and incident polarizations. As indicated by polarized reflection spectroscopy, we observe three distinct resonances with in- and out-of-plane polarization selection rules that can be widely varied by changing the length of only a single resonator arm. Such polarization control is expected to play an important role in optimizing light-matter interactions.

1. Introduction
The ability of surface plasmon polaritons (SPPs) to enhance local fields provides major benefits for surface enhanced spectroscopy and sensing. Furthermore, since chemicals and molecules tend to have specific selection rules, controlling the polarization of SPPs can influence the coupling between light and matter. While research continues to investigate ways in which SPPs interact with and manipulate polarized light [1-2], the high losses of metals limit the ability to harness plasmonic effects in the infrared (IR) and explore new physical phenomena. In contrast, SPhPs support, low-loss, high-quality (Q)-factor resonances that allow us to directly observe physical phenomena otherwise obscured by the losses in traditional SPPs.

We observe the effects of symmetry breaking on SPhP resonances that are supported by SiC L-nanoresonators. As opposed to work previously performed on plasmonic L-shaped nanoresonators, where the spacing [2] or angle [3] between resonator arms was varied, we investigate how resonances are modified by changing the relative length between the two arms of the L-resonator. By controlling the relative arm length (characterized by an aspect ratio, AR), we find that we can control the relative orientation between the two fundamental modes of the L-resonator. In addition, we find that the degree to which modes are linearly polarized in-sample-plane is also affected by controlling the AR. Using polarized reflection spectroscopy, we are able to determine the polarization selection rules for three localized SPhP resonances that are supported by the L-geometry. Furthermore, the optical behavior of these modes is fully captured by full-wave electromagnetic modeling.

2. Experiment
2.1. Fabrication
Arrays of L-shaped pillars made up of 6H-SiC were fabricated on a bulk 6H-SiC substrate. Refer to reference 4 for fabrication details. Each L-resonator geometry is characterized by an aspect ratio, defined as the length ratio between the long and short arms. Here, we focus on resonators with nominal ARs of 1, 1.5, and 2. Fig. 1a shows an SEM of one of our structures for an AR of 1.5.

Figure 1: a) Scanning electron micrograph (SEM) image of a SiC L nanoresonator with nominal AR of 1.5, and incident polarization orientation denoted by φ. b) Typical unpolarized reflection spectra measured for an AR = 1 L structure.

2.2. SPhP Mode Assignment
The resonant energies, Q-factors, and polarization selection rules of SPhP modes supported by the L-resonators are investigated through polarized reflectivity measurements. To determine the polarization selection rules of these modes, we track the magnitude of resonances as a function of incident polarization angle. Three distinct modes are observed in the reflection spectra for all three L-resonator patterns (AR=1 shown in Fig. 1b). As indicated by the polarization orientation that yields maximal differential reflectance (see figure 2a), the three observed modes are optimally excited when the incident polarization is oriented at φ = 135° for the mode at 832.6 cm⁻¹ (where φ is defined in Fig. 1), φ = 60° for the mode at 847.6 cm⁻¹, and φ = 90° for the high-energy mode at 866.4...
Based on full-wave electromagnetic modeling (COMSOL), we are able to identify these modes as antisymmetric, a symmetric and a higher order symmetric resonances, respectively (as indicated by resonant charge distributions). Unlike the low-energy symmetric mode, the higher order symmetric mode has a large polarization component oriented out-of-plane. The antisymmetric and symmetric resonances are similar to those found in previous reports of SPPs analogs [1,3].

Figure 2: a) Experimental differential reflection between the SiC substrate (R_{sec}), and L-resonators (R_L), showing the polarization orientation of the antisymmetric (orange squares), symmetric (light blue circles), and higher order mode (purple stars) for the AR = 1 resonator array. Illustration of the in-plane charge distribution for the b) the antisymmetric mode, c) the symmetric mode, and d) the higher order mode.

3. Discussion

As shown in Fig. 2a, the antisymmetric mode of the AR=1 L-resonators has a polarization dependence that is typically observed for a linearly polarized mode that lies fully within the sample-plane. In comparison, the symmetric mode has a noticeable waist that does not fully extinguish the resonance when the incident polarization is perpendicular (\(\phi = 150^\circ\)) to the main excitation axis of the mode (\(\phi = 60^\circ\)). This indicates that a portion of this mode is oriented out-of-plane. In contrast to the symmetric and antisymmetric modes, the polarization of the higher order mode, lies largely out of plane.

The polarization direction of the antisymmetric and symmetric modes is highly affected by the change in the relative leg lengths. As shown in Fig. 3a, the antisymmetric mode exhibits a rotation of the in-plane polarization orientation as the AR increases. We explain this behavior by noting that the antisymmetric mode is a dipole mode, with a dipole oriented along the hypotenuse of the structure. As the length of one arm increases, the angle between the legs and the L-hypotenuse is modified, which translates into an in-plane rotation of the polarization selection rule. On the other hand, the symmetric mode is only weakly dependent on AR, as shown in Fig. 3b. However, unlike the antisymmetric mode, the symmetric mode gains a significant out-of-plane polarization component as AR increases, which is indicated by the broadening of the polarization ellipse as AR is increased (Fig. 3b). In order to quantify the degree of out-of-plane polarization, we calculate the ratio of the minimum to maximum extinction (P) for each mode, where P=0 corresponds to a mode that is perfectly polarized in-plane, P=1 corresponds to a mode that is largely polarized out-of-plane. For the symmetric mode, the polarization ratio increases from 0.28 to 0.71 as AR increases, indicating a significant portion of the mode is polarized out-of-plane, which can be controlled by the carefully designing the resonator. However, for the antisymmetric mode, P varies from 0.007 to 0.067, as AR increases, indicating the antisymmetric mode remains largely polarized in-plane for this range of AR.

Figure 3: Experimental data showing the polarization orientation of the a) antisymmetric, and b) symmetric resonance for AR = 1 (red squares), 1.5 (green circles) and 2 (blue stars).

4. Conclusions

Overall, this work demonstrates that both the in-plane and out-of-plane selection rules of localized SPhP resonances that are supported by L-shaped nanoresonators can be manipulated by controlling the resonator geometry. The symmetric mode is especially interesting since our measurements indicated that its selection rules can be widely tuned from an in-plane to out-of-plane mode by simply elongating a single arm of the L-resonator.

Abstract
Plasmonic materials are utilized in plenty of areas like optoelectronics and photonics, due to their unique electromagnetic properties. Nanoparticles with plasmonic properties are added to the materials to greatly enhance their optical performance e.g. luminescence, Raman scattering or optical non-linearities.

The aim of our work is to develop an efficient microlaser based on the sodium borophosphate glass (NBP) co-doped simultaneously with plasmonic silver nanoparticles (AgNPs) and cadmium telluride quantum dots (CdTe QDs). Introduction of NPs into the matrix is carried out by the NanoParticle Direct Doping method [1]. AgNPs greatly enhance the intensity of PL from the light emitters. Microspheres are obtained by the method described by Ward et al. [2]. Response of the system exhibits strong dependence on excitation power. What is more, PL spectra are different in various points in the microsphere, showing whispering gallery modes fine structure while the illumination is centered on the edge of the microbead (Figure 1).

Miniaturization of the laser opens possibilities of its integration into e.g. microfluidic system or can lead to new applications, such as biosensing in vivo. Observation of WGM gives promise to utilize the plasmonic microspheres in optical switches or as a narrow band laser.

Off-axis digital holography for cathodoluminescence microscopy

Nick Schilder¹, Femius Koenderink¹, and Albert Polman¹

¹Center for Nanophotonics, AMOLF, Science Park 104, 1098 XG, Amsterdam, The Netherlands
*corresponding author, E-mail: schilder@amolf.nl

Abstract
We introduce off-axis digital holography for cathodoluminescence microscopy. We perform experiments on nanoholes in aluminium. The incident electron directly excites both surface plasmon polaritons and transition radiation simultaneously. The former scatter from the nanoholes and subsequently interfere in the farfield with (p-polarized) transition radiation, which serves as a reference field. By numerically isolating the interference terms of the farfield intensity, the complex-valued p-polarized electric field can be extracted.

1. Introduction
With cathodoluminescence microscopy fast electrons (1–100 keV) are used to characterize optical properties of nanostructures. The localized excitation of nanostructures allows deep-subwavelength imaging of modes. Each radiative mode has its own angular and wavelength dependent electric field amplitude, polarization and phase. Recent achievements in the field have enabled measuring both the angle-resolved amplitude and the polarization [1,2]. Access to the phase in cathodoluminescence microscopy has been elusive so far.

From other spectroscopy techniques such as near-field scanning optical microscopy (NSOM) or Fourier microscopy, we know that access to the wave front of light is important in for example the study of chiral light. This work shows the first steps towards phase-resolved cathodoluminescence microscopy. We use off-axis digital holography to retrieve the complex-valued electric field scattered by a nanostructure on a metallic film. It is the interference between scattered surface plasmon polaritons (SPPs) and transition radiation as the reference field that gives access to the phase.

2. Transition Radiation as Reference Field
For any interferometric technique, a (coherent) reference field is needed. Whenever a fast electron crosses an interface, broadband transition radiation is produced, which has a donut shape radiation pattern in the upper hemisphere and is perfectly p-polarized. This reference field serves to retrieve the complex p-polarized electric field scattered by an object that is positioned away from the excitation place of the electron.

3. Off-axis digital holography for cathodoluminescence
We use nanoholes in aluminium as scattering object. The incident fast electron excites both cylindrical SPPs and transition radiation. The SPPs induce multipoles in the structure that subsequently radiate. The p-polarized scattered light interferes with the spherical wave front of transition radiation in the farfield. This leads to interference fringes in the farfield, where the interference distance depends on the spatial separation of the sources (see Fig. 1). The farfield intensity has four components: \( I_{TR} + I_{scatter} + E_{TR}E_{scatter}^* + E_{TR}^*E_{scatter} \). When calculating the Fourier transform of the farfield intensity, the last two interference terms show up as displaced patterns from the origin. By isolating these terms, the intensity and phase pattern are retrieved (see Fig. 2).

Abstract

Optical switches selectively switch optical signal from switched-on to switched-off. Compared to the traditional electronic switches, optical switches are not limited by thermal effects or electromagnetic interferences. Here we show metamaterials-based probing of weak quantum absorber in coupled three-resonator system which reveals the signature of optical switching. The polarization dependent probing of molecular overtones excited in a hybrid system tune the state: when the system is illuminated by transverse magnetic polarized light the switch is on while for the transverse electric polarized light the switch is off.

1. Introduction

All-optical switching allows light controls light through unique optical effects. As the field of optical fiber technology has expanded \cite{1}, optical switches have been studied and progressed naturally \cite{2,3} giving rise to new configurations such as optically switchable organic light-emitting transistors \cite{4}, sub-femtojoule switches \cite{5}, plasmonic bandpass filter thermal switches \cite{6}, optical control of antiferromagnetic domains \cite{7}, utilizing high-mobility of cadmium oxide for ultrafast polarization-controlled \cite{8}, multimodal switching of a redox-active macrocycle molecules state toggle \cite{9} active control of anapole states by structuring the phase-change alloy \cite{10} ultrafast optical switching of infrared plasmon polaritons in high-mobility graphene \cite{11}. The efficiency of the switch is defined by its size which dictates the number of input and output ports; switching time of reconfiguration from one state to another; propagation delay time; switching energy to turn on the switch; power dissipation during the switching; crosstalk due to the power leakage to other ports; and physical dimensions \cite{2}. Even though the optical fibers are considered as a pivot of conventional optic telecommunication system \cite{1} their role in switching and processing of photonic signals is limited and fulfilled by electronics. Here we report on all-optical switch due to the excitation of molecular overtones in hybrid plasmonic-dielectric configuration. By coupling of photons with the conductive charges at the metal-dielectric interface, plasmonics gives rise to nanoscale optical devices operating at sub-wavelength regime \cite{13}. Hybrid plasmonic-dielectric configuration possesses a unique property to controlling the switch with polarization state of light that allows two different plasmonic modes co-exist while exciting single molecular overtone absorption band. Due to the possibility of developing energy efficient, real-time analyzing, and ultra-compact components at an affordable cost, plasmonics may be the next arrangement in optical communications. Despite the fact that many plasmonics-based applications appeared, such as sensors \cite{14}, detectors, modulators, switches, and microwave components, no attempts were done so far to designing all-optical hybrid plasmonic-dielectric switching systems based on effect of excitation of forbidden molecular overtones transitions.

![Figure 1: (a) Schematic illustration of polarized beam incident the switch. The state ‘off’ is activated when the TE polarized beam hits the switch, (b) the state ‘on’ is activated when the TM polarized light hits the switch. (c) Artistic representation of experimental setup. (d) Mechanism of coupled oscillators.](image-url)
2. Results and Discussion

Here we study on all-optical switch due to the excitation of molecular overtones in hybrid plasmonic-dielectric configuration. Figure 1 illustrates the concept of the system based on molecular excitation under TE and TM polarized light. In the state ‘off’, Figure 1a, TE polarized light is being transmitted through the medium. Figure 1b illustrates state ‘on’ in which TM polarized light excites molecular overtone transition resulting in a well-defined resonance due to the strong light absorption. Calculated far-field radiation diagrams in subplots Figure 1a and Figure 1b show the directivities for each state. At lower wavelengths however, excited molecular signatures experience different response to the incident light under TE and TM polarizations.

Figure 1c shows the modeled and tested experimentally system in which polarized incident polychromatic light illuminates the facet of the prism. Thin film composed of silicon on silver is placed on the prism with matching oil. N-Methylaniline molecule is dripped on the surface of the film together with gold nanorods. Light hits the base of the prism and penetrates through the thin film while exciting the guided modes. Guided modes in turn excite the molecular overtones. The energy transfer occurs between the molecular overtone vibrations to the localized surface plasmon excited in nanorod. We treat the coupling between the guided wave-to overtone-to localized surface plasmon as a system with three coupled oscillators having eigenfrequencies $\omega_{1,2,3} = \sqrt{\omega_1 \omega_2 \omega_3}$ coupled together with coupling spring constants $k_1, k_2$ and $k_3$ and masses $m_1, m_2$ and $m_3$. Figure 1d shows the oscillating mechanism of the system. Oscillator 1 is the guided mode surface plasmon, oscillator 2 is the molecular overtone vibration and oscillator 3 is the localized surface plasmon oscillator. The oscillators requirement is extremely demanding.

3. Conclusions

In summary, we explored the system in which three coupled oscillators are excited. Despite the relatively low oscillator strength of the corresponding forbidden dipole transition in harmonic oscillator approximation we constructed an optical switching system based on polarization depending properties of the plasmon-to-overtone coupled modes. This all-optical switching manifold is realized by excited localized surface plasmons (LSP) which couple to the molecular vibrations overtones. LSP in the system are excited by the extended surface plasmons (ESP) which in turn are excited by the guided modes of a waveguide structure.

Abstract

We discuss the possibility of implementing a novel biosensing platform based on surface plasmon resonances (SPRs) for investigating mechanotransduction and force generation by mechanosenory cells and organs. In particular, we present a study about the generation and analysis of optical resonances caused by gold nanorods (GNRs) adsorbed on films, separated by a polyelectrolyte (PE) thin layer assembled using a Layer-by-Layer (LbL) deposition technique. These devices with different PE layer/GNRs coupling were characterized and tested in phosphate buffer saline (PBS) in order to be able to control in a dynamic way the PE layer thickness swelling. Moreover, controlling the wettability of the surface, in particular after the deposition of GNRs, allows adjusting the hydrophilic/hydrophobic character of the surface, considering that the wetting property and wetting process are closely related to the surface morphology and roughness. We performed a deep study to confirm that this sensor, exploiting SPR, can be dynamic and compatible with biological environments.

1. Introduction

Sensing of force and movement in biological systems involves the conversion of an external mechanical stimulus into a biochemical signal, a process termed mechanotransduction. It plays important role in biology, from e.g. embryogenesis, to physiology and pathophysiology, from cancer to neurodegenerative disorders, and in a variety of sensory systems including those that respond to sound, acceleration, and touch [1, 2]. Analysis of cellular mechanotransduction has focused on identification of critical mechanosensitive molecules and cellular components. In this work, we present results on an innovative biomechanical sensor based on plasmonic nanostructures for sensing forces at the cellular level. When light impinges on a metallic structure, resonant oscillation of the conductive electrons, known as surface plasmons, are excited. Metallic nanoparticles smaller than the wavelength of the light can support localized surface plasmon resonance (LSPR) and confine light in a region beyond the diffraction limit with greatly increased local density of states enabling a variety of applications: from super resolution imaging [3] to biosensing [4] and photodetectors [5]. Systems in which GNRs are within a short distance from a gold film are optically very sensitive to any modification occurring in the gap and represent a promising platform for creating next-generation biosensors [6]. Here, we focus on the specific system where GNRs are coupled to a thin gold film in SPR configuration, in order to interrogate small, dynamic molecular conformational changes by measuring the actuation of molecular spacer layer in response to aqueous solution.

2. Experimental section

We performed numerical analysis and experimental spectroscopy of GNRs over a gold thin film with a precisely sized polyelectrolyte layer defining the gap between them. We studied this system as a function of gap size and determined modifications of its plasmon modes. GNRs were chemically synthesized using seed mediated growth and sized polyelectrolyte layer defining the gap between them. The final size were 35 ± 5 nm in length and 20 ± 4 nm in width. Substrates were prepared by evaporating 50 nm of Au film onto 5 nm of Ti adhesion layer covering a silicon wafer via electron beam evaporation. Dielectric spacer layers of varying thickness in the range 1± 9 nm, composed of alternating polyelectrolyte (PE) layers of poly (allylamine hydrochloride) (PAH-3mM) and polystyrene sulfonate (PSS-3mM) were deposited onto the gold film via Layer-by-Layer deposition. The sequential deposition of PAH and PSS was continued until the desired thickness was attained, with the terminating layer being cationic (PAH). Negatively charged GNRs were absorbed onto the terminal PE layer via short incubation with the colloidal solution. The films were rinsed with ultrapure water and dried with N2. The schematic arrangement of the GNRs over metal film system is presented in Fig. 1A. The GNRs as fabricated and after deposition on the gold film were observed, respectively, by a Transmission Electron Microscope (TEM) (Fig. 1B) and by Scanning Electron Microscopy (SEM). Reflectance spectra at normal incidence were measured with a custom made optical setup. Samples were positioned on an upright microscope, modified to accommodate for a reflectometry path. Broadband, incoherent light (Ocean Optics HL 2000) passing through a 100 µm pinhole was collimated with a lens (focal 250 mm), reflected by a beam splitter (50/50) and
focused on the sample with a low numerical aperture (NA), infinity-corrected objective (5x, 0.13 NA). The reflected light passing, through the beam splitter, was injected into a multimode optical fiber with an objective lens (20x, NA 0.5) and sent to a spectrometer (Horiba Scientific iHR320) equipped with an EMCCD camera (Horiba Scientific Synapse, 1600x200 pixels).

2. Results and Discussion

The plasmonic nanostructures are formed from colloidally synthesized metal nanorods deposited on top of a metal film and separated by a polymer spacer with nanometer accuracy. There are several appealing nanoscale properties of this plasmonic architecture. For example, the plasmon resonance between the metal nanorods and the film can be precisely controlled by varying the thickness of the polyelectrolyte spacer layer and the rods size. We created a GNRs-film sample with 50 nm gold film, a polyelectrolyte spacer layer of different thickness and gold nanorods, which produced a GNRs-film separation distance starting from 1 nm to 9 nm. The higher the separation, the higher the blue-shift of the coupled nanoparticles-film SPR. The spacer layer between the nanorods and the gold film is completely transparent at visible and near IR wavelengths. Fig. 2 shows the position of the measured resonance as a function of the overall thickness under the rods, assuming that the nanorods-film separation distance is the sum of the PE spacer layer thickness and the 5 nm thickness of the stabilizer coating that surrounds the rods. The position of the resonance can be accurately determined by 3D simulation (Fig. 2A). As typical with nano-plasmonic systems, their resonances are extremely sensitive to the thickness and the dielectric properties of the spacer layer, making the reflectance properties of the surface easily tunable by slightly changing the gap dimension. Based on our simulations, in which a single nanorod is coupled to a metallic film, we could expect a small reflectance even for low surface coverage. Changes in the refractive index (RI) near the nanoparticles induced a shift in the SPR peak position (Fig. 2B). Both simulation and experimental results showed that the plasmon resonance of the nanorods blue-shifts with increasing gap size. The agreement between our experiments and simulations confirms that our numerical model is adequately capturing the physics of the nanorods metal film coupling system.

Figure 1. Au nanorods over a Au film (A). TEM image of GNRs as fabricated (B).

Since our biosensor will be in contact with the cells, it is desirable to be able to control both the swelling level of the PE layer by specific stimulus and the wettability of the surface. PE layers of different thickness were assembled with the dipping solution at pH 6-6.5. We started studying the properties of the PE layer composed of PAH/PSS in PBS (pH 7.4). To compare PE layers swelling behavior, the films were examined as prepared and then a time course of 30 minutes was acquired during immersion in PBS. The films were dried to examine whether if swelling influences the dry-state thickness and to determine a “molecular memory” caused by previous treatment. Afterward, to understand the wettability of the surface a contact angle experiment in sessile drop mode was performed. The wetting state of surface can be controlled physically from the highly hydrophobic to hydrophilic states using GNRs by means of contact angle, because the wetting property is closely related to the surface morphology and roughness.
Contact angle measurements were carried out on GNRs deposited on the PE film and on PE film with no nanoparticles, to study the wettability in presence (or absence) of the nanorods and at different thickness of the dielectric layer [7]. The nanorods deposition on the PE layer increased the surface roughness, leading to higher contact angles values.

We next used the GNRs-film coupling in the plasmonic configuration to interrogate small, dynamic molecular conformal changes by measuring the actuation of molecular spacer layers in response to aqueous solution like water or Phosphate Buffer Saline (pH-7.4). It is well known that multilayer films assembled from PAH/PSS under specific pH conditions exhibit unique time-dependent swelling behavior. Fig. 3 shows representative GNRs-film SPR data at different time during PBS immersion and after drying. The GNR-film coupled resonance, which is between 645 and 655 nm, blue shifts when immersed in PBS solution but during the immersion, we can notice a red shift. This implies that during immersion the GNRs on the top of the PE layer are further away from the film, because the spacer layer is swollen, but when we came back to the dry state, the nanorods are closer to the film because of the PE layer shrinking.

This particular behavior was verified in both 7 and 9 nm PE layer samples. Based on these observations, the tuning of the plasmon resonance observed in our experiment is mostly likely caused by the increasing and decreasing of the thickness of the PE layer. Immersion in PBS for 30’ of a 7 nm thick PE layer leads to an SPR resonance corresponding to that of a 9 nm thick unswollen sample, demonstrating that the amount of thickness increase in the swelling process is about ~2 nm.

In conclusion, we have fabricated and measured the spectra of GNRs coupled to a gold thin film. Using experimental and numerical analysis of this geometry, we found that the observed resonances can be understood as waveguide cavity modes, where the gap between the GNRs and the metal film defines a waveguide cavity where electromagnetic energy can resonantly reflect back and forth. These resonances are extremely sensitive to the gap size separating the GNRs from the gold film, a property that could potentially be exploited for novel biosensing platforms. The wetting state of surface can be controlled from highly hydrophobic to hydrophilic states by using nanorods. Indeed, contact angle measurements show that by increasing the surface coverage of the PE layers using nanoparticles the contact angle increases to high values, with a difference of ~20° between the non-covered surface and the one covered with nanorods. A nanorods-film coupling is used in SPR spectroscopy mode to characterize the induced swelling of a PE layer. Spectra show a shift of the coupled NR-film SPR by incubation in PBS, suggesting that the gold nanorods have been pushed away from the gold film because the PE layer is in a swollen state. The system goes back to its previous state when the sample is dried, suggesting PE layer deswelling, so the PE layer has not any significant “molecular memory” of previous swelling treatment. It is also shown that the immersion in PBS for 30’ of a 7 nm thick PE layer leads to an SPR resonance corresponding to that of a 9 nm thick unswollen sample, demonstrating that the amount of thickness increase in the swelling process is of about ~2 nm. These results represent a step towards a fiber-embedded biomechanical sensor, where tiny cell pressures lead to shift of the SPR resonance wavelength because of the reduced thickness of the spacer layer.

Abstract
We propose a deep sub-wavelength scale surface plasmon polariton(SPP) travel wave amplifier (TWA) with multiple quantum wells (MQW) working at 1310nm communication window. The InGaAlAs tensile MQW are adopted for the polarization-independent amplification. We analyze this TWA’s electrical and optical characterizes by the finite element method. Simulation results suggest that the completely independent polarization gain appears at 1317nm in which the mode gain 110cm⁻¹ and mode width 163nm are obtained at the 5 × 10⁻⁶/m³ injected electron concentration and 260nm × 10nm gap size.

1. Introduction
The SPP components are being developed for ultra compact photonic integrated circuits (PIC). But the high propagation loss of the SPP wave is the main obstacle in the progress. In order to solve this problem, various structures and active media are proposed to construct the SPP amplifiers, such as the SPP with MQW[1-4], the DLSPP with Schottky junction[5], the gap SPP with double heterostructure[6-11]and so on.

Specially compensating the SPP loss with MQW was proposed first in the Ref. [2]. Also in the Ref. [1, 4] the MQW SPP with insulator-metal-insulator structure was explored by experiments.

Theoretically the SPP wave is TM polarization in the infinite slab structure. But in the real finite-size-device the SPP wave is a hybrid one in which both TM and TE polarization field exist simultaneously.

In normal lattice matched MQW structures, the TE polarization field gain is higher than that of the TM’s. For high fidelity amplification of the hybrid SPP wave, it is necessary to adopt the strain MQW which has the equal gain about the TE and TM field[12].

In this paper, we propose a deep sub-wavelength scale SPP TWA with the lateral current injection (LCI) MQW. There are two creative points in our works. First a tensile strain MQW is designed for high-fidelity amplification of the hybrid SPP wave. Second, by adjusting the gap layer height and width, both the little mode width and the high mode gain are obtained simultaneously. So far to our best knowledge, the polarization independent MQW SPP TWA has not been designed and researched before.

2. The SPP TWA Structure
The reason of using the LCI MQW in our SPP TWA is as following. The SPP wave reaches its peak at the metal-dielectric-interface and decays quickly from both sides of this interface. For effectively amplifying the SPP mode, it is necessary to push the amplification medium close to the interface enough. As the nanoscale-thickness-barrier and the LCI in MQW, the effective amplification area, i.e. the quantum well (QW) can reach the metal-dielectric-interface very closely and amplify the SPP wave effectively. Therefore the MQW with LCI is adopted in our SPP TWA. The SPP TWA cross section is shown in Fig. 1. From top to down there are air cladding, noble metal Ag, SiO₂ gap, MQW and substrate InP. On each lateral side of the MQW there are the p-InP and n-InP which guide current to MQW from both sides, i.e. the LCI. And the p-InP and n-InP doping concentration are 4 × 10²⁴/m³.

In Fig. 1 the MQW plays two roles. One is to amplify the SPP wave. The other is a part of the gap SPP waveguide which includes the high-index-MQW, low-index-gap(SiO₂)and metal Ag.

Also in Fig. 1 the SiO₂ is selected as the gap material for three reasons. First, SiO₂ is insulator, which isolates the metal Ag from current injection area. Second, the SiO₂ has low refractive index, which is necessary in the gap SPP waveguide. Third, it is transparent in 1310nm window.
which is the SPP TWA working range.

And shown in Fig. 1 both the positive and negative electrodes are 5μm width and are apart from the MQW edges 2.5μm. And the InP substrate is 5μm thickness.

By adjusting the low-index SiO₂ gap height \( h_\text{g} \) and width \( w_\text{g} \), the SPP mode field size and propagation loss can be changed. In addition, the metal Ag and MQW width also are \( w_\text{s} \).

3. The Design of the MQW

In QW structures the light generated by recombination of electron-heavy hole and electron-light hole is TE or TM polarization separately. In general QW structures, the transition probability between an electron and a heavy hole is higher than that between an electron and a light hole, so that the TE polarization is dominant in the optical gain[12]. This results in large optical gain polarization dependence in the general QW optical amplifier. So a number of designs have been developed to minimize the optical gain polarization difference in InP-based QWs[13-17].

In this paper, we design a tensile strain QW structure for SPP wave polarization-independent amplification. For a relevant material system, we adopted the In\(_{0.75}\)Ga\(_{0.25}\)As, Ga\(_{0.5}\)Al\(_{0.5}\)As to realize the layers of the MQW since it is known to have superior characteristics in temperature performance.

In Fig.1 the MQW is consisted of 20 QW units, each of which includes the 5nm-barrier, 9nm-tensile-QW, 5nm-barrier from top to down. And these QWs are separated by the 10nm separate confinement heterostructure (SCH) layers. Also shown in Fig. 1 at the top of the MQW it is the 5nm-thickness-InP which is next to the gap area. Simulation indicates that the multi-mode will appear if the whole MQW thickness is larger than 620nm. Therefore we use 20 tensile strain QWs to compose the 605nm-thickness-MQW.

The Eq. (1) is the relationship between the energy gap \( E_\text{g} \) and the composition ratio \( x,y)[18] \):

\[
E_\text{g} = \begin{cases} 
0.75+1.548y & \text{and} \quad (1-x-y = 0.53) \text{as lattice matched} \\
0.79+1.568y & \text{and} \quad (1-x-y = 0.38) \text{as 1% tensile strain} \\
0.81+1.578y & \text{and} \quad (1-x-y = 0.307) \text{as 1.5% tensile strain} \\
0.83+1.588y & \text{and} \quad (1-x-y = 0.225) \text{as 2% tensile strain} 
\end{cases}
\]

(1)

First the energy gap of the barrier, QW and SCH are decided on the principle of the gain peak being in the 1310nm window. Second, circularly carrying on these following three steps: adjusting the QW tensile strain coefficients, utilizing the Eq(1) to calculate the ratio \( x,y \), estimating the TE and TM polarization gain by the software Crosslight PIC3D until these two gain coefficient curves are as close as possible in the 1310nm window. Finally we get the composition ratio \( x,y \) of the barrier, QW and SCH layers to be \( [0.203,0.267],[0.4198,0.0625] \) and \( [0.0646,0.4054] \)

In above process, the TE and TM polarization gain is calculated using the software Crosslight PIC3D from the Eq. (2) proposed in the Ref[19] in the condition of the MQW being infinite slab layer structure.

\[
G(\varepsilon) = \frac{q^2 |M_\varepsilon|^2}{E \varepsilon_0 m_\text{e}^2 c^2/hn_\text{g}T} \cdot \sum_{ij} \int_{E_\text{g}}^E m_\text{ij} C_\text{ij} (f_i-f_j) L(E)dE
\]

where

- \( q \) is the electron charge.
- \( |M_\varepsilon|^2 \) is the bulk momentum transition matrix element.
- \( E \) is the photon energy.
- \( \varepsilon_0 \) is the free space permittivity.
- \( c \) is the vacuum speed of light.
- \( n_\text{g} \) is the effective refractive index of the laser structure.
- \( T \) is the thickness of the quantum well.
- \( i \) and \( j \) is the conduction and valence band quantum numbers.
- \( m_\text{ij} \) is the spatially weighted reduced mass for transition.
- \( C_\text{ij} \) is the spatial overlap factor between the state \( i \) and \( j \).
- \( A_{ij} \) is the angular anisotropy factor.
- \( f_i \) and \( f_j \) is the electron quasi-Fermi functions in the conduction and valence band, respectively.
- \( L(E) \) is the Lorentzian lineshape function, commonly used to include the spectral broadening of each transition.

The infinite slab MQW gain are shown in Fig. 2, from which it can be found that the TE and TM gain are equal at 1317nm wavelength from \( 3 \times 10^{24} \) to \( 6 \times 10^{24} \left( \text{m}^{-3} \right) \) injected electron concentration .

Fig. 2 The gain coefficient of the infinite slab MQW

4. The SPP TWA Characteristics

4.1. The electrical properties

By the Crosslight PIC3D simulation, as the applied voltage is 1.3v, the 500nm-width MQW electron concentration is obtained and shown in Fig.3(a). In Fig.3(b) it is the electron concentration along the middle white dashed line in Fig. 3(a). From Fig.3(a) (b), we can know that the electron
concentration can reach about $5 \times 10^{24} / m^3$. And in this condition the MQW local gain can reach about 2000 cm$^{-1}$ shown in Fig. 3(c)(d). The Fig. 3(d) is the gain along the white dotted line in Fig. 3(c).

4.2. The optical properties

As mentioned above, at 1317 nm the MQW have equal polarization local gain coefficient 2000 cm$^{-1}$. Therefore we simulate and analyze the SPP TWA characteristics at 1317 nm with local gain coefficient 2000 cm$^{-1}$ in the QW area. And the dielectric constants of these media in the SPP TWA are gotten as the following. The $In_{x-y}Ga_xAl_yAs$ dielectric constants $\varepsilon_{InGaAlAs}$ are gotten from Eq. (3)[12].

$$\varepsilon_{InGaAlAs} = (1-x-y)\varepsilon_{InAs} + xe_{GaAs} + ye_{AlAs}$$

where $\varepsilon_{InAs}, \varepsilon_{GaAs}$ and $\varepsilon_{AlAs}$ are the InAs, GaAs and AlAs dielectric constant which can be gotten by interpolating the data from the Ref [20]. From the equation(2), the barrier, the SCH, the tensile QW dielectric constants are calculated to be 11.2181, 11.8544, 11.8398 respectively. The silver permittivity is -67.3544-6.3369i, the gap SiO$_2$ one is 2.3409 and the InP substrate, n-InP, p-InP are assumed to be the equal one 10.2674[20]. Additionally the metal Ag thickness is 100 nm. And the substrate InP is semi-infinite during simulation. We use the software COMSOL Multiphysics to get the relationship curves between the gap size and SPP wave characteristics including the mode effective refractive index $n_{eff}$, mode gain and mode width.

The definitions of the mode gain and mode width are explained as follows. If the mode power is amplified by $e^{\alpha z}$ after propagating distance z (cm), the mode gain is defined as $\alpha$ (cm$^{-1}$) [21]. Because the mode field lateral distribution size is important in realizing the high integration density PIC, we propose the mode width to describe the mode field lateral distribution. Assuming the horizontal and the vertical axis to be x and y separately, the TWA cross-section to be symmetric along y axis and the mode Poynting vector is $\mathbf{A}$. If

$$\iint_{|s|<\infty} \mathbf{A} \cdot d \mathbf{s} = \eta$$

the mode width is defined as $x_g$ in the x direction. Here $\eta$ is the ratio of the mode power in $x \in \left[ -\frac{x_g}{2}, \frac{x_g}{2} \right]$. In this paper it is assumed $\eta = 50\%$.

By simulation the mode characteristics curves are got and shown in Fig.4(a)(b)(c) respectively.

First the guided mode has cut-off width illustrated in Fig.4(a). As $w_g$ is less than this width, the guided mode will not exist. Shown in Fig.4(a), when $h_s$ is fixed to be 6 nm or 10 nm, the guided mode effective index $n_{eff}$ falls down with $w_g$ narrowed. Until $n_{eff}$ drops lower than 3.20 which is the lateral p-InP and n-InP refractive index, the guided mode disappears. As a matter of fact the cut-off width of $w_g$ is about 200 nm as $h_s = 6$ nm.

Second illustrated in Fig. 4(b), as the $h_s = 2$ nm or 6 nm, the mode gain is less than zero although the MQW local gain is 2000 cm$^{-1}$. However, as $h_s = 10$ nm and...
The mode gain is larger than zero, which is necessary for SPP TWA.

Third shown in Fig. 4(c), at $h_g = 6\text{nm}$ or $10\text{nm}$ mode width have a minimum with $w_g$ variation, which originates from the following illustrations. The guide mode is the hybrid one from the interaction between the general dielectric waveguide and SPP one. As the SPP one is dominant, the mode width and mode gain decrease with $w_g$ diminished. However, as the general dielectric waveguide is superior, the mode width will rise with $w_g$ falling down. Therefore the minimums of the mode width and mode gain appear at the junction point of these two actions.

In the Fig. 4(d) it is the mode field as the gap size $[h_x, w_x]$ is $[10, 260] \text{nm}$. And in this condition that the SPP mode gain is $110\text{cm}^{-1}$ and mode width is $163\text{nm}$ which is deep sub-wavelength scale.

5. Conclusion

We propose a LCI MQW SPP TWA with deep-sub-wavelength mode confinement size. In this SPP TWA the InGaAlAs tensile MQW is designed for the polarization-independent amplification. Simulation suggests that at $1317\text{nm}$ wavelength the MQW gain is completely polarization independent. And at this wavelength the mode width is $163\text{nm}$, the mode gain is $110\text{cm}^{-1}$ in the condition of $260\text{nm} \times 10\text{nm}$ gap size and $5 \times 10^{24} / \text{m}^3$ injected electron concentration.

Abstract

We computationally design highly reflective, plasmonically enhanced coatings for more sensitive and versatile radiation detectors in the infrared regime. The large scattering cross-sections of microinclusions are exploited to design devices and spectrally sensitive coatings for sensors, high temperature insulators, and solar applications. We focus on core-shell microinclusions composed of silver or low-bandgap semiconductor which have plasmonic resonances with excellent and tunable scattering properties without suffering from losses at high temperatures. These particles display a rich spectral response dependent on the complex refractive index of the particles.

1. Introduction

Fires and explosions are a threat to life, property, and environment. About one-third of the thermal energy in fires is released as thermal radiation, i.e. electromagnetic radiation in the IR range [1]. Technologies based on gradient heat flux sensors allow small, non-intrusive detectors to directly and instantaneously measure the heat flux [2], unlike in detectors which measure the consequences of fire (heat convection or smoke). To distinguish between radiation from fire and other heat sources, it is necessary to extract spectral information from the detectors. A promising approach is to coat the sensors with a spectrally-sensitive film embedded with semiconductor microinclusions. The embedded particles reflect unwanted wavelengths using localized surface plasmons allowing the gradient heat flux sensors to distinguish between emission sources. Indeed, the enhanced scattering by the plasmonic resonances in low-bandgap semiconductor microinclusions can maximize reflectance of the incident infrared radiation even at small volume fractions in an insulating dielectric [3]. These properties can be exploited for preventing radiative thermal losses in high temperature applications. The localized surface plasmon resonances of the spherical semiconductors have been shown to reflect up to 90\% of the incident light at specific wavelengths [4]. These applications will lead to improved work safety, reduced fire-induced losses, and better incident management capabilities. In addition to improving sensor technologies for fire safety, these microcomposite bandpass filters can be used as high temperature insulators and solar applications and can provide new understanding of radiation transport through films.

In general, the scattered field is a superposition of normal modes, each weighted by the appropriate coefficient $a_n$ or $b_n$. The plasmon frequency and scattering efficiency of semiconductors are highly tunable by adjusting the size, geometry, and dielectric environment [3]. The plasmon resonance frequencies of doped semiconductors can be modified by changing the material’s electronic structure, and is another method of controlling the resonances [5]. In core-shell particles, the interaction between the sphere and cavity yields a splitting of the plasmon resonance into a symmetric or bonding and an antisymmetric or antibonding plasmon which is controlled by the thickness of the shell layer [6].

In this paper, we solve the dielectric response of small particles in an external electromagnetic field using Mie theory and polarizability equations. In the following, we study the resonances in multilayered spherical microparticles. First we consider core-shell particles with Si as the core material which is coated with TiO\textsubscript{2}, SiO\textsubscript{2}, or ZrO\textsubscript{2}. Next we focus on hollow Ag particles which can be treated with the Drude theory.

2. Methods

We consider the problem of scattering by a homogeneous sphere coated with a homogeneous layer of uniform thickness. This is one of the simplest examples of a particle with a spatially variable refractive index. We solve the dielectric response of an electromagnetic wave incident on a coated sphere with inner radius, $r$, and outer radius, $R$, as shown in Figure 1. Solving Maxwell’s equations yields the electric and magnetic Mie coefficients $a_n$ and $b_n$, respectively, which contain the Ricatti-Bessel functions in spherical coordinates. If the permeability of the particle and the surrounding medium is considered to be the same, then the coefficients for a multilayered sphere are given by

$$a_n = \frac{\psi_n(y) [\psi_n(m_2y) - A_n \chi_n(m_2y)] - m_2 \psi_n(y) [\psi_n(m_2y) - A_n \chi_n(m_2y)]}{\xi_n(y) [\psi_n(m_2y) - A_n \chi_n(m_2y)] - m_2 \xi_n(y) [\psi_n(m_2y) - A_n \chi_n(m_2y)]},$$

(1)
Consider now a core-shell spherical particle with Si as the core material of \( r = 0.6 \mu m \) and an oxide shell with thickness, \( t \), varying from \( t = 0 \) to \( 0.5 \mu m \), in a host medium of refractive index \( n_m = 1.5 \). Figure 2 presents the scattering efficiency for these particles such that the blue lines are the maximum of the scattering efficiency and \( y \) axis shows the variable oxide shell thickness. According to Mie theory for gold nanoparticles \[10\] the average particle size is proportional to the displacement of the scattering wavelength peak. Figures 2.a) and 2.b) show red-shifting of Si–TiO\(_2\) and Si–ZrO\(_2\) with increasing size of the particles. Compared to Si–TiO\(_2\) and Si–ZrO\(_2\) it is observed that there is no red-shifting for Si–SiO\(_2\). This sequence illustrates the affect of a different shell material on the scattering efficiency. In the SiO\(_2\) coated particles, the relative refractive index, \( m_2 \), is approximately \( \sim 1 \). When \( m_2 = 1 \), the Mie coefficients reduce to those for a sphere of radius \( r \) and relative refractive index \( m_1 \) \[7\]. Thus there is no shifting in the SiO\(_2\) coated particles. For TiO\(_2\) and ZrO\(_2\) \( m_2 > 1 \) and the resonances redshift with increasing shell thickness. These different patterns show the role of the refractive index of the shell (\( m_2 \)). For photon energies which are large compared with the band gap in semiconductors, electronic transitions are only slightly perturbed by the presence of the gap; the valence electrons in this instance act like free electrons. Thus, the high-energy optical properties of semiconductors are similar to those of free-electron metals. But there are marked differences in their low-energy optical properties \[7\]. In the following, we mostly focus on metals, especially for silver. Relatively small energies are required to excite electrons in metals, and metals tend to be highly absorbing and reflecting at visible and infrared wavelengths. The optical response of a collection of free electrons can be obtained from the Lorentz harmonic oscillator model.

Figure 3 shows the scattering efficiency of an air-silver particle with a total particle size of \( R = 20 \) nm and hollow core with an inner radius \( r = 16 \) nm. Additionally, it shows the absolute value of the first three Mie coefficients \( a_1, a_2 \) and \( b_1 \). The position of Mie coefficients on the scattering efficiency of a composite sphere indicated by vertical arrows.

### 3. Results

#### 3.1. Surface Modes in Small Spheres

**3.1.1. The Lorentz-Drude Model**

Silver and gold are commonly used metals for plasmonic experiments in visible and near-infrared experiments \[11\]. Here the dielectric function of silver is described well by the Drude theory. The dielectric function for a electron-
the dielectric function for the system of simple harmonic oscillators is
\[ \varepsilon = 1 + \frac{\omega_p^2}{\omega^2 - \omega_0^2 - i\omega\gamma}. \] (4)
For frequencies much less than the resonance frequency, the real and imaginary parts are given by
\[ \varepsilon' \approx 1 + \frac{\omega_p^2}{\omega_0^2}; \]
\[ \varepsilon'' \approx \frac{\gamma\omega_p^2}{\omega_0^4}. \]
The optical response of a collection of free electrons can be obtained from the Lorentz harmonic oscillator model, the dielectric function for free electrons follows from (4) with \( \omega_0 = 0 \). For metal with low interband absorption, the dielectric function can be described by the Drude model,
\[ \varepsilon = 1 - \frac{\omega_p^2}{\omega^2 + i\omega\gamma}. \] (5)

where \( \omega_p \) is bulk plasmon frequency [7].

3.1.2. Polarizability
In the electrostatics approximation the scattering and extinction efficiency of a small sphere is given by
\[ Q_{sca} = \frac{8}{3} \pi r^4 \left| \frac{\varepsilon_1 - \varepsilon_m}{\varepsilon_1 + 2\varepsilon_m} \right|^2, \] (6)
\[ Q_{ext} = 4\pi r^2 \Im \left| \frac{\varepsilon_1 - \varepsilon_m}{\varepsilon_1 + 2\varepsilon_m} \right|^2. \] (7)
where \( \varepsilon_1 \) and \( \varepsilon_m \) are the permittivity of the sphere and the surrounding medium, respectively. In addition the polarizability of a small sphere in a uniform field (electrostatic approximation) is
\[ \alpha = \frac{V}{\varepsilon_1 + 2\varepsilon_m}. \] (8)
where \( V \) is particle volume [7].

The term \((\varepsilon_1 - \varepsilon_m)/(\varepsilon_1 + 2\varepsilon_m)\) that can be seen in equations (6) and (8), illustrates a connection between electrostatics and scattering by particles small compared with the wavelength. By minimizing the denominator of equation (8), the Fröhlich condition is satisfied, which for the case of small \( \Im[\varepsilon] \) around the resonance simplifies to
\[ \Re[\varepsilon(\omega)] = -2\varepsilon_m. \] (9)
At \( \varepsilon(\omega) = -2\varepsilon_m \) the polarizability will become very large, which is known as the surface plasmon resonance. Inserting equation (5) into equation (8) in free space leads to
\[ \alpha = \frac{V}{\omega_p^2 - 3\omega^2 - i\omega\gamma}. \] (10)
The polarizability can be compared with the earlier calculation of the Mie coefficients. Figure 4 shows an agreement in the wavelength of the polarizability and \( a_1 \) maxima of a core-shell sphere at \( \lambda = 0.326 \, \mu\text{m} \). We will examine the nature of the second \( a_1 \) peak below.
a = 1 - \varepsilon_l - \varepsilon_2 + 2)(1 + 2 = + 1)

and \varepsilon_2

we can find \varepsilon_1 + 2

\alpha = \varepsilon_1 + 2 + f(\varepsilon - 2)(\varepsilon_2 + 2\varepsilon_2) + f(2\varepsilon_2 - 2\varepsilon)(\varepsilon_1 - \varepsilon_2)^2.

(16)

where \(f\) is the fraction of the total particle volume occupied by the core. The condition for excitation of the first order surface mode or the Fröhlich mode can be obtained by minimizing the denominator of equation (16),

(\varepsilon_2 + 2\varepsilon_2)(\varepsilon_1 + 2\varepsilon_2) + f(2\varepsilon_2 - 2\varepsilon_2)(\varepsilon_1 - \varepsilon_2) = 0. \quad (17)

By considering a hollow sphere in air (\(\varepsilon_m = 1\)) we can find the resonance condition as

(\varepsilon + 2)(1 + 2\varepsilon) + f(2\varepsilon - 2)(1 - \varepsilon) = 0, \quad (18)

where \(\varepsilon\) is the dielectric function of the shell. The roots of equation (18) are given by

\[\varepsilon_{\pm} = \frac{-5 + 4f \pm 3\sqrt{1 + 8f}}{4 - 4f}.\] \quad (19)

These roots are known as the symmetric (\(\varepsilon_-\)) and antisymmetric (\(\varepsilon_+\)) modes [7]. Figure 5 illustrates the absolute value of the polarizability for two different sizes of the core for a core-shell air-silver system. The symmetric mode has a red shift with increasing hollow core. The antibonding resonance is weaker and narrower than the bonding one [12]. There is a minimum at \(\varepsilon = -1/2\) which is indicated by a dashed line that according equation (15) comes from the Fröhlich mode and is independent of the core size.

3.4. Void Plasmons and Hybridization Model

The polarizability of a particle consisting of a dielectric core (air) and a thin metallic shell (silver) can be described using the quasistatic Mie equation (16). These two fundamental dipolar modes of a core-shell nanoparticle can be explained by the hybridization of the dipolar modes of a metallic sphere and a dielectric void. In other words, two hybridized plasmon modes are the result of the interaction of the plasmons of a nanoparticle on the inner (metallic sphere) and outer (dielectric void) surfaces. The frequencies of these modes are given by

\[\omega_{l,\pm}^2 = \frac{\omega_p^2}{2} \left[ 1 \pm \frac{1}{2l+1} \sqrt{1 + 4l(l + 1) \left( \frac{r}{R} \right)^{2l+1}} \right], \quad (20)\]

where \(r\) and \(R\) are the inner and outer radius of the shell, respectively. The \(|\omega_+\rangle\) and \(\langle\omega_-|\) modes correspond to the antisymmetric and symmetric modes, respectively [6].

4. Conclusions

We have simulated the scattering from surface coatings embedded with spherical microparticles using Mie theory. By adjusting the material, the size of the core or the shell, and
refractive index of medium, the energy of the surface plasmon resonances can be tuned to match the incident spectrum.

In the scattering efficiency equation of a metallic nanoparticle in the quasi-static approximation, there is a polarizability term. Indeed for metal nanoparticles both absorption and scattering are resonantly enhanced at the dipole particle plasmon resonance. Further, it can be seen by expanding the Mie coefficients for a bare sphere the polarizability term exists in lowest term of $a_1$.

The hybridization model explains the polarizability of a dielectric void and a thin metallic shell which defines two dipolar modes of this system. We have been shown with increasing size of core symmetric mode has blue shift.

Abstract

We demonstrate gain mediated propagation of hybrid plasmonic-photonic modes in near-infrared at temperatures ranging from 95 K to 300 K. Hybrid modes are formed in an oxide layer sandwiched by a gold film and an InP substrate. Optical pumping at 750 nm results in photoluminescence from InP which couples to surface plasmon polaritons. In contrast to the photoluminescence efficiency, the propagation losses are only weakly temperature dependent. We attribute this weak dependence predominantly to scattering caused by the gold film’s polycrystallinity.

1. Introduction

To leverage the interconnect bottleneck, the realization of directly integrated III-V infrared nanolasers is crucial, since it would enable high-speed optical on-chip communication [1, 2]. Hybrid plasmonic-photonic structures would offer a suitable solution to shrink optical components to dimensions closer to that of integrated electronic devices. Hybrid modes achieve longer propagation lengths compared to pure plasmonic modes, while allowing sub-diffraction confinement compared to pure dielectric modes [3]. Here we demonstrate the propagation of such hybrid plasmonic modes via the near-infrared (NIR) luminescence of optically pumped InP at different temperatures.

2. Results and Discussions

Figure 1 shows the layer stack of the waveguide. The oxide layer is deposited on indium phosphide (InP) via atomic layer deposition. Aluminum oxide (Al₂O₃) is chosen since it ensures a good interface at the substrate. A 1 nm thick germanium (Ge) adhesion layer and 100 nm gold (Au) are deposited by successive e-beam evaporation. Various shapes of plasmonic structures are fabricated by electron-beam lithography using HSQ as resist and patterns are transferred into the gold by argon-ion milling. The excitation of the hybrid modes and the imaging of the outcoupled light are performed by a 100× objective with a numerical aperture of 0.6. A laser beam at 750 nm is focused on one edge of a gold pattern to generate photoluminescence (PL) from the InP. The scattered light collected by the same objective is imaged by a camera after passing an analyzer and a long-pass filter with cutoff wavelength at 800 nm, to ensure that only the PL and the transversal magnetic polarized light is imaged. As illustrated in Figure 1 we expect a co-propagation of the pump- and emission wavelengths along the metal-dielectric interface. Here we investigate different geometries for hybrid plasmon propagation such as straight waveguides and slabs with slits for exciting the PL and staircased out coupling slots. Scanning electron micrographs (SEM) of those structures are shown in Figure 2. Figure 3 shows images of a 13 µm long waveguide where experiments were performed at temperatures ranging from 95 K to 300 K. The PL intensity decreases with increasing length, as expected. The brightness of the images is enhanced for better visibility. Figure 4 depicts typical images for different waveguide lengths. To evaluate the propagation loss, we normalize the outcoupled PL intensity to the value of the shortest waveguide at the given temperatures (see Figure 5). This normalization gives the possibility to correct for variations in emission efficiency as well as initial coupling loss to the waveguide. Interestingly, the plasmonic losses are only weakly temperature dependent. A possible explanation could be that the propagation in our films is mainly limited by the roughness and polycrystallinity rather than temperature-dependent electrical properties of our films, such as electron-electron or electron-phonon scattering [4]. Indeed, the atomic force microscope (AFM) image in Figure 6 shows that the film is smooth (surface roughness: 0.7 nm RMS) but grainy. The propagation loss coefficient α lies between 0.18 µm⁻¹ (at 95 K) and 0.33 µm⁻¹ (at 300 K) and is obtained by an exponential fit as shown in Figure 5. This value is much lower than the coefficient obtained from finite difference time domain simulations, where we obtain α = 1.9 µm⁻¹ for a mode propagating at 900 nm. This may indicate that the propagation losses are counterbalanced by the PL gain provided by the continuous optical pumping of the InP with a pulsed laser source and the resulting co-propagation of the pump light. Figure 7 summarizes the results shown in Figure 4 and 5: The incoupling and outcoupled PL intensity for different temperatures for a 13 µm long waveguide are compared. Since the incoupled PL is oversaturated in the camera, the oversaturation width in pixels is studied at the dashed blue line in the inset image. The outcoupled intensities are extracted by intensity integration in the region marked by the dashed orange rectangular in the inset image and corrected by background subtraction. The PL intensity from
the InP shows a decreasing trend with increasing temperature. This trend cannot be seen for the propagation losses, in the case where the PL intensity is normalized with the intensity of the shortest waveguide.

3. Conclusion

We showed PL mediated plasmon propagation on different Au structures on InP with a thin oxide layer sandwiched in between and investigated the temperature dependence of the propagation. While the PL emission is strongly temperature dependent, the losses in the plasmonic waveguides are dominated by scattering at grain boundaries of the Au film.

Figure 1: Layer stack of the studied waveguide. The InP wafer serves as a gain material, with a PL peak ranging from 880 to 905 nm, depending on the temperature. The gold film enables the presence of plasmons. The laser excites the InP which results in PL emission. Both the laser and the PL light can couple to plasmon modes.

Figure 2: SEM images of the studied waveguides. The structures are formed via Argon ion milling after being written and developed in HSQ using electron beam lithography.

Figure 3: PL of incoupled and outcoupled light (contrast enhanced for visibility) for a 13 μm long waveguide at temperatures ranging from 95 K to 300 K. The PL intensity decreases with increasing temperature.

Figure 5: Outcoupled PL intensity for waveguides with different lengths, normalized to the outcoupled intensity of the shortest waveguide. This normalization is done to account for the impact of the stronger PL at lower temperatures. The propagation losses show only a weak temperature dependence. Propagation loss coefficients lie between 0.18 μm⁻¹ (at 95 K) and 0.33 μm⁻¹ (at 300 K) and are extracted by an exponential fit using the inset formula.

Figure 6: AFM image of the Au surface. The surface roughness is 0.7 nm RMS and the film is granular and polycrystalline.
Figure 7: Width of the intensity oversaturation of incoupling PL in pixels (blue, extracted at the profile of the blue dashed line) and outcoupled intensity (orange, extracted by intensity integration in the region of the dashed orange rectangular and corrected by background subtraction) for a 13 µm long waveguide at different temperatures. The incoupled PL intensity and thus the outcoupled intensity too, show a decreasing trend with increasing temperature. Once the outcoupled PL intensity is normalized with respect to the shortest waveguide (red), there is only a weak temperature dependence for the propagation loss at transition to 300 K.

Ultimate Material Selection Methodology for Ultra-Broadband M-I-M Metamaterial Absorber

Imre Ozbay

Department of Electrical and Electronics Engineering, Middle East Technical University, Ankara Turkey 06810
Corresponding authors: ozbayimre@gmail.com

Abstract

We demonstrate an ultra-broadband metal-insulator-metal (MIM) metamaterial absorber of unrivaled bandwidth within the near-infrared (NIR) regime.

For any metal with a given n-k data, the maximum attainable absorption bandwidth for a MIM cavity is investigated. An ideal metal in such structures should have positive real permittivity part in the NIR regime. Through our novel analysis methodology based on transfer matrix method (TMM), we reveal and exploit the extraordinary optical response of Bismuth (Bi) metal. Contrary to noble and lossy metals utilized by most research groups within the field, this requirement is satisfied only by Bismuth, whose data greatly adheres to the ideal material properties predicted by our analysis. A Bi nano disc MIM resonator with an absorption above 0.9 in an ultra-broadband range of 800 nm- 2410 nm is designed, fabricated, and characterized. To the best of our knowledge, this is the broadest absorption bandwidth (BW) reported for a MIM cavity in the near infrared with its upper to lower absorption edge ratio of more than three.
Photogenerated Excitons of Cesium Lead Bromide Perovskite Quantum dots through ligand Passivation

Sunjoong Park, Hyunjin Cho, Wonseok Choi, Hongjoo Shin and Duk Young Jeon

Dept. of Materials Science and Engineering, Korea Advanced Institute of Science and Technology, 291 Daehak-ro, Yuseong-gu, Daejeon 305–338, Korea

Abstract

We investigated the mechanism of exciton decay dynamics of cesium lead bromide (CsPbBr3) perovskite quantum dots (QDs) through the X-type ligand passivation process. 1-Dodecanethiol (DDT) ligand passivates the Br vacancy of CsPbBr3 QDs and photoluminescence quantum yield (PLQY) is increased from 76.7 % to 99.76 %. To clarify this phenomenon, we observed exciton decay dynamics by varying the temperature (80k ~ 300k). Our results suggest that Br vacancy of CsPbBr3 QDs affects the increased exciton lifetime;
Rapid and Highly efficient annealing process for photoluminescence efficiency improvement of quantum dots using intense pulse light

Chulhee Lee, Taeyoung Song, and Duk Young Jeon

Korea Advanced Institute of Science and Technology, Korea

Abstract

Typical quantum dots (QDs) have surface trap sites causing low photoluminescence efficiency. To solve this issue, we have introduced the intense pulse light (IPL) annealing that almost instantaneously supplies heat within very short time and brings enough energy to QDs. The IPL annealing technique is possible to remove the defect by applying optimum amount of heat to QDs using very short pulse, and we have observed considerable improvement from 20% to 40% of quantum efficiency of the QDs.
Tunable Infrared Energy Transfer through Surface Phonon Polaritons

Abstract

Realizing and designing switchable cavities in order to establish effective communication between two large distance separated points at the infrared frequencies is crucial for achieving novel integrated photonic circuits. In the infrared and terahertz regime, polar dielectrics can support propagation of surface phonon polaritons with the ability of tuning through carrier concentration. In this context, we investigate a tunable heterojunction elliptical cavity for efficient energy transfer through coupled surface phonon-plasmon polariton modes.

Abstract

The combination of topologically protected states with plasmonic systems presents the opportunity to control electromagnetic waves reliably on the nanoscale. Motivated by these effects we investigate arrays of plasmonic nanoparticles with hallmarks of topological effects, including band inversion and unidirectional edge states. These states are a result of particular lattice symmetries. By treating the nanoparticles as point dipoles and applying the coupled dipole method, we model infinite arrays and semi-infinite ribbons.

1. Introduction

Topological insulators are materials which are insulating in the bulk and which possess conduction states protected against disorder along the surface [1]. The success of these systems has inspired research into photonic and other bosonic analogues. Topological states in electronic materials rely on specific properties of fermions and their behaviour under time-reversal symmetry operations. Alternative techniques are therefore required to design photonic topological insulators but there has been considerable success in this area [2].

Time reversal invariant systems are particularly appealing as they do not require complicated set ups such as background magnetic fields. A method of designing a quantum spin Hall like effect in a photonic crystal using the symmetry properties of the lattice itself was proposed [3] and has since been applied to a wide array of bosonic systems. Whilst not a strict topological effect, the hallmarks of topological systems such as band inversion and unidirectional edge states are demonstrated to exist in this scheme.

Plasmonic systems have attracted significant attention over the past decade, finding applications in sensing, subwavelength imaging and waveguiding. The coupling of plasmons with light offers unprecedented control of electromagnetic fields on the nanoscale. This is due to the enhancement and localisation of electric fields accompanying plasmon resonances [4]. Metallic and dielectric nanoparticles and graphene nanodisks can host localised surface plasmon resonances. When arranged in lattices, the resonances of individual nanoparticles can couple with each other becoming delocalised across the lattice [5]. The properties of these surface lattice plasmon resonances can be tuned by changing the lattice arrangement or the resonators themselves. In the regime where lattice constants are small compared to the resonant wavelength of the elements, collective excitations arise. Unlike three dimensional metamaterials, these plasmonic metasurfaces are easier to fabricate and realise experimentally and their two dimensional nature suggests on-chip applications [6].

In this work, we lay the foundation for designing topological states in plasmonic systems at optical frequencies by applying a method which ensures unidirectional, spin locked edge states at $\Gamma$ [3]. By first taking a quasistatic approximation, we set up a semi-analytical model which allows us to quickly model the behaviour of the system. This model is built upon by considering radiative and retarded interactions in order to provide a realistic description of the plasmonic array.

2. Theory

The honeycomb lattice of plasmonic nanoparticles has been studied previously in the context of topological states [7]. It is shown that the out of plane and in plane polarised modes can be decoupled such that they can be studied independently. We go further by considering spheroids elongated along the z-axis, in order to separate the frequency ranges of the out of plane and in plane modes. By approximating the nanoparticles as point dipoles, electromagnetic interactions are modelled using Green’s functions.

Figure 1: Layout for the lattice. Metallic rods are arranged in hexagons. The size of the hexagons within the unit cell determines the topological phase.
3. Results

3.1. Bulk systems

The honeycomb lattice has a Dirac degeneracy at the K point, which is folded onto Γ (\(q = 0\)) when the unit cell is extended. By perturbing the system away from the honeycomb, the degeneracy is broken [3]. The phase transition from the trivial to the topological phase is associated with a band inversion, where the dipolar and quadropular bands switch at Γ. A similar band inversion occurs in the in plane modes.

Figure 2: Demonstration of the band inversion in the out of plane modes associated with a topological phase transition in the system. Long range interactions in a quasistatic approximation are used.

3.2. Ribbon systems

Interfaces between regions of different topological phases allow edge states to be explored. The necessary breaking of the lattice symmetry at an interface results in a band gap always existing at Γ but despite this the edge states persist. The absence of linear Dirac dispersion at Γ is evidence of these edge states not being strictly topologically protected.

Figure 3: States localised at the interface between topological and trivial regions of the lattice.

4. Conclusions

In this work, we show that it is possible to design unidirectional edge modes in plasmonic systems. These modes are inspired by the quantum spin Hall effect but instead rely on lattice symmetries. They suggest a reliable way of controlling electromagnetic waves on the nanoscale.

We find that the out of plane modes in this system and the modes in photonic crystals previously studied possess similar properties. By perturbing the lattice away from a honeycomb lattice a band inversion occurs accompanied by unidirectional edge modes. These modes are localised along the interface between trivial and topological phases of the lattice.

Whilst not studied in detail here, the in plane modes also show topological properties. Unlike the out of plane modes they can not be trivially classified as dipolar or quadropolar. A band inversion still occurs when the phase transition takes place but more bands are involved in the inversion.

The coupled dipole method is readily applicable to the study of topological effects which rely on other symmetries, such as valley topological effects associated with inversion symmetry.

Abstract

We study the dynamics of entanglement for a composite system that consists of a pair of two-level quantum emitters, with picosecond free-space decay time, each one close to a MoS$_2$ nanodisk. We take into consideration the counter-rotating terms and present the time evolution of the concurrence, our entanglement measure, for different initial states of this hybrid system, under strong coupling conditions.

1. Introduction

It is well known that the localized surface states emerging in photonic nanostructures dramatically change the local photonic environment. Thus, putting a quantum emitter (QE) close to such a nanostructure, strong light-matter coupling effects could be observed, which are really important for various applications, including quantum technology and nanotechnology. It has been recently realized that entanglement dynamics between two QEs is strongly influenced by strong coupling phenomena at the nanoscale by placing the QEs near plasmonic nanostructures, like plasmonic nanoshells, nanospheres and nanocavities, and phenomena such as non-Markovian dynamics and entanglement trapping are found [1, 2, 3, 4]. Here, we propose another photonic nanostructure that may induce strong coupling effects in the entanglement dynamics of two QEs, in significantly larger distances than the plasmonic nanostructures. To succeed this, we explore the localized exciton-polariton modes of a MoS$_2$ nanodisk.

2. Theoretical methodology

We consider a two-level QE located at $r = (0, 0, z)$ of a coordinate system with origin at the center of a MoS$_2$ nanodisk, as shown in Fig. 1. The dynamics of the QE is described by the following integro-differential equation for the probability amplitude of the upper state $|1\rangle$, $c_1(t)$, which has been obtained without using the rotating wave approximation and taking into account the presence of the photonic nanostructure (here the MoS$_2$ nanodisk) [3]:

$$
\dot{c}_1(t) = -\int_0^t dt' \int_0^\infty dw J(\omega, r) e^{i(\omega t - \omega t')} c_1(t'),
$$

(1)

$$
J(\omega, r) = \left(\frac{2\omega_0}{\omega_0 + \omega}\right)^2 \frac{\Gamma_0(\omega_0)}{2\pi} \lambda(\omega, r) \left(\frac{\omega}{\omega_0}\right)^3,
$$

(2)

where $\omega_0 = \omega_0 + \Delta \omega_0$, with the relative frequency shifts being $\Delta \omega_0 = -\int_0^\infty dw \frac{2\omega_0}{(\omega_0 + \omega)^2} \frac{\Gamma_0(\omega_0)}{2\pi} \lambda(\omega, r) \left(\frac{\omega}{\omega_0}\right)^3$. Here, $\Gamma_0(\omega_0)$ is the free-space decay rate of the QE with resonant frequency $\omega_0$ and $\lambda(\omega, r)$ is the Purcell factor due to the positioning of the QE at distance $r$ close to the nanodisk.

The presence of the MoS$_2$ nanodisk strongly modifies the density of modes around it. As a result, the Purcell factor for a QE in the vicinity of the nanodisk increases significantly and also have a rather narrow frequency distribution, due to the localized exciton-polariton modes that emerge in the nanodisk [5]. This leads to strong coupling effects.

We take that our composite system consists by two identical QEs. Each QE is near a two-dimensional MoS$_2$ nanodisk of radius $R$. The two QEs are far apart so they do not interact with each other and assume that our composite system is prepared in the Bell-like states

$$
|\Phi\rangle = a|01\rangle + \sqrt{1-a^2}|10\rangle,
$$

(3)

$$
|\Psi\rangle = a|00\rangle + \sqrt{1-a^2}|11\rangle,
$$

(4)

with $0 \leq a \leq 1$. In this work we use concurrence as a measure of entanglement [3]. The calculation of concurrence for these specific initial states gives [3]

$$
C_\Phi(t) = 2a\sqrt{1-a^2}|c_1(t)|^2,
$$

(5)

$$
C_\Psi(t) = 2\max[0, C(t)],
$$

(6)

Correspondingly, with

$$
C(t) = \sqrt{1-a^2}|c_1(t)|^2 \left[a - \sqrt{1-a^2}(1-|c_1(t)|^2)\right].
$$

(7)

We notice that for both cases concurrence depends on the time evolution of the upper state population $|c_1(t)|^2$.
Figure 2: (a) Time evolution of concurrence in the presence of the nanodisk for the initial state $|\Phi\rangle$. The qubits have $\hbar\omega_0 = 1.949$ eV and free space decay rate is $1/T_0(\omega_0) = 82.7$ ps (corresponding to J-aggregates). For solid blue curve $a = 0.1$, for dotted red curve $a = 0.3$, for dashed yellow curve $a = 1/\sqrt{2}$ and for dot-dashed green curve $a = 0.9$. (b) The same as (a) but for the initial state $|\Psi\rangle$.

3. Numerical results

Figure 2 shows the time evolution of concurrence when the QEs have prepared in the initial state $|\Phi\rangle$ [Fig. 2(a)] and $|\Psi\rangle$ [Fig. 2(b)]. Each QE is at distance $r = (0, 0, 15)$ nm from a MoS$_2$ nanodisk with radius $R = 30$ nm. For the computation of concurrence, we first find the Purcell factor, calculating the electromagnetic Green’s tensor near the MoS$_2$ nanodisk using the method of Ref. [5] to determine $J(\omega, r)$ and $\Delta\omega_0$, then we solve numerically the integro-differential Eq. (1) using the effective mode differential equation methodology [6], and finally apply Eqs. (5) and (6).

We observe that for the initial state $|\Phi\rangle$, see Fig. 2(a), concurrence has the same decaying oscillatory behaviour for all values of the parameter $a$, as its value is proportional to $|c_1(t)|^2$, and its magnitude depends strongly on $a$, with the higher value for $a = 1/\sqrt{2}$ and the lower for $a = 0.1$. However, this is not true for the initial state $|\Psi\rangle$, see Fig. 2(b), where we find that for small values of $a$ the phenomenon of entanglement sudden death (ESD) takes place [7]. Specifically, ESD emerges for $a < 1/\sqrt{2}$, as the term $C(t)$, takes negative values as the system evolves in time. Additionally, in Fig. 2(b) we note the manifestation of another interesting phenomenon, the revival of entanglement, for some values of $a$ (e.g. see the dotted red curve for $a = 0.3$), which occur as the term $C(t)$ can take negative values for some initial time period and then for another small period of time can take again positive values. For $a > 1/\sqrt{2}$, concurrence has an oscillatory character which decays gradually to zero, similar to the initial state $|\Phi\rangle$, as the term $C(t)$ takes always positive values. We emphasize the fact that although at $t = 0$ we have the maximum entanglement for $a = 1/\sqrt{2}$ for both initial states, this does not happen during the whole time evolution for the initial state $|\Phi\rangle$, since after some time the dominant value of concurrence occurs for $a = 0.9$. Interestingly, in both cases, the non-Markovian dynamics happens in much larger distances (about five times larger) than in plasmonic nanostructures, such as for example, metallic nanospheres [3, 4].

4. Conclusions

In conclusion, we have analyzed the entanglement of two initially entangled qubits, each interacting locally with a MoS$_2$ nanodisk, and study how entanglement evolves with time. Using Bell-like states as initial states of our composite system, we observe some interesting phenomena induced by strong coupling, including clear non-Markovian dynamics, as well as, ESD and revival of entanglement for specific initial states. We also note, that besides changing the initial conditions, we can also control the non-Markovian character of entanglement dynamics simply by changing the distance of each QE from the corresponding nanodisk (not shown here).

Abstract

As a quantum field theory in curved spacetime, Hawking radiation has been extensively studied in various analogue systems. However there remains debate on its experimental verification. One challenge is that a long-lived event horizon is difficult to achieve experimentally. Here we theoretically propose a novel analog of Hawking effect based on topological phase transition from a type-II to type-I Dirac cone, where their interface (a type-III Dirac cone) acts as a stable event horizon.

1. Introduction

Hawking radiation [1] is a quantum field theory in curved spacetime. However it is difficult to be probed in gravitational black hole (BH) for its extremely low temperature. A sonic BH analog [2] proposed by Unruh opens a new avenue for studying Hawking effect. However, although extensive theoretical and experimental studies of various BH analogs have emerged [3], an undisputed confirmation of Hawking radiation remains elusive. One challenge is that a long-lived horizon is difficult to achieve experimentally because it is usually unstable [4].

Topological phase transition from a type-II to type-I Dirac cone (DC) in inhomogeneous systems shows corresponding features with the evolution of light cone in BH [5-7], providing a novel optical analogue platform. The transition interface (a type-III DC) between type-II and type-I DC simulates an event horizon. Trapped photons in the type-II region quantum mechanically tunnel through the horizon to emit as a analog of Hawking radiation. Here we design a long-lived horizon arising from a stationary “spacetime” configuration in an inhomogeneous waveguide array based on a tight-binding model.

2. Hawking radiation analog

The effective Hamiltonian around Dirac points (DPs) in two-dimension is:

$$H(k) = c_k \delta k \sigma_x + c_\gamma \delta k \sigma_y + v_\gamma \delta k \sigma_z,$$  (1)

where $\sigma_x$ and $\sigma_y$ are Pauli matrices, $\sigma_0$ is the unitary matrix, $c_k$ and $c_\gamma$ is the tilt angle along the $k_x$ and $k_y$ direction respectively, and $v_\gamma$ determines the tilt of DC relative to $k_x$. DC is tuned by $v_\gamma$ to be type-I for $|v_\gamma| < |c_k|$, type-II for $|v_\gamma| > |c_k|$ and type-III for $|v_\gamma| = |c_k|$.

![Figure 1. (a) Sketch of the inhomogeneous graphene-like photonic lattice. It contains a centered-square lattice of waveguides (blue dots), whose inter- and intra-hopping $(t_1, t_2)$ can be constructed by a chain of waveguides. The type-II DC gradually evolves into type-I DC with the decrease of intra-hopping $t_2$ along $x$ direction. Their interface (dashed line) represents the event horizon. Calculated band diagram for (b) type-II DC with a conical-like Fermi surface (the intra-hopping $t_1 = 0.63 t_0$, the inter-hopping $t_2 = 0.9 t_1$), (c) type-III DC $(t_1 = 0.57 t_1$, $t_2 = 0.57 t_1$) and (d) tilted type-I DC with a point-like Fermi surface $(t_1 = 1.9 t_0$, $t_2 = 0.3 t_1$). The intra-hopping $t_1$ is tuned to maintain DP at the same level.](image)

Next we demonstrate the three types DC in an inhomogeneous graphene-like photonic lattice [8], as shown in Fig. 1(a). According to tight-binding model, the diffraction of light in waveguide arrays is determined by

$$i \partial_z \psi_{mn}(z) = \sum_{n',m'} t_{mn'n'} \psi_{m'n'}(z),$$  (2)

where $t_{mn'n'}$ is the hopping strength between two adjacent waveguides, and $\psi_{m'n'}$ is the amplitude of the $m$, $n$ waveguide. The Hamiltonian $H = \begin{pmatrix} h'(k) & h(k) \\ h'(k) & h'(k) \end{pmatrix}$ is
obtained, where
\[ h(k) = t_1 (1 + \cos k_x + \cos (k_y - k_z) + i \sin k_y + i \sin (k_z - k_y)) \]
\[ h'(k) = 2t_2 \cos k_y. \]

The position of DC is replaced by \( |h(k)| = 0 \). Light velocity \( c_x = \partial \text{Re}(h(k))/\partial k_x \) and \( c_y = \partial \text{Im}(h(k))/\partial k_y \) depend on intra-hopping \( t_1 \). Dragging velocity \( v_y = \partial h'(k)/\partial k_y \) is only related to inter-hopping \( t_2 \).

By gradually decreasing the inter-hopping \( t_2/t_1 \) along \( x \) direction, DC is tuned from type-II [Fig. 1(b)] to type-III [Fig. 1(c)] and then to type-I [Fig. 1(d)].

The inhomogeneous photonic lattice creates an effective fluid flow as an analog of optical BH spacetime. The outgoing mode [blue lines in Fig. 1(b-c)] is mainly related to Hawking effect. In type-I region, the dragging velocity is smaller than light velocity so that the outgoing photons can escape. The dragging velocity overtakes light velocity in type-II region, where outgoing photons are trapped. The outgoing mode is stationary at their interface, i.e. type-III region. Thus type-II region simulates an optical BH, type-III region plays the role of an event horizon, and type-I region is outside the BH. Photons in type-II region can quantum mechanically tunnel through the horizon from type-II to type-I region to emit a radiation. This analogous Hawking radiation has a temperature
\[ T_H = \frac{\hbar}{2\pi k_B} \frac{dv_y}{dx} |_{x_0}, \]
which depends on surface gravity \( E_{sp} = dv_y/c_y dx |_{x_0} \) at the horizon. Here \( k_B \) is Boltzmann constant.

3. Discussion

Waveguide arrays provide a stationary “spacetime” configuration and hence create a long-lived event horizon. They can be fabricated via the femtosecond laser direct-writing method [9]. Two adjacent waveguides couple with each other by a chain of waveguides. Hopping is tunable by modifying the refractive index of the waveguide chain. Hawking temperature can be improved by increasing the surface gravity at the horizon.

4. Conclusions

We theoretically propose a new optical BH analog by topological phase transition from type-II to type-I DC. Their interface simulates a long-lived event horizon. Photons tunnel through the horizon to emit as Hawking radiation. We demonstrate this analog in an inhomogeneous waveguide array.

\section{topological edge states in quantum walks}

A quantum walk is a quantum version of the classical random walk and a kind of Floquet systems, since the quantum walk has discrete time-periodicity. Quantum walks describe dynamics of quantum particles and have several unique features. For example, probability distributions of particles in quantum walks are quite different from those in classical random walks due to quantum interference. Grover search algorithms can be implemented by using quantum walks, energy levels of quantum walks have $2\pi$ periodicity due to discrete time-periodicity, and so on. Among these unique features, it is peculiarly interesting that quantum walks can have nontrivial topological phases which result in emergence of edge states. Topological phases of quantum walks have been studied theoretically\cite{Ken} and experimentally\cite{Kitagawa}. Quantum walks have been realized experimentally using single photons or laser beams passing through optical devices, and real space observations of edge states have been done in quantum walks of single photons\cite{Kitagawa}. Quantum walks have been paid attention to, since such observations of edge states with high resolution are difficult in topological materials. Not only the real space observation of edge states, but also quantum walks have uniqueness in comparison to topological materials. For instance, in quantum walks, there exist not only 0 energy edge states but also $\pi$ energy edge states, whose origin is time-periodicity\cite{Ken}. Another example is that photon loss effect can be introduced in quantum walks and it drastically changes the behavior of edge states\cite{Xiao}.

\section{non-linear quantum walks}

In addition to the above interesting features, non-linear effects in quantum walks have been considered theoretically\cite{Shikano}. The theoretical proposition is as follows. At some positions and time-steps in the dynamics, intensity of light is detected. By using results obtained from the detection, conditions of optical devices are changed, which the beam passes through in the next step. Such feed-forward controls generate non-linear effects in the dynamics of quantum walks. It is expected that, the non-linear effect can make dynamics of quantum walks richer.

\section{stability of topological edge states in non-linear quantum walks}

In 2016, it was clarified that, in a non-linear one-dimensional quantum walk, topologically protected edge states become attracter or repeller, depending on its chirality\cite{Gerasimenko}. This has been done by using a linear-stability analysis of edge states for an effective Hamiltonian which is derived from the time-evolution operator of the quantum walk by taking the continuum limit for space and time. On the other hand, time-evolution operators play a key role in quantum walks, as it include the effect of the time-periodicity. Also, different from many other Floquet systems, time-evolution operators are explicitly defined in quantum walks, without approximation. Therefore, it can be said that the stability analysis in Ref. [5] does not fully make use of features that quantum walks possess, since the effective Hamiltonian in the continuous limit loses the effect of the discrete time-periodicity. In this work, we study stability of topologically protected edge states in non-linear quantum walks, without taking the continuous limit. As a result, we find bifurcations where edge states change from attracter to repeller, irrespective to chirality of edge states. The bifurcations we shall show are unique to Floquet non-linear systems, as it originates from the time-periodicity of quantum walks.

Abstract

In this paper, we investigated the band structures and quantum magneto transport properties of the In$_{0.53}$Ga$_{0.47}$As (d$_1$=100Å)/InP(d$_2$=70Å) type I superlattice (SL) at low temperature. These studies were based on the envelope function formalism. We studied the effect of d$_1$, d$_2$, the band valence offset and temperature on the cut-off wavelength in the short infrared region and on the band gap of the present superlattice. The result of the computed density of states and the position of Fermi level indicates that this sample is n-type quasi two-dimensional system. Moreover, the cutoff wavelength predicts that this sample can be employed as a short-infrared detector. Furthermore, we interpreted theoretically the photoluminescence, the Shubnikov de Haas and quantum Hall effects observed by Pusep et al.

1. Introduction

The In$_x$Ga$_{1-x}$As/InP heterostructures are considered as one of the most important semiconductor superlattices (SLs), due to their technological applications, especially in infrared optoelectronics, THz, superlattice-emitter resonant tunneling bipolar transistor (SE-RTBT) and photodetectors. Moreover, such materials can be used in spintronics and quantum information processing field. Their electronic properties can be tuned by varying layers thicknesses and indium composition x. Their application in infrared detectors have generated a lot of interest for low cost, low dark current, high speed and high temperature operation detectors in short wavelength infrared (SWIR) [1,2].

In general, the In$_x$Ga$_{1-x}$As/InP structure is grown by molecular beam epitaxy (MBE) technique with different indium fraction x. This periodic SL is made from repeated layers of two materials which have nearly a similar structure but a different electrical properties, In$_x$Ga$_{1-x}$As (well) and InP (barrier) [3].

It is well known that the reduction of the dimensionality of a system under extreme conditions like low temperatures and high magnetic fields, conduct to the observation of quantum electronic transport effects like Shubnikov-de Haas effect (SDH) and quantum Hall effect (QHE).

In the literature the calculation of the energy band structure and the effect of basic parameters on the band gap of this SL are very rare or inexistent. So we are attempted to calculated the band structure of the In$_{0.53}$Ga$_{0.47}$As(d$_1$=100Å)/InP(d$_2$=70Å) type I SL in the envelope function formalism [4]. The aim of this work is to show the correlation between calculated bands structures and magneto-transport properties in In$_{0.53}$Ga$_{0.47}$As/InP nanostructure superlattice. We studied the effects of thickness d$_1$ of well (d$_2$ of barrier), the valence bands offset and temperature on the band gap. These results permit us the interpretation of the photoluminescence, the SDH and QHE Effects observed by Pusep et al. [5] in the same sample.

2. Theoretical formulations and computation of type I superlattices bands structure

2.1 Dispersion relations in In$_x$Ga$_{1-x}$As/InP superlattice

In general the calculations of electronic band structure for semiconductors based on the k.p theory [6], it provides a detailed description of a material’s energy [7]. For our calculations of the spectra of energy E(k$_z$) in the direction of growth and E(k$_p$) in plane of this superlattice, we adopted the envelope function formalism.

The expression of dispersion relation for In$_x$Ga$_{1-x}$As/InP superlattice, within this formalism and effective mass approximation, is given by [8,9] :

$$\cos[k_z(d_1 + d_2)] = \cos(k_{d_1}d_1)\cos(k_{d_2}d_2)$$

$$\frac{1}{2} \left[ (\xi + \frac{1}{\xi}) + \frac{k_p}{4k_1k_2}(r + \frac{1}{r} - 2)\sin(k_{d_1})\sin(k_{d_2}) \right]$$

(1)

Where the subscripts 1 and 2 refer to In$_x$Ga$_{1-x}$As and InP layers, respectively. With k$_z$ the wave vectors in the growth direction axis and k$_p$(k$_1$,k$_2$) the superlattice wave vector in plane. In this superlattice, the origin of energy E has been chosen at the top of InP valence band as shown in the Fig. 1. With k$_1$ and k$_2$ describe the movement perpendicular to the layer of bulk materials.

2.2 Electrons and light holes mini-bands:

The expression of $\xi$ and r for light particles are:

$$\xi = \frac{k_1}{k_2}r$$  and  $$r = \frac{E - \varepsilon_2}{E - \varepsilon_1 - \Lambda}$$

(2)
Figure 1: Schematic illustration of band lineup between In_{0.53}Ga_{0.47}As and InP along the growth direction with different parameters of electronic band structures. (E_{c}), (E_{v}), and ε_{i} where i= 1, 2 are the conduction and valence bands edges and band gap of bulks, respectively.

Here ε_{i}(i= 1, 2) the band gaps of bulk materials and Λ is the valence band offset (VBO). At a given energy, the two-band Kane model [10], gives the wave vector (k_{i1}+k_{i2}) in each host material (i=1 or 2) by:

\[
2P_{i}^{2}\hbar^{2}(k_{i1}^{2}+k_{i2}^{2}) = 3(E-\epsilon_{i}-\Lambda)(E-\Lambda) \quad \text{for In}_{x}\text{Ga}_{1-x}\text{As} \\
2P_{i}^{2}\hbar^{2}(k_{i1}^{2}+k_{i2}^{2}) = 3E(E-\epsilon_{i}) \quad \text{for InP} 
\]

We calculated the Kane matrix element P_{i} using the formula of Kane energy E_{pi} [11]:

\[
P_{i}^{2} = \frac{E_{pi}}{2m_{0}}
\]

For our calculations, we adopted the values of E_{pi} cited in [12].

2.3 Heavy holes mini-bands

The superlattice heavy holes mini-bands can be obtained from the Eq. (1) with the following relations:

\[
-\hbar^{2} (k_{1}^{2} + k_{2}^{2}) = 2(m_{hh1}^{*})_{1} (E-\Lambda) \quad \text{for In}_{x}\text{Ga}_{1-x}\text{As} \\
-\hbar^{2} (k_{1}^{2} + k_{2}^{2}) = 2(m_{hh1}^{*})_{2} E \quad \text{for InP}
\]

With \(\xi = k_{1}/k_{2}\) and \(r = \left(\frac{m_{hh1}^{*}}{m_{hh2}^{*}}\right)\).

Here, \((m_{hh1}^{*})_{1} = 0.47m_{0}\) and \((m_{hh2}^{*})_{2} = 0.6m_{0}\) are the heavy holes effective masses of In_{0.53}Ga_{0.47}As and InP respectively as given in [13,14].

The band gaps parameters ε_{i}(i=1,2) used here, are obtained by the empirical expressions of In_{x}Ga_{1-x}As and InP respectively, as a function of alloy composition x and temperature T [15,16]:

\[
\epsilon_{i}^{\Gamma}(T,x) = 1.045 - 0.625x + 0.475 \times (1-x)^{2} - \left(\frac{4.19}{(T+271)} - \frac{5.8}{T+300}\right)10^{-4}T^{2}x - \frac{5.8 \times 10^{-4}T^{2}}{T+300}
\]

We use the experimental valence band offset (VBO) Λ= 346 meV determined by by admittance spectroscopy [17].

We solve the previous relations using the adopted parameters to compute the electronic structure and related properties for the investigated sample.

3. Theoretical results and discussions

3.1 Band structures, band gap and effective mass

Figure 2: Energy of both conduction (upper part) and valence (lower part) sub-bands as function of well thickness d at 1.7 K with d_{1}=1.43 d_{2}. The solid areas show the width of sub-bands in the first Brillouin zone.

The Fig. 2, shows the energy of conduction (E_{c}) light-hole (lh) and heavy-hole (hh) mini-bands at the center \(\Gamma(k_{z}=0)\) and the limit \(k_{z}=\pi/d\) of the first Brillouin zone as a function of well thickness d_{1} with the ratio d_{2}/d_{1}=0.7. The calculated band gap, from the bottom of the first conduction \(E_{c}\) to the top of the first valence sub-bands \(E_{v}\) at T=1.7 K is \(E_{g}(T) = E_{1} - E_{0} = 852\text{ meV}\), as indicated by a vertical dashed line. This value agree favorably with the direct gap of 820 meV measured by photoluminescence by Y.A. Pusep et al. [5]. The difference of 4% between two values obtained

\[
e_{\Gamma}^{\Gamma}(T) = 1.421 - \frac{4.9 \times 10^{-4}T^{2}}{T+327}
\]

Figure 3: Width of the band gap as a function of the discontinuity Λ of the valence bands (VBO).
can be due to the basic parameters adopted here, particularly, the valence band offset (VBO). In Fig. 3, we can see the effect of the VBO on the band gap of the investigated superlattice at 1.7 K. The band gap increases to a maximum at 70 meV, then decreases prabolically when the valence band offset increases. As the figure shows the experimental gap is obtained for λ near of 615 meV. Nevertheless, we used the measured experimental value λ=346 meV by spectroscopy and X-ray photoemission spectroscopy for χ=0.53 [18]. The difference observed can be due also to the small incertitude on the measured thickness d₁ and d₂ and/or to the strain effects which create a large piezoelectric field in these structures, and modify the band structure due to a large change in their energy band edges [19]. When the well's thickness d₁ increases, the band gap and the sub-band width decreases to discrete energy levels of isolated quantum wells for d₁ ≥ 170Å° (Fig. 2). So the electron gas is bidimensional.

We are interested to explain the effect of some basic parameters on the band gap like well thickness and temperature. We plotted the evolution of the band gap E₉ at the centre Γ of the first Brillouin zone, as a function of well width d₁ for various temperatures in Figure. 4. For a given T,

\[ E_g(T) = E_g(0) - \alpha \left( \frac{T^2}{T + \beta} \right) \]  

(8)

In our case, the best fitting was obtained with \( \alpha = 0.49 \) meV K⁻¹, \( \beta = 331 \) K and the gap at absolute zero \( E_g(0) = 851 \) meV. These values are in agreement with those indicated in Ref. [23]. From other hand, there are novels theoretical models out of fitting parameters, one was proposed of Peiji Geng and al. [24].

We calculated the detection cut-off wavelength in Fig. 5, using the formula:

\[ \lambda_c(\mu m) = \frac{1240}{E_g(meV)} \]  

(9)

The variation 1.46 ≤ \( \lambda_c(\mu m) \) ≤ 1.55 indicated that this sample can be used as short-infrared detector.

Fig. 6 shows the band structure of InₓₐₓGaₙ₋ₓₐₐₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐₐₚₐ₌
Figure 6: Calculated band structures of the investigated superlattice along the growth direction $k_z$ and in-plane $k_p$.

Figure 7: Carriers effective mass ratio of the first conduction and valence mini-bands with $m_0$ the rest mass of an electron growth direction $k_z$, and in-plane $k_p(k_x,k_y)$, in the first Brillouin zone. Near the forbidden energy gap, two first conduction ($E_1$ and $E_2$), three heavy holes $hh_{1,2,3}$ and light holes $lh$ mini-bands are observed. The plot of $E(k^2)$ shows that all the mini-bands are parabolic in the first Brillouin zone. There is a weak variation following $k_z$, which can be due to the weak coupling between superlattice wells layers. We deduce that the electronic transport is dominated in-plane of this superlattice. We can also see that the top of valence band is dominated by the heavy holes $hh_1$.

The electrons and holes effective masse are given in Figure 7, in the plane $k_p(k_x,k_y)$, and along the growth direction $k_z$ of the reciprocal space. We extract the carriers effective mass from the dispersion of the curves in Figure 5, using the following relation given by Kittel [25]:

$$\left(\frac{1}{m}\right)_j = \frac{1}{\hbar^2} \frac{\partial^2 E(k)}{\partial k_i \partial k_j}$$

(10)

Where $i$ and $j$ are $x,y$ or $z$-axis directions.

Along $k_p$ direction, we remark that the heavy holes and electrons effective masses still almost constant. The corresponding values are: $m_{hh1} = -0.47 m_0$ and $m_e = 0.109 m_0$ respectively. Whereas, the light-holes decreases slightly from $m_{lh1} = -0.07 m_0$ to $m_{lh2} = -0.06 m_0$.

The figure 8 show the relation between the longitudinal $m^*_{i,j}(k_z)$ along $k_p$ and the well thickness $d_1$ at different temperatures. The carriers’ effective mass marked an important decrease approaching 16 % when $d_1$ increases from 5 to 100. It is obvious that the thickness $d_1$ (or $d_2$) have a strong impact on $m^*_{i,j}$. Such result can be useful in varying the widths of materials superlattice to attain the carrier mobility requested, which can be applied technologically.

As seen in the Fig. 9, we have plotted the evolution of the calculated $k_F$-point energy of heavy-holes, light particles bands and the two-dimensional (2D) Fermi level, as a function of temperature. When the temperature increases from $1.7 \, K$ to $300 \, K$, the energy of the $hh_i (i=1,2)$ states remain almost constant, that of $lh_1$ decreases with a small variation and that of $E_1$ suddenly decreases by $100 \, meV$. The later confirm the decrease of the band gap $E_g = E_{hh1}$.

Figure 8: Evolution of the effective mass at the bottom of the conduction band at $k_F$ as a function of $d_1$ and/or $d_2$ for In$_{0.53}$Ga$_{0.47}$As/InP($d_1$)/lnP($d_2$) with $d_1=1.43 \, d_2$.

On the other hand, the Fermi level energy ($E_F$) does not depend on temperature which is the signature of a two-dimensional electrons gas.

3.2 Fermi level and density of states

In order to determine the Fermi level, we used the measurements of Pusep et al. [5] of the longitudinal magneto-resistance ($\rho_{xx}$) at $1.7 \, K$. The oscillations of $\rho_{xx}$ at low temperature and under high magnetic fields, are periodic with respect to $1/B$. The calculated period $\Delta_{1/B}$ allows us to determine the density of electrons $n_{2D}$, by the formula:

$$n_{2D} = \frac{e^2}{\pi \hbar^2 \Delta_{1/B}}$$

(11)

The relation between the inverse of the minima $1/B_{min}$ and the entire N, Landau level index is given by:

$$1/B_{min} = \Delta_{1/B} \left( N + 1/2 \right)$$

(12)

The oscillations period obtained by the straight line slope of (Eq. 12), $\Delta_{1/B} = 0.11985 \, T^{-1}$ and the value of the electrons concentration, is $n_{2D} = 2.02 \times 10^{11} \, cm^{-2}$. The Fermi wave vector of two-dimensional electron gas
Figure 9: Evolution of band energy of light particles and heavy holes, calculated at the Fermi wave vector $k_F$, as a function of temperature of In$_{0.53}$Ga$_{0.47}$As/InP(100 Å/50 Å). $E_i$(2D) represents the Fermi level energy.

![Graph showing band energy evolution](image)

Figure 10: Density of states versus energy arising from the two lowest conduction mini-bands $E_1$ and $E_2$. was calculated using the formula: $k_F^2 = 2\pi n_{2D}$, which give, $k_F = 0.0127$ Å$^{-1}$ as indicated in Fig. 6 and 7, by blue vertical dashed line. The corresponding electron effective masse is $(m^*_{E1})_{EF} = 0.097 m_0$ from Fig. 7.

The Fermi level energy is given by the following relation:

$$ [E_F - E_i] = [\hbar^2 k_i^2 / (2m_i^*)] = n_{1D} \pi h^2 / (m_i^*) $$

Since $E_e = 1.196$ eV, so $E_F = 1.200$ eV and the half of the band $E_1(k_F)$ is full (Fig. 6). This shows that the studied sample has n-type conductivity at 1.7 K.

The Fermi level energy using the Fermi–Dirac integral as a function of temperature [26, 27]. The resolution of such integrals give the exact value, $E_F = 1.996$ eV.

The density of states (DOS) of the $i$th mini-band for a finite mini-band energy width $\Delta E^{(i)} = E^{(i)}_{max} - E^{(i)}_{min}$, is given by [28]:

$$ \rho_{DOS}^{(i)}(E) = \begin{cases} \left( \frac{m^*}{\pi^2 \hbar^2} \right) k_i(E) & \text{for } E^{(i)}_{min} \leq E \leq E^{(i)}_{max} \\ 0 & \text{otherwise} \end{cases} \quad (14) $$

The generalization of Eq.(14) required a sum over all mini-bands:

$$ \rho_{DOS}(E) = \sum_{i=1}^{N} \rho_{DOS}^{(i)}(E) \quad (15) $$

Fig.10, shows the density of states of the first two conduction subbands of this sample. We can see that only the first conduction subband $E_1(k_z)$ is occupied ($E_1 < E_F$ in Fig. 6) and the density of states is quantified in terms of $m^*/\pi\hbar^2d^2$. The position of the Fermi level energy, indicated by dashed vertical line, shows that $E_1$ and all the bands below are occupied and the sample had n-type conductivity at 1.7 K. A very weak dispersion of $E_1$ along $k_z$ occurs indicating that the quantum wells are weakly coupled from each other and the system is quasi two-dimensional.

We calculated the Landau levels (LLs) for the conduction band $E_1$ as a function of magnetic field by

$$ k_F^2 = (2N + 1) \frac{eB}{\hbar}, \quad (16) $$

We have computed the Fermi level energy as a function of $B$, by using the following formula:

$$ n_{2D} = \int_{0}^{\infty} \rho_{DOS}^{2D}(E, B) f(E) dE \quad (17) $$

with $f(E) = 1 / \left( 1 + \exp \left( E - E_F / k_BT \right) \right)$. The expression of the DOS(B) is given in [29]:

$$ \rho_{DOS}^{2D}(E, B) = \frac{\hbar^2}{k} \sum \delta \left( E - E^{(i)} \right) \quad (18) $$

$$ n_{2D} = B / \rho_{xy}e, \text{ with } e \text{ the charge of electron, is obtained from the measured } \rho_{xy}(B) \text{ by } [5].
When the magnetic field increases, crossovers between the calculated Landau levels (for \(N = 0 \rightarrow 4\)) and Fermi level indicate the same minima of the transverse magnetoresistance \(\rho_{xx}(B)\) oscillations (Shubnikov–de Haas effect), observed in Ref. [5] as shown in table 1, at \(B = 6\), 3.87, 2.75, and 2.21 T. We calculated the filling factor using the formulate: \(\rho_{xx}(\Omega) = \hbar/\nu N_{SL} e^2\) [30]. At these values of magnetic field, the Hall resistance, \(R_{xy}\), shows quantized plateaux. So we interpreted the Shubnikov de Haas oscillations and the Quantum Hall (QHE) plateaux observed by Pusep et al.

To observed such oscillations and the QHE, the separation \(\hbar \omega_c\) (\(\omega_c = eB/m^*_{EF}\) is the cyclotron pulsation) between LL must be superior to activation thermal energy \(k_B T\). The magnetic field \(B\) must be greater then 0.2 T (\(B > k_B m^*_{EF} T/\hbar e\) with \(m^*_{EF} = 0.109 m_0\)).

We calculated also the transport scattering time \(\tau_p = \mu H / m^*_{EF} e = 3.22 \text{ ps}\) for the measured Hall mobility \(\mu_H = 5.2 \times 10^7 \text{ cm}^2/\text{Vs} \) at 1.7 K by [5] with our \(m^*_{EF} = 0.109 m_0\). This value of \(\tau_p\) is comparable to the quantum relaxation time \(\tau_q = 0.5 \text{ ps}\) and \(\tau_p = 2.34 \text{ ps}\) measured in AlGaN/GaN two-dimensional electron gas [31]. The velocity of electrons on the Fermi surface is \(v_F = \hbar k_F / m^*_{EF} = 1.35 \times 10^6 \text{ m/s}\). This is a clear demonstration of faster collision between electrons and phonon and high transport performances of this SL.

### 4. Conclusion

We have investigated the electronic transport properties of \(\text{In}_{0.53}\text{Ga}_{0.47}\text{As}\left(d_1 = 100\text{Å}\right)/\text{InP}\left(d_2 = 70\text{Å}\right)\) SL at 1.7 K on the basis of the bands structure using the envelop function formalism. The optical band-gap \(E_g\) and the cut-off wavelength \(\lambda_c\), were calculated as a function of \(d_1\) and/or \(d_2 = 0.7 d_1\) and temperature. In the range of 1.7-300 K, 1.46 ≤ \(\lambda_c(\mu\text{m})\) ≤ 1.55 shows that the investigated sample can be used for the active zone photodetector in short-infrared SWIR atmospheric windows. The position of the Fermi level, on the density of states showed n type conductivity and quasi-two-dimensional electrons gas. We calculated Fermi level energy and LLs as a function of magnetic field and calculated Fermi level energy and LLs as a function of magnetic field permit us the interpretation of the photoluminescence, the Shubnikov de Haas and quantum Hall Effects observed by Pusep et al. These transport parameters results are useful for the design of this nanostructure SL as short-infrared detector and other applications.

Abstract
Titanium oxyxinitride (TiON), being metal-dielectric nano-composite ceramics, near the percolation threshold exhibits a double epsilon-near-zero (2-ENZ) behavior. It favours super-coupling of the incident laser light to surface plasmon resonances. In this work, we experimentally observe stimulated Raman gain emission from continuous and nano-structured TiON thin films exposed to low-power laser light. It is shown that super-resolution of <100 nm (better than λ/80) in the far-field is achieved due to both the enhanced third-order optical nonlinearity and the multiplicative nature of four-wave mixing.

1. Introduction
Titanium oxyxinitride (TiON) thin films, for the first time synthesized by Mihai and coworkers,1 exhibit a tunable double epsilon-near-zero (2-ENZ) behavior in the visible and near-infrared regions. These refractory ceramics comprise a mixture of TiN, TiOy, and TiO2Nz compounds. Using the Maxwell-Garnett theory (MGT), the origin of this phenomenon can be understood by diluting nano-sized metallic inclusions of TiN within a TiO2 host.1 Near-field interactions between adjacent metallic inclusions can be further enhanced through excitation of delocalized surface plasmon-polaritons (SPPs) or leaky plasmon modes (LPMs). Interparticle junctions behave as hot spots that are able to enhance electric fields as strongly as interatomic fields, thus, higher-order optical nonlinearities become possible on the nanoscale.2 If the metamaterial of interest is a Raman-active medium then inelastically scattered Raman photons, downshifted by the phonon frequency Ω, are generated. Strong internal electrical fields allow a confined Raman-active medium to freely couple and/or decouple with the SPP/LPM, not using such couplers as a prism, a grating, etc.

In this paper, we report on LPM-assisted stimulated Raman scattering from continuous and nano-structured TiON thin films exposed to continuous-wave (cw) laser light with the power of a few mW’s. We demonstrate the superlensing effect by showing a super-resolution of <100 nm in the far-field region, respectively. This effect is a recognition of the multiplicative nature of the SRS and the enhanced third-order optical nonlinearity. With the latter, we show that the sub-wavelength resolution is achieved through the strong localization of the internal electric fields at Stokes frequencies that sustains quasi-bound slow modes inside lossy media with the increased group refractive index.

2. Discussion
It is well-established that SPP-assisted stimulated Raman scattering may occur in confined Raman-active media.3 The intensity of the localized Stokes wave, as a function of the distance L, experiences an exponential growth at the down-shifted frequency ωs : I(L) = I(0) exp[−L(ωs/L)] . Clearly, the strength of the optical amplification is provided by minimizing the product L(ωs/L). Since we deal with the confined medium, L → 0, and the low-intensity pump I(0) (a few mW/cm2 ), the SRS performance is improved by enhancing the Raman factor χR(ωs). The energy exchange between the pump and the Stokes components can be greatly supported by surface plasmon resonances.

In the SRS regime all four waves (ωs = ωp + ω0 − ωs) become enhanced. Thus, the third-order Raman susceptibility changes as

\[ \chi_3^{(3)}(ω_p, ω_s, −ω_p, ω_0) \rightarrow \chi_3^{(3)}(ω_p, ω_s, −ω_p, ω_0) \rightarrow g_0^2 \chi_3^{(3)}(ω_p, ω_s, −ω_p, ω_0), \]

where g0 and gm are the local field-enhancement factors for the pump and the Stokes signal, respectively. With that, the Raman gain factor χR(ωs) reads as:
\[ \chi^{(3)}(\omega_a) = -\frac{3\omega_m}{\omega_m n_m c} g_m^2 n_m^2 \text{Im}[\chi^{(3)}_e], \tag{2} \]

where \( n_0 = n(\omega_p) \) and \( n_m = n(\omega_m) \) are the group refractive indexes for the pump and the Stokes wave, \( c \) is the speed of light in vacuum. Compared to the approach considered in Ref.3, both the field enhancements of the pump and the Stokes wave are taken into account in Eq. (2). The real part of \( \chi^{(3)}_e \) contributes into the accumulated Raman phase shift \( \Delta \phi_a \) for the Stokes wave and it corresponds to the Kerr optical nonlinearity. As follows from Eq. (2) a link between the group and effective refractive index, \( n_m \) and \( n_{\text{eff}} \), at the Raman shift \( \omega_a \) is expressed by the following relationship

\[ g_m = \frac{n_m}{n_{\text{eff}}}. \tag{3} \]

Most intriguing feature of the 2-ENZ metamaterial is its capability to far-field superlensing. We fabricated a 100x100 nm² square antenna on the TiON thin film with focused ion beam milling, as shown in Fig. 1. With that, it is demonstrated far-field spontaneous and stimulated Raman scattering of this antenna. In the latter case, we achieve the improvement of spatial resolution down to 80 nm (\( \lambda/8 \)).

Figure 1: Far-field spontaneous and stimulated Raman scattering of a square TiON nanoantenna.

The physical origin of this phenomenon can be clarified by the increased group refractive index due to the local field enhancement factor, Eq. (3). The enhanced leaky slow-mode propagates along conducting nanoparticles chains within near-zero refractive index media. As a result, the Airy function \( \text{PSF}(\rho, \theta) \), inevitably becomes narrower

\[ \text{PSF}(\rho, \theta) = |J_1(k_n \rho \sin(\theta)/2)/k_n \rho \sin(\theta)/4|^2, \tag{4} \]

where \( J_1(x) \) is a Bessel function of the first kind. Thus, as follows from Eq. (4), the spatial resolution is eventually determined by the local field-enhancement factor \( g_m \). It is important to note that this result is valid for the Stokes components \( \omega_a = \omega_p - m \Omega \) only. It means that in the total scattered light we can observe the super-resolution effect at the anharmonicity-free overtones.

It may be realized that the whole antenna surface radiates more or less uniformly and this is not localized to the edges of the sample, as has been observed with the planar TiN antenna. This follows the slight deviation of the dispersion curve of the 2-ENZ metamaterial from the light line and the presence of the intrinsic roughness of the antenna surface. Previously, the similar result was obtained through coherent anti-Stokes Raman scattering by using a Toraldo-style pupil phase filter.4

Another important contribution into the resolution improvement is the multiplicative nature of the SRS. It is well established that the third-order nonlinear effects are recognized by (1) the cubic behavior of the SRS intensity \( I_m \) vs the pump power \( I_0 \):

\[ I_m = a I_0 + b I_0^3, \tag{5} \]

where \( a \) and \( b \) are constants for spontaneous and coherent contributions, respectively, and (2) the decrease of the full width at half height with the pump power.

3. Conclusions

In conclusion, we have demonstrated the superlensing effect by showing a super-resolution of <100 nm in the far-field region using the SRS. We believe that our findings will provide a basis of diffraction-free far-field optical microscopy.

Haze removal method based on decomposition

Abstract
To obtain a reflected image free of haze, a new haze-removing method is proposed based on decomposition, which effectively reconstructs a reflected image from the hazy image. The decomposition problem can be formulated as a constrained quadratic programming optimization problem which can be obtained by combining the Bregman method with the fast Fourier transform method. Compared with existing methods, our results show that our method can effectively remove the haze and improve image qualities such as contrast, sharpness and color.

1. Introduction
Image haze-removal technologies can effectively improve outdoor vision system performance (e.g., sharpness, color, and contrast). Particularly, single image haze-removal technology has become an important subject for computer vision. At present, many classical single image haze-removal methods have been propose. Tan estimated the optimized atmospheric light value by combining a Markov random field (MRF) with the theory of graph cuts to improve image quality. Fattal derived the shading and transmission by the statistical decomposition method based on the assumption that the shading and transmission functions are locally statistically uncorrelated. He, et al. performed a rough estimate of the transmission map by applying the darkness prior, and then used the soft matting method to improve it.

These single image haze-removal methods have a common disadvantage: the MASM physical model solution is an ill-posed inverse problem. The solution often results in great computational complexity resulting in the need for an optimized tool. To obtain an effective transmission map, we introduce a new optimized method based on the regularized total variance method. Compared with existing methods, experimental results show that the proposed method can effectively remove haze from poor weather conditions to improve image quality (e.g., sharpness, color and contrast.).

2. MASM model
Using Narasimhan’s9 scattering theory, we explain the classic MASM model, defined as:

\[ I(p) = J(p)t(p) + A(1-t(p)) \]  

where \( p \) is the pixel position of the image, \( I(p) \) is the observed image with haze, \( J(p) \) is the image without haze to be estimated, \( t(p) \) denotes atmosphere transmittance, and \( A \) is the atmospheric light. It was assumed that \( A \)'s value (a global value) is unrelated to the pixel position. The first term of equation (1) is the direct attenuation, while the second term is the indirect attenuation. To use the classic Retinex model, we begin by rewriting equation (1) as

\[ A - I(p) = (A - J(p))t(p) \]  

which is like the classic Retinex model, which assumes the image can be represented as the product of reflectance and illumination. From equation (2), it can be observed that the observer image can also consist of two parts: similar reflectance and illumination. To make use of edge-preservation and scale-dependent decomposition capacity11 of the L2 model, we take the logarithm of equation (2) to obtain the additive impact of illumination:

\[ i(p) = j(p) + b(p) \]

\[ i(p) = \log(A - I(p)), j(p) = \log(A - J(p)), b(p) = \log(t(p)) \]

Since the illumination \( b \) is assumed to be a smooth variation, the reflectance \( j \) is assumed to have details, such as texture and edges. To decompose the image, we proposed a new decomposition method based on relative smoothness, which is like the classic Retinex method.

3. Proposed method
To obtain a clear image without haze from multiple models, we implement a new method by constructing an effective energy function to extract a clear image. The TV+L2 method can remove the reflection with defocus blur based on a single image. However, the edges and texture of the image obtained by the method remain blurred, and the step effect of the image is easily observed. Hence, we introduce a new variation regularized model to reduce these defects. The energy of the new variation regularized model is defined as

\[ \min \| \nabla r \|^2_2 + \frac{\alpha}{2} \| \Delta (r) \|^2_2 + \frac{\beta}{2} \| i - r \|^2_2 \]

s.t. \( e = \Delta (i - r) \)

where \( i \) is a normal space, where \( p \) is selected as 1 or 2. \( \beta \) and \( \alpha \) are constants that control the smoothness of the output image. The first two terms are regular and preserve the smoothness of the decomposition image. The third term is a residual term that preserves some main features of the observed image. That is, the
reflectance \( r \) is like that of the input image. We address the new constraint by introducing the following Lagrangian; equation (4) was modified to the unconstrained form

\[
\min \frac{1}{2} \| \nabla r \|_2^2 + \frac{\alpha}{2} \| \Delta (r - i) \|_2^2 + \frac{\beta}{2} \| i - r \|_2^2 + \frac{\lambda}{2} \| \epsilon + \Delta r - \Delta - be \|_2^2
\] (5)

For the solutions of equation (5), we adopted a split Bregman iterative algorithm. To easily obtain a solution for \( r \), we can apply a 2D FFT. The solution of equation (5) is defined as

\[
F(r) = \frac{\lambda F_i + F_s + \lambda F_b + F_x - \lambda F_p + F_e + \alpha F_e + F_0 + \beta F}{F_i + F_s + F_x + F_e + F_0 + \lambda F_p + F_b + \beta}
\] (6)

where \( F_i, F_s, F_x, F_e, F_b \) and \( F \) are the fast Fourier transforms of the variables \( l, x, y, \epsilon, b_x \) and \( i \), respectively.

we obtained the approximate atmospheric transmittance map by analyzing the ALATM. First, the AATM \( t \) was subtracted from the constant \( cn \), expressed as

\[ t = k \left( \exp \left( \max(\text{ALATM}) \right) - cn \right) \] (7)

where the variables \( k \) and \( cn \) are two controlling transmission factors.

4. Experimental results and discussion

In this subsection, we verify the performance of our method using MATLAB 2010b in a computer with a 1.8 GHz Intel i5 Processor. We make several experiments to assess the performance of our method for different kinds of hazy images and compare our results with He’s results and Fattal’s results.

Figure 1 shows the dehazed results and the corresponding assessment values using different haze-removal methods utilizing the swan image. As we can see in Figure 1, the proposed method can effectively remove haze from scenes by comparing other state-of-the-art methods, including He’s, Tan’s, Kratz’s and Nishino’s methods. In Figures 1(c), 1(d), and 1(e), the colors of the results are often over-saturated since their transmission maps may be underestimated. Our proposed method and He’s method can both recover the color features. However, the proposed method can obtain improved sharpness, as shown in Figures 1(b) and 1(f). There are halo artifacts in all the results. Nevertheless, results from the proposed method and He’s method have significantly smaller halo artifacts.

From the perspective of the assessment values, we can find that the effect of the haze-removal using the method proposed by Tan is the best. However, the color of the dehazed image is over-saturated. The assessment values of the image produced using our proposed method is closer to Tan’s value. However, the color of our result is better.

5. Conclusions

In this study, we modified the monochrome atmospheric scattering model to obtain the approximate Retinex model, and then the approximate atmospheric transmittance map was computed by decomposing the approximate Retinex model, based on the constrained regularized total variance method. To obtain a solution to the constrained regularized total variance model, we effectively combined the Bregman iteration method to obtain an optimum solution for the approximate logarithmic atmospheric transmittance map, and then the approximate atmospheric transmittance map was computed by taking the maximum channel out of the three channels of the decomposition transmittance map. Finally, the reflectance image was obtained using the MASM. Compared with other existing methods, our results show that the proposed method can effectively remove haze from bad weather conditions and improve image quality, including the contrast, sharpness, and color.

Abstract
In order to obtain the accurate estimation of the atmospheric light, we present a new and effective method for computing the atmospheric light based on the salient region of the input haze image, which estimates the atmospheric light by combining the statistical characteristics of between the darkness channel and the region of the atmospheric light. Compared with existing methods, our results show that our method can accurately recover the atmospheric light and effectively remove the haze from the bad weather.

1. Introduction
Images captured from the haze weather is prone to suffering from some degradations including low visibility, poor contrast and color distortion because of the scattering of the air light by the larger particles in the air, which greatly affects the further analysis of images. In order to improve the image quality, some experts make a lot of efforts and propose some removal haze methods based on the single image. For instance, Tan et al enhance the contrast of the image for removing the haze by maximizing the local contrast[1]. Fattal improves the quality of the image by estimating the albedo of the radiance image[2], and He et al restore the radiance image relying on the dark channel prior[3]. Above mentioned methods can improve the colorless, visibility or contrast. However, each method has different estimation of the atmospheric light. Tan’s method treats the brightest pixels in the input image as the estimation of the atmospheric light[1]. Fattal’s method treats the sky regions as the estimation of the atmospheric light[2], and He’s method treats the top 0.1% brightest pixels in the dark channel as the estimation of the atmospheric light[3]. To improve the image quality, we propose a new estimation of the atmospheric light method for removing the haze, which effectively combines the salient region of the input. Compared with existing methods, experimental results show that the proposed method can effectively remove haze from poor weather conditions to improve image quality.

2. MASM model
The MASM[4] widely used in the bad weather condition is usually defined as

\[ I(x) = J(x)t(x) + A(1-t(x)), \]  

where \( I \) is the input image with haze, \( J \) is the scene radiance with free haze, \( x \) denotes the image position, \( A \) is the global atmospheric light, \( t \) is the transmission map describing the portion of scene reaching the camera. The first term is the direct attenuation of the scene and the second is the indirect attenuation by the atmosphere. The radiance image \( J \) based on the MASM theory can be rewritten as

\[ J(x) = \frac{I(x) - A}{\max(t(x),th)} + A. \]  

where the variable \( th \) is a threshold, in this paper, \( th \) can automatically be adjusted.

3. Proposed method
The proposed removal haze method is illustrated in Fig.1. As one can see, the method consists of five parts: input, computing the atmospheric light, computing the transmission map, restoring the radiance image and color correction.

3.1. Estimation of the atmospheric light
The atmospheric light is a key factor for removing the haze based on the MASM model. The more precision its estimation is, the better the performance of haze removal will be. In order to further improve the precision, we effectively combine the salient region with the dark channel prior to estimate the atmospheric light because it is very small that the probability of the atmospheric light is located in the salient area of the image. The salient region is computed by analyzing the log-spectrum of an input image, and then adaptively extract the spectral residual of an image in spectral domain. After obtaining the salient region, we integrate with the dark channel prior to estimate the atmospheric light.
3.2. Computing transmission map

According to the equation (1), the transmission map \( t(x) \) is rewritten as:

\[
 t(x) = 1 - \min_{c} \left( \min_{q(i)} \left( \frac{J_c(q)}{A} \right) \right) / \min_{c(i)} \left( \min_{q(i)} \left( \frac{J_c(q)}{A} \right) \right)
\]

posing a dilemma. To resolve this, He et al assume that the radiance image \( J \) is close to zero based on statistics of the dark channel of outdoor images because the equation in which two variables are to be solved for. We also assume that the dark channel of the radiance image is close to zero and we combine the salient region to automatically adjust the threshold. On the contrary, the classical He’s method computes it by fixed threshold. The transmission map \( t(x) \) is then computed with (2). After obtaining the rough transmission map, we observed that the transmission map contains some block effect and needed to be refined. Therefore, we refine it by the multi-kernel guided filter to enhance the image quantity. Finally, the radiance image is restored using the equation (2) and the refined transmission map. In order to further improve the image quality, we adopt a new white balance method to correct the color of the removal haze.

4. Experimental results and discussion

In this subsection, we verify the performance of our method using MATLAB 2010b in a computer with a 1.8 GHz Intel i5 Processor. We make several experiments to assess the performance of our method for different kinds of hazy images and compare our results with He’s results and Fattal’s results. Fig. 2 shows the results of Fattal’s, He’s method and our method for several different hazy images. The left column is the input images, the second shows the results of fattal’s method, the third shows the results of He’s method, and the right shows the results of our method. As we can see in Fig.2, the proposed method can effectively remove haze from scenes by comparing other state-of-the-art methods, including He’s and Fattal’s methods. In Fig.2 (b), the colors of the results are often over-saturated since their transmission maps may be underestimated. Our method and He’s method can both recover the color features. Fig.2(c), the sharpness obtained by He’s method is weaker than that of our method because the estimation of the atmospheric light obtained by our method is precise than that of He’s method. Consequently, the proposed method can obtain improved sharpness, as shown in Fig.2(d).

To further evaluate the performance of the proposed method, we compare the assessment LSIA\(^5\) of each method as shown in Table 1. In Table 1, we label the top LSIA in each by bold font, and we find that our method outperform He’s method and Fattal’s method. That is to say, our method not only can obtain better color, contrast, and visibility with respect to performance of the removal haze but obtain high image assessment value.

| Table 1: Comparisons of Assessment values of different method |
|-----------------|-----------------|-----------------|-----------------|
| input           | Fattal          | He             | our             |
| cones           | 0.8451          | 0.8550          | 0.8591          | \textbf{0.8918} |
| pumpkins        | 0.8789          | 0.8761          | 0.8870          | \textbf{0.8887} |
| pizza_          | 0.9023          | 0.9294          | 0.8919          | \textbf{0.9316} |

5. Conclusions

In this paper, we present a new and efficient method for removing haze, which is based on new estimation of the atmospheric light. We can effectively remove the haze from different scenes and obtain better color, contrast, and visibility, especially the precision of the atmospheric light. Compared with He’s method and Fattal’s method, the proposed method can obtain better performance. However, our method still will produce small halo artefacts at boundaries with abrupt depth changes for a lot of dense haze, which is left to future research.

Abstract

The optical transmittance of a monolayer of Au plasmonic coupled nanoparticles and percolation-like films with nanoslits is controlled from 54% to 86% and from 13% to 54%, correspondingly, upon excitation by intense nanosecond laser pulses.

1. Introduction

Strongly coupled plasmonic nanosystems with nanometer scale gaps are an emerging generation of plasmonic systems in which the focusing of incident electromagnetic energy in the near field is highly efficient. These systems provide great opportunities for ultra-sensitive molecular sensing based on SERS and fluorescence enhancement, high harmonics generation, design of super-resolution tools. Moreover, coupled plasmonic nanostructures show new nonlinear optical properties that differ from those of isolated particles, opening promising opportunities in the modulation of light transmission by the use of intense laser pulses. We study the optical bleaching of a monolayer of Au plasmonic coupled nanoparticles and percolation-like films with nanoslits using Z-scan technique.

2. Array of plasmonic coupled nanoparticles

A macroscopic array of self-assembled plasmonic coupled Au nanoparticles with distribution maximum near 8 nm and separating gaps of 3-8 nm were prepared by pulsed laser deposition at high Ar pressure. The optical transmittance spectrum reveals two broad bands with local minima near 770 nm and 350 nm. The presence of those two absorption maxima is well understood and is attributed to the hybridization of dipolar plasmon excitations, which results in “bonding” and “anti-bonding” modes for nanoparticle pairs. Note that a plasmon band of isolated Au nanoparticles of comparable sizes is typically observed near 520 nm. We numerically modeled the arrays of hemispherical and semi-elliptical particles of different sizes, shapes and separating gaps and have found several important trends, which support the red shift and broadening of the particles absorption spectra. The nonlinear optical properties were studied using the z-scan technique in combination with nanosecond laser excitation. This was done as function of incident laser irradiance at wavelengths within the bonding and anti-bonding hybridized plasmonic bands as shown in Figure 1.

![Figure 1](image-url)

**Figure 1:** Irradiance dependent transmittance of plasmonic coupled Au nanoparticle array measured by the z-scan technique in the open aperture configuration for excitation within “bonding” (a) and “anti-bonding” (b) bands at 600 nm and 415 nm, correspondingly.

At 600 nm excitation by nanosecond pulses near the beam waist the absorption coefficient is effected by optical nonlinearities; once the fluence threshold is reached, transmission increases from ~63 to ~90%, i.e. nonlinear optical bleaching of the Au layer is observed. Interestingly,
the z-scan curve measured at 415 nm is fundamentally different from that measured at 600 nm, and has a similar shape as those typically observed for isolated Ag or Au particles in solutions, nano-composites, or glass hosts.

3. Discussion

The observed phenomenon can’t be explained by nonlinear plasmonic scattering effect but is caused by particles absorption only. Indeed, the Au nanoparticles larger than ~40 nm do effect also the scattering, which give input to detected extinction even in linear regime. In nonlinear regime the scattering of such objects normally evolves to strong defocussing of beam, i.e. results in the enlargement of a Gaussian beam in detector plane during z-scan measurement. Besides, “speckle-like” pattern of multiple bright spots is normally observed for scattering objects. The studied nanoparticles are too small to show some detectable scattering and the there was no any sign of beam profile change/speckle pattern observed in support to our argumentation. Moreover, if any nonlinear defocussing occurs, the z-scan would show the central dip similar to those reported for larger isolated particles. For our plasmonic coupled system we in contrast observed the significant optical bleaching which is opposite to transmission decrease for larger isolated nanoparticles where both nonlinear scattering and multi-photon absorption reduce the transmission.

The irradiance dependent transmittance of the plasmonic coupled nanoparticle arrays is also very different from that of isolated nanoparticles at this excitation wavelength. In particular, at moderate incident laser irradiances, isolated nanoparticles typically show a small transmittance increase induced by optical absorption saturation. At higher laser fluence, z-scan curves typically reveal a valley around \( z = 0 \), corresponding to an “opening” of the two-photon absorption channel. In contrast, for the present case of plasmonic coupled nanoparticles, the two-photon absorption channel does not open by increasing the incident irradiance, instead the samples gradually becomes more transparent. When power density is below ~140 MW/cm\(^2\) (irradiance on beam axis lower than 1 J/cm\(^2\)), the observed effect is well reproducible without degradation of the nanoparticles. The large change in transmission of 27%, from the lower to the higher irradiance regime, is comparable to that found in plasmonic coupled particle-cluster aggregates in solution. Thus, in contrast to studies on isolated particles, z-scan curves of the coupled nanoparticles, excited at 600 nm, do not show a crossover from saturable absorption to transmission decrease.

Remarkable, that similar and even more pronounced nonlinear effects were observed later for percolation-like Au films with nanoslits as shown in Figure 2.

4. Conclusions

We demonstrate the unusually large nonlinear optical transmission increase in a macroscopic quasi-homogeneous array of plasmonic coupled nanoparticles, which is controllable by the irradiance of nanosecond laser pulses.

These plasmonic coupled structures show both linear and nonlinear wavelength and irradiance dependent optical properties very unlike to those of isolated nanoparticles.

Figure 2: Nonlinear optical transmittance change of Au percolation-like film with nanosized slits

In contrast to single plasmonic nano-objects, the usual saturation absorption to transmission decrease turnover in z-scan curves is not observed, when exciting in the “bonding” plasmon band. However, for excitation within the “anti-bonding” band, z-scan curves resemble those characteristic for isolated particles. These phenomena are observed when coupled particles are excited by nanosecond laser pulses, which is very different from the previously reported nonlinear-induced transparency increase on femtosecond and picosecond timescales and can’t be explained in terms of electron-phonon relaxation dynamics only. For nonlinear optical bleaching in nanosecond timescales we provide an explanation based on light retardation effects and the destructive interference phenomenon known in literature as electromagnetically induced transparency.

Multiple Weyl and Double-Weyl Points in Elastic Chiral Lattices
Yao-Ting Wang\textsuperscript{1}, Ya-Wen Tsai\textsuperscript{2}

\textsuperscript{1} Department of Physics, Imperial College London, London, SW7 2AZ, United Kingdom
\textsuperscript{2} Department of Materials Science and Engineering, National Tsing-Hua University, Hsinchu, 30068 Taiwan

In the past decade, Weyl semimetals, which are categorised into solid state crystals and its Fermi energy is located precisely at Weyl points, have been widely investigated in condensed matter physics. Here we prove that multiple Weyl and double Weyl points exist in a chiral elastic system via stacking two-dimensional honeycomb elastic structures. On the distinct $k_z$ plane, the band structures given by a $p_x-p_y$ tight-binding model show the emergence of Weyl points at K point and double Weyl Points at Brillouin centre. Based on the theoretical prediction, a practical chiral mechanical structure can be constructed by current 3D printing technology. The numerical calculation presents several Weyl and double-Weyl points as expected in our analysis of the tight-binding model. To verify the topological feature, the topological charge of degeneracy and the band Chern number are both calculated. Due to the presence of the band Chern numbers marked in Fig. 1a, there are two topologically non-trivial bandgaps guaranteed by bulk-boundary correspondence. Fig. 1b depicts the projected band structures on the $k_z = \pi/2c$ plane and there are surface states within two bandgaps. To further verify its topological protection feature, at $k_z = \pi/2c$ and $f = 6.70$ kHz, the elastic waves present a one-way transport along the truncated surface and propagate robustly against the disorder, as shown in Fig. 1c.

Fig. 1 (a) Fixing $k_z$ values as the synthetic gauge field for the band structure in the 2D subdomain. Numbers attached to bands denote the corresponding Chern numbers. (b) Projected band structure with truncation along $x$ axis. Topological surface modes are coloured in red and green to differ from the surface modes located at the upper and lower boundaries. On the different $k_z$ planes, the surface modes with topological protection are demonstrated in (c).
Phononic Crystals with Archimedean-Like Tiling’s: Transmission, Band Structure and Transformation of Sound

Zafer Ozer¹,*

¹Mersin Vocational High School Electronic and Automation Department, Mersin University, Mersin, Turkey  
*zaferozer@hotmail.com

In this study we investigate acoustic wave propagation in 3D phononic crystal (PnC) slabs which scatterers having different cross sections by using finite element method (FEM). The PnC consists of scatterers embedded in the host material arranged in a square lattice and with Archimedean-like tiling’s (bathroom and ladybug) as seen in fig.1 and 2. By determining the eigenmodes and band gaps complete and accurate band structures and transmission spectra are obtained. Compared to traditional square lattice PnC’s, it has been observed that the bands obtained in Archimedean-like structures may have some advantages in terms of width and position. It was also shown that the low frequency response of two Archimedean-like structures was similar in with respect to the traditional square lattice.

Abstract

Double-zero-index properties in electromagnetic and acoustic waveguides have been recently realized, however, limited research has been reported on double-zero-index structural systems of elastic waveguides. Here, we report an elastic metamaterial consisting of non-perforated taper holes with a periodic array of Lieb-like lattice. Based on the proposed elastic medium, two separated elastic-wave Dirac-like cones are simultaneously observed at the Brillouin zone center, and double-zero-index properties at the neighborhood of Dirac-like points are theoretically, numerically and experimentally investigated.

1. Introduction

A rich variety of distinctive phenomena not typically found in nature have been revealed by both quantum and classical transports in crystals and metamaterials [1-3], depending on interparticle interactions, lattice topology, presence of disorders and external energy. As a topic of particular interest, flat-band systems with a Dirac cone, which can generate dispersionless and macroscopically degenerated energy bands, have attracted ever-increasing attention. The flat-band properties around the Dirac/Dirac-like cone was pioneeringly realized in electromagnetic waveguides. Recently, much effort has been devoted to Dirac/Dirac-like cones in phononic/ acoustic counterparts.

The acoustic Dirac-like cones can be divided into three main types. The first type is a single Dirac cone composed of two linearly touching bands at the corner of the Brillouin zone (BZ). The second category comes from an accidental three-fold degeneracy of two linearly dispersing bands and an additional flat-band, and the Dirac point occurs at the center of BZ. The third type is an emerging double-Dirac cone with a four-fold degeneracy, where a pair of identical Dirac cones overlap at a single Dirac point at the BZ center. Most recently, the Dirac/Dirac-like cones at the center of BZ have been already demonstrated as an approach of enormous potential to realize double-zero-index properties in electromagnetic and acoustic waveguides, i.e., epsilon-and-mu-near-zero or simultaneously zero effective density and infinite bulk modulus. However, the extension of zero-index structural systems to elastic waveguides remains an open challenge since elastic waves in solid structures have more polarization degrees of freedom, various deformation modes and scattering complexity than electromagnetic and acoustic waves. Up to now, very limited research has been devoted to elastic wave Dirac-like cones, even much less attempt has been conducted regarding the double-zero-index elastic phononic waveguides [4].

In this research, we present the development of an elastic Lieb-like lattice metamaterial to realize two separated Dirac-like cones at the BZ center [5]. The double-zero-index effective properties for various elastic wave modes around both Dirac-like points are theoretically, numerically and experimentally investigated. The unique elastic wave control and manipulation in the proposed elastic phononic waveguide are explored.

2. Design and results

2.1. Elastic Lieb-like metatamaterial

A schematic of the proposed elastic Lieb-like lattice metamaterial is illustrated in Fig. 1(a).

![Figure 1](image_url)

Figure 1: (a) Schematic of the proposed Lieb-like lattice elastic metamaterial. (b) Cross section and isometric view of a periodic unit cell.

Three geometric inhomogeneities with non-perforated taper holes, which are built symmetrically from both the upper and lower surfaces, are arranged as a Lieb-like periodic symmetry. The y-z cross section of each inhomogeneity is
exhibited in Fig. 1(b), two semi-elliptic holes are symmetric with respect to the mid-plane of plate. For this infinite structural waveguide, it can be further described by a unit cell, with a periodic array of square C4v symmetry.

2.2. Dispersion spectrum and dual Dirac-like cones

The material of aluminum is applied to the proposed elastic metamaterial. By carefully selecting the geometric parameters of a unit cell, we can obtain an exciting dispersion spectrum that exhibits two Dirac-like points at two different frequencies, as shown in Fig. 2.

Figure 2: (a) Dispersion relations of an infinite Lieb-like lattice metamaterial. (b) Three-dimensional dispersion surfaces around Dirac-like point I and (c) Dirac-like point II.

2.3. Elastic wave control

According to the boundary effective medium theory, double-zero-index property is verified for A0 mode at Dirac point I, and for S0 mode at Dirac point II. On basis of the double-zero-index properties, we further investigate the elastic wave control by using the proposed metamaterial. We obtain the nearly full transmission without phase variation around the frequencies of Dirac points, and further capture the performance of wave-front shaping numerically and experimentally.

3. Conclusions

Two separated Dirac-like cones around different Dirac points have been simultaneously generated by an elastic Lieb-like metamaterial at the BZ center. Double-zero-index properties of the proposed elastic waveguide have been theoretically, numerically and experimentally investigated around the frequencies of both Dirac-like points. The unique transmission properties and the performance of wave-front shaping have been further observed for various wave modes.

Abstract

In this study, quasi Sierpinski-carpet phononic crystals (PnCs) were first identified as unit cells and the band structure obtained in the direction of the $\Gamma$-X-M-$\Gamma$. The Floquet periodicity conditions are applied to the supercells and the band structures are obtained by using the finite element method (FEM). The band gap structure, transmission spectra and displacement fields of eigenmodes of the proposed structures are calculated by using FEM.
Nonviscous damping effects on the wave dispersion and dissipation of locally resonant acoustic metamaterials

Taufeeq Ur Rehman Abbasi¹, Hui Zheng¹*

¹State Key Laboratory of Mechanical Systems and Vibration, Institute of Vibration, Shock and Noise, Shanghai Jiao Tong University, Shanghai 200240, China
*corresponding author, E-mail: huizheng@sjtu.edu.cn

Abstract

Periodic structures for various level of wave dispersion and dissipation use material damping, which may contribute to the performance enhancement of locally resonant acoustic metamaterials (AMMs). We investigate the wave dispersion and dissipation performance of AMM by considering the effects of nonviscous damping. A new state-space method in a symmetric form based on an anelastic displacement fields (ADF) model for the analysis of periodic structures is developed. It is demonstrated that the effect of nonviscous damping increases the wave dispersion and dissipation performance of AMM by suitable selection of material parameters.

1. Introduction

Engineering problems involving wave dispersion and dissipation are frequently encountered in the periodic structures. It is usually significant to control elastic and/or sound waves propagation by introducing material that contains unusual dynamic properties called acoustic metamaterial (AMMs). AMM is the engineered designed material, which forms frequency band gaps for stopping the wave propagation to provide superior vibration suppression performance. In AMM design, the inclusion of local resonance is the primary component, which makes the metamaterials applicable for novel applications including an acoustic waveguide, noise and sound treatment, and underwater acoustics [1, 2]. The local resonance mechanism-based design approach provides wave attenuation in the low-frequency and advantages over the traditional approaches that normally required large and/or heavy structures [2, 3]. Metadamping defined by the combination of locally resonant elements and damping material enhanced its importance for various practical applications that demand to control the wave propagation [4].

It is therefore important to consider the factor of damping modeled as viscous and/or nonviscous system for the dispersion and dissipation analysis of periodic systems. Viscous damping is used for the systems in which energy-dissipation by the viscosity is the dominant dissipative mechanism. Owing to modeling errors, the viscous model does not accurately calculate the damping behavior of vibrating systems. Nonviscous damping is more suitable for the materials, for example, polymers that exhibit material loss and/or perform micromechanical relaxation process [5]. The influence of nonviscous damping on the wave dispersion and dissipation behavior of AMM will be studied by developing the new method for wave propagation problems.

2. Bloch’s theorem based state-space method for wave propagation problems

The state-space matrices based on Bloch’s theorem for the nonviscously damped unit cell are represented by

\[
\begin{bmatrix}
0 & \bar{M} & 0 & \cdots & 0 \\
\bar{M} & D & 0 & \cdots & 0 \\
0 & 0 & \frac{\Delta l}{\bar{K}} & \bar{V} & \cdots & 0 \\
\vdots & \vdots & \vdots & \ddots & \ddots & \vdots \\
0 & 0 & 0 & \cdots & \frac{\Delta l}{\bar{K}} & \bar{V}
\end{bmatrix}
\]

(1)

\[
\begin{bmatrix}
-\bar{M} & 0 & 0 & \cdots & 0 \\
0 & (\bar{K} + \bar{K}^{V(0)}) & -\Delta l & \bar{K} & \cdots & -\Delta l & \bar{K} \\
0 & -\Delta l & \bar{K} & \Delta l & \bar{K} & \cdots & 0 \\
\vdots & \vdots & \vdots & \ddots & \ddots & \ddots & \ddots \\
0 & -\Delta l & \bar{K} & 0 & \cdots & \Delta l & \bar{K}
\end{bmatrix}
\]

(2)

The damping ratio and frequency for calculating the wave dispersion and dissipation are dependent on the wavevector as defined by

\[
\xi_s(\kappa) = \frac{\text{Re} [\lambda_s(\kappa)]}{\text{Abs} [\lambda_s(\kappa)]}, \omega_d(\kappa) = \text{Im} [\lambda_s(\kappa)]
\]

(3)

3. Numerical results and discussions

3.1. Effect of nonviscous damping on the performance of AMM

The performance of AMM in terms of nonviscous damping is studied by using Eqs. (1-3) and varying the damping intensity from $\alpha/\omega_0 = 0.1$ to $\alpha/\omega_0 = 0.4$ across the wavenumber axis. A unit cell is considered from the system shown in Fig. 1 and their values of the mass, stiffness and damping ratios are set as $\theta_2 = 9, \delta_2 = 1$ and $\tau_2 = 1/2$, while parametric value of resonant frequency $\omega_0 = 149.07$ rad/s. Fig. 2a shows the increasing trend of optical curves of AMM with the increase of damping intensity across the wavenumber domain. The shifting of op-
are kept the same. The dissipative diagram is shown in Fig. 2b. It is shown that the value of damping ratio increases further by decreasing the value of $\omega_0$, which imply that the lower values of $\theta_2$ and $\omega_0$ are more suitable to enhance the wave dissipation performance of AMM.

4. Conclusions

In conclusions, the performance of acoustic metamaterials in terms of wave dispersion and dissipation is studied by introducing nonviscous damping. It is verified that the wave dispersion performance of AMM is higher in the nonviscous damping. The analysis also reveals that the nonviscous damping increases the wave dissipation performance of AMM by the selection of suitable material parameters. Further discussions on the performance of AMM in terms of the metadamping phenomenon will be presented.

Abstract

We propose a dissipative triatomic elastic metamaterial to extend the range of the asymmetric elastic wave transmission and to control the elastic wave in two low-frequency bands. A triatomic metamaterial structure consisting of several small-sized unit cells is proposed and verified analytically. The analytical results are verified numerically by analytical lattice and continuum models. We further explore the asymmetric wave transmission experimentally, and the transient wave responses in the time and frequency domains are also investigated to verify the results.

1. Introduction

Elastic wave propagation is considered symmetric in regular materials and structures. As a matter of recent interest, asymmetric transmission of elastic waves has attracted more attention due to the difficulties to achieve one-way elastic wave transmission, as well as the potential of many practical applications [1]. Many methods have been proposed to obtain asymmetric elastic wave transmission. These methods can be classified, based on whether an external energy is needed, into two categories: active and passive designs. By utilizing a circulating fluid as an odd-vector bias, Fleury et al. proposed a linear ring cavity and split the structure’s azimuthal resonant modes, which lead to giant acoustic nonreciprocity [2].

By means of nonlinear mechanisms, various passive designs have also been reported to break the acoustic reciprocity without depending on the external energy. Liang et al. suggested a pioneer nonlinear acoustic rectifier and observed the significant rectifying effect experimentally [3]. Also, to realize asymmetric elastic wave transmission in low-frequency bands, Li et al. proposed and designed linear diatomic metamaterial structure which can exhibit large asymmetric transmission in multiple low-frequency regions [4,5].

However, the frequency bandwidths for asymmetric transmission in these structures are normally limited to narrow frequency ranges, and to the number of internal resonators which are difficult to manufacture for practical applications, and the potential to realize asymmetric elastic wave transmission in multiple broadband frequency regions still needs more research. Moreover, less research has been done on the damping effects of asymmetric wave transmission in triatomic structures. In this work, we propose a dissipative triatomic metamaterial to obtain broadband asymmetric elastic wave propagation. The broadening effects of the asymmetric transmission band bandwidths induced by the dissipative oscillators are systematically analyzed and performed by analytical equations and numerical verification in both continuum model and lattice system. In addition, we perform experimental observation of asymmetric elastic wave transmission in the proposed structure. We further show the transient wave responses in time and frequency domains for the experimental results.

2. Design and equivalent models

The schematic design and the dimensions of the proposed triatomic structure are shown in Figure 1.

![Figure 1: Schematic of the continuum model for the proposed dissipative triatomic elastic metamaterial.](image)

One-unit cell of the triatomic metamaterial rod can be mathematically described by a mass-spring-dashpot model to investigate the unusual characteristics of elastic metamaterials. By utilizing the concept of equivalent mass in mass-spring model, this dissipative triatomic mass-spring-dashpot system can be further described by an equivalent dissipative mass-spring-dashpot model. The original triatomic chain can be symbolized by three effective masses: $m_1'$, $m_2'$, and $m_3'$.
2.1. Non-dissipative model

Asymmetric elastic wave transmission in the proposed dissipative triatomic metamaterial is investigated analytically and verified numerically without introducing damping effects for better comparison later. The results from the analytical dispersion relation along with the continuum model are compared in Figure 2(a). The transmission coefficients are compared in Figure 2(b).

![Figure 2: (a) Analytical and continuum dispersion relations of the infinite periodic rod. (b) Transmission coefficient-frequency profiles obtained by a finite continuum rod consisting of 6-unit cells along directions L and R.](image)

2.2. Dissipative model

To quantitatively explore the damping effects on the ATB bandwidth, we calculate the asymmetric contrast ratio under various damping coefficients. The contrast ratio $\alpha$ is calculated by defining the total transmission coefficients along left direction $L$ and right direction $R$ as:

$$\alpha = \frac{T^L_T - T^R_T}{T^L_T + T^R_T}$$

The Rayleigh damping is applied to the soft material of the continuum model to represent the performance of damping on the lattice system.

2.3. Experimental verification

The experimental results for the two opposite directions are also verified. It is noticed that the transmission properties along both directions are very similar before 480 Hz, then clear separation starts to occur in the experimental data. The separation region between 484-1592 Hz represents the first asymmetric transmission band, while the second ATB band exist between 1650-3650 Hz.

3. Conclusion

By using the proposed dissipative triatomic metamaterial structure, asymmetric elastic wave transmission can be realized in two frequency bands compared with dual resonator system which is hard to be manufactured. The effect of damping on the ATB bandwidth is systematically investigated by 6-unit cells continuum model and verified systematically by a theoretical mass-spring-damper model. It is observed that ATB bandwidths can be enlarged by using the merging effects induced by using the proper damping design.

Acoustic Metamaterial Lenses for 40kHz Ultrasound
Fabricated with Consumer 3D-printers

James Hardwick, Jordi Prat-Camps, Sriram Subramanian

Interact Lab, Department of Informatics, University of Sussex, Brighton, United Kingdom

Abstract

With the advent of high resolution 3D printing we can now fabricate complex and intricate structures with relative ease and low cost. In this project we design different acoustic lenses for ultrasonic waves of frequency 40kHz using a set of phase delaying unit cell bricks arranged into specific patterns. We use different consumer 3D printers to fabricate them and compare the results of these different printing techniques. Finally, we test the performance of each in terms of acoustic field control.

1. Unit Cells & Lens Construction

Acoustic metamaterials allow new methods for controlling ultrasound fields which were not available only a few short years ago. Previously the techniques available for focusing a given ultrasound field were limited to costly phased arrays of transducers or bulky static lenses [1, 2]. As demonstrated by Memoli et al. [3], it is possible to construct a transmissive metasurface lens from a series of unit cells, each providing a well-defined delay to the phase of any ultrasound wave which passes through them. These unit cells take the form of small maze-like structures which coil the space within them [4]. They each have a height of $\lambda$ and a side-length of $\lambda/2$. The working frequency is a constant 40kHz and it is assumed the waves are travelling through air at 25°, corresponding to a wavelength of $\lambda \approx 8.66$mm. These unit cells, which we call “bricks”, consist of a rectangular cuboid-shaped channel with four bars protruding inwards at a perpendicular angle to the wall. The mazes are increased in complexity by altering the length ($l$) and spacing between these bars ($s$). By carefully tuning these two parameters a set of bricks were designed which offers 16 different phase delays spread equally between 0 and 2$\pi$. A cross section of three bricks is shown in Fig.1. We performed 3D finite-element simulations with COMSOL Multiphysics to verify that the designed bricks imprint the desired phase delays.

As mentioned before, these bricks have a side-length of $\lambda/2$. In terms of acoustic pressure reconstruction, a better performance could be achieved by considering smaller bricks. However, it has been shown that the sampling of a continuous analog phase map at a spatial frequency of $\lambda/2$ makes it possible to achieve an excellent pressure reconstruction in the far field while still offering a good balance in the tradeoff between acoustic pressure control and ease of fabrication [5].

Fig.1 – Here we see a cross section of bricks 1, 7 and 15 corresponding to phase delays of 22.5°, 157.5° and 337.5° respectively. We also see how the two parameters, $l$ and $s$, change in order to increase the phase delay provided by each.

The bricks are then assembled into lenses. So far, these take the form of convergent lenses with different focal lengths. The focal length is arbitrary and can be specified by the user during the construction process. A short algorithm was written which takes the desired brick array and focal lengths and uses simple Pythagorean geometry to determine the analog phase map for a lens which conforms to these parameters. The algorithm then discretizes this by finding the average phase value of each $\lambda/2$ by $\lambda/2$ (1 unit cell) area of the lens and realigns it to the closest brick phase value out of the 16 available. This newly discretized phase map can then be translated directly into positions for the appropriate bricks in a number of 3D modelling programs and made into a printable lens.

The fabrication of the lenses is done using commercial 3D printers. In order to aid in the printing process the outer edges of the lens are made thicker. A buffer layer is added to raise the whole structure from the floor of the printer and a skirt is built around the bottom to help prevent the entire structure from curling upwards during the course of the printing. The prototypes were created using three different consumer-level 3D-printers. The Stratasys F370 & Flashforge Creator Pro are both Fused-Filament (FF) printers and used ASA and PLA as printing materials respectively. The stereolithographic Form2 used Formlabs resin (RS-F2-GPGR-04). The Flashforge is the cheapest of the three and does not use a support material to aid printing. The Stratasys is the most expensive of the three and uses a
water soluble material for support. The Form2 has a cost somewhere between the other two. It also requires an extensive scaffold-like support structure, made from the same Formlabs resin, to achieve a successful print. An image of one completed lens from each of the three printers is shown in Fig.2. The results of each of these printing methods were compared to see which gave the best balance between accuracy and cost. The low resolution of the Flashforge meant it struggled to print the thin bars properly. The Stratasys performed reasonably well in this regard but the low resolutions endemic to FF printers were still noticeable. The higher resolution and stereolithographic nature of the Form2 made it superior to both FF printers at producing the extremely thin unit cell bars accurately but it struggled to make it through a full print without an extensive network of supportive scaffolding, increasing the cost of the print significantly. New iterations are still being tried with all of the printers and until we can properly test the capabilities of each printed lens with our upcoming measurement system, we won’t know for sure which gives us the best results.

**Fig.2** – Three 100mm focal length lenses each created in a different printer and with different materials. A: Stratasys F370 using ASA material. B: Flashforge Creator Pro using PLA. C: Form2 using Formlabs resin.

### 2. Measurements

In order to compare the performance of the different lenses, we intend to perform acoustic measurements of the pressure distribution on the far side of each of the lenses when an $f_0=40$kHz acoustic wave is sent through it. The source of waves is a single ultrasonic transducer (Murata MA40S4S) which is fed with a sinusoidal signal of frequency $f_0$ and is placed at a distance of 16 cm from the lens. The transmitted pressure is measured with a B&K microphone (model 4138-A-015), which is connected to a conditioning amplifier (Nexus Type 2692, final gain: -20dB) and this, in turn, to a PicoScope data acquisition unit (Pico Instruments, model: 5444b). The microphone is mounted on a 3D computer-controlled stage that allows it to scan the pressure distribution at multiple planes. At the time of the submission of this abstract we are in the process of completing the measuring setup and we expect to start acquiring experimental data in the coming weeks and months.

### 3. Future Perspectives

Currently the only lenses designed and built are convergent lenses which create a focal point above their center points. We plan to design, fabricate and measure other kinds of structures such as steering lenses that alter the direction of the incident field in a uniform way rather than focusing it. Multiple steering and focusing lenses can even be stacked on top of one another to create more complex field manipulation devices which allow both steering and focus and could be described as “acoustic tractor beams” [6].

In this investigation the linear and nonlinear optical properties, band structures and electro-optic effects of Sn$_2$P$_2$X$_6$ (X=S,Se) ferroelectrics are studied by the density functional theory (DFT) in the local density approximation (LDA) expressions based on first principle calculations. We present calculations of the frequency-dependent complex dielectric function ($\varepsilon^* = \varepsilon_1 - i\varepsilon_2$) and the second harmonic generation response coefficient $\chi(2)(-2\omega,\omega,\omega)$ over a large frequency range in different phases. The electronic linear electro-optic susceptibility $\chi(2)(-\omega,\omega,0)$ is also evaluated below the band gap. These results are based on a series of the LDA calculation using DFT. Results for $\chi(2)(-\omega,\omega,0)$ are in agreement with the experiment below the band gap and those for $\chi(2)(-2\omega,\omega,\omega)$ are compared with the experimental data where available. Also, in present work the acoustic band structure and acoustic wave propagations in a two-dimensional (2D) phononic crystals (PC) containing a Sn$_2$P$_2$X$_6$ ferroelectrics were investigated theoretically and numerically by the plane-wave-expansion (PWE) method. Two-dimensional PC with square lattices composed of semiconducting ferroelectric cylindrical rods embedded in the organic/inorganic matrix is studied to find the existence of stop bands for the waves of certain energy. This phononic bandgap–forbidden frequency range–allows sound to be controlled in many useful ways in structures that can act as sonic filters, waveguides or resonant cavities. Phononic band diagrams for a 2D PC wywy plotted versus the wavevector k along the $\Gamma$-X-M-$\Gamma$ path in the square Brillouin zone (BZ) show four stop bands in the wide frequency range. The unusual properties of matrix and ferroelectric properties of Sn$_2$P$_2$X$_6$ give us ability to control the wave propagation through the PC in over a wide frequency range.
Negative phase velocity sound propagation in 1D hyperbolic phononic metamaterials

Abstract

Analytical formulas are obtained for the tensor of effective mass densities and for the effective elastic modulus of a binary superlattice in the long wavelength limit. They are valid for high frequencies and oblique propagation. Within the region of frequencies with anomalous dispersion, the equifrequency curves are hyperbolic and the effective masses exhibit strong anisotropy. It is demonstrated that hyperbolic dispersion in a 1D periodic system leads to negative refraction for phase velocity. The group velocity refraction remains positive.

1. Introduction

Homogenization procedures developed for elastic superlattices allow numerical calculation of the effective parameters (effective mass density and effective elastic modulus) for long wavelength sound [1, 2]. The obtained effective parameters reproduce well the exact dispersion curves [3] provided that sound propagates along the superlattice axis. Numerous applications of elastic superlattices require more general information about the effective parameters, in particular, the explicit dispersion relation for a sound wave propagating in arbitrary direction. Here we propose a homogenization procedure based on a simple and natural dynamical assumptions that lead to the analytical formulas for the effective parameters. We apply the obtained analytical results to detailed study of the process of refraction of sound waves through a finite-size slab of periodic water-steel layers. The effective parameters show the region of frequencies with hyperbolic dispersion of sound in the slab. This, however, does not lead to negative refraction, as it occurs for 2D layered phononic crystals: perforated plates [4] or membranes [5]. In 1D periodic structures, the refraction related to the directions of the phase velocities turns out to be negative, while the group velocity follows positive refraction. Thus, 1D periodic elastic structures cannot be used as the basic element of a superlens.

2. The effective parameters

The frequency dispersion relationship for the case of oblique propagation of acoustic waves through homogeneous media takes the form:

\[ \frac{k_x^2}{\rho_x} + \frac{k_y^2}{\rho_y} = \frac{\omega^2}{\lambda}. \]  

(1)

If \( \rho_x \rho_y < 0 \), then the equifrequency curves take a hyperbolic form. Since all the effective parameters are strongly frequency dependent in the higher bands, the formulas in the quasi-static limit are not applicable. Therefore, we developed a new homogenization method which is based on a natural requirement that the acceleration and displacement of the effective medium in an oscillating acoustic field must coincide with the corresponding quantities averaged over the unit cell. The proposed method leads to the following analytical expressions for the effective parameters:

\[
\begin{align*}
\rho_x &= \frac{\rho_a \{ \rho_a k_b \sin (ak_a/2) \cos (bk_a/2) + k_a \rho_b \cos (ak_a/2) \sin (bk_a/2) \}}{\rho_a [k_a \sin (bk_a/2) + k_b \sin (ak_a/2) \cos (bk_a/2)] + k_b \rho_b \cos (ak_a/2) \sin (bk_a/2) - 2k_a \rho_b \sin^2 (a/4) \sin (bk_a/2)}, \\
\rho_y &= -\frac{0.5(a + b)k_a \rho_b k_b \rho_a \rho_b \sin (ak_a/2) \sin (bk_b/2) \cos (bk_a/2) - k_a \rho_b \cos (ak_a/2) \cos (bk_b/2)}{(a + b)k_a \rho_b k_b \sin (ak_a/2) \sin (bk_b/2) + k_b \rho_b \sin (ak_a/2) \cos (bk_b/2)}, \\
\lambda &= \frac{0.5(a + b)k_a \lambda_k \rho_b \sin (ak_a/2) \sin (bk_b/2) - k_a \rho_b \cos (ak_a/2) \cos (bk_b/2)}{\lambda_a k_b^2 \rho_b \sin (bk_b/2) + k_b \lambda_b \rho_b \sin (ak_a/2) \cos (bk_b/2) - 2 \rho_a k_b \sin^2 (ak_a/4) \sin (bk_b/2)}.
\end{align*}
\]

Here, the wavevectors in each layer are defined as \( k_i = \sqrt{\omega^2/c_i^2 - k_0^2} \), where \( i = a, b \). These formulas are valid near \( \Gamma \)-point, if \( kd \ll 1 \), where \( k \) is Bloch vector. The frequency \( \omega \) is not necessarily small. In the limit \( \omega \to 0 \) the quasi-static results are recovered. Note that the effective parameters (2) take into account the effects of spatial dispersion. Therefore, the dispersion relation Eq. (1) in
Material $a$, water: $\lambda_a = 2 \times 10^9 \text{Pa}$, $\rho_a = 1000 \text{ kg/m}^3$, $a = 10 \text{ mm}$

Material $b$, steel: $\lambda_b = 2 \times 10^{11} \text{Pa}$, $\rho_b = 7900 \text{ kg/m}^3$, $b = 1 \text{ mm}$

d/2

Figure 1: Symmetric unit cell of water-steel structure. Arrow shows oblique propagation with Bloch vector $\mathbf{k}$.

Figure 2: Equifrequency contour diagrams for water (black), water-steel composite (orange) and effective media (blue) for frequency 95.1 kHz.

general case defines a curve of order higher than two.

3. Structure of equifrequency curves

The equifrequency curves in Fig. (2) are plotted for 95.1 kHz that is very close to the top of the second allowed band (95, 115) Hz, which exhibits anomalous dispersion. Both, the blue curve obtained from Eqs. (1, 2) and the orange curve obtained from the exact Rytov’s equation exhibit hyperbolic dispersion. They coincide asymptotically at $\Gamma$-point. For the frequencies near the top of the second band these curves remain close to each other. The group velocities in Fig. (2) are directed toward the gradients $\nabla k \omega$. The directions of the phase and group velocities in Fig. (2) correspond to anomalous dispersion along the superlattice axis (axis $x$).

The refraction of sound waves at the interface between water and the superlattice is shown in Fig. (3). The angle of incidence is $8^\circ$ and the angle of refraction is $36^\circ$ for the group velocity. The direction of the group velocity in the superlattice (green arrow) with respect to the direction of incidence (yellow line) corresponds to positive refraction. However, the phase velocity in the superlattice is directed towards the interface. For the phase velocity, the angle of refraction is $130^\circ$ which is the manifestation of strong anisotropy of the effective medium together with anomalous dispersion. Indeed, the effective masses not only have opposite signs, but their absolute values are very different, $\rho_x/\rho_y \approx 10^{-2}$. Very light effective mass $\rho_x$ is due to small curvature of the dispersion curve near $\Gamma$-point. Exactly at this point the effective mass vanishes and sound does not propagate since a standing wave is formed.

4. Conclusions

Our study demonstrates that a layered medium (without internal structure) in the long wavelength limit may behave as a hyperbolic metamaterial. However, unlike the layered media with internal structures, [4, 5] it does not exhibit negative refraction for the group velocity. The refraction for phase velocity remains anomalous – the vector of phase velocity rotates by an angle greater than $90^\circ$.

Abstract

In plane elastic moduli of lattice mechanical metamaterials include elastic moduli in the X and Y directions and a shear modulus. Historically, these moduli were described by positive real values considering the deformation of the material under a static stress field. When dynamic behaviour of lattice metamaterials are considered, it is possible to express elastic moduli as functions of frequency. In this case, it is first theoretically shown that there exist a critical frequency beyond which the elastic moduli become negative. The analysis is based on a dynamic equilibrium of a unit cell. Experimental investigations involve dynamic testing of a hexagonal lattice made of a titanium alloy. Theoretical predictions of equivalent elastic moduli and negative frequency values are validated with experimental results.

1. Introduction

A mechanics-based bottom-up framework, combined with experimental dynamic testings, is proposed for probing the frequency-dependence of metallic lattice material microstructures. Under a vibrating condition, effective elastic moduli of such microstructured materials can become negative for certain frequency values, leading to an unusual mechanical behaviour with multitude of potential applications. We first show the fundamental theoretical limits for the minimum frequency, beyond which the negative effective moduli of the materials could be obtained. An efficient dynamic stiffness matrix based approach is adopted to obtain the closed-form limits, which can capture the sub-wavelength scale dynamics. The limits turn out to be a fundamental property of the lattice materials and depend on certain material and geometric parameters of the lattice in a unique manner. An explicit characterization of the theoretical limits of negative elastic moduli along with adequate physical insights would accelerate the process of its potential exploitation in various engineered materials and structural systems under dynamic regime across the length-scales.

The global mechanical properties can be engineered in lattice materials by intelligently identifying the material microstructures as the properties in these materials are often defined by their structural configuration along with the intrinsic material properties of the constituent members. This novel class of materials with tailorable application-specific mechanical properties (like equivalent elastic moduli, buckling, vibration and wave propagation characteristics with modulation features) have tremendous potential applications for future aerospace, civil, mechanical, electronics and medical applications across the length-scales. Naturally occurring materials cannot exhibit unprecedented and fascinating properties such as extremely lightweight, negative elastic moduli, negative mass density, pentamode material characteristics (meta-fluid), which can be achieved by an intelligent microstructural design [1, 2]. For example, the conventional positive value of Poisson’s ratio in a hexagonal lattice structure can be converted to a negative value [3] by making the cell angle $\theta$ in Figure 1(b) negative.

![Figure 1: The hexagonal lattice and the corresponding unit cell](image)

Lattice microstructures are often modelled as a continuous solid medium with a set of effective elastic moduli throughout the entire domain based on an unit cell approach [4]. The basic mechanics of deformation for the lattices being scale-independent, the formulations developed in this context are generally applicable for wide range of materials and structural forms. Two dimensional hexagonal lattices of natural and artificial nature can be identified across different length-scales (nano to macro) in auxetic and non-auxetic forms [5]. This has led to our focus on hexagonal lattices in this article while selecting a lattice configuration to demonstrate the concepts.

2. The dynamic stiffness approach

A bottom-up theoretical framework is developed here (refer to Figure 1) to investigate the limits of natural frequency that would cause negative axial or shear moduli. A lattice-like structure can be analysed by considering an unit cell as shown in figure 1(b), while the unit cell consists of beam elements. In a vibrating condition, the dy-
Dynamic motion of the overall lattice corresponds to vibration of individual beams, which would exhibit a different frequency-dependent deformation behaviour compared to the conventional static analyses. Thus, we first form the frequency-dependent elastic stiffness matrix for a beam element \( \mathbf{D}(\omega) = [D_{ij}], \) where \( i, j \in [1, 2, 3, 4] \) and \( \omega \) is the frequency of vibration) and thereby, the frequency-dependent deformation characteristics of an unit cell are developed. Eventually, frequency-dependent equivalent elastic moduli of the overall lattice structure are derived based on the deformation behaviour of a unit cell. The theoretical limits of frequencies to obtain negative elastic moduli are obtained using their respective frequency-dependent expressions.

The equation of motion of free vibration of a damped beam depicting one element of the unit cell in Figure 1(b) can be expressed as

\[
EI \frac{\partial^4 V(x,t)}{\partial x^4} + \bar{c}_1 \frac{\partial^3 V(x,t)}{\partial x^3 \partial t} + m \frac{\partial^2 V(x,t)}{\partial t^2} + \bar{c}_2 \frac{\partial V(x,t)}{\partial t} = 0
\]

(1)

It is assumed that the behaviour of the beam follows the Euler-Bernoulli hypotheses. In the above equation \( EI \) is the bending rigidity, \( m \) is mass per unit length, \( \bar{c}_1 \) is the strain-rate-dependent viscous damping coefficient, \( \bar{c}_2 \) is the velocity-dependent viscous damping coefficient and \( V(x,t) \) is the transverse displacement. The length of the beam is assumed to be \( L \). Considering a harmonic motion with frequency \( \omega \) we have

\[
V(x,t) = v(x) \exp [i\omega t]
\]

(2)

where \( i = \sqrt{-1} \). Substituting this in the beam equation (1) one obtains

\[
\frac{d^4v}{dx^4} - b^4v = 0; \quad b^4 = \frac{m\omega^2 - i\omega \bar{c}_2}{EI + i\omega \bar{c}_1}
\]

(3)

The constant \( b \) is in general a complex number for any physically realistic damping values.

The stiffness and mass matrices of the element can be obtained following the conventional variational formulation [6]. It can be shown that the dynamic stiffness matrix [7] is given by the following closed-form expression

\[
\mathbf{D}(\omega) = \frac{E_{1h}}{c_0 c_1} \begin{bmatrix}
-b^2(cS + Cc) & -sbS & b^2(S + s) & -b(C - c) \\
-sbS & -cS + cS & b(C - c) & -S + s \\
b^2(S + s) & b(C - c) - b^2(cS + Cc) & sbS & -S + s \\
-b(C - c) & -S + s & sbS & -cS + cS
\end{bmatrix}
\]

(4)

where \( \alpha = \frac{E_{1h}}{c_0 c_1} \), \( C = \cosh(bL) \), \( c = \cos(bL) \), \( S = \sinh(bL) \) and \( s = \sin(bL) \). The elements of this matrix are frequency dependent complex quantities because \( b \) is a function of \( \omega \) and the damping factors.

3. Experimental approach

Following [8], it can be shown that the elastic moduli \( E_1(\omega) \) and \( E_2(\omega) \) can be expressed in terms of the element of the dynamic stiffness matrix as

\[
E_1(\omega) = \frac{D_{33} l \cos \theta}{(h + l \sin \theta) b \sin^2 \theta}, \quad E_2(\omega) = \frac{D_{33} (h + l \sin \theta)}{l b \cos^3 \theta}
\]

(5)

For certain values of the frequency, the real part of the above elastic moduli will become negative. A hexagonal lattice made of Titanium alloy Ti-6Al-4V shown in Figure 2 will be used to experimentally investigate the negative elastic moduli.

Figure 2: The hexagonal lattice made of Titanium alloy Ti-6Al-4V \((E=115\text{GPa}, \nu=0.34)\)

4. Conclusions

It has been theoretically shown that in certain frequency ranges the effective elastic moduli of lattice materials can be negative. This paper explores this using experimental approaches using dynamic testing of metallic lattice metamaterials.

Abstract

A chiral metamaterial with crossed-S resonators is proposed and demonstrated experimentally based on the broken symmetry along the propagation direction, which enables a high efficient, broadband and mutually independent dual-band asymmetric transmission (AT) in both x and y polarized directions. It is worth mentioning that the AT performance is robust against a wide range of oblique incidence and suitable different linearly polarization. The proposed multilayer chiral metamaterial in our work provides an alternative way to improve its response to the terahertz wave and will be a significant candidate in the applications of communications and ultrafast information processing.

1. Introduction

Metamaterials with periodic arrays of artificially designed subwavelength elements can achieve exotic electromagnetic properties that are inaccessible in naturally occurring materials [1]. Over the past decades, many attempts have been devoted to manipulating the polarization, phase, amplitude and propagation direction of electromagnetic wave [1]. Meanwhile, various intriguing phenomenon have been presented in metamaterial, including optical activity [2], anomalous refraction [1], asymmetric transmission (AT) [3]. The AT phenomenon was first discovered and investigated by Fedotov et al in an intrinsically 2D-chiral metamaterial for circularly polarized waves at normal incidence [3], which belongs to the asymmetric effect in a reciprocal system. It is well known that the AT response of linearly and circularly polarized waves have been extensively reported [3-8]. Terahertz (THz) technology highly demands high-quality terahertz devices. However, the asymmetric transmission of the terahertz metamaterials is still weak, therefore, it is of great significance that here we realize high-performance AT of THz waves for more flexible polarization manipulation.

2. Asymmetric transmission of the metamaterial

The proposed metamaterial configuration is schematically illustrated in Fig. 1(a). A free-standing polyimide film with the thickness of \( t = 24 \) \( \mu \)m is embedded in two layers of metallic crossed S-shaped resonators (CSR). The two CSRs are identical in their geometry except that the back layer is mirrored along the x axis and twisted by 90° along the z axis with respect to the front one. Furthermore, two layers polyimide coating with the thickness of \( t_m = 10 \) \( \mu \)m are also added upon the outermost layer so as to protect the CSR metallic layer against external environment pollution. Each CSR layer is made from 200nm thick aluminum. Other dimensions are set as \( w = 10 \) \( \mu \)m and \( g_1 = g_2 = g_3 = g_4 = 10 \) \( \mu \)m as shown in Fig. 1(b). Conventional photolithography was employed to fabricate the sample, which consists of 300 \( \times \) 300 unit cells with a period of \( a = 60 \) \( \mu \)m. Photograph of the sample is shown in Fig. 1(c).

Figure 1: The schematic of the bilayer metamaterial. (a) The view of the front layer. (b) The view of the back layer. (c) The picture of the fabricated metamaterials.

Figure 2 illustrates the simulated transmission spectra in the CSRs chiral metamaterial. For a y-polarized wave propagating the forward (-z) direction at normal incidence, the simulated cross-polarization transmission coefficient \( t_{xy} \)
has two resonant peaks with a maximum of around 81.7% and 80% corresponding to the frequencies of 0.53 and 0.90 THz, which shows an FWHM of ~0.7 THz. Likewise, the coefficient \( t_{xx} \) exhibits a maximum of 71% with the FWHM of ~0.63 THz at around 1.42 THz for \( x \)-polarized incident wave. The two cross-polarization passbands interchange with each other along the two opposite propagations based on the reciprocity theorem. In addition, the two weak co-polarization coefficients of ~30% are exactly equal to each other regardless of the propagation directions.

Figure 2: Simulated transmission of linearly polarized wave in metamaterial.

The calculated simulated and measured AT parameters \( \Delta \) for the forward propagation are illustrated in Fig. 3. Obviously, \( \Delta x \) and \( \Delta y \) are exactly contrary to each other as expected. The \( \Delta y \) yields a maximum of 0.63/0.66 and 0.64/0.59 at around 0.53/0.50 THz and 0.90/0.83 THz as well as a minimum of -0.43/-0.34 at around 1.42/1.42 THz in the simulation and measurement, respectively. Despite of some shift in frequency and slight difference in amplitude between the simulation and experimental results stemming from imperfections in sample preparation, they are in very good agreement. Therefore, the proposed CSRs chiral metamaterial can fulfill the strong and mutually dual-band AT effect in the THz spectral.

Figure 3: Simulated and measured asymmetric transmission of the metamaterial for linearly polarized wave.

3. Conclusions

In summary, we numerically and experimentally demonstrate a high-performance AT response for normally incident linear polarized waves in multilayer chiral metamaterial with crossed-S patterns. The results indicated that a mutually independent dual-band AT response can be implemented with a maximum of 0.64 and 0.53 for \( x \)- and \( y \)-polarized waves, respectively. The proposed multilayer chiral metamaterials are beneficial in designing polarization control devices and offer considerable opportunities and flexibility for practical applications.

Abstract

Chiral plasmonic nanostructures enable the \(\leq pg\) detection of biomaterials. Sensing capabilities are associated with the chiral asymmetry of generated near fields which can be greater than circularly polarized light, a property known as superchirality. We show that chiral sensing is correlated to the thickness of a nanostructure which we reconcile with a previously unconsidered mechanism for the phenomenon. It involves the “dissipation” of optical chirality into chiral material currents through the interference of fields generated by two spatially separated chiral modes.

1. Introduction

The detection and characterisation of inherently chiral biological materials is of both fundamental and practical interest, with applications in the life and analytical sciences. The presence of chiral dielectric materials, such as biomacromolecules, within the near field region of chiral nanostructures induces asymmetric changes in the optical properties (CD, ORD and reflectance spectra) of chiral plasmonic nanostructures \cite{1} and hence can form the basis of biological sensing.

The origin of this asymmetry is undoubtedly the chiral asymmetry of the near fields which are generated around the nanostructure. This chiral asymmetry can be parameterized by an optical chirality factor \cite{2}. If the optical chirality of near fields is greater than that of equivalent CPL then it is “superchiral”\cite{2}.

In this work, we present evidence to suggest that the sensing capability of a chiral structure is dependent upon a chiral dielectric inducing asymmetry in the capacity of left and right handed structures to convert the chirality of light into chiral surface charge distributions, a process which has been referred to as the dissipation of optical chirality \cite{3}, \cite{4}.

To account for this asymmetry we propose a previously unconsidered mechanism of optical chirality dissipation based on the interference between chiral fields generated by spatially separated sources. The far field photon (energy) fluxes, which are monitored to obtain extinction spectra, have contributions due to absorption and scattering. Thus by analogy we propose the hypothesis that optical chirality, a conserved quantity like energy, is dissipated through both absorption and scattering.

1.1. Modelling Procedure

Numerical electromagnetic (EM) simulations were performed using the finite element method implemented on the COMSOL Multiphysics platform. The structures studied are periodic (periodicity = 570 nm) gammadions of varying heights \((h = 5, 30, 100 \text{ nm})\) with dimensions shown in Fig. 1. Each planar face of the structure is either intrinsically left (L) or right (R) handed thus the surface plasmons associated with these interfaces are chiral. We embed each structure in achiral and chiral dielectrics of refractive index 1.523. The approach for modelling chiral dielectrics has been described previously \cite{5}.

2. Results & Discussion

Simulations were performed with left and right circularly polarised light (LCP/RCP) incident on L and R faces of the structure (i.e. four combinations). Circular dichroism spectra were derived from the differential transmission of LCP/RCP, Figure 2 for the structures in achiral and chiral electrics.

In both the achiral and chiral media, a CD signal is observed for all gammadion thicknesses and the sign is dependent on the handedness of the planar surface light is incident upon. The 5 nm structure shows the smallest CD, an order of magnitude smaller than the 30 nm structure which in turn is 5 times smaller than the 100 nm structure. When surrounded by chiral media, the 100 nm thick structure shows the largest asymmetry, several orders of magnitude larger than in the thinner structures.

The chiral asymmetry of near fields is parameterized by the optical chirality parameter \(\mathcal{C}\). By analogy with Poynting’s theorem the following expression is derived for the optical chirality flux \(\mathcal{F}\):
\[
\frac{\partial \mathbf{c}}{\partial t} + \frac{1}{\mu} \nabla \cdot \mathbf{F} = -\frac{1}{2} (\mathbf{j} \cdot \nabla \times \mathbf{E} + \mathbf{E} \cdot \nabla \times \mathbf{j})
\]

(1)

where \(\mathbf{j}\) are material currents and \(\mathbf{E}\) are time dependent electric fields. The implication of Equation (1) is that chiralities of electromagnetic fields and electronic motion can be interconverted.

![Chiral and Achiral Dielectrics](image1)

We calculate time-average optical chirality flux \(\mathbf{F}\) for the two directions of light incidence and incident light polarization states for each of the structure thicknesses, Figure 3. It has previously been shown that \(\mathbf{F}\) is proportional to the level of circular polarization measured in the far field [4].

![Normalized Optical Chirality Flux](image2)

In all cases, the 100 nm thick structure shows the largest dissipation of optical chirality. Equation (1) states that changes in \(\mathbf{F}\) must be offset by a commensurate change in the chirality of the electron distributions which we have calculated for each of the thicknesses. Data is presented only for RCP incident on an R face for brevity; however other combinations show a similar pattern.

For \(h = 5\) and 30 nm the top and bottom faces are identical and 180° out of phase respectively (which, when time averaged would show the same distribution). Their side profiles also show very little asymmetry. In the 100 nm thick case however, the two faces show distinct charge distributions and the side profile shows a large asymmetry. Consequently, for \(h = 100\) nm the time averaged surface charge distribution acts as a significant chiral perturbation lifting the horizontal mirror plane of the gammadion.

For combinations which are related by symmetry (such as LCP incident upon a L face and RCP incident upon a R face) the \(\mathbf{F}\) spectra show equal but opposite behaviour. However, when surrounded in the chiral dielectric this relationship no longer holds.

![Surface Charge Density Plots](image3)

We propose a model for the dissipation of optical chirality flux through an interference mechanism. The model assumes that the two oppositely handed faces of a gammadion act as spatially separated sources of chiral near fields which can interfere both which each other and light incident upon the structures. The result of which is that the optical chirality flux \(\mathbf{F}\) is dependent on the phase differences between the two sources and incident light; a phase difference which can be modulated by changing the height of the nanostructure.

In achiral media, this phase difference is the same for combinations related by symmetry. In chiral media however, the presence of a chiral dielectric (molecules) has an asymmetric influence on the phase difference between the two sources of chiral fields, leading to an asymmetry in the level of conversion of optical chirality to chiral material currents. This leads to an asymmetric change in the (chir)optical properties of the plasmonic structures which manifests itself in an asymmetry in the resulting CD spectra. Thus our work provides the starting point for the development of a design framework to optimise the sensing capabilities of chiral plasmonic nanostructures.

Abstract

We report an all dielectric frequency-division multiplexing wave plate metasurface, which simultaneously possesses the function of broadband half/quarter-wave plates for transmission spectral in mid/near-infrared. The structure units of our metasurface are silicon cross-nanoblocks, which are easy to be fabricated by planar processes. Besides, at wavelengths with the function of high working efficiency half-wave plate, the structure units can be used to design variety of wavefront optical devices, such as metalens and holographic imaging.

1. Introduction

It is of critical importance to control the polarization states of light in the field of coding, imaging and communication. Linear and circular polarization are two basic states, and the wave plates, including half/quarter-wave plate, are tools achieving the mutual conversion between them. In general, wave plate Metasurfaces can conquer the disadvantages of typical wave plates, such as bulky and complicated processing\cite{1}. But it appears that most of them can only achieve a single function of wave pale either half-wave plate or quarter-wave plate, suffering from low working efficiency and narrow conversion band\cite{2, 3}. Here we experimental demonstrate an all dielectric high efficiency and broadband frequency-division multiplexing half/quarter-wave plate metasurface. It has promising application in wavefront manipulation optical elements and is easy to be fabricated.

2. Structure design

The units of our design are cross silicon nanoblocks, and by tuning the parameter of central rectangular column, the elements of general complex Jones matrix can satisfy the magnitude and phase requirements of being half/quarter-wave plate in different wavelength band, respectively.

3. Results and discussion

This metasurface, as shown in figure 1, is fabricated by simple planar processes (including lithography, deposition, and etching)\cite{4}. The transmission spectral is simulated by commercial software CST Microwave Studio and characterized by Fourier transform infrared (FTIR) spectrometer. The results appear that our metamaterial implements the function of high efficiency and broadband frequency-division multiplexing half/quarter-wave plate in mid-infrared.

Figure 1: The SEM image of the top view of fabricated frequency-division multiplexing wave plate metasurface, and the scale bar is 2 μm.

4. Conclusions

We proposed a novel design for all dielectric frequency-division multiplexing wave plate metasurface, which is easy to be fabricated by planar processes. For its high working efficiency and broad working band, our metasurfaces are highly promising for potential application in the field of communication, imaging and coding.

Abstract

We reported multi-band absorption in bilayered asymmetrically split ring metamaterials. The absorption can be coherently modulated by a second counterpropagating wave. The spectrally overlapped electric and magnetic resonances can be selectively observed based on the interaction of light with light on metamaterials. In particular, the scheme for realizing multi-band coherent perfect absorption operates from microwave to optical frequency.

1. Introduction

The field of metamaterials has been developing rapidly in recent years. Metamaterials with subwavelength elements can control properties of electromagnetic wave to realize desirable amplitude, phase-shift or polarization conversion in unconventional way that can be unachievable using traditional materials. Recently, it was demonstrated that in slabs of linear material of sub-wavelength thickness optical manifestations of birefringence and optical activity can be controlled in the coherent technique [1-9]. We will show that multi-band coherent perfect absorption (CPA) can be achieved in bilayered asymmetrically split ring metamaterials via coherently controlled technique. Such control can be applied at arbitrarily low intensities, thus arguably allowing for fast handling of electromagnetic signals without facing thermal management and energy challenges.

2. Coherent perfect absorptions

If a metamaterial of subwavelength thickness is placed at a node or antinode of the standing wave, it will lead to different results in controlling intensity and absorption of the output beams when two coherent beams named “Signal Beam ” and “Coherent Beam ” pass though it normally shown in Fig. 1(a). Generally, the nodes and antinodes of the standing wave are defined in the electric field. An electric antinode corresponds to the magnetic node, or vice versa. Firstly, if the ultrathin film is placed on electric nodes (corresponding to the phase difference of $\phi = 180^\circ$ between two input beams), the metamaterial is transparent to both counter-propagating incident beams. In this case, the ASRs experiences no electric excitation, however, strong magnetic excitation in ASRs is twice larger than the case of one beam illumination. Secondly, two output beams totally vanish when the film is placed at an antinode (corresponding to the phase difference of $\phi = 180^\circ$ between two input beams). In this case, twice electric excitation of the ASRs compared to one beam illumination and no magnetic excitation happen. When modulating phase of the coherent beam, the intensity of the output beam changes correspondingly. The structures of bilayered asymmetrically split rings (ASRs) are shown in Fig. 1(b). The ASRs are periodic along the x and y directions with a lattice constant of $d = 15\text{mm}$. The ASRs etched from the copper cladding can be fabricated on either side of the FR4 printed circuit board with a thickness $t = 1.5\text{mm}$. Each ASR consists of two copper wire arcs with open angles of $\alpha = 140^\circ$ and $\beta = 160^\circ$. The inner radius of the ASRs is $r = 5.6\text{mm}$ and the wire width is $w = 0.8\text{mm}$. Each stereo ASR dimer consists of two spatially separated ASRs, which are structurally identical.

Figure 1: (a) The principle of coherent perfect absorption. (b) Snapshots of unit cells of bilayered metamaterials consisting of asymmetrically split rings (ASRs).

Based on full-wave simulations using a three-dimensional Maxwell finite element method solver (COMSOL Multiphysics), the absorption spectra are shown in Figure 2. In the simulations, the copper was treated as a perfect electric conductor and a permittivity $\varepsilon = 4.05-i0.05$ was assumed for the lossy dielectric substrate. The bilayered metamaterial exhibits triple-band absorption in the frequency range from 4 GHz to 8 GHz for an $x$-polarized input beams illumination while it exhibits double-band
absorption in the frequency range from 8 GHz to 12 GHz for a y-polarized input beams illumination along the z direction, respectively. The both input beams are x- or y-polarized in the coherent case. The intensity of the beam is defined as 1 in the case of one beam illumination while the intensities of two input beams are defined as 0.5 in the coherent case. Obviously, the bilayered metamaterial reveals distinct absorption peaks at electric nodes and anti-nodes of the standing wave. More importantly, three absorption bands can be selectively switched on/off at lower frequencies and other two absorption bands occur at higher frequencies, depending on the phase difference of two input beams. Figure 2 shows the absorption spectra surface current density of the bilayered metamaterial. In Figure 2 (a) and (b), electric and magnetic responses can be selectively enhanced or eliminated with the phase difference varies for same polarization of input beams. The experimental setup is shown in Fig. 2(c) and the measured coherent absorption spectra are given for x-polarized wave in Fig. 2(d).

Figure 2: Simulated coherent perfect absorption of metamaterials as a function of frequency and phase difference in for (a) x- and (b) y-polarization. (c) Experimental setup. (d) The measured results for x-polarized wave.

3. Conclusions

In summary, we numerically and experimentally demonstrate polarization-sensitive coherent perfect absorbers in bilayered metamaterial based on the full wave simulations. The bilayered metamaterial are constructed by asymmetrically split rings. The polarization-sensitive coherent perfect absorption can be realized depending on electromagnetic mode switching effect, i.e., the in-phase electric resonances are only coherently excited at an electric antinode while the out-of-phase magnetic resonances only at a magnetic antinode. We also measured three selected frequencies when x-polarization waves incident. The coherently controlled metamaterials will be promising candidates for designing selective multiband absorbers and this technique offers considerable flexibility of operating at any frequencies from the microwave to optical range and provides an opportunity to realize coherent data processing network and recognize the nature of electromagnetic modes.

Abstract
We propose a compact photonic device that presents an improved and controlled emissivity on specific tight infrared wavelengths intervals, consisting in an infrared thermal source and a metasurface absorber. The source is composed of 200nm thick chromium layer in meander configuration, the line width is 100µm and the resistor area is 1mm². The metasurface is tailored to attain almost perfect absorption on infrared wavelengths intervals specific for gases that may be found in industrial infrastructures like methane or carbon dioxide.

1. Introduction
The most frequent toxically gas molecules present in industrial infrastructures are: methane (CH₄), carbon oxides (CO₂, CO), azote oxides (NO₂, NO), ozone (O₃), formaldehydes (H₂CO/CH₂O), etc. The absorption wavelengths of each one of these gases are close to one another, therefore, for work security and health purposes it is necessary to develop highly sensitive sensors for tight IR wavelength intervals [1]. Our objective is to develop IR sources with high emissivity control, in order to obtain sensors for each specific gas. The emission control is achieved by tailoring a metamaterial to attain approximatively total absorption for a wavelengths intervals with the peck at the maximum absorption of the specific gas.

Metamaterials have specific properties such as negative permittivity, permeability and refraction index, allowing them to be used for beam shaping or for realization of a perfect absorber for photonic and optoelectronic applications. With a specifically tailored metamaterial one can achieve an absorption value close to 1 in any frequency domain [2, 3]. Furthermore, Kirchhoff law states that the emissivity of a material is equal to the absorption at equilibrium [3] which makes this type of structures ideal for our designated application.

2. Model and discussion
We develop a highly emissivity control IR source consisting in an infrared thermal source and a metasurface absorber, which can be integrated in gas detection systems for industrial infrastructures. In figure 1 one can observe the diagram of our proposed system with the IR source and two Fresnel lenses, one to collimate the source emission and one to focalize the radiation on the commercial detector.

Fig.1 Diagram of the gas detection system

The IR thermal source consists in a resistor with a 200 nm thick chromium layer in meander configuration. The line width of the meander is 100 µm and the resistor area is 1 mm².

In figure 2 we represent the diagram of the proposed resistor and the black body emission distribution calculated for 550K temperature corresponding to a maximum emission in medium IR.

Fig 2. a) IR thermal source; b) Calculated blackbody radiation spectrum at 550K temperature
The fabrication of the meander source is realized by classical microfabrication techniques such as: sputtering for metal deposition (chromium for the meander resistor and gold for the contact pads); photolithography to pattern the meander and contact pads, and lift-off to obtain the final metal structure. For the photolithography step we use three photolithographic masks designed with CleWin software: i) the first one is designed to pattern the meander resistor and the metallic contact pads; ii) the second one is used to remove the thin gold film from the meander area, this layer being utilized only on the contact pads; iii) the third one is employed in micro-patterning the gold pillars metasurface. In order to achieve the selectivity of the IR source, we proposed an absorber metasurface place on top of the meander resistor. This metasurface is composed of gold pillars micro-patterned on an amorphous silicon thin layer. The aim of this pillars array is to filter a specific tight wavelengths interval. In figure 3 one can observe the configuration of the tailored metasurface pattern on top of the IR thermal source.

Fig. 3 Diagram of the developed source with controlled emissivity

3. Conclusions

We calculated, fabricated and measured a thermal IR source based on a meander chromium resistor. Also, an IR absorber metasurface was fabricated using photolithography and lift-off method. In order to obtain an IR source with controlled emissivity we decided to place the absorbent metasurface on top of the meander resistor source. In the first instance we considered as insulator layer between the two structures a SiO₂ deposited by RF-Sputtering. After the deposition of the amorphous silicon substrate necessary for the absorption configuration we observed the exfoliation of the SiO₂ due to the fact that was deposited on a 3D profile of 1µm height. In order to resolve the insulator adherence problem we will replace the SiO₂ insulator with Al₂O₃ obtaine by Atomic Layer Deposition.

The radiance spectra were measured using an OL750 spectroradiometer system from Gooch&Housego in configuration for emittance measurements. The system is composed by double monochromator with IR diffraction gratings and 5 mm slits/apertures at the entrance, middle and exit ports, a collimation optical system, and a standard InSb detector with high sensitivity in the spectral range 1 - 5.5 microns.

Abstract
We demonstrate the fabrication and characterization of an array of plasmonic metamaterial nanostructures based on asymmetric split H (ASH) resonators on a zinc selenide substrate that produce plasmonic resonances matched with the molecular vibrations of an organic material. Estrogenic hormones; 17β-Estradiol (E2) and Estrone (E1) were chosen as analytes for coupling with the plasmonic resonances. The experimental results show there is a good match with the molecular bond resonances of the C-H, C=O and C=C observed in estrogen and we have also shown that it is possible to differentiate the molecular bond resonance spectrum of E2 in a mixture with E1.

1. Introduction
Surface enhanced infrared absorption (SEIRA) spectroscopy is widely used in sensing applications for environmental monitoring and clinical diagnostics. By applying an organic analyte on the metal-air interface of the metamaterial structures, the characteristic molecular vibrations of the analyte material can be detected and enhanced if they coincide with the plasmonic resonant wavelengths. The resultant red-shift in the plasmonic resonance can be measured and used to calculate the sensitivity for use as an optical biosensor [1]–[3]. In this paper, we show that analytical techniques based on the plasmonic properties of gold nanostructures, to be eventually used for rapid environmental analysis. We present the plasmonic metamaterial nanostructure arrays of asymmetric split H (ASH) resonators that have been optimized to produce plasmonic resonances that match the resonant molecular vibrations of a biological material [4]. ASHs were designed for sensing organic molecules of two selected estrogens, 17β-Estradiol (E2) and Estrone (E1). Also, the target is to identify the common (O-H, C-H and C=C bonds) and different (C=O bonds) molecular bond resonances for the two estrogen molecules in the mid infrared (IR) wavelength range (2 to 8 μm).

Estrogen is one of the endocrine disruption compounds (EDC) that has been discovered regularly in various water sources. It has been found at concentrations as low as 1 to 10 ng/l due to its poor solubility. EDC contamination is potentially found in food, the water supply and consumer products and can lead to adverse health effects, particularly with regard to reproduction and the bodily development process. EU government has suggested monitoring the issues in the water source contamination because of the potential harm to the aquatic species, such as alterations of sexual development and inter-sex species (e.g. feminization of male fish) [5]–[8]. E2 is a steroid hormone and a major sex hormone in females that functions in the development of reproductive systems and other physical features. E1 can be found after the menopause in the female body.

2. Plasmonic Metamaterial Nanostructures
We have fabricated ASH arrays using electron beam lithography on a zinc selenide (ZnSe) substrates. This transparent and high refractive index material allows detection in the longer wavelength range of 600 nm to 21 μm. The ASH nanostructures were formed with asymmetric vertical dipoles and cross bar dipoles. Scanning electron micrograph (SEM) images of ASHs are shown in Figure 1. The two different sizes of ASH labelled as ASH₁ and ASH₂, with ASH₁ arm length (L₁ and L₂) varying between 450 nm and 800 nm and ASH₂ arm lengths between 1.2 μm and 1.6 μm were chosen for the mid-IR region. When the incident wave is polarized along y-axis, parallel with the vertical asymmetric arms, the basic structure exhibits two plasmonic resonance peaks, due to the asymmetry of the arm-lengths.

Figure 1: Scanning electron micrograph of (a) an array and (b) one-unit cell of asymmetric split H (ASH) resonators.

3. Optical Sensing of estrogenic hormones
Table 1 shows that E2 and E1 exhibit a strong molecular vibration of the C-H bond at wavelengths between 3.40 μm and 3.49 μm. Carbon to carbon double bond stretching (C=C) also occurs in the wavelength range from 6.30 μm to 7.00 μm. The significant chemical difference between E1 and E2 lies in a single bond, which is a C-OH in E2 and the C=O bond in E1. Molecular vibrations for this C=O bond
occur at wavelengths of 5.79 µm and 5.85 µm. The plasmonic nanostructures were coated consecutively with a thin layer of E1 in absolute ethanol (1mg/ml), a thin layer of E2 (1mg/ml) and various mixtures of E2 and E1, all with a total estrogen concentration of 2mg/ml but different E2:E1 ratios. The samples were left to evaporate overnight before the measurements were performed - by which point the estrogen had crystallized on top the resonators. The ASH structures were tuned to resonate at the wavelength of the C-H bonds of interest and found good matches with ASH1 resonant using the length sizes of L₁ = 800 nm, L₂ = 600 nm. While for ASH2 the sizes of L₁ = 1.5 µm and L₂ = 1.2 µm demonstrated close matches to the two double bond resonances.

A substantial resonance red-shift was produced between the positions for the uncoated ASHs and the corresponding positions when the ASHs were coated with estrogen. The resonance shifted 220 nm from the initial position of the uncoated ASHs. For instance, the resonant wavelength for ASH2 was shifted from 5.46 µm to 5.68 µm and from 6.39 µm to 6.63 µm. When the mixture of E2 and E1 was deposited on the nanostructures, transmittance resonance (Figure 2 (a) and (b) in red lines) produced a small feature at a wavelength of around 5.79 µm as shown for ASH2 in Figure 2(b), that matched the vibration of the C=O bond present in E1. The vibrational signal enhancement of estrogen deposited on nanostructure arrays could be quantified by comparison with the deposition of the estrogen mixtures on the bare ZnSe substrate (green line in Figure 2). Baseline corrections were used to extract the peak strengths of the various molecular vibrations. We found that the molecular bond resonances are typically five times larger, easily visible and differentiated the ASHs, as compared with those deposited on bare substrates. Additionally, we could quantitatively separate out the contribution of each type of estrogen.

Figure 2: Plots transmittance resonances from the (a) ASH1 and (b) ASH2 with the mixture of E2 and E1 (50:50) show the vibrational resonances and the baseline corrected in the fingerprints of O-H, C-H, C=O and C=C bonds

### 4. Conclusions

In conclusion, we tuned the geometry of the asymmetric split H resonators which can be utilized to enhance the molecular C-H, C=O and C=C bond resonances of E2 and E1. The plasmonic resonance were red-shifted towards longer wavelengths through the deposition of organic materials on the nanostructures. This study will support the development of plasmonic biosensors that can be used to detect and differentiate the presence of small amounts of different organic molecules with lower detection limits.

Abstract

The research work carried out sheds light on wave propagation in different configurations of mechanical metamaterials with vibration energy harvesters.

1. Introduction

Understanding the dynamics of periodic structures has been a key area of research for the past few decades due to its complexity and potential to be exploited efficiently. Periodic structures are artificial (man-made) structures which possess specific characteristics that are not found naturally and as the name suggests, they have an element of periodicity in them.

Periodic structures or periodicity can be found in many mechanical designs and this characteristic can be exploited to harvest vibration energy and power electronic devices. These structures or mechanical designs can be referred to as mechanical metamaterials.

The theoretical and experimental aspects of wave propagation and harnessing vibrational energy to efficiently generate power have received significant attention in terms of research as they carry an immense amount of scope.

One (1 degree of freedom) and two (2 degree of freedom) dimensional mechanical metamaterials with vibration energy harvesters were modelled in SOLIDWORKS. The various configurations addressed in the paper include 1D and 2D metamaterials with monoatomic and diatomic unit cells and the piezoelectric shunt circuit comprising of a resistor and inductor and just a resistor.

Mathematical models were formulated and dispersion relations (equations in terms of the natural frequency) for different configurations were obtained. Two different approaches to obtain the dispersion relations have been discussed. Both the approaches involve the implementation of the solution for propagating waves. One approach involves the utilization of non-dimensional parameters and the other involves the employment of the state space method. The two approaches discussed were used to compute wavenumber dependent natural frequencies as either complex and non-dimensional or dimensional values. The dispersion equations obtained were exploited to compute the phase velocities and group velocities.

2. Mechanical Designs

Figure 1 shows an image of one of the 1D (1 dof) monoatomic unit cells. As the unit cells are monoatomic, they consist of only 1 mass. The assembly of the square block, spring, dampener, two beams, green coloured piezoelectric patches and shunt circuits is designated as a unit cell and can be clearly seen in the figure. A combination of the unit cells forms the mechanical metastructure or metamaterial.

Figure 2: An image of one of the 2D monoatomic unit cells
Figure 2 shows an image of one of the 2D (2 dof) monoatomic unit cells. The assembly of the square block, two springs, two dampeners, beam, green coloured piezoelectric patches and shunt circuits is designated as a unit cell and can be clearly seen in the figure.

3. Mathematical Models

Mathematical models for different configurations of the 1D and 2D cases shown in figures 3 and 4 have been presented and the wavenumber dependent natural frequencies have been obtained by implementing the solution for propagating waves in the governing equations.

4. Examples of Results

Dispersion curves have been plotted using MATLAB for each of the configurations presented. An example of a 1D and 2D dispersion curve is illustrated in figures 5 and 6 respectively. Study was also performed to understand the behaviour of the dispersion curve as the values of the constants involved in the dispersion relation are varied.
Tunable high-birefringence metamaterial nanoparticles dispersed in water

Abstract

We present the design, fabrication, and characterization of birefringent multilayer metamaterial particles (MMP) at nanoscale, dispersed in aqueous solutions. We have designed MMP using the effective medium theory (EMT) and the finite element method (FEM). Our top-down fabricated MMP feature optical properties that are tunable through changes in the composite material filling ratio. The MMP are also chemically stable, highly uniform, and ready for volume production and wide range of applications such as optical torque wrench (OTW).

1. Introduction

Nanoparticles made of various materials have been widely used in diverse fields of science and engineering. However, their application has been fundamentally limited by the fixed material properties of the naturally given materials. For example, the OTW allows the direct application and measurement of both torque and angle on single molecules or rotary nanomotors. To maximize the applicable torque in an OTW, it is preferable to use probe material with large birefringence. However, naturally available highly-birefringent materials also tend to exhibit a large refractive index Fig. 1(a), which severely limits the trappable probe dimension due to the large scattering. To overcome this kind of conflicting requirements for material properties, tailored metamaterials can provide solutions. Here, we suggest dielectric multilayer metamaterial as a probe material for OTW. Unlike most of the conventional OTW probe materials, these MMP can have large birefringence at only moderate refractive index to expand the range of 3D-trappable particle dimensions. Moreover, by changing the filling ratio of the composed materials in fabrication, the optical properties of such OTW probe can be adapted to each specific application.

2. Birefringent metamaterial nano-particle

2.1. Design

An artificial material with optical birefringence is obtained using multilayers. With a succession of low and high index dielectric layers, with sub-wavelength thicknesses, one can mimic birefringence. To anticipate the optical response of the multilayer structure, the EMT is used. The effective optical permittivity of the structure can be approximated by a tensor:

\[
\begin{bmatrix}
\epsilon_\parallel & 0 & 0 \\
0 & \epsilon_\parallel & 0 \\
0 & 0 & \epsilon_\perp
\end{bmatrix},
\]

where \(\epsilon_\parallel\) and \(\epsilon_\perp\) are the permittivity component parallel and perpendicular to the interface of the multilayer stack, respectively. The values of them are given by

\[
\epsilon_\parallel = f\epsilon_1 + (1-f)\epsilon_2, \quad \epsilon_\perp = \frac{1}{f\epsilon_1^{-1} + (1-f)\epsilon_2^{-1}},
\]

where \(f\) is the material filling ratio in a unit cell and \(\epsilon_1\) and \(\epsilon_2\) are the permittivity values of the two consisting materials, respectively.

The consisting dielectrics chosen here are SiO₂ and Nb₂O₅. In Fig. 1(b) the effective refractive indices of SiO₂/Nb₂O₅ multilayer stack as functions of filling ratio are shown. It can be seen that the \(n_\parallel\) is a straight line as a function of filling ratio \(f\), while the \(n_\perp\) is a concave curve, being always smaller than \(n_\parallel\). Effectively the multilayer metamaterial behaves as a negative uniaxial birefringent material with \(n_e < n_o = n_\perp\).

The resulting optical properties of such birefringent material are tunable. The MM can achieve relatively low index of refraction from 1.5 to 2.2 and achieve a large birefringence topping above 0.15 (in comparison with the parameter of the conventional crystalline materials used as OTW probes see Fig. 1(a)).

2.2. Fabrication

The square cuboids nanoparticles (Fig. 1(c)) are fabricated using a top-down fabrication process. First, a 100 nm sacrificial chromium (Cr) layer is deposited on the silicon wafer. Then in total 300 nm or 400 nm thick SiO₂/Nb₂O₅ multilayer films are deposited using reactive magnetron sputtering. Resist is spin-coated, followed by electron-beam lithography for patterning the particle shape with aspect ratios

\[
\begin{bmatrix}
\epsilon_\parallel & 0 & 0 \\
0 & \epsilon_\parallel & 0 \\
0 & 0 & \epsilon_\perp
\end{bmatrix},
\]

where \(\epsilon_\parallel\) and \(\epsilon_\perp\) are the permittivity component parallel and perpendicular to the interface of the multilayer stack, respectively. The values of them are given by

\[
\epsilon_\parallel = f\epsilon_1 + (1-f)\epsilon_2, \quad \epsilon_\perp = \frac{1}{f\epsilon_1^{-1} + (1-f)\epsilon_2^{-1}},
\]

where \(f\) is the material filling ratio in a unit cell and \(\epsilon_1\) and \(\epsilon_2\) are the permittivity values of the two consisting materials, respectively.

The resulting optical properties of such birefringent material are tunable. The MM can achieve relatively low index of refraction from 1.5 to 2.2 and achieve a large birefringence topping above 0.15 (in comparison with the parameter of the conventional crystalline materials used as OTW probes see Fig. 1(a)).

2.2. Fabrication

The square cuboids nanoparticles (Fig. 1(c)) are fabricated using a top-down fabrication process. First, a 100 nm sacrificial chromium (Cr) layer is deposited on the silicon wafer. Then in total 300 nm or 400 nm thick SiO₂/Nb₂O₅ multilayer films are deposited using reactive magnetron sputtering. Resist is spin-coated, followed by electron-beam lithography for patterning the particle shape with aspect ratios.
Figure 1: (a) The average refractive index of the most common birefringent crystals materials and their index difference; (b) The effective index and index difference of SiO$_2$ & Nb$_2$O$_5$ multilayer structure as a function of material filling factor. (c) MMP trapped in the focus of a beam. (d) Scanning electron microscopy (SEM) image of fabricated MMP.

(AR) of 3-5. After development, a Cr hard mask layer is deposited on top using sputtering. For the lift-off process, adhesive tape is used to remove most of the top Cr layer, and then the resist is removed in a resist stripper solution. The substrate is soaked in a chromium etchant to remove the remaining Cr etch masks and dissolve the underlying sacrificial Cr layer. Finally, the particles are released from the substrate (Fig. 1(d)) and become free-floating, by immersing the substrate into de-ionised water.

2.3. Modeling

The FEM is used to calculate the optical response of the free floating MMP in water. Each square cuboid particle is enclosed by water, and the water domain is terminated by a perfectly matched layer. The scattering of the particle is calculated under the background illumination of a highly focused Gaussian beam. The optical force and torque is retrieved by integrating Maxwell stress tensor on a virtual sphere surrounding the particle. [1]

The viscous drag coefficient in water is also obtained, using the computational fluid dynamics calculations. The solutions of Navier-Stokes equations result in force and torque as a function of the speed of medium flow, from which the linear (rotational) drag coefficients can be extracted.

3. Results

Several batches with different dimensions (W=300-4000 nm, AR=3-5) and filling ratios (0.3-0.5) were fabricated and measured. The OTW experiments were conducted with a home-built system.[2] It shows that the MMP are trappable and can be rotated. The particles within the same batch behave very consistently (within 10% relative standard deviation). This confirms that our particles are very uniform and with controllable optical properties.

The measured linear and angular stiffnesses agree well with the trend of the calculation outcomes, being 60% of the calculated values, probably due to the aberrations of the optical system that are not considered in the calculations.

The MMP exhibit almost the same optical properties as like calcite (Fig. 1(a)) but do not become dissolved in water unlike calcite. The well-defined high-birefringence of MMP is evidenced by the torque measurements. A typical trace of transferred torque as a function of polariisation rotation frequency is shown in Fig. 2. It can be clearly seen that as the polarisation rotation increases, the amount of transferred torque also increases linearly. After the maximum transferable torque takes place, the particle can no longer follow the rotation of the polarisation and hence the amount of transferred torque drops. These particles can achieve > 10 nN·nm torques at the rotational frequencies of a few kHz (at 92 mW input laser beam power) in water.

![Figure 2](image_url)

Figure 2: A typical frequency sweep trace measurement for the MMP. The MMP with W = 400 nm and filling ratio 0.3 is shown here. The three traces (B3, B4, B5) are obtained from MMP with different aspect ratios (AR = 3, 4, 5).

4. Conclusions

We have designed, fabricated and characterised free-floating birefringent nanoscale metamaterials based on dielectric multilayers. These particles have been successfully demonstrated in an OTW set-up. Thanks to their adaptable optical properties and free-floating nanoparticle formation, they have a large potential of applications in diverse field of science and engineering in which nanoparticles are being used.

Abstract

High contrast gratings (HCGs) are an attractive alternative to Distributed Bragg Reflectors (DBRs) as highly reflective mirrors for Vertical-Cavity Surface-Emitting Lasers (VCSELs). In our group we investigate the use of monolithic HCGs (MHCGs) to reduce the vertical thickness and simplify the epitaxial structure of VCSELs. In this work we present power reflectance measurement for MHCGs and we discuss properties of these diffraction grating structures.

1. Introduction

Vertical-Cavity Surface-Emitting Lasers (VCSELs) have numerous advantages in comparison to commonly used Edge Emitting Lasers (EELs): single-longitudinal-mode operation, low threshold current, modulation at very high frequencies, and on-wafer testing which is allowed by the device’s vertical geometry. Due to their small relative gain VCSELs require mirrors with very high power reflectance (close to unity). Usually, Distributed Bragg Reflectors (DBRs) are employed as mirrors. To fabricate proper DBRs we have to use two materials, which meet the following conditions: a high contrast of refractive indices; the lowest possible mismatch of the lattice constants and thermal expansion coefficients; and low thermal and electrical resistance. For now only GaAs-based VCSELs are commercially available at large volumes. In other material systems (especially nitride and phosphide based) problems with materials for DBRs are the main obstacle to fabricate efficient and high performance VCSELs.

To overcome the limitations of semiconductor DBRs other than those based on AlGaAs for emission at 600-1100 nm, High refractive index Contrast Gratings (HCGs) can be employed. HCGs are diffraction gratings with subwavelength period and thickness made of materials of high, in comparison to the surroundings, refractive index [1]. HCGs can be realized in different ways, for example as a membrane suspended in air [1], as a grating put on a cladding layer [1], as a zero-contrast grating [2], or a monolithic HCG (MHCG) made of the same material as cladding layer [4].

In our group we investigate MHCGs as mirrors for VCSELs. As we showed in [5], MHCGs can be made of any semiconductor material with a refractive index higher than 1.75. In [6] we showed a first MHCG VCSEL, which is based on GaAs and emits around 980 nm. Recently S. Kim et al. reported also first MHCG-cavity polariton laser [7]. In this paper we discuss different designs of MHCGs, and their optimization and fabrication. We also present power reflectance measurements for GaAs MHCGs.

2. MHCG: optimization and fabrication

To investigate the properties of MHCG we employed a computer model developed by the Photonics Group from Lodz University of Technology. This is a three-dimensional fully-vectorial model, which is based on the Plane-Wave Admittance Method (PWAM) described in [8]. To find the optimal parameters of an MHCG we consider power reflectance as a three dimensional function of the grating’s parameters: 1) period of the grating; 2) height of stripes; and 3) width of stripes (see figure 1).

Figure 1: Schematic structure of a monolithic high contrast grating mirror, where $L$ is the period of the structure, $h$ is the height and $a$ is the width of stripes. The arrow shows the direction of incident light.

As we showed in [6] numerous sets of MHCG spatial parameters which provide high power reflectance can be found for different materials. Also MHCGs can be designed for transverse electric (TE) and transverse magnetic (TM) polarization of incident light. For TE polarization the electric field is perpendicular to the grating stripes and for TM electric field is parallel to the grating stripes.

To fabricated an MHCG we employ electron-beam lithography (EBL) and Inductively Coupled Plasma Reactive Ion Etching (ICP-RIE). Example SEM photographs of an MHCG fabricated at the Technical University of Berlin is shown in Figure 2. EBL and ICP RIE enable us to fabric-
cate MHCG with a broad range of parameters with tens of nanometers of precision. However, the spatial parameters of a fabricated MHCG can be slightly different than planned.

![Example SEM photographs of a top view (left) and of a cross-sectional view (right) of an MHCG.](image)

**Figure 2: Example SEM photographs of a top view (left) and of a cross-sectional view (right) of an MHCG.**

### 3. Power reflectance of MHCGs

We fabricated a set of GaAs MHCGs with different spatial parameters. All MHCGs are designed for TM polarization and have the same period $L = 605$ nm and height of stripes $h = 400$ nm. We varied the fill factor $F$, which is the ratio of the grating stripe width divided by the grating period. We obtained different values of fill factor by changing the electron beam lithography (EBL) writing mask pattern or by varying the EBL exposure dose.

In Figure 3 one can see the setup, which we used to measure power reflectance of fabricated MHCGs. Measurements were taken for wavelengths between 900 and 1040 nm. In Figure 4 one can see measured power reflectance spectra in comparison with calculated spectra for three different MHCGs with fill factors of 0.37, 0.41 and 0.47.

![Experimental set up employed to to perform the power reflectance measurements of the MHCGs.](image)

**Figure 3: Experimental set up employed to to perform the power reflectance measurements of the MHCGs.**

The agreement between theory and experiment is quite good. For both one can notice, that power reflectance spectra move in the direction of longer wavelength for larger fill factors. The difference between the simulated and the measured results is most likely due to processing imperfections.

### 4. Summary

MHCGs can have very high power reflectance and replace DBRs in VCSELs. For now we are able to fabricate MHCGs of power reflectance of about 80%, MHCGs with this power reflectance should be supported with around 7 pairs of DBRs to reach 99% power reflectance of the composite out coupling mirror of a VCSEL. This could reduce the vertical height of VCSELs by 30%. The ultimate goal is to eliminate the top DBR completely and fabricate VCSELs with MHCG-only top out coupling mirrors characterized by power reflectance exceeding 99%. This can be achieved by further optimization of the MHCG’s design and processing.

Frequency Shift of Light in Highly Dispersive Time-Varying Metasurfaces

Jagang Park¹, Hyukjoon Cho¹, Hyun Sung Park¹, and Bumki Min*¹

¹Department of Mechanical Engineering, Korea Advanced Institute of Science and Technology, Daejeon, Republic of Korea
*corresponding author, E-mail: bmin@kaist.ac.kr

Abstract
This work suggests a new class of time-varying metasurface for efficient frequency shift of light. The proposed metasurface is properly designed to exhibit highly dispersive phase responses, so that a dynamic change in the spectral response gives a rapid phase sweep of transmitted light, which directly corresponds to a frequency shift. The frequency-converted waves through the metasurface are analysed based upon a temporal coupled-mode formalism. Furthermore, we compare our time-varying metasurfaces with the conventionally studied angular Doppler effect.

1. Introduction
Instead of the common usage of nonlinear materials for frequency conversion of light, time-varying media can be alternative candidates in the cases when the light intensity is weak or a suitable nonlinear material for the target frequency has been undiscovered. Since the first speculation by Morgenthaler [1], his concept of the velocity modulation has been implemented on a variety of platforms to observe frequency conversion of light, for example, by dynamically modulating the resonance frequency of an optical cavity or the effective refractive index of an optical waveguide [2-4]. Most of attempts exploited adiabatic evolution of the optical modes inside the media, therefore relatively high conversion efficiency and large frequency shift were achieved.

Recently, the idea of frequency conversion with time-varying media has been expanded to the field of metasurfaces, where the new spectral components were generated by sudden merging of meta-atoms [5]. However, the sudden change in the resonance mode breaks the adiabaticity, and provides only a much smaller conversion efficiency compared to adiabatic cases.

Here, we suggest an adiabatic version of time-varying metasurface that can promise high conversion efficiency within a deep subwavelength thickness, by dynamically sweeping the phase of light. We show that a continuous and rapid phase sweep can be realized by tailoring a particular transmission spectrum with multiple meta-atoms, and modulating their resonance frequencies in time. We analyse the dynamics of the time-varying metasurfaces based upon a temporal coupled-mode formalism, and calculate exact solutions for simple cases. Furthermore, we compare the similarities and differences between the proposed time-varying metasurface and the conventionally studied angular Doppler effect, which is a frequency shift induced by a mechanically rotating half-wave plate [6].

2. Result
First, we develop the highly dispersive metasurface, whose unit cell consists of multiple anisotropic resonators. The transmission is analysed with temporal coupled-mode formalism. Second, a temporal modulation of the resonance frequencies is assumed, and the frequency-shifted spectrum is presented. Lastly, the behaviour of the time-varying metasurface is compared with the conventional angular Doppler effect.

2.1. Design of the metasurface and its static response

Figure 1: (a) Incoming and outgoing ports are depicted on both sides of the metasurface (gray rectangle). The ports are circular polarization-dependent. The schematic illustrations of the metasurfaces with (b) a single anisotropic resonator and (c) multiple anisotropic resonators.

Based on the configurations depicted in Fig 1, the temporal coupled-mode equations can be written as follows.

\[
\frac{da}{dt} = (\Omega(t) - \Gamma)a + K^T s_+
\]  

(1)

\[
s_- = Cs_+ + Da
\]  

(2)

Because the resonators are linearly anisotropic while the ports are established with the circular polarization basis, the coupling coefficient between the ports and the q-th resonator.
\[ d_q = j \sqrt{\frac{\gamma}{2}} \left( \begin{array}{cccc} e^{i\phi_q} & 0 & 0 & 0 \\ 0 & e^{-i\phi_q} & 0 & 0 \\ 0 & 0 & e^{i\phi_q} & 0 \\ 0 & 0 & 0 & e^{-i\phi_q} \end{array} \right) \]  \hspace{1cm} (3)

For the case of the proposed metasurface as shown in Fig. 1c, the angles of the resonators are set to be 0, \( \pi/2 \), \( \pi \), 3\( \pi/2 \). Therefore the coupling matrix can be specified as below.

\[ D = j \sqrt{\frac{\gamma}{2}} \left( \begin{array}{cccc} 1 & j & -1 & -j \\ 1 & -j & -1 & j \\ 1 & j & -1 & -j \\ 1 & -j & -1 & j \end{array} \right) \]  \hspace{1cm} (3)

As clearly shown in Fig. 2, the metasurface exhibit high flat-top transmission window, in which the phase forms a steep gradient.

![Figure 2: Static cross-polarization transmission response of the proposed metasurface](image)

2.2. Time-varying responses

As a representative example, we assume that all the resonance frequencies of the meta-atoms are linearly varying in time.

\[ \Omega(t) = \Omega_0 + at \]  \hspace{1cm} (4)

For this case, the exact solution for the outgoing waves can be obtained, and the spectrum of the polarization-converted transmitted wave is shown in Fig 3.

![Figure 3: Transmission spectrum of the time-varying metasurface](image)

2.3. Comparison with angular Doppler effect

The amount frequency shift and the conversion efficiency depend of the rate of resonance shifting, similar as they depend on the angular velocity in the angular Doppler effect.

![Figure 4: Transmission spectra of polarization-converted waves through (a) the time-varying metasurface and (b) the mechanically rotating metasurface](image)

3. Discussion

The concept of resonators and metasurface can be applied over a broad frequency range from microwave to visible in principle. For a microwave at a target frequency of 10 GHz, the resonance frequency of the time-varying metasurface should be changed in a nanosecond scale to observe the frequency shift of 1 GHz. However, 1 GHz frequency shift corresponds to 30 billion rpm in the angular Doppler effect. If this metasurface is used in visible, the equivalent angular velocity becomes much higher.

4. Conclusions

We theoretically investigated a new way to shift the frequency of light with time-varying metasurfaces. The highly dispersive metasurface was suggested for efficient frequency shift and its response was analysed with temporal-coupled-mode equations. The amount of frequency shift and the conversion efficiency can be controlled with the rate of change in the resonance frequencies.

Abstract
Scaling of resonance structures and resonance frequencies therein has always been important for applications. We demonstrate that although the classical scaling rule does not work for open resonance structures, the effect of permittivity of substrate/spacer on resonance frequencies can be quantified. Examples of the scaling are presented for few-layer metasurfaces and miniature microwave antennas.

1. Introduction
The interest to the scaling problem has recently been stimulated by demand in subwavelength resonators for radiation and transformation of electromagnetic waves. The general approach to the scaling assumes that a proportional change of all geometrical parameters of a resonance structure leads to an inversely proportional change in resonance frequency, i.e., \( f \propto a^{-1} \), where \( a \) is a geometrical size. The said above is true for both open resonance structures and closed resonance structures (cavities), assuming the used materials to be weakly dispersive and weakly lossy. In the microwave cavities, change in permittivity of the filling medium, \( \varepsilon \), leads to the classical scaling rule for resonance frequencies, \( f \propto \varepsilon^{-1/2} \), while all sizes are fixed. In open resonance structures, including the ones based on subwavelength resonators, results of changing \( \varepsilon \) of the substrate/spacer material cannot be quantified without a detailed numerical study. This occurs due to the fact that there is no definite boundary of the volume occupied by the resonance field. The main purpose of this work is to obtain examples of quantification of the scaling, which is possible due to variations in \( \varepsilon \) of the substrate/spacer material in open structures comprising subwavelength resonators.

2. Examples of Scaling
We consider two types of open microwave resonance structures, which are used (i) in polarization manipulation and (ii) in miniature microwave antennas. The first one represents few-layer metasurfaces based on two coupled arrays of U-shaped subwavelength resonators, one of which is rotated by 90°, see Fig. 1, inset. The second one represents the metamaterial inspired miniature antennas with split loop(s), as shown in Fig. 2, inset.

2.1. Coupled Arrays for Polarization Manipulation
The structure in Fig. 1(a) generally contains five layers: two outer arrays, two spacers, and a centered metallic grid. The physical mechanism of polarization conversion has been discussed in [1]. For a part of the studied performances, there are three layers, i.e., no grid and one spacer. Permittivity of the spacers is varied from 1 (vacuum) to 100 (ceramics, K-100).

![Image](https://via.placeholder.com/150)

Figure 1: First normalized resonance frequency, \( f \), vs. relative permittivity of spacers, \( \varepsilon \), for a structure with a centered grid: blue solid line - numerical results (CST Microwave Studio); red dotted, green dash-dotted, and violet dashed lines - \( f(\varepsilon)=\varepsilon^{-\alpha} \) with \( \alpha = 0.45, 0.35, \) and 0.25, respectively; \( f(l) = 1 \); inset – front, back, and side view of a unit cell of two coupled arrays of subwavelength resonators, which are separated by a centered grid and two spacers; PEC approximation is adopted here for the resonators and grid.
The incident linear polarization is converted to the orthogonal one at polarization-conversion resonances. The results in [2] show that the first resonance frequency can be approximated, for the two selected structures, by \( f \propto \varepsilon^{-0.39} \) and \( f \propto \varepsilon^{-0.45} \). However, these estimates do not take into account the specifics of the different parts of the entire \( \varepsilon \)-range. The main purpose here is to quantify the changes in the resonance frequencies in different parts of the \( \varepsilon \)-range.

According to the results shown in Fig. 1, \( \alpha = 0.45 \) is better suitable to approximate the effect of \( \varepsilon \) between 1 and 2.1 and then above 20. Smaller values of \( \alpha \) (e.g., 0.25) can be more suitable for \( \varepsilon \) between 2.1 and 20. The observed difference between the results in Fig. 1 and the classical scaling rule is not dramatic because of the strong field confinement in the resonators of the studied structure. While polarization state of the incident wave, at which conversion may occur in transmission mode, depends on the presence of a centered metal grid, the scaling rule is not affected strongly. This indicates the dominant role of the properties of the resonator arrays for the value of \( \alpha \).

Note that polarization-conversion resonances appear in the entire \( \varepsilon \)-range, and conversion may be (nearly) perfect in the lossless approximation, starting from a certain value of \( \varepsilon = \varepsilon_{\text{per}} > 1 \). Similar fitting of the obtained numerical data has been performed for metasurfaces with and without rotation of one of arrays and for complementary metasurfaces, with the use of a lossy-metal model in THz and microwave ranges.

2.2. Miniature Antennas Inspired by Metamaterials

For small antennas, the scaling rule aspect is directly connected with the extent of achievable miniaturization. Moreover, number of resonances observed in the subwavelength range depends on \( \varepsilon \) of the substrate.

![Figure 2: First normalized resonance frequency, \( f \), vs. relative permittivity of substrate, \( \varepsilon \); blue solid line – numerical results (CST Microwave Studio); red dashed, green dashed, black dotted, and black dashed lines - \( f(\varepsilon) = \varepsilon^{-\alpha} \) with \( \alpha = 0.4, 0.3, 0.25 \), and 0.2; \( f(1) = 1 \); inset – top view of the studied coaxial-fed single-split-loop antenna; losses are taken into account via \( \tan \delta \).](image)

Figure 2 demonstrates how quantification of the scaling of resonances can be introduced for a near-field coupled single-split-loop antenna, while \( \varepsilon \) is varied in a wide range. The studied configuration is similar to but simpler than that in [3]. It is observed that at \( 1<\varepsilon<15 \), \( \alpha = 0.2 \) provides the best approximation. On the other hand, at \( 25<\varepsilon<100 \), \( \alpha = 0.25 \) might be more suitable, whereas \( \alpha \) tends to grow with \( \varepsilon \). Hence, deviation from the classical scaling rule is stronger here than for the above discussed arrays for polarization conversion. It is noteworthy that radiation occurs in the entire range of \( \varepsilon \), and the lowest radiation frequency is just gradually shifted while varying \( \varepsilon \). In the talk, the results will also be presented for the antennas with three split loops and different location of the loops with respect to each other.

3. Conclusion

The presented examples of quantification of the resonance scaling in open microwave resonance structures may serve a good starting point for development of approximate physical models, and for understanding limits and design of practical devices based on subwavelength resonators. For the studied structures, \( 0.25 \leq \alpha \leq 0.45 \) in the general form of the scaling rule, i.e., \( f \propto \varepsilon^{-\alpha} \). Presently, the scaling of resonances in plasmonic near-infrared structures is under study, and some examples will be presented in the talk.

Abstract

A metamaterial based dual-band microwave energy harvester is investigated. The miniaturized unit cell is composed of two distinct types of resonators, a rectangular split ring resonator coupled together with a T-type resonator, to achieve the desired resonances at 7.16 GHz and 9.25 GHz. The resonance frequencies can be controlled independently with very few parameters. The structure is backed by a metal film. A via on each of the resonating elements is used to divert the current to resistive loads. The power conversion efficiency and the power harvesting efficiency for the structure at 7.16 GHz (9.25 GHz) are 74.7% (65.6%) and 60.5% (51%), respectively.

1. Introduction

Metamaterial (MTM) based composite structures have been widely used in different applications, e.g., bio-medical devices, sensors for characterization of materials, frequency selective surfaces, and integrated circuits, etc. More recently, they have been explored as energy harvester for wireless power transmission systems. MTM based energy harvesters have advantages over conventional designs due to the extraordinary properties of MTMs, which allow resonance control, polarization stability, miniaturization, and impedance matching, etc. [1].

In wireless sensor networks, many sensor nodes are spatially distributed in large areas to gather information, such as temperature and humidity, and send it to a sink node (for example, a base station) for processing. The sensor nodes may be positioned arbitrarily at locations, which are inaccessible. In such situations, the sensor nodes must be highly efficient, consume low power, and work for a long period of time. One way of managing the power is that the nodes go into sleep mode on idle and periodically wake-up after a predefined duration of time [2]. This approach is not efficient because the node may well stay awake and consume power even if no information is requested. Therefore, a more dynamic power management method is required. As a solution, MTM based energy harvesters can be used to wake-up the nodes to send/receive information whenever it is required at the base station.

The design of an energy harvester can be broken down into a two-step process, firstly, designing an MTM structure, which absorbs the incident electromagnetic (EM) wave. This is achieved by matching the input impedance of the absorber to the impedance of the medium of the incident wave and by delivering the absorbed power to the load. Maximum power can be transferred when the load impedance is equal to the conjugate of the output impedance of the structure.

A recently proposed MTM design in [3] is investigated for a dual-band energy harvesting response and improved efficiencies. The efficiencies that determine the performance of the energy harvester are: absorption efficiency ($A_e$), it is the ratio of the power accepted ($P_a$) by the MTM unit cell to the incident power ($P_{in}$) over the unit cell; harvesting efficiency ($H_e$), it is the ratio of the power delivered to the load ($P_l$) to $P_{in}$; and conversion efficiency ($C_e$), it is the ratio of $P_l$ to $P_a$.

2. Design

Two distinct types of resonating elements, a T-type resonator and a rectangular split ring resonator (RSRR), are combined together on a dielectric substrate RO5880 as shown in Fig. 1. The dielectric layer is backed by a copper film, which acts as ground, followed by another dielectric layer. The dielectric substrates have a thickness of 0.254 mm with a relative permittivity equal to 2.2 and a loss tangent of 0.0009. The vias of equal diameter are placed at the bottom of each resonator to connect the load to the ground. The structure has been simulated in CST Microwave Studio using the frequency domain solver.
3. Results and Discussion

Consider an electromagnetic plane wave incident normally on the proposed MTM structure. The incident wave is y-polarized and it is travelling in the $-z$-direction. The wave is partly reflected and partly transmitted from the structure at the resonance frequencies. Since the structure has two resonating elements placed close together, the individual resonance frequencies of the RSRR and the T-type resonator will be affected by the mutual coupling between them. To design an energy harvester, the goal is to minimize the reflection of the incident wave so that the absorption can be maximized at the resonance frequencies. This is done by matching the impedance of the structure with the incident medium, which is free space and its value is $376.7 \, \text{Ω}$. An identical permittivity and permeability of the structure will result in achieving a matched condition. To deliver absorbed power to the load the power must be retained within the structure. Therefore, a metal film is used to minimize the transmission back into free space. The concept of harvesting energy at two different frequencies with two different loads, respectively, is illustrated through a three-port network shown in Fig. 2 where different ports (2 and 3) are used for two different loads. In order to achieve maximum power transfer to the loads, the output impedances of the structure must be equal to the complex conjugate impedances of the loads; otherwise, matching networks will be required. In this paper, resistive loads are modeled for simplicity. Vias are used to connect the loads to the structure. Fig. 3(a) shows the reflection coefficient for all the ports. The resonance frequencies (load resistance) for the RSRR and the T-type resonator are 7.16 GHz (1040 Ω) and 9.25 GHz (750 Ω), respectively. Fig. 3(b) shows the power absorbed, the power delivered to the loads, and the power dissipated in the dielectric ($P_d$) and the metal ($P_m$).

Figure 3: (a) Magnitude of the reflection coefficients at different ports as a function of frequency. (b) Power absorbed by materials and loads as a function of frequency.}

4. Conclusions

A highly efficient miniaturized microwave energy harvester was presented, which can absorb and deliver power to different loads at 7.16 GHz and 9.25 GHz simultaneously. The normal incidence case was discussed and an equivalent three-port network layout was demonstrated. The structure can be used in nodes in wireless sensor networks.

Abstract

In this paper, we experimentally analyze the absorption of two metamaterial perfectly absorbers made of different materials: gold (Au) and tungsten boride (WB, a refractory ceramic). We show that WB has wider absorption bandwidth than that of the gold counterpart. Moreover, WB reveals better performance with absorption more than 90% over the spectral range from 950 to 1400 nm.

1. Introduction

Metamaterials bring new opportunities for absorbers due to their designed electrodynamic properties: they provide versatile and strong control of their absorption, reflection, and propagation of electromagnetic waves [1, 2]. Metamaterials are used in different applications such as perfect lenses, black holes, plasmonic sensors and energy harvesting concepts [3, 4]. The performance of metamaterials absorbers [5, 6] depends on their constituent materials and geometry. Different types of metals have been used such as Au, Ag, Cu and Ni as metamaterials absorbers in the optical ranges due to their ability to considerably rise the optical cross section of the structure, leading to greatly improved absorption in certain spectral ranges caused by surface plasmon excitations [7]. However, due to the resonant nature of the plasmon excitation, the absorption bandwidth is limited. The key parameters for designing a perfect absorber is the efficient suppression of reflection of light and transmission. One of the recent technique for high absorption is to use single ultrathin film deposited on metals or polar materials. Such metamaterial devices have a large bandwidth and near zero reflectivity, which is attractive for energy harvesting application such as solar thermal photovoltaics (STPV) [8, 9]. On the other hand, tungsten boride (WB) is an inexpensive, super hard and lossy material [10]. By combing the plasmonic nature and large intrinsic loss of WB, we are able to design metamaterial structures toward high optical absorption over a broad range.

In this work, a WB metamaterial perfect absorber (MMPA) with efficient, broadband light absorption was designed and fabricated. The resulting 200 nm thick metamaterial absorber with square structure exhibits polarization-independent (patterns are symmetric) broad absorption over the near infrared range of 900–1400 nm at a large incident angle (up to 60°). Most importantly, the fabricated WB metamaterial absorber shows vastly improved high power absorption in comparison with Au counterpart, illustrating its potential for the high power applications such as STPV.

2. General description of the devices

The proposed metamaterials absorber was fabricated on a Si substrate consisting of three different material layers as shown in Figure 1: metallic structures made of Au (yellow) or WB (Maroon) as a top layer, a SiO2 layer (light grey) of 140 nm in the middle, and the bottom Cr layer (deep grey) of 400 nm as a ground reflector for the absorber. The optimized geometrical parameters of the metallic structures are as follows: the length of each square L equals its width W as 322 and 400 nm, pitch of the device P is 900 and 1030 nm, and the thickness t is 100 and 200 nm for Au and WB, respectively.

Figure 1: 3D-view schematic diagram of (a) Au and (b) WB metamaterial absorbers. W and L represent the width and length of each rectangular metallic structure along the x and y axis respectively, and h1 and h2 represent the thickness of dielectric spacer and bottom Cr layer respectively. P indicates the lattice constant.
3. Fabrication and characterization
To fabricate the WB metamaterial absorber, a sputter was first employed to deposit 400 nm Cr on a silicon substrate with a deposition rate of 2.58 nm/min. Then a SiO$_2$ layer of 140 nm was deposited by a plasma enhanced chemical vapor deposition (PECVD) system with a deposition rate of 48 nm/min. After that, 5 nm Cr as an adhesion layer and 200 nm WB were deposited on top (deposition rate of WB was 4.8 nm/min) by the sputter. Finally, we patterned square structure on the Cr layer by focused ion beam (FIB) milling. On the other hand, 100 nm Au metallic structures were obtained by electron-beam deposition followed by electron-beam lithography (EBL) and lift-off process as an experimental reference. Figure 2 shows the fabricated patterns and experimentally measured absorption as a function of wavelength in different incidence angles for Au and WB metamaterials respectively.

![Figure 2: (a) SEM image and (b) measured absorption spectra of the fabricated Au metamaterial absorber. (c) SEM image and (d) measured absorption spectra of the fabricated WB metamaterial absorber.](image)

We used a variable angle spectroscopic ellipsometer (V-VASE) for reflection measurement with optional focusing probes, which focuses the beam to a spot size diameter of around 300 µm. Therefore, we prepared the metallic particle arrays with a size of about 400 µm × 400 µm to make sure the whole measured area was covered. We also optimized the injected current by measuring several WB samples. Figures 2 (b) and (d) show the measured absorption spectra for Au and WB, respectively. The nature of the proposed metamaterial absorber is similar to the infrared absorber demonstrated in [9]: both are attributed to the excitation of the fundamental electromagnetic resonant modes. The mechanism may be explained as the localized electromagnetic fields which are strongly enhanced at a resonance. The incident light is trapped efficiently between metallic particle array and ground metallic layer and then the absorbed light is dissipated due to losses. The proposed device is independent of polarization of normally incident of light due to the symmetrical pattern (the length and width of the Au and WB particle are set to be equal in x and y axes) [25]. Moreover, the absorption is strong for inclined incident angle for such type of absorber. It can also be observed from Figure 2 that the WB metamaterial shows wider bandwidth as compared to the Au counterpart. It may be due to the placing of metallic resonators along the horizontal direction which allows broadband perfect absorption by mixing multiple resonances.

4. Conclusions
In summary, we have designed, fabricated and optically characterized a WB broadband absorber with an average absorption of 90% over the range of 950–1400 nm. In contrast with noble metal optical absorbers which utilize only plasmonic resonances to achieve high absorption, the WB absorber enables us to combine both the intrinsic loss of the material and the plasmonic resonances in the near infrared range for high power applications.

Metasurfaces based coils for MRI

Abstract

Metasurfaces represent a new paradigm in artificial subwavelength structures due to their potential to overcome many challenges typically associated with bulk metamaterials. The ability to make very thin structures and change their properties dynamically makes metasurfaces an exceptional meta-optics platform for engineering advanced electromagnetic and photonic metadevices. Here, we suggest and demonstrate experimentally several metasurfaces capable of enhancing significantly the local image quality in magnetic resonance imaging (MRI).

1. Introduction

In order to boost the performance of MRI without increasing the static magnetic field, it is necessary to increase its intrinsic sensitivity [1]. This allows a reduction in the scanning time, increased spatial resolution, and can enable low-field strength systems (which are much cheaper and can be used to scan patients with metallic implants) to have a higher signal-to-noise ratio (SNR) so that they are comparable to more expensive higher field strength systems. In this contribution, we demonstrate a new generation of radiofrequency field enhancing and shaping devices based on metasurfaces. These structures can substantially enhance SNR, thus potentially increasing image resolution or allowing faster examinations.

2. Metasurface for improvement of transmit efficiency

The vast majority of clinical MRI scans use a body coil for transmission. While this allows homogeneous excitation over all body parts at a field strength of 1.5 T, it is naturally quite inefficient for imaging relatively small regions of the body such as the extremities. Although specific absorption rate (SAR) is not typically a limiting factor at 1.5 T, it does become an issue when patients with metallic implants have to be scanned. In this case the local SAR limits must be reduced significantly, even if the body part being imaged does not correspond spatially to a region of high SAR. Therefore, it would be highly advantageous to be able to increase the local transmit efficiency close to the imaging region-of-interest since the overall power, and therefore SAR delivered to the patient can be decreased while maintaining optimum image quality. We demonstrate proof-of-principle experiments in the form of in vivo scans using a metasurface, formed by an array of brass wires embedded in a high permittivity low loss medium, for local enhancement of the RF magnetic field in the region of interest under clinical scanning conditions [2]. This metasurface can be considered as a wireless coil that redistributes electromagnetic fields and increases the local transmit efficiency in the area of interest. As such it operates in a very similar way to inductively coupled wireless local coils, and indeed the mode structure is related to that of a low-pass planar “ladder” coil, albeit with the advantage of more flexible and intrinsically symmetric tuning via the dielectric rather than a large number of lumped element capacitors.

3. Volumetric wireless coil based on split-loop resonators

Here, a new wireless coil design for wrist imaging on a 1.5 T clinical scanner was proposed and characterized numerically and experimentally [3]. The wireless coil was designed to provide high image homogeneity and to operate via inductive coupling with a birdcage coil, the latter being used for both transmit and receive. The proposed wireless coil based on a periodic array of coupled split-loop resonators (SLRs). The coil is self-resonant and uses structural capacitance of overlapping traces printed on dielectric substrates connected with telescopic brass tubes allowing to tune the first resonance of the structure to 63.8MHz. An experimental comparison in terms of SNR of the wireless coil to a standard cable connected receive coil of similar dimensions in combination with the same transmitting birdcage coil is presented. Moreover, the issues of the mutual coupling between the wireless coil and the birdcage coil, local SAR and B1 redistribution are discussed. The wireless coil placed into birdcage coil gave the measured B1 increase of the latter by 8.6 times for the same accepted power. The phantom and in vivo wrist imaging showed that the birdcage coil in receiving with the wireless coil inside reached equal or higher signal-to-noise ratio than the conventional clinical setup comprising the transmit-only birdcage coil and a commercial receive-only flex-coil and created no artifacts. Simulations and on-bench measurements proved safety in terms of SAR and reflected transmit power.
4. Conclusions

The results showed that the proposed metasurfaces based coils could be an alternative to standard cable-connected receive coils in clinical magnetic resonance imaging. As an example, with no cable connection, the metamaterials based coil allowed wrist imaging on a 1.5 T clinical machine using a full-body birdcage coil for transmitting and receive with the desired signal-to-noise ratio, image quality, and safety.

Interference phenomena and pulse propagation in a plasmonic wide-ridge metal-dielectric waveguide

Abstract
We demonstrate characteristics of plasmonic wide-ridge waveguides made from an Al₂O₃-Au-Al₂O₃ sandwich formed on a fused quartz substrate. Interference of travelling waves in the long-range plasmon propagation regime, their damping, throughput and cross-talk were studied when using pulsed laser source.

1. Introduction
Over the past decade plasmonic waveguides are extensively studied due to their great potential for miniaturizing optical circuits and for improving their functionalities [1-3]. The most intriguing are the plasmonic waveguides utilizing the idea of long-range plasmon (LRP) [4-8]. These LRP waves propagate at both interfaces of an ultra-thin noble metal film, and the best condition for them to exist—to propagate over long distances—is when the film faces (or sandwiched in) the same dielectric background. Another important feature of LRP waves is their spatial localization.

In the present work, we discuss properties of plasmonic wide-ridge waveguides made from an Al₂O₃-Au-Al₂O₃ sandwich formed on a fused quartz substrate. It was found that the waveguiding modes can travel along different paths and build an interference pattern. We also report on main characteristics of these waveguides of different length (attenuation constant, pulse propagation, bandwidth and cross talk).

2. Samples and experiment
Experimental samples were 70 µm-wide and 0.5-1 mm-long ridge waveguides formed by etching an Al₂O₃-Au-Al₂O₃ sandwich grown on a fused silica substrate. It was prepared by electron beam evaporation and had the next structural parameters: a 240 nm-thick top Al₂O₃ layer, a 10 nm-thick Au layer and the bottom 70 nm-thick Al₂O₃ layer.

Experiments were done by utilizing the following instruments: a tunable pulsed laser source Fianium (NTK Photonics) with a pulse width of 150 ps and a repetition rate of 40 MHz, an Ntegra system (NT-MDT), a Beamage CMOS camera (Gentec-EO) and a tunable delay line for resolving sequence of pulses.

To excite the LRP wave, light beams with Gaussian profiles were focused (FWHM = 2 µm). For the waveguides, working wavelengths were in the vicinity of λ = 765 nm, and all the structural parameters were optimized so that to support a single LRP mode for only the E-field oscillating along the ridge.

To couple/decouple light, input/output 1D gratings were etched through top Al₂O₃ layer and Au of the Al₂O₃-Au-Al₂O₃ sandwich. Incident light was focused onto the input grating by an objective (60x/0.7), and decoupled light was visualized by a system having a 100x/0.5 objective and the CMOS camera. Visualization of decoupled LRP waves was done by Beamage CMOS camera detecting over the full area (40×70 µm) of the output grating. Images were acquired with commercial software (PC-Beamage V1.03.04) and further processed. Figure 1 shows a typical captured image of the light intensity.

Pulse propagation was studied by a photon counting module of the Ntegra system, and the delay line was used to tune a time gap (150-300 ps) between the nearest pulses.

3. Results and discussion
Figure 1 illustrates the interference pattern, which appears upon the output grating for the LRP wave traveling from the left-hand side, and an intensity profile that is cut across the propagation direction. The observed amplitude was found to strongly depend on the excitation coordinate; the maximum was when only one half of the radiation spot was in the area of the input grating and the other half struck the Al₂O₃-Au-Al₂O₃ sandwich, i.e. when the spot was shifted towards the output grating.

Plot (b) shows a series of bright spots similar to the case of two-beam interference. It is obvious that the side walls of the ridge waveguide act as reflection mirrors, and the total interference pattern is likely built by the LRP wave propagating directly along the waveguide and reflected form the side walls. It is worth noting that image (a) has spots various in brightness and manifests presence of fabrication imperfections.
experiments was 8 Gbit/s, which was limited by the used laser source. It should be mentioned that the fitting curve (black line) did not coincide with the experimental one because of the instrument function of the detecting Ntegra system.

4. Conclusions

Characteristics of plasmonic Al₂O₃-Au-Al₂O₃ wide-ridge waveguides have been studied. The 0.5-1 mm-long waveguides supported propagation and interference of the LRP waves from a pulsed laser. The studied plasmonic wide-ridge wave guides are proposed for the first time and are of interest from both fundamental and application points of view.

Miniature Spectroscopes with Metasurfaced Transmitted Color Filters Integrated on a Photodiode Array

Yoshiaki Kanamori*, Daisuke Ema1, and Kazuhiro Hane1,

1Department of Finemechanics, Tohoku University, Sendai, Japan
*corresponding author, E-mail: kanamori@hane.mech.tohoku.ac.jp

Abstract
As an application of metamaterial, we fabricated metasurfaced transmitted color filters integrated on a photodiode array for miniature spectroscopes. The color filters consisted of two-dimensional guided-mode resonant metal grating filters. Characteristics of the fabricated color filters and miniature spectroscopes were evaluated. Transmittance characteristics of the fabricated color filters showed that the peak wavelengths were proportional to grating periods as designed. From measurement of the fabricated spectroscopes using monochromatic lights, obtained spectra agreed with the center wavelengths of the monochromatic lights.

1. Introduction
Since Ebbesen et al. discovered extraordinary transmission phenomenon in 1998 [1], various metamaterial color filters have been studied [2,3]. In recent years, novel spectrometers that do not require diffraction gratings have been reported by combining plasmonic color filters and complementary metal-oxide semiconductor (CMOS) sensors [4,5]. The color filter is formed on each pixel of the CMOS sensor, and spectral information is obtained by post-processing using signals obtained from each pixel. Such filter array spectrometers are believed to have the potential to broaden the scope of use of spectroscopic devices because of the miniature size with low cost features. There are a few studies on filter array spectrometers as far as we know. The spectral characteristics depend on the filter characteristics, and improvement of the filter characteristics is desired.
Recently, we designed novel metamaterial color filters, and fabricated miniature spectroscopes in which the color filters were integrated on a photodiode array [6]. It is the first demonstration of filter array spectroscopes combining two-dimensional guided-mode resonant metal grating filters and photodiodes. Here, we discuss about the characteristics of the fabricated color filters and miniature spectroscopes in detail.

2. Concept of device
Figure 1(a) shows a perspective view of proposed spectroscopes in the case of 2 by 2 pixels. Metasurfaced color filter array is integrally formed on the Si photodiode array, and the photocurrent signal from each photodiode is read out sequentially. Then, spectrum of incident light is reconstructed by post-processing. Figure 1(b) shows a cross-section of one pixel consisting of a metasurfaced color filter formed on a photodiode through an SiO2 spacer. The color filter consists of a two-dimensional guided-mode resonant metal grating which is coated with an SiO2 layer. The metal grating and waveguide layers consist of Al and HfO2, respectively.

Figure 1: Schematics of proposed spectroscopes. (a) Perspective view in case of 2 by 2 pixels. (b) Cross-section of one pixel.

Figure 2: Fabrication steps.
3. Fabrication

Figure 2 shows fabrication steps. First, photodiode array is fabricated from n-Si wafer using etching, deposition, ion implantation, and rapid thermal annealing processes. Second, spacer layer is formed with SiO$_2$ deposition. Third, color filter structures are formed with deposition, etching, and patterning processes. At the last, SiO$_2$ deposition for a cover layer and etching for contact holes are carried out. Figure 3 shows a reflection image of an optical microphotograph of fabricated device (left) and scanning electron microscope (SEM) image of one color filter with a period of 220 nm (right). The color filters are fabricated in 25 (5 by 5) patterns with grating periods between 220 nm and 460 nm at increments of 10 nm. It can be seen that electrical wirings are also formed.

4. Device characteristics and Discussion

Figure 4 shows reconstructed incident light spectra with solid lines. By way of comparison, spectra of incident light measured with a commercially available spectrometer (HR4000CG-UV-NIR, Ocean optics, Inc., Largo, FL, USA) are shown as original spectra with dotted lines. Figure 5 shows peak wavelengths of reconstructed spectra as a function of center wavelengths of monochromatic lights extracted from the results of Figure 4. It is apparent that the peak wavelengths of the reconstructed spectra are in good agreement with the original spectra. From figures 4 and 5, we believe that the spectroscopic measurement was successfully performed with the fabricated device.

5. Conclusions

We fabricated meta-surfaced transmitted color filters integrated on a photodiode array for miniature spectrometers. The color filters consisted of two-dimensional guided-mode resonant metal grating filters. 25 color filters with grating periods between 220 nm and 460 nm at increments of 10 nm were fabricated on respective photodiodes with high accuracy. It was found that the peak wavelength could be reconstructed with high accuracy by using fabricated spectroscope device.

Abstract

Metamaterials made of epsilon-near-zero indium tin oxide and dielectric multiple layers were investigated for wideband perfect light absorption in the near wavelength range. The enhanced wideband absorption was used for nonlinear optical second harmonic generations.

1. Introduction

Materials with vanishing real part of the electric permittivity in certain wavelength regions are promising optical materials for many applications. This type of materials are called epsilon-near-zero (ENZ) materials because the real part of the electric permittivity crosses zero at certain wavelengths [1]. The most common ENZ materials are transparent conducting oxides and doped semiconductors. One such ENZ material is indium tin oxide (ITO) with an ENZ wavelength around 1550 nm. ITO material has been previously investigated for making tunable devices [2] and nonlinear optics [3]. In this work, multiple ENZ material and dielectric layer structures were investigated for wideband absorption and nonlinear optical applications.

2. Wideband perfect light absorbers using multiple dielectric and ENZ material layers

Previously, wideband perfect light absorbers made of multilayer metal and dielectric layers were reported for absorbing wideband solar light radiations [4,5]. In this work, we replace the metal layers with ITO ENZ layers for wideband absorption and nonlinear optical second harmonic generation applications. Figure 1(a) shows the multilayer ITO/SiO₂ structure. Starting from the top, there are alternative thin SiO₂ layer and ITO thin film layers that form optical cavities for trapping light and enhancing absorption. A 200 nm optically thick TiN layer is at the bottom to prohibit light transmission from the device. Figure 1(b) shows the measured real part and imaginary parts of the electric permittivity, where the crossing-zero wavelength is around 1.45 micron [6].

The measured electric permittivity of 100 nm ITO film was used for calculating optical absorptance. The optical absorptance curves of devices of different number of SiO₂/ITO pairs versus wavelength were calculated and shown in Figure 2 (a). It can be seen from this Figure 2(a) that ITO/dielectric multilayer structures have high absorption in the near infrared region. By increasing number of pairs, multiple absorption resonance modes result in wide absorption band. Devices with different number of SiO₂/ITO pairs were fabricated and the absorbance curves were measured. Figure 2(b) shows the measured absorbance curves of fabricated devices with different number of SiO₂/Ti pairs. It shows that as the number of pairs increases, the absorption band increases. Second harmonic generation from fabricated...
wideband absorber devices was measured. Strong enhancement of SHG was observed when the devices were excited within the absorption band.

![Graph](image)

Figure 2: (a) Calculated absorptance versus wavelength for devices with different number of SiO$_2$/ITO pairs. (b) Measured absorptance versus wavelength for fabricated devices with different number of SiO$_2$/ITO pairs.

3. Summary

Metamaterials made of epsilon near zero ITO and SiO$_2$ multiple layers can have wideband near perfect absorption in the near infrared wavelength range near the ENZ wavelength. Optical absorptance with different number of ENZ-dielectric thin film pairs was calculated. Simulation results show that the periodic ENZ-dielectric thin film structures have near perfect light absorption over a wide spectral range. Increasing number of pairs results in more absorption resonance modes and wider absorption band. Devices were fabricated and characterized and the results agree well with simulation results. Second harmonic generations were measured and it has shown that enhanced nonlinear optical effect occurs near the ENZ wavelength within the near perfect absorption band.

Abstract

The multifunctional structural composites have gained more attention due to their incorporation of electromagnetic (EM) features into light-weight host materials. In this work, we present a composite medium demonstrating strong microwave dispersion properties enabled by an array of short-cut microwires. They behave as radiative elements with different structural properties into polymer-based composite. The arrangement of wires plays a remarkable role in achieving the controllable EM response.

1. Introduction

A metamaterial is intended to be an engineered material having unusual physical properties beyond the natural materials[1]. Over the years a vast interest is seen in the development of engineered multifunctional composites containing micro or nanoscale fillers in terms of their electromagnetic properties for microwave applications phenomena such as reconfigurable and tunable microwave devices to non-destructive testing[2]. Glass-coated ferromagnetic microwires¹ gained more attention due to their fine size and properties like magnetoimpedance (MI) with enhanced soft magnetic characteristics which makes them distinguished from other materials. These wires act as radiative elements when incorporated into polymer matrix providing various EM properties[3]. The effective EM response of a wire filled composite is mainly controlled by the high frequency MI properties of wires, distance between them, and by external stimuli such as magnetic field, stress, or temperature[4]. In order to expand the choice of microwave dispersion characteristics of the wire filled composites, we propose a new DC current annealing procedure for the wire inclusions together with their special structural ordering. Previously such work elsewhere [5] has not been fully exploited. In the approach developed in this work, modulation of the resonant response of wire media to an EM wave is achieved by incorporating differently annealed wires of same composition ordered in different arrangements. This permits one to improve significantly the design variety and helps programing the operation frequencies with the active use of an adjusting parameter of arrangement of wires.

Fig. 1. Arrangement of wires; (i) & (ii) are the as-casted (labeled as A) and current annealed wires at 40 mA (labeled as B). Whereas, (iii), (iv) & (v) are the incorporated wires with different arrangements as AAABBB, ABABAB & ABBAAB respectively.

In our experiments, we used a CoFeSiB alloy composition of microwire. Six pieces of short-cut wires were arranged parallel to each other in an array with a spacing of 2mm in between them in a polymer-based composite, as shown in Fig. 1. The annealing of wires was done by applying DC 40 mA at specific duration.

2. Results and Discussion

Fig. 2 represents the X-Ray Diffraction (XRD) spectra for glass-coated microwire with the alloy composition of Co80Fe15Si10B15 having a diameter of metallic core 27.2 um and total diameter of wire is 35.4 um produced by Taylor Ulitovski technique. The spectra confirm that as-cast wires present amorphous structure (black spectrum) consisting of a halo originating from the glass shell and amorphous halo from the amorphous phase. After current annealing at 40 mA for 10 minutes, the XRD is almost the same as in as-cast state (red spectrum). This method of annealing helps to boosting the magnetic properties that could influence the EM properties as it will be elucidated later, revealing a novel way to program the EM responses in a composite.
Transmission co-efficient (S21/12) of the wire composites are measured by a vector network analyzer (VNA) in the rectangular waveguide (22.86 x 10.16 x 2 mm³). Fig. 3 shows the measured transmission spectra of as-cast-A, current annealed at 40 mA-B wire array-composite and integrated wire array-composite with different arrangements. For A-wires, a transmission minimum occurs at 11.96 GHz corresponding to the Lorentz-type dielectric resonance or dipolar behavior of the short-cut microwires. Short-cut wire inclusions act as dielectric dipoles when interacting with the electrical component of waves[3] with the resonance frequency \( f_{res} = \frac{c}{2l}\sqrt{\frac{\varepsilon_m}{\varepsilon_{rel}}}, \) where \( c \) is the speed of light, \( \varepsilon_{rel} \) is the relative permittivity of composite matrix, and \( l \) is the length of the wire. Taking \( \varepsilon_{rel} \) as 2 and \( l \) as 10.16 mm (fixed in our case) into above equation, we obtain \( f_{res} = 10.44 \) GHz, which fairly coincides with the identified minimum in Fig. 3.

Fig. 3. Measured dispersion of the transmission coefficient for wires of the types A and B and differently arranged having spacing of 2mm in between them.

The visible change is seen in the current annealed wire which shifts the transmission spectra towards lower frequency, i.e. 11.06 GHz. This shift was caused by the change in the structural relaxation of the wire alloy produced by current annealing. The annealing at 40 mA current is high enough (but lower than the crystallization temperature, as evidenced in Fig. 2) for structural relaxation and partial relief of the internal residual stresses[6].

For the composites containing combination of the as-cast and annealed wires (Fig. 1), the wire arrangement has shown a profound impact on the transmission minimum and amplitude. When different types of wires are added in the same amount but in different order as shown in Fig. 1, the transmission minimum or dipolar resonance trends to the lower frequencies than to the as-cast wires. This trend coincides to that of the composites containing the same type of wires (AAAAAA and BBBB), the most pronounced red-shift is of the AAABBB sample i.e., 10.82 GHz beyond to that of individual wire frequency range for as-cast and current annealed wires. When the wires are arranged in an alternate manner i.e. ABABAB, the transmission minimum follows the trend with frequency, i.e. red-shifting with the incorporation of 40 mA-annealed wire B closer to as-cast wire, i.e. 11.26 GHz. Finally, when the two wires in the middle of array ABABAB are swapped, i.e. ABBAAB, the critical frequency once again shifts on the side of the 40 mA-annealed wires B, i.e. 10.795 GHz. In addition, the transmission amplitude of the composites also decreases as the wires B is incorporated in the array. Therefore, we can infer a dominant influence of the annealed wires over the as-cast wires on dictating the EM response of the composites.

From our experimental results, we can conclude that the current annealing of wires causes an effective improvement to its magnetic properties especially structural relaxation. These tailored wires can effectively mixed with cast wires, producing a composite with controllable behavior.

3. Conclusions

We have demonstrated that a small DC current can be used as an EM property control parameter. The proposed annealing procedure together with different wire arrangements allowed us to strongly modify microwave dispersion properties of the wire filled composites.

Dielectric metamaterials with epsilon-near-zero regime

Ekaterina E. Maslova1,* and Mikhail V. Rybin1,2

Abstract
We consider all-dielectric metamaterials with electric response allowing an epsilon-near-zero regime. The metamaterials being a hexagonal lattice of dielectric rods are studied. We construct a photonic phase diagram by analyzing photonic band diagrams. A near-boundary phase with a strong spatial dispersion is found in the structures with a hexagonal lattice, which is not observed in the case of a square lattice.

1. Introduction
Near-zero refractive index provides many opportunities for studying light-matter interactions [1]. Related materials can be classified as epsilon-near-zero (ENZ), dielectric permittivity $\varepsilon \approx 0$, mu-near-zero (MNZ), magnetic permeability $\mu \approx 0$, and epsilon-and-mu-near-zero (EMNZ), $\varepsilon \approx 0$ and $\mu \approx 0$ media. The dispersion relation $\omega^2 = \varepsilon \mu |k|^2$ leads to a wavelength ‘stretching’ effect for the case of near-zero regime, and thus a spatial (wavelength) and a temporal (frequency) field variations are decoupled. It allows an unconventional physics of structures with near-zero parameters, which has both an academic interest and a great application potential in unusual device designing, since the near-zero index regimes can be exploited to enhancement of the light-matter interactions.

Metamaterials are artificial structures described by effective indices, permittivity $\varepsilon$ and permeability $\mu$, as conventional materials. A special design of structure allows for these parameters to take a desired positive or negative value, which depends on properties of the structural elements. Since natural materials enable dielectric permittivity in a wide interval of values including ENZ, the main efforts were focused on the development of structures with artificial magnetic response. For a long time, material losses were the challenger problem, until low-losses dielectric systems with the structural elements supporting magnetic and electric Mie resonance was introduced [2]. The periodic dielectric structures are usually considered either as a photonic crystal, which properties are related to Bragg resonances, or metamaterials operating due to local Mie resonances sustained by each structural elements.

A phase diagram for a square lattice of dielectric rods was developed as a function of rod density and permittivity [3]. This phase diagram uncovers the range of parameters allowing the dielectric metamaterials with magnetic response. Although dielectric metamaterials were the subject of intensive studies, the structures with resonant electric response were reported in 2018 only [4].

Here we construct a phase diagram “photonic crystal – metamaterial” for a hexagonal lattice of dielectric cylinders in the case of TE (the magnetic field oscillates along the rod axis) and TM (the electric field oscillates along the axis) polarization. The phase diagram is constructed by analyzing the photonic band diagrams of the periodic structures. The first branch in the band diagram has minimum at the $\Gamma$ point and increases to boundary of the Brillouin zone. In a photonic crystal structure related to a Bragg resonance the second branch of dispersion has a minimum on boundary of the Brillouin zone and a maximum at the $\Gamma$ point. In the case of metamaterial the band diagram has a polaritonic feature [5]. Unlike the case of square lattice, we find a near-zero refractive index, which allows for strong spatial dispersion in the structures with hexagonal lattice.

Figure 1: Photonic band diagrams of dielectric rods arranged in a hexagonal lattice for TM polarization. (a) A photonic crystal with $\varepsilon=12$ and $r/a=0.1$. (b) A near-boundary phase with $\varepsilon=20$ and $r/a=0.1$. (c) A metamaterial with $\varepsilon=30$ and $r/a=0.1$. The second branches in the diagrams are marked by thick lines. The red circles correspond to the bottom boundary of the second band at $a/\lambda=0.504$. 
2. Results

We consider a hexagonal lattice of dielectric rods in the case of TM polarization. Fig. 1 demonstrates a modification of the band diagram with the increase of the rod permittivity. Fig. 1a shows the band diagram of photonic crystal, which exhibits a typical Bragg gap (the second branch has the minimum at the M point).

We find a near-boundary phase existing for the structure with \( \varepsilon \approx 20, r/a = 0.1 \). Its dispersion is shown in Fig. 1b. In the near-boundary phase the second branch has a local minimum inside the Brillouin zone and there are a range of two states per a single frequency value indicating conditions of a strong spatial dispersion. Therefore, the structure in the near-boundary phase cannot be described by using effective material parameters \( \varepsilon \) and \( \mu \).

When we increase the dielectric permittivity the minimum of second branch moves to the \( \Gamma \) point (Fig. 1c) forming the polaritonic feature that is the signature of metamaterial phase. However, when the permittivity is relatively small the band diagram shows a weak polaritonic feature and we simulate a propagation of electromagnetic wave to verify that it is metamaterial regime indeed.

We study the wave propagation through confined structures [4, 6] with different shapes (prism, circle and square), which consist of about 1100 rods (the actual rod number depends on the shape and the lattice orientation). A Gaussian beam with a 10\( a \) waist impinges the metamaterial structures. Results illustrate that in the metamaterial regime it is possible to observe ENZ regime. A distribution of electric field is uniform throughout the structures and it does not depend on their shape, which confirms the metamaterial regime of these dielectric structures (Fig. 2).

To summarize, we have considered dielectric structures with the hexagonal lattice, in which the near-boundary phase having a strong spatial dispersion has been found. We have shown that the metamaterial in the ENZ regime does not undergo the lattice orientation and sample shape. Metamaterials with ENZ modes make it possible to enhance the light-matter interactions and pave the way for sensitive devices.

Anti-crossing of counter propagating modes within the Brillouin Zone

Milo Baraclough, William L. Barnes, Ian R. Hooper

Department of Physics and Astronomy, University of Exeter, Exeter, United Kingdom, EX4 4QL
*corresponding author, E-mail: mb504@exeter.ac.uk

Abstract

Bandgaps resulting from anti-crossings between modes are a common feature of periodic media. Typically they occur at the Brillouin zone boundary, or result from interactions between forward propagating modes of different character. By breaking the symmetry of a metamaterial waveguide that supports both forward and backward propagating modes we demonstrate an anti-crossing within the Brillouin zone that exhibits band edges with zero group velocity.

1. Introduction

Chains of meta-atoms of various types have proved to be promising candidates for sub-wavelength guiding of electromagnetic energy [1, 2]. Recently it has been demonstrated that they can even support backward propagating waves; waves whose phase velocity is in the opposite direction to their group velocity [3, 4, 5].

Figure 1: Model of non-bianisotropic framed resonator as designed by Seetharaman et al where the orange areas are 30 µm of copper. The inner and outer rings have external radii of 16 and 13.6 mm respectively, thickness of 1.2 mm and a split size of 1.5 mm. The frame has an inner radius of 17.2 mm, a height of 37 mm and a width of 38.5 mm.

Figure 2: Chain of symmetry broken framed resonators.

Though chains of meta-atoms that support both forward and backward propagating waves are possible, to our knowledge these have previously always occurred within different frequency bands. Here we present a design that supports forward and backward going modes within the same frequency band, allowing us to probe their interactions.

2. Design & Methods

We use a variant of a meta-atom investigated by Seetharaman et al. [5] that supports a backwards propagating wave over a wide bandwidth. By taking the negative of that structure we obtain the meta-atom design shown in Figure 1. The outer metallic frame of this meta atom supports a backward propagating wave, whilst the inner ring structure supports a forward propagating wave. Importantly, this structure can be designed so that the frequency bands of the different modes overlap.

This meta-atom design is non-bianisotopic, the fields of the forward and backward propagating modes are orthogonal (the forward has only longitudinal magnetic dipole moments, the backward has only transverse electric dipole moments) and thus do not interact with each other. However, by breaking the symmetry through a simple rotation of the splits of the outer ring, we can controllably introduce bianisotropy. This results in the modes coupling together to
Figure 3: Modelled dispersion of a chain of broken symmetry framed split rings stacked with a period of 3 mm. Anti-crossing between backwards propagating mode and forwards propagating mode can be seen at a k value of 450 m\(^{-1}\).

produce anti-crossing.

3. Results

Figure 3 shows the modelled band-structure of an infinite chain of our meta-atom design. A clear anti-crossing at a wavevector of approximately 450 m\(^{-1}\) is evident between two of the modes. The additional mode corresponds to a dipolar mode associated with the frame, oriented in the direction in which symmetry has been maintained; as a result it does not interact with the forward propagating mode and they cross at approximately 700 m\(^{-1}\).

Intriguingly, since the anti-crossing is a result of an interaction between a forward and backward propagating mode (as opposed to the usual case where it is between two forward propagating modes, or a forward propagating mode and a stationary mode), the anti-crossing exhibits band edges with zero group velocity within the Brillouin zone. This character would usually be associated with bandgaps formed at Brillouin zone boundaries due to counter-propagating modes resulting from scattering due to the periodic nature of the structure. Achieving this behaviour within the Brillouin zone may be of significant interest to researchers interested in slow light, pulse-shaping, etc.

4. Summary

We have demonstrated a 1D waveguide formed of a periodic chain of meta-atoms that exhibits an anti-crossing between forward and backward propagating modes within it's Brillouin zone. The band edges of this anti-crossing have zero group velocity and resemble the bandgaps one usually finds at the Brillouin zone boundary of periodic systems. These results may be of significant interest to researchers working in the fields of slow light, pulse shaping, etc. However, more generally it is a highly unusual phenomenon that researchers in other areas of solid-state physics may also find intriguing. Further work to test the results of this numerical modelling through experiment are currently underway.

Synthetic Biological Approaches for the Fabrication of Optical Metamaterials

*Simon Butler¹, Prof. Rebecca Seviour¹

¹School of Computing and Engineering, University of Huddersfield, West Yorkshire, UK
*corresponding author, E-mail: simon.butler@hud.ac.uk

Abstract
Conventional nanofabrication techniques lack the throughput and fidelity to create large scale metamaterial structures capable of operating in the optical regime [1]. Synthetic biological approaches can create nanometer feature size [2] DNA based nanostructures with throughput in the region of over a million individual constructs, per reaction, with high fidelity [3]. We present a pathway for the design of arbitrary, via a modular DNA origami circuit/breadboard, and fabrication, of continuously metalised, 10 nanometer feature size structures by someone unfamiliar with the methodology.

Introduction
As described by Pendry [4] a metamaterial must have a period cell significantly smaller than any specific wavelength of interest. As the optical regime lies, roughly, between 400 and 800 nanometres in wavelength, any metamaterial operating in this range would need to be between 40 and 160 nanometres in size (Assuming a unit cell between 5 and 10 times smaller than the wavelength). This caveat of optical metamaterial creation means that their construction sits firmly within the boundaries of nanofabrication (Where we define nanofabrication as the creation of an artefact with at least 1 feature size of less than 100 nanometres).

Currently all conventional nanofabrication systems suffer from the same broad limitations, where throughput is limited by our ability to either create a completely defined system (Where nanofabrication approaches atomic definition), or wield external force in a manner capable of reproducibly modifying the system (Or accurately modifying enough systems within a time frame to make the approach viable).

Originally demonstrated by rothemund [5] scaffolded DNA origami, where a single, none repeating strand of DNA, typically created by biological systems, such as a harmless viral plasmid, can be annealed by smaller, chemically synthesised sequences, creating tension and causing a rigid super structure to be formed of both scaffold and staples. However, DNA, while useful for construction/scaffolding, is electromagnetically inert and only exists stably in the, comparatively, mild environments dictated by physiological condition with few minor exceptions. For a material to be readily incorporated into DNA Origami based design, in a site specific manner, it must first be somehow complemented by its own unique DNA sequence. Mirkin first demonstrated that DNA sequences ended with sulphur containing thiol groups [6] could attach directly to the surface of a gold nanoparticle, once a gold nanoparticle, or any functional moiety stable in DNAs buffers solution or ultra purified water, has a DNA sequence attached it can be site specifically annealed to a DNA origami design [7].

1. Design – Metamaterial

As the rough size of individual unit cells is already stipulated by our metamaterial definition HFSS simulations were conducted on a split ring resonator design within our fabrication capabilities.

HFSS was used to simulate exposure of an infinite 2D sheet of these structures (Fig 1) to EM waves of interest. From these simulations scattering parameters (S11 and S21) were be recovered.

Figure 1 A single resonator in its unit cell

Figure 2 The real (Green) and imaginary (Red) components of the refractive index over the frequency range of 1 – 1000 terahertz
The components of the refractive index (Fig 2) were then recovered using a modified Nicholson-Ross-Weir approach described by Smith [8].

2. Design – Origami Board

We use the P7249 scaffold and ~200 smaller staples strands to create a 50 x 50 x 2 nanometer breadboard. Interhelical crossovers points, facilitated by staple strands, give structure to the longer scaffold sequence, while functional points, where components are attached, are created by simply extending the existing staples out into the area around an individual origami design.

Both crossovers and functional points take advantage of the naturally occurring helical pitch of a DNA helix (Fig 3). As the antiparallel helix progresses base by base it will come into close proximity to its neighbouring strands, or conversely, be travelling parallel to the edge of the structure. It is at these points that crossovers and functional points can be placed effectively without disrupting the overall structure of the final design.

As individual DNA bases bind only via their 5’ carbon to their neighbours 3’ carbon a DNA sequence is effectively directional. Wherever a sequence is extended to ‘leave’ the origami its neighbour can also be extended in a similar manner to ‘enter’. This method allows close proximity anchoring points to be created, and several sequences used to bind single nanoparticles, with high precision, and reliable attachment rates.

3. Fabrication

Fabrication can be divided into 3 stages: Fabrication of the DNA origami board, synthesis and functionalisation of gold nanoparticles, and then the purification of any created structures from their respective fabrication components, leaving a solution containing only correctly fabricated structures.

The origami board is fabricated by adding all required staples strands to a scaffold solution, under specific ionic conditions followed by a specific thermal ramp cycle. Thermal ramping begins at a temperature where all hydrogen bonding between strands breaks down, and is then lowered gradually to a specific molten globular folding point where, hydrogen bonding is restored, and most folding occurs.

Once the origami structures have been fabricated they must be separated from all remaining fabrication components. A common issue preventing correct fabrication is the presence of DNA strands with complementing sequences to functional groups still being present in solution but not attached to an origami structure. If this is the case, due to their relatively high mobility compared to their sisters anchored in boards, they will attach to complementing sequences must quicker, preventing correct attachment by competitive inhibition. Fig 2 shows a sample which has been purified from its fabrication components and is ready to go on to be functionalized with nanoparticles.

Synthesis of gold nanoparticles is conducted via an inverse Turkevich approach [9] which produces stable, polydisperse, 10 nanometer gold nanoparticles.

Once purified, functionalized, gold nanoparticles, and DNA origami boards are fabricated they are conjugated in solution by incubation at room temperature (Fig 4). This solution can be concentrated via centrifuge.

Conclusion

We present the principles and methodology, along with a detailed report/supplementary paper, which precisely details the protocols, and methods to identify protocols when deviation from our device is required, we use to fabricate continuously metalised origamis.

Abstract
In present work, the acoustic band structure of a 2D phononic crystal (PC) containing piezoelectric materials (Bi₁₂XO₂₀, X=Si, Ge, Ti; LiTaO₃) were investigated by the finite element method. 2D PC with triangular and honeycomb lattices composed of piezoelectric cylindrical rods are in the air and liquid matrix. The existence of stop bands are investigated for the waves of certain frequency ranges. This phononic band - forbidden frequency range - allows sound to be controlled in many useful ways in structures. These structure can be used as sonic filters, waveguides or resonant cavities. The calculated phonon dispersion results indicate the existence of full acoustic modes in the proposed structure along the high symmetry points. We have also calculated the band structures of the different types of unit cells that are yielded by space group symmetry operations of the triangular resonators. The results show that these acoustic metamaterials with Helmholtz resonators can be used successfully to reduce the Dirac cone frequencies. Dirac cone frequency decreases gradually with increasing filling ratio, which indicates a possible way to control wave propagation on the subwavelength scale. Numerical simulation results show that acoustic metamaterials can behave like zero-refractive-index media and can be applied to acoustic tunneling.

In present work, the elastic and mechanical properties of piezoelectric materials have been investigated by means of first principles calculations, too. The elastic constants of these materials were calculated using the strain-stress method as implemented in the VASP. The bulk modules, shear modules, Young’s modulus and Poisson ratios, anisotropy factors, sound velocities, and Debye temperatures of investigated piezoelectric compounds have been calculated using VASP.
Split Ring Resonator Loaded Double Opposite E-shaped Left-Handed Metamaterial for Modern Electronic Communications

Abstract

A compact double opposite E-structured metamaterial emerged on split ring resonator (SRR) is introduced and discussed for quad-frequency applications. CST Microwave Studio software has been utilized for the design and simulation perspectives. The unit cell is formed by etching copper on FR4 and its size is 11.12×11.12 mm\textsuperscript{2}. The unit cell shows both the characteristics of negative refractive index and double-negative characteristics. The metamaterial unit cell has SAR reduction about 84\% and 78\% for 1gm and about 91\% and 90\% for 10gm at 1768 MHz and 2164 MHz, respectively. These results proceed to a guideway of better SAR reduction of modern electronic communications.

1. Introduction

Electromagnetic (EM) metamaterials, with their extraordinary properties which cannot be obtained in most naturally existing materials, have been shown tremendous potentials in many fields of science and technology [1]. These properties are negative permeability, negative permittivity, and negative refractive index [2]. Due to these properties, nowadays metamaterials have been using in different applications like super lenses [3], invisible cloaking [4], antenna performance enhancement, SAR reduction [5] etc. SAR is the estimation of the electromagnetic field (EMF) of higher radio frequency (RF) consumed by the human body when utilizing an electronic or communication gadget. This rate is estimated in a standard estimation of watts per kilogram (W/Kg) as the power observed inside a characterized region of body tissue. SAR measures 100 KHz to 10000000 KHz frequency range exposure that includes electronic and communication devices such as laptops, smart mobile phones, and WiFi routers etc.

2. Design of Unit Cell

The structural design of the metamaterial unit cell has been shown in Figure 1 along with the parameters present in Table 1. Copper (Annealed) has been used as conducting element which is etched on the FR4 dielectric material. The following unit cell is developed by creating EF-structure surrounded by SRR which is added to create the negative permeability along with the negative permittivity.

Figure 1: (a) Configuration of unit cell (b) Equivalent circuit of the unit cell.

Table 1: Parameters of the EF-structured meta-atom.

3. Methodology and Experimental Setup

High frequency electromagnetic simulation software has been used to design, simulation, and SAR evaluations of the metamaterial unit cell. Experimental set up has been done as like a simulation setup where the unit cell has been set on between the two waveguides of negative and positive sides of Z - axis. Limit states of perfect electrical field and perfect magnetic field has been set independently to the X – and Y - axis. Measurement has been done from 1 to 7 GHz.

Figure 2: Simulation of unit cell between two waveguides.
While diverse sorts of strategies are accessible, the Nicolson-Ross-Weir (NRW) has been used to extract the permittivity and permeability from the $S_{11}$ and $S_{21}$.

4. Results and Discussions
Transmission coefficient ($S_{21}$) of the introduced metamaterial unit cell has been presented in Figure 3. The unit cell shows resonance at frequencies at 1768 MHz, 2164 MHz, 4780 MHz, and 5860 MHz having values of -23.62 dB, -19.24 dB, -24.76 dB, -22.41 dB, respectively.

The unit cell metamaterial additionally displays double-negative properties over the frequency ranges from 3.934–4.576 GHz, 5.17–5.488 GHz, 6.286–6.784 GHz and negative refractive index from 3.142–7 GHz.

4.1. SAR Evaluations
SAR performances has been investigated by placing the unit cell into the mobile phone phantom model to check compatibility of it for using it with the modern mobile phones. The metamaterial unit cell has electromagnetic absorption rate about 84% and 78% at 1768 MHz and 2164 MHz, respectively for 1gm whereas it has reduction rate about 91% and 90% at 1800 1768 MHz and 2164 MHz, respectively for 10gm.

5. Conclusions
In this article, a novel SRR loaded double opposite E-shaped metamaterial is presented which is applicable in quad-frequency applications. The metamaterial unit cell has a high effective medium ratio of about 14.82. The metamaterial also exhibits double-negative properties along with negative refractive index over the frequency ranges. The meta-atom has average SAR reduction about 85%. Overall, a novel unit cell metamaterial has been presented where the compactness of the size of the meta-atom and its performances makes it compatible to use for the applications of 1768 MHz, 2164 MHz, 4780 MHz, and 5860 MHz i.e. for digital cellular system (DCS), earth exploration-satellite communications (EESC), lower band 5G mobile communications, and WiMAX applications, respectively.

Much Ado About Nothing: Applying a Metamaterial Model with Negative Energy to Address the Vacuum Catastrophe

Thomas P. Weldon and Kathryn L. Smith*

Department of Electrical and Computer Engineering, University of North Carolina at Charlotte, Charlotte, NC, USA
*corresponding author, E-mail: Kathryn.Smith@uncc.edu

Abstract

The vacuum catastrophe remains one of the great enigmas of physics, with more than 50 orders of magnitude separating the observed nanojoule per cubic meter vacuum energy from the theoretical electromagnetic quantum vacuum energy density. Toward bridging this wide gap, we consider an unconventional model for the vacuum using hypothetical metamaterial foam including pockets having negative parameters and negative energy density. The proposed metamaterial properties are selected to preserve normal vacuum behavior after homogenization.

1. Introduction

The vacuum catastrophe remains one of the great unsolved problems in physics, where astronomical observations provide a measured vacuum energy density of $\sim 6.4 \times 10^{-10} \text{ J/m}^3$ compared to the predicted theoretical electromagnetic quantum vacuum energy density of $\sim 10^{114} \text{ J/m}^3$, with a ratio of $\approx 1.6 \times 10^{128}$ [1, 2]. More recently, the discrepancy has been reduced to 54 orders of magnitude in Martin [3]. This huge disparity suggests that any resolution of this problem is likely to require a substantial deviation from existing theory, rather than some modest adjustment to existing theory. We therefore investigate an unorthodox metamaterial model of vacuum, where vacuum is comprised of a metamaterial foam including pockets that have negative parameters and negative energy density.

2. Metamaterial Model of Vacuum

Our proposed model is in part motivated by “space-time foam” notions in certain quantum gravity models, and by earlier investigation of the role of dispersive “foamy” vacuum models in resolving observation of the late arrival of high-energy gamma rays in short gamma bursts [4, 5]. For our vacuum-catastrophe model, we similarly propose a “foamy” structure for the vacuum, where the vacuum is a metamaterial comprised of a mixture of regions having positive and negative permeability and permittivity (and possibly gain or loss) and positive and negative energy densities. The resulting proposed “foamy-vacuum metamaterial” (FVM) must exhibit the normal properties of vacuum, but with the added feature of eliminating the vacuum catastrophe error factor of $\approx 10^{54}$.

In one possible embodiment of the proposed FVM, the metamaterial foam illustrated in Fig. 1 can be comprised of sub-wavelength regions with negative relative permittivity $\varepsilon_{rn} < 0$ and permeability $\mu_{rn} < 0$ embedded in a medium with relative permittivity $\varepsilon_r = 1 - \varepsilon_{rn}$ and permeability $\mu_r = 1 - \mu_{rn}$. For this example, if the negative regions occupy 50% of the volume, the effective permittivity and permeability of the composite would be $\varepsilon_r = 1$ and $\mu_r = 1$ and equivalent to vacuum [6]. Here, the primary motivation for the new model is to divide space into an embedding positive index that contains regions of negative index, where the positive-index regions have very large positive energy densities and very large negative energy densities respectively. Such negative energy densities have been proposed by a number of investigators [7, 8]. Importantly, the average energy density at large scales can be much smaller than the local energy densities when the positive and negative densities nearly cancel each other. The primary motivation is that this model may then simultaneously support the lower energy densities associated with astronomical observations of $\sim 6.4 \times 10^{-10} \text{ J/m}^3$ along with localized high energy densities that may be associated with the $\approx 10^{54}$ larger quantum vacuum energy densities.

In the foregoing example, the overall medium should not suffer from dispersion issues, since $\varepsilon_r = 1$ and $\mu_r = 1$. Although the model includes large local field energies, the total average energy at large scale would equal the observed zero-point or vacuum energy. In essence, passivity and energy conservation are taken to be phenomena applicable at larger scale. Depending on the nature of the underlying metamaterial unit cells and quantum concentrations, it

Figure 1: Illustration of vacuum metamaterial model. The foamy vacuum metamaterial model consists of subwavelength regions (illustrated as spheres above) with different relative permittivity and permeability than the embedding medium, such that the overall medium exhibits the normal vacuum parameters $\varepsilon_r = 1$ and $\mu_r = 1$. 

seems possible that the distribution of energies could be similar to Boltzman, Bose-Einstein, or Fermi-Dirac statistics, but somehow recast in a manner to properly accommodate local negative energy densities.

### 3. Field Energy Considerations

The primary goal of the proposed model is to provide the large energy densities in line with electromagnetic quantum vacuum energy, while retaining the low vacuum energy density at large scale, consistent with astronomical observations. In a region with no sources, Poynting’s theorem is

\[
\int E \times H \cdot \partial s = - \int \left( E \cdot \frac{\partial D}{\partial t} + H \cdot \frac{\partial B}{\partial t} \right) \partial v. \tag{1}
\]

With \( D = \varepsilon_r \varepsilon_0 E \) and \( B = \mu_r \mu_0 H \), Poynting’s theorem in the positive-index regions is then

\[
\int_p E \times H \cdot \partial s = \\
- \int \varepsilon_r \varepsilon_0 E \cdot \frac{\partial E}{\partial t} \partial v - \int \mu_r \mu_0 H \cdot \frac{\partial H}{\partial t} \partial v. \tag{2}
\]

Similarly, Poynting’s theorem in the in the negative-index regions with \( D = \varepsilon_n \varepsilon_0 E \) and \( B = \mu_n \mu_0 H \) is

\[
\int_n E \times H \cdot \partial s = \\
- \int \varepsilon_n \varepsilon_0 E \cdot \frac{\partial E}{\partial t} \partial v - \int \mu_n \mu_0 H \cdot \frac{\partial H}{\partial t} \partial v. \tag{3}
\]

Finally, Poynting’s theorem in a composite region (overlapping many spheres and their embedding regions in Fig. 1) with effective relative permittivity and permeability \( \varepsilon_r = 1 \) and \( \mu_r = 1 \) is simply given as in (1). As noted above, the proposed model is designed to support localized high energy densities within the spheres and within the embedding regions, as may be associated with the large quantum vacuum energy density. Furthermore, the model is also designed to simultaneously present the much lower average energy densities of astronomical observations within composite volumes comprised of both materials.

As a first approximation, suppose that the terms associated with the magnetic and electric field components are of similar proportion in (2) and (3). Next, let \( \varepsilon_r \ll 1 \), \( \varepsilon_p = 1 - \varepsilon_r \), and \( \mu_p / \varepsilon_p = \mu_r / \varepsilon_r = 1 \). Then, to have the ratio of local energy density to large-scale energy density be \( \approx 10^{34} \), would require \( \varepsilon_r \approx -\varepsilon_r \approx 10^{54} \), and similarly \( \mu_r \approx -\mu_r \approx 10^{54} \). The large-scale energy density over a large spatial volume would be \( \approx 10^{54} \) times smaller, since \( \varepsilon_r + \varepsilon_r = 1 \) and \( \mu_r + \mu_r = 1 \) after homogenization over large regions.

Beyond the foregoing example, more complicated redistribution of local energies between electric and magnetic fields could be possible, but in even the most extreme redistribution of local electric and magnetic energy, at least one parameter would be of the order \( \approx 10^{54} \). In addition, the results clearly do not depend on a 50% volume fraction. Lastly, retaining an average effective medium with \( \varepsilon_r = 1 \) and \( \mu_r = 1 \) down to Planck scale may require the unit cells to be less than the Planck length of \( 1.5 \times 10^{-35} \) m.

### 4. Conclusion

A metamaterial model for vacuum has been presented as a possible avenue to explain the \( \approx 10^{54} \) ratio of theoretical and experimental energy densities known as the vacuum catastrophe. The model preserves the measured large-scale permittivity, permeability, and measured energy density of vacuum, while locally admitting energy densities \( \approx 10^{54} \) larger than the large-scale average energy density.

Abstract

We report a study of ENZ behavior in thin-film ITO samples by exciting the Ferrell-Berreman mode. We excite this mode in ITO films on glass, and ITO films with a 10 nm Pt metal backing. We demonstrate that the presence of this 10 nm Pt backing significantly enhances the absorption from this mode from 52.6\% without to 89.9\% with the metal.

1. Introduction

Epsilon-near-zero metamaterials are materials that exhibit a zero or near-zero dielectric permittivity, \( \varepsilon \) in their dispersion. The novel physics of these materials have been studied theoretically and experimentally including effects such as infinite phase velocity\cite{1}, reduced group velocity\cite{2}, super-coupling\cite{3}, and a decoupling of electricity magnetism\cite{4} have all been reported. Of particular interest is the ability to achieve perfect, or near perfect absorption\cite{5} about the ENZ region, attributed to the excitation of a bulk plasmon polariton mode lying to the left of the light line known as the Ferrell-Berreman mode\cite{6}. Initially it was believed that this mode could only be excited by an ENZ material with a metallic backing, however Campione et al. demonstrated the excitation of this mode on ITO on glass in 2016. We examine the excitation of this mode in thin films of ITO, a transparent conducting oxide with ENZ behavior in the near-infrared.

2. Drude model for ITO

ITO, being a transparent conducting oxide with free electrons can be modelled using the Drude Model.

\[ \varepsilon(\omega) = \varepsilon_\infty - \frac{\omega_p^2}{\omega(\omega + i\gamma)} \]  

where \( \varepsilon_\infty \) is the high frequency permittivity, \( \gamma \) is the scattering rate, and \( \omega_p^2 \) is the plasma frequency, given by

\[ \omega_p^2 = \frac{N e^2}{m^*\varepsilon_0} \]  

where \( N \) is the carrier concentration and \( e \) is the charge of an electron, and \( m^* \) is the effective mass of the charge carriers. The ENZ frequency can then be determined using

\[ \omega_{ENZ} = \sqrt{\omega_p^2 - \gamma^2} \]  

The ITO films used in this research were purchased from Sigma Aldrich and the Drude parameters were determined by fitting data taken from NIR spectroscopic ellipsometry to a Drude model. The fitted parameters are listed in Table 1.

3. Transfer matrix method for multilayer structures

The structures studied in the research are composed of multiple thin films layers and due to this we use a technique known as the transfer matrix method to model the reflection and transmission from the multilayered ENZ structure. The transfer matrix method examines the reflected (E\(^-\)) and transmitted (E\(^+\)) components of the incident TM polarized electric field at the boundaries of the layer \( i \) and \( i+1 \) for the film of thickness \( d \). The propagation of the electric field through successive layers can be described using a 2\( \times \)2 transfer matrix, \( M_{i,i+1} \), which is composed of the Fresnel reflection and transmission coefficients.

\[ \begin{pmatrix} E_{i+1} e^{ik_z (d+i)} & 0 \\ 0 & E_{i+1} e^{-ik_z i} \end{pmatrix} = \begin{pmatrix} f_{i,i+1} & t_{i,i+1} \\ t_{i,i+1} & f_{i,i+1} \end{pmatrix} \begin{pmatrix} E_{i} e^{ik_z i} & 0 \\ 0 & E_{i} e^{-ik_z (d+i)} \end{pmatrix} \]  

(4)

Here \( k_z \) is the wavevector normal to the incident plane of the layer and is given by

\[ k_z = \sqrt{\frac{\varepsilon_0 \omega^2}{c^2} - k_0^2 e^2 \sin^2 \theta} \]  

(5)

where \( k_0 \) is the wavevector incident from free space. The transfer matrix of the overall structure then be obtained by taking the product of the successive transfer matrices for each layer, i.e.

\[ T = \prod_i M_{i,i+1} \]  

(6)

From this, the reflection and transmission coefficients for the composite structure can be determined and the absorption can be determined by taking \( 1 - R - T \).

4. Results & Discussion

Figure 1 compares experimental data (a) for ITO thin films of thicknesses 127 nm, 17 nm, and 11 nm for samples 8 – 12, 30 – 60, and 70 – 100 \( \Omega \) sq\(^{-1}\) respectively. There is a region of particularly low reflection in the wavelength range 1000 – 1200 nm and between 30\(^\circ\) – 70\(^\circ\) incidence. The samples were excited from air from the ITO side and this region of low reflectivity is attributed to the excitation of the Ferrell-Berreman mode of ITO. Figure 1(b) shows the T-matrix simulations using the fitted Drude parameters from
The films are quoted in terms of their sheet resistance range, $8 - 12$, $30 - 60$, and $70 - 100 \, \Omega \text{sq}^{-1}$ with thicknesses $127$ nm, $17$ nm, and $11$ nm respectively. (b) The corresponding T-matrix simulations and (c) a comparison of experimental and simulated reflectivities at $53^\circ$.

Table 1. There is high agreement between experiment and simulation, demonstrating that these simple models can be used in conjunction to model the ENZ behavior of ITO films. There is some minor disagreement in the relative values, however this is attributed to the limits of detection of the apparatus used. From this, the reflection and transmission coefficients for the composite structure can be determined and the absorption can be determined by taking $1 - R - T$. Figure 1(c) compares simulation and experiment for the reflectivity at $53^\circ$ incidence. The reflectivity data is presented on a log scale to aid visibility. Transmission measurements were also taken, and the absorption was determined. The $8 - 12 \, \Omega \text{sq}^{-1}$ sample exhibited the largest absorption and this data is presented in Figure 2(a). The absorption in the ITO film alone was $52.6\%$. 10 nm of Pt metal was then deposited on the ITO side of the sample using argon ion sputtering with a Gatan PEC system. This sample was then given the same treatment as before. Figure 2(b) shows the absorption for this Pt-backed sample. The presence of the Pt metal causes a significant enhancement in the absorption of the Ferrell-Berreman mode, bringing the absorption from $52.6\%$ without the metal to $89.9\%$ with the metal.

5. Conclusions

We conclude that the relatively simple Drude free-electron model combined with the transfer matrix method can accurately model ENZ behavior in ITO thin films. We also conclude that the Ferrell-Berreman can indeed be excited without the need for a metal backing, but that the metal backing serves to enhance the absorption of light at the NPA wavelength.

Figure 2(a) Absorption data for an ITO film of $127$ nm thickness, (b) absorption data for the same film with $10$ nm of Pt deposited on the ITO side, and (c) comparison of absorption at $53^\circ$. As shown, there is significant enhancement of the Ferrell-Berreman with the addition of $10$ nm of Pt.

Blueshift in graphene-based hyperbolic metamaterials as a tunable narrowband reflection modulators

Alessandro Pianelli*, Rafał Kowerdzieł, Marek Oliwierczuk, Karol Sielezin, Michał Dudek, Janusz Parka

Military University of Technology, Faculty of Advanced Technologies and Chemistry, Warsaw, Poland

*corresponding author, E-mail: alessandro.pianelli@wat.edu.pl

Abstract

Here, we examine numerically the hyperbolic metamaterials based on graphene(1D-GHMM) in mid-IR frequencies. Using the ability to tune the hyperbolic dispersion of graphene-based HMM by varying the chemical potential, we report a tunable narrowband blueshift in reflectance, especially for different incidence angle in TE/TM modes. Furthermore, a type II and type I hyperbolic dispersion and an effective metal behavior are presented.

1. Introduction

The hyperbolic metamaterial (HMM) is a new class of uniaxial anisotropic metamaterials that has drawn the attention of several engineers and scientists as one of the most influential media in optical and quasi-optical frequencies. HMMs are classified as Type I and type II. In the case of Type I (\( \varepsilon_\parallel > 0 \) and \( \varepsilon_\perp < 0 \)) the materials behaves as a dielectric in the plane xy and as a metal in the z direction. Type II (\( \varepsilon_\parallel < 0 \) and \( \varepsilon_\perp > 0 \)) instead has two components of the dielectric tensor negative (in-plane) whereby the HMM behave as a metal [1]. This anisotropic behaviour therefore causes an unusual hyperbolic dispersion for the medium and as a result, many interesting phenomena have been observed as light enhancement [2], sub-wavelength imaging [3] etc. Lately, graphene plasmonics and HMMs based on graphene (1D-GHMM) have stirred great interest in the scientific community because of the ability of graphene to tune the conductivity by changing the chemical potential (\( \mu \)) [4-6].

2. Model and theory

The anisotropy of hyperbolic metamaterials can be described by their effective dielectric tensor \( \tilde{\varepsilon} = [\varepsilon_{xx}, \varepsilon_{yy}, \varepsilon_{zz}] \). The dielectric components direction in plane and out-plane to the interface of the 1D-GHMM are \( \varepsilon_{xx} = \varepsilon_{yy} = \varepsilon_\parallel \) and \( \varepsilon_{zz} = \varepsilon_\perp \) respectively. The graphene-based HMM consisting of a unit cell (N) of graphene/dielectric (SiO₂) stack. The inset image in the Fig. 1 (a) is possible to see one unit cell (N=1). The value of the tensor components are as follows [7]:

\[
\varepsilon_\parallel = \frac{t_d \varepsilon_g + t_g \varepsilon_d}{t_g + t_d}, \quad \varepsilon_\perp = \frac{t_g \varepsilon_d (t_g + t_d)}{t_g \varepsilon_d + t_d \varepsilon_g} \tag{1}
\]

Here, \( t_d \) and \( \varepsilon_d \) are the thickness and dielectric permittivity of dielectric layer which in our calculations have been set at 150 nm and 2.10, respectively. Since the graphene thickness is negligible compared with dielectric layer, the perpendicular dielectric tensor can be considered equal to the permittivity of the dielectric layer (\( \varepsilon_\perp \equiv \varepsilon_d \)). The graphene’s effective permittivity can be written as [7]:

\[
\varepsilon_g = 1 + \frac{\sigma(\omega, \mu, \Gamma, T)}{\omega \varepsilon_0 \varepsilon_g} \tag{2}
\]

where \( \varepsilon_0 \) is the vacuum permittivity and \( \sigma \) is the conductivity of a single layer of graphene. The surface conductivity for a single layer of graphene is given by Kubo formula [8]:

\[
\sigma(\omega, \mu, \Gamma, T) = \sigma_{\text{intra}} + \sigma_{\text{inter}} \tag{3}
\]

\[
\sigma_{\text{intra}} = \frac{-i e^2}{\hbar n_{\omega + i 2 \Gamma}} \int_0^\infty \xi \left( \frac{\partial f_g(\xi)}{\partial \xi} - \frac{\partial f_d(-\xi)}{\partial \xi} \right) d\xi \tag{4}
\]

\[
\sigma_{\text{inter}} = \frac{i e^2 (\omega + i 2 \Gamma)}{\pi \hbar^2} \int_0^\infty \frac{f_d(-\xi)-f_d(\xi)}{(\omega + i 2 \Gamma)^2 - 4 (\xi/\hbar)^2} d\xi \tag{5}
\]

\[
f_d(\xi) \equiv \frac{1}{\exp((\xi-\mu)/2k_B T)+1} \tag{6}
\]

where \( \omega \) is the angular frequency of the incident electromagnetic wave, \( \Gamma \) is the scattering rate which we set equal 0.1 meV, \( \mu \) is the chemical potential , \( T \) the temperature, \( e \) is the electron charge, \( h \) is the reduced Plank constant and \( k_B \) is the Boltzmann constant. The equation (6) is the Fermi-Dirac distribution. The two conductivity terms in (4) and (5) are referred to as the intraband and interband terms, respectively.

3. Result and discussion

Figure 1. (a), show a blue-shift in reflectance (up to 2.7 \( \mu m \)) as well as narrow band edge for the 20 bilayers of graphene/dielectric stack structure with 6 monolayers of graphene (6MG) for different value of chemical potential. The permittivity tensor components for different monolayer of graphene is depicted in the Fig. 1 (b), transition for elliptic regime to hyperbolic type II regime is observed for the case (6MG) and (3MG).
Fig. 1. (a) Reflectance spectrum as a function of the chemical potential, (b) permittivity tensor components for different monolayer of graphene, (c) and (d) reflectance spectra for TE and TM modes respectively.

stunning and fascinating behavior for the structure with 1MG; it is possible to observe different isofrequency dispersion: \( \epsilon_\parallel \cdot \epsilon_\perp > 0 \) elliptic, isotropic \( \epsilon_\parallel = \epsilon_\perp \), Type I \( \epsilon_\parallel > 0, \epsilon_\perp < 0 \) as well as effective metallic one \( \epsilon_\parallel \cdot \epsilon_\perp < 0 \). Figures 1(c) and (d), illustrate the reflectivity spectra for the TE and TM modes for different angles of incidence \( \theta \); in here while the characterization angles dependency is less in the case of TM a more dependency of the incident angles is observed for the TE mode.

4. Conclusions

In this article, we investigate hyperbolic metamaterials based on graphene (1D-GHMM). The excellent advantage of using graphene instead of metal is the possibility to tune the optical properties in THz, infrared and in optical frequencies ranges as well by adjusting the chemical potential thus providing an active control of the hyperbolic dispersion. We have demonstrate how a tunable narrowband blueshift can be achieved in terms of reflectance in the mid-IR range. A type I and type II hyperbolic dispersion and an effective metal behaviour were obtained by modifying the number of graphene monolayers. The observed features make the 1D-GHMM as one of the most suitable candidates in terms of reflection modulator, tunable edge and narrowband spatial filter for novel optoelectronic applications.

Abstract

In this study, a new broadband metamaterial absorber based on cross-shaped nano-antennas was designed in order to improve the light absorption in organic active layers. The structure was composed of three layers, in which three split cross nano-antennas, made of metal aluminum, are encrusted on the top of different organic active layers, namely poly(3-hexylthiophene-2,5-diyl) (P3HT), Pheny1-C61-butyric acid methyl ester (PCBM) and bulk heterojunction of P3HT:PCBM. A numerical simulation has been performed by using high-frequency structure simulator (HFSS). According to the simulated results, our designed structure has significantly enhanced the light absorption in the organic thin films, whereby exhibited a broadband in the visible and infrared spectrum of light. When cross resonators are coated on the top of the active layers, an obvious redshift along the optical absorption edge was noticed. We believe that the proposed nano-antenna based metamaterial structure can be a promising approach for the application of organic and hybrid solar cells.

1. Introduction

Photovoltaics (PV) technology is the most dynamically developing area of today’s renewable electricity production by means of using solar energy. PV devices are successfully utilized to convert sunlight energy into electricity by means of solar cells comprising various architectural designs and active materials [1–4]. However, conventional solar cells based on inorganic materials are suffering from the high cost and high-energy requirement during the production process. Alternatively, organic based PV devices have received considerable attention for their flexible, transparent and lightweight properties [5–7]. In this way, various binary bulk heterojunction (BBHJ) and ternary bulk heterojunction (TBHJ) architectures have been proposed to achieve an improved absorption of light by the active layers [3, 8–12]. Upon having larger thickness of organic thin films, the increased light absorption comes at the expense of charge transport efficiency. This is because the larger thickness of the active layer can become a bottleneck in front of the soon arrival of free charge carriers (electrons and holes) to their respective electrodes, leading to the recombination of charges and hence a decreased charge mobility. The utilization of nanosized structures [13] or subwavelength sized materials, known as metamaterials [14, 15], is technically important [16, 17]. In the past decade, metamaterials have attracted increasing research attention in artificial engineering and synthetic composite material for their exhibiting properties unattainable in naturally occurring materials [18, 20]. These advanced metamaterials have been applied in cloaking [21], energy harvesting [22], solar cells [23] and super lens [24]. Furthermore, researches on perfect metamaterials absorber (MMA) in the microwave frequency [25], THz frequencies [26], infrared [27] and optical [28] ranges have been widely carried out. In the process of designing perfect metamaterial absorber structures, one of the most important steps is the selection of their size, shape and geometrical orientation (geometrical parameters) for any intended metamaterial absorber unit cell. Researchers have considered various metamaterial shapes, namely sawtooth, rectangular and circular shapes to improve the light absorption by organic and inorganic thin films for the application of solar cells [17, 29, 30], while little attention has been paid to the utilization of cross-shaped metamaterials for the light absorption enhancement in organic thin films. Hence, in the current research work, a new broadband metamaterial unit based on cross-shaped structure is designed and utilized to improve the light absorption in organic active layers.

2. Design and Simulation of the Proposed Structure

The architectural design of the proposed metamaterial structure is shown in Figure 1, which consists of three main layers deposited onto a glass substrate from bottom to top as follows: ITO, organic active layer and aluminum resonators (cross-shaped nano antenna). Hereafter, the whole proposed design is referred to as metal-absorber-metal (MAM), while the three active layers, namely P3HT, PCBM and P3HT:PCBM are investigated for their absorption profile in the visible and infrared spectral range with
and without coating the metamaterial nano-antenna onto their surfaces. Table 1 presents the optical and magnetic related parameters of the three layers that were used in the simulation process. The nano-antenna was chosen to be a metal aluminum with an electric conductivity of about $3.56 \times 10^7$ S/m.

The other geometric parameters that appear in Figure 1 are as follows: $p_x = p_y = 520$ nm, $W = 30$ nm, $l = 100$ nm, $h_1 = 20$ nm, $h_2 = 35$ nm, $h_3 = 70$ nm and $h_4 = 15$ nm. A full-wave electromagnetic simulation was performed by using finite-element analysis based on the High-Frequency Structure Simulator (HFSS). The periodic boundary conditions (PBCs) and Floquet port are utilized to simulate the infinite periodic cells.

$$A(w) = 1 - |S_{11}(w)|^2$$

The reflectance $R = |S_{11}(w)|^2$ is relatively high except where the metamaterial has a strong impedance matching with the incident wave medium and it reaches its minimum value. Hence, the transmission value can be removed from the equation,

$$A(w) = 1 - |S_{11}(w)|^2$$

Furthermore, the dispersive behavior of the extinction coefficient and refractive index of the organic active layers in the visible regime are shown in Figure 2.

Figure 1: Schematic structure of the designed MAM (a) top view (b) oblique view (c) side view.

Figure 2: Dispersion spectra of the P3HT, PCBM and P3HT:PCBM thin films: (a) extinction coefficient (b) refractive index.

In the simulation process, the values of relative permittivity ($\varepsilon_r$) and relative permeability ($\mu_r$) were considered around the characteristic absorption peaks of the films, whereas the simulation program compensated for the dispersive response of the active layer. The relative permittivity and relative permeability were calculated respectively from the following equations [34].

$$\varepsilon_r = n^2 - k^2$$

$$n = \sqrt{\varepsilon_r + \mu_r}$$

3. Results and Discussion

The overall absorptivity characteristic of the proposed structure can be calculated by using the well known equation:

$$A(w) = 1 - |S_{11}(w)|^2$$

Where $S_{11}(w)$ and $S_{21}(w)$ represents reflection and transmission coefficients of the metamaterial unit cell, respectively. As it is expected, simulations indicate that the transmittance $T = |S_{21}(w)|^2$ is effectively zero across the entire frequency range due to the metallic ground plane.

Figure 3 shows the normalized absorption curves for P3HT active layer with and without cross nano-antenna. Noticeably, the absorption spectrum without resonator, resembling the experimentally observed spectrum, shows a single peak at 595 nm. This is ascribed to the electronic transitions from bonding ($\pi$) to antibonding ($\pi^*$) energy levels [35]. Comparatively, in the presence of nano antenna, there are two essential peaks at 525 nm and 710 nm observed corresponding to the absorptivity of 92% and 100%, respectively. The coating of three cross nano antenna on the top of P3HT has led to a broadened absorption spectrum and redshift in the absorption peak (shifting towards higher wavelength), as shown in Figure 3. This is specifically important for solar cells application because a wider range of solar spectrum can be possible to be absorbed by the active layer, which in turn results in a larger charge carrier generation and hence higher efficiency is yielded [36].

Figure 4 shows the simulated absorption spectra generated for PCBM with and without the cross shaped nano-antenna. The active layer without nano-antenna (pristine
PCBM) exhibits an absorption peak around 355 nm, which is close enough to that of the experimentally grown PCBM films [12, 32]. The shape consistency of the characteristic peak of PCBM with nano-antenna indicates the existence of a strong coupling between cross nano-antenna and PCBM film, whereby interesting electromagnetic scattering and constructive interference have been resulted.

In order to investigate the variations happen in the apparent optical energy gap of the proposed structures due to the coating of the nano-antenna resonators, Tauc’s equation was applied to plot curves of \((\alpha h\nu)^2\) against the energy of photons thereby estimating the precise value of energy band gap (absorption edge position), as shown in Figure 6(a). Where, \(\alpha\) is the absorption coefficient, \(h\) is Planck’s constant and \(\nu\) is the photon frequency. Complete information regarding the use of this equation to determine the optical band gap is given in [31]. One can find the value of energy gap \(E_g\) directly from the intersection of x-axis at the point where \((\alpha h\nu)^2 = 0\). By using this technique, energy gap of the proposed metamaterial absorber for P3HT layer with nano-antenna and without nano-antenna were estimated to be 1.5 eV and 1.7 eV, respectively. In this way, the band gap of the active layers is interestingly reduced, meaning that the low energy photons of sunlight can also be involved in the process of photo-absorption. Conclusively, the wider range of photon absorption results in higher free electrons and holes generation, thereby improving the overall performance of organic solar cells. These energy gaps are corresponding to the wavelength of 824 nm and 727 nm, respectively, indicating the present of a useful red-shift in the absorption spectra of the P3HT organic thin film.

It is seen from Figure 6(b) that when the PCBM active layer is coupled with the nano-antennas, the active layer exhibited a broad absorption band comprising three absorption peaks. Consequently, the absorption edge of the spectrum is greatly redshifted, i.e. the apparent energy gap of the metamaterial unit is considerably reduced. The value of energy gap was measured to be 2.76 eV and 1.95 eV for the MAM structure without and with the nano-antenna coated onto the PCBM layer, corresponding to the absorption edge of 449 nm and 635 nm, respectively.
Noteworthy, the energy gap of P3HT:PCBM (see Figure 6(c)) was found to be higher than that of pristine P3HT film (see Figure 6(a)). This could be attributed to the influence of PCBM absorption which is mainly in the ultraviolet region [37]. It was noticed that the value of apparent energy gap is 2.49 eV before coating the nano-antenna resonators onto the P3HT:PCBM. However, by considering the nano-antenna into account, the absorption edge in terms of energy gap was significantly reduced to 1.61 eV. As such, the deposition of cross nano-antenna on top of organic thin films can greatly enhance their light absorption capability, suggesting the viable contribution of cross shaped resonators in the improvement of light absorption of organic thin films.

To investigate the photovoltaic performance of a representative OSC based on the proposed P3HT:PCBM/Al-resonator system, theoretical equations were utilized to estimate the short circuit current ($J_{sc}$), open circuit voltage ($V_{oc}$) and maximum power ($P_{m} = V_{m} \times I_{m}$), thereby extracting the current-voltage (I-V) characteristic of the device. From the spectrally resolved absorption $A(\lambda)$ in the active layer, short circuit current density ($J_{sc}$) was calculated as follows [38]:

$$J_{sc} = \int \frac{q}{\hbar c} A(\lambda) \Lambda M 1.5G(\lambda) d\lambda$$  \hspace{1cm} (5)

where $q$ is the electron charge, $h$ is Planck’s constant, $c$ is the speed of light and $AM 1.5G$ defines the global spectral solar irradiance [14]. Interestingly, the value of $V_{oc}$ was determined according to this formula [39]:

$$V_{oc} = \frac{nKT}{q} \ln(\frac{J_{sc}}{J_o} + 1)$$  \hspace{1cm} (6)

where $n$ is the ideality factor of the cell, $T$ is the cell temperature in Kelvin, $k$ is Boltzmann’s constant and $J_o$ is the saturation current which can be determined by:

$$J_o = N_e N_A \mu KT \exp(-\frac{E_g}{KT}) \frac{1}{LN_A}$$  \hspace{1cm} (7)

Where $N_e/C$ is the effective density of states in the valence/conduction band, $L$ is the diffusion length, $N_A$ is the acceptor density and $\mu$ is the mobility. We have previously noticed that for thiophene based OSC, the ratio of $V_{oc}/V_m$ is about 1.60 [12]. Consequently, by assuming an ideality factor of $n = 2$ for the devices and considering the single-diode modelling [40], simulated I-V data for the proposed structure with and without the presence of cross shaped nano-antenna resonators have been extracted. Figure 7 shows the I-V characteristic curves of the proposed design, while Table 2 tabulated the photovoltaic parameters and devices efficiency. Results showed that the deposition of cross shaped nano-antenna resonators onto the P3HT:PCBM active layer has led to improvement in the overall efficiency of the device from about 2.61 % to 2.66 %. It is worth mentioning that the addition of resonators acted to increase $J_{sc}$ but a trivial decrease in $V_{oc}$, whereas the overall power was seen to be increased and hence a better device performance was achieved.

In order to understand the absorption mechanism of the proposed metamaterial structure and the resonance behaviour, the electric field and magnetic field distribution for the three different active layers were investigated at the
main characteristic absorption peak of the active layers.

Figure 8 shows the electric field distribution of the resonator-coated organic thin films at different resonant wavelengths for the different organic active layers. It is noticed that at resonant wavelength of 710 nm for the P3HT layer and 750 nm for the P3HT:PCBM the electric field is weakened. When the structures are illuminated by the low energy incident light, localized surface plasmon is difficult to reach the excitation threshold due to the mismatched frequencies between the absorbed photons and the characteristic absorption peak of the active layer. While for the PCBM at incident wavelength of 560 nm, the electric field intensity is mostly concentrated around the edge of cross-shaped resonators. This is because the high energy/frequency electric field component of the incident wave produces surface current in the cross-shaped metamaterial [41], thereby oscillating the surface charges along the external electric field. This demonstrates effects of the localized surface plasmon in metamaterials [17].

Figure 8: Electric field distribution of the proposed structures at the main characteristic absorption peaks of the organic thin films.

Figure 9 shows the colour map representation of magnetic field distribution for the three organic active layers at main resonance wavelengths. For the P3HT active layer at resonance wavelength of 710 nm, a strong magnetic field in the centre of cross resonator was observed. This is in agreement with our previous observation, where the electric filed distribution is weak/strong at the certain resonant wavelength, instead, the magnetic field confinement spreads within the whole structure and is strong/weak at the corresponding resonant wavelength. Thus, strong magnetic field is observed at 710 nm [17]. At the incident wavelength of 560 for the PCBM, magnetic field distribution is weak compared to that of the P3HT layer. For the structure of ITO/P3HT: PCBM/resonator, the magnetic field distribution at 750 nm showed a strong localized field at the centre of cross resonator. According to the simulated results, both electric field and magnetic field resonances are capable of well improving the light distribution within the organic active layers.

Figure 9: Magnetic field distribution for the metamaterial absorbers at 710 nm incident wavelengths for the PEHT, 560 nm for the PCBM and 750 for the P3HT:PCBM active layers, respectively.

4. Conclusions

A new metamaterial structure was designed by incorporating cross-shaped metamaterial resonators on the top of organic active layers of P3HT, PCBM and P3HT:PCBM. The main characteristic peak of P3HT:PCBM is redshifted from about 565 nm to 725 nm with the presence of resonators. The apparent energy gap can be reduced from 2.49 eV to 1.61 eV by incorporating aluminum resonators with the P3HT:PCBM system. The electromagnetic field distribution exhibited that red shifting in the absorption peaks is provided by the cross-shaped resonators. The designed structure has significantly enhanced light absorption ability in organic thin films and exhibited a broadband in the visible and infrared spectra. The proposed metamaterial structure was found to improve the overall performance of organic solar cells based on P3HT:PCBM active layer, suggesting a viable utilization of cross shaped resonators for enhancing organic and hybrid solar cells.

Abstract

This paper demonstrates a study Circular Patch Antenna using SINRD substrate. The SINRD structure is the air holes used in the substrate. The proposed antenna is designed at an operating resonant frequency of 2.4 GHz to meet Wi-Fi 802.11 applications. The designed microstrip patch antenna’s gain, bandwidth and directivity are analyzed before and after introducing SINRD structure. From the comparison of three different configurations of SINRD substrate have been studied. The simulation has been performed using CST Microwave Studio.

I. INTRODUCTION

The microstrip patch antennas have been increasingly used in recent years in wide range of application in wireless communication systems and satellite communication systems due to their great advantages: light weight, low cost, low profile, and conformable. On the other hand, it suffers from some disadvantages as: narrow bandwidth, low gain, excitation of surface waves.

Among the most popular configuration is the circular patch. It also has received a lot of attention not only as a single element [1-3]. Some technique was used to increase the gain and directivity of microstrip antenna in microwave frequency regime, and topologies have been investigated in several researches [4-5].

A solution proposed in this work is the concept of substrate integrated circuits (SICs), which was used of a specific air hole pattern that can effectively lower the dielectric constant of a dielectric substrate region of interest, thus, creating a wave-guiding dielectric channel in the substrate. This synthesized channel becomes a substrate integrated NRD guide or SINRD [6].

The substrate integrated nonradiative dielectric (SINRD) waveguide belongs to the family of substrate integrated circuits [7], [8], a promising low-cost high-performance technology for millimeter-wave and terahertz applications. In this technology, the air region of a nonradiative dielectric (NRD) guide is replaced by air holes or a low-dielectric agent on the same substrate, which removes the problem of mechanical support and assembling of the planar substrate that arises in the case of hybrid planar/NRD schemes [9].

In this letter, we propose a new design of realizing high directivity of the patch antenna under CST software working at a frequency of 2.4 GHz, inspired by a work already done for rectangular microstrip patch antenna. We will carry out several simulations of patch antennas based on standard dielectric substrates and then based on SINRD substrates with different configurations of the air holes.

At the end a comparative study was made between the results of circular microstrip patch antenna and of the rectangular microstrip patch antenna.

II. DESIGN AND ANALYSIS

The microstrip patch antenna is a planar antenna whose radiating element is a generally square conductive surface, separated from a conductive reflector plane (ground plane) by a dielectric sheet called substrate as shown in Fig. 1(a).

![Figure 1a. Patch antenna with rectangular radiation.](image)

In this configuration, upper conducting layer is the source of radiation where electromagnetic energy fringes off the edges of the patch and into the substrate. The lower conducting layer acts as a perfectly reflecting ground plane, bouncing energy back through the substrate and into the free-space. The antenna size mostly depends on the frequency band of operation.

Topology of the proposed SINRD guide is illustrated in Fig. 1(b). shows the pattern of air holes used to lower dielectric constant of the substrate with geometrical dimensions.
In this equivalent guide, \( \varepsilon_r \) equals to \( \varepsilon_{eff} \) of the air holes patterned region.

The equivalent NRD guide greatly simplifies the design of SINRD circuits. Note that the air hole pattern should not be subject to the generation of electromagnetic bandgap (EBG) phenomena.

A. Design Circulaire Microstrip Patch antenna

The parameters of the radiating microstrip patch antenna are calculated with the following equations [10].

\[
\alpha = \frac{T}{\left[1 + \frac{2b}{\pi \varepsilon_r \left[\ln\left(\frac{\pi a}{2b}\right) + 1.7726\right]\right]^{1/2}} (1)
\]

\[
F = \frac{8.791 \pi \mu_0^9}{\varepsilon_r \sqrt{\varepsilon_r}} (2)
\]

The dominant mode is the \( TM_{110} \) whose resonant frequency is:

\[
\left( f_r \right)_{110} = \frac{1.8412v_0}{2\pi \alpha \sqrt{\varepsilon_r}} (3)
\]

The resonant frequency of equation (3) does not take into account fringing. Fringing makes the patch look electrically larger and it was taken into account by introducing a length correction factor. Similarly for the circular patch a correction is introduced by using an effective radius \( \varepsilon_{eff} \), to replace the actual radius \( \varepsilon_r \).

\[
\varepsilon_{eff} = \alpha \left[1 + \frac{2b}{\pi \varepsilon_r \left[\ln\left(\frac{\pi a}{2b}\right) + 1.7726\right]\right]^{1/2} (4)
\]

Therefore the resonant frequency of equation (3) should be modified by using equation (4) and expressed as:

\[
\left( f_r \right)_{110} = \frac{1.8412v_0}{2\pi \alpha \sqrt{\varepsilon_{eff}}} (5)
\]

Where \( v_0 \) is the speed of light in free-space.

B. Design air hole pattern

The first step in the design of an SINRD guide is to evaluate \( \varepsilon_{eff} \) for a specific cell lattice with a specific dielectric material. It is known [11–12] that an appropriate air hole arrangement in a planar dielectric substrate could reduce the effective dielectric constant of the structure. The choice depends on the dielectric profile needed, the layout of the circuit and the, mechanical strength of the substrate [7]. Three possible holes patterns, namely, a square lattice, an equilateral triangular lattice and a star lattice. In each case, the static effective dielectric constant of one cell can approximately be calculated by using [8].

\[
\left( f_r \right)_{110} = \frac{1.8412v_0}{2\pi \alpha \sqrt{\varepsilon_{eff}}} (5)
\]

Where, \( \varepsilon_{eff} \) is the area of a unit cell of the pattern and \( \varepsilon_{air} \) is the area of air holes in the unit cell.

Table I gives the value of \( \varepsilon_{eff} \) of each pattern (or lattice) for different holes diameters.

C. Circular Microstrip Patch Antenna with SINRD substrate

The design of the circular patch antennas with SINRD substrate are based on the same model of the waveguide...
(width of the non-perforated zone, radius of the air holes "R" and the distance between the holes "Gap") integrated in the substrate Dielectric FR-4 for the three arrangements of the SINRD holes.

The choice of the geometry of the SINRD substrate was made according to several criteria:
- R should be as large as possible to improve antenna performance and reduce the losses in the guide.
- Gap must also be as large as possible to allow the mechanical integrity of the guide.
- The diameter of the air holes must be limited to prevent the phenomena of Electromagnetic BandGap (EBG) in the desired frequency band.

The Fig. 3 and 4, 5 shows integration of SINRD structures for the circular patch antenna with air holes in dielectric square, triangular, star lattice respectively at 2.4 GHz frequency region.

IV. RESULT SIMULATION AND DISCUSSION

The result simulation was obtained using TIME DOMAIN solver in CST Microwave Studio with accuracy -40dB.

A. Impedance bandwidth

The simulated return loss of circular microstrip patch antenna S11 represents the reflection coefficient at the antenna input. This parameter also allows ensuring the adaptation of the antenna to the resonant frequency. The curve of the modulus of the coefficient of reflection of the antenna structure shows a good adaptation of about -31.56 dB at the resonant frequency of 2.4 GHz.

The impedance bandwidth for this antenna is 39.8 MHz calculated at -10dB return loss.

The adaptation of the patch antenna with SINRD substrate square lattice is very satisfactory with a reflection coefficient of less than -10 dB between 2.39 and 2.42 GHz and a minimum of -21.19 dB at 2.4 GHz as shown in Fig. 6. The impedance bandwidth equal to 32.05 MHz is largely sufficient for our antenna.
The Fig. 7 represent the reelection coefficient of the patch antenna with SINRD substrate triangular lattice, the impedance bandwidth is 21.20 MHz calculated at -10dB.

Adaptation of the circular microstrip patch antenna with SINRD substrate star lattice is done on a bandwidth of 32.98 MHz around 2.4 GHz, which is wider, compared to that found by the single microstrip patch antenna with a minimum of -27.78 dB as like represented in Fig. 8.

B. Radiation pattern
The simulated radiation pattern for the gain and directivity of the circular microstrip patch antenna and the circular microstrip patch antenna with SINRD substrate with different structure (square, triangular, star) are indicated in Fig. 9, Fig. 10 and Fig. 11, Fig. 12, Fig. 13, Fig. 14 respectively at 2.4 GHz frequency.

Figure 7: Simulation S11 for circular microstrip patch antenna with SINRD triangular lattice.

Figure 8: Simulation S11 for circular microstrip patch antenna with SINRD star lattice.

Figure 9: Diagrams of the gain of the four antennas in Cartesian coordinates.

Figure 10: E plane far Radiation pattern of gain for Phi=0° for circular microstrip patch antenna with different substrate.

Figure 11: E plane far Radiation pattern of gain for Phi=90° for circular microstrip patch antenna with different substrate.

Figure 12: Diagrams of the directivities of the four antennas in Cartesian coordinates.
The simulation results show that the main lobe direction for the gain reaches a maximum of 6.98 dB, and directivity 7.32 dBi of circular patch antenna with star lattice.

The Table II summarizes the simulated results obtained with different configurations of circular microstrip patch antenna.

The electromagnetic wave transmission properties of the circular patch antenna show that all of the improvements are due to the SINRD structure substrate.

Optical and Nonlinear-Optical Properties of Gold Nanorods’ Based Hyperbolic Metamaterials

Moscow State University, 119991 GSP-1, Leninskie Gory, Moscow, Russia
*corresponding author, E-mail: irisha@shg.ru

Abstract

We present the experimental results on optical and nonlinear-optical effects in hyperbolic media based on gold nanorods arrays in porous anodic alumina, demonstrating pronounced effects attributed to epsilon-near-zero and epsilon-near-pole dispersion points. In the spectral vicinity of the epsilon-near-zero, an enhancement of the optical activity and of the second harmonic intensity are observed.

1. Introduction

Physics of hyperbolic metamaterials (HMM) that are artificial anisotropic uniaxial metal-dielectric nanostructured media [1, 2] attracts much attention nowadays. The main property of this type of material is the hyperbolic optical dispersion law. The two simplest designs of the HMM are (i) films of alternating conducting and non-conducting layers and (ii) arrays of metal (usually Au or Ag) nanorods in a dielectric matrix, which lead to the appearance of specific points in the $\epsilon$ components’ spectra - epsilon-near-zero (ENZ) and epsilon-near-pole (ENP) [3], where a giant enhancement of optical effects is expected. Besides, new properties that are not observable in natural materials can appear close to these specific spectral points. Along with these spectral features, HMMs exhibit strong birefringence [4] and hyperbolic dispersion. It leads to the giant enhancement of well-known effects and appearance of novel optical phenomena that are not observable ordinary media. As an example negative refraction, enhancement of spontaneous emission, transformation of the evanescent field into propagating mode in the far field have been observed in HMM [1]. These effects are perspective for applications in nanophotonics, biosensing, high-resolution imaging, waveguiding. As well HMM are promising from the point of view of observing for the nonlinear optics [5, 6]. Although there are several works in this field, most of them are theoretical [5, 6]. It has been shown that the HMM dispersion law allows one to satisfy the phase-matching conditions for the sum- or difference-frequency nonlinear processes [7]. Spectral dispersion of HMM dielectric tensor components allows one to achieve various phase synchronisms involving different dispersion law regimes in frequency conversion process [7]. Numerical calculations predicted a strong enhancement of the third harmonic generation [8] and difference frequency generation [9] due to the phase-matching in hyperbolic multilayered films at definite spectral points. To the best of our knowledge the corresponding experiments have not been performed yet.

Nonlinear-optics is very sensitive to the resonant effects [10, 11] and electromagnetic field localization within an irradiated structure [12]. Particularly, the amplification of second harmonic generation (SHG) in a hyperbolic medium by the excitation of the Fabry-Perot modes in an effective film was observed [13]. It was shown that when the pump or second-harmonic wavelength lies in the region of hyperbolic dispersion, the value of effective second-order susceptibility is comparable with the susceptibilities of well-known nonlinear crystals such as lithium niobate (LiNbO$_3$) and potassium dihydrogenophosphate (KDP). The second-harmonic generation intensity can be enhanced in a wide spectral range due to the multiple waveguide modes in an anisotropic HMM film [14].

Nonlinear-optical effects in the spectral vicinity of the ENZ points have been analyzed in a number of papers. Due to the appearance of a singularity of the TM fundamental electric field $E_m$ for a material with the permittivity close to zero, nonlinear optical response should be enhanced many-fold. It takes place in an isotropic film with ENZ as well [15, 16], and quite recently was observed in the second harmonic generation (SHG) for arrays of nanorods in anodic aluminum oxide (AAO) [13] and ITO nanolayers in the visible range [17]. It should be noted here that third-order nonlinear effects are also enhanced near the ENZ point [18]. Nevertheless, listed works concern materials with poor plasmonic behaviour, where the ENZ point doesn’t separate spectral regions with elliptical and hyperbolic dispersion.

One of the effective and convenient techniques for the HMMs fabrication is templated electrodeposition of gold or silver inside the cylindrical channels of anodic aluminum oxide (AAO) matrices. Such arrays of nanorods in dielectric matrix possess two plasmon resonances (along and perpendicular to the nanorods axes) that correspond to the electron gas oscillations [19].

In this paper the comparative experimental and numerical studies of the linear optical spectroscopic ellipsometry, SHG intensity and SHG phase spectroscopy of anisotropic gold-nanorods-based HMMs in the spectral vicinity of the ENZ and ENP points are presented.
2. Samples and experimental techniques

Arrays of gold nanorods in anodic aluminum oxide (AAO) matrices were made by templated electrodeposition as described in [20, 21]. Au nanorods of about 40 nm in diameter and 580 ± 40 nm in length are aligned perpendicularly to the sample’s surface, the volume fraction of metal being about 8%. Transmittance of the prepared films was studied using a halogen lamp as a broadband p-polarized light source. The polarization of the transmitted radiation was estimated using the commercial ellipsometer WVASE by J.A. Wollam Co., Inc. For the SHG experiments, we used the p-polarized output of a 80 fs pulsed Ti:Sapphire laser at tunable in the wavelength range, repetition rate of 80 MHz and the average power of 50 mW, focused on the sample into a spot of ≈50 μm in diameter. The sample was mounted on the rotation stage allowing changing of the angle of incidence. The transmitted SHG radiation was spectrally selected by a color filters and detected by a photomultiplier.

In order to reveal the variation of the second harmonic phase close to the ENZ point, the SHG phase spectroscopy was performed by means of the interferometry technique [22], when using a 50-nm-thick ITO film as a reference SHG source. The scheme of the experiment was similar to that described in [23]. During the measurements we changed the relative distance z between the reference ITO film and the sample varying the phase difference between the SHG waves generated in sample and reference due to the dispersion of air. The interferometry patterns were measured for all the accessible wavelengths of the pump radiation and were approximated by the function $I_{2\omega} \propto I_0 \cos(2\pi z/d + \varphi_S) + \text{const}$, thus the spectrum $\varphi_S(\lambda)$ was obtained. Then the similar measurements were performed while the sample was replaced by another ITO film to obtain the spectrum $\varphi_R(\lambda)$ analogously. To normalize over the spectral changes of the period d of the interferometry pattern the phase $\varphi_R$ was subtracted from the phase of the sample $\varphi_S$.

Simulations of nonlinear-optical spectra were performed for the effective slab, taking into account strong anisotropy of the medium, the distribution of the vectorial electric field within the structure and neglecting the spectral dependencies of the second-order susceptibility tensor components.

3. Experimental and simulation results

Transmission spectrum of the sample (Fig. 1 (a)), measured for the angle of incidence of $\theta = 45^\circ$ shows the two minima centered at about 540 nm and 820 nm, which correspond to the transverse and longitudinal local plasmon resonances of free electrons Au rods in the directions perpendicular and parallel to the nanorods’ axis, respectively [19]. Longitudinal resonance cannot be excited at normal incidence of pump radiation and the depth of the long-wavelength minimum increases with increasing $\theta$ as was discussed earlier [20]. It is worth noting that the minima are absent for bulky Au or AAO.

The main ellipsometry parameter $T_1$ was estimated as the ratio of the complex field transmission coefficient, $T_1 = T_{pp}/T_{ss} = \tan \Psi e^{i\Delta}$, with $pp$ and $ss$ subscripts denoting the polarization of the incident and transmitted light. Fig. 1 (b) shows the obtained $T_1$ spectrum with the indicated ENP and ENZ points. One can see that the smallest absolute value of $T_1$ corresponds to the ENZ point characterized by a strong absorption of p-polarized light in this spectral region.

Both experimental and simulation data indicate that the spectral behavior of the SHG spectra strongly depends on the angle of incidence (Fig. 2). For $\theta = 25^\circ$ we observed about five times enhancement of the nonlinear signal in close vicinity of 820 nm fundamental wavelength, corresponding to the the long-wavelength minimum of linear transmission. At the same time for the normal incidence and for $\theta = 45^\circ$ no SHG intensity enhancement was revealed in the spectral region under study which agreed qualitatively with the numerical results.

The interferometry measurements were performed for the angle of incidence $\theta = 25^\circ$, as it corresponds to the enhancement of the SHG intensity. A typical interferometry pattern (for pump wavelength $\lambda = 840$ nm), i.e. the dependence of the SHG signal on the position of the reference sample, is shown in Fig. 3 (a). The period of the pattern $d = 6.3$ mm corresponds to the value, predicted in [22] for this wavelength due to the air dispersion. Similar graphs were obtained for other accessible wavelengths and the spectrum of the SHG phase was calculated accordingly to the procedure described above. The spectrum of the SHG phase relative to that of the reference film is shown in Fig. 3 (b). One can see the phasesshift modulation of about 120-130° in the available spectral region, including the resonance at $\lambda = 820$ nm. This modulation should be attributed solely to the HMM, as the reference film does not possess specific features in the studied spectral range.

4. Discussion

As the studied HMM is an uniaxial anisotropic medium, its optical properties are defined by two components of the effective dielectric tensor $\epsilon_{\perp}$ and $\epsilon_{\parallel}$, which describe the optical response of the composite in the directions that are per-
near-zero point confirms the increase in the local field at the wavelength polarization light converter. Contributions of these components to the SHG intensity can vary depending on $\theta$. Finally, in the spectral vicinity of the ENZ point strong absorption of the TM radiation occurs that can lead to the decreasing of the nonlinear-optical response.

For the normal incident no longitudinal resonance can be excited that is why no enhancement of the SHG intensity near the ENZ point was observed (Fig. 2, red circles). For the case $\theta = 25^\circ$ the resonant increase of the nonlinear-optical response prevails over the strong absorption effects. It leads to the maximum of the SHG intensity near the ENZ point $\lambda = 820$ nm (Fig. 2, black circles). At the same time, for $\theta = 45^\circ$ absorption is high and prevails over other effects that results to the observed slight spectral dependence of the SHG intensity.

Simulation results are qualitatively similar to the experimental ones. Broadening of the resonant curve in the experimental data (Fig. 2 (a), black circles) compared with simulated curve (Fig. 2 (b), black circles) can be caused by the dispersion of the nanorods’ length in the sample under study.

The spectrum of the SHG phase is the result of resonant, nonresonant and double-resonant contributions of the second-order susceptibility tensor components, indicated above. These contributions possess the phase modulations equal to $\pi$, zero, and $2\pi$ when passing through the ENZ point, respectively [23, 25]. The Fano-type interference between these components gives the value of the phaseshift about 120-130° in the available spectral region.

5. Conclusions

We studied optical and nonlinear-optical properties of an array of gold nanorods in porous anodic alumina matrix. Epsilon-near-pole and epsilon-near-zero spectral points appear as the minima in the linear transmission spectrum. We demonstrated considerable polarization state changes of light passed through the HMM, which acts as the subwavelength polarization light converter. Contributions of the birefringence and the linear dichroism in polarization variations are discussed. Strong enhancement of the SHG response revealed in the spectral vicinity of the epsilon-near-zero point confirms the increase in the local field at
the fundamental wavelength within the structure.

Abstract

We present a theoretical and experimental study of coupled Fabry-Pérot resonators based on layered thin films of silver and a dielectric. Despite the optical losses of the metal we show how these resonators can achieve narrow bandwidths of less than 5 nm at optical wavelengths. By adding several pairs of silver-dielectric layers and reducing the film thickness we reach the regime of hyperbolic metamaterial. We present some advantages of employing these multilayered materials in plasmonic applications.

1. Introduction

Plasmonic resonances in isolated particles have in general small $Q$-factors ($Q < 10$) due to the optical losses of the metal. Planar resonators provide a better solution for achieving much larger $Q$-factors. One of the most simple examples is the IMIMI planar structure, a metal-insulator-metal (MIM) surrounded by two dielectric layers, supporting leaky and guided modes. When the thickness of the insulator is of the order of $\lambda/2$ the IMIMI operates as a Fabry-Pérot resonator (FP). Such resonators were used to investigate the fluorescence lifetime of dye molecules [1]. Theoretical calculations based on plane waves predict $Q$-factors surpassing 100 by using a coupled system of two or more resonators. In general, the full-width at half-maximum (FWHM) of the FP resonances measured in reflection, or in transmission can reach values between 5 nm and 20 nm, at optical wavelengths. Coupled FP cavities are not very sensitive to variations of the refractive index of the medium outside the cavity, but are very sensitive to a small variation of the refractive index of the cavity material. When one of the media of the coupled FPs is replaced by a polymer, or by a liquid where the refractive index changes sensing applications can be envisaged. On the other hand, these structures support non-radiating plasmonic guided modes and can be applied in radiative decay engineering [2].

When the thickness of the metal and dielectric layers decrease there is a blue shift and a broadening of the resonances. By stacking several MIM structures together, one obtains a highly anisotropic uniaxial metamaterial. The effective dielectric function becomes under certain conditions hyperbolic [3]. Hyperbolic metamaterials (HMM) have received an increasing attention in plasmonics due to their exceptional light propagation properties. HMMs are most advantageous because their dispersion contains modes of large $k$-vector arising for evanescent guided waves. If a nanometer sized radiation source is localized near the layered material it decays faster than near a single metal surface (Purcell effect) and its angular spectrum forms a cone (conical emission) [4]. We discuss the properties of FP resonators and their extension to hyperbolic metamaterials using simple multilayered materials based on silver and aluminum oxide (Al2O3).

2. Methods

The optical properties of layered structures of silver and a dielectric were investigated both experimentally and theoretically. The reflection, transmission spectra and the guided modes were calculated using the transfer matrix method (TMM) [5]. Near-fields across the structure were also investigated using a MATLAB based code relying on the scattering matrix [6, 7]. The dispersion relation for propagating and evanescent modes was obtained from the theory of Ford and Weber [8]. We assume a dipole located in the first semi-infinite medium, 10 nm away from the next interface. The theory predicts the dissipated power of the dipole as function of the $k$-vector (real and complex) and the wavelength. The dipole can be oriented vertically, horizontally, or isotropically comparing to the plane of first interface. For a fixed wavelength the dissipated power decays exponentially as the $k$-vector mismatches the guided modes. Therefore, the color scale appearing in the dispersion maps is logarithmic.

The fabrication of the samples consists on the successive deposition of silver and dielectric thin films, by electron-beam evaporation on glass cover slides, silica, or quartz substrates. The investigation of the optical reflection at quasi-vertical incidence was done using an optical microscope with confocal detection and a small numerical aperture objective for illumination, coupled with an optical spectrometer. An angle resolved spectroscopy system was used for other angles of incidence.
3. Discussion

The number of adjacent resonances appearing in the reflectance and transmittance spectra equals the number of Fabry-Pérot resonators formed in the multilayer (see Fig. 1). The spectral separation between the resonances depends on the thickness of the metal film, which is related to the coupling constant between two independent resonators. Surprisingly, by stacking several FP resonators the FWHM of the resonant bands decreases. A drawback in the experimental fabrication is the increasing surface roughness and polycrystallinity associated with the number of layers deposited, which penalizes the FWHM (see Fig. 3 and 4). The spectral position of the narrow bands varies slowly with the angle of incidence of a plane wave. Thus, a slight tuning of the reflected, or transmitted band can be achieved by sample tilting (see Fig. 2). Moreover, if the last silver layer of the resonator is made thick enough to prevent transmission of light total absorption at the narrow bands can be achieved.

The stacking of several coupled FP resonators of lower metal film thickness (in the range of 10-50 nm) leads to resonance broadening and band overlapping (see Fig. 7). The transmittance for short wavelengths can reach values over 70%. This property in the reflectance can be exploited in the design of colored filters. Since 2012, the properties of colored thin films using absorbing layers have been investigated [9, 10]. But the resulting colored mirrors were only useful for reflection. Metamaterials based on multilayer metal-dielectric stacking can also be used in transmission.

Hyperbolic metamaterials have been proposed as good candidates for broadband Purcell effect, due to the band structure of the evanescent waves [3]. We also have investigated the band structure of some multilayered MIMs. Our calculations of the dispersion were neither based on the homogenization of the dielectric function used in the effective medium theory (EMT), nor on the Bloch equation for periodic multilayers.

In this article the materials used in the experiments and calculations were Ag and Al2O3, because of the low absorption loss of Ag and the hardiness and relative high refractive index of Al2O3. However, Al, Au, TiO2, MF2 and other materials can be used as well. The optical constants of the materials used in the calculations were taken from the articles of Johnson and Christy for Ag [11] and the Refractive Index Database for Al2O3 using the Sellmeier equation [12].

3.1. Reflectance and transmittance of Fabry-Pérot coupled resonators

We have investigated theoretically and experimentally the reflectance spectra of a single IMIMI and longer stacked multilayer using for the Al2O3 dielectric layer a thickness around 150 nm. The FP resonators are optically coupled because of the transmission of the middle Ag layers. The outer Ag layers can be made slightly thicker to improve the reflected, or transmitted light at specific resonance wave-lengths. The theoretical calculations predict a decrease of the FWHM of the first resonance (shortest wavelength) by attaching several FP resonators, comparing to the result for a single FP resonator. However, the experimental results cannot confirm this Q-factor increase. The main reason for that could be the roughness of the films surface and the polycrystallinity. Single crystal films could achieve that improvement in the VIS and NIR spectral regions. In Fig. 1 we compare the theoretical reflectances achieved for vertical incidence for single and double FP resonators. In Fig. 2 are presented the reflectance and transmittance for all angles of incidence between 0 and 90°. For small angles on incidence we observe a slight shift of the resonances with the angle of incidence. The experimental results are shown in Fig. 3 and Fig. 4. The differences in the spectra among the samples are due to different thickness of the films deposited.

3.2. Reflectance and transmittance of hyperbolic layered metamaterials

Already in 1955, Rytov dedicated an investigation on the optics of stratified materials [13]. Long after the theoretical developments and applications of planar dielectric waveguides in photonics a deeper interest on plasmonic multilayers emerged in the last decades of the 20th century. These materials have several properties that make them attractive for classical and quantum optics applications: they can strongly confine and guide light along the metal-dielectric interfaces and they can increase the local density of optical states leading to large Purcell effect [4, 14]. An emitter near a plasmonic multilayered material may decay faster than near a mirror.

The optical modes of IMIMIs and more complex planar structures can be calculated using the transfer matrix method, the scattering matrix method, or by numerical
Figure 2: Reflection (top) and transmission (bottom) of a planar Ag-Al\textsubscript{2}O\textsubscript{3} layered structure, based on two coupled Fabry-Pérot cavities. The Al\textsubscript{2}O\textsubscript{3} cavities are 150 nm thick and they are separated by a 40 nm film of Ag. The spectral FWHM of the reflection notch filters, or transmitted bands is approximately 6 nm.

Figure 3: Experimental reflectance of a single FP-resonator of Ag films separated by a layer of Al\textsubscript{2}O\textsubscript{3} with 150 nm thickness. Q-factors above 100 can be reached.

Figure 4: Experimental reflection of two coupled FP-resonator of Ag films separated by a layers of Al\textsubscript{2}O\textsubscript{3} with 150 nm thickness. In contrast to the theoretical prediction, the experimental Q-factors of the resonances do not increase comparing to a single resonator, mainly because of the increasing surface roughness with the number of layers and material polycrystallinity.
Effective Medium Theory: Al2O3(30 nm) - Ag(30 nm) multilayer

Figure 5: EMT real and imaginary parts of the dielectric functions $\varepsilon_{\parallel}$ and $\varepsilon_{\perp}$ for an undefined layered material of 30 nm Al2O3 and 30 nm Ag. For wavelengths above 600 nm the real part of the homogenized dielectric function component parallel to the layers becomes negative, like in plasmonic materials. Simultaneously, the corresponding imaginary part remains very small. The real part of the perpendicular component also becomes negative for shorter wavelengths, but the corresponding imaginary part becomes very large in that spectral region.

An example of effective dielectric functions $\varepsilon_{\parallel}$ and $\varepsilon_{\perp}$ obtained using the EMT calculation of an undefined medium based on 30 nm Ag and 30 nm Al2O3 layers is presented in Fig. 5.

However, this method is not adequate for a small number of layers, or if the layer thickness varies across the structure and has other limitations [17, 18]. It should be only used as a first approach to calculate the dispersion. We used direct methods of the calculation of the dispersion avoiding approximations. Fig. 6 show the experimental reflectance for a HMM made of 5 bilayers of Ag (30 nm) and Al2O3 (70 nm). Fig. 7 shows the reflectance and transmittance for the 5 bilayers on top of a silica substrate, illuminated from the air side. These results are propagating waves using external far-field illumination. Guided modes present in the metamaterial require other mechanisms of coupling light with surface plasmons.

3.3. Guided modes

The experiments and theoretical results presented above are restricted for $k_x < k_0 = n_0(\omega/c)$, i.e. exclude evanescent waves. However, the most interesting properties exhibited by HMM materials are for large $k$-vectors ($k_x = k_{\parallel} > k_0$). We analyze in this section some results of the dispersion for a IMIMI resonator and for a HMM with 5 bilayers of Ag and Al2O3 and the near-field amplitude profiles of the modes for a fixed wavelength.

The dispersion for IMIMI resonator with a central dielectric layer of 150 nm has 4 modes (Fig. 8). The number of modes equals the number of metal-dielectric interfaces. The surface plasmon polaritons (SPP) supported in a IMI structure have a long ranged symmetric mode and a short ranged antisymmetric mode. For a fixed propagation constant the corresponding symmetric frequency $\omega_s > \omega_a$. Both modes degenerate to a single surface plasmon mode.

Figure 6: Experimental reflectance of samples prepared with 5 bilayers of Ag (30 nm) and Al2O3 (70 nm) on a cover slide substrate. All films were deposited by electron beam evaporation. The spectra of the reflected light were measured using an optical spectrometer and the illumination was done using an objective of small numerical aperture ($NA = 0.15$) mounted at normal incidence.

Figure 7: Reflection and transmission spectra of a hyperbolic metamaterial made of 5 bilayers of silver (30 nm) and aluminum oxide (70 nm). When the metal and dielectric thickness decreases the FP modes overlap in the short wavelength range. The transmission can reach values over 70%.
Figure 8: Dispersion of the guided modes for a single FP cavity. The $k$-vector was normalized to the propagation constant of the first medium. The dispersion was calculated based on the power dissipated by an isotropic dipole localized 10 nm above the first silver layer. The left region ($k_\parallel < k_0$) corresponds to propagating modes through the stratified material. The TM-modes merge with the symmetric surface plasmon mode. Indeed, there is a mode hybridization between the symmetric and anti-symmetric plasmon modes and the leaky FP modes. The TE-mode at left in the propagating region has no contribution to the guided modes.

as the thickness of the metal layer increases. As we couple two IMI structures to form the IMIMI we end up with a hybridization between the FP mode and the SPP mode. However, the TE-mode of the FP resonator never crosses the light line. The same occurs for the HMM material. Here two aspects must be mentioned: for a fixed wavelength, the $k$-vector separation between modes increases as the thickness of the metal and dielectric layers decreases; the symmetric and antisymmetric plasmon modes, that separate the upper branch from the lower branch of the modes, do not necessarily converge to the light line for long wavelengths (see Fig. 9).

If the substrate and cover are of the same material of the dielectric layers, the symmetric and antisymmetric surface plasmon modes converge to the light line for long wavelength. If not they do not overlap as the wavelength increases (see Fig. 9). When the filling factor of metal reaches 0.5 the symmetric and antisymmetric surface plasmon modes merge. For a fixed wavelength, the reduction of the layers thickness leads to an increase of the $k$-vector of the modes and an large separation between them. In conclusion, a HMM with large number of guided modes, all of large $k$-vector requires a stack of many thin layers of metal and dielectric (Fig. 10).

The near-field amplitude profile for each mode was calculated based on the scattering matrix. This method is more robust numerically, than the transfer matrix method and thus, preferred for thin metal-dielectric layers. For every fixed value of the wavelength, we can obtain the near-field amplitude profiles ($H_y$) for each mode of Fig. 8 and Fig. 9.

Figure 9: Dispersion of a hyperbolic metamaterial made of 5 double layers of Ag (30 nm) and aluminum oxide (70 nm) on top of a SiO2 substrate. The symmetric and antisymmetric surface plasmon modes do not converge to the light line for long wavelengths due to the mismatch of the refractive index of the substrate.

Figure 10: Dispersion of a hyperbolic metamaterial made of 5 double layers of Ag (30 nm) and aluminum oxide (30 nm) on top of a Al2O3 substrate. When the thickness of the layers becomes much smaller than the wavelength the symmetric and antisymmetric surface plasmon modes overlap. The effective index and $k$-vector of the guided modes and their relative separation also increases when the thickness of the layers decreases.

The results for $\lambda = 633$ nm ($E \simeq 1.96$ eV) are presented in Fig. 11 and Fig. 12. The order of the modes labeled $k_i$ is set according to the increasing value of $k_x$. Due to the number of layers there is no pure symmetry, or antisymmetry of the field profile across the metal layer as in the simple IMI. Despite that, the full profile of the field has a mirror symmetry in the center of the structure. The modes labeled $k_i$ have symmetric, or antisymmetric profile in an alternating way.

4. Conclusions

Multilayered metal-dielectric materials can either be used as narrow band optical filters for transmission of light, or
Figure 11: Field profiles of $H_y$ for the guided modes of a single FP resonator. The mode labeled $k_1$ is smaller than $k_0$ and then is not a guided mode, rather a FP-mode for $\lambda = 633$ nm. Therefore, only two symmetric and one antisymmetric mode exist for this wavelength.

Figure 12: Field profiles of $H_y$ for the guided modes of a layered material with 5 bilayers of Ag (30 nm) and aluminum oxide (70 nm). By increasing the number of layers the maximum amplitude of some guided modes also increases, e.g. $k_6$. The near-field profiles are almost never symmetric across the metal films, except in the central Ag layer, but all profiles have a mirror symmetry in the center of the structure.

as reflection notch filters. The stacking of several IMIMI resonators and a corresponding thickness reduction leads to hyperbolic metamaterials, with high impact in quantum plasmonics and radiative decay engineering. A large density of long very long $k$-vectors increases the density of optical states. The lifetime of emitters localized near the surface of the multilayers can be modified for a broadband of wavelengths. We have investigated the dispersion of metamaterials formed by a small number of metal-dielectric bilayers in order to understand how large $k$-vectors are obtained and give an intuitive description how HMMs can be achieved.

Abstract
We propose a kind of all-dielectric touching-dimer metagratings that can achieve flat-top broadband all-angle high asymmetric diffractions in visible light. High diffraction light deflection is obtained by proper design of two touching titanium dioxide pillars with various cross-section shapes in each unit-cell of the metagrating, without creating a discrete gradient phase profile as traditional metasurfaces always do. The touching-dimer architecture is superior to many previous multiple scatters metagrating designs that are typically optimized at single wavelength and incident angle, and is promising for many high-performance angle-controllable wavefront shaping applications.

Introduction
In the past few years, advances in metasurfaces technology have enabled optical manipulation at wavelength or sub-wavelength scales[1]. Phase-gradient metasurfaces require spatially-varying building block structures to realize the discrete levels of a given phase profile, which suffer from the fundamental limits on the overall efficiency and fabrication challenge on spatial resolution, especially for extreme large angle wavefront shaping[2]. In this regard, high diffraction metagratings with identical structure in each unit-cell are proposed [2-6]. To achieve the high diffraction efficiency in metagrating, one can either break the symmetry of the building block of the metagrating, or break the symmetry of the illumination condition of the metagrating (typically by oblique incidence). In previous asymmetric metagrating designs, separated multiple inclusions are typically employed to optimize the maximum diffraction efficiency at a given wavelength and incident angle. Here, we propose a kind of touching-dimer metagratings (Fig. 1(a)), which can achieve high asymmetric diffraction with all-incident angles in the full visible range. The building block of the metagrating is formed by touching two different shaped polygons, which supports the ultra-high directional scattering (Fig. 1(b)). Arranging such asymmetric building blocks as a periodical array to form a metagrating, maximum asymmetric diffraction up to 90% and bandwidth of nearly 200 nm in the visible range for normal incidence can be obtained (Fig. 1(c)). In addition, by changing the direction of incidence angle, broadband can be obtained in the range of 0 to nearly 90 degrees, covering almost the whole visible range (Fig. 1(d)). Our research can provide a feasible scheme for broadband large-angle arbitrary
wavefront shaping applications.

Abstract

We present a metalens composed of double layer crystalline silicon metasurfaces to achieve an optical needle focusing with ultra-high resolution of λ/5. This metalens is promising for non-intrusive, far-field super-resolution optical imaging.

1. Introduction

Metasurfaces are ultra-thin optical structures relying on the scattering properties of subwavelength scale optical resonators to control the polarization, phase, amplitude and dispersion of light [1]. Recent years have witnessed the fast development of metasurfaces in optical focusing and optical field manipulation, showing that metasurfaces is a versatile platform for photonic engineering [2-4]. Among the dielectric metasurfaces, the high index dielectric materials of crystalline silicon (c-Si) has been shown to be used in the high transmission metasurfaces at visible wavelength because of its low loss and low cost [5-7]. Furthermore, we have showed that c-Si allow metasurfaces to be embedded into other solid materials as the ultra-high NA metalellens, indicating that c-Si metasurfaces can be vertically integrated to build miniaturized systems [7].

The c-Si integrated metalellens has the potential to be used in the super-resolution imaging system. The Traditional objective lenses in modern microscopy are restricted by the Rayleigh diffraction limit 0.61λ/NA (where NA is numerical aperture). Great efforts, such as near-field scanning optical microscopy (NSOM), stimulated emission depletion microscopy (STED), photo-activated localization microscopy (PALM) and stochastic optical reconstruction microscopy (STORM), have been devoted to overcome the limit in either near-field or far-field during the past decades. However, all of these approaches are either optically intrusive or physically intrusive that none of them is a truly non-intrusive universal imaging technique. On the contrary, the manipulation of cylindrical vector beams provides a promising method for the non-intrusive imaging. A sharper focusing needle beyond the diffraction limit can be generated in any medium with spatially modulated radially polarized (RP) and azimuthally polarized (AP) beams [8]. However, this technique requires precise alignment of optical alignments that it brings significant challenges to be experimentally set up [9].

In this work, we firstly showed our previous work of an oil front-immersion metalellens with NA = 1.48, a bandwidth of 211 nm and a focusing efficiency of 48% at 532 nm wavelength, based on a 500 nm thick c-Si on sapphire [7]. Then we propose an integrated metalellens to generate optical needle with ultra-small resolution in the far-field. The miniature system consists an ultra-high NA metalellens and a vector beam controlling metasurface. With the evolutionary algorithm for inverse design, the first metasurface performs as a metalellens enabling NA = 1.48 to realize sharp focusing; while the second metasurface is able to efficiently convert the linearly polarized (LP) beam into RP beam. An optical resolution of 0.22λ is achieved with the proposed integrated system. This integrated system can be fully fabricated by mature micro-electronic process with nano-level alignment accuracy, giving rise to achieve truly non-intrusive, far-field nano-imaging in an easy and cost-efficient way.

2. Results

The first metasurfaces behaves as a controller to generate pure RP beam with ellipsoid meta-atoms. For the second layer, the metasurfaces performs as a metalellens that only contains the high spatial frequencies. The central part of the metalellens (corresponding to low spatial frequencies) is covered by gold. The high spatial frequencies part consists of a series of large angle deflectors. The deflectors are inverse-designed by our hybrid optimization algorithm to ensure simultaneously high transmission and large angle deflection on x and y incident polarizations. Then two metasurfaces layers are bonded and aligned together.

The designate large angle deflector and RP controller are shown in Fig. 1, respectively. The focusing performance of the integrated metalellens is also shown in Fig. 1. The high spatial frequencies design will naturally elongate the focal spot to an optical needle, while the lateral resolution of the optical needle is reduced beyond the diffraction limit. The inverse-design deflectors yield a deflection angle of 78.2412°, indicating a 1.48 numerical aperture of the metalellens under immersion oil with the index of 1.515. The full width half maximum (FWHM) of the optical needle is ...
115 nm, showing an 0.22λ lateral resolution at the wavelength of 532 nm. The depth of focus (DOF) is about 10 μm (=18λ) with the diameter of 50 μm of the metalens, ensuring high tolerance in axial positioning. All these benefits enable us to achieve a high-quality image for a large-area object at a high scanning speed under laser confocal microscope. Moreover, the precise alignment of the layered metasurfaces ensures high symmetrical vector beam focusing, which significantly simplifies the complexity of the system and increases the imaging robustness.

Figure 1: The schematic show of the integrated metalens. The large angle deflectors guarantee that the focal spot is mainly contributed by the light with high spatial frequencies. The focal spot then is elongated by the high spatial frequencies and is compressed at the lateral resolution by the modulation of RP beam.

3. Conclusion

Here we show an c-Si integrated metalens to generate an optical needle with ultra-high resolution. The structure composed of two metasurfaces with precise alignment. One metasurface is able to efficiently convert LP beam into RP beam, while the other one enable a large angle focusing of the RP beam. With the modulation of the two metasurfaces, an optical needle is achieved with a lateral resolution of 115 nm (0.22λ) and DOF of 10 μm (=18λ) at the wavelength of 532 nm. The unique features of this integrated metalens shows various benefits in nano-scale imaging, including high tolerance in axial positioning, high quality imaging at a high scanning speed and a higher resolution. We envision that this integrated design will significantly reduce the complexity of the construction of super-resolution imaging system, giving rise to achieve truly non-intrusive, far-field nano-imaging in an easy and cost-efficient way.

Abstract
Using the FDTD-aided numerical simulation, we show that uniform linearly or circularly polarized light passing through the proposed optical metasurface with m=2 and then tightly focused with a binary zone plate generates an on-axis near-focus energy backflow comparable in magnitude with the incident energy. Notably, the magnitude of the reverse energy flow is shown to be the same when focusing a circularly polarized optical vortex with topological charge m=2 and a light beam with the second-order polarization singularity.

1. Introduction
Optical vortex beams have been known for a long time [1]. Such beams have a spiral phase, which affects the propagation properties of these beams [2]. Interest in them results from a variety of possibilities for use. For example, vortex beams can be used in telescopes for detecting distant planets [3], controlling the movement of microparticles in optical tweezers [4, 5], etc. Another possibility of using optical vortices is to create beams with an area where the energy flows in the opposite direction for the propagation of the beam [6]. In this work a metalens containing binary zone plates with a numerical aperture close to one and a set of binary subwavelength diffraction gratings that work as half-wave plates and rotate the polarization vector of the incident field by the angle mφ is considered. It is theoretically and numerically shown that the metalens forms an m-th order converging polarization vortex (with linearly polarized incident light) or phase vortex with topological charge m and circular polarization (when circularly polarized incident light is used). In the sharp focus of such a converging light beam on the optical axis, there is a reverse flow of light energy, comparable to the direct flow.

2. Focusing a field with polarization singularity
Projections Ex and Ey of the electric vector in case of polarization singularity are shown in Fig. 1.

Fig. 1. Projections of the E-vector on the X- and Y-axes (a): the maximum value is marked with white color (+1), the minimal value - with black color (-1), and zero value marked as grey; Pattern of polarization states in the field (b)

The polarization pattern of the field is depicted in Fig. 2b, with the unit intensity assumed over the entire field. Figure 3 depicts the result of focusing the beam from Fig. 2a using a binary zone plate. Shown in Fig. 3 a,b are two-dimensional patterns of intensity:

\[ I = I_x + I_y + I_z = |E_x|^2 + |E_y|^2 + |E_z|^2 \] (1)

and the longitudinal component Sz of the Poynting vector

\[ S = \frac{1}{2} \text{Re} [\mathbf{E} \times \mathbf{H}^*] \] (2)

in the focal plane (z=600 nm). Using an FDTD-aided approach, we numerically simulated the focusing of the beam with polarization singularity with a six-ring binary zone plate on the assumption of the incident wavelength λ=633 nm, focal length f=λ, and a λ/30 increment of the simulation grid on all three coordinates. The field and the zone plate were bounded by a 8-µm circular aperture.
It is seen from Fig. 3d that when focusing the field of interest, an on-axis energy backflow occurs in the focal spot.

3. A metalens for simultaneous polarization conversion and focusing of light

The idea is that the metasurface-assisted polarization converter (MPC) and a focusing binary zone plate can be combined, resulting in a single metalens. Presented in Fig. 4a is the external appearance of a MPC composed of subwavelength 16-sector binary diffraction gratings.

Fig. 3. Intensity $I$ of the light field (a) and longitudinal component $S_z$ of the Poynting vector (b) in the focal plane 0.6-μm behind the zone plate.

Fig. 4. A combined metalens (a) to simultaneously generate and focus the polarization vortex; longitudinal projection of Poynting vector $S_z$ in the focal plane 0.6-μm away from the metalens for a linearly polarized incident wave (b) and left-circular polarized incident wave (c).

It is seen from fig. 4b,c that at $m=2$, for both the polarization and phase singularities, the on-axis near-focus reverse flow of light energy is comparable in magnitude with the incident energy.

Abstract

We investigated a spiral metalens fabricated on a thin film of amorphous silicon and consisting of a set of subwavelength binary diffractive gratings. The metalens converts linearly polarized incident light into an azimuthally polarized optical vortex, and focuses it at a distance approximately equal to the wavelength of the incident light 633 nm. Using a scanning near-field optical microscope, it is shown experimentally that the metalens forms an elliptical focal spot with diameters smaller than the diffraction limit: 0.32 and 0.51 of the wavelength. The experimental results are close to the those of a numerical simulation using the FDTD method, with 0.37 and 0.49 of the wavelength.

1. Introduction

A significant number of recent scientific papers have been devoted to the investigation of metasurfaces, thin optical elements that simultaneously control the amplitude, phase and polarization of propagated light \cite{1}. Metasurface-based elements can focus light into a ring \cite{2}, a segment \cite{3}, or a spot \cite{4}. A special case of a metasurface is a simple subwavelength grating. Subwavelength gratings are anisotropic, meaning that TE- and TM-polarized waves propagated through them have different phases. Based on this effect, it is possible to create analogues of the classical half-wave plates, which rotate the direction of polarization. In our work, we have investigated elements based on subwavelength gratings that are designed to produce cylindrical vector beams, that is, beams in which the direction of polarization has radial symmetry \cite{5}.

In this work, we investigate a 16-sector spiral metalens consisting of subwavelength gratings. This metalens converts linearly polarized light to an azimuthally polarized optical vortex and focuses it. Using a scanning near-field optical microscope, it is shown experimentally that the metalens forms a focal spot with a diameters smaller than the diffraction limit: FWHMx = 0.32\(\lambda\) and FWHMy = 0.51\(\lambda\).

2. Design and manufacturing

The investigated spiral metalens (Fig. 1a) is a combination of a spiral zone plate with a topological charge \(m = 1\) (Fig. 1b) and a sectorial subwavelength grating that acts as a halfwaveplate. The lens consists of 16 radial sectors, each of which rotates the polarization of the incident light to produce the azimuthal polarization (Fig. 1c). Each sector is divided into sub-areas in the shape of a circular arc. The angle of the relief in neighboring areas within one sector is chosen such that the polarization of the light passing through them differs by \(\pi\) (Fig. 1c). Linearly polarized incident light (the incident polarization in Fig. 1 is directed vertically) is transformed into a focused, azimuthally polarized optical vortex. The period of the grating is 220 nm, and the depth of the relief is 120 nm. The focal length of the zone plate (shown in Fig. 1b) is equal to the illumination wavelength, \(f = \lambda = 633\) nm.

A metalens with the relief shown in Fig. 1a was fabricated using electron beam lithography. A 130-nm-thick amorphous silicon film (a-Si) (with refractive index \(n = 4.35 + i0.486\)) was deposited on a transparent pyrex substrate (with refractive index \(n = 1.5\)), coated with a 320-nm-thick PMMA resist, and baked at a temperature of 180C. To prevent charging, the surface was sputtered with a gold layer 15 nm in thickness. A binary template was transferred onto the resist surface using reactive electron beam. The specimen was developed in water blended with isopropanol in the ratio 3:7, and the template was then transferred from the resist into the a-Si film, using reactive

![Figure 1: (a) Spiral metalens, (b) corresponding binary spiral zone plate with topological charge \(m = 1\), (c) polarization of light transmitted through the metalens.](image-url)
3. Experiment

The focusing by the fabricated spiral metalens was investigated experimentally using a scanning near-field optical microscope (Ntegra Spectra, NT-MD). In this experiment, a light beam from an He-Ne laser (wavelength \( \lambda = 633 \) nm) was used to illuminate the metalens. The full width of the incident beam was 30 \( \mu \)m. The intensity of the focal spot was measured using a hollow, metalized, pyramid-shaped probe with a 100 nm pinhole in the vertex. After passing through the pinhole, the light was collected by a 100x objective lens before travelling to the CCD camera (Andor, DV401-BV).

Fig. 2 shows the results of focusing. The intensity distribution is shown in Fig. 2a, and its sections along the x and y axes are shown in Fig. 2b and 2c, respectively. The focal spot diameters in Fig. 2 were FWHMx = 0.32 \( \mu \)m (Fig. 2b) and FWHMy = 0.51 \( \mu \)m (Fig. 2c). The maximum intensity of the focal spot was seven times larger than the maximum intensity of the input beam.

Next, we FDTD-simulated the propagation of light through the metalens with the manufactured relief. The focal length in this simulation was equal to 633 nm. Fig. 3 shows the intensity distribution of the focal spot.

The simulation shows that the manufactured metalens forms an elliptical focal spot with half-maximum diameters that are smaller than the diffraction limit: FWHMx = 0.37 \( \mu \)m and FWHMy = 0.49 \( \mu \)m.

4. Conclusions

In this work, we investigate a spiral metalens based on subwavelength gratings. The metalens converts linearly polarized light to an azimuthally polarized optical vortex with topological charge \( m = 1 \) and focuses it. The metalens was fabricated using electron beam lithography applied to an amorphous silicon film deposited on a pyrex substrate. Using a scanning near-field optical microscope, it was shown experimentally that the metalens forms a focal spot with diameters that are smaller than the diffraction limit: FWHMx = 0.32 \( \mu \)m and FWHMy = 0.51 \( \mu \)m. The experimentally obtained values are close to the results of a numerical simulation of the manufactured metalens using the FDTD method, which are FWHMx = 0.37 \( \mu \)m and FWHMy = 0.49 \( \mu \)m.

Abstract
Metasurfaces having a large degree of freedom are highlighted in order to replace absorptive paints for microwave stealth function. We suggested new methods to design and to manufacture bitmap-type microwave absorber metasurfaces based on an inductive and a deductive design approaches and mechanical machining technologies in this study. A manufactured metasurface having 300mm in size showed less than -10dB reflectivity from 9GHz to 12GHz.

1. Introduction
Microwave stealth technology against radar detection is becoming ever more important in protecting soldiers and assets and in assuring the success of mission, with recent development of various counter-measures. So far, absorptive paints have been the dominant material technology for the microwave stealth function. However, the paint is expensive and requires frequent reapplications. Moreover, once applied, the paint has a fixed frequency band of effectivity. In order to address these problems, we propose bitmap-type microwave absorber metasurfaces in this study. The suggested metasurfaces are relatively easy to manufacture by mechanical machining technologies and have a large degree of freedom in terms of the choice of the target microwave frequency and the bandwidth.

2. Design of microwave absorber metasurface
We utilized two design approaches to optimize the bitmap structure: a genetic algorithm (an inductive method) and an equivalent circuit model (a deductive method). The target microwave band was selected as the X-band (8–12 GHz), but the design can be scaled to other bands as well. The whole structure is composed of a back reflector (optically thick metal layer), a dielectric spacer, and the top patterned conductive ink layer. The equivalent circuit model was first used to investigate the general performance boundaries achievable by a single or dual resonances near the target frequency, irrespective of the actual implementation of those resonances. Then, the genetic algorithm was used to obtain an optimized bitmap structure as shown in Fig. 1. By comparing the performance of the resulting design to the performance of a hypothetical design with optimal resonances, it was confirmed that the current design is very near to the global optimum. The conductive ink is filled in an dielectric substrate according to the optimized pattern (black squares in Fig. 1). The optimized bitmap structure in Fig. 1 is a unit cell and it can be periodically arranged along both the X-axis and Y-axis to meet the required size of microwave absorber. For example, the unit cell can be repeated by 20×20 to produce a absorptive surface of 300mm×300mm in size.

3. Manufacturing and characterization of microwave absorber metasurface
Materials of transparent acrylate plate as the dielectric spacer at the black squares in Fig. 1 were removed by micro end-milling technology in order to fill the commercial
conductive ink as the top patterned layer. The micro end-milling technology is proper to machine discrete squares, circles and et al. with high-speed. The shape error between the designed squares and the machined squares was generally below 1%. Then, the conductive ink was coated on whole top surface of the dielectric spacer, and only the conductive ink on the white squares was removed by ultra-fine planing technology. The ultra-fine planing technology is proper to machine precise flat surfaces having several tens of nanometers of roughness [1]. After ink removing, the conductive ink was filled only at the black squares. Fig. 2 and Fig. 3 show the processes from ink coating to final ink removing and the manufactured unit cell of microwave absorber metasurface, respectively. The unit cell was periodically repeated 20×20 for characterization at X-band, finally, a metasurface of 300mm×300mm in size was manufactured.

Figure 2: A schematic diagram of processes from ink coating to final ink removing.

Figure 3: A manufactured unit cell of a bitmap-type microwave absorber metasurface.

The reflectivity at normal direction of the manufactured metasurface at X-band was measured. The measured reflectivity was continuously decreased from 8GHz to 9.5GHz and relatively stable from 9.5GHz to 12GHz. Especially, the reflectivity was less than -10dB from 9GHz to 12GHz. It was verified that bitmap-type microwave absorber metasurface which was newly designed by the two approaches and manufactured by the mechanical machining technology in this study had microwave stealth function at X-band.

4. Conclusions

We designed and manufactured a bitmap-type microwave absorber metasurface in this study. The details are below.

1) The shapes of a bitmap-type microwave absorber metasurface were optimized effectively by a genetic algorithm and an equivalent circuit model according to target microwave frequency and the bandwidth.
2) A bitmap-type microwave absorber metasurface was manufactured precisely by micro end-milling technology, ink-coating technology and an ultra-fine planing technology according to the optimized design.
3) The manufactured metasurface having periodically repeated 20×20 unit cells of 300mm×300mm in size showed less than -10dB reflectivity from 9GHz to 12GHz.
4) Based on the results, we suggest that a bitmap-type microwave absorber metasurface can be used as a microwave stealth panel without absorptive paints.

Abstract

We propose a new class of periodically modulated surfaces, which are able to couple light to surface polaritons over a continuum of frequencies by exploiting geometrical singularities in their subwavelength structure. We illuminate how this concept shares its roots with dimensional compactification in high-dimensional field theories, and demonstrate this effect on realistic platforms with plasmons in graphene and phonons in hexagonal boron nitride, paving a novel route towards broadband polaritonics.

1. Introduction

Surface polaritons are coupled light-matter modes confined near a surface, which can break the diffraction limit and achieve remarkable field enhancement. Periodic structuring of a surface can provide the necessary momentum to strongly couple far-field radiation to these surface waves over a discrete set of frequencies at a given angle of incidence. However, the periodicity of these subwavelength structures typically defines a length scale over which the bound modes quantise. This poses limitations on their bandwidth, so that typically only a few polaritonic modes can be excited within the frequency window over which they can exist.

Here, we report a novel class of subwavelength gratings which can be used to excite polaritons over remarkably broad bands, due to adiabatically vanishing thickness, or, equivalently, optical conductivity [1]. The analytical framework of transformation optics highlights a curious analogy between singular surfaces and the concept of compacted dimensions in theoretical physics, by demonstrating that these structures are spectrally equivalent to systems of higher dimensionality [2]. We demonstrate this exotic effect on a periodically doped graphene sheet, in the limit where the doping level periodically approaches the charge neutrality point, and show the resulting merging of the discrete surface plasmon spectra into a continuum. We report equivalent results with phonon polaritons in hBN, and highlight the robustness of this effect against imperfections.

2. Results and Discussion

In the subwavelength limit, the optical response of a polaritonic system is governed by the scalar potential $\phi(x, y)$, which obeys $\nabla^2 \phi = 0$. The symmetry of the Laplace operator under a conformal transformation $\tilde{z} \rightarrow \tilde{z}'$ implies that $\phi(x, y) = \phi(x'(x, y), y'(x, y))$ is conserved across such a transformation, so that conformally related structures share the same spectral response [3].

A translationally invariant slab may be transformed into a smooth grating via the transformation shown in Fig. 1: each length $d$ of the slab is first wrapped into an annulus. Secondly, inverting the structure with respect to the shifted origin (green dot) returns a non-concentric annulus. Finally, after shifting the origin to the center of the smaller (black) circle (purple dot), the structure can be unwrapped via a logarithmic transformation, thus realising a smooth grating shape. Due to the aforementioned symmetry, all these structures share the same response, as long as their size is much smaller than the free-space wavelength.

The desired singular structure consists of the limit where the valley thickness of the grating is strongly suppressed. This can be achieved by a two-step limiting procedure: as the inversion point $\tilde{z}_1 = \omega_0$ is let approach the inner circle in (b), the yellow dot is mapped to $\tilde{z}_2 \rightarrow -i\infty$, resulting in a grating of diverging thickness. However, since the length $d$ of the original slab rescales both the real and imaginary part of $\tilde{z}$, letting $d \rightarrow \infty$ renormalises the final structure, while squeezing the valley-point thickness to an arbitrarily small extent.

We demonstrate the effect of such modulation by calcu-
Figure 2: The transmittance spectrum of a conventional graphene metasurface features dips at the discrete frequencies at which surface plasmons are excited (left). This spectrum changes dramatically in a singular metasurface, where the Fermi level of the graphene sheet is strongly suppressed periodically, while keeping the same maximum doping. As the loss is increased, the finely spaced transmission dips merge in a broad band of plasmon modes extremely confined near the singular point.

lating transmittance through a graphene sheet, whose conductivity is spatially modulated (e.g. via an external gate voltage) according to the design above, as illustrated in Fig 2. When THz radiation impinges on a conventional graphene metasurface (left plot), surface plasmons can be excited at a discrete set of frequencies, which results in strong transmittance dips. By contrast, a singular metasurface (right plot), realised by periodically suppressing the doping level of graphene by a factor of the order of $\sim 100$, results in the merging of these transmission dips into a plethora of finely spaced resonances, which eventually become a continuum as a result of broadening.

The conformal map used to design this metasurface holds the key to understanding its behaviour: the length $d$ of the slab in the $\tilde{z}$ frame must diverge, in order to realise the singular grating. This length encodes the quantisation box which accounts for the periodicity of the grating. Hence, as this length tends to infinity, the plasmons are effectively quantised over an infinite period, thus forming a continuum of modes, as can be witnessed by folding the dispersion relation over a first Brillouin zone which is renormalised according to the stretching of the periodicity in the slab frame [4]. However, quite remarkably, the physical period $d'$ of the grating is unchanged.

In fact, as $d \to \infty$ a third dimension is intruded into the slab frame, which constitutes a periodic system, with an infinite period. In the grating frame, this extra dimension is hidden from sight in the singular point, which effectively acts like a sink for the plasmon, which travels towards this point, without, in a local model, ever reaching it. The hiding of an extra dimension is known as compactification, and it is customarily used in high-dimensional string theories in order to explain the fact that spacetime appears, to our measurements, only four-dimensional [5]. The practical consequence is the availability of an extra spatial degree of freedom, and its corresponding momentum component, which allows incoming radiation of any frequency and wavevector to satisfy the polaritonic dispersion relation.

Finally, far from a mere mathematical curiosity, this effect is extremely robust against limitations in the fabrication process: in fact we found that the merging of a polaritonic spectrum can be observed with a grating which consists of a sequence of only six linear segments, which is well within current lithographic capabilities.

Abstract

We present the experimental and theoretical study of an ultrafast graphene-based thin film absorption modulator for operation in the THz regime. The flat modulator is composed of a graphene sheet placed on a dielectric layer backed by a metallic back-reflector. A near-IR pulse induces the generation of hot carriers in the graphene sheet reducing effectively its conductivity. The system provides a platform with ultrafast modulation capability for flat optics and graphene-based metasurfaces applications.

1. Introduction

Graphene is a two-dimensional material made of carbon atoms arranged in a honeycomb lattice with unique mechanical, thermal, electrical and optical properties. Particularly in the THz spectrum, graphene exhibits a Drude-like response due to its easily generated and controlled free carriers; therefore, it is considered a suitable platform for dynamically tunable metasurface components [1]. Such an example, are the so called thin film absorbers that are structures capable of absorbing all power of incident electromagnetic waves [2]. Within the concept of metasurfaces, thin film absorbers, are usually implemented by placing a lossy material, uniform or with features, on the top of a perfectly conducting metallic plate A simple but yet remarkable graphene component/metasurface is based on the coherent absorption principle. It consists of a single uniform sheet of graphene placed on top of a dielectric film which is placed on a metallic plate [3]. Here we demonstrate experimentally ultrafast (of the order of few ps) THz amplitude modulation of such a graphene based ultra-thin absorber induced by photoexcitation via an optical pump signal [4]. For the experimental characterization we use a broadband THz time-domain-spectroscopic system (THz-TDS) in an IR pump-THz probe configuration. Absorption modulation at 2.17 THz in the order of 40% is reported through a decrease in the conductivity upon photoexcitation.

Detailed analysis of the experimental observations reveals the negative dynamics of the THz photo-conductivity in the graphene sheet which is observed in highly doped samples [5]. Our study unveils the capability of such an ultrathin system to provide ultrafast modulation appropriate for the demanding future flat optics modulation applications and graphene-based metasurfaces.

2. Discussion

In Figure 1(a) we present the schematic of the component under investigation. It consists of an uniform graphene sheet placed on a backplated dielectric substrate. The stucture is designed to provide enhanced absorption though the coherent intererference of the impinging and backreflected waves at the lossy graphene sheet. This is achieved when the equivalent metasurface is impedance matched with the free space. Impedance match is forced by properly engineering the detail condition of the graphene and the thickness of the substrate. The modulation of the THz absorption spectrum upon photoexcitation is presented in Figure 1(a). For the characterization we use a powerful THz-TDS system that provides the ability of measurements in reflection mode. It is based on a pump-probe, coherent detection approach, and uses an amplified kHz Ti:Sapphire laser system delivering 35 fs pulses at 800 nm central wavelength and maximum energy of 2.3 mJ/pulse. The initial beam is focused in ambient air after partial frequency doubling in a beta-barium-borate (BBO) crystal (50 m thick) to produce a two-color filament and subsequently, THz radiation (>200 kV/cm). The inset in Figure 1(a) presents the optical pump induced THz relative reflectivity change (DR/R) as a function of pump delay. The measurement refers to the peak of the first pulse reflected by the graphene sheet, prior to cavity. The observed change in the reflectivity points to a reduction of the graphene conductivity in the regime under investigation. This counterintuitive result is connected with the detail conditions of the graphene sheet. In fact, it has been demonstrated that photoexcitation in a graphene sheet
results provide evidence that in our highly doped sample photoexcitation leads to a reduction of the THz conductivity with a decay of 2.79 ps, resulting to an absorption intensity decrease of 40%. We have discussed the dynamics of the photoinduced reduction of the conductivity which is connected with the generation of hot carries, the increase of the electronic temperature and the overall increase of the scattering rate. Our system provides ultrathin, ultrafast modulation appropriate for the demanding future flat optics modulation applications.

Abstract
Reconfigurable coded metasurface is introduced inspired by electric split ring resonator (eSRR) that is working in the terahertz frequency range. The proposed metamaterial structures can be structurally reconfigured to determine its effect on scattering parameters and effective properties by bending its metal strip. Three different kinds of structures are investigated here for coded metasurface with 0, π and 2π phase response. The metamaterial structure shows polarized tunability by reconfiguring its structure size. The tunability dependent on the polarization and it is verified by electromagnetic simulation.

1. Introduction
Metamaterials are the new era of artificial material that shows abnormal electromagnetic properties of their geometry rather than their chemistry or band structure. Motivated by the perception of coding metasurface where two different unit cell is used to establish the programmable, coded and digital metamaterial concept using the different phase response [1]. Laser light illumination was used to vary effective properties in electromagnetic field in various methods in [2, 3]. External magneto static field’s external bias voltages electrical or thermal effects in liquid crystals [4] and nonlinear effects of resonators or substrates were also used to demonstrate the effect on effective properties.

In this work, three different types of metamaterials structure are proposed to demonstrate reconfigurable coded metasurface and justify their ability to manipulate electromagnetic wave by using coding structure sequences. The proposed metamaterial structure shows two resonance frequencies and double negative properties in 25.40 THz. Three phase response is also analyzed to determine the coding sequence. It also shows large negative refractive index almost 1.50THz bandwidth. Geometrically reconfigurable two other design are compared with the proposed metamaterial structure. That two reconfigurable eSRR shows MNG (mu-negative) properties. Three eSRR structure are not only shows negative resonance frequency, but also polarization based tunibility.

2. Design and Methodology
The proposed V shaped eSRR metamaterial design schematic view is presented in Figure 1. The parameter specification is presented in Table 1. The proposed metamaterial structure is designed on silicon substrate (10 × 10 µm²) where its permittivity is 11.9 and dielectric constant 0.00025. The aluminium metal strip is used to design the structure on Si substrate. The thickness of the silicon substrate is 2 µm and the aluminium metal strip thickness is 0.035 µm.

A finite integration technique based electromagnetic simulator CST microwave studio was applied to determine the scattering parameters (transmission coefficient S21 and reflection coefficient S11). Two types of polarization are investigated here extraordinary polarization and ordinary polarization. So boundary conditions are applied here in two times for ordinary polarization x and y axis are set as perfect electric and perfect magnetic boundary respectively.

(a)
The electromagnetic force is applied in the z direction and for extraordinary polarization the direction is opposite that are applied in ordinary polarization. The capacitance and inductive effect are created in split gap and metal strip respectively in metamaterial. Resonance frequencies are varied by increasing or decreasing the metal strip or split gap. There are two types of new modified proposed metamaterial structure are presented that are shown in Figure 1(b) and (c). These two structures are shown different types of transmission characteristics. Furthermore, establishing the coding sequence planner wave is used and it’s RCS (radar cross section) is determined along with far field.

3. Analyzing Results

Proposed three structures are investigated in two important polarization position; normal polarization and extraordinary polarization position. In ordinary polarization effect on without bending metamaterial structure is resulted by its transmission coefficient in Figure 2 (a). By applying Nicolson rose wire method its abnormal effective parameters are determined in Figure 2 (b). Three structures combinations are exhibited 2-bit coding metasurface. It exhibits double negative properties in the 25.6 THz frequency range. To investigate its bending metal strip to reducing or increasing the capacitance or inductance effect on metamaterial other two bending structures is also applied ordinary polarization effect. They simultaneously showed MNG (mu-negative) properties in its two resonance frequencies for bending one V-arm. For two V-arm bending three resonance frequencies is found, but its dB is quite lower than other two designs. Three metamaterial structural results comparison is presented in Figure 2 (c).

4. Conclusions

The proposed reconfigurable coding metamaterial concept is presented with the three electric split ring resonators (eSRR). The reconfigurable metamaterial bending design scattering parameters are investigated in the terahertz frequency region. The composite metamaterial represent 2-bit coding. The proposed structure shows large negative refractive index and double negative properties. The design metamaterial investigated polarized based variation in transmission characteristics by bending the metal strip.

Abstract
We present a single-shot multispectral imaging system using pixel-scale color splitters based on silicon nitride metasurfaces. We demonstrate that the system can computationally create multispectral images without the degradation of the signal levels and spatial resolution achievable in monochrome image sensors. These features are promising for developing high-sensitivity, high-spatial-resolution multispectral imaging system in an integrated device fashion.

1. Introduction
Multispectral imaging provides both spectral and spatial information about objects, which can be useful for machine-vision applications. So far, such imaging has extensively been explored by utilizing dispersive optics (e.g., a grating or prism) or tunable filters (e.g., liquid-crystal tunable filters) in imaging systems. However, these approaches often require bulky and heavy optics, and more importantly, they commonly need multiple shots to acquire multispectral images, which inherently limits the temporal resolution and thus induces motion artifacts. A recent approach introduced a multispectral filter array (e.g., plasmonic filters [1]) in front of an image sensor to realize multispectral imagers. Although this approach enables a single-shot operation with a cost-efficient, integrated imager system, it suffers from low signal sensitivity due to the absorption of light outside the passband of each filter. An imager employing transparent multi-level diffractive optics has also been proposed for single-shot multispectral imaging with increased signal levels [2]; however, crosstalk between neighboring sensor pixels due to the diffracted light inherently limits the achievable spatial resolution.

Here, we demonstrate an alternative imager system to achieve single-shot multispectral imaging without absorptive multispectral filters. This is accomplished by employing dielectric-metasurface-based, pixel-scale color splitters [3] in combination with computational imaging techniques. Since our system spectrally disperses incident visible light on a few sensor pixels using transparent splitters, multispectral images can be computationally created without significant optical losses while preserving the spatial resolution of state-of-art image sensors.

2. Results
Figure 1(a) schematically shows the proposed imager system. The system consists of metasurface color splitters arranged on a monochrome image sensor. The splitters are based on dielectric nanoposts that can be designed to provide the degrees of freedom for controlling optical phases while preserving high transmittance (i.e., impedance matching) [4, 5]. By utilizing a dispersion-managed metasurface concept [6], a dielectric metasurface pattern can be designed to achieve spatial splitting of incident light into the three primary colors even within a pixel-scale footprint. Therefore, the three pixels under the splitter yield completely different spectral responses without the use of absorptive filters, as schematically shown in Fig. 1(b). Since computational techniques [2, 7] can estimate an incident spectrum from three-pixel signals with such pre-defined spectral responses, our system can potentially reconstruct spectral information at each set of three pixels, thus leading to the creation of multispectral images in the visible wavelength range.

To experimentally verify the proposed system, we fabricated metasurface color splitters designed for a high-pixel-density image sensor with a 1.43 × 1.43 μm2 pixel size. Figure 1(c) shows scanning electron microscopy (SEM) images of fabricated splitters. Each splitter consists of 615-nm-thick silicon nitride (SiN) nanoposts with widths of 125 and 295 nm [3]. The characterization of the system was performed with an optical-microscopy-based setup that virtually realizes the image sensor configuration by imaging the plane where the pixel array is assumed to be placed (3.2 μm away from the splitters). A shortpass filter (< wavelength λ0 = 650 nm) was inserted into the setup to remove near-infrared light. We used an “N” character composed of known color filters as a target object. Once the monochrome image was measured with this setup, the pixel size in the image was resized to match 1.43 × 1.43 μm2 in physical dimensions by averaging signals of multiple neighboring pixels. Computational spectrum estimation was then performed at any set of neighboring three pixels. This enables the spectrum estimation on each pixel. We here considered this estimation to be a typical inverse problem and solved it by using an iterative algorithm; however, other numerical methods can potentially be employed.
Figure 1: (a) Schematic of a single-shot multispectral imaging system with metasurface-based color splitters. (b) Schematic of the side view of the image sensor configuration. (c) SEM images of the fabricated splitters. (d) Computationally reconstructed multispectral images of a colored “N”. (e) Estimated spectra at the three different points in the “N” image.

Figure 1(d) shows spectral images (ranging from 400 nm to 650 nm separated by a 10-nm wavelength step, 130×166 pixels) reconstructed from the measured single-shot monochrome image. They show different intensity distributions depending on the wavelength. The estimated spectra at the three points (i–iii) in the image are shown in Fig. 1(e). The intensity of each spectrum is normalized to its maximum. These spectra are in good agreement with the reference spectra measured with a conventional spectrometer (also plotted in the graphs). The spectral errors, defined as the root-mean-square errors between the estimated and reference spectra, were also calculated for each point. For this purpose, the reference spectra were down-sampled to match the spectral resolution of the estimated spectra. The errors are 7.20, 10.32, and 16.99% for the points (i), (ii), and (iii), respectively.

3. Discussion

The experimental results indicate that our single-shot imager system can provide spectral information at the spatial resolution of state-of-art image sensors. The light transmission averaged over the visible wavelengths was ~96% for the splitter array. Thus, it is clear that almost all the incident light is utilized for multispectral imaging. This feature is the great advantage our system has over filter-based counterparts, and it will significantly improve the sensitivity or temporal resolution. To quantify the spectral resolution Δλ, we calculated the spectral correlation function that quantifies the change in wavelength required to generate an uncorrelated intensity distribution on the pixels [7]. From this analysis, Δλ was estimated to be ~40 nm. The simultaneously measurable spectral range was also estimated using the simple relation 2MΔλ, where M is the pixel number used for the estimation on one pixel (i.e., M = 3 in our case) [7]. The spectral range was estimated to be ~240 nm, well matching the entire visible spectral range. To further improve the spectral accuracy within the fixed spectral range (e.g., the visible spectral range), it is necessary to simultaneously decrease Δλ and increase M. Decreasing Δλ will require a highly dispersive metasurface to enhance the spectral decorrelation of the intensity distribution on the pixels. To create such a metasurface, the advanced optimization method in [8] may be promising. Increasing M is straightforward: it can be done by redesigning the sensor configuration to utilize more pixels with different spectral responses for the spectrum estimation, at the expense of spatial resolution. As such, there is a trade-off between the spectral accuracy and the spatial resolution, and which one is given priority will depend on the application. From this viewpoint, the system shown here can be regarded as a multispectral imaging system specialized for high spatial resolution.

4. Conclusions

We presented a filterless, single-shot multispectral imaging system based on metasurface-based color splitters and computational techniques. We demonstrated that our system can create multispectral images by utilizing almost all the incident light while preserving the spatial resolution of state-of-art image sensors. This configuration also enables high-sensitivity color imaging with color signal processing [3]. Therefore, our system can provide both color and multispectral images without the degradation of the signal levels and spatial resolution achievable in monochrome image sensors. Further, the CMOS-compatible feature of SiN metasurfaces opens a pathway to their monolithic integration into CMOS image sensors. These features will enable high-sensitivity, multi-information imaging in an integrated device fashion.

Abstract

A fair amount of theoretical work has showed that Huygens’ metasurfaces modulate electromagnetic waves by designing electrical impedance and magnetic admittance. In this work, a transmission type Huygens’ metasurfaces with a two-layer metal structure is studied, which achieves reflectless phase modulation at a specific frequency for linear polarization. Simulation results show that this metasurface can achieve 2\pi phase coverage in 0.83 THz, and phase change can be achieved by changing a single geometric parameter of the structure, with similar transmission effect. We design a beam deflector to realize an anomalous refraction angle with 19.8\degree.

1. Introduction

Metasurfaces, as 2D nanostructures, have attracted enormous attention since they provide unprecedented opportunities in controlling light-matter interaction as well as propagation of electromagnetic waves [1, 2]. In general, metasurfaces are able to modify phase, amplitude and polarization of electromagnetic waves. Novel phenomena and devices have been developed by properly engineering the geometries of nanostructures in metasurfaces [1-3], such as strong spin-orbit interaction, ultra-thin focusing or diverging lens, nonlinear phase control, anomalous refraction and reflection. Huygens’ principle can be applied to design metasurfaces with well engineered electromagnetic responses [4]. In recent years, there have been many researches on Huygens’ metasurfaces [4-12], involving from microwave to light wave. However, there is few reports on terahertz Huygens’ metasurfaces that are desirable for practical terahertz applications.

Here, we introduce a kind of Huygens’ metasurface with metal structure, which is used to control the linear polarization electromagnetic wave in terahertz band. Compared with the existing Huygens’ metasurfaces, such as the wire/loop type metasurfaces working in microwave and the three-layer shunt-admittance unit cell, it has a simpler structural design.

2. The design of metamaterials

Huygens’ metasurfaces are characterized by its surface impedance \( Z_{se} \) and surface admittance \( Y_{ms} \), inducing discontinuities in tangential magnetic and electric field components, respectively, given by the generalized sheet transition conditions (GSTC)

\[
\frac{1}{2} \left( \mathbf{E}_2 - \mathbf{E}_1 \right) = Z_{se} \left( \hat{n} \times (\mathbf{H}_2 - \mathbf{H}_1) \right),
\]

\[
\frac{1}{2} \left( \mathbf{H}_2 + \mathbf{H}_1 \right) = Y_{ms} \left( -\hat{n} \times (\mathbf{E}_2 - \mathbf{E}_1) \right).
\]

The Huygens’ metasurfaces designed in this paper focuses on the efficient transmission and control transmission direction of electromagnetic wave while maintaining the polarization. The following formula can be derived,

\[
\eta = \frac{E_{inc} - E_{trans} - E_{ref} \left( \frac{E_{inc}}{E_{trans}} + E_{ref} \right)}{2Z_{se}},
\]

\[
\frac{1}{2\eta} \frac{E_{inc} - E_{trans} + E_{ref}}{E_{inc} + E_{trans} - E_{ref}}.
\]

Eq.(2) is the same as the formula given in [5]. By directly connecting the surface impedance and surface admittance with the reflection and transmission characteristics of the structure, it is very convenient to carry out the metasurface design. Phase modulation in the 2\pi range and high transmission efficiency can be achieved by reasonably designing the surface impedance and surface admittance of the metasurfaces.

Figure 1: The schematic of cut-wire terahertz metasurface. (a) The front and lateral views. (b) The whole view. The light blue and yellow colors indicate gold and the dielectric material BCB.

Figure 1(a) shows the model diagram of one unit cell, and Figure 1(b) shows the whole design of the metasurfaces. A
group of metal wire pairs were designed on both sides of the dielectric layer with a thickness of \( h = 44 \mu m \) and the 24-um-width metal pairs’ thickness is 200nm, respectively. One unit cell has different period lengths in the x and y directions in order to reduce unnecessary coupling. The spacer is a benzyocyclobutene (BCB) layer with a permittivity of \( \varepsilon = 2.67 \) and a loss tangent of \( \delta = 0.012 \). The metal layers are made from gold with the conductivity of \( \sigma = 4.56 \times 10^7 \) S/m. The spectral response of the unit cell was calculated using CST Microwave Studio TM simulations. The incident wave is a plane wave with the electric field along the x-axis, as shown in Fig. 1(a). For the transmitted Huygens’ metasurfaces, we expect that \( \text{Re}(\eta/Z_m) = \text{Re}(\eta/Y_m) = 0 \) and \( \text{Im}(\eta/Z_m) = \text{Im}(\eta/Y_m) \) can be used to achieve perfect transmission. We choose eight resonators with different length as shown in Fig. 1(a), where the parameter \( \alpha_1 \) is the only parameter related to the phase change of the transmitted wave. The amplitude and phase of the transmitted wave of this design are shown in Fig. 2. The transmission coefficient of this structure remains above 0.78, while the phase covers 0-2\( \pi \) range.

![Figure 2](image-url): The amplitude and phase of eight cut-wire pairs in the Huygen metasurface. The lengths is from 62.5 to 127.5um.

Figure 3 shows the simulation results of energy distribution in the direction of diffraction, these results show that the main diffraction along 19.84° (not shown here) occupies about 66% of the incident energy at 0.83THz. Compared with the Huygens’ metasurfaces of wire/loop structures realized in microwave, the superstructure surface we designed reduces the structural complexity and manufacturing difficulty, especially in terahertz range.

![Figure 3](image-url): Simulated anomalous refraction of the Huygen metasurface. The metasurface is composed of eight cut-wire pairs with different lengths from 62.5 to 127.5um.

3. Conclusions

In conclusion, we designed a direct Huygens’ metasurfaces with a two-layer metal structure. These metasurfaces use carefully designed structural elements to achieve both electric and magnetic dipole resonance at the desired frequency to form Huygens sources. This discontinuous field on the surface can interact with the incident electromagnetic wave and modulate the transmitted light’s phase in 2\( \pi \) range while maintaining a low reflection. Compared with the equivalent Huygens surface with three-layer metal design, our design retains the view that huygens source is formed directly on the metasurface, and further research on this basis may realize the broadband Huygens’ metasurfaces.

Efficiency improvement in wireless power transfer system using artificial magnetic conductors

Lijuan Dong*, Fusheng Deng, Yanhong Liu, Lixiang Liu and Yunlong Shi

Shanxi Provincial Key Laboratory of Electromagnetic Functional Materials for Microstructure, Shanxi Datong University, Datong, China

Abstract

In this paper, transfer performance improvement in wireless power transfer (WPT) system using a mushroom-type artificial magnetic conductors (AMC) is reported. Numerical simulations confirm that AMC possesses great power for enhancing the WPT efficiency between two non-resonant coils.

1. Introduction

Since the earliest imagination of wireless power transfer (WPT) by N. Tesla in 1914, the concept of wirelessly transmitting electric power from one place to another has gained enormous attention from researchers and engineers. Among several sorts of WPT methods, the magnetic induction is the most powerful scheme to achieve high efficiency in mid-range. Especially, the magnetically resonant version by A. Kurs and his colleagues from MIT invented an considerably efficient way to wirelessly convey the electric energy over short or mid distance by making the coils self-resonant[1]. In this case, the magnetic coupling strengthened by magnetic resonance eventually leads to fast energy exchange rate, realizing high overall efficiency. However, this technique is very sensitive to the transfer distance. Once the gap between two resonant coils becomes shorter than the perfect-coupling distance, the transfer efficiency will naturally decrease since the frequency splitting takes place, due to the over-coupling effect [2]. In order to modulate the transfer performance of WPT, much efforts have been devoted in the development of complexity of external matching circuits [2]. In addition to those traditional methods, feasible regulation functions from metamaterials are increasingly favored by both physicists and engineers.

Metamaterials (MMs) refers to a sort of periodic artificial electromagnetic micro-structures[3]. In the past decade, MM has captured great research interests. One of the most well-known finding is the artificial magnetic conductors (AMC)[4], which is characterized by high-impedance and in-phase reflections for incident waves over a specific frequency band[4]. They can modulate the propagation behavior of electromagnetic (EM) waves significantly. Major breakthroughs of AMC include reducing backradiation[5], increasing gain[6], and broadening bandwidth when they are employed as the antenna ground plane. These works inspire people with great confidence for the practical applications of AMC in a wider region.

In this paper, we propose to utilize a mushroom-type AMC, positioned behind the source, to realize the improvement on transfer performance of WPT system and magnetic shielding for unexpected field. The AMC structure consists of an array of capacitive patches on the top of a grounded ferrite substrate, and shorting via-holes connecting the patches to the ground plane. Lumped capacitors are used between the patches for AMC miniaturization. By introducing the AMC slab into non-resonant coils, the overall efficiency is significant enhanced, due to the magnetostatic resonant modes within the slab. Further investigations on the spatial magnetic-field distributions demonstrate that a variety of magnetic-field patterns in a near range can be effectively realized, and also show the superior performance in magnetic shielding. Importantly, all these improvements are not at a cost of transfer distance, which increases the practical applications of this composite AMC-WPT structure.

2. Working principle and design of AMC

Now, we give a simple schematic shown in Fig. 1 to illustrate our AMC-based inductively non-radiative WPT system. The transmitter and receiver of WPT, sharing the same diameter of 15 cm, are set with a transfer distance l. They are extremely smaller than the wavelength, and can be treated as magnetic dipoles. A mushroom-type AMC structure, positioned behind the transmitter with a spacing h=1 mm, is used to realize the improvement on transfer performance of WPT system. The physical mechanism is electromagnetic power resonates of AMC driven by the current loop and in-phase reflection at air-AMC interface.

Figure 1: Schematic of our AMC-based inductively non-radiative WPT system.
The proposed mushroom-type AMC structure is shown in Fig. 2. It is made up of an array of capacitive patches on the top of a grounded dielectric substrate, and shorting via-holes connecting the patches to the ground plane. Lumped capacitors are used between the patches for AMC miniaturization. The detailed dimensions are as follows. The AMC slab consists of 20×20 unit square patches. The patches have a separation of 2 mm, with an edge length of m=50 mm, and the resulting period is p=52 mm. The patches are situated on a barium cobalt hexaferrite substrate, BaCo2Fe12O24 (Co2Z), with a permeability of 150 and a thickness d=5 mm. The value of lumped capacitors used is C=0.72 nF.

Figure 2: Geometry of the mushroom-like AMC structure.

Figure 3: (a) Simulated transfer efficiencies at 10 cm for w/o AMC cases. (b) Simulated efficiencies at 15.2 MHz for w/o AMC cases as a function of transfer distance from 1 cm to 13 cm.

3. Simulation results and discussion

Numerical simulations are carried out by a commercial finite-integration-technique (FIT) EM solver from CST Microwave Studio. For comparison, the transmission spectrum of non-resonant wireless power transfer w/o AMC is figured out, shown as Figure 3(a). It is clear that the efficiency is increased from 5 % to 76% at 15.2 MHz after the AMC slab is introduced, with transfer distance l=10 cm. Also important phenomenon is that the appearance of many transmission peaks, as named from I to IX. The peaks indicate that the magnetic field at these corresponding frequencies receive great enhancement simultaneously. Note that, there is no material placed into the transfer path, which increases the practical applications of this method. Figure 3(b) shows that as the transfer distance becomes larger from 1 cm to 13 cm, the efficiency of composite AMC-WPT scheme at 15.2 MHz drops from 92% to 73%, larger and decreasing slower than that of the original non-resonant WPT system. It is worth mentioned that, this efficiency improvement is with an ideal AMC. As a real AMC implemented, the ohmic loss and resonant loss of AMC and the impedance mismatch will lead to a relatively low efficiency. Fortunately, the experience in previous works indicates that these losses in fabricated metamaterials can be controlled to be small compared to the efficiency gains.transfer distance from 1 cm to 13 cm.

4. Conclusions

To sum up, a mushroom-type artificial magnetic conductors (AMC) is proposed to regulate non-resonant wireless power transfer. Significant enhancement in the overall efficiency of the non-resonant wireless power transfer has been demonstrated by adding the AMC to non-resonant coils. Since the wireless power transfer system based on AMC has many benefits, we believe it can be widely used in medical research, electric vehicle charging, civilian industry, and so on.

Abstract

In this paper, coding Huygens’ metasurface (CHM) is proposed for holographic imaging with enhanced quality. A weighted holographic algorithm is utilized to calculate the phase distribution at the interface and to design the CHM. Experimental demonstration performed in the microwave region validates holographic imaging with the ability to modulate energy distribution among focal points and improve the quality of the image. By judiciously engineering both electric and magnetic dipolar resonators, the proposed digital Huygens’ meta-atom is able to provide a full transmission-phase covering the whole range of $2\pi$ together with a near-unity transmission efficiency. The proof-of-concept experiments show that the quality of holographic imaging can be indeed improved by utilizing digital meta-atoms with several bits. The proposed CHM hologram shows great potential in a variety of application fields, such as programmable high-resolution imaging lenses, microscopy, data storage, information processing and computer-generated holograms.

1. Introduction

Metasurfaces, the two-dimensional (2D) version of metamaterials, show great ability in manipulating wavefronts in arbitrary manner by introducing corresponding phase discontinuities at the interface. A metasurface is typically composed of an array of subwavelength artificial meta-atoms with specially designed geometries [1] and orientations [2, 3], and several devices have been implemented based on the construction of metasurfaces, including couplers [4], beam shapers [5], invisibility cloaks [6], imaging systems [7, 8], and other functional devices [9-11]. A main challenge for most metasurfaces operating in transmission mode is to fully control the transmission phase, while at the same time being able to guarantee high transmission efficiency. It can also be solved by using the so called Huygens’ metasurface [12] that enables to fully control both the phase and the amplitude of co-polarized transmitted wave without polarization conversion losses. Due to the outstanding ability in manipulating electromagnetic waves, applications of the Huygens’ metasurface have been reported in beam-refracting [13], focusing [14, 15], beam-shaping [16], and hologram imaging [17].

Recently, the concept of coding metasurfaces has been proposed [18] and applied in beam-editing [19], diffuse scattering [20] and energy radiations controlling [21]. Coding metasurface presenting the ability to describe information in a digital way is usually composed of digital meta-atoms with different out-of-phase responses, allowing to manipulate electromagnetic waves. The meta-atoms with different designed functions can be represented by binary codes, which are deemed to be coding elements. For example, based on the out-of-phase responses, binary coding elements for the simplest 1-bit coding metasurface are “0” and “1”, which correspond to “0” and “$\pi$” phase response, respectively. Similarly, a 2-bits coding metasurface is composed of four coding elements “00”, “01”, “10” and “11”, which have “0”, “$\pi/2$”, “$\pi$” and “3$\pi/2$” phase response, respectively. The generation of n-bit coding metasurface obeys the same rule. In this way, the information of the metasurface can be recorded in a digital way, which creates the connection between the physical meta-atom and digital codes. The digital description of metasurfaces has changed the way of describing, analyzing, and designing metasurface.

Here in this work, we propose the concept of coding Huygens’ metasurface (CHM) for microwave holographic imaging. To construct the CHM, we use Huygens’ meta-atoms as the basic coding elements. By correctly designing geometrical parameters of the electric and magnetic dipoles, meta-atoms able to cover full $2\pi$-phase range with near-unity transmission amplitude can be obtained. A weighted holographic algorithm is proposed to calculate the phase distribution along the metasurface. Then, arbitrary n-bit CHMs can be realized by discretizing the calculated phase distribution by $2^s$ over $2\pi$. For validation of the proposed concept, 1-, 2-, and 3-bits CHMs are designed, fabricated and measured to find the relationship between imaging quality of the CHM holograms and phase-quantization level. Moreover, we modulate the intensity distribution of focal points using the proposed 3-bits CHMs to verify the feasibility of our proposed weighted holographic algorithm. Experimental verifications performed at microwave frequencies agree qualitatively with theoretical calculations and numerical simulations, indicating the feasibility and
high imaging quality of the proposed CHM holograms.

2. CHM holograms

In order to achieve the desired holographic imaging, the phase profile at the interface of the metasurface is designed from the proposed holographic algorithm [22]. Different from algorithm for manipulating the radiation pattern of the antenna [23], we propose holographic algorithm to converge the incident wave to four specific focal points in the near field, at a distance about 3.3λ away from the metasurface. The schematic diagram for the theoretical analysis is illustrated in Fig. 1. One fundamental method is that we are able to select ideal point sources as virtual sources and place them at pre-designed focal points positions. We consider N focal points located at \((x_i, y_i, z_i)\) (i = 1 to N). Then, by supersposing the electromagnetic field generated by all the virtual sources, which can be described utilizing Green function, the phase delay at the position of each meta-atom \(\phi(x_i, y_i, 0)\) (i = 1 to M) can be retrieved. Accordingly, the reconstructed electric field is converged to the pre-designed focal points. However, the assumption of in-phase radiation can only ensure the convergence of the incident wave to the preset focal points, but is not sufficient to modulate the intensity distribution of the focal points. This problem is solved by introducing a weight factor \(w_n\) so as to modify the phase distribution on the metasurface and hence to modulate energy distribution. An iterative procedure is adopted to obtain the phase distribution \(\phi_m\) on the CHM, as follows:

\[
\phi_m^p = \arg \left( \sum_{n=1}^{N} e^{i \omega_n^p} \frac{w_n^p |E_n^p|}{r_n^m} \right)
\]

Where \(r_n^m\) is the distance between the \(m^{th}\) meta-atom and the \(n^{th}\) focal point, \(k\) is the phase constant, \(w_n^p\) presents the intensity ratio of \(n^{th}\) focus to the first one, and the superscript \(p\) represents the \(p^{th}\) iteration. Once the phase value of each meta-atom is obtained, the reconstructed field can be calculated by supersposing the field component emitted by each meta-atom. Since the radiation of the meta-atom also obeys the Greens' function, the reconstructed electromagnetic field at the position of each focal point can be retrieved as:

\[
E_n^p = \sum_{n=1}^{N} \frac{e^{-i \omega_n^p s_n}}{r_n^m} E_n^p
\]

\[
w_n^p = w_n^p \sum_{n=1}^{N} \frac{|E_n^p|}{E_n^p} \sum_{n=1}^{N} s_n
\]

where \(s_n\) is the preset intensity ratio of the \(n^{th}\) focal point. According to the above details about the algorithm, \(w_n^p\) is adjusted to eliminate the deviations of \(|E_n^p|\) from the desired intensity. The initial condition is set as:

\[
w_n^1 = 1, \quad \phi_n^0 = \frac{2\pi n}{M}
\]

Figure 1: Schematic illustration of the holographic imaging process. A weighted Huygens' metasurface incorporating coding electric and magnetic dipolar resonators is illuminated by an incident plane wave to produce a hologram. Photography and structural details of a fabricated CHM sample (image lower right).

3. Design of the coding elements

The proposed CHMs consist of a two-dimensional square array of Huygens’ meta-atoms as shown in Fig. 2(a). A split-ring resonator (SRR) is placed on one side of the substrate playing the role of the magnetic dipole and an electric-LC resonator acting as the electric dipole is arranged on the other side of the substrate. With the combination of magnetic and electric dipole sources, the meta-atom can be considered as a small Huygens’ source. To reveal the mechanism of the proposed Huygens’ meta-atom, the surface current flowing along the metallic patterns of the meta-atom is plotted in Fig. 2(b). A photography of a fabricated CHM sample is shown in the inset of Fig. 1. The proposed CHMs, which are fabricated using conventional PCB photolithography, consist of coding elements covering an area of 205 × 201.2 mm². A CHM is assembled by stacking 41 identical circuit board strips with 3.5 mm air gap between each strip, and each board strip consists of 57 meta-atoms. The top and the bottom sides of the strips provide the required electric and magnetic currents, respectively.

In our proposed Huygens’ meta-atom, by changing the length \(l_e\) and \(l_m\) of the electric and magnetic resonators, electric and magnetic sheet impedances can be adjusted to achieve the desired amplitude and phase responses. Therefore, a flexible and efficient method to engineer electromagnetic wavefronts can be anticipated. The proposed meta-atom with fixed parameters \((l_e=3.5\,\text{mm}, \, l_m=2.7\,\text{mm})\) is simulated using the commercial software CST Microwave Studio by applying unit cell boundary conditions in x- and y-directions under y-polarized plane wave incidence. The simulation results are shown in Figs. 2(c) and 2(d). It can be observed that the resonance frequency of the meta-atom is around 10GHz, so the operating frequency of our proposed CHM is designed to be 10 GHz. By modulating the parameters \(l_e\) and \(l_m\), the amplitude of the transmission coefficient ranges from 0 to 0.99, and the phase of the transmission coefficient covers...
the whole $2\pi$ range at 10 GHz, as shown in Figs. 2(e) and 2(f). It is important to observe that the transmission phase can be freely manipulated by changing $l_e$ and $l_m$, while keeping the transmission amplitude at a high level. The designs of 1-, 2-, and 3-bits coding elements with different phase shift of $\pi$, $\pi/2$ and $\pi/4$ are depicted in Fig. 3. The transmission amplitude of all the coding elements can be kept above 0.9 so as to achieve a high transmittance efficiency.

![Figure 2](image)

Figure 2: This is the figure caption. Color figures are acceptable. Design of the coding elements. (a) Schematic view of the Huygens’ meta-atom composed of electric and magnetic dipoles. The thickness of the substrate ($s_e = 3$ and $\tan \delta = 0.002$) is 1.5 mm and the periodicity of the elementary meta-atom is respectively 5 mm and 3.53 mm along x- and y-directions. (b) Simulated electric and magnetic currents along the metallic electric and magnetic dipolar resonators excited by a y-polarized incident wave. (c) Simulated amplitude of the transmission coefficient and (d) simulated phase of the transmission coefficient of the Huygens’ meta-atom with fixed parameters $l_e$ and $l_m$. (e) Simulated transmission amplitude and (f) transmission phase of the Huygens’ meta-atom with different parameters $l_e$ and $l_m$.

A series of CHMs is fabricated to generate holograms and to modulate focal intensity ratio of the focal points. For the uniform holograms, all the intensity ratio $s_n$ are set to the same value and are equal to 1, such that the incident energy can be transformed equally into each focal point. To evaluate the imaging quality, two parameters are adopted here: the imaging efficiency and the root-mean-square error (RMSE). The imaging efficiency is defined as the ratio of the energy converged to designated points to the energy of the incident wave. The RMSE describing the deviations between the measured intensity ratios and the theoretical values, is used to evaluate the manipulation ability of energy allocation of focal points. Particularly, the RMSE can be calculated as:

$$\sigma = \sqrt{\frac{1}{N} \sum_{n=1}^{N} \left( \frac{|E_n|}{\sum_{n=1}^{N}|E_n|} - \frac{s_n}{\sum_{n=1}^{N}s_n} \right)^2}$$

Figure 3: Coding elements for 1-, 2-, and 3-bits CHMs extracted from the simulation results of the Huygens’ meta-atom.

Based on the proposed weighted holographic algorithm, the phase profile at the interface of the CHM can be obtained. The focal distance is chosen to be 100 mm because of the convenience of measurement. To replace continuous phase distribution in proof-of-concept prototypes, approximated discrete phase values are used. Then arbitrary n-bit CHM can be built through discretization of the phase profile over $2\pi$ by $2^n$. Taking for instance 1-bit CHM as example, the calculated phase profile at the interface can be divided into two intervals over $2\pi$. The phases for the two intervals are quantified to be 0 and $\pi$, which are represented by code “0” and “1”, respectively. In this way, the phase information can be described by codes distribution on CHM. Figure 4 shows the code distribution of the proposed 1-, 2-, and 3-bits CHMs for uniform holograms, and code distribution of the 3-bits CHMs for modulation of focal intensity distribution. Utilizing the calculated code distributions, the CHMs can be easily built up by arranging coding elements at corresponding positions.

![Figure 4](image)

Figure 4: Code distribution of the proposed CHMs for (a) 1-bit, (b) 2-bits, (c) 3-bits uniform holograms, and code distribution for modulation of focal energy.

4. Experimental results and discussion

The fabricated samples of the CHMs are experimentally validated using a near field scanning system. A feeding horn antenna is placed 65 cm away from the metasurface to ensure the incident quasi-plane wave at 10 GHz. A fibre
optic active antenna is used as field probe to measure the electric field distribution in the transmission region. The vector network analyzer (Agilent 8722ES) is connected to the feeding horn antenna and field receiving probe to measure the transmission coefficients. The holographic image of a rhombus is realized with uniform intensity distribution as shown in Fig. 5. Figure 5(a) shows the theoretical result obtained from the Huygens’ metasurface with the calculated continuous phase profile. Figures 5(b)-5(d) show the measured images at the frequency of 10.2 GHz of the 1-, 2-, and 3-bits CHMs at a distance of 100 mm above the CHMs. The parameters used to evaluate the imaging quality of the CHM holograms are listed in Table 1, where we can clearly observe that imaging efficiency is significantly improved from 27.1% for 1-bit hologram to 51.5% for 3-bits hologram, which is superior compared with previous metasurface holograms [14, 17]. It can also be noted that the total image efficiency is improved by 57.2% from 1-bit to 2-bits, and 20.9% from 2-bits to 3-bits hologram, meaning that the imaging quality improvement effect will be slight when the phase-quantization increases to a relatively high level. Therefore, we need to take both design complexity and imaging quality into consideration and choose coding elements with suitable bits for real-life practical applications.

Table 1 also depicts the RMSE of the uniform holograms. For the 3-bits hologram, the measured RMSE can be as low as 0.77%, indicating a low deviation between calculation and measurement when the incident energy is transformed to the desired focus points equally. The signal to noise ratio (SNR), which is defined as the ratio of the peak intensity in the image to the standard deviation of the background noise [20], is found to be above 10 for all the measured CHM holograms as shown in Table 1. Figures 5(e)-5(g) show the measured images at 9GHz, 10GHz and 11GHz, respectively. The image quality will decrease when the operating frequency deviates from the designed one. Since the phase responses of the meta-atoms are extracted from the simulated results at 10 GHz, and the phase distribution at the interface is calculated using the operating wavelength at 10 GHz, which means the phase delay at the focal plane will be affected when the operating frequency deviates. The simulation results of 3-bits CHM at different focal distance of 90 mm, 100 mm and 110 mm are also given in Figs. 5(h)-5(j). When the focal distance deviates from the designed value, the image quality will decrease owing to the change of phase delay on the focal plane.

5. Conclusion

In conclusion, CHM holograms are realized using Huygens’ meta-atoms as coding elements and are experimentally validated in microwave regime. By adjusting the geometrical parameters of the electric and magnetic dipoles, 1-, 2-, and 3-bits coding elements are built based on the transmission phase. A weighted holographic algorithm is proposed to achieve the phase profile along the metasurface, and 1-bit, 2-bits and 3-bits CHM holograms are designed, fabricated and measured. The imaging efficiency of the 3-bits CHM hologram is measured to be as high as 51.5%, showing outstanding imaging quality. Based on the measured results, the influence of the phase-quantization level to the imaging quality is discussed to improve imaging quality. Moreover, several 3-bits CHMs designed to modulate intensity distribution among focal points are experimentally demonstrated. The RMSE of the measured results verify the great intensity modulation ability of our proposed CHMs. The proposed CHM holograms provide more freedom to electromagnetic wave manipulation, which may have many practical applications in computer-generated holograms, imaging lenses and microscopy. Furthermore, the concept shows great potentials in constructing programmable CHMs by loading controllable elements to realize dynamic holograms and wave focusing.
of 3-bits CHM at different focal distances of 90 mm, 100 mm and 110 mm respectively.

Broadband flattened parabolic reflector antenna based on metasurface

Vivien Taverny¹, Badreddine Ratni¹, and Shah Nawaz Burokur¹

¹LEME, UPL, Univ Paris Nanterre, F92410 Ville d’Avray, France
*corresponding author, E-mail: badreddine.ratni@parisnanterre.fr

Abstract
A flattened parabolic reflector antenna is designed to operate under right-hand circular polarization (RHCP) by using a reflective metasurface composed of square patches printed on a grounded dielectric substrate. A circularly-polarized patch antenna placed at the focal point of the metasurface reflector is used as the primary feed. Numerical simulations are conducted and far-field simulation results show a highly directive beam with a realized gain of 20 dBi.

1. Introduction
Planar version of metamaterials called metasurfaces have been developed these last two decades. They are known for having reduced profile and reduced losses compared to the 3D bulky version of metamaterials [1]. Their characteristics allow their implementation in different types of antennas such partially reflecting surface (PRS) based Fabry-Perot cavity antennas [2-5], lens antennas [6] and reflector antennas [7-8].

2. Metasurface-based reflector
The use of metasurfaces makes it possible today to realize a very great variety of extraordinary structures. We have recently demonstrated that we can use metasurfaces to make different reflector antennas [8]. In this previous work, we have used a reconfigurable metasurface that allows frequency and angular reconfigurability. The proposed structure was composed of unit cells that incorporate varactor diodes. Nevertheless, although this structure was able to cover a wide frequency band spanning from 9 GHz to 12 GHz, the instantaneous bandwidth was narrow due to the resonant nature of the unit cells. In this work, we propose a new broadband passive metasurface that is used to design a flattened parabolic reflector antenna able to operate and cover the targeted frequency band from 10.7 GHz to 12.7 GHz. The unit cell composing the multi-layer metasurface is shown in Fig. 1 and is composed of three layers. The first layer consists of a continuous metallic ground plane while the second and third layers are each composed of square metallic patch with geometric dimensions \( a \) and \( k*a \), respectively. At a fixed dimension of the parameter \( a \), the factor \( k \) has been optimized in such a way to obtain the least variation of the phase on the entire frequency band (from 10.7 GHz to 12.7 GHz). In our case, the periodicity of the unit cell is fixed to \( p = 6 \) mm and the dimensions of the square patches is varied from \( a = 0.2 \) mm to \( 5.9 \) mm. The most optimum \( k \) factor is found to be 0.9. Two layers of F4BM dielectric substrate (relative permittivity \( \varepsilon_r = 2.2 \)) with thickness \( t_1 = 1 \) mm and \( t_2 = 1.5 \) mm are chosen as spacers.

Figure 1: Schematic view of the designed unit cell with periodicity of \( p = 6 \) mm.

3. Results
In order to obtain the characteristics of a parabolic reflector, the phase profile is calculated as follows:

\[
\varphi(x) = \frac{2\pi}{\lambda} \left( \frac{x^2 + y^2}{4f} \right) + \varphi_0
\]

where \( \lambda \) is the operating wavelength, \( f = 30 \) mm is the focal distance and \( \varphi_0 \) is the reflection phase shift at \( (x = 0 \) mm, \( y \) = 0 mm). The calculated phase profile along the whole metasurface composed of 30 x 30 unit cells, is presented in Fig. 2. By varying the dimensions of the square patches the reflection phase response can be varied from -180° to 180°. The metasurface is then designed by optimizing each unit cell to obtain the required phase response. Once designed, the metasurface reflector is fed at the predefined focal point \( (f = 30 \) mm) by a wideband circularly polarized patch antenna. Full-wave simulations are performed using a finite
element based commercial solver. A directive beam is obtained over the entire band spanning from 10.7 GHz to 12.7 GHz. The simulated radiation patterns at 10.7 GHz and 12.7 GHz are presented in Fig. 3. A right handed circular polarization (RHCP) is obtained with an axial ratio lower than 3 dB over the entire frequency band. The realized gain of the patch antenna is around 6 dBi while the metasurface-based flattened parabola allows to increase the gain to 20 dBi.

![Figure 2](image1.png)

Figure 2: Applied phase distribution along the metasurface for a focal point fixed at $f = 30$ mm.

![Figure 3](image2.png)

Figure 3: Simulated far-field radiation patterns showing RHCP directive beam with a gain of 20 dBi at the frequencies of (a) 10.7 GHz and (b) 12.7 GHz.

4. Conclusions

In summary, a broadband planar parabolic reflector antenna based on metasurface is proposed. The metasurface is composed of square patches printed on a grounded dielectric substrate. A broadband patch antenna placed on the focal point is used as a primary feed. Simulation of the proposed antenna structure is performed and the results show a highly directive beam with a high realized gain of 20 dBi.

Mitigating Chromatic Dispersion with Hybrid Optical Metasurfaces

Rajath Sawant¹, Purva Bhumkar¹, Alexander Y. Zhu², Peinan Ni¹, Federico Capasso², Patrice Genevet¹*

¹CNRS-CRHEA, Université Côte d’Azur, Sophia Antipolis, Valbonne, France

Abstract
Metasurfaces, arrays of subwavelength spaced nanostructures, control various properties of light. The dispersion of outgoing light can also be controlled using the phase gradient of a metasurface. Exploiting this property, hybrid refractive-metasurface devices is designed to realize nondispersive refraction in the visible. The dispersion of hybrid component, characterized by using a Fourier plane imaging microscopy setup, is essentially achromatic over about 200nm in the visible. Broadband focusing with composite plano-convex metasurface lens is also proposed.

Introduction
Conventional optical components are macroscopic in size which is a hindrance for miniaturization of optical devices. Dispersive response from the material used is their major drawback leading to chromatic aberration. For example, to correct the chromatic aberration of a lens a popular technique in practice is to use series of cascading lenses, which results in bulky devices. Metasurfaces, an array of nanoantennas of sub-wavelength thickness can be employed to achieve this as they are compact and effective. Metasurfaces are known to cause abrupt phase and polarization shift in the outgoing light. Recently, the dispersion of metasurfaces has been shown to vary from positive to zero to negative in the infra-red region [1]. Also a general approach to design an achromatic metalens has been demonstrated in the visible region using the geometric phase property [2]. In this work, we demonstrate dispersion compensation of a prism and a plano convex lens by a simpler method using phase gradient metasurfaces [3].

For a desired functionality, one can fabricate the metasurface with corresponding phase profile using nanoantennas. For our study, we use constant phase gradient metasurface made of TiO₂ nanopillars (dielectric material) on SiO₂ substrate. Using FDTD technique, the phase and transmission map for nanopillars of different radius for different incident wavelength is computed. Phase gradient is obtained by placing 0 to 2π phase elements in the increasing order along one particular direction and periodically repeating the same arrangement. One can see that this mimics the conventional blazed gratings in design and also functionality. The generalized laws of refraction at the metasurface-air interface [4] are used for the calculations. The phase gradient is a parameter to design the metasurface given the angle of incidence (30°) and the design wavelength of light [Eqn 1]. The technique of Fourier plane imaging and spectroscopy is utilized to study minute angles of dispersion in the prism’s case (Fig 2). The results obtained are for broadband visible region of 550-800 nm. Extending the same principle to a plano-convex lens, to mitigate its chromatic aberration phase gradient metasurface is placed on its planar side. Phase gradient of the device varies linearly as a function of distance from the center of the lens unlike in the case of prism [Eqn 2].

1.3 Equations

Phase gradient relation of metasurface for chromatic aberration mitigation of (1) Prism, (2) Plano convex lens

\[
\frac{d\phi}{dx} = \frac{2mB}{\lambda_0^3} \quad (1)
\]

\[
\frac{d\phi}{dr} = \frac{4\pi B r}{\lambda_0^3 R} \quad (2)
\]

Where B is the co-efficient of \( \lambda^{-2} \) in Cauchy’s relation and \( \lambda_0 \) is the design wavelength of metasurface. ‘R’ is the radius of curvature of lens and ‘r’ is the height of incident ray from the centre of lens.

2. Discussion

The motivation behind this work is to combine refractive components with normal dispersion and metasurfaces with negative dispersion to design hybrid achromatic devices. Metalenses reported so far are constructed by engineering phase at each point, have low numerical aperture and efficiency. On the other hand, we have exploited phase gradient property of the metasurface which is a global parameter. They have an efficiency of atleast 60%.

3. Conclusions

All in all, we report mitigation of dispersion of prism to atleast 80% (experimental) and lens upto 94% (ray tracing results) using metasurfaces in broadband visible region of 600-800 nm. Other aberrations of lens can also be addressed using the same approach.

Abstract:

We demonstrate a metasurface-based flat reflectarray antenna with the capability of beam collimation and focusing. The reflectarray is designed to operate at 12 GHz with a focal distance of 50 cm in a center-fed configuration. It consists of 32 metallic patch resonators of variable sizes to cover a full 2π phase range. The reflectarray exhibits a measured gain enhancement of 28 dBi at the central operating frequency of 11.8 GHz and focuses at 50 cm with a depth of focusing of 8 cm and has a 3 dB directivity ±1.6°. The demonstrated reflectarrays may enable low-cost, lightweight, and high-gain deployable transceivers for small-satellite platforms.

Introduction:

Small satellites (SmallSats) are emerging space research capabilities for many intriguing applications such as sensing, imaging, tracking, surveillance, and high-speed communications. The use of SmallSats has been rapidly growing in recent years due to multiple factors including miniaturization of electronics, high-speed data processing and high-density data storage, ride-share with other satellites, and reduced cost for their design, build, and operation. Antennas are the key component for satellites to transmit/receive electromagnetic signals for wireless communications. Conventional satellites employ parabolic dish antennas for wireless communication links. Due to the limited size, weight, and power (SWaP) requirements of SmallSats, they mostly rely on small, light-weight, and isotropic antennas such as dipole, monopole, or helix. Although SmallSats are capable of collecting huge amounts of data, they severely suffer from a bottleneck effect while transmitting/receiving data to the ground/command stations due to the inherit limited performances of these inefficient antennas. Therefore, it is very important to explore alternative approaches to enable lightweight high-gain antennas that occupy a considerably small fraction of the payload and volume of SmallSats. There have been a handful of initiatives in realizing high-performance lightweight antennas for small satellites[1] including Fabry-Pérot cavity antennas[2], deployable mesh reflectors[3], inflatable balloon reflectors[4], and deployable waveguide slot antennas[5]. Very recently, planar reflectarrays have been studied as a viable option for enabling high-gain antennas for SmallSat applications[5].

Our proposed flat parabolic reflectarray is based on a single layer metasurface which consist of patches separated from a metallic ground plane by a thin dielectric spacer as shown in inset of Fig 1(a). The metasurface is polarization-dependent, with the electric field of the incident/ emitted microwave radiation along the longer axis of the patches. We use a square unit-cell of size 10 mm to operate at 12 GHz, which introduces ~2000 pixels in the reflectarray surface. To cover the required full 2π phase range, we vary the structural parameters length (L), width (W), gap (g) of the resonators and obtain 32 phase values from 0 to 2π in increments of π/16 as shown in Fig 1(a) with their corresponding reflectance higher than 85%. The discrete values of the phase are derived using commercially available full-wave numerical simulation software (CST).

The polarization-dependent ultrathin flat reflectarray works similarly to parabolic dish antenna and its operational frequency, focal length of the designed metasurface can be tuned by scaling the resonator and redistributing the phase profile. In a center-fed reflector or a lens, where the phase distribution is radially symmetric as shown in Fig 1(b). The required phase distribution as a function of position (x, y) on the metasurface is given by

$$\psi(x, y) = \frac{2\pi}{\lambda}\left\{\sqrt{x^2 + y^2} - z_f\right\}$$

Where \(\lambda\) is the operating wavelength and \(f = z_f\) is the focal length. The size of our proposed reflectarray
is $440 \text{mm} \times 440 \text{mm}$ with a focal length of $500 \text{mm}$.

![Figure 1](image1)

**Figure 1:** (a) Phase (red) and reflectance (blue) of meta-atoms. (b) Spatial phase profile of the metasurface (c) fabricated reflectarray antenna

Fig 1(b) shows the spatial phase profile of the metasurface, where the color coding represents the use of 32 discrete phase values. The metasurface reflectarray was fabricated on a double copper cladding printed circuit boards (PCBs) from Rogers Corporation (RO 4003C, thickness=0.508 mm) using chemical etching of copper. An image of the fabricated reflectarray is shown in Fig. 1(c) and it was characterized inside an anechoic chamber using a pair of broadband horn antennas and a vector network analyzer.

![Figure 2](image2)

**Figure 2:** Measured gain of the antenna as a function of the azimuth (horizontal) scan angle. (c) 2D plot of the power density profile for $0^\circ$ reflect angle

We investigate the far-field radiation pattern of the emitted microwave radiation from our off-axis parabolic reflectarray and measured the angle-dependent gain as a function of azimuth angle, varying from $-15^\circ$ to $+15^\circ$ for a fixed elevation angle as shown in Fig 2(a). A net gain of 27.5 dBi is observed for an azimuth angle of zero degree, confirming the validation of our reflectarray design for beam focusing/collimation. The measurement was repeated for each elevation angle from $-15^\circ$ to $+15^\circ$. The measured 2D plot of the angle-dependent gain is shown in Fig 2(b). The radiation pattern shows a dominant Gaussian type main lobe, which is symmetrically bounded within $\pm3^\circ$ for both azimuth and elevation angles. The angle of 3-dB gain enhancement is less than $2^\circ$, confirming good directionality and beam collimation. The circular field distribution is also a manifestation of good beam collimation, a pre-cursor for long-haul communication link.

In conclusion, we have designed, fabricated, and characterized a metasurface-based reflect array antenna at microwave frequencies consisting of an anisotropic resonator array with focusing/collimation. The fabricated reflect array demonstrates excellent focusing and collimation of the radiated microwaves from a feed-horn antenna. The measured results show a gain enhancement as high as 15.5 dBi, in addition to the 12 dBi gain from the feed horn antenna.

Abstract

We investigate numerically and experimentally the image reconstruction crosstalk as function of the incidence angle for a broadband stereoscopic hologram metasurface operating in the visible range. To this end, we define a metasurface acceptance cone in which good performance can be achieved with reduced polarization crosstalk. The stereoscopic hologram is made of a birefringent metasurface with elliptical crystalline silicon (c-Si) nanoposts. The optimal wavelength (transmission) efficiency calculated at normal incidence reach 52.3% (76.9%) at the design wavelength of 532 nm.

1. Introduction

Metasurfaces are planar subwavelength structures that allow local control of phase, amplitude and/or polarization of light [1]. Metasurfaces are fabricated either with metals (such as Au and Ag) or entirely with dielectrics. However, all-dielectric metasurfaces are the preferable choice because of their intrinsic lower losses [2]. Amorphous silicon (a-Si), for instance, has proven to be a suitable candidate due to its high refractive index in the visible range, resulting in structures with small aspect ratio (at the expense of high absorption losses). Crystalline silicon (c-Si), in contrast, is more adequate for holography applications than a-Si and poly-silicon (p-Si) due to its smaller absorption at these wavelengths [3]. In addition, c-Si based metasurface holograms have shown successfully broadband operation in the visible range [4, 5]. Most of the proposed metasurfaces, including those based on c-Si, rely on normal incidence. Nevertheless, it would be useful to assess the metasurface’s performance under oblique incidence so that the degree-of-freedom allowed by this platform could be increased even further. In this sense, we suggest here an acceptance cone as a figure-of-merit to characterize the metasurface response in terms of the incidence angle for holography applications. To this end, we use a broadband birefringent c-Si metasurface capable of encoding holographic stereograms for imaging with depth perception [5]. The metasurface design is based on elliptical nanoposts capable of phase-shifting independently the transmitted light of two linear polarization states. The independent phase control allows the encoding of two different holograms in the same metasurface [5]. The metasurface acceptance cone (MAC) is defined in terms of the hologram’s reconstruction quality (via signal to noise ratio), transmission and diffraction efficiencies, and cross-polarization crosstalk. The MAC performance is assessed numerically and verified experimentally.

2. Metasurface design

The metasurface’s building blocks consist of c-Si elliptical nanoposts on top of a sapphire substrate, as illustrated in Fig. 1(a). The phase shift imparted on the transmitted light by this structure is different for light polarized along each of its semi-axes (x or y). Thus, independent phase control can be achieved with four phase levels for each polarization with high transmission for a 190 nm unit cell size [5]. The nanoposts are designed to operate at the wavelength of 532 nm. Nevertheless, this structure has demonstrated broadband operation with high quality experimental reconstructions even in the blue region of the spectrum [5]. The metasurface is fabricated on a 230 nm thick c-Si on sapphire (SOS) by electron beam lithography (EBL) and inductively coupled plasma (ICP) etching. The fabrication process is shown in Fig. 2. SEM images of the fabricated sample are shown in Figs. 1(b) and (c).

Figure 1: (a) Schematic representation of the birefringent c-Si based metasurface unit cell. (b) and (c) show SEMs of one of the fabricated metasurfaces. (d) Representation of the metasurface’s acceptance cone (MAC) with open angle 2θ. The maximum acceptable angle, θ, is measured relative to the metasurface’s normal.
3. Stereoscopic imaging

As described in [5], this design allows the encoding of two completely different phase distributions on the same metasurface, with one accessible by either x- or y-polarized light. This allows us to encode the CGHs of both images of a stereogram in the same metasurface. The encoding process is repeated here for completeness. First, we generate two stereogram images, as illustrated in Figs. 3 (a) and (b). Then, we calculate a four-phase level CGH with 1024×1024 pixels for each image (Figs. 3 (c) and (d)) and encode them in a c-Si birefringent metasurface, as illustrated by each square in Fig. 3 (e). Note that the final metasurface is composed of a 2×2 hologram array. Thus, the size of the final metasurface is 389.12 µm × 389.12 µm.

We theoretically assess the metasurface’s performance through a reconstruction analysis based on the Rayleigh-Sommerfeld (RS) integral [4]. Figs. 3 (f) and (g) show the resulting reconstructions for x- and y-polarizations, respectively, at 532 nm at normal incidence (the ideal case). The resulting diffraction (transmission) efficiencies for this case are 51.7% (76.9%) and 52.3% (76.7%) for x- and y-polarized light respectively, which are remarkable results for the visible range.

Figure 3: (a) and (b) show the two images that compose the stereogram. For each one, a four-phase level CGH with 1024×1024 pixels is calculated, as illustrated in (c) and (d). These CGHs are then encoded in a single birefringent c-Si-based metasurface, represented by one square in (e). Note that the final metasurface is composed of a 2×2 hologram array. Thus, the size of the final metasurface is 389.12 µm × 389.12 µm. The inset highlights the pixel representation. (f) and (g) show the reconstruction of each stereogram image calculated through the Rayleigh-Sommerfeld integral at 532 nm [4].

The MAC, measured both experimentally and numerically, is defined in terms of the reconstructed image quality via signal-to-noise ratio, transmission and diffraction efficiencies, and cross-polarization crosstalk. The MAC cone is illustrated in Fig. 1 (d). This concept assumes that good quality image reconstruction can still be conveyed by the metasurface hologram if the incidence angle is within the MAC. Preliminary results indicate that the incidence condition for high contrast metasurfaces, such as (c-Si)-based metasurfaces, can be relaxed still maintaining good image reconstructions (low polarization crosstalk). A set of simulation and experimental results will be shown during the conference.

4. Conclusions

We have investigated, both numerically and experimentally, the angular dependence of the incidence beam on the performance of a broadband (c-Si)-based stereoscopic hologram metasurface in the visible range. Preliminary results suggest that high contrast metasurfaces, such as those based on c-Si, allow a certain degree-of-freedom for the incidence angle without sacrificing the 3D image reconstruction (low polarization crosstalk). This allowed us to define a new figure-of-merit, named metasurface acceptance cone, which is given in terms of the image reconstruction signal-to-noise-ratio, transmission and diffraction efficiencies, and cross-polarization crosstalk. We hope this investigation can pave the way for future metasurface designs with relaxed excitation conditions.

Abstract

Optical metasurfaces have emerged as a new generation of building blocks for multifunctional optics. Design and realization of metasurface elements place ever-increasing demands on accurate assessment of phase alterations introduced by complex nanoantenna arrays. Here, we report on a new strategy in incoherent holographic imaging of metasurfaces, in which unprecedented spatial resolution and light sensitivity are achieved by taking full advantage of the polarization selective control of light through the geometric (Pancharatnam-Berry) phase.

1. Introduction

One of the fastest-growing areas of research in photonics is the field of metasurfaces, where nanoantennas and their ability to control light-matter interaction are utilized in light focusing, polarizing, and holography. In many of these metasurfaces, tailoring the near-field phase response among the individual building blocks is used to modify (e.g., to focus or to bend) the wavefront of light beam and thus modulate its far field projection. Compared to traditional refractive optics, metasurface-based components are physically thin and introduce abrupt phase changes observable in the far field. For the assessment of phase alterations introduced by a complex nanoantenna metasurface, the high-resolution quantitative imaging of the phase directly in the metasurface plane is highly appreciated.

During the past years, this task has been addressed only in a few approaches including scanning near-field optical microscopy, which is inherently slow, and interference-based techniques, which require scanning to obtain widefield information. These drawbacks are partly solved in coherence-controlled holographic microscopy (CCHM) [1]. This technique allows widefield quantitative imaging of both the intensity and the phase in the metasurface plane and enables also 3D phase mapping of the wavefronts above the focusing metasurface [2]. Additionally, polarization-filtered CCHM has been used to map the phase of broadband Laguerre-Gaussian vortex beam converters based on Pancharatnam-Berry geometric phase [3]. Although the diffraction limit attainable in optical imaging is close to the size of nanoantennas, widefield imaging of metasurfaces with the resolution and the sensitivity sufficient for phase monitoring of a single nanoantenna has not yet been demonstrated and still remains a challenge.

Here, we present a new experimental strategy that overcomes the current state of the art by providing unprecedented spatial resolution and light sensitivity down to a single nanoantenna in the widefield quantitative phase mapping of plasmonic metasurfaces [4].

2. Results and discussion

The developed phase imaging technique, in this text referred to as quantitative 4G optics microscopy (Q4GOM), was implemented in Nikon Eclipse L150 microscope with an add-on geometric-phase imaging module. This module benefits from the unique capabilities of a

![Image](image.png)

Figure 1: Experimental setup for high-resolution, widefield measurement of phase alterations introduced by plasmonic metasurfaces. (a) Geometric phase grating (GPG) for polarization-selective angular separation of leakage and scattered light coming from the metasurface. (b) Optical scheme of the imaging path: RHCP, right-handed circular polarization; LHCP, left-handed circular polarization; MO, microscope objective; BS, beam splitter; TL, tube lens; GPG, geometric phase grating; M, mirror; L1, L2, Fourier lenses; LP, linear polarizer; CCD, charged coupled device.
geometric-phase grating (GPG), providing polarization-selective angular separation of incident waves. The scheme of the setup used for the phase measurement of the metasurfaces is shown in Figure 1. The phase is quantitatively reconstructed from the mutual coherence function provided by off-axis holographic correlation records. The metasurfaces are excited by broadband spatially incoherent illumination and unlike other methods, the leakage light is not canceled, but its partial spatial correlation with the scattered light is used to capture the holographic records.

To demonstrate the capabilities of Q4GOM for the inspection of metasurfaces, we prepared a benchmark sample with a Pancharatnam-Berry type of metasurface. The sample is composed of identical nanoantennas schematically illustrated in Figure 2a, which were fabricated using electron beam lithography. The benchmark sample used in the measurement consists of 19 square areas with the size of \((10 \times 10) \, \mu m^2\). In the areas numbered in ascending order, the angular rotation of the nanoantennas increases with a step of \(10^\circ\) as shown in Figure 2b, providing gradual variations of the geometric phase across the range \(0, 2\pi\), and the resulting phase maps measured by Q4GOM are presented in Figure 2d.

Figure 2: Phase imaging of the benchmark sample and single nanoantenna sensitivity verification. (a) Schematic illustration of a single nanoantenna. (b) Enlarged parts of SEM images showing the orientation of the nanoantennas in individual areas of the benchmark test. (d) Phase image of the benchmark test restored from correlation records acquired by Q4GOM. (c) Cross-section phase profile along the individual antennas shown above.

To convincingly demonstrate the unique capability of Q4GOM to capture and quantify the geometric phase altered by a single nanoantenna, we prepared a metasurface array composed of nanoantennas with the spacing of 2.5 \(\mu m\) and alternating angular orientation, which introduced the geometric phase with values \(-\pi/2\) and \(\pi/2\), respectively. The larger spacing of the nanoantennas was chosen to ensure an independent operation, in which restoration of the single nanoantenna phase remains unaffected by the signal from other nanoantennas. The cross-section phase profile of the restored phase image shown in Figure 2c demonstrates the high precision of the measurement and the ability to obtain the phase from individual nanoantennas which was achieved for the first time using widefield quantitative phase imaging methods.

3. Conclusions

In conclusion, we have presented a new concept of non-scanning imaging of plasmonic metasurfaces providing broadband achromatic operation, unprecedented spatial resolution and amplitude and phase sensitivity down to a single nanoantenna. The unique ability of Q4GOM to realize a complete mapping of alterations in amplitude and phase produced by individual nanoantennas represents a significant progress in the diagnostics of metasurfaces. Combination of high spatial resolution, measurement accuracy, and single shot operation might be of great importance also for studies of fundamental effects and dynamics of phase variations in active metasurfaces or plasmonic biosensors. We envision that the method can be used for real-time monitoring of active metasurfaces, possible identification of failing or lagging building blocks can also find its place in the study of plasmonic-enhanced chirality and chiral biomolecule sensing.

Abstract

We successfully demonstrate grating-based reflective spatial filtering devices. Modulation of the refraction index on the sub-micron scale exhibits optical beam shaping with transverse invariance. The paper presents a theoretical model for the proposed metamirrors based on multiple scattering theory. The theoretical results coincide with the numerical ones. The metamirror may serve as a versatile tool for narrowing beam with high efficiency and transverse invariance.

1. Introduction

Spatial filtering element is essential for many photonic applications. In recent years, scientists have started crafting tiny, thin diffraction optical devices during the photonic product became much smaller. However, spatial filtering devices based on external gratings are not capable for microlasers, semiconductor lasers [5] and vertical-cavity surface-emitting laser (VCSELs) because they are unavoidably low efficient and bulky. Moreover, conventional filtering methods require not only many curved lenses that filter along with an optical axis. Therefore, such external spatial filtering devices with an optical axis are barely used for many photonic applications.

Many novel researches based on photonic crystal (PhCs) have exposed numerous results for the spatial filtering such as one-dimensional (1D) [1] and two-dimensional (2D) photonic crystals [2] [4]. Our team have also presented a concentric ring to achieve the spatial filtering but the proposed ring was limited by its axisymmetric configuration that result in an optical axis [3]. Furthermore, all these arrangements are based on the beam transmitted structure. In this paper, we propose a reflective spatial filtering device without an optical axis. Our main purpose is to achieve a narrow and clean beam whose large angular components have been filtered out.

For the reason that we propose a compact reflective angular filtering device upon the reflection based on metamirrors, they present the property of transverse invariance due to its periodic refraction index modulation. Moreover, device is sub-micron scale so the operating area of the spatial filtering is available for broad emissions from microlasers.

2. Reflective gratings for spatial filtering

2.1. Spatial filtering based on gratings

The main analyzing approach of the micro scale configuration combined by a flat metallic mirror and many of ellipse gratings by using Finite Difference Time Domain (FDTD) method to confirm this reflective metamirror grating. FDTD is a useful numerical simulation technique for solving the problems related to electromagnetism. The ideal arrangement of this structure is a metallic mirror with nearly 100% reflection and periodical ellipse-shaped gratings. Fig.1 shows the composed of metallic mirror and gratings can be regards as fold gratings. The parameter Dz is the distance between gratings and metallic mirror, which means the unfold gratings are separated by double Dz. The refractive index of the proposed ellipse-shaped gratings is 1.5. The longitudinal distance between each gratings Dx is 2μm.

Figure 1: Illustration of the fold spatial filtering gratings which composed by one metallic mirror (white slim hollow rectangle) and the ellipse-shaped gratings (green ellipse) which distance between two components is Dz. The unfold gratings are combined by two lines ellipse-shaped gratings (green ellipse and light green ellipse) which distance between two lines gratings is 2Dz.
The analytical theory for this ideal model is based on paraxial approximation with a simple plane wave \( U = e^{i k_0 z} \) which has wavelength 1 \( \mu \)m. Focusing on the diffraction zero-order intensity \( U = e^{i k_0 z} \) in far-field area since the other order \( U = e^{i k_{n+1} z} \) or \( U = e^{i k_{n+2} z} \) diffraction in far-field area became negligible. Thus, employed the zero-order diffraction value to plot the 2D figure versus incident angle and \( D_2 \) in Fig. 2(a). Fig. 2(a) it be apparently observed that diffraction pattern is periodically with respect to the incidence angle, and some regular feature with respect to \( D_2 \).

2.2. Simulation of gratings far-field filtering

A gaussian beam is incident into the periodical grating structure. The width and the operating wavelength of gaussian source is 4 \( \mu \)m and 1\( \mu \)m. The spatial filtering effect in the far field is obtained from the Fourier transformation of the electric field in the near field. The field distribution after reflecting from the gratings is calculate by using FDTD method. The comparison of far-field distributions of the gaussian beam between with and without the consideration of gratings are shown in Fig. 2. Fig. 2(b) and 2(d) both obviously show that the width of the gaussian beam become narrower through the grating structure. The imperfect spatial filtering result is shown in Fig. 2(c). Consequently, the filtering performance is dependent of the distance between the scatter and mirror, \( D_2 \).

Figure 2: The spatial filtering performance in metamirror gratings. (a) The diffraction plot recorded the characteristic of diffraction zero-order intensity with variable incident angle and \( D_2 \). The vertical axis in (b), (c), (d) means the far-field intensity and horizontal axis indicates the angle from \(-90^\circ \sim 90^\circ \). (b) \( D_{21} = 4 \ \mu \)m (c) \( D_{22} = 8 \ \mu \)m (d) \( D_{23} = 12 \ \mu \)m.

3. Discussion

Although Figure 2 uncovering the inspiring results for tiny PhCs devices which filter the gaussian beam effectively. However, the shaped of the gratings and refractive index of the material might also influence the ability of spatial filtering. Therefore, all these factors will be employed during the future optimization process of this gratings structure.

4. Conclusions

In this article, the simulation results have shown the metamirror for the spatial filtering in reflection. The narrow and clear spatial filtering effect is achievable in the micro-scale. Such tiny reflective grating is quite suitable for VCSELs or the other optical devices. The analytical model for the calculation of zero-order diffraction pattern is developing to compare with the FDTD results. The geometrical shape or the refractive index of these gratings results in varying performance of spatial filtering. We further optimize this metamirror for a cleanly and narrowly filtered beam.

Reaching the Abbe-Sine condition with curved conformal metasurfaces

Sandeep Yadav Golla\textsuperscript{1}, Patrice Genevet\textsuperscript{1*}

\textsuperscript{1}CNRS-CRHEA, Université Côte d’Azur, Sophia Antipolis, Valbonne, France

Abstract

Metasurfaces have a variety of wide applications in the field of optics. We exploit the concept of conformal metasurface to account for the different types of aberration corrections analytically through wave optics approach and support the results with numerical simulations.

1. Introduction

Optical aberrations are the unavoidable phenomenon of the light which are not nullified even to date completely to all of its orders using conventional refractive optics. Recent developments in the field of metasurfaces have enabled new ultra-thin lenses capable of focusing light with diffraction limited performances\cite{1}. The latter present serious aberrations which could significantly hamper their utilisation in imaging systems. This problem has been carefully studied already and several solutions exist, in particular in considering a metalens disposed on curved interfaces. Refraction across a curved metalens has been already considered by treating the problem using the ray optics approach\cite{2}. Perfect imaging, related to the realization of the Abbe-Sine condition\cite{3}, is shown to be achieved when the radius of curvature of the substrate hosting the metalens is equal to the focal distance of the compound system. Going beyond the ray optics approach, we are considering the recently developed concept of conformal boundary optics to address refraction across interfaces of arbitrary geometries\cite{4} and demonstrate that the Abbe-sine condition holds for proper interface curvature. The problem is solved in two steps, in the first section we introduce the general problem of conformal optics and it’s application to the arbitrary geometries. In the second section we impose focusing condition of a normally incident plane wave passing across interfaces having different curvatures. Thus we extract the susceptibilities matching normal incident light with spherical wavefronts. For imaging purpose, light is generally coming at various oblique angles, rather than normal incidence. The purpose of our calculation is to see the evolution of the aberrations as a function of the interface geometry. To do so, we calculate the transmitted fields for the case of oblique incidence considering previously obtained susceptibilities. The analytical expressions of the transmitted fields in the case of non normal incidence are decomposed using the wave aberration function through which we can identify the order of aberrations\cite{2}.

2. Electromagnetic fields at the interface of arbitrary geometries

Electromagnetic field boundary conditions at an arbitrary shaped metasurface separating two media, as shown in the fig. 1, are given by

\begin{equation}
\begin{pmatrix}
0 & 1 & \frac{\partial}{\partial j}
\end{pmatrix}
\begin{pmatrix}
E_x^+ \\
E_y^+ \\
E_z^+
\end{pmatrix} = \iota \omega \varepsilon
\begin{pmatrix}
\chi_{xx}^{uv} & \chi_{xy}^{uv} & \chi_{xz}^{uv} \\
\chi_{yx}^{uv} & \chi_{yy}^{uv} & \chi_{yz}^{uv} \\
\chi_{zx}^{uv} & \chi_{zy}^{uv} & \chi_{zz}^{uv}
\end{pmatrix}
\begin{pmatrix}
H_x^+ \\
H_y^+ \\
H_z^+
\end{pmatrix}
\end{equation}

\begin{equation}
\begin{pmatrix}
0 & 1 & \frac{\partial}{\partial j}
\end{pmatrix}
\begin{pmatrix}
H_x^+ \\
H_y^+ \\
H_z^+
\end{pmatrix} = \iota \omega \mu
\begin{pmatrix}
\chi_{ex}^{uv} & \chi_{ey}^{uv} & \chi_{ez}^{uv} \\
\chi_{xe}^{uv} & \chi_{xy}^{uv} & \chi_{xe}^{uv} \\
\chi_{xe}^{uv} & \chi_{xe}^{uv} & \chi_{xe}^{uv}
\end{pmatrix}
\begin{pmatrix}
E_x^+ \\
E_y^+ \\
E_z^+
\end{pmatrix}
\end{equation}

In the equation (1, 2) x, y, z are the ambient coordinate systems which describe the media on either side of the metasurface and u, v, n the coordinate system of the metasurface, which are mapped vice-versa through x = u, y = v and z = f(x, y) or f(u,v). The quantities E^+ and H^u are calculated using the fields on either side of the metasurface as mentioned in the paper\cite{4}.

2.1. Calculation of susceptibilities for the normal incidence

In this section we obtain the susceptibilities of the surface f(x, y) by plugging the input normal plane wave and transmitted wave with spherical wavefront directly in Eq.(1, 2). After a rigorous
algebra it reduces to,
\[
\chi_{E}^{uv} = \frac{H_{y}^{0} + \frac{\partial}{\partial u} H_{z}^{0}}{i \omega \mu_{0} E_{0}^{2}} \\
\chi_{E}^{uw} = \frac{E_{y}^{0} + \frac{\partial}{\partial u} E_{z}^{0}}{-i \omega \mu_{0} H_{0}^{2}} \\
\chi_{E}^{vw} = \frac{E_{z}^{0} + \frac{\partial}{\partial u} E_{z}^{0}}{i \omega \mu_{0} H_{0}^{2}}
\]
(3)

and all the remaining susceptibilities are taken zero in order to make the system of equations consistent and soluble as discussed previously[6]. Note that our method require to calculate the susceptibilities for each different shape of the metasurface. The interface curvature \( f(u, v) \) ranges from plane surface, parabolic surface, elliptic surface and spherical surface, decreasing the curvature. The different expressions obtained are similar to the one shown in equation (3), not shown here as they are simply obtained by substituting \( f(u, v) \) in expression (3).

2.2. Calculation of the transmitted fields for oblique incidences

Given the susceptibilities as functions of the shape of metasurface from equation (3), we are considering incident oblique plane and transmitted wave given by:
\[
E^{-} = \begin{pmatrix} 0 \\ 1 \\ 0 \end{pmatrix} \xi^{-} H^{-} = \begin{pmatrix} \cos \theta' \\ 0 \\ -\sin \theta' \end{pmatrix} \frac{\xi^{-}}{\eta}
\]
(4)

and transmitted field as
\[
E^{+} = \begin{pmatrix} E_{x} \\ E_{y} \\ E_{z} \end{pmatrix} \xi^{+} \\
H^{+} = \begin{pmatrix} H_{x} \\ H_{y} \\ H_{z} \end{pmatrix} \xi^{+} / \eta \frac{\xi^{+}}{\omega \mu_{0}}
\]
(5)

where
\[
\xi^{+} = e^{-i\left(k_{0}x + k_{y}y + k_{z}z\right) + \omega t} \\
\xi^{-} = e^{-i\left(k_{0}x + k_{y}y + k_{z}z\right) + \omega t} \\
\eta = \frac{k_{0}}{\omega \mu_{0}} = \sqrt{\frac{\mu_{0}}{\varepsilon_{0}}}
\]
(6)

The former incident fields are known and the latter have to be determined after plugging the input oblique plane wave and calculated susceptibilities in the equation (1, 2) we obtain the following four equations
\[
\begin{align*}
(E_{y} \xi^{+}^{-} - \xi^{+}) + E_{z} \xi^{+} \frac{\partial}{\partial u} = -i \omega \mu_{0} \chi_{E}^{uv} (H_{x} + \cos \theta') \frac{\xi^{+}}{\eta} \\
-E_{y} \xi^{+} + \xi^{+} + E_{z} \xi^{+} \frac{\partial}{\partial u} = -i \omega \mu_{0} \chi_{E}^{uw} (H_{x} + \cos \theta') \frac{\xi^{+}}{\eta} \\
H_{x} + \frac{\partial}{\partial u} (H_{y} + \sin \theta') \frac{\xi^{+}}{\eta} = i \omega \mu_{0} \chi_{E}^{vw} E_{z} \xi^{+} \\
-(H_{x} - \cos \theta') \frac{\xi^{+}}{\eta} - \frac{\partial}{\partial u} (H_{y} + \sin \theta') \xi^{+} = i \omega \mu_{0} \chi_{E}^{uw} E_{z} \xi^{+}
\end{align*}
\]
(8)

Considering total transmission conditions, we obtain two additional expressions,
\[
K_{x}^{2} + K_{y}^{2} + K_{z}^{2} = 1 \\
E_{x}^{2} + E_{y}^{2} + E_{z}^{2} = 1
\]
(9)

Now using the set of equations from equation(8,9) we can analytically obtain the transmitted E-M fields and decompose into terms corresponding to the types of aberration and also can be solved numerically to support the analytical expressions.

3. Conclusion

In this presentation, we are utilizing the conformal boundary optics concept to analytically and numerically calculate the susceptibilities of arbitrary shaped metasurface and are further utilizing these quantity to study the impact of interface curvature on the focusing properties of metalenses. We show that the aberrations are considerably affected by the curvature of interface hosting the metalens. This approach could help in designing spherical or non conventional metasurface that could achieve perfect focusing.

**Abstract**

A metasurface is designed with a view to monitor the hemp concrete hydration. The metasurface is due to be implemented with a hemp concrete sample in an R-band waveguide. By measuring the variations of the resonance frequency of the obtained structure, the dielectric permittivity of the sample can be monitored during the sample hydration (i.e. during the first days or weeks following the material fabrication). In this paper, we optimize a metasurface and study the proposed monitoring method using finite elements simulations.

1. **Introduction**

Hemp concrete is an ecological building material used for hydric regulation and thermal insulation in buildings [1-2]. It consists of lime, chenevotte and water [3]. Monitoring the reaction between these elements during the first weeks of the manufacturing can be useful to understand hydration phenomena in hemp concrete. The variations of the volume fractions of each element during hydration implies a variation of the real dielectric permittivity $\text{Re}(\varepsilon_r)$ of the concrete. Recently, we have proposed to estimate the dielectric permittivity of a hemp concrete sample after hydration by measuring its S-parameters in a rectangular waveguide [4]. These parameters are then inverted to obtain the dielectric permittivity by means of the classical Nicolson-Ross-Weir method [5-6]. This first approach is suitable to observe permittivity variations. Nevertheless, the inversion of the parameters may feature some uncertainties due to the computation, which could make it difficult to monitor small variations. For this reason, a novel approach is proposed which should permit to monitor the hydration of hemp concrete by means of a resonant structure. The emergence of these thin periodic structures has enabled a considerable evolution in the control of electromagnetic (EM) waves [7]. Indeed, they enable to tailor effective local EM responses, whether in terms of magnitude, phase or polarizability. By measuring the variations of the resonance of the proposed structure, it is possible to follow the evolution of $\text{Re}(\varepsilon_r)$ and consequently that of the hydration of a hemp concrete, which can be useful with civil engineering applications in view.

2. **Metasurface-based resonator**

The proposed metasurface is made up of $(8 \times 4)$ unit cells and it operates in the R waveguide frequency band [1.72 GHz – 2.61 GHz]. Each unit cell is made up of four metallic strips printed on an FR4 dielectric substrate ($\varepsilon_r = 4.4$, $\tan \delta = 0.02$). The first two strips which are separated by a $g = 0.225 \text{ mm}$ gap and are oriented perpendicularly to the electric field play the role of a capacitance. The two other strips which are parallel to the electric field play the role of an inductance. Thus, the whole structure makes it possible to obtain an LC resonator. The periodicity of each unit cell is fixed at $p = 13.625 \text{ mm}$. This value is chosen so that the metasurface which is made up of $8 \times 4$ unit cells can be implemented into an R-band waveguide the dimensions of which are $109.22 \text{ mm} \times 54.61 \text{ mm}$. Starting from these dimensions, a structure was optimized with a finite elements (FE) modeling (HFSS software) in order to obtain a resonance in the targeted frequency band. The final geometrical dimensions are $L_1 = 6.4 \text{ mm}$, $L_2 = 10.5 \text{ mm}$, $s = 0.3 \text{ mm}$ and $g = 0.225 \text{ mm}$.

---

**Figure 1 : Schematic view of the designed unit cell with a periodicity of $p = 13.625 \text{ mm.}$**
3. Simulation results

Figure 2: (a) Reflection and (b) transmission coefficients for different values of the real part of the permittivity.

FE simulations using HFSS software were carried out considering a device consisting in the optimized metasurface (8 x 4 unit cells) placed in contact with a hemp concrete sample. The thickness of the sample is fixed at 50 mm. These simulations were carried out for a variety of values of the real part Re(εr) of the dielectric permittivity of the material under test ranging from 1 to 5. Note that further developments could focus on designing a structure adapted to Re(εr) higher than 5. Fig. 2 shows the simulated reflection and transmission coefficients corresponding to Re(εr) values fixed at 1, 2 and 5 respectively. It is to be noted that the device resonance frequency shifts from 2.5 GHz to 1.83 GHz. In addition, monitoring the imaginary part of εr is also an interesting approach in order to follow the evolution of the absorption of the electromagnetic signal in the material. For studying this point, Re(εr) was fixed at a given value whereas the loss factor tan δ varied in the [0.01 to 0.1] range. Fig. 3 shows that the variation of tan δ leads to absorption variations. According to these results, the proposed structure allows the monitoring of the dielectric permittivity of a hemp concrete under hydration to be envisaged.

4. Conclusions

A metasurface based on LC resonance operating in the R band has been proposed and designed with a view to monitor the hydration of hemp concrete. The metasurface is due to be implemented with a material sample in a rectangular waveguide. The monitoring approach relies on the measurement of both the device resonance frequency and material absorption. The design of the metasurface has been optimized by simulations. The simulation results, either considering the use of the real or imaginary parts of the dielectric permittivity of the material, show a significant enough sensitivity for envisaging a device to be built and experimentally characterized.

Abstract

In this article, we introduced the random interleaved geometric meta-surface solution for the reconstruction of the controllable C-points in contrast to the kinoform operation. Lemon beams of the C-points are present. The ±1st order of the polarization-singular beams has same polarization singularity indices with the opposite handedness. Furthermore, spin-induced rotation of the Lemon beams are verified experimentally under different incident linear polarization states. Our work can be extended into other polarization singularity of C-points.

1. Introduction

Polarization singularities have attracted more attention in scientific community due to exotic space-varying polarization distributions. Polarization singularities can have undefined orientation and handedness [1,2], called C-point and V-Point[3,4]. The polarization-singular beams (PSB), also named full Poincaré-beam[5], are characterized by the polarization singularity indices [5], \( I_c = \frac{1}{2} \oint \mathbf{V} \cdot d\mathbf{l} \). The well-known cylindrical vector beams (CVB) have a V-point singularity of index +1 and have been investigated in a plethora of practical application including metrology, optical manipulation and quantum communication. Recently, the lower order C-point singularities of index ±1/2 have proved the ability of the potential enhancement of chiral light-matter interaction [7], spin-orbit coupling [8] and surface structuring[9]. The current approaches to the beams carrying polarization singularities are the specific q-plate or the coherent superposition of structured left-and right-handed circularly polarized light spatial light modulator(SLM) , and interferometer[10,11]. Recently, dielectric metasurfaces, the monolayer of ultrathin a engineered artificial materials compared with conventional refractive optics, have been applied in the enormous interests in the control of an optical wavefront[12-16]. Especially, arbitrary orthogonal polarization states can be imparted with two independent phase profile [13, 14] for fascinating applications[15].

In this work, inspired by the interleaved geometric meta-surface [12], we introduce a random interleaved geometric meta-surface to realize the spin-controllable polarization state of C-point. The ±1st order of the polarization-singular beams has same polarization singularity indices with the opposite handedness. The C-Points orientation angle can be modulated by switching the axis-angle of the incident linear polarization.

2. Experimental and results and discussion

The geometric meta-surface consists of the rotated TiO2 nano-fins that have proved high performance in visible range[13,15,16], which introduce opposite phase on the orthogonal circular polarization. Each nano-fins acts as a perfect half wave-plate with phase difference \( \pi \) between the long and short axis. The TiO2 nano-fins are designed at the 532nm with designed length \( L = 250nm \), width \( w = 95nm \) and heigh \( h = 600nm \), which is similar to the design in reference[16]. The cells are arranged with periods \( P_x = P_y = 350nm \). The area of the sample is \( \pi \times 50 \times 50\mu m^2 \). The imparted Pancharatnam-Berry phase distribution \( \Psi \) are designed with spatially random-interleaved phase profile of the component of \( \phi_1 \) and \( \phi_2 \)

\[
\Psi = \text{Rand}[\phi_1, \phi_2]
\]

Where

\[
\begin{aligned}
\phi_1 &= \text{angle}\left(\exp(i k_x x)\right) \\
\phi_2 &= \text{angle}\left(\exp(-i k_x x + m\theta)\right)
\end{aligned}
\]

The function Rand is to randomly distribute the combination of \( \phi_1 \) and \( \phi_2 \), respectively. Figure 1 show the PB-phase profile RIGM of \( m=1 \). The ±1st order diffractions (Fig. 1 (b) ) have same index and opposite handedness. As shown in Figure 2, the orthogonal polarization distribution of lemon beams are verified with the quarter wave-plate and analysis polarizer. As shown in Figure 3, spin-induced rotation of the lemon beams beam are verified experimentally under different incident polarization states.

3. Conclusions

In conclusion, we demonstrate a random-interleaved procedure of the geometric meta-surface for the spin-controllable C-Points. By switching the incident linear beam, we control the orientation of C-points. The procedure can be extend into q-plate, SLM for active design and other relevant frequencies using silicon meta-surface. We believe our work can promote the practical research involving C-points.

Abstract
We demonstrate the arrays of titanium dioxide nanocubes, which support electric dipole resonance, magnetic dipole resonance and lattice resonances. By choosing the lattice periods along the x and y directions, we achieve a full overlap between the electric dipole resonance and magnetic dipole resonance and realize the resonant lattice Kerker effect. Meanwhile, we present a new fabrication process to eliminate the influence of the substrate on the electric dipole resonance and magnetic dipole resonance.

Keywords: Resonance, Kerker effect, metasurface

1. Introduction
With the rapid development of the concept of light-induced artificial electromagnetics in the field of metamaterials, the Kerker effect (resonant suppression of the backward scattering or reflection) has been promoted as never before and quickly penetrated into nanophotonics [1]. Many optical phenomena such as perfect reflection and perfect transmission are linked directly to the multipolar interference mechanism of the generalized Kerker effects [2]. Nanostructures enabling Kerker effect have been demonstrated for example the periodic array of spherical and core-shell silicon nanparticles [3]. In this work, we numerically investigate the single cube-shaped titanium dioxide (TiO₂) particle which support electric dipole resonance (EDR) and magnetic dipole resonance (MDR) and the arrays of cube-shaped TiO₂ metasurfaces which support resonant lattice Kerker effect. Transparent TiO₂ is widely considered as a good candidate for fabricating all-dielectric metasurfaces in the visible range since it has lower loss than silicon and has larger refractive index than silica and polymer [4]. The resonant lattice Kerker effect of the TiO₂ metasurfaces and the scattering cross section of the single TiO₂ particie are investigated by the finite difference time domain (FDTD) method.

2. Simulations and discussion
The structure in Fig. 1 we propose comprises the periodic arrays of TiO₂ nanocubes with the length of side D = 200nm. The periods of the arrays are Pₓ = 540nm and Pᵧ = (480 to 680) nm in steps of 10nm. Normal incidence of light with electric field E along the x-direction.

Figure 1: The tilt-view schematic of the arrays of TiO₂ nanocubes.

Figure 2: The scattering cross section of single cube with D = 200nm. The positions of EDR and MDR on the spectrum are pointed with arrows. Inset: The magnetic and electric field profiles of the EDR and MDR at peak wavelength respectively. White lines indicate the substrate and particle
2.2. Resonance lattice Kerker effect in nanocubes

Then we investigate the arrays of TiO$_2$ nanocubes by varying periods $P_y$ with fixed $P_x$ and we excited lattice resonances (LR) at the wavelength close to Rayleigh anomalies (RA, from the side of long wavelengths). Resonant lattice Kerker effect can be observed when MDR and LR overlap at $\lambda = 610$ nm for the period of the array in y direction $D_y = 580$ nm. We can see that reflectance is well suppressed at the overlap in Fig. 3.

![Figure 3: The reflectance of metasurface versus the array period $P_y$ and wavelength for $P_x = 540$nm. It present that the peak resonance wavelength changes with the array period $P_y$. Red line shows wavelength of RA. White arrow points out the resonant lattice Kerker effect where the reflection is suppressed, EDR, MDR and LR respectively.](image)

2.3. Fabrication process

In practice, the substrate has a large influence on the array in order to fabricate it. To eliminate the influence of the substrate as much as possible, we present a new fabrication process. The fabrication process is as follows. First, 200 nm thick TiO$_2$ film is deposited on the quartz substrate by magnetron sputtering. Second, 170 nm thick PMMA resist is spin-coated and then exposed by e-beam lithography. Third, 40 nm thick Cr film is deposited by electron beam evaporation. Finally, Cr etching mask is formed by lift-off and the pattern is transferred to TiO$_2$ and the quartz substrate by dry etch.

![Figure 4: Fabrication process for the arrays of TiO$_2$ nanocubes in order to eliminate the influence of the substrate.](image)

3. Conclusions

We have demonstrated the single TiO2 nanocube which support electric dipole resonance and magnetic dipole resonance and the arrays of TiO2 nanocubes which support resonant lattice Kerker effect. It is shown that the Kerker effect can be assisted by the lattice resonance and be inhibited by the substrate. After simulation verification and the proposed fabrication process, the metasurfaces with perfect transmission can be fabricated and provide a guidance to novel designs of optical metadevices for advanced applications.

Abstract

All-dielectric nanophotonics attracts more and more attention nowadays due to the possibility to control and configure light scattering on high-index semiconductor nanoparticles. It opens a room of opportunities for designing novel types of nanoscale elements and devices, paving the way to advanced technologies of light energy manipulation. One of the most perspective and interesting effects is directive light scattering provided by the so-called Kerker and anti-Kerker effects giving a possibility to realize Huygens light sources, fully transparent metasurfaces, different types of nanoantennae etc. Another one corresponds to the realization of so-called “anapole states” providing near-zero scattering accompanied with strong near-fields. Here we briefly review some new results on the induced invisibility regarding fully transparent metasurfaces based on the simultaneous cancellation of the forward and backward scattering via particular optical responses of multipoles (similar to Kerker effect), and invisible objects and structures governed by the novel type of anapoles – hybrid anapole states.

1. Introduction

Optical properties of high-refractive-index dielectric nanoparticles are attracting a great scientific interest nowadays [1,2,3]. These subwavelength scatterers can support the excitation of electric and magnetic multipolar resonances which allow the control over the electric and magnetic components of light by changing the nanoparticle size, geometry, and material [4,5]. Special interest is attracted by subwavelength structures - metamaterials and metasurfaces, allowing to manipulate light at the subwavelength regime [6-11]. Dielectric metasurfaces appeared as a counterpart of metallic plasmonic metasurfaces in the optical range. In contrast to plasmonic structures, dielectric metasurfaces can work effectively in transmitted-light regime. For fine tuning their optical properties, their size, shape, aspect ratio, material dispersion and surrounding medium properties should be controlled [12,13]. Their applications range from lossless waveguides [14] and nanoantennas, to cloaking devices and nonradiating configurations [15-17].

2. Results

Here we consider the transverse scattering by high-index nanoparticles with the simultaneous suppressing both forward and backward scattering. We consider silicon particles of the simplest forms (spheres and cubes) without any requirements on radial anisotropy, gain or non-symmetric form etc. For the first time we obtain essential conditions for the multipoles’ contributions, and reveal the step-by-step procedure of the lateral-only scattering pattern formation [18]. The appropriate conditions for multipoles are as following:

$$c_{p,m} = 1; \quad c_{Q} = 1; \quad 2c_{p,m} = -1,$$

where p, m, Q, M – are electric and magnetic dipoles and quadrupoles respectively. We reveal and explain in details the strong suppression of the reflection from the metasurfaces taking place due to the aforementioned cancellation of forward and backward scattering. In this case light waves propagate through the metasurfaces almost without amplitude and phase changes (in spite the case of Huygens metasurface providing strong phase shifts) (Fig. 1 a,b) [19].

Secondly, we demonstrate another way to achieve a strong invisibility effect in the optical range induced by a hybrid anapole state, consisting of four overlapping anapoles originating from different terms in the Cartesian multipole expansion of the fields. The Fano-like shape of the hybrid anapole [17] has its local maxima close to its local minima, which may allow fast optical switching from invisibility to visibility states. Consequently, a metasurface consisting of such anapole particles becomes invisible, but the
mechanism is totally different from the previous one, Fig. 1 c,d. Moreover, suppression of all dominant scattering channels in both the mentioned cases results in the field confinement inside the nanoparticle. Engineering of these energy hotspots could make them useful for nonlinear optics applications in the future.

Figure 1. Two invisible metasurfaces based on either transverse scattering (a,b) or on hybrid anapole state (c,d); (a,c) – full fields in the metasurfaces. In (a) the metasurface consists of cubic Si nanoparticles with 250 nm edge, λ = 790 nm, spacing D = 400, (left), D = 300 nm, (right). (b) – amplitudes (blue) and phases (red) of the multipole ratios providing transverse scattering for a cube with the edge of 250 nm and the period D = 400 nm, and the corresponding reflection coefficient (the black curve filled with blue). (c) – the metasurface consists of cylindrical Si particles with diameter 200 nm and height 300 nm, λ = 630 nm, D = 400 nm substrate - glass. (d) – scattering cross-section of a particle from the metasurface in Fig. 1c on glass substrate.

3. Conclusions

In summary, we have discussed the conditions for the formation of the transverse scattering pattern for high-index nanoparticles. This unusual behaviour takes place when the in-phase electric and magnetic dipoles are in anti-phase with the in-phase quadrupoles and all of them have comparable values. We considered regular metasurfaces consisting of the nanoparticles with the transverse scattering patterns and showed zero reflection spectral region corresponding to the similar conditions. Contradictory to “Huygens” structures the considered metasurface scattered neither forward, nor backward being almost invisible for an incident light. Moreover, we showed one more way to achieve a fully invisible metasurface based on utilizing high-order hybrid anapole states consisting of four overlapping anapoles of electric and magnetic types. This metasurface shows similar behaviour, but is governed by different physical mechanism and provides different near-fields. Dissimilar ways to achieve full transparency could be useful for designing novel coded metasurface architectures and holographic patterns.

A dual-to-single mode metasurface absorber using phase transition of vanadium dioxide

Ayman Negm¹, Mohamed Bakr¹, Matiar Howlader¹, Shirook Ali²

¹Department of Electrical and Computer Engineering, McMaster University, Hamilton, Canada
²School of Mechanical and Electrical Engineering Technology, Sheridan College, Brampton, Canada
*corresponding author, E-mail: negmal@mcmaster.ca

Abstract
A tunable and polarization-insensitive absorber is proposed. The design employs a gold-based metasurface hybridized with vanadium dioxide. The phase-transition property of vanadium dioxide is used to control the operation of the metasurface absorber. In this paper, we study the behavior of the metasurface operating at mid-infrared frequencies in single or dual-band mode based on the operating temperature.

1. Introduction

The interest in using metasurfaces as electromagnetic absorbers significantly increased following the realization of the first perfect absorber metasurface by Landy et al. [1]. Metasurfaces can behave as perfect absorbers because they can satisfy impedance matching with air at the resonating wavelengths [2]. One of the most popular metasurface designs is the metal-insulator-metal (MIM) configuration. Examples of MIM metasurfaces include circular rings [3] and rectangular patches [4]. Metasurfaces can provide perfect multiband absorption using multiple elements of different sizes each resonating at different wavelengths [5], or using a single patterned geometry [6].

A phase-change material is a material that can exist in metallic or semiconductor phase by applying external effect such as electric field [7], current [8], or temperature [9]. Vanadium dioxide (VO₂) is a popular material that experiences a change from semiconductor to metallic phase around a temperature of 67°C [10]. This interesting property can be used to design metasurfaces with tunable properties by modifying the operating temperature.

In this work, we introduce a hybrid gold-VO₂ MIM metasurface with tunable resonance properties in the infrared range by employing the phase-transition property of VO₂. Fig. 1 shows the general geometry of the proposed MIM metasurface absorber. The top layer is a hybrid pattern of gold and VO₂ structures. The optical response of this layer changes with the change of the operating temperature. The thickness of the bottom gold layer of the MIM absorber is selected to be larger than the skin depth of gold at the operating wavelengths. This prevents the wave incident on the structure from being transmitted, and so can be confined within the structure for further absorption. Silicon dioxide is chosen as the dielectric material between the two metallic layers. To find the absorption characteristics of the structure, a normally incident transverse electric magnetic (TEM) plane wave is excited upon the metasurface. The absorptance $A$ can be calculated using Equation (1):

$$A = 1 - R - T,$$

where $R$ and $T$ are the reflectance and transmittance respectively. The calculations were performed using finite-element modeling solver in COMSOL Multiphysics 5.3.

Hybrid achromats with metasurfaces for IR imaging

Philippe Lalanne

1LP2N, Institut d’Optique Graduate School, CNRS, Univ. Bordeaux, 33400 Talence, France
*corresponding author, E-mail: Philippe.lalanne@institutoptique.fr

Abstract

We report on the fabrication of hybrid achromats with metalenses for IR imaging.

1. Introduction

An achromatic lens or achromat is a lens that is designed to limit the effects of chromatic and spherical aberration. Achromatic lenses are corrected to bring two wavelengths (typically red and blue) into focus on the same plane.

The most common type of achromat is the achromatic doublet, which is composed of two individual lenses made from glasses with different amounts of dispersion. Typically, one element is a negative (concave) element with a relatively high dispersion, and the other is a positive (convex) element with a lower dispersion. The lens elements are often cemented together, and shaped so that the chromatic aberration of one is counterbalanced by that of the other. The drawback is that the association of a divergent and a convergent lens boost geometrical aberrations, and therefore one needs triplets …

An alternative solution is the hybrid diffractive-refractive achromat [1]. Its operation principle is simple. Longer wavelengths (red) are diffracted more with gratings, but refracted less than shorter wavelengths (violet) with prisms. Thus, by associating a prism and a grating, it is conceivable that blue and red light may be deviated identically. And since the diffractive dispersion in gratings is an order of magnitude larger than that of most refractive materials, the grating of the hybrid has a large periods and then fabricated.

A hybrid diffractive-refractive achromat works the same. It is composed of a refractive lens and a diffractive one, the latter being composed of zones that are all much larger than the wavelength. It is easy to fabricate and offers large efficiencies, close to one at the central wavelength.

Hybrids lenses are studied for infrared imaging since 40 years or more [2]. The diffractive part can be fabricated either
• as a Fresnel lens with échelette continuous profile for instance with diamond turning tools,
• or as multivalued binary etched using multistep photolithography and several masks, typically 3 to 4. None of these approaches is a panacea. Diamond turning is sequential and thus expensive, making replication techniques in high-index material highly desirable. Photolithography with multisteps need a precise alignment of the masks and a good control of resist redeposition.

Hereafter we report on our efforts to develop hybrids with metalenses [3] for IR imaging to lower the cost productions. Compared to visible light operation, much larger minimum feature sizes are required and the fabrication can be performed with standard photolithography. Additionally, one needs only a single photolithographic step.

2. AR coats of metagratings

Figure 1. AR-coated metagrating fabricated at Thalès Angénieux.

In the IR, metalenses are rather fabricated in a high index semiconductor material. It is important to achieve an antireflection coating. Figure 1 shows an AR coated metagrating using zinc sulphide (ZnS), with a refractive index of 2.2, for operation at 10.6 μm. A fine tuning is carried out to maximize the transmitted first-order diffraction efficiency as a function of the grating depth and the zinc sulphide layer thickness. An efficiency of 93% in the transmitted first-order is obtained numerically while...
4.9 μm and h₁ = h₃ = 1.2 μm. Experimentally, an efficiency of 80% at normal incidence is measured for TM polarization [4].

3. Hybrid metalens achromat

Our design takes into consideration the fact that the efficiency of most diffractive optical components varies with the wavelength, and blazing is achieved only at a specific nominal energy, the blaze wavelength. The existence of spurious light in undesirable orders represents a severe limitation that prevents using diffractive components in broadband systems, like for IR imaging.

We have experimentally demonstrated that broadband blazing over almost one octave can be achieved thanks to metalens dispersion chromatism. The design carefully exploits the highly chromatic behavior of semiconductor structures with mesoscopic dimensions only slightly smaller than the wavelength. Its peculiarity is the use of two different subwavelength patterns for achieving the 2π-phase variation across the grating periods. The combination relaxes the fabrication constraints on the etch depth and allows us to fully exploit the highly dispersive nature of artificial dielectrics with mesoscopic dimensions to render the 2π-phase variation almost achromatic.

The metalens is fabricated on 2-inch 300-μm-thick GaAs wafer. Figure 2 shows the diffraction efficiencies of the 0th, −1st and −2nd orders for illumination at normal incidence. The efficiency is defined as the ratio between the energy funneled into a specific order normalized by the specular transmission of the GaAs wafer illuminated outside the patterned region. The salient result of Fig. 2 is evidenced by the blue rectangular window. The later shows that the incident energy is dominantly funneled into the −1st order over almost one octave, from 8 μm to 15 μm. On spectral average, the relative efficiency of the −1st order is 90%, whereas the relative efficiencies of the 0th and −2nd orders are smaller than 6% and 3%, respectively. About 85% of the total transmitted light is funneled into the desired order.

The dotted curves represent theoretical predictions of the efficiencies. They are obtained with a semi-analytical method that combines scalar and vector-theory [6]. The method takes into consideration many fabrication imperfections, such as the actual measured size of the cylinders and pillars, which differs from the design values and the fact that the etching depth varies from 4.3 μm for tiny holes to 7 μm for large holes and pillars. The theoretical predictions confirm the realization of broadband blazing. We note however that the −1st order experimental values are lower than the theoretical ones. The systematic offset may be explained by the rounded (not square) shape of the fabricated indentations that is not considered in the theoretical model and to an inevitable 2% scattering loss induced by the geometry rupture at the pillar-hole transition.

Abstract

We demonstrate the control of the polarization state in the second harmonic generated by periodic nanostructures. The knowledge of Mie-resonances in single dielectric nanoantennas enables to exploit their scattering features to design the polarization state of the harmonic field. We fabricate AlGaAs-on insulator nonlinear metasurfaces allowing to decouple polarization and diffraction features obtained by single resonators. This results in the possibility to collect a polarization-engineered second harmonic signal in a small angle around the normal to the surface.

1. Introduction

The efficient control of light-matter interaction through subwavelength resonating elements is a main interest issue in nanophotonics. Nanoresonators have recently attracted the interest of nonlinear optics community for the possibility to tightly confine the electromagnetic field in small volumes and enhance in turn nonlinear generation efficiency with respect to bulk materials. Furthermore, nanoresonator periodic arrays have shown to offer a large control for engineering polarization and phase of light in the nonlinear regime. Promising results in this sense have been obtained with plasmonic metamaterials, where the geometry and orientation of each meta-atom shapes the localized surface plasmon resonance responsible for the properties of scattered field. That approach led to the validation of polarization and phase control of nonlinear emitted beam [1]. An alternative solution is represented by all-dielectric resonators offering both (1) a strong confinement inside the structure volume allowing to exploit the bulk nonlinearity of the material, and (2) negligible ohmic losses with respect to plasmonic counterparts. These features allowed to enhance by more than three orders of magnitude the nonlinear generation efficiency of single resonators compared to metallic structures [2]. As expected by Mie-theory, high-refractive-index subwavelength nanoparticles exhibit both electric and magnetic resonances which can be exploited to shape the phase and polarization of emitted field [3].

The possibility to engineer the polarization state of the harmonic beam around the normal direction to the surface is particularly interesting for practical applications. Here we demonstrate the control of second harmonic (SH) polarization state via a metasurface made of AlGaAs nanocylinders which exploit the properties of single resonators while partially redirecting the emitted beam.

2. Design procedure

The working principle of the devices prosed here is sketched in figure 1. The building block of our metasurfaces is an Al₈₀.₈₂Ga₂₀₈₂As nanocylinder about 350nm height laying on an AlOₓ substrate around 1µm thick. Resonators are designed to work at 1550nm and SH generated signal is collected in back-reflection.

Figure 1 Artist's view of SHG by a metasurface, with the scattered signal collected in backward direction.

We propose two approaches for SH polarization control. In the first one we fix the fundamental frequency (FF) linear polarization along the [100] crystallographic direction and we exploit the orientation of elliptical base nanocylinders to break the symmetry of the system. In the latter we fix the geometry of circular base nanocylinders and rotate FF polarization from horizontal (aligned along [110]) to diagonal (along [100]). In both cases our polarization control mechanism relies on the properties of Mie-resonances in single resonators assuming the pillars far enough not to interfere in the near-field [4]. The directivity depends instead on far-field interference of independent emitters. For this reason, our design procedure starts from the study of resonant behavior of isolated structures. Pillar geometry has been optimized through finite element computations performed with COMSOL, using as figures of merit the contrast between orthogonal SHG polarizations and nonlinear generation efficiency.

Let us highlight that in the first approach the modes excited at SH when the ellipse is aligned along [110] or [1-10] near field distribution are identical except for a 90° rotation (see figure 2b), resulting in two mainly orthogonally polarized SH signals. In the second approach, the geometry is set and pump polarization is changed, which induces different dominating terms of nonlinear susceptibility tensor.
elements in photonic devices for quasi on-directionality, making us envisage the integration of this concept to periodic structures, giving a further control on emission from single structures. The extension of this idea to array elements was achieved by means of a wire grid polarizer to verify that polarization and directivity properties of SH signal and redirect the emission close to the normal direction, see figure 2e.

In turn, different modes are excited at SH when the pump is along [100] or [110], resulting in SH mainly polarized along [010] and [1-10] respectively.

If this general idea proves the possibility to engineer emission features exploiting different resonating modes, it is also true that for isolated structures SH polarization and directivity properties are strictly related. This is shown in figure 2c,d which shows the computed far-field distribution and polarization state restricted to 0.8 numerical aperture.

When we move to periodic structures, in the assumption independent emitters the total radiation intensity can be expressed as the product between the far-field response of single emitter and the array factor of the metasurface. It is possible in this way to decouple polarization and directivity properties of SH signal and redirect the emission close to the normal direction, see figure 2e.

3. Measurements and discussion

Our measurements were carried out using a pulsed beam at 1550 nm, with SH collected in back-reflection. SHG is characterized in directivity by back focal plane imaging. The study is firstly performed for single structures and then for periodic array, moving from a numerical aperture NA=0.8 to NA=0.2 to ensure a collective excitation and a good angle resolution in the Fourier space. Good agreement between model and measurement found in both cases as reported in figure 2c,e. Successively, polarization is analyzed by mean of a wire grid polarizer to verify that polarization properties conferred by single structures are preserved when moving to metasurfaces. Results for the four analyzed configurations are reported in figure 3.

4. Conclusions

We showed how Mie-resonances of all-dielectric nanocylinders can be used to generate nonlinear emission with a well-defined polarization state. The extension of this concept to periodic structures, giving a further control on directionality, make us envisage the integration of this elements in photonic devices for quasi on-axis applications.

Abstract

This paper presents a theoretical and experimental study of the effect of ballistic electrons on the optical response of a MIM (Metal-Insulator-Metal) like hyperbolic metamaterial structure. The simulated model using standard parameters and the experimental optical transmission shows a 20% peak difference due to the presence of ballistic transport in the metal. A semi-analytic approximation based in Drude’s model is used for accurately predicting the optical response of the hyperbolic substrate and plasmon damping.

1. Introduction

In the past years, hyperbolic metamaterials have been widely studied due to the possibility of light confinement at the nanoscale. As hyperbolic metamaterials have its isofrequency surface given by a hyperbola, the wave propagation vector ($\mathbf{k}$) can by infinity in certain directions. Hence, the light wavelength for a direction in this material would be infinitely small, if the physical properties of its constituent material were perfect [1]. This exotic property permits optical confinement causing a spontaneous emission enhancement leading to a the large Purcell factor [2] of this class of metamaterial’s. Emerging applications on lasing [5], LED’s [3, 4] (quantum-)sensing [6, 7], imaging [8, 9] have been recently reported showing the interest of continue efforts in this area.

However, in the design of these devices, thin layers of metals with precise thickness are often used. As the metal thickness decreases, the effect of ballistic electrons is neglected as the models are usually fitted for a single thickness. Experimentally, this is seen by the increase of optical attenuation in the transmitted.

This paper presents a theoretical and experimental study of the effect of ballistic electrons on the optical response of a MIM (Metal-Insulator-Metal) like hyperbolic metamaterial structure consisting of silver and silicon oxide thin films. A semi-analytic model was construct based in the experimental data and the Drude’s model with ballistic transport considerations. Finally, the effect of increased electron damping behavior was analyzed related to the plasmonic behavior of the structure.

2. Optical response of silver thin films

The Drude’s model is the classical way of explaining the optical response of metals. However, when the mean free path of electrons in the material is comparable to its thickness, an extended description must be considered taking into account the effect of ballistic electrons on the material’s complex permittivity.

2.1. Drude Model

The Drude’s model considers that the electrons aren’t bounded and move freely in a given metal. Hence, electrons excited by an exterior electromagnetic field move accordingly to the field, being only limited by the viscosity of the electrons in the metallic lattice. Mathematically, the movement is similar to a harmonic oscillator, Equation 1, where $m$ represents the electron mass; $\Gamma$ the damping factor; $e$ the electron charge, $\mathbf{r}(t)$ the electron movement and $\mathbf{E}(t)$ the electromagnetic excitation.

\[ m \frac{\partial^2 \mathbf{r}(t)}{\partial t^2} + m \Gamma \frac{\partial \mathbf{r}(t)}{\partial t} = -e \mathbf{E}_0 e^{-i \omega t} \]  \hspace{1cm} (1)

The electronic movement induced by the exterior field defines the optical response of the material. The complex permittivity is given by the Equation 2 as a consequence of the Equation 1, where $\omega_p$ the plasma frequency; $\Gamma$ the damping factor; $\varepsilon_\infty$ the offset permittivity due to bounded electrons in the material [10].

\[ \varepsilon(\omega) = \varepsilon_\infty - \frac{\omega_p^2}{\omega^2 + \Gamma^2} + i \frac{\omega_p^2 \Gamma}{\omega(\omega^2 + \Gamma^2)} \]  \hspace{1cm} (2)

2.2. Optical Response of Silver Thin Films

Physically, the damping has a direct relation to the mean free path of the electron in the metal. Smaller the electron difficult of moving, bigger the mean free path. However, especially in silver which has a mean-free path of $53.3 \ nm$ [11], films of the order of tenth’s of nanometers imposes a new movement boundary for the electron. Therefore, increasing, the damping effect. These electrons have now a ballistic motion due to the interface limitation, as the thickness of the film is smaller than the mean-free path.

Equation 3 shows how the interface thickness ($R$) relates to the damping factor increase ($\Gamma^*$), where $v_F$ : Fermi velocity and $a$ : prefactor dependent of the geometry [10].
\[ \Gamma^* = \Gamma + a \frac{v_F}{R} \]  

(3)

Using equations 2 and 3, we construct the permittivity as a function of the wavelength for different thickness as shown in Figure 1. The numerical values of silver constants are taken from the data available for silver in Cai et al [10] where \( \Gamma = 0.032 \times 10^{15} \text{ [s}^{-1}] \), \( \omega_p = 14.0 \times 10^{15} \text{ [rad/s]} \) and \( v_F = 1.4 \times 10^6 \text{ [m/s]} \) and \( a = 1 \) due to geometric symmetry of a continuous film.

Figure 1: Drude’s model of the Silver Permittivity in function of the thickness, real part (\( \text{Real}(\varepsilon) \)) in blue and imaginary part (\( \text{Im}(\varepsilon) \)) in red.

2.3. Addition of ballistic effects in Experimental Data

Although the modelling of ballistic effect in thin films is expressed analytically in Drude’s model, the real optical behaviour of materials takes into account external orbital interactions and atom bounded states. Nevertheless, the available experimental fit for materials usually is done for a single thickness and it doesn’t consider the ballistic effect of electrons. For example, Palik’s data for silver consider films of 30nm [12]. Hence, for verifying the validity of the standard silver models, the transmission of a 30 nm thermally evaporated silver is compared of Palik, CRC and Jonhson and Christy’s models in Figure 2.

However, the experimental and simulated models are only valid for this thickness due to ballistic electrons effects in smaller thickness. Therefore, for improving simulations results for considering ballistic electrons effects, we use a semi-analytic method. This method consists in scaling experimental data in function of the proportionally seen between the optical response of silver films of different thickness in the Drude model. The coefficients \( \alpha_{L(nm)}(\omega) \) and \( \beta_{L(nm)}(\omega) \) describes the ratios in function of the thickness(L) and the film with 30nm for real and imaginary, respectively.

\[ \alpha_{L(nm)}(\omega) = \frac{\text{Real}(\varepsilon_{Drude}(\omega))_{L(nm)}}{\text{Real}(\varepsilon_{Drude}(\omega))_{30nm}} \]  

(4)

\[ \beta_{L(nm)}(\omega) = \frac{\text{Im}(\varepsilon_{Drude}(\omega))_{L(nm)}}{\text{Im}(\varepsilon_{Drude}(\omega))_{30nm}} \]  

(5)

Therefore, the silver experimental permittivity data can be scale in function of the thickness based in the analytic ratios \( \alpha_{L(nm)}(\omega) \) and \( \beta_{L(nm)}(\omega) \) extract from drude model.

\[ \varepsilon^*(\omega, L) = \alpha_{L(nm)}(\omega)\cdot\text{Real}(\varepsilon(\omega))_{30nm} + i\beta_{L(nm)}(\omega)\cdot\text{Im}(\varepsilon(\omega))_{30nm} \]  

(6)

Figure 3 shows the correction realized in the experimental data available in CRC Handbook [13] for silver optical films.

Figure 2: Experimental and Simulated transmission in a 30 nm silver film for CRC’s, Palik’s and Jonhson and Christy’s model.

Figure 3: Interpolated Silver Permittivity Experimental Data and its correction in function of the thickness, real part in blue and imaginary part in red.
2.4. Optical Response of Hyperbolic Substrate

The hyperbolic substrate considered in this paper is a multi-layered MIM (Metal-Insulator-Metal) like structure (9 in total) film over a glass substrate. The top layer is a 7.5 nm silver layer and the other layers are alternating from 15 nm silver (Ag) and 60 nm silicon oxide (SiO$_2$) [6]. Figure 4(a) is a three dimensional model of such structure.

The fabrication of this film is done by alternating cycles of thermal evaporation, for silver layers, and e-beam evaporation, for the silicon dioxide layers. The thickness was controlled by the standard oscillator frequency shift method embedded in both evaporators, and a posteriori, the total thickness was controlled by a Dektak XT Profilometer.

Figure 4(b) shows the film optical response for experimental and simulated substrate. The experimental optical response is obtained using a UV-Vis spectrometer. The optical transmission of the hyperbolic substrate is realized numerically with the software FDTD Lumerical© considering in a first time the standard CRC model, and next, the CRC with the proposed correction described in the precedent section. Figure 4(c) shows the simulated numerical electrical fields for different wavelengths.

2.5. Optical Response of Hyperbolic Metasurfaces

In this work, two metasurfaces were studied, a linear array of slits with 250 nm period and 50 nm width and a concentric array of circular rings with 50 nm width separated by 350 nm. They were fabricated over a 20μm × 20μm surface. Both structures were fabricated using a focused ion beam for milling the pattern over the previous substrate.

Figure 5(a) and 6(a) show the 3D modeling of the structures, and figure 5(b) and 6(b) the SEM images of the fabricated structure over the substrate.

The simulation of both structures was realized using the previous model with ballistic effects using symmetries for reducing memory need for mesh size while keeping a precise mesh within the structures. 128 Perfect Matched Layers were used for suppressing numerical oscillations. Figure 5(c) and 6(c) shows the optical transmission of the structure for both metasurfaces and the computed electric fields in the structure for different wavelengths. For the case of the periodic array of linear slits, two different polarization where used for exciting the TE (transverse electric), electric field parallel to the slits, and TM (transverse magnetic), electric field perpendicular to the slits, respectively. While for the array of concentric rings just one simulation was realized due to its invariant to polarization, but considering both standard and corrected models for the silver films.

Figure 5(d-e) present the optical image of the structures obtained by shining white light into the linear array using a Olympus transmission microscope. Each mode was excited by rotating a linear polarizer placed before the sample.
Finally, Figure 6(d) present the optical image of the structures obtained by shining white light into the rings array using a Olympus transmission microscope. Figure 6(e) presents the image from Figure 6(d) using a 594nm high-pass filter.

3. Discussions

Figure 4(b) shows the simulated with both models (standard and corrected) and experimental results of the substrate with almost the same behavior in the blue spectral range. However, the experimental data shows a peak transmission of about 20% lower than the one simulated using the bulk silver parameters. The model using the semi-analytic approximation reproduces more accurately the optical response including the 20% attenuation didn’t see in the bulk silver constants. The mismatch observed near the pick happens due a interpolation inaccuracy in the simulation software.

This same effect must be considered in the treatment of the light transmitted in the metasurfaces region. As the electron mobility decreases, the plasmon quality may also decrease due to the greater material resistance. Using the semi-analytic approximation, a more thrust worth simulation of the proposed metastructures of the Figures 5(a) and 6(a) can be obtained.

The optical transmission of the linear array of slits presents in TE, 5(c), mode a blue spectra similar to what is optically observed in Figure 5(d). For TM mode a blue-green spectra similar to what is optically observed in Figure 5(e). Similarly, the same is observed for the array of concentric rings. The simulation predicts a weak red signal with emission in two principal lobes which is verified in the optical image using a red filter. The blue light transmission seen in the spectrum is due to the transmission mainly from the substrate without interacting with the structure. Also, Figure 6(c) shows the damping in the plasmonic response while considering the ballistic transport.

4. Conclusions

Therefore, this paper presented the effect of ballistic electrons of silver thin films in hyperbolic metasurfaces causing the underestimation of the attenuation factor in simulation compared to experiments. The ballistic transport also affects the plasmon quality in the structure due to increased resistance in its transport. A proposed semi-analytic approximation based on ballistic electrons effects in the Drude’s model is used to accurate predict the optical response of the hyperbolic substrate and the metasurfaces.

Abstract

The present work is a study of the band structure, the transport and magneto-transport properties of GaAs(d₁=183.95Å)/Al₀.₁₈Ga₀.₈₂As(d₂=42.45Å) superlattice at temperature of 0.3K. Our calculations have been made in the envelope function formalism and the approximation of the effective mass. We have gone down the effect of the discontinuity of the valence band and the temperature on the forbidden band. This superlattice has a band gap of 1.53 eV and can be used as a near infrared detector. The calculation of the density of states and the band gap of 1.53 eV and can be used as a near infrared devices [6]. In particular, for GaAs/Al₅₋ₓGaₓAs superlattice show that they have a band gap in the near-infrared range [6]. In this work, we investigated the GaAs/Al₀.₁₅Ga₀.₈₅As SL electronic band structure in the envelope function model, the approximation of the effective mass and the effect of different parameters such as the layers thickness of SL, temperature, valence band offset (VBO) on variation of band gap energy.

In order to characterize this superlattice, we studied the properties of magneto-transport, using the magnetoresistance experimental measurements of Pusep et al. [8]. At a sufficiently low temperature and under high magnetic field, the Shubnikov-de Haas (SdH) effect, which consists of oscillations in the magnetoresistance, allows us to deduce several transport parameters. For example, the periodicity of the oscillations of longitudinal magnetoresistance gives the carriers density and the Fermi level. We also showed some correlations between the band structures and the effect of SdH from the study of the density of states in the presence of magnetic field.

2. Dispersion relations in GaAs/Al₁₋ₓGaₓAs superlattice

For semiconductors, the k.p theory makes it possible to describe the electronic bands with a relatively important accuracy [9]. We considered the k.p method to describe these states in the case of semi-conductor superlattice with the formalism of the envelope function and the approximation of the effective mass, in terms of some parameters noted by 1 and 2 for GaAs and Al₀.₁₅Ga₀.₈₂As bulk materials, respectively.

The general expression of dispersion relation for GaAs/Al₀.₁₅Ga₀.₈₂As superlattice, within the envelope function formalism and effective mass approximation, is given by [10, 11]:

\[ \cos[k_z(d_1 + d_2)] = \cos(k_1d_1)\cos(k_2d_2) \]
\[ \frac{1}{2} [(\zeta + \frac{1}{\zeta}) + \frac{k_p}{4k_1k_2}(r + \frac{r - 2}{r}) \times \sin(k_1d_1)\sin(k_2d_2)] \]

(1)

With \( k_z \) the wave vector in the direction of growth and \( k_1(k_1, k_2) \) in the plane of the superlattice. \( k_1 \) and \( k_2 \) describe the movement perpendicular to the layer of bulk materials.

The SL light particles (electrons and light holes) subbands are obtained from the same Eq. (1) with:
- The expression of \( \zeta \) and \( r \) in the Eq (1) are:
  \[ \zeta = \frac{k_1}{k_2} \quad \text{and} \quad r = \frac{E - e_1}{E - e_1 - A} \]
Where $\epsilon_i$ (i= 1, 2) the band gaps of bulk materials and $\Lambda$ is the valence band offset (VBO).

At a given energy, the two-band Kane model [12] gives the wave vector $(k_i^z + k_p^z)$ in each host material (i = 1 or 2) by:

$$\frac{2}{3} p_i^2 \xi (k_i^z + k_p^z) = (E - \epsilon_i - A) (E - A) \quad \text{for GaAs}$$

$$\frac{2}{3} p_i^2 \xi (k_i^z + k_p^z) = E (E - \epsilon_i) \quad \text{for AlxGa1-xAs}$$

The Kane matrix element $P_i$ was calculated by using the Kane energy $E_{pi}$ formula [13]:

$$P_i^2 = \frac{E_{pi}}{2m_0}.$$  \hspace{1cm} (4)

We used here, the empirical expressions of GaAs and AlxGa1-xAs band gaps $\epsilon_i$ (i= 1, 2), at $\Gamma$ point, for $x \leq 0.69$ as a function of temperature $\{14, 15\}$:

$$\epsilon_i (T, x) = (1.517 + 1.39x) \frac{5.5 + 3.35x}{T + (255 + 88x)} .$$  \hspace{1cm} (5)

From the same equation (1), the superlattice heavy hole subbands can be calculated with the following relations:

$$\frac{\hbar^2}{2 m_{HH}} \frac{1}{2} (k_i^z + k_p^z) = (E - A) \quad \text{for GaAs}$$

$$\frac{\hbar^2}{2 m_{HH}} \frac{1}{2} (k_i^z + k_p^z) = E \quad \text{for AlxGa1-xAs}$$

With $\xi_i = \frac{k_i^z}{k_p^z}$ and $r = \frac{m_{HH}^i}{m_{HH}^p}$,

where $m_{HH}^i = 0.34 m_0$ and $m_{HH}^p = (0.33 + 0.18 x) m_0$ are the heavy hole effective masses of GaAs and AlxGa1-xAs bulks, respectively [15, 16].

The sample studied here consists of alternating $d_1$(GaAs) = 138.93 Å and $d_2$(Al0.18Ga0.82As) = 42.45 Å. Consequently, $d_1/d_2 = 4.33$. The superlattice period is $d = d_1 + d_2 = 240$ Å. We used the valence bands offset 105.66 meV from $\Lambda (eV) = 0.587x$ calculated by Wang et al. [17, 18] in atomistic first principles approach.

### 3. Results and discussions

The results plotted in Figure 1 represent subbands energies and bandwidths of electrons ($E_i$), light holes ($h_i$) and heavy holes (HHi), in the first Brillouin zone as a function of the barrier thickness ($d_2$) at 0.3 K for $d_1 = 4.33$. When $d_2$ increases, the band gap decreases. This can be attributed to the creation of authorized state levels in the band gap. As $d_2$ increases, the confinement of charge carriers in the GaAs (well) then augments. The superlattice acts as a set of isolated quantum wells and the band gap energy converges to that of GaAs.

The thickness of the barrier $d_2$ of the sample studied is indicated by a vertical dotted line. The gap energy is the difference between the first subband of electrons $E_1$ and heavy holes HH1: $E_g = E_1$ - HH1. For the studied sample $E_g = 1.53$ eV. This result is in good agreement with $E_g =$ 1.523 eV obtained by PL measurements of Pusep et al. [8].

In figure 1b, we illustrated the band gap $E_g$ as a function of well thickness $d_2$ for various ratio $d_1/d_2$. For each $d_2$, the calculated $E_g$ increases as $d_1/d_2$ decreases. For a given ratio, when the thickness $d_2$ increases, the band...
The effect of the VBO on the band structure was studied by varying the VBO and we set the other parameters. In figure 2, we show the SL band gap, for the temperature 0.3 K, as a function of $\Lambda$. The band gap increases to a maximum at $\Lambda = 41$ meV and then decreases. Our chosen offset is indicated by a vertical dashed line.

In figure 3, we illustrated the variation of the band gap SL and the cutoff wavelength in the range of 0.3 to 300 K. At low temperatures, the band gap changes weakly and then it decreases when the temperature increases. The cutoff wavelength in this range of temperature, 811 nm $\leq \lambda_c \leq 867$ nm, situates this sample in the near-infrared region.

In figure 4, we have the dispersion curves of the first conduction and valence sub-bands in the first Brillouin zone (in the direction of the wave vector $k_z$ and in the planes $k_{\parallel}$). The dispersion of energy subbands in the plane direction is larger compared to that along the growth direction. This indicates a weak interaction between adjacent wells. This result shows that the electronic transport is dominated in the plane of this superlattice (GaAs layers).

As the superlattice is anisotropic, the carrier’s effective mass of the conduction and valence subbands is defined by the tensor whose elements in directions $i$ and $j$ are given by the following expression:

$$\left( \frac{1}{m^*} \right)_{ij} = \frac{1}{\hbar^2} \frac{\partial^2 E}{\partial k_i \partial k_j}$$

Figure 5 represents the effective mass of the first conduction and valence sub-band in the plane and along the growth direction $m(k_x, k_y)$. Along $k_z$, effective masses of heavy holes, light holes and electrons are almost constant and equal to $-0.33m_0$, $-0.08m_0$ and $0.11m_0$, respectively.
In order to determine the Fermi level, we used the experimental measurements of Pusep et al. [8] of longitudinal magneto-resistance ($\rho_{xx}$). The oscillations $\rho_{xx}$, at low temperature and under high magnetic fields, are periodic with respect to $1/B$. The determination of the period $\Delta_{1B}$ allows us to determine the sheet density $n_{2D}$ of electrons by the following relation:

$$n_{2D} = \frac{e}{\hbar} \left( \frac{1}{\Delta_{1B}} \right)$$ (10)

Once the $n_{2D}$ is known, the Fermi wave vector $k_F$ of two-dimensional electron gas can be calculated by the following expression: $k_F = 2\pi n_{2D}$. Therefore, $n_{2D} = 4.95 \times 10^{11}$ cm$^{-2}$ and $k_F = 0.017$ Å$^{-1}$. The corresponding heavy hole ($m^*_h$) light hole ($m^*_l$) and electron ($m^*_e$) effective masses are -0.33$m_0$, -0.084$m_0$ and -0.105$m_0$, respectively.

The Fermi level at low temperature is given by the following relation:

$$E_F - E_i = h^2 k_F^2 / \left( 2m^*_e \right)_{E_i} = n_{2D} \hbar^2 / \left( m^*_e \right)_{E_i}$$ (11)

Since $E_c = 1.627$ eV, so $E_F = 1.637$ eV. This shows that the sample studied has n-type conductivity.

The VBO is one of the important design parameters for some device applications. Several theoretical approaches and experimental measurements on VBO of GaAs/Al$_x$Ga$_{1-x}$As SL. In this work, we have used the experimental measurements of T.E. Ostromek and P. Pfeffer et al. [19, 20] and the approach of Ref. 17.

The density of states of the ith mini-band of width $\Delta E^{(i)} = E^{(i)}_{\text{max}} - E^{(i)}_{\text{min}}$ of SL, is given by [21]:

$$\rho_{\text{DOS}}^{(i)}(E) = \begin{cases} \left( \frac{m^*}{\pi \hbar^2} \right) k(E) & \text{for } E^{(i)}_{\text{min}} \leq E \leq E^{(i)}_{\text{max}} \\ 0 & \text{otherwise} \end{cases}$$ (12)

The term $k(E)$ corresponds to the permissible states, which are solutions of the dispersion relations of the superlattice. The general expression of the density of state is:

$$\rho_{\text{DOS}}(E) = \sum_{i=1}^{n} \rho_{\text{DOS}}^{(i)}(E)$$ (13)

Figure 6, shows the density of states of the first two conduction subbands of the studied sample. We found that only the first conduction subband is occupied ($E < E_F$) and the density of states is quantified in terms of $m^*/\pi \hbar^2 d$. We also found that the system is almost two-dimensional and a very weak dispersion following $k_z$ occurs. Therefore, quantum wells are weakly coupled from each other.

In the presence of an intense external magnetic field applied, at low temperature, on a GaAs/Al$_{0.18}$Ga$_{0.82}$As superlattice in the direction of growth, the quantization of DOS and the degeneration of each subband (i), in a series Landau subbands, takes place. Figure 7 shows the degeneration of the first conduction subband of Landau using the following total energy expression:

$$E^{(i)}(E) = E^{(i)}(k_z) + \left( N^{(i)} + 1/2 \right) \hbar \omega_{k_z} + E^{(i)}_{\text{Zeeman}}$$ (14)

where $E^{(i)}(k_z)$ is the energy associated with the movement of charge carriers along the z axis. While the energy associated with carrier motion in the plane is completely quantized in terms of $(N^{(i)} + 1/2)\hbar \omega_{k_z}$ with $N^{(i)} = 0, 1, 2, ..$ represent the index of Landau of the $i^{th}$ sub-band. We can assume, here, that Zeeman spin splitting energy $E_{\text{Zeeman}} = \pm \frac{\mu_B}{2} B$ is negligible compared to Landau mini-band splitting $\hbar \omega_{k_z} = \hbar eB/m^*$.

The allowed states in the energy space, shown in Figure 7 (a), (c) and (e) for three values of magnetic fields, show that for a given $N^{(i)}$, charge carriers in the plane of the superlattice can have quasi-continuous values of $E^{(i)}$ between the center $E^{(i)}(k_z=0)$ and the limit $E^{(i)}(k_z=\pi/d)$ of the first Brillouin zone as we can see in figure 6.

For this quasi-two-dimensional SL, the presence of a strong perpendicular magnetic field leads to the quantization of the state density in terms of Dirac functions $\delta$ separated by cyclotron energy $\hbar \omega_{k_z}$, represented in figure 5b, d, and f for three values of magnetic fields, whose expression is written as [22]:

$$\rho_{\text{DOS}}^{(i)}(E, B) = \frac{eB}{\hbar} \sum_{y, z} \delta(E - E^{(i)})$$ (15)

In Figure 7, we made a comparison of the density of states for three values of magnetic fields. As the magnetic field decreases, cyclotron energy $\hbar \omega_{k_z}$ decreases and the gap between Landau levels decreases. When B becomes lower than 0.8T, the cyclotron energy becomes lower than $\Delta E^{(i)}$, so there is an interference between the levels of the density of states, it is the quantum limit.

The highest occupied level corresponds to the Fermi level, each time a subband of Landau crosses the Fermi level, and it depopulates the electrons that will contribute to the electronic transport, resulting in a minimum of longitudinal magnetoresistance $R_{xx}$. At very high magnetic fields, only the basic Landau subband $(N^{(i)} = 0$ or 1) is populated Figures 7 (a) and (b). Consequently, by varying the intensity of the magnetic field, the number of occupied Landau sub-bands varies with B, which leads to oscillations of magnetoresistance (Shubnikov-de Haas effect).
Such effects can be observed only if $\Delta E^{(i)} < \hbar \omega_c$. According to our calculations for $B<0.8T$, the two effects SdH and quantum Hall effect are no longer observed, since all the energies above $E^{(i)}_{\text{center}}+(N+1/2)\hbar \omega_c$ are allowed (continuous energy spectrum) as can be seen in figures 7 (e, f) These results are in good agreement with the experimental measurements of Pusep et al.

The application of an external magnetic field leads to the creation of Landau levels. Figure 8 represents calculated energies for $E_1$ and the variation of Fermi levels as a function of magnetic fields. These results are obtained by using the in-plane wave vectors quantification rule of superlattice given by the formula (16) and the expression (17) of the concentration of the $n_{2D}$ electrons in the conduction band.

$$k^z_p = \left( 2N^{(i)} + \frac{1}{2} \right) \left( \frac{eB}{\hbar} \right)$$

(16)

Where $N^{(i)}$ de notes the Landau index of the $i$th sub-band.

$$n_{2D} = \int_{0}^{\infty} \rho_{\text{DOS}}(E, B) f(E) dE$$

(17)

with $f(E) = 1/(1+\exp(E-E_F/k_BT))$ the distribution of Fermi-Dirac.

We can see that the energy of the Landau sub-bands increases linearly with the magnetic field $B$. The values of $B$, extrema indicate by the intersections between these sub-bands of Landau and the level of Fermi, are in good agreement with those of oscillations of the longitudinal magnetoresistance $R_{xx}$ observed in Ref. 8, as shown in Table 1 and Figure 7.

However, it should be noted that under high magnetic fields, peaks of Shubnikov-de Haas oscillations (maxima of $R_{xx}$) occur at the jumps of the transverse magnetoresistance $R_{xy}$ and each minima of $R_{xx}$ corresponds to a plateau of $R_{xy}$ (quantum Hall effect).
FIG. 7. (a), (c) and (e) Degeneracy lifting of the first conduction mini-band \( E_1 \) into Landau mini-bands in the first Brillouin zone. (b), (d) and (f) total energy versus the electron density of states under different magnetic fields.
FIG. 8. Energy position of the calculated Landau levels of the first conduction $E_{1}$ sub-bands, and the Fermi level $E_{F}$, as a function of magnetic field

On the other hand, the neighbor magnetoresistance minima observed at the magnetic fields 9.7T, 4.8T, 3.2T and 2.5T correspond to the quantized Hall states with the filling factors $v$ = 2, 4, 6, 8 respectively.

4. Conclusions

In this work, we have studied the GaAs/Al$_{0.18}$Ga$_{0.82}$As superlattice, in the framework of the envelope function model and the effective mass approximation. The results obtained show that, when the thickness of the barriers $d_{2}$ increases, the separation of the conduction and valence bands, as well as the width of the forbidden band, decrease and tend to those of an isolated quantum wells (discrete levels). We showed the effect of VBO and the temperature on the band gap. The variation of the density of states of the system as a function of energy shows that this superlattice has an almost two-dimensional character with a small dispersion. The $E(k_{x}, k_{p})$ curves in the direction of growth and in the plane of the superlattice show that the first conduction and valence subbands are parabolic. The calculated Fermi level position $E_{F}$=1.637eV indicates that this sample has $n$-type conductivity. In the presence of an intense magnetic field, the separation of the Landau subbands increases with $B$, which shows the presence of Shubnikov-de Haas and quantum Hall effects. According to our calculations, these two effects can be observed only if $B$>0.8T for the temperature of 0.3K. We have interpreted the oscillations of longitudinal magnetism $R_{xx}$ and transverse $R_{xy}$ observed by Pusep et al.

Abstract

Thermal radiation from bulk disorderly placed nonresonant emitters is incoherent, broadband and isotropic. However, the angular emission diagram and polarization of thermal radiation can be controlled by the emitter symmetry. In this work we study a chiral metasurface which has guided resonant modes in the middle infrared range. We demonstrate that due to the absence of a mirror symmetry of such metasurface, the thermally generated electromagnetic waves are circularly polarized with the circular polarization degree of 0.87. Using the Fourier modal method we study the structure eigenmodes and analyze the field distributions in them.

1. Introduction

In recent years, the study of thermal emission of periodic materials attracted a great deal of attention from researchers due to its high potential for important applications in near- and far-field thermal management [3, 1]. Usually, the thermal radiation from bulk emitters is incoherent, broadband and isotropic. By changing the emitter symmetry one can control the angular emission diagram and the polarization of thermal radiation. For instance, a structure which lacks a mirror symmetry emits circularly polarized thermal radiation. The mirror symmetry can be broken down by creating a structure with a chiral surface. Chiral metasurfaces can be used for obtaining circularly polarized photoluminescence of quantum dots [4]. The highest theoretically predicted circular polarization degree was as high as 99% while the corresponding experimental value was 81%. The degree of circular polarization depends on the surface geometry and can be optimized.

Here we use the concept of a chiral metasurface for generating circularly polarized thermal radiation. We demonstrate a structure with artificial rotational anisotropy which radiates the circularly polarized thermal emission and discuss this effect in detail.

2. Model structure and theory

In this paper, the thermal emitter consists of a ZnSe waveguide on KCl substrate. The waveguide has a two-dimensional array of etched rectangles (Fig. 1a). The bottom surface of rectangles is covered by 40-nm thick layer of Si₃N₄. In this work we study the guided resonance modes of this waveguide in the 7–15 µm wavelength range. ZnSe and KCl are transparent in the middle infrared range and therefore do not emit thermal emission. In contrast, Si₃N₄ has a wide absorption band and hence is the source of thermal radiation in the structure.

The emissivity spectra is calculated in accordance with the Kirhoff’s law which states that the emissivity and absorptivity are equal. In turn, the absorptivity is calculated by the rigorous coupled wave analysis (RCWA) [5]. The scattering matrices were calculated using the Li’s factorization rules with 13 x 13 = 169 spatial harmonics.

Figure 1: (a) Schematics of chiral metasurface. (b) LCP (blue) and RCP (red) emissivity spectra of the chiral metasurface.
3. Results and discussions

To demonstrate the circularly polarized thermal emission, we calculate the emissivity spectra of chiral metasurface in left circular polarization (LCP) and right circular polarization (RCP) as well as the circular polarization degree (CPD). As shown in Fig. 1b, in the displayed spectral range, the emissivity spectra have two peaks at $\lambda \approx 12.7 \mu m$ and $13 \mu m$ which have different amplitudes in LCP and RCP. As a result, the degree of circular polarization is non-zero and reaches the values of 0.87. As shown in [2] for similar structure, the origin of the resonance behavior of emissivity is the guided resonance modes. Indeed, the periodic layer of ZnSe represents a waveguide since it’s surrounded by the layers of smaller refractive index. Due to the metasurface periodicity, these eigenmodes are folded into the first Brillouin zone and, hence, are visible in the far field of thermal radiation.

Finally, our chiral metasurface can be considered as a beam router for clockwise and counterclockwise circularly polarized emitters (see Fig. 2).

4. Conclusion

In conclusion, we have demonstrated that the chiral metasurface can emit the circularly polarized thermal radiation with the circular polarization degree as high as 87%. We attribute this effect to the shape anisotropy of the photonic crystal part of the structure.

Abstract

By drawing inspiration from the fin heat sink, we propose a new kind of thermal camouflage device. The working principle lies in the high thermal conductivity of the folded fins, and the target objects will be concealed inside. The proposed device can work under dynamic background and moving anything inside will be thermal camouflaged adaptively and effectively. We also propose qualitative and quantitative index to evaluate the effect. Both steady and dynamic simulations were conducted to discuss and evaluate the thermal camouflage performance.

1. Introduction

Adaptive thermal camouflage refers to the function to conceal targets dynamically with adaption to the change of background temperature, which is more promising and powerful, compared with the conventional static camouflage, especially for movable targets like humans and animals. The current thermal camouflage reports mainly focus on the static one. Some work claims to move targets for thermal camouflage, but they just move the camouflage signature from one place to another while the real targets are still fixed and background temperature should be provided in advance. On the other hand, most the existing thermal camouflage devices are designed based on the theory of transformation thermotics or scattering cancellation, resulting in the critical requirement of anisotropic and inhomogeneous metamaterials. In this paper, we proposed background-independent adaptive thermal camouflage devices, which can realize good thermal camouflage performance and apply for the targets during the moving process. Both steady and dynamic simulation is conducted to verify the performance, with qualitative and quantitative analysis to evaluate the effect of thermal camouflage.

2. Background-independent

We design the device as illustrated in Fig. 1. Comparing the temperature fields in Figs. 1(a) and 1(b), it is seen that when adding some fins, the temperature equivalence of $T_1$ (fin tip) and $T_2$ (fin root) could still be valid if the thermal conductivity of the fins is large and the fin height is small enough. It is perceived that the temperature in Fig. 1(b) will be the same as that in Fig. 1(a) in the IR camera projected downwardly. Keeping in mind with the goal of maintaining of $T_d=T_b$ from point to point, we bend the fins towards to the center in both sides without moving the endpoints, resulting in an adjustable space in the center, as shown in Figs. 1(c) and 1(d). The actual structure is shown in Figs. 1(e). When some target object sit inside the adjustable space of folded fins, it will be concealed from the top IR camera, thus the thermal camouflage effect is achieved. It is seen that the thermal camouflage performance relies on the folded fins with high thermal conductivity, which is independent on the background plane no matter how the background temperature changes.

3. Simulation and Discussion

In the simulation, the plate with a length of 1000 mm, a width of 500 mm and a height of 50 mm is used as a background plate, and the material of the base plate is cast iron, $\kappa=50$ W/(m*K). The length of the base plate is lengthened to simulate the characteristics of the device moving on the base plate. Fifty copper fins of different lengths ($\kappa=400$ W/(m*K)) were mounted on the base plate to form an angular structure with a total length of 300 mm, and the maximum height of the fins is 32 mm. The angle between the angular structure and the horizontal plane is $\theta=12^\circ$. Part of the fins are bent at 90 degrees so that a square cavity is left in the middle. In order to ensure that the angular structure appears smooth and continuous from the side, the upper surface of the fin is machined to be inclined by 12° with respect to the horizontal plane. High temperature is set on the left side of the base plate and low temperature is on the right. The angular structure is moved from left to right on the plate. The steady-state temperature distribution map of the top view and the main view at different positions are shown in Fig. 2.
We define a parameter $\sigma$ to denote the temperature variance between the top temperature from the device and the reference plate, as

$$\Delta T^2 = \frac{\sum_{i=1}^{k}(T_{id} - T_{ob})^2}{k}$$

(1)

where $T_{id}$ is the temperature of point $i$ on the device and $T_{ob}$ is the temperature of point $i$ from the corresponding positions on the background, $k$ is the number of point taken. The larger the $\sigma$ is, the larger the difference in temperature between device and background is, which means the effect of camouflage is worse.

Figure 2 Steady temperature field distribution with the camouflage device at three different locations: (a) left, (b) middle, and (c) right.

Taking $\theta=12^{\circ}$ and $\kappa_1/\kappa_2 =8.1$, we plot the temperature distribution of the front view and the top view at 10 min, 20 min, 40 min, 80 min, 120 min and steady state as Fig 5(a). It is found that the deviation coefficient $\sigma$ first rises and then falls. The device undergoes an overshooting process, then it finally approaches the steady state. When $\kappa_1/\kappa_2$ is large which means the thermal conductivity of the fin is significantly higher than that of the base plate, the heat flow conducts further faster in the fin than the base plate, so that the temperature of the top of the blazing plate can be quickly adjusted to the base plate. The same, so that when the target and the device move, still achieve a good transient effect. In this way, the temperature at the top of the fin can be quickly adjusted to be the same as the base plate, so that the target and the device can still achieve a good transient effect when moving.

4. Conclusions

To sum up, we design a thermal camouflage structure by drawing inspiration from the fin heat sink. Relying on the high thermal conductivity of the folded fins, the proposed thermal camouflage device can work well without knowing the background temperature in advanced. Both steady and dynamic simulations were conducted to discuss the thermal camouflage performance. We also propose a qualitative and quantitative index which is temperature variance to evaluate the camouflage effect. In this way we can analyze and compare camouflage levels visually. The temperature variance increases as the angle $\theta$ increases. This can also be used as a basis for structural design and material selection.

Abstract

We have developed a numerical model and fitting algorithm which combined the classical two-temperature model, the thermal conduction phenomena and a 3D Finite-Element-Method to link the spatial and temporal distribution of temperature to the transient optical response of a metallic sample heated by ultrashort laser pulse. Using a pump-probe setup, the spectro-temporal optical response of different thin gold films were quantitatively compared to our model. Study of the dependency and importance of the different model’s parameters was also realized.

1. Introduction

The ability to control electromagnetic energy in subwavelength volumes with surface plasmon polaritons has attracted much attention during the past decade in the field of nanosciences. To date, most of the work in plasmonics has been devoted to minimizing the heat dissipation process related to the oscillation of charges in nanostructures. Recently, work has focused on turning this problem into an opportunity: this emerging branch of plasmonics is called thermoplasmonics [1–3] and has potential for numerous applications in medicine, thermotronics, and energy conversion. To study quantitatively these photothermal phenomena in thin metallic films and nanoparticles, we have developed an ultra-fast pump-probe setup and a numerical model to retrieve the spatial and temporal distribution of electronic and lattice temperatures from the optical response of these samples heated by an ultrashort laser pulse.

2. Experimental Setup

A pump-probe based setup was built to acquire the spectro-temporal optical response of a sample with high temporal resolution. The laser source is a Ti:sapphire oscillator coupled to an optical parametric amplifier. The sample is heated with short laser pulse pulses (~70 fs) and small changes in the sample’s reflectivity (or transmission) is observed with the time-delayed white probe pulses using lock-in detection. The pump and probe wavelengths can be adjusted in the range of 400 nm to 2000 nm. The ability to generate white pulses enables a full spectral characterization in the range of visible and near-infrared as depicted on Figure 1(left).

3. Numerical modeling and results

The dynamic of photothermal phenomena is governed by a three-step mechanism involving electronic heating through photon absorption (~100 fs), thermalization via electron-phonon interaction (~ ps), and thermal diffusion outside the pump focal point (~ ns)). To model these processes a numerical model [4] was developed which is based on the two temperatures model, well-known in the field of ultrafast heating process, with a full 3D Finite Element Method electromagnetic (FEM EM) code considering the geometry of the sample. Electronic and lattice thermal conduction through the metal and substrate are also included in this model (Figure 2).
Figure 2. Schematic of the numerical model and fitting algorithm. The sample is described by FEM. The algorithm uses a two temperatures model combined with electronic (at short time scale) and lattice conduction (at long time scale) to estimate the electronic and lattice temperature spatial distribution.

Experimental transient optical responses can then be fitted with this model to retrieve the electronic and lattice temperatures spatial distribution and the different parameters involved in the photothermal phenomena. Figure 1 (right) shows an example of the fitting result on a 50 nm gold film for different pump fluences. An excellent agreement is obtained.

Electronic and lattice temperature can then be extracted from the experimental data as can be seen in Figure 3 which shows the evolution of the maximum reach by these two temperatures after pump heating, as a function of pump fluence. A similar study was done for different film thickness. Preliminary results were also obtained on nanoparticles arrays.

Monolithic Graphene single-mode Vertical-cavity Surface-emitting Lasers

Abstract
An inter-cavity contact single mode 850 nm VCSEL was fabricated with a graphene assisted self-assembly curved dielectric bubble Bragg mirror for the first time. Taking the advantage of graphene’s uniform low surface energy, the low cost dielectric bubble DBR (Si3N4/SiO2) was deposited on top of the graphene/half-VCSEL structure via van der Waals Force (vdWF) without using any additional spacing elements and sacrificial layer release-etch process.

1. Introduction
Recent years have seen a burst of activity in VCSEL chips directed towards the development of functional integrated optical, which are based on single-mode optical fiber and high-speed VCSELs are developed. Such VCSELs have to be single transverse mode to enable efficient laser fiber coupling and to prevent excessive pulse broadening over longer transmission distances caused by chromatic dispersion in the fiber. Although VCSEL possess advantageous properties, however, VCSELs typically lase in multiple transverse modes as a result of strong index confinement from the oxide layers. High-power single mode operation is desired for a number of applications, including optical imaging and scanning, as well as data communication over single mode fiber. A fundamental issue to obtain a single mode VCSEL is that this usually requires reduction of the cavity cross section area to decrease the number of transverse modes that are supported. However, this produces reduced active volume, which can substantially limit the output power of the fundamental mode. Moreover, VCSEL structures, which increase the loss of higher order modes often also increase the loss of the fundamental mode, albeit to a lesser extent. Therefore, demonstrating high power fundamental mode emission from a VCSEL has to date been a challenge. We investigated graphene, a monolayer of carbon atoms with a regular sp2-bonded atomic-scale hexagonal pattern. Its intriguing properties, like high carrier mobility, massless Dirac fermions, mechanical strength, thermal conductivity and stable chemical characteristics. Successful growth of high quality graphene has facilitated efforts to use it as a transparent electrode material in photodetector, nanolaser, and solar cells. Mechanical characteristics and flexibility of graphene have been extensively investigated for numerous applications including flexible batteries, super capacitors, sensors, displays and flexible electronics. Particularly, graphene, as 2D materials buffered layer, can allow crystalline growth via van der Waals epitaxy, reducing defect density. These applications realize multi-use of graphene as transparent conducting electrodes in flexible optoelectronic devices and also for the growth of vertical high-performance optics composites that require formation of initial films with high optical function.

2. Fabrication and Design

![FIG. 1. (a) Schematic structure, (b) Schematic diagram of the transferring and device fabrication process. The Graphene films are synthesized by the CVD method on a copper foil with polishing in advance. The PMMA/CVD-G film was finally transferred to a Half-VCSEL substrate for device fabrication. And the dielectric Si3N4/SiO2 layers were deposited at last.](Image)

The scheme of the graphene modulator-integrated VCSEL is shown in Fig. 1(a). The Half-VCSEL vertical structure is the same as that of conventional 850nm VCSELs. The bottom mirror consists of a 30-period Si-doped Al0.9Ga0.1As/Al0.12Ga0.88As distributed Bragg-reflector (DBR). The active region has three Al0.3Ga0.7As/Al0.12In0.18Ga0.82As quantum wells sandwiched in one-λ cavity. The top mirror consists of a 2-period carbon-doped Al0.9Ga0.1As/Al0.12Ga0.88As DBR. The second chip is 7-period dielectric Si3N4/SiO2 bubbled DBR on the graphene via van der Waals regrow as a perfect mirror. A build-in strain gradient results in a concave curvature of this top DBR and allows an easy and tilt insensitive alignment of the two parts without any additional spacing elements, while regulating the waveguide routes with a curved shape guides a strong leaky travelling wave in the lateral direction from the VCSEL into an loss mode, which forms the single transverse mode in the VCSEL with larger oxide aperture. The device fabrication procedure is schematically shown in Figure 1(b).

The light absorption is directly associated with the graphene. This can be easily understood that the monolayer graphene absorbs about 2.3% of the impinging light in both
visible and near-infrared regions. However, on the graphene anchored surface the light gets transparent because of multiple internal reflections in the gaps of bubble DBR. Also, the graphene layer dimensions are very smaller than the wavelength. When the distances between the graphene and airgap interface are appropriate, light would interact differently on the graphene structures due to the equivalent gradient refractive index. Electromagnetic simulations using FDTD (finite difference time domain) were carried out to simulate the light absorption in a cell section extracted from bubble DBR with graphene structure. The simulated absorption curves of DBR with graphene and without graphene reveal that the graphene have limited effect on the absorption which is less than 3%. Reflectance and transmittance of bubble DBR with graphene demonstrated a small reduce compared to without graphene film (Fig. 2b), the differential reflectivity is less than 2%.

**Fig 2a. Calculated cross-sectional electric field distributions of partial of bubble DBR with graphene at 850 nm.**

**Fig 2b. Calculated reflectivity spectra of the bubble DBR with graphene layer (black) and without (red)**

### 3. Discussion

The concave-curve interference rings in Fig. 3 (a) are obvious and the reflectivity spectra are significantly broader. Larger fabrication tolerance in high contrast dielectric bubbled DBR was firstly experimentally demonstrated by our group in the context of VCSELs. In our method, the regrow of the dielectric Si₃N₄/SiO₂ layers on the graphene surface was induced by the accumulated internal strain of the build-in strained layer weak adhesion to graphene, as shown in Figure 3 (b). It was critical to select a proper strained material that satisfied the following conditions for uniform with a high yield: first, there is no chemical reaction to maintain the purity of the graphene; second, the adhesion energy to the graphene is weaker than between graphene and p-GaAs; and there is enough high build-in strain energy to separate from the graphene/GaAs interface. The adhesion energies between graphene and these substrate materials can be expected as $T=2(\gamma_{Gr} \times(\gamma_{surface})^{1/2}$, where $\gamma_{Gr}$ is the surface energy of graphene and $\gamma_{surface}$ is the surface energy of substrate material, respectively. As reported, the values of adhesion energy derived from the measured monolayer graphene/SiO₂ is 0.45 ± J m⁻², however to the GaAs (110) surface, the energy is about 0.86 J m⁻², so the values of adhesion energy of monolayer graphene/GaAs is $T=2(\gamma_{Gr} \times(\gamma_{GaAs})^{1/2}=0.829$ J m⁻², which near more than two times of graphene/SiO₂ adhesion energy. In addition, the surface roughness also affects the adhesion between graphene and their substrates, making the adhesion energy of (0.275-0.4) J m⁻². The optical microscope images in Fig. 3 show that the transfer process of epitaxial graphene layer have been completely finished, including rectangular p-GaAs contact from the Half-VCSEL surface, and the Raman spectrum indicates that the quality of the graphene is maintained during the transfer (no D peak in the spectra). However, for obtaining perfect monolayer graphene and bubbled DBR in laser device, it is essential to selectively deposition by PECVD.

### 4. Conclusions

In summary, we have demonstrated fully functional Gr-VCSEL directed vdW grow of high-quality dielectric bubbled DBR structure on epitaxial graphene/Half-VCSEL substrates. An average single mode output power graphene-VCSELs were achieved, which are within the range to those of regular structure grown on the GaAs substrates by using MOCVD. In addition, the flexible, transparent, low resistance and resilient coating characteristics of the electrode technology also could be a powerful tool in improving high-frequency and polarization modulation of VCSEL.

Abstract
Recently our group proposed a metamaterial laser design, which enables the independent control of the stored energy and its outcoupling to radiation. The principle of operation is based on the excitation of a dark mode, i.e. a mode of zero net electric/magnetic moment that does not consequently radiate. With the aid of a small non-resonant scatterer, the dark mode is then coupled to radiation modes. Here we examine the proposed scheme in implementations that represent realistic experiments.

1. Introduction
In search of coherent light sources that can be integrated in small-scaled photonic systems, nanolasers have been the object of sustained research in latest years [1-3]. In order to scale the laser dimensions down, many diverse materials and techniques have been utilized so far. For example, all-dielectric systems have proven to offer high $Q$ factors, but their size is limited to the order of magnitude of the operating wavelength [1]. With plasmon-based systems, on the other hand, the laser dimensions can become subwavelength but at the expense of very low $Q$ factors, due to very high dissipative loss in the metal inclusions [2,3]. Our proposed laser system [4-6] overcomes this trade-off and offers radiation damping tunability, along with many other features, such as directionality, subwavelength integration and simple layer-by-layer fabrication.

2. Principle of operation
Our proposed laser consists of a very thin dielectric slab, in which silver of the same thickness is periodically inserted, as illustrated in Fig. 1(c) (a single unit cell is shown). This way, the continuous dark bound state of the dielectric slab (red line in Fig. 1(a)) is quantized and hence a discrete set of resonant dark states is achieved with wavevector at multiples of $\pi/a$. In fact, a band structure emerges, splitting the states into high $Q$ (bottom of gap) and low $Q$ modes (top of gap), as illustrated in Fig. 1(a) with the filled and open blue dots. Depending on the branch of the dispersion, an isolated mode with the desired operation frequency and spatial distribution can be then chosen for operation. Here we choose to work with the dark mode which is highlighted.

Figure 1: The dark-mode laser principle of operation. (a) Dispersion relation of the unpumped uniform dielectric slab of thickness $d$ (red line) and band structure of the composite dielectric-metal system (connected dots). The shaded area depicts the linewidth of the gain material and the red circle marks the operation point. The $Q$ factor of each mode is also shown below. (b) Spectral emission profile of gain material. (c) Perspective view of a single unit cell without the scatterer (top) and lasing snapshot (bottom). (d) Perspective view of the same unit cell with the scatterer incorporated (top) and lasing snapshot (bottom). The unit cell is periodically repeated along the $x$, $z$ directions, forming an infinite radiating meta-surface.
Figure 2: Intensity $|E_z|^2$ (grayscale density plot) and power flow (yellow arrows) for (a), (b) infinite system and (c), (d) a finite system of $N = 60$ unit cells. In (a), (c) no scatterer is present. In (b), (d) a scatterer with dimensions $w_{\text{scat}} = 60$ nm, $t_{\text{scat}} = 30$ nm has been placed at $\delta x/a \sim 0.31$ [see Fig. 1(d)]. The black line in the middle of each panel denotes the metasurface. Each double bright peak at the metasurface level corresponds to one unit cell, as it contains one sine-like dark mode [see Fig. 1(c), (d)].

4. Conclusions

In this work we examine a new laser system that utilizes the concept of lasing into a dark mode. For sufficiently large systems the lasing power is not coupled to radiation unless some scatterer is incorporated and coupling can be therefore tuned independently of the energy storage mechanism. For smaller systems, leakage from the edge may alter the picture. We show how to obtain control on leakage and intended outcoupling for the realization of subwavelength coherent light sources in realistic finite-aperture designs.

Abstract
Resonance interaction between molecular excited states and localized electromagnetic field allows to control fundamental properties of a matter. In this study we have measured the emission spectra of Rhodamine 6G organic dye being placed in a precisely tunable Fabry-Perot microcavity. We have demonstrated emission from both upper and lower polaritonic states of strongly coupled organic dye excitons with relatively low and unoriented dipole moments. Rabi splitting estimated from emission spectra was as large as 225 meV.

1. Introduction
Light-matter interaction of dipole transition in ensembles of molecules is of special interest nowadays [1]. Hybridization of energy states of molecular excitons and electromagnetic modes in cavities or plasmonic nanostructures leads to the formation of new polaritonic states, which properties are significantly different from the properties of the original uncoupled states. Strong dependence of polaritonic state properties on electromagnetic mode characteristics leads to the ability to control them [2] using tunable microcavity modes. In previous studies [3] we have developed tunable microcavity cell (TMC) based on unstable Fabry-Perot resonator. Developed TMC provides an ability to precisely control cavity length at nanometer scale and hence mode volume, quality factor and spectral position of the mode. These properties of TMC provide an ability to directly measure the dispersion of polaritons in transmission as well as in emission of the light. In most studies, authors use ensembles of molecules with large dipole moments or highly oriented aggregates in order to increase the light-matter coupling strength [1]. It allows one to achieve strong coupling even with the use of optical microcavities with relatively large mode volumes. However, many organic dye molecules, which are widely used as the fluorophores due to the high quantum yields and large absorption cross-sections, have relatively low values of dipole moment and do not form oriented aggregates. Thereby, strong coupling regime has been previously reached mostly with the use of extremely localized plasmonic modes [4,5], which significantly limits the potential of practical applications for such coupled systems.

In reporting study, we have encapsulated the Rhodamine 6G (R6G) molecules in a polymer matrix, placed them in the developed TMC and investigated their emission and its dependence on the properties of microcavity modes [6]. Such an approach can be used to create novel tunable sources of coherent spontaneous emission.

2. Materials and methods
The design of developed TMC has been described in detail elsewhere [3]. Briefly, TMC consists of an unstable Fabry-Perot microcavity with flat bottom and top convex mirrors. Distance between mirrors could be finely tuned at few nanometer scale with Z-piezopositioner in range of up to 10 μm. Sample was deposited directly on the flat mirror surface. Such configuration leads to automatic fulfilment of plane-parallelism in one point of convex mirror, which is the nearest to the flat surface. On the other hand, curve surface leads to efficient mode selection and significantly lowers the mode volume [3,7]. A 488-nm line of Ar+ laser was used in emission measurements. Transmission spectra were obtained with the use of white LED emission. R6G molecules were encapsulated in poly(methyl methacrylate) (PMMA) matrix and deposited on flat mirror surface using spin-coating [6]. The thickness of the R6G-PMMA film was measured using atomic force microscopy and estimated to be around 105 nm.

3. Results and discussion
In the previous study we have shown that the use of one convex mirror in developed TMC leads to significant...
decrease of mode volumes down to few $(\lambda/n)^3$ what could help to achieve an order of magnitude higher coupling strength [7]. Although such values of the mode volumes are still few orders of magnitude larger than those of plasmonic modes, the optical TMC have much higher quality factors and could be precisely tuned thus allowing investigation of a wide range of materials with excitons transition in strong and weak coupling regimes. In this study, we R6G-PMMA films with relatively low concentrations of dye molecules have been investigated. At the same time, weak transmission of microcavity and low signal-to-noise ratios led to the conditions in which number of exciting photons greatly overcomes the number of excited states in molecular ensemble thus avoiding the observation of coupling in transmission spectra (Figure 1). The results of emission measurements from R6G-PMMA film placed inside and outside of microcavity with presented transmission spectra are shown in Figure 1

Figure 1: Normalized fluorescence spectrum of R6G-PMMA film in a tunable microcavity (black curve) in comparison with the normalized fluorescence spectrum of the same film on the substrate outside the microcavity (grey curve) and corresponding transmission spectrum of the microcavity (red curve).

Broadband emission spectrum of R6G splits into two distinct peaks corresponding to the lower and upper polariton emissions with peak energies of 2.07 and 2.28 eV, respectively. We speculate that the unusual appearance of both polaritonic branches is due to the low amount of uncoupled states in the ensemble. Otherwise, fast recombination of excitation from upper polaritonic state to the uncoupled state would prevail over the radiative relaxation to the ground state, and higher energy peak would not be observed [8]. In order to investigate the dispersion of polaritonic states and measure the anticrossing, the TMC was detuned using different mirror separations in a range from 1424 nm to 1552 nm, with the 25 nm step. Strong dependence of polariton state energy on the distance between mirrors has been measured. Resulting dependence of emission peak position on detuning has demonstrated clear anticrossing behavior. Rabi splitting was estimated to be around 225 meV, which is a rather large value for an ensemble of organic dye with exciton transitions coupled to the electromagnetic modes of the optical microcavity.

4. Conclusions

We have demonstrated controllable emission of strongly coupled organic dye excitons with relatively low unoriented dipole moments in tunable optical microcavity. Broadband emission spectrum of ensemble of R6G molecules has two distinct peaks related to the emission from the both, lower and upper polaritonic states. Dispersion of polaritonic branches has been measured while changing the cavity length and clear anticrossing behavior has been demonstrated. Estimated Rabi splitting energy was as large as 225 meV. Strong coupling regime being reached in optical microcavity with the few microns distance between the mirrors opens up great prospects for various practical applications, such as development of novel light sources, fabrication of flow cells for realization of dynamic strong coupling of the transitions of molecules in a microfluidic channel for biosensing and control of chemical reactions.

Abstract
We present the experimental realization of the first-of-its-kind vertical-cavity surface-emitting laser (VCSEL) incorporating a monolithic high-contrast grating (MHCG). The incorporation of an MHCG results in a 20% reduction of the epitaxial material usage, and enables stable linear polarization of the emitted light and single mode operation for more than a three times larger electrical oxide aperture diameter in comparison to a standard oxide-confined VCSEL. Our MHCG VCSELs are promising light sources for smartphones, optical communication systems, and sensing systems.

1. Introduction
A state-of-the-art vertical-cavity surface-emitting laser (VCSEL) is one of the most complicated optoelectronic devices. In a typical design, the \( m \cdot \lambda / 2 \)-optically thick cavity, where \( m \) is a positive integer, houses a multiple-quantum-well (QW) active region that is sandwiched between two distributed Bragg reflectors (DBRs) of very high \((R > 0.99)\) power reflectance. In order to sufficiently decrease the device’s electrical resistance, the whole structure or at least a large fraction of it should be doped using a rather deliberate doping scheme which results in diminishing the heterojunction electron and hole energy barriers at the DBR layer interfaces. Additionally, to decrease thermal resistance, improve heat spreading, increase reliability, and enable straightforward planar processing the structure should be grown monolithically.

A DBR is a stack of alternating pairs of \( \lambda / 4 \)-optically thick layers chosen in such a way as to provide the largest possible refractive index contrast and at the same time the lowest possible lattice constants mismatch and lattice expansion coefficients mismatch between the DBR layers. Unfortunately, most pairs of semiconductor materials do not satisfy at least one of these requirements. As a result, high quality DBR mirrors made of GaAs, AlAs, and AlGaAs of various compositions can be monolithically grown with the rest of a VCSEL’s cavity only in the arsenide material system, which allows for emission in the \(~600 – 1100\) nm range. In order to extend the emission range of VCSELs, phosphide- and nitride-based III-V devices must be realized. An attractive alternative for poor quality native or dielectric DBRs for those material systems is strongly required.

We proposed [1] a monolithic high-contrast grating (MHCG) mirror, which is a special case of a broad class of subwavelength high refractive index contrast gratings (HCGs) [2], as a mirror for a VCSEL. The MHCG is characterized by large polarization discrimination, an optical thickness comparable to \( \lambda \), and can be designed to provide almost 100% power reflectance \((R \sim 1.0)\) at normal incidence as required for a VCSEL.

Figure 1. Schematic cross-section of an MHCG, were \( L \) is the period, \( F \) is the fill factor defined as the stripe width divided by the period, \( h_{\text{HCG}} \) is the grating height, and \( n \) is the refractive index.

In this paper we show experimental results of the first electrically-injected, 980 nm GaAs-based VCSEL incorporating an MHCG mirror. Our MHCG is combined with a 5.5-pair GaAs/AlGaAs DBR to stabilize the resonant wavelength.

2. Structure
The VCSEL structure is a \( \lambda / 2 \)-optically thick cavity with 5 InGaAs QWs sandwiched between a 37 pair bottom GaAs/AlGaAs n-doped DBR and a 5.5 pair top GaAs/AlGaAs p-doped DBR, on top of which a GaAs MHCG mirror is placed. Between the top DBR and the MHCG an \(~400\) nm-
thick GaAs layer for phase matching is grown. Two 20 nm-thick Al<sub>0.98</sub>Ga<sub>0.02</sub>As layers for the formation of a current confinement aperture are placed in the Al-rich AlGaAs layers near the QWs. The devices are fabricated via our standard planar processing techniques and electron beam lithography (for the MHCG patterning). We used a high frequency layout for our VCSEL processing with ground-signal-ground metal contact pads (see Fig. 2).

Figure 2. Example SEM images of the processed MHCG VCSEL. Top view of the entire structure a); and close-up view of the top mesa region and the MHCG b).

3. Results

We measured light-current-voltage (LIV) characteristics of our MHCG VCSELs at temperatures from 15 to 85 °C. The devices show lasing in a continuous wave regime up to 85 °C, with threshold currents as low as 2.5 mA and optical output powers (L) as high as ~1.0 mW. An example LIV curve for a VCSEL with L ~1.0 mW is shown in Fig. 3.

Figure 3. LIV measurements for device of 21 μm oxide aperture diameter taken at temperatures from 15 to 65 °C.

An exemplary emission spectrum of a ~13.5 μm oxide aperture diameter MHCG VCSEL is presented in Fig. 4. The device emits in a quasi-single transverse mode (the side-mode suppression ratio is ~36 dB) in a large range of bias currents from threshold to the LI rollover. A larger 16.5 μm device has a double peak emission mode (not shown here) at bias currents from threshold to LI rollover.

Figure 4. Emission spectrum of a quasi-single mode MHCG VCSEL with φ ~13.5 μm taken at 25 °C.

From spectral measurements at different temperatures we extract the thermal resistance of the VCSEL [3]. The 13.5 μm, single-mode device is characterized by a 0.59 ± 0.09 K/mW thermal resistance from a temperature of 15 to 75 °C. This result is comparable to the best result ever obtained for a single mode VCSEL [4].

4. Conclusions

We present the first VCSELs incorporating an MHGC mirror. The devices are electrically-injected and emit in a continuous wave regime up to 85 °C. Our static measurements show good performance and near-record low thermal resistance.

Optimal design of Quantum-Cascade Vertical-Cavity Surface-Emitting Laser

Sandra Grzempa¹, Włodzimierz Nakwaski¹ and Tomasz Czyszanowski¹ *

¹ Institute of Physics, Lodz University of Technology, Wólczańska 219, Łódź, Poland

Abstract
Quantum-Cascade Vertical-Cavity Surface-Emitting Lasers (QC VCSELS) are anticipated to exhibit advantages of both the vertical-cavity surface-emitting lasers (VCSELs) and the unipolar quantum-cascade lasers (QCLs). In QC VCSELS vertical resonance and stimulated emission occurs due to positioning of QCs in the stripes of the monolithic high (refractive-index) contrast grating (MHCG). The performance of QC VCSELS relies on sophisticated design of MHCG and the active regions which takes into account distributions of the QC VCSEL modes.

1. Introduction
Quantum-Cascade Vertical-Cavity Surface-Emitting Laser (QC VCSEL) [1] combine the best features of two types of semiconductor lasers: Quantum-Cascade Lasers (QCLs) [2] with emission in broad range of infrared radiation up to 100 μm and Vertical-Cavity Surface-Emitting Lasers (VCSELs) [3]. The most common applications for QCLs are in spectroscopy and for free space optical communication. For each of these applications important operation properties include their high modulation speed, narrow emission spectrum, high coherence and low beam divergence. These properties can be provided by VCSELs. However when a quantum cascade is embedded into a conventional VCSEL structure stimulated emission is impossible because of the absence of the electrical field component which is perpendicular to the layers. In QC VCSELS stimulated emission of photons and vertical resonance is possible due to embedding QCs into the stripes of a monolithic high (refractive index) contrast grating (MHCG) [4].

2. Design of Quantum-Cascade Vertical-Cavity Surface-Emitting Laser (QC VCSEL)
Unipolarity of quantum cascades allows us to use more than one QC active region each preferably at an anti-node of the z component of the electromagnetic field (E_z) distribution. Distribution of active regions is expected to increase the efficiency of stimulated emission by enhancing interaction between the optical modes and the active region and hence reduces the laser threshold. The performance of QC VCSELS, is strongly dependent on MHCG design that must provide high power reflectance and efficient coupling between optical field and QCs embedded in MHCG. To meet those requirements finding an optimal values of three MHCG parameters: the width of the stripe L, the period of stripe F and the duty cycle D (fig. 1) is essential.

Figure 1. The structure of MHCG with three parameters: L-the period of grating, F-the duty cycle, H-the width of the stripe

Interactions between modes and the active regions is determined by the dimensions of the laser cavity and the positions of the active regions and provide the highest intensity of laser radiation. Spatial distributions of the modes are highly unintuitive and their numerical determination require the use of sophisticated, fully vectorial numerical methods solving Maxwell equations.

3. Conclusions
Taking into account technological limitations, QC VCSEL wafer should be possibly limited in vertical direction. In this paper, we present a designs with different numbers of the active regions and optimal parameters of the MHCG-the resonant cavities for a typical active-area thickness of 2 micrometers emitting wavelengths around 9 μm and compare their performance. We demonstrate a dependence between number of stripes in the MHCG and a threshold current.

Abstract
We demonstrate that in a two-dimensional plasmonic distributed feedback laser where the pumping spot is smaller than the laser surface, the nonlinear interaction between the laser modes via the active medium can result in a new effect, namely, mode cooperation [1]. Mode cooperation arises due to non-orthogonality of the laser modes in the pumped area and leads to decrease their laser thresholds. In the plasmonic distributed feedback laser mode cooperation results in broadening of the radiation pattern, which has been observed in recent experiments [2].

1. Introduction
The two-dimensional plasmonic distributed feedback lasers are promising sources of the coherent radiation for optoelectronics and sensorics applications [3, 4]. Such lasers consist of a periodic plasmonic structure and an active medium [3, 4] is created by the external pumping. The interaction of the Bloch modes of the periodic plasmonic structure with the pumped active medium leads to the stimulated emission, and at a sufficiently high rate of pump to lasing.

In our work we study the multimode effects in the two-dimensional plasmonic distributed feedback lasers [1, 5]. We demonstrate that a new effect, named, mode cooperation takes place in two-dimensional plasmonic laser when the pumping spot is smaller than the laser surface [1]. In this system the Bloch modes of the plasmonic structure are no orthogonality within the pumping spot. For this reason, the electric field intensity in the pumped area of active medium depends on the difference phase between the modes. If the electric fields of the different modes add in phase then the electric fields of the different modes, which interact with each other via the active medium we named as mode cooperation.

In the two-dimensional plasmonic distributed feedback laser mode cooperation is manifested as the lasing of the bright modes with nonzero Bloch wavevectors instead of the dark modes with zero Bloch wavevectors. For this reason, above the threshold the radiation pattern of the two-dimensional plasmonic distributed feedback laser is wider than follows from Kogelnik’s theory [6]. This result has been observed in recent experiments [2].

2. Laser equations
To describe the plasmonic distributed feedback laser we use multimode equations derived in Ref. [7]

\begin{equation}
\frac{dn_{jk}}{dt} = -\left(\gamma_j + \gamma_k\right)n_{jk} + i\left(\omega_j - \omega_k\right)n_{jk} + \sum_{\alpha=1}^{N_{\text{opt}}} \left(\Omega_{\omega \alpha} \varphi_{\alpha m} + \Omega_{\alpha m}^* \varphi_{\alpha m}^*\right)
\end{equation}

\begin{equation}
\frac{dD_m}{dt} = -\gamma_0 (1 + D_m) - 2\sum_{j=1}^{N_{\text{opt}}} \left(\Omega_{\omega m} \varphi_{jm} + \Omega_{jm}^* \varphi_{jm}^*\right)
\end{equation}

\begin{equation}
\frac{d\varphi_{jm}}{dt} = -\gamma_a \varphi_{jm} + i\left(\omega_j - \omega_a\right)\varphi_{jm} + \Omega_{jm}^* \frac{n_{jm}}{2} \left(D_m + 1\right) + \sum_{\alpha=1}^{N_{\text{opt}}} \Omega_{\omega jm} D_m
\end{equation}

Here $n_{j\alpha}$ is the photon numbers in the $j$th Bloch mode; $n_{jk}$ is an interference term responsible for the flow of photons from the $k$th to the $j$th mode, when $j \neq k$. $D_m$ is the population inversion of the $m$th atom and $\varphi_{jm}$ describes the energy flow between the $m$th atom and $j$th mode. The parameters $\omega_j$ and $\gamma_j$ correspond to the real and imaginary parts of the eigenfrequencies of the modes; $\omega_a$ and $\gamma_a$ are the atom transition frequency and the relaxation rate of the population inversion of the atoms; $\gamma_0$ is the relaxation rate of the phase of the atom polarization. $\Omega_{\omega jm}$ is the Rabi constant of coupling between the $jm$th mode and the mth atom. These equations generalize the rate equations widely used in laser theory [8]. In addition to the dynamics of the photon number in each mode and the population inversion of each atom, they take into account the interference between the electric fields of the different modes, $n_{j\alpha}$.

3. Results
Based on the Eqs. (1)-(3) we demonstrate that when the pumped area is smaller than the laser surface the nonlinear interaction between the Bloch modes of periodic plasmonic structure via the active medium can leads to a phase...
synchronization of such modes [1]. Since, the pumped area occupies only part of the plasmonic structure the Bloch modes are no orthogonality within the pumped area. For this reason, the intensity of the electromagnetic field inside the pumped area depends on the phase difference between the modes. The electromagnetic fields of the synchronized modes constructively interfere within the pump area that leads to increase of the coupling constant of such modes with the active medium. As a result, the lasing threshold of the synchronized modes decreases [1]. Thus, the interaction between the laser modes via the active medium can leads to decrease of the lasing threshold of such modes. This effect is opposite to mode competition and therefore, we name of it as a mode cooperation.

In the two-dimensional plasmonic distributed feedback the mode cooperation leads to lasing frequency shift in the allow band. Below the threshold the behavior of the laser is determined by the spontaneous emission which does not depend on the phase difference between the modes and so the maximum number of the photons is in the dark mode that has smallest radiation losses. Above the threshold the maximum number of the photons is in the bright modes in allow band which have greater radiation losses. That is the lasing takes place at the bright modes in the allow band instead of the dark mode at edge of the band gap. As a result the output power of the laser is greater than the than follows from conventional theory [8]. Since below the threshold the laser operates at the dark modes whereas above the threshold the one operates at the bright modes the transition to lasing is accompanied by the sharp increase of the output power, see Figure 1.

Moreover, since the modes lie in allow band have non-zero Bloch wavevectors the radiation pattern of the two-dimensional plasmonic distributed feedback laser is wider than follows from Kogelnik’s theory [6] which take not into account the mode cooperation, see Figure 1. This distinction has been observed in recent experiment [2].

Figure 1: The dependence of output power on the input power.

4. Conclusions

It is shown that in the two-dimensional plasmonic distributed feedback laser where the pumping spot is smaller than the laser surface effect mode cooperation takes place [1]. Mode cooperation consist in the decrease of laser thresholds for modes interacting with each other via the active medium. In the plasmonic distributed feedback laser mode cooperation results in broadening of the radiation pattern, which has been observed in recent experiments [2].

Abstract

Despite major advances, nanolasers require either cryogenic temperatures or high thresholds. We demonstrate theoretically that optical nanopatch antenna lasers can yield thresholds orders of magnitude lower by enhancing the atom-cavity interaction into the strong coupling regime. This work presents the first analytic investigation of laser in film-coupled nanoparticles by expanding the optical field in a set of quasi-normal modes. Ohmic, radiative, surface plasmon, and spontaneous decay channels are included analytically, and which allows structures to be optimized to minimize threshold.

1. Introduction

One of the key devices for improving on-chip optical computing and communications is a fast, sub-diffractional laser with low threshold power, ideally operating at room temperature. While lasers with dielectric laser cavities are limited in size by the diffraction limit, plasmonic cavities can reduce the size of the laser cavity to dimensions much smaller than the wavelength. Reducing the cavity size creates large field enhancements, which can lead to giant Purcell enhancement, enhanced Raman scattering, and even strong coupling at room temperature. The disadvantage of plasmonic resonators, however, is that the Ohmic losses in the metal typically increase the cavity decay rate. In this paper, we demonstrate that a careful analytic approach can be used to design a plasmonic cavity with enhancements strong enough give a cavity interaction time that is sufficiently faster than the cavity decay rate to cause the system to be strongly coupled. This eventually yields designs for nanolasers with a threshold several order of magnitude lower than any other published optically pumped nanolaser at room temperature with a laser dye gain material.

2. Strong Coupling in Optical Nanopatch Cavities

The two key parameters for reducing threshold and increasing nonlinear and quantum effects in cavity quantum electrodynamics in general are the saturation photon number, \( n_0 = \frac{2\gamma_\parallel \gamma_\perp}{g^2} \), and the critical atomic number, \( N_0 = \frac{2\gamma_\parallel \gamma_\perp}{g^2} \). These are given in terms of \( \gamma_\parallel \) and \( \gamma_\perp \), which are the decay and dephasing rates, respectively. The decay rate of the cavity is \( \kappa \), and the cavity coupling parameter \( g = \mu \cdot E / \hbar \) is defined as the dot product of the atomic dipole moment \( \mu \) with the electric field when there is one photon with energy \( \hbar \omega \) in the cavity. Most fundamentally, the field-enhancement that is observed in cavities with reduced mode volume increases the rate of the atom-cavity interaction given by \( g \) by concentrating the electromagnetic field of the photon. The parameters \( n_0 \) and \( N_0 \), are therefore a comparison of two different timescales in the atom-cavity system: the rate of the atom-cavity interaction given by \( g \), and the loss and dephasing mechanisms in both the gain material and the cavity. While reducing the saturation photon number and the critical atomic number to sub-unity values brings the atom-cavity system into the strong coupling regime, this work is focused on minimizing these parameters in order to minimize threshold for nanolasers.

3. Quasienormal mode analysis of lasing in nanopatch antennas

In order to solve for the evolution of the electromagnetic field in the cavity due to the coupling with the gain material a Green’s function for a cavity that has both radiative
and Ohmic losses needs to be developed. This is done by expanding the field in a set of optical modes using quasinormal mode (QNM) theory.[2] \[ \mathbf{E}(\mathbf{r}, \omega) = \sum_{\mu} a_{\mu}(\omega) \mathbf{E}_{\mu}(\mathbf{r}). \]

Each QNM is a solution to the source-free Maxwell’s equations, but is distinct from normal modes by the requirement that the modes \( \mathbf{E}_{\mu}(\mathbf{r}) \) satisfy the Silver-Müller radiation condition as \( r \to \infty \). This boundary condition yields Maxwell’s equations non-Hermitian even in the presence of lossless materials, yielding complex eigenfrequencies for each QNM. Moreover, they are no longer orthogonal with respect to the standard conjugated Hermitian inner product, and instead the orthogonality relation is given by

\[ \langle \mathbf{E}_{\nu} | \mathbf{E}_{\mu} \rangle = \frac{1}{2} \int_V \frac{\partial [\omega \mathbf{e}(\mathbf{r}, \omega)]}{\partial \omega} \mathbf{E}_{\nu} \cdot \mathbf{E}_{\mu} - \mu_0 \mathbf{H}_{\nu} \cdot \mathbf{H}_{\mu} dV. \]

(1)

The modes are then normalized such that \( \langle \mathbf{E}_{\nu} | \mathbf{E}_{\mu} \rangle = \delta_{\nu\mu} \omega_\nu. \) Once the eigenmodes are known, the cavity decay rate \( \kappa \) is given by the imaginary part of the eigenfrequency. The coupling to each mode by a polarization or magnetization in the cavity

\[ a_{\mu}(\omega) = \frac{\omega^2}{2 \hbar \omega_\mu^2 (\omega_\mu - \omega)} \int (\mathbf{E}_\mu \cdot \mathbf{P} - \mu_0 \mathbf{H}_\mu \cdot \mathbf{M}) dV. \]

(2)

can be used to model coupling with the gain material. Moreover, the mode expansion can be used to develop a Green’s function, the imaginary part of which yields the Purcell-enhanced spontaneous emission rate \( \gamma_{sp} = \sum_{\nu} \text{Im} \{ \omega_{\nu}^2 g_{\nu}(\mathbf{r})^2 / \omega_\nu^2 (\omega_\nu - \omega) \} \) in terms of the cavity coupling parameter, \( g_{\nu} = \mu \cdot \mathbf{E}_\nu / \hbar \).

4. Results

The field expansion is then used in a four-level optical Bloch quantum mechanical model of Rhodamine 600, including the spatially varying spontaneous emission rate. Evaluating these equations at a point yields eigenvalue equations for Rabi splitting and the strong coupling parameters shown in fig. 2.

Alternatively, integrating the rate equations over the volume of the cavity yields an eigenvalue equation for the lasing frequency, which is purely real when the population is sufficiently inverted. The model is continued to predict the required number of pump photons in the cavity and incident beam intensity using the same quasinormal coupled mode theory techniques.

Figure 3 gives a holistic picture of various physical processes in the cavity that are analytically predicted and compared with full-wave simulation, beyond the accurate prediction of the lasing threshold (vertical black line). The total population inversion in the simulated cavity \( N_{2,c}^f \) approaches the analytically predicted critical value \( N_{2,c}^f \) as the intensity approaches threshold.

5. Conclusions

The development of an accurate analytical model of lasing in plasmonic cavities gives two unique benefits. First, the fast modeling technique enables optimization of the geometry of the resonator for a particular gain material. Second, it uncovers the underlying physical mechanisms behind lowering the threshold in a low quality factor cavity, and allows direct comparison of all loss rates. This model leads to optical sources with ultralow threshold and fast switching times.

Abstract

We numerically investigate the spatio-temporal dynamics of lasing action in a metallic resonant cavity with four-level gain media, based on defect modes on 2D groove metal array. By performing semiclassical time-domain simulations based on the finite-element method, we obtain dynamical distributions of populations and fields in gain medium and threshold behavior of the laser.

1. Introduction

Plasmonic nanolasers have attracted great interest for their fundamental and technological potential from spectroscopy, sensing, and integrated nanophotonic devices to quantum physics. Spoof surface plasmon polaritons (SPPs) on a structured metallic surface[1] have been widely applied for focusing[2], guiding[3], and localizing[4, 5] THz and GHz waves in a deep subwavelength scale. For development of coherent light sources at the nanoscale, the spoof SPPs would be a good candidate to localize infrared (IR) and visible waves at the nanoscale region because localization of the spoof SPPs allows confining and enhancing light fields at subwavelength scales. Furthermore, the increase of light-matter interaction can enhance the gain by an active medium close to a spoof SPP structures. Recently, spatio-temporal simulations have been exploited to investigate the nonlinear dynamics of active plasmonic system[6, 7, 8]. The spatio-temporal modeling of the spoof SPP modes at visible and IR frequencies could make contribution toward development of plasmonic light sources in nanoscale.

In this work we report on a numerical study of the spatio-temporal dynamics in a small metallic resonant cavity array with four-level gain media for lasing light at IR frequency, based on guided spoof SPPs on 2D groove metal array(GMA). We investigate this problem by using three-dimensional semiclassical simulations based on a time-domain finite-element method[7, 8]. By performing these simulations, we are able to obtain the nonlinear spatio-temporal dynamics arising from the interaction of the gain medium with the nonuniform field distribution characterizing the system. The threshold behavior of the laser can be analyzed, as well.

2. Results

Figure 1 shows a resonant cavity array in this study which is composed of defect structures in formed by introducing two defect structures with defect depth hD = 85 nm on 2D GMA. The 2D GMA inside a MIM structure is composed of two overlapping 1D groove metal arrays perpendicular to each other with the lattice constant a = 150 nm, width w = 60 nm and depth h = 110 nm. The optical response in this resonant cavities is modeled by solving 3D Maxwell equations via the finite element method. The permittivity of metal εm is expressed by Drude model with the plasma frequency ωp = 2π × 2.175 × 1015 rad/s−1 and the damping constant γ = 2π × 6.5 × 1012 rad/s−1. The refractive index nD of the dielectric material is 1.49.

A four level gain medium with size of 150 nm × 300 nm × 25 nm is placed above the defect structures. The artificial gain medium is characterized by the lifetimes τ10 = τ21 = 50 fs, τ23 = 5 ps, and τ30 = 1 ps. The coupling constants are Kp = 10−6 C2/kg and Ke = 10−4 C2/kg, and the linewidths of their corresponding transitions are γp=1/100 fs and γe=1/100 fs. Finally, the initial population density parameter is N1 = 5 × 1023 m−3. The population densities of the four level gain medium obeys the rate equations, and the gain medium interacts with the electromagnetic field through the gain polarization. Figure 2(a) shows simulated transmission, reflection, and absorption spectra for passive cavity. The spectra for the passive cavity show two resonances located at 231.8 and 250.6 THz, respectively. Also, from the electric field distributions as shown in insets of Fig. 2(a), we can verify that the cavities have resonances in the form of the Fabry-Perot resonance. Figure 2(b) shows
Figure 2: (a) For the passive cavity, simulated reflection, transmission, and absorption spectra for the passive cavity (without gain). The inset shows the $z$-component of electric fields, where I and II indicates the first and second resonant mode, respectively. (b) For the active cavity, total absorption as well as absorption in metal and absorption in the gain medium.

Figure 3: (a) Time evolution of electric field intensity (black line) at output plane and population inversion (blue line) averaged at the output plane for 40 MW/m$^2$ in pump power intensity. (b) Steady state lasing intensity vs. pump intensity. (c) Spatial distribution of the population inversion inside the active region computed at three representative times (labeled as $t_A$, $t_B$, and $t_C$ in (a)).

3. Conclusions

In summary, we have numerically studied the spatio-temporal dynamics of lasing action in a metallic resonant cavity with four-level gain media, based on defect modes on 2D groove metal array. By performing semiclassical time-domain simulations, based on the finite-element method, we obtained the nonlinear spatio-temporal dynamics arising from the interaction of the gain medium with the nonuniform field distribution characterizing the system. Also, the threshold behavior of the laser have been analyzed.

Photonic crystals
It is well known that for the crystalline states, the interaction of local pseudo-Jahn-Teller distortions lead to structural transitions [1]. In the case when the local distortions are of the dipole type, the crystal in the ordered phase turns out to be spontaneously polarized. Relation are obtained between the parameters of the vibronic coupling we used in the spatially-periodic systems-time crystals (TC) [2]. TC are the temporal analogue of the photonic crystals (PCs) [2]. Usually, PCs are designed with a refractive index that changes periodically in space. However, due to the unique duality of time and space in waves equations, one can think of a photonic time crystal-PTC where the refractive index or dielectric permittivity (t), changes periodically in time, rather in space [2].

In present paper we analyzed a spatially homogeneous material with permittivity (t), which is modulated in time, such that ε(t) changes periodically, with period T, in a step-like manner. This results in a binary PTC with two time segments. In the first time-segment (t)=ε1 for a duration of t1 seconds, followed by a second time-segment in which ε(t)=ε2 for t2=T−t1 seconds. The field is polarized in the x direction, and propagates in the z direction. With every modulation of (t), a time reflection occurs, causing waves to partially reflect to their time reversed pair, while preserving the momentum k due to the homogeneity of space. The time reversed partner of a wave is a wave with the same momentum but with opposite spatial frequency. This is analogous to a wave conserving its energy, and scattering backwards in space in a PC. We proposed the concept of the PTC, and simulated electromagnetic wave propagation in 1D, and 2D PTC, the simulated results indicate that the scatter fields in PTC are more intensive than those in conventional PC, and the band gaps in PTC are larger than those in conventional PC.

Abstract

Recently, bottom-up assembly of colloidal particles into structural colors represent a major research interest of optical devices for coating, sensing, and display. Despite much breakthroughs in the preparation of structural colors, the film forming strategy is still highly relied on conventional evaporation-induced processes. Herein, inspired from membrane separation processes, we develop a membrane separation-assisted assembly (MSAA) strategy for the preparation of angle-independent structural colors. The process is carried out by separating between water and solid particles in colloidal latex, allowing them to facilely form amorphous structures with robust functions.

Introduction

Angle-independent structural colors have received considerable attention on account of their abilities to control and manipulate light propagation.¹ These structures could be found in natural creatures such as elytra of longhorn beetles and the blue skin of the mandrill. Much efforts have been done for the construction of angle-independent structural colors, such as spray-coating of colloidal latex, fabrication of spherical colloidal crystal beads and improving refractive index of microspheres.² However, their practical applications are still limited. Also, it is desirable to develop new methods, or to extend current method which allow colloidal particles self-assemble into amorphous structures in a fast and low-cost way. Thus, this motivates us to develop new strategies for facilely producing amorphous structures with improved color saturation without sacrificing its brightness.³ Herein, inspired by the graphene-based separation processes, we introduce a membrane separation-assisted assembly (MSAA) strategy to construct a new kind of amorphous photonic structure representation of angle-independent structural colors (Figure 1a, b).⁴ Besides, we also propose an approach to use our structural color film in out-door thermal management applications, which is essential for personal cooling and energy saving.⁵ By combining the synergetic effects of constructive scattering and slow photon, a maximal reduction of 6.9 °C was achieved when exposed to sun radiation (Figure 1c). This finding opens a new pathway for fabrication of amorphous colloidal structures for personal thermal management applications.

Figure 1. a) Schematic illustration of the fabrication of rGO-SPM and assembly progress of the colloid film/graphene hybrid ordered membranes via MSAA method. b) Photograph of as-prepared colloidal film and its optical performance. c) Schematic illustration of the application of a rGO/poly(St-MMA-AA) membrane for outdoor thermal management.

Discussion

Figure 2a presents optical images of three different colloidal films, which are composed of poly(St-MMA-AA) microspheres with diameters of 195 nm, 218 nm and 256 nm, respectively. These colloidal films display virtually identical structural colors at the view angles changing from 90° to 30°. To visually characterize the angle dependence of the colloidal films, the angle-resolved reflection spectra and their corresponding contour maps were measured. As shown in Figure 2b, band positions of colloidal films prepared by MSAA barely shift (less than 5 nm) when the incident angle varies from 90° to 30°, indicating angle-independent property. Meanwhile, the corresponding contour maps with reflection wavelength (λ) on the x axis, view angle (θ) on the y axis and reflection intensity (I) being converted to colors in maps also prove their angle-independent behavior. The contour maps of colloidal films prepared by MSAA exhibit...
consecutive and linear reflection bands that are vertical to \( x \) axes.

![Figure 2](image1)

**Figure 2.** a) Photographs of three different photonic films observed at angles from 90° to approximately 30° reflection spectra and b) corresponding contour maps.

The second set of experiments was focused on studying the passive cooling of structural color film (Figure 3). We studied the impact of stopband position on the efficiency of thermal insulation. To evaluate the influence of stopband positions on heat dissipation process, 8 individual structural colors that are composed of poly(St-MMA-AA) microspheres with different corresponding diameters are prepared. The obtained colors, covering the whole visible light regime are derived from MSAA method and are uniform and independent of viewing angles as demonstrated above. In a typical procedure, a colloidal film with a diameter of 50 mm was placed on top the shelf (obtained from a 3D printer). Under natural sun light radiation, the temperature of structural color film with stopband centered at 650 nm, increased from 24.6 °C to 34.3 °C within 360 s. In contrast, the bulk polystyrene film without a structural color showed a rapid temperature increase from 24.6 °C to 45.5 °C. The infrared photographs of sample films after 15 min of irradiation are shown in Figure 3a. The inserts are temperature differences (\( \Delta T \)) between different sample surfaces (\( T_{\text{sample}} \)) and the cement floor background (\( T_{\text{floor}} \)). With the increase of stopband position, \( \Delta T \) appears a downward trend. The stopband of a structural color film that inhibit certain wavelength propagation is the main reason for this result. The structural color films that possess red or near-infrared colors can prohibit more longer-wavelength light from absorption. For a more realistic case, we adopted structural color film to integrate on human skin, where the film was attached to a human hand. Figure 2d-f are human hands with structural color film (stopband centered at 650 nm), rGO-SPM film and bulk polystyrene film (without a color), respectively. Before measurement, all samples are in thermal equilibrium after solar radiation for at least 15 min. The temperature of bulk polystyrene film and rGO-SPM was 35 °C and 36 °C, respectively. On contrary, for structural color film, the temperature was maintained at 30.5 °C, lower than skin temperature 33 °C. This is consistent with the above results. It is worthwhile to note that our structural color film is composed of two sides: the structural color side and the black rGO-SPM side. It is expected that the color side can be processed to decrease solar radiation in summer, while the black rGO-SPM side been processed to absorb more in winter.

![Figure 3](image2)

**Figure 3.** a) Structural colors prepared by MSAA by varying the diameters of poly(St-MMA-AA) and corresponding infrared photographs after 15 min of irradiation. Schematics of comparison between b) structural color film and c) bulk polystyrene film. Infrared images of d) structural color film, e) bulk polystyrene film and f) rGO-SPM (attached to human body) under radiation.

**Conclusions**

In summary, we report a strategy for the preparation of colloidal films with angle-independent structural colors based on membrane separation-assisted assembly (MSAA) method. By taking advantage of the water transport channels in sulfonated rGO, water and submicron particles could be separated easily, along with colloidal particles assembles into amorphous structures. We investigated the influence of structural colors on thermal insulation and applied it to personal thermal management. A maximal reduction of 6.9 °C can be achieved when the stopband of structural color is centered at 650 nm. Such colloidal films with angle-independent structural colors may provide new opportunity for out-door thermal management materials.

Abstract

Inspired by commonly-seen “milk skin” phenomena, a general and versatile scheme, namely the polymer colloid ensembles (named “colloid skin”) -regulated assembly route, is demonstrated here for colloidal film deposition, which easily addressed the ubiquitous issues associated with the asymmetrical evaporation processes, implying a new broad-spectrum film-forming strategy.

Introduction

Colloidal photonic crystals (CPCs) with periodic micro/nanostructures, have attracted much attention because of their excellent iridescent structural colors. However, they suffer from the ubiquitous “coffee ring” negative-effect phenomenon due to asymmetrical film-forming. Hence, it is still challenging for applications of the CPC coatings with a large scale in a variety of fields, such as advanced inks, printing, flexible display, packaging, textile printing and dyeing and chemical/biological sensors. Also, the development of a new broad-spectrum kind of film forming strategy is still a high concern, especially in frontiers of nanoimprinting, nanoink, etc. In this work, we offer a novel and efficient concept for governing film forming and regulated assembly of CPCs for the first time. The strategy is mainly based on that fact, just as the commonly-seen “milk skin” phenomena of hot milk-containing liquids, the colloidal inks would also cause colloid coalescence on its top surface, forming a layer of “colloid skin” whilst evaporating (Figure 1A).

Discussion

Specifically, aqueous mixtures containing 15 wt% of polystyrene (PS) colloids and 10 wt% of ethylene glycol (EG) were first prepared as the printing “ink”, and a commercial printer (Jetlab 4, MicroFab Corp.) was used to generate tiny ink droplets with sizes ranging from 100 to 300 micrometer (Figure 2A and 2B). As Figure 2C shows, after the ejected droplets were deposited onto the substrate, a layer of colloid ensembles was noticed immediately on their top surfaces, forming the so-called “colloid skin”. The possible mechanism could be attributed to that, similar to commonly-seen “milk skin” phenomena of hot milk-
containing liquids, herein, the hydrophobic PS colloids could also crystallize out from the ink droplets whilst evaporating and thus produce a layer of “colloid skin”. More attractively, this preformed “skin” would give rise to totally different late-stage colloid assembly behavior, facilitating the formation of uniform CPC deposits. When the evaporating flux was ultralow due to the extremely high humidity of 80 % and low temperature of 20 °C, the color of drying mirodroplets varied gradually from pale color to green and finally blue, giving plain-shaped deposits (Case III in Figure 2C, 2D). The phenomena could be explained by that the high humidity reduced the outward flow. Hence, the solvents in drying droplets were evaporated evenly and thus uniform colloid distribution was finally attained (Case III in Figure 2E).

Figure 2. (A) Real-time droplet ejecting process ahead of the printer nozzle (Nozzle Orifice 70 μm) and (B) the confocal micrographs of printing dots. Scale bar = 100 μm. (C) Four typical colloid assembly processes correspond to the droplets drying at a temperature and humidity of (30 °C, 40 %), (40 °C, 50 %) and (20 °C, 80 %), (20 °C, 40 %) respectively. (D) Confocal micrographs of the final colloidal deposits. (E) Proposed mechanism for the colloidal deposition processes.

The “colloid skin”-regulated self-assembly strategy could also be applied to produce large-area colloidal crystal films through the spray-painting technology. Accordingly, a well-executed palette of structural colors was prepared by alternately spraying the inks containing PS colloids of 195, 215 and 272 nm onto the glass substrate (Figure 3A). The optical characteristics of multiple photonic bandgaps indicate that their colors originate from the overlay of different colloidal crystal deposits (Figure 3B). More attractively, the intermittently air-sprayed film displays identical colors rather than angle-dependent colors shown in conventional colloidal crystal film (Figure 3C). This feature can be attributed to the hemispherical symmetry of the dome-shaped deposits, resulting in identical photonic responses independent of the rotation of the axes. Accordingly, an orange-colored “Dragon” pattern was facilely prepared on a flexible polyethylene glycol terephthalate (PET) film (Figure 3D). This feature frees us from heavy synthesis burden and provides a simple but effective route to prepare full-spectrum structural colors with the synergy effects of colloid species.

Figure 3. (A) Colloidal crystal films with diverse colors attained by alternately spraying the PS Colloids. (B) Optical photographs and corresponding reflectance spectra of the colloidal crystal films obtained by alternately spraying. (C) Optical images and reflectance spectra of the films at different viewing angles. (D) The angle-independent dragon pattern on PET films.

Conclusions

In conclusion, a “colloid skin”-regulated drying strategy was demonstrated in this work to achieve better control over the colloid deposition processes. Accordingly, the coffee-ring effect could be sufficiently suppressed. Perhaps, more importantly, this “colloid skin” concept suggests the development of a new broad-spectrum kind of film-forming strategy, and the issues associated with the asymmetrical evaporation process of latexes could be addressed. Also, this “colloid skin” concept could be applied in film forming of other water-borne resins, and thus a number of defects occurred during film forming for other waterborne films might be easily solved.

Abstract

Through microfluidics and chips a variety of particles self-assembled more complex shapes, anisotropic nature, and diverse functionalities. We group develop an available magnetic-directed assembly strategy to construct a series of molecular-analogue photonic crystal cluster particles involving dot, line, triangle, tetrahedron, and triangular bipyramid configurations from solid–liquid Janus building blocks. These versatile multiplex molecular-analogue structural clusters can open a new promising access to a variety of robust hierarchical microstructural particle materials.

Introduction

Photonic crystal have received increasing attention due to their potential for applications such as remote manipulation, electrophoretic displays, self-assembly of multidimensional ordered structures, and sensors.1,2 Herein, we developed a triphasic microfluidic-directed self-assembly to construct supraparticles with controllable and predictable shape, and selectively introduced advanced functions to them.2 The triphasic microfluidic technique is a co-flowing system that produces continuous microdroplets comprising two immiscible phases. By adjusting the interfacial tension of each phase in the microfluidic system, supraparticles with tunable shape, varying from crescent, meniscus, and ellipsoid to spherical were prepare by the self-assembly of the monodisperse colloidal particles in these microdroplet templates.3 In this work, we demonstrate an operable magnetic-directed assembly strategy to engineer PC particles into a series of molecular-analogue superstructural morphologies based on Janus building blocks. Herein, Janus building block composed of colloid PCs as the solid hemisphere and superparamagnetic nanoparticles confined in the other liquid part can be successfully designed via triphasic microfluidics. Importantly, diverse functions can be integrated into the colloid PCs hemispheres of the Janus building block by loading fluorescent dyes or quantum dots (QDs), whereas the superparamagnetic liquid hemispheres allow the formation of hierarchical anisotropic structures via their coalescence upon collision under externally magnetic field, which confer the resulting materials on remote-controlled locomotion function.

Discussion

Figure 1 presents the entire preparative strategy for producing magnetic-fluorescent PC clusters. Well-defined poly(styrene-co-2-hydroxyethyl acrylate) (PS-co-PHEA) cores and poly(Nvinylimidazole-co-2-hydroxyethyl acrylate) (PVI-co-PHEA) shells were designed as micoreactors for the fundamental carrier to fabricate CdS QDs-loaded hybrid latexes, enabling PC to have both photonic bandgap and fluorescent properties. In the first step, we chose monodispersed PS-co-PHEA colloids as cores and poly(VI-co-HEA) hydrogels as shells to synthesize core–shell structural monodispersed colloids via seeded emulsion copolymerization. Taking advantage of the chelation of PVI within a shell to coordinate Cd2+. CdS QDs with yellowish green fluorescence were in situ prepared within monodispersed microspheres after introducing a sulfur source (Na2S). Next, a triphasic microfluidic device

Figure 1. Anisotropic photonic crystal clusters constructed from solid–liquid Janus building blocks.
To realize batch production of molecular-analogue photonic crystal structures, the magnet array was designed and applied for the organization of Janus building blocks. As described in Figure 2a, the magnetic needle array was immobilized on a flat substrate with the configuration of hexagonal modules. Because the Janus units can freely rotate under magnetic field, when the vessel containing solid–liquid Janus building blocks was placed on the magnet array (Figure 2b), the liquid hemispheres oriented toward the nearest magnet, driving the mobile of Janus units to the corresponding magnet needle. The Janus building blocks then met at the center of the magnetic field, and their liquid hemispheres collided and merged with each other into a larger hierarchical one (Figure 2c–e). After the magnet array was removed, the solid compartments on the surface of liquid always appeared as the colloidal molecules with spherically symmetric distribution (Figure 2f).

Figure 2. The assembly process of solid–liquid Janus building blocks into PC clusters under magnet arrays.

Conclusions

We have successfully established a robust strategy to fabricate a series of molecular-analogue photonic crystal structures with hierarchical microarchitectures based on solid–liquid Janus building blocks. The exceptional performance of these architectures presents a significant step toward construction of complex anisotropic particle materials with diverse geometries and versatile functions. The capability to precisely tune PC clusters into multiantangular configurations (dot, line, triangle, and tetrahedron to triangular bipyramid) unlocks a vast potential for pipelined integration of photoelectricity material toward information communication. With this approach, we assert that various well-controlled molecular-analogue supraparticles can be designed and applied in anticounterfeiting, biolabeling, and information encoding.

Abstract
A novel method for facile preparation of photonic crystal (PCs) bead two-dimensional (2D) code patterns through microfluidic 3D printing technology is developed. Poly(styrene-methyl methacrylate-acrylic acid)-CdTe/ZnS (P(St-MMA-AA)-CdTe/ZnS) hybrid microspheres with structure color and fluorescence are prepared by conjugating P(St-MMA-AA) and CdTe/ZnS quantum dots (QDs) using PAMAM dendrimers as bridges. This work open a promising way for the fabrication of multi-signal 2D code patterns with structural color and fluorescent properties, which has potential application in anti-counterfeiting and optoelectronic field.

1. Introduction
Photonic crystals (PC) have attracted intensive interesting due to their unique optical properties and extensive applications. Owing to their bright structure colors, PCs can be applied to construct multicolor patterns with bright, tunable and fadeless colors, which have potential applied in various fields of sensing, display, detection and security areas. Much effort has been carried out to manufacture the functional PCs patterns, such as inkjet printing, screen printing, 3D-printing and microfluidic. However, it is still a great challenge to improve their information capacity, color quality and functional performance, which are essential for practical applications. In this work, we exploit a facile method to precisely construct PCs 2D code patterns via microfluidic 3D printing technology, where PC beads were served as pixels. The as-prepared PCs patterns possessed both structural colors in daylight and fluorescence under UV light as well as it could be applied to facilely construct 2D robust codes. This novel microfluidic 3D printing technology developed in this work may pave a new way for the fabrication of multifunctional PC patterns.

Discussion
The synthesis process of P(St-MMA-AA)-CdTe/ZnS hybrid microspheres is exhibited in Fig.1 (a). Firstly, we prepared monodisperse core-shell P(St-MMA-AA) microspheres by taken polystyrene (PS) as a core using seed emulsion copolymerization. Then, the as-prepared colloid particles with abundant carboxyl groups were further grafter with generation 2 polyamindoamine (G2 PAMAM) dendrimers with rich terminal amino groups. Taking advantage of the interaction between the functional groups on the surface of CdTe/ZnS QDs and dendrimers, we successfully synthesized the P(St-MMA-AA)-CdTe/ZnS hybrid microspheres (Fig. 1a).

![Figure 1](image1.png)

![Figure 2](image2.png)
in Fig. 2(a), the hybrid microspheres keep a well-defined spherical shape. The core-shell structure of microspheres can be clearly in sight in Fig. 2(b), which testifies that the hybrid microspheres are surrounded by CdTe/ZnS QDs. Fig. 2(c) shows the uniform dispersion of QDs with an average particle size of 3-4 nm on the surface of the microspheres. The high-resolution TEM (Inset in Fig. 2(c)) reveals the distinct lattice fringes of CdTe/ZnS QDs with the lattice spacing of about 0.34 nm, corresponding to the crystal plane of cubic CdTe/ZnS QDs (111). The lattice structures were further attested by XRD analysis. Three characteristic peaks at 2θ values of 24.3°, 40.4°, 47.7° are clearly observed in curve 1 of Fig. 2(d), corresponding to the (111), (220), (311) planes of cubic CdTe/ZnS QDs structure. The as-synthesized P(St-MMA-AA)-CdTe/ZnS hybrid microspheres (curve 3 of Fig. 2(d)) exhibit three characteristic peaks at the same values with CdTe/ZnS QDs, which is non-existence in P(St-MMA-AA)-G2 PAMAM microspheres (curve 2 of Fig. 2(d)). Above all, the results confirm this method realize the loading of QDs on the PCs.

For practical applications, we applied the as-fabricated PCs with fluorescence for 2D code patterns. Microfluidic 3D printing technology was adopted to fabricate PCs 2D code patterns using trimethylolpropane triacylate (TMPTA) as external phase and hybrid microspheres as internal phase (Fig. 3(a)). Through precise control and arrangement of the PC beads, we successfully achieved 2D code pattern with two structural colors (red and green) (Fig. 3(b)), which also presents two fluorescence colors (red and green) under UV light (Fig. 3(c)). Compared with the traditional 2D code, the PCs bead 2D code was designed by endowing every pixel with special photonic bandgap and fluorescence features thus giving the code with information transmission and anti-counterfeiting potentials. Despite immense progresses have been made, much efforts should be donated into improving information capacity of PC patterns. That motivates us to explore multifunctional PC patterns to satisfy the demand in practical applications.

Conclusions

In conclusion, we developed a new method for the rapid preparation of multi-signal PCs 2D code pattern through microfluidic 3D printing equipment. CdTe/ZnS QDs are loaded onto the surface of P(St-MMA-AA) microspheres by in situ reaction, endowing the hybrid microspheres with fluorescence properties. In virtue of a microfluidic 3D printing device developed in this work, we fabricated multi-signal PC 2D code pattern with different structural colors and fluorescent properties, which shows great potential in anti-counterfeiting and sensing applications.

Abstract

The paper shows the recent process towards the design of flat focusing optics in the near field and the far field. An important feature of the near-field flat focusing mirrors - the transverse invariant, i.e. they do not possess any optical axis, very different from the far-field flat optics. The paper also summarizes the near-field and far-field flat optics with a future outlook.

1. Introduction

Over the last few years, scientists have started crafting tiny, thin and flat lenses with a new methodology as shown in Fig. 1. Flat optics have been studied recently by with planar artificial nanostructures such as metasurface [1]. Such subwavelength-spaced phase shifters on the metal–dielectric interface can introduce abrupt phase variations in incident waves by either resonant phase retardation. However, to focus a light as a spherical lens, the nano-patterns on the flat optics must follow a radial distribution of phase discontinuities. Therefore, they unavoidably present optical axes due to symmetrically customized structures.

On the other hand, a new physical principal of flat focusing with a negative refractive index (NRI), also called a ‘left-handed’ medium, was proposed by the Russian scientific Victor Veselago theoretically [2]. The main advantages of such unprecedented flat lens are its transverse invariant and an arbitrary large NA, that traditional curved lenses/mirrors can never achieve.

Over the past decades, the implementations of these focusing features had generally been realized by the artificial materials in transmission but none of them were studied for focusing upon reflection. Until a few years ago, the authors demonstrated the first flat focusing mirror, which provided an adequately long focal length in the near field [3]–[7]. Such unprecedented features open new challenges for focusing and imaging arrangements.

2. Near-field and far-field focusing

2.1. Near-field focusing

The approach to making a near-field flat lens without an optical axis has been demonstrated by the near-field flat focusing mirror (FFM). These FFMs can focus a point source or a tightly-focused beam, regarded as a superposition of different plane waves propagating at different angles by manipulating the lateral displacement. The principle of the FFM relies on the anomalous dependence of the lateral shift $s$ of the different light rays on the angle of incidence, as illustrated in Fig. 2. The condition is that the slope of the lateral displacement with respect to the angle of incidence should be negative. All the observations are compatible with the requirement of a negative slope of lateral shift with respect to angles and such a condition can also be applied to Pendry’s flat lens as shown in Fig. 2a.
Spatial manipulation of radiation in optical systems is conventionally performed by curved lenses/mirrors which represent a well-known type of far-field focusing. It should be noted that the focusing mechanism of carefully engineered high-contrast gratings (HCGs) and metallic optical antennas (metasurface) is based on far-field lensing. These planar focusing devices modulate the transmitted/reflected phase by tailoring spatial distribution symmetrically and it modifies the angles of refraction (far-field components) as shown in Fig. 3.

On the other hands, ultrathin flat lenses have undergone considerable development based on HCGs and metasurfaces, they all present optical axes like conventional lenses. It is not possible to eliminate the optical axis because the spatial modulation on a large spatial scale breaks the transverse invariance.

4. Conclusions

To conclude, this paper is devoted to the idea of flat focusing devices especially for focusing upon reflection with a prominent property: they do not have any optical axis. The review starts with the thoughtful discussion about different focusing mechanisms between far-field lens/mirrors and near-field lens/mirrors.

3. Discussion

All the evidences show that the topic of flat focusing mirrors without any optical axis is relevant, innovative and groundbreaking. Such flat focusing mirror will be a major improvement towards widespread future application of flat optics that will certainly attract the interest of the industry.
Classification of deformed photonic Dirac cones

Jungmin Kim, Sunkyu Yu, and Namkyoo Park

Photonic Systems Laboratory, Department of Electrical and Computer Engineering, Seoul National University, Seoul 08826, Korea
*corresponding author, E-mail: nkpark@snu.ac.kr

Abstract

We investigate the classification of photonic band structures in relation to the perturbed effective Hamiltonian for the Γ-point eigenmodes and their eigenfrequencies. As an example, by top-down engineering the relative spectral distribution of monopole and dipole modes, we classify the modification of the Dirac dispersion. The behavior of wave phenomena inside the designed structure, such as anisotropic Dirac dispersion, will also be discussed.

1. Introduction

The discovery of the massless Dirac fermion in graphene has opened a new horizon in condensed matter physics [1]. The photonic Dirac cone (PDC) for electromagnetic waves, as an optical analogue of the Dirac cone in electronics, has also attracted much attention due to various peculiar phenomena near the PDC, including the zero effective index of refraction [2], and a topological edge state [3].

Compared to the electronic Dirac cone in the graphene structure on the K and K' edges of the Brillouin zone, which originates from the parity symmetry of two basis atoms [4], in contrast, the accidentally induced triple degeneracy of the PDC at the Γ-point is not protected by such symmetries [2]. Therefore, the PDC is very sensitive to the on-site potential; a very small perturbation in elemental dielectric rods could result in to the collapse of the PDC.

This delicacy in PDC structure on the other hand, could provide a new degree of freedom for the manipulation of the band structure near the Dirac point. For example, the PDC spawns a ring of exceptional points under the broken time-reversal symmetry [5]. There also exist several reports on the splitting of a Dirac cone into a pair of bulk Fermi arcs, carrying a nontrivial topological charge due to the broken rotational symmetry [6]. Connected with the topological properties, the manipulation of PDC band structures has recently become an emerging topic, covering broad areas of research: including topological photonics, metamaterials, and quantum-optical analogy.

Here, we apply the effective Hamiltonian theory for the systematic description and classification of the modulated PDC band structure. By examining the influence of each term on the variation of the band shape, we also discuss the modulation of the Γ-point eigenmode.

2. Results

We begin with a theoretical model to examine the band structure at the vicinity of the Γ-point. This model enables the prediction of the effect of the Γ-point eigenmode and eigen frequency on the band shape.

In a two-dimensional structure, the governing harmonic equation with frequency ω and TE-mode (E_z) wave is given by \( \nabla^2 E_z + k_0^2 \epsilon(r) E_z = 0 \), where \( k_0 = \omega/c \) and \( \epsilon(r) \) is the periodic function of relative permittivity for a nonmagnetic square-lattice photonic crystal. Due to the discrete translational symmetry, \( E_z \) is expressed by a Bloch wave \( E_z(r) = e^{ik \cdot r} u_k(r) \). Using the k \( \cdot \) p perturbation theory, this equation can be approximated as an eigenvalue equation: \( \hat{H}(k) |u_k\rangle = \omega_k |u_k\rangle \), where

\[
\hat{H}(k) = \begin{pmatrix}
\omega_s & v_x k_x & v_y k_y \\
v_x^* k_x & \omega_{px} & 0 \\
v_y^* k_y & 0 & \omega_{py}
\end{pmatrix}
\]

and \( |u_k\rangle \) is a vector spanned by \( \{|s\rangle, |p_x\rangle, |p_y\rangle\} \) basis [6]. Here \( \omega_s (\omega_{px}, \omega_{py}) \) and \( |s\rangle (|p_x\rangle, |p_y\rangle) \) denotes the monopole (dipole) eigenfrequency and corresponding mode profile at the Γ-point. \( v_x \) and \( v_y \) are overlap constants determined by the eigenmodes.

We emphasize that the relative values of the diagonal terms (\( \omega_s, \omega_{px}, \) and \( \omega_{py} \)) significantly affect the topology

![Image](https://via.placeholder.com/150)

Figure 1: Lattice schematics (upper) and their band dispersions calculated by the effective Hamiltonian theory along \( k_x \) and \( k_y \) axes (lower) for (a) the photonic Dirac cone: \( \omega_s = \omega_{px} = \omega_{py} \), (b) the parabolic–like dispersion: \( \omega_s > \omega_{px} = \omega_{py} \), and (c) the anisotropic Dirac dispersion: \( \omega_s = \omega_{px} = \omega_{py} \).
of the Hamiltonian on the \( k \)-space. For instance, we obtain the PDC characterized by linear dispersions as depicted in Fig. 1a, by setting \( \omega_s = \omega_{px} = \omega_{py} \), while achieving a parabolic-like dispersion with flat band and bandgap in the case of \( \omega_s \neq \omega_{px} = \omega_{py} \) (Fig. 1b) \[7\]. The dispersion shown in Fig. 1c, where the linearity of the band structure retains along \( x \)-directions but not for \( y \)-direction \[8\] is realized in the case of \( \omega_s = \omega_{px} > \omega_{py} \).

3. Conclusions
We developed an effective Hamiltonian theory for the photonic band structure, especially for the classification of the deformation of the PDC. We expect an engineering of direction-selective linear dispersion based on our results. We will also discuss the design principle of the PDC photonic crystal structure based on our approach, for the realization of controlled band structure, and the wave flows.

Abstract

We present the study of bound surface modes sustained at the termination of truncated bulk dielectric photonic crystals and isolated metasurfaces of dielectric meta-atoms. We discuss the origins of bound modes in the two systems and their relation. For both systems, we theoretically study and experimentally demonstrate wavefront manipulation, in particular directional emission, frequency splitting and beam collimation achieved by coupling of the bound states to radiation modes through leaky wave radiation mechanism using properly designed scattering gratings.

1. Introduction

Surface modes are non-radiating states that are found bound to the interface of different media. Traditionally bound states have been investigated at the interface of semi-infinite dielectric and metallic interfaces at the optical frequencies, the known, so-called surface plasmon polaritons (SPP). SPPs offered a very good platform for highly confining propagating waves and may enable the minimization of electromagnetic components. However, at the same time, dielectric/metalllic SPPs suffer from high dissipation losses which pose various application restrictions. However, it was also known that bound states can also be supported in dielectric media. These bound states stem from the excitation of coupled Mie resonances in the dielectric system and lead to light confinement (Mie modes are generally more spatially extended than SPPs). The fact that dielectric media suffer no dissipation losses has brought the non-radiating bound states at the center of attention of composite, all-dielectric resonant structures and metamaterials [1]. In this work we present two type of structures that sustain surface modes, one consists of a metasurface of dielectric meta-atoms [2] and the other consists of truncated photonic crystals [3]. In the first case we demonstrate experimentally that beam collimation can be sustained at large distance via a system of cascading dielectric metasurfaces and in the other case we present the controlled directional emission engineered at the exit of photonic crystal line defect waveguide. For both cases we present the corresponding experimental demonstration which is conducted in the microwave regime and provides a proof of concept verification our analysis. The dielectric structures are be scaled down for the optical/NIR regime [4]. Additionally we will present a theoretical framework that analyses the nature and the origins of the bound surface states in the termination of truncated bulk photonic crystals and their relation to bound states sustained in isolated dielectric metasurfaces.

2. Discussion

The first structure under consideration consists of a system of dielectric metasurface bilayers; the first layer of each bilayer supports surface states and the rear, the grading layer couples the surface states to radiation modes. The first layer of each bilayer consists of 35 alumina circular rods with a lattice constant of \( \alpha = 11 \text{ mm} \), while the second layer of square alumina rods with lattice constant \( b = 2\alpha \). The experimental set-up consists of an HP E8364B network analyser, a horn antenna as the transmitter and a dipole antenna as the receiver. The horn antenna transmits a Gaussian beam with \( E \) polarization (the electric field parallel to the dielectric rods) and the dipole antenna scans the 2D experimental table, measuring the intensity of the local field at the exit of a system of bilayer dielectric metasurfaces at the resonant frequency: case of (a) two metasurfaces and (b) four metasurfaces structure. (c) Normalized \( x \) cross section field distribution for the two cases at propagation distance 100λ.

![Figure 1: Simulation of the 2D field strength at the exit of a system of bilayer dielectric metasurfaces at the resonant frequency: case of (a) two metasurfaces and (b) four metasurfaces structure. (c) Normalized x cross section field distribution for the two cases at propagation distance 100λ.](image)
photonic crystal terminate by a dielectric layer of the same periodicity and different size than the bulk photonic crystal. The dispersion diagram of the surface state in the bulk termination, shown in red, stands within the photonic crystal

![Dispersion diagram](image)

Figure 2: Dispersion diagram in a bulk, infinite dielectric photonic crystal of dielectric rods. The dispersion curves are calculated via the plane wave expansion method for the infinite periodic structure. (b) Dispersion curves for the finite PC along with the surface layer. They are calculated by applying the plane wave expansion in the supercell shown above. The surface mode dispersion is plotted in red; it lies within the badgap and below the light line (blue curve), and occurs at 10.1−12.2 GHz.

bandgap and below the light line which indicates that the mode is dark, bound between in the surface layer the bulk photonic crystal and the air as it is presented in Figure 2. It is in fact almost identical to that of the isolated metasurface of the dielectric of rods. This indicates that the origins of the surface states in the both system are similar. A line defect waveguide formed in the bulk photonic crystal feeds the dark mode that propagates to the exit sides of the structure. A grating layer with double periodicity placed after the surface layer undertakes the coupling of the surface modes into forward radiation. Forcing a small asymmetry in the grating layer leads to the frequency selective modification of the angle of the forward propagating waves. The angle of the emission obeys the surface mode dispersion and grating equation that describes the leaky wave radiation mechanism. In Figure 3 we present the experimentally measurement and numerical study of the near and intermediate field exciting the line defect waveguide. For the experimental study we use the same set-up as described in the discussion of Figure 1. Oblique directionality at different frequencies is observed enabling the frequency splitting operation. Similar

![Experimental and simulated 2D plots](image)

Figure 3: Experimental (a) and simulated (b) 2D plot of the strength of the outgoing near and intermediate field at the exit of a photonic crystal terminated by a surface layer and an asymmetric grating layer at frequency $f_{\text{exp1}} = 11.70$ GHz and $f_{\text{exp2}} = 11.68$ GHz. Axis $x$ is parallel to the grating layer and axis $y$ perpendicular to the grating layer. Experimental (c) and simulated (d) 2D plot of the intensity of the outgoing near and intermediate field at frequency $f_{\text{exp1}} = 10.20$ GHz and $f_{\text{exp2}} = 10.18$ GHz.

operation can be achieved in silicon based inverse photonic crystal for operation in the near infrared and optical regime. The corresponding structure and operation is thoroughly discussed in Ref. [4].

3. Conclusions

We studied theoretically and demonstrated experimentally the realization of wavefront manipulation functions based on the excitation and handling of dark bound surfaces states in dielectric resonant media such as photonic crystals and periodic metasurfaces made of dielectric meta-atoms. In particular, we have demonstrated the sustaining of the beam collimation is possible in a system of cascading dielectric metasurfaces. Additionally we showed that frequency selective, directional emission from a line defect photonic crystal waveguide can be attained if the bulk photonic crystal is properly terminated. The characteristics of the bound states are similar for the two systems indicative of their common origins. Experiments have been conducted in the microwave regime and the structures can be directly scaled in the near infrared and optical frequencies. Due to the absence of ohmic losses, the non-radiating bound states provide a promising platform for the manipulation of light attract the growing attention of the nanophotonic community

Abstract

In this paper we show a silicon nitride external cavity (SiN EC) laser based on a 250µm long AlInGaAs Reflective Semiconductor Optical Amplifier (rSOA) edge-coupled to a series of Si₃N₄ waveguides side-coupled to Si₃N₄ 1D photonic crystals that acting as wavelength selective resonators mirror. The laser shows power outputs over 5 mW, lasing threshold of 25 mA with a characteristic Side-Mode Suppression Ratio in the range of 45 dB. This laser shows a mode-hop free lasing regime over a range of 50 mA (from 25 mA to 70 mA). Further on, the 1D photonic crystal resonators are 50um long and 2um wide, leading to reduction in footprint of this type of reflector by a factor of 30 compared to conventional gratings. All of this, combined with the very low thermo-optic coefficient of Si₃N₄ leads to neglectable wavelength drifts with temperature, paving the way to integrated SiN EC laser in Dense WDM and optical interconnect technologies, where transceivers have to operate over a wide temperature range without requiring active cooling.

1. Introduction

The ever-increasing demand higher data transmission bandwidths in long and short range telecommunications [1], leads to a critical need for new and energy efficient narrow linewidth laser sources which are compact and cost-effective in order to be integrated in dense Wavelength Division Multiplexing (dWDM) technology.

This kind of optical interconnects have to be employed in small spaces and in extreme environments that expose them to significant temperature variations, which fundamentally affects their wavelength of operation, hence complicating their utilization in application that require accurate wavelength control and stability, namely WDM [2]. Furthermore, Complementary Metal-Oxide Semiconductor (CMOS) processing is the only technology in which is possible to achieve fabrication of photonics in a cost-effective manner, due to the strict high yield and fabrication repeatability requirements.

The very inefficient light emission properties of silicon are greatly hindering the employment of the promising Silicon-On-Insulator (SOI) platform in optical applications. However, lattice mismatch and CMOS compatibility problems greatly reduce direct III-V materials growth and integration as active medium for WDM lasers.

Our solution to this problem consists in the deployment of hybrid external cavity lasers [2,3], whose cavity is composed by a commercially available Reflective Semiconductor Optical Amplifier (RSOA) edge-coupled to waveguides on a silicon nitride chip, which are side-coupled to 1D photonic crystals to function as narrow resonators.

This configuration allows separate fabrication of the active and the passive chips, unlocking the possibility of separate optimization of the chips and the independent modulation of the external cavity of the laser.

Currently, optical links for WDM applications in most datacenters and operating at telecom wavelengths consist in DBR lasers and external modulators [4]. These devices are actively cooled [5] to counter the operating wavelength thermal drifts due to the high Thermo-Optic Coefficient (TOC) of the material subjected to the varying temperatures of the operation environment. This leads to a very high energy consumption and cost.

However, the very low TOC and free-carrier absorption of Si₃N₄ compared to silicon and its CMOS compatibility make it a valid material alternative for this of hybrid lasers, which have already shown a greatly reduced wavelength thermal stability [6].

In this paper we demonstrate a single-mode hybrid EC laser based on SiN 1D photonic crystal cavities, which operates in a mode-hop free regime over a broad range of driving currents, exhibiting low threshold, high power and 10 times narrower resonances compared to conventional Distributed Bragg Reflectors, to further improve laser stability. Furthermore, the 1D resonators are reducing footprint on the silicon chip by a factor of 30 compared to gratings, greatly enhancing integrability. Moreover, the wavelength thermal stability of the laser due to Si₃N₄ TOC could eliminate the need of active cooling of any kind, potentially making this type of lasers the devices of choice for WDM applications.
2. Laser Design

Figure 1a. shows schematics of one of the SiN 1D photonic crystal cavity side coupled to the waveguide. Figure 1b. shows the RSOA edge-coupled to the SiN chip. The waveguides on the silicon nitride chip have been designed to match the mode on the output of the RSOA, thus lowering coupling losses. The 1D photonic crystals are 50 μm long by 2 μm wide, greatly reducing the resonators footprint on chip, unlocking the route to high integration densities and high channel counts and allowing for short cleaving of the chip to improve packaging solutions. The 1D SiN resonators have been designed to operate in the S, C and L telecommunications bands. Intrinsic Q-Factors have been calculated in the range of $3 \times 10^6$ and FWHM of the resonances have been measured to be approximately 0.09 nm.

![Figure 1 - a. Schematics of the 1D photonic crystal cavity side-coupled to the waveguide, b. schematics of the RSOA edge-coupled to the SiN chip](image)

The RSOA consisted in a 250 μm long gain composed by AlInGaAs quaternary quantum wells, in which the prevention of carriers leakage provided by the Al$^{3+}$ ions at temperature over 60°C [7], leading to an improvement of the RSOA emission at high temperatures. The end facet of the RSOA was AR coated to be used as one of the mirror of the laser, achieving a reflectivity of approximately 90%.

Each carrier injected in the RSOA recombine inside the quantum wells, generating a photon. The light emitted is then coupled to the SiN waveguide and is guided towards the end facet of the SiN chip. The portion of light not in resonance with the resonators is completely transmitted and dropped at the output of the SiN chip. The on resonance component of light on-resonance instead evanescently couples into the 1D photonic crystal cavity on the side of the waveguide and is partially coupled out in the waveguide towards the RSOA, leading to a wavelength-selective amplification loop between the resonator and the reflective edge of the RSOA, that constitutes the mirrors of the laser, whose characteristics are predicted by the overlapping of the gain curve and the longitudinal modes of the cavity.

3. Experimental Results and Discussion

The spectra of transmission of the 1D photonic crystal cavities have been collected through an end-fire setup, in which the light of a broadband source was propagating through an optical fiber, was collimated into the waveguides on the sample through a system of lenses and the light was collected on the output of the waveguides in an optical spectrum analyzer and a photodiode.

![Figure 2 - Optical spectrum of the normalized transmission of one of the 1D photonic crystal cavities](image)

After measuring the passive chips, the characteristics of the laser have been measured with increasing driving currents, with both the RSOA and SiN chips standing on temperature controlled stages. Figure 2 shows the hybrid EC laser time-averaged optical spectrum plotted in a false color map against increasing driving current. By accurately matching the longitudinal mode of the laser cavity with the resonance of the 1D photonic crystals, a mode-hop free single mode lasing regime has been achieved over a broad range of currents, from 21 mA to 70 mA. A low lasing threshold of 20 mA has been recorded.

![Figure 3 - Time-averaged optical spectrum of the EC laser against driving current](image)

The light at the end facet of the SiN waveguide was collimated with a lens onto a power-meter sensor, and the hybrid EC lasers power have been measured to be all in the range of 3 to 5 mW.

4. Conclusions

To conclude, we have demonstrated a hybrid single mode EC laser based on SiN 1D photonic crystal cavities coupled
to a RSOA gain chip, characterized by low lasing threshold of 20 mA and high output power in the mW range, showing a mode-hop free regime over the driving current range from 21 mA to 70 mA, further improvable with AR coatings of the SiN chip. This associated with the very low TOC of SiN paves the way for future deployment of very compact photonic crystal cavities based SiN chips, with densely spaced resonances, coupled to arrays of RSOAs to build a network of low-cost, compact and potentially athermal transmitters, reducing their energy consumption, thus making these hybrid EC lasers the devices of choice for cost-effective dWDM technologies.

Emerging applications
Broadband photoacoustic microscopy based on surface plasmon resonance sensing

Changjun Min1*

1 Nanophotonics Research Centre, Shenzhen University, 518060, China

Abstract

The ability to accurately detect pressure transients is critical for photoacoustic (PA) imaging of anatomic and functional information in biological tissues. Here, we propose a surface plasmon resonance (SPR) sensing approach for PA pressure detection, relying on the modulation of PA pressure to the refractive index. We realize a much broader PA bandwidth more than ~170 MHz and in vivo imaging of the microvasculature from mouse ears. This SPR sensing method has great potential in PA imaging for biomedical investigations.

1. Introduction

Relying on rich optical absorption contrasts within biological tissues, photoacoustic (PA) imaging technology contributes significantly in revealing physiological and pathological processes of biological tissue [1,2]. As a result of biomolecules’ light absorption to laser pulses, pressure transients are produced thermo-elastically, which subsequently generate broadband ultrasounds (i.e., PA waves). Physiological information carried in PA waves allows for quantifying blood flow, oxygen metabolism, and cell micromorphology [3]. Among various PA imaging technologies, optical-resolution photoacoustic microscopy (OR-PAM) has attracted increasing attentions in biomedical researches, since its optical-diffraction-limited lateral resolution leads to better understanding to optical absorption-based molecular specificities at the cellular and even subcellular level.

OR-PAM usually employs piezoelectric transducer for ultrasonic detection, which is not sufficient for responding PA pressure transients due to the very limited bandwidth (centered at its resonance frequency) originated from inherent physical properties of the piezoelectric materials [4]. This degrades the resolution capability along the depth direction in OR-PAM, resulting in one order of magnitude worse compared to its lateral resolution.

Optical technologies of ultrasonic detection offer a promising alternative that potentially addresses the drawbacks in PA imaging, such as plano-concave optical microresonator, Fabry-Perot interferometer, and light interferometry. Unfortunately, inadequate frequency response (less than 70 MHz) can only give the PAM’s depth resolution of more than 20 μm. Recently, optical surface wave (OSW) sensing approaches, such as surface plasmon resonance (SPR) sensor [5] and polarization-dependent reflection ultrasonic detection (PRUD) [6], have been developed for detecting PA pressure. However, low sensitivity in both SPRS and PRUD leads to very limited signal-to-noise ratio (SNR) in PA imaging.

2. Principle and Method

OSW sensing of ultrasonic waves offers opportunities to overcome the aforementioned difficulties from the traditional piezoelectric transducers. Here, we developed PAM system incorporating an OSW senser for PA detection. The sensor is configured at Kretschmann structure (Figure 1a), consisting of a gold layer deposited onto the surface of a quartz prism. A drop of deionized water serves as the coupling medium of laser-induced acoustic waves. In this work, we adopted the 50-nm thickness gold film as the sensing material, respectively. Figure 1b shows the light field distribution of the sensor with Au layer as a function of incident angle. Its angular-dependent reflectance spectra indicate that only the p-polarized electric field vector with the typical incident angle can excite the SPR. While SPR is independent on the s-polarization component.

Figure 1: (a) Schematic diagram of optical surface wave (OSW) sensor for PA pressure detection. (b) Angle-dependent light reflection of p- and s-polarized light for SPR-based sensor.

During PAM imaging, a nanosecond laser pulse is focused onto the sample, generating ultrasonic pressure transients that sequentially impinge on the interface of the water (the coupling medium) and the sensing layer (Au film). Thus, a time-varying RI within the water is caused from...
compressions and strains of the ultrasonic mechanical force, leading to temporal perturbations in the polarization-dependence OSW sensing. In consequence, we achieve a PA transient measurement by recording the time-varying light intensity difference between $s$- and $p$-polarization reflectance.

3. Results and discussion

We study the response of the OSW sensors to the PA pressure transient in Figure 2. A PA point source is created by coating a 30-nm graphene film onto a glass sheet. For the SPR sensor, Figure 2a shows the time-resolved PA impulse and its frequency spectrum with a 6-dB bandwidth. The frequency component up to $\sim 170$ MHz (Figure 2b) indicates an estimated axial resolution of $\sim 7.8\ \mu m$.

Distinct from other optical technologies of ultrasonic detection, strongly-localized evanescent field forms nearby the interface, enabling a rapid temporal response. Thus, the PA pressure detection achieves an enhanced bandwidth of more than 100 MHz. Additionally, the sensors potentially quantify the optical absorption more accurately because the broadband detection effectively alleviates the saturation limitation.

In vivo images from mouse ears are acquired by the OSW-based PAM system. Based on strong optical absorption of hemoglobin at 532-nm illumination, PAM can noninvasively image the vasculature. With PAM equipping with the OSW sensor, both the major blood vessels and capillaries (with an estimated diameter of less than 10 $\mu m$) are visualized. During PA imaging, the excitation laser energy in the SPR-based sensor maintains equal values at 500 nJ per pulse. Both images of microvascular structures are observed at nearly identical SNR, suggesting the comparable ultrasonic detection sensitivity.

4. Conclusions

Based on the high detection sensitivity and broadband frequency response of the SPR sensor, we developed an OR-PAM system giving spatially isometric resolutions of a few micrometers. Label-free volumetric imaging was performed of the vascular microarchitecture in mouse ear in vivo. This photoacoustic microscopy may help in visualizing other anatomical sites, including the brain and the eye, and provide high-resolution information in biomedical research, including tumor microenvironments, neuroscience, and ophthalmology.

Abstract

An experimental study of Bloch surface wave (BSW) based sensor which utilizes a one-dimensional photonic crystal (1DPhC) is presented. The 1DPhC is represented by a multilayer interference filter and we measure the response of a BK7 prism/multilayer/analyte system in the Kretschmann configuration. Dip in the reflectance spectrum for s-polarized wave represents the coupling of light wave to BSW and this is demonstrated for air and water. When the angle of incidence is decreased the dip depth is substantially enlarged due the conversion of the BSW to the radiation mode. We also model the response of the system and confirm agreement with the experiment.

1. Introduction

Bloch surface waves (BSWs) are waves that exist at the interface between a periodic system and homogeneous dielectric. In comparison to the surface plasmon wave propagating along the interface between a dielectric and thin metal film [1], BSWs are waves within the forbidden bandgap of a photonic crystal that can be excited at any wavelength by suitably changing the refractive indices and thicknesses of the dielectric materials in a multilayer structure. Consequently, sensors based on BSW are mechanically and chemically robust offering the possibility of operation in various environments and applications [2, 3, 4].

In this paper, an experimental study of BSW based sensor which utilizes a one-dimensional photonic crystal (1DPhC) is presented. The 1DPhC is represented by a multilayer interference filter comprising TiO$_2$ and SiO$_2$ layers of different thicknesses and we measure the response of a BK7 prism/multilayer/analyte system in the Kretschmann configuration. Dip in the reflectance spectrum for s-polarized wave is demonstrated for air and water, and when the angle of incidence is decreased the dip depth is substantially enlarged due the conversion of the BSW to the radiation mode. The theoretical model for the above system confirms good agreement between the experiment and theory.

2. Experimental method

The experimental setup used for measurement of s-polarized reflectance comprises a halogen lamp, a launching optical fiber terminated by collimating lens from which a light beam passes through the coupling equilateral prism made of glass BK7 to which a slide with a multilayer system, parameters of which are specified elsewhere [5], is attached. After the reflection from the structure, the light beam passes through analyzer oriented at 90° with respect to the plane of incidence, so that s-polarized component is propagating. The light is coupled into a read optical fiber which is connected to a spectrometer. In the experimental setup, the angle of incidence was varied [6, 7] to resolve the resonance.

3. Experimental results

First, we have used the setup to confirm experimentally that the resonance takes place for a suitable angle $\alpha$ between the incident beam and the normal to the entrance prism face. As an example, in Fig. 1 are shown the spectral dependencies of the response for s-polarized beam and two angles $\alpha$, when the analyte is air. It is revealed that for angle $\alpha = 28^\circ$ a resonance takes place due to excitation of the BSW and this is accompanied by a shallow dip in the signal at a wavelength of 813.18 nm. For angle $\alpha = 29^\circ$ a resonance in the signal with the largest depth takes place due the conversion of the BSW to the radiation mode [5] at a wavelength of 818.12 nm.

Contrary to the surface plasmon resonance, for which the resonance takes place for p-polarized component, in this case s-polarized component is responsible for the dip. In addition, the dip is substantially narrower compared to the SPR dip [6]. Similarly, in Fig. 2 are shown the spectral dependencies of the response for s-polarized beam and wa-

![Figure 1](image-url)

**Figure 1:** The spectral dependence of s-polarized signal for air and two angles of incidence $\alpha$. 
Figure 2: The spectral dependence of s-polarized signal for water and two angles of incidence α.

Figure 3: The theoretical spectral dependence of s-polarized signal for air and two angles of incidence θ.

Figure 4: The theoretical spectral dependence of s-polarized signal for water and two angles of incidence θ.

4. Theoretical results

To model the response of the multilayer system represented by the interference filter, the sample was inspected by scanning electron microscopy and five layers of TiO₂ and four layers of SiO₂ were revealed. Material characterization of glass substrate and layers [5] was done employing a technique of the variable angle spectral ellipsometry (VASE, Woolam, Inc.). In addition, we assumed that the extinction coefficients for TiO₂ and SiO₂ layers are $1.6 \times 10^{-3}$ and $3.4 \times 10^{-4}$ [8], respectively. To express the response of the structure for s-polarized wave, a transfer matrix method [5, 7] was used.

Figure 3 shows the spectral dependencies of the theoretical response for s-polarized beam for air and two angles of incidence θ. It is clearly seen that for angle $\theta = 41.5°$ a resonance takes place due to excitation of the BSW and this is accompanied by a shallow dip in the signal at a wavelength of 810.6 nm. In this case, an exponential tail of the surface wave in the analyte is obtained from the intensity distribution $|E|^2$ in the structure at the resonance wavelength [5]. For angle $\theta = 41°$ a resonance with the largest depth takes place due to excitation of the BSW to the radiation mode at a wavelength of 813.2 nm. In this case, irradiation from the structure is obtained which is supported by the intensity distribution $|E|^2$ in the structure at the resonance wavelength [5]. Similarly, Fig. 4 shows the spectral dependencies of the theoretical response for s-polarized beam for water and two angles of incidence θ. For angle $\theta = 62°$ a resonance takes place due to excitation of the BSW and this is accompanied by a shallow dip in the signal at a wavelength of 696.8 nm, and for angle $\theta = 61.5°$ a resonance with the largest depth takes place due the conversion of the BSW to the radiation mode at a wavelength of 702.7 nm. The results obtained are in good agreement with the experimental ones.

5. Conclusions

In this paper, an experimental study of surface electromagnetic wave sensor utilizing a 1DPhC has been presented. The 1DPhC is represented by a multilayer interference filter, and the response of the system comprising a BK7 prism/multilayer/analyte in the Kretschmann configuration has been measured. We have revealed a shallow dip in the reflectance of s-polarized wave demonstrating a surface wave resonance. When the angle of incidence is decreased, the dip depth is substantially enlarged due the conversion of the BSW to the radiation mode, which is promising for sensing applications. Experimental results obtained for air
and water are supported by theoretical results. A transfer matrix method has been applied and good agreement between the results has been achieved.

In comparison to the surface plasmon resonance, the BSW or radiation mode resonance dip is narrower, but the sensitivity is approximately one order of magnitude lower. In any case, multilayer systems are mechanically and chemically robust so that the BSW based sensors are promising in various applications.

Abstract
We fabricated a nanowire array using titanium nitride, which has a high melting point, by dynamic oblique deposition of titanium and subsequent thermal treatment in ammonia. The opposite signs of in-plane and out-of-plane permittivity indicate that fabricated nanowire array behaves as a hyperbolic metamaterial. The nanowire array presented here is a promising candidate for hyperbolic metamaterials in high-temperature applications due to the high melting point of titanium nitride.

1. Introduction
Hyperbolic metamaterials (HMMs) are attracting attention due to the unique properties arising from their extreme optical anisotropies[1]. HMMs are characterized by the hyperbolic dispersion relation of the isofrequency surface $\left( k_x^2 + k_y^2 \right) / \varepsilon_\parallel + k_z^2 / \varepsilon_\perp = (\omega / c)^2$, where $k_x$, $k_y$, and $k_z$ are the $x$, $y$, and $z$ components of the wave vector, respectively, $\omega$ is the angular frequency, and $c$ is the speed of light). The hyperboloid shapes in the dispersion relation appear when the out-of-plane permittivity $\varepsilon_\perp$ and the in-plane permittivity $\varepsilon_\parallel$ have opposite signs. This unique dispersion relationship offers potential for exotic applications such as subwavelength imaging[1] and broadband super-Planckian radiative heat transfer[2].

Metal nanowire arrays (NWAs) are promising candidates for HMMs because $\varepsilon_\parallel > 0$ while $\varepsilon_\perp < 0$[1]. Unique applications of metal NWAs have been reported including negative refraction, near-field thermal transfer, and thermal waveguides. Conventional metal NWAs for HMMs have been fabricated by embedding noble metals with low melting points, such as Ag, in an anodic alumina membrane dielectric host[3]. However, the low melting temperature of noble metals limits the potential of these metal NWA HMMs for high-temperature applications such as thermophotovoltaics[4].

Titanium nitride (TiN) is attracting attention as an alternative to noble metals for metamaterials because of its similar optical properties to Au, high melting point (> 2900 °C), and chemical stability[5]. TiN is being considered for high-temperature applications such as broadband absorbers and plasmonic heating.

In this study, we fabricated a TiN NWA by dynamic oblique deposition of Ti and subsequent thermal treatment in ammonia. The optical anisotropy of the TiN NWA was characterized by spectroscopic ellipsometry.

2. Method

2.1. Fabrication of the TiN NWA.

The titanium NWA was fabricated on a fused quartz substrate using electron beam deposition. For the deposition source material, a granular Ti metal (99.9%, Kojundo Chemical Lab.) with a diameter of 10 mm and thickness of 5 mm was used in a carbon crucible. The substrates were set at a parallel distance of 40 mm and a height of 250 mm from the metal source. The titanium NWA was annealed in ammonia using argon as the carrier gas. The crystal structure was characterized by X-ray diffraction measurement (XRD). The cross-section image of the sample was observed using a field emission scanning electron microscope (FE-SEM) after ion-beam polishing. The surface morphology was observed by a FE-SEM.

The observed peaks of XRD matched those of TiN well. Figures 1 (a) and (b) show the cross-sectional SEM image and the image observed from above, respectively. The TiN NWA was found to be densely fabricated on the SiO$_2$ substrate. The average height and diameter of the nanowires deduced from the cross-sectional SEM image were 1.7 μm and 110 nm, respectively.

![Figure 1: SEM images. (a) Cross-section image. (b) Image observed from above.](image)

2.2. Evaluation of the optical anisotropy

The optical anisotropy of the fabricated TiN NWA was characterized by spectroscopic ellipsometry. Spectroscopic ellipsometry measures the amplitude ratio $\Psi$ and phase difference $\Delta$ between s- and p- polarizations.

The measured spectra of ellipsometric parameters $(\Psi, \Delta)$ are fitted by a Fresnel reflection theoretical model considering the optical anisotropy and multiple reflections occurring in the nanowire layer.

The in-plane and out-of-plane permittivity were described by using Bruggeman effective medium theory.

---
where \( \varepsilon_{\text{air}} \) and \( \varepsilon_{\text{TiN}} \) are the permittivities of air and TiN, respectively, \( f \) is the volume fraction of TiN, and \( g \) is a depolarizing factor that is set as 0.5 for the in-plane component of permittivity \( \varepsilon_{\text{eff},\perp} \), \( g \) is 0 for the out-plane component of permittivity \( \varepsilon_{\text{eff},\parallel} \). \( \varepsilon_{\text{TiN}} \) is expressed by the Drude–Lorentz model as

\[
\varepsilon_{\text{TiN}} = \varepsilon_b - \omega_p^2/(\omega^2 + i\gamma) = \varepsilon_b - \omega_b^2/(\omega^2 - \alpha^2 - i\gamma),
\]

where \( \varepsilon_b = 3.13 \), \( \omega_b = 5.26 \) eV, \( \gamma_b = 1.12 \) eV, \( f_1 = 3.45 \), \( \omega_1 = 1.50 \) eV, \( \gamma_1 = 1.50 \) eV, and \( f = 0.43 \). The literature values of SiO\(_2\) permittivity are used for the substrate.

![Figure 2: Real part of in-plane (solid line) and out-of-plane (dashed line) components of the permittivity.](image)

The spectra of the real part of \( \varepsilon_{\text{eff},\parallel} \) and \( \varepsilon_{\text{eff},\perp} \) determined by fitting the experimental ellipsometric parameters are shown in Figure 2. The real part of \( \varepsilon_{\text{eff},\parallel} \) exhibits positive values. On the other hand, the real part of \( \varepsilon_{\text{eff},\perp} \) is negative for wavelengths longer than 850 nm.

3. Discussion

Opposite signs of \( \varepsilon_{\text{eff},\parallel} \) and \( \varepsilon_{\text{eff},\perp} \), shown in Figure 2 produce the hyperbolic dispersion of isofrequency surfaces. The TiN NWA was characterized as an HMM for wavelength longer than 850 nm. HMMs with positive \( \varepsilon_{\text{eff},\parallel} \) and negative \( \varepsilon_{\text{eff},\perp} \) are called type-I HMMs, and HMMs with negative \( \varepsilon_{\text{eff},\parallel} \) and positive \( \varepsilon_{\text{eff},\perp} \) are called type-II HMMs[1]. The TiN NWA presented here is classified as a type-I HMM, and type-I HMMs have more advantageous optical loss than type-II. Type-I HMMs in the near infrared and infrared ranges are desirable for thermal applications such as thermal waveguides[6]. The TiN NWA in this study is a particularly promising candidate for thermal waveguides because TiN has a high melting point, and the metal NWA maintains type-I hyperbolic dispersion in the infrared range[7]. Note that dynamic oblique deposition allows us to fabricate the TiN vertical nanostructure without nanofabrication techniques such as lithography. In addition, the fabrication technique shown here is suitable for large-scale production.

4. Conclusions

In conclusion, we fabricated a TiN NWA using the dynamic oblique deposition of Ti and subsequent thermal treatment in ammonia. Spectra of ellipsometric parameters were fitted by a Fresnel reflection theoretical model considering the optical anisotropy, in which the effective permittivity was fitted using effective medium theory and the Drude–Lorentz model. The vertical component of the effective permittivity was negative at \( \lambda > 850 \) nm, whereas the horizontal component was positive, which indicates that the fabricated nanowires have hyperbolic dispersion of isofrequency surfaces. The TiN NWA presented here has potential for high-temperature applications such as thermophotovoltaics.

Abstract
Deposition of CuInS$_2$ (CIS) quantum dots (QDs) on ZnO nanowires (NWs) with interlayer of In$_2$S$_3$ as photoelectrode has been successfully fabricated on FTO via the facile solution routes for photoelectrochemical application. The morphology and structure of the CIS QD/In$_2$S$_3$/ZnO NWs heterostructure are systematically analyzed with a SEM, TEM and XRD. In comparison with pristine ZnO NWs, the CIS QD/In$_2$S$_3$/ZnO photoelectrode illustrates efficient charge separation and charge transport path to achieve the highest photocurrent of 2.4 mA cm$^{-2}$ that is competitive with other Cd- and Pb-free QD-based materials.

1. Introduction
Because solar light is a clean, sustainable, and abundant renewable source of energy, the conversion of solar energy into a usable fuel has attracted substantial attention in the last decades. Among all techniques for the solar conversion, a photoelectrochemical (PEC) process via direct conversion of solar energy into hydrogen fuel through water splitting by semiconductors constitutes an attractive solution. Although the intense efforts of various morphologies and materials of semiconductor electrodes on the PEC performance carried out in the recent years, the satisfaction of all the stability, efficiency, and cost conditions required for industrial products of this technology haven’t been achieved by single material [1]. The development of the hetero-structural photoelectrode for highly efficient PEC hydrogen generation is an important route. Recently, non-toxic I-III-VI$_2$ group QDs, especially CuInS$_2$ (CIS) QDs, with high absorption coefficient ($\sim$10$^5$ cm$^{-1}$) and tunable band gap energy are attractive alternatives to the highly toxic cadmium and lead chalcogenide QDs [2]. In the concern on the green process and nontoxic materials, we propose the CIS QD/In$_2$S$_3$/ZnO NW array as efficient photoanode, because the In$_2$S$_3$ has similar band width to CdS. In this study, the colloidal CIS QDs was synthesized by chemical solution route, and then the deposition of CIS QDs on ZnO NWs was utilized the dip-coating process while the ZnO NW was decorated the In$_2$S$_3$ layer by successive ionic layer adsorption and reaction (SILAR) method before used. Finally the CIS QD/In$_2$S$_3$/ZnO NW was thermally treated to remove the capping ligands. Significantly, this novel CIS QD/In$_2$S$_3$/ZnO NW photoelectrode illustrates the excellent PEC activity in comparison with CIS QD/ZnO NW and other Cd- and Pb-free QDs photoelectrodes.

2. Experiments

2.1. Electrode preparation
In the synthesis of CIS QDs, 1 mM of copper iodide and 1 mM of indium acetate were employed as precursors, and 5 ml of DDT was used as solvent, S donor, and capping ligand. Under vacuum, the reaction was heated for 30 min at 100 °C, and then the temperature was raised to 230 °C. To complete QDs synthesis, the temperature was kept constant, and the time of the reaction was hold for 30 min. After synthesis, the temperature was naturally cool down 25 °C, and the as-synthesized CIS QDs were stored in N$_2$-purged toluene until further utilization. In the synthesis of ZnO NW, a 10-15 nm thin layer of ZnO nanoparticles was deposited onto a FTO as seeded substrate by dip coating of 5 mM zinc acetate solution and heat treatment at 350 ºC for 5 minutes in air. The seeded substrate was placed in an aqueous solution containing 5 mM zinc nitrate, 5 mM hexamethylenetetramine, 5 mM polyethyleneimine, and 0.25 M ammonium hydroxide at 90 ºC for 5 h for the growth of the ZnO NW array. Subsequently, for the SILAR, 0.1 M InCl$_3$ and 75 mM Na$_2$S served as the precursor solutions of In and S ions. The ZnO template was immersed in the solution with order and time as InCl$_3$ 60 s, DI water 30 s, Na$_2$S 240 s, DI water 30 s, InCl$_3$ 60 s and DI 30 s in each cycle; this cycle was repeated and reproduced five times to fabricate the In$_2$S$_3$ nanostructure on the ZnO NW arrays. Then, the In$_2$S$_3$/ZnO NW was immersed into CIS QDs colloid for 3 s and rinsed with acetone. The as-prepared samples were then thermally treated at temperatures of 350 ºC in vacuum for 1 h.

2.2. Characteristic analysis
The morphology of hierarchical CIS QD/In$_2$S$_3$/ZnO NW arrays was examined with a scanning electron microscope (SEM, JEM-4000EX); the structure of the samples was analyzed with a X-ray diffractometer (XRD, Bruker D8 Advance, Cu K$_\alpha$ radiation, $\lambda$=0.1506 nm). The chemical states of the elements were determined by X-ray photoelectron spectra (XPS, Perkin-Elmer model PHI 1600). The detailed microscopic structure and the chemical composition of the CIS QD/In$_2$S$_3$/ZnO NW were
investigated using high-resolution scanning transmission electron microscopes (HR-STEM, JEM2010F and JEM2200FS operating at 200 kV, JEOL). The PEC characteristic of the electrodes was measured in 0.1 M Na₂S and 0.35 M Na₂SO₃ solution with a potentiostat/galvanostat (CHI 6273D).

3. Discussion

The morphologic variation of CIS QD/In₃Sₓ/ZnO NWs was determined by SEM images. Figure 1a-c shows the surface morphologies of ZnO NW arrays synthesized via the hydrothermal method and decoration of CIS QD. After coating In₃Sₓ and CIS QD layer on ZnO NW, their surface morphologies were displayed in Fig. 1c. The NW density is still remained, besides the slight aggregation of NWs owing to the evaporation of solvent during the SILAR process. To further analyze the heterostructural CIS QDs/In₃Sₓ/ZnO NWs, the HRTEM was performed. The Cu-, In-, S-, Zn- and O-compositions within single CIS QD/In₃Sₓ/ZnO multi-shell NW are also determined from EDXS line profiles, which are recorded along a line that passes through the NW and is perpendicular to its axis (Fig. 1d). SAED pattern of CIS QD/In₃Sₓ/ZnO NW (Fig. 1e) shows a few Debye-Scherrer rings with orange, green, and red colors, which can be attributed to the hexagonal ZnO, tetragonal CIS, and In₃Sₓ crystallites, respectively.

To realize the PEC performance of the CIS QD/In₃Sₓ/ZnO NW array electrode, 3-electrode PEC cell was adopted in an electrolyte of 0.1 M Na₂S and 0.35 M Na₂SO₃ solution for analysis. The photocurrent-potential curves of uncoated ZnO, and CIS QD/In₃Sₓ/ZnO NW arrays were recorded via linear sweep voltammetry (LSV) under continuous and chopped illumination, as shown in Fig. 2. The pristine ZnO NW shows low photocurrent of approximately 0.5 mA·cm⁻² owing to the narrow absorption region of UV light. Remarkably, the photocurrents were significantly enhanced and the dark current decreased after the deposition of In₃Sₓ layer in between the CIS QD and ZnO NWs. This indicates that the In₃Sₓ inner layer could compensate the band mismatch and facilitate the photo-induced electron transport to ZnO. The high photocurrent of 2.4 mA·cm⁻² can be achieved, which is two orders of magnitude greater than the CIS QD/ZnO NW sample and also higher than that of many other CIS-based photoelectrodes with Cd- and Pb-free.

![Figure 1: FESEM images of (a) pristine ZnO NWs, (b) In₃Sₓ/ZnO NWs, (c) CIS QDs/In₃Sₓ/ZnO NWs samples, (d) HAADF-STEM image of multi-shell NW and the quantification of the EDXS line scan, (e) SAED pattern of CIS QDs/In₃Sₓ/ZnO NW.](Image)

![Figure 2: LSV of ZnO NW and CIS QDs/In₃Sₓ/ZnO NW samples under illumination.](Image)

4. Conclusions

Hierarchical heterojunction of CIS QD/In₃Sₓ/ZnO NWs arrays were successfully synthesized by a dip-coating process in CIS QD colloids. While the ZnO NW was decorated the In₃Sₓ layer by SILAR method. Significantly, the CIS QD/In₃Sₓ/ZnO NWs photoelectrode exhibits excellent photocurrent of 2.4 mA·cm⁻², which is two orders of magnitude higher than that of pristine ZnO NWs.

Scattering-type scanning near-field optical microscopy and spectroscopy for real space observation of various polaritons

Philip Schäfer1*, Adrian Cernescu1, Sergiu Amarie1, Andreas Huber1

1neaspec GmbH, Haar (Munich), Germany
*Philip Schäfer, E-mail: philip.schaefer@neaspec.com

Abstract
Scattering-type Scanning Near-field Optical Microscopy and Spectroscopy is the ideal mean for the nano-scale analysis of sub-wavelength excitations in 2D-materials and meta-materials. Confining an incident light beam to the apex of a metallic AFM tip allows the local excitation as well as the local detection of phonon polaritons, exciton polaritons and surface plasmons. This enables a new routine analysis tool for quantum phenomena on the 10-nanometer length scale and sub-picosecond time scale.

1. Introduction
Two-dimensional materials like graphene, boron-nitride or transition-metal dichalcogenides are of rising interest for novel plasmonic and opto-electronic applications due to their unique characteristics and their broad application range. However, being highly sensitive to the local environment, their properties can strongly vary on the nanometer length scale, severely limiting the macroscopic performance of such novel devices. Scattering-type Scanning Near-field Optical Microscopy (s-SNOM) and nanoscale FTIR spectroscopy (nano-FTIR) systems have become the key technology to understand and resolve these limitations by measuring the optical and electronic properties of such nanostructures down to the 10-nanometer length scale.

2. s-SNOM on 2D-materials and metamaterials
Scattering-type Scanning Near-field Optical Microscopy (s-SNOM) is a scanning probe approach to optical microscopy and spectroscopy bypassing the ubiquitous diffraction limit of light to achieve a spatial resolution below 20 nanometers. s-SNOM employs the strong confinement of light at the apex of a sharp metallic AFM tip to create a nanoscale optical hot-spot. Analyzing the scattered light from the tip enables the extraction of the optical properties (dielectric function) of the sample directly below the tip and yields nanoscale resolved images simultaneous to topography [1]. In addition, the technology has been advanced to enable Fourier-Transform Infrared Spectroscopy on the nanoscale (nano-FTIR) [2] using broadband radiation from the visible spectral range to THz frequencies. Alternatively, interferometric s-SNOM can be used to map the nanoscale distribution of local optical fields.

2.1. Dirac plasmons in graphene
First visualization and analysis of Dirac plasmons propagating along graphene was realized using infrared light focused to the AFM tip in 2012. These studies demonstrated graphene plasmon interference mapping that allowed the direct extraction of local material properties such as conductivity, intrinsic doping and defects [3, 4]. Furthermore, relation with the control parameters: gate voltage, refractive index of the substrate and incident light were characterized. Direct control of propagating surface plasmons on graphene with resonant antennas and conductivity patterns could further be demonstrated [5, 6]. Additionally, the highly flexible design of our s-SNOM microscope enables a complete new level of correlation microscopy: near-field microscopy in ultrafast pump-probe configuration [7] could identify an increase in the effective electron temperature upon NIR pump and monitor its pico-second relaxation dynamic. s-SNOM could also be applied for the investigation of carrier relaxation in high-purity graphene in 2D-heterostructures [8] as well as for near-field photocurrent measurements on graphene device structures [6, 9]. Furthermore, a technological breakthrough in the field of near-field optics has been achieved with cryogenic near-

Figure 1: s-SNOM images of graphene at 8.5 K: a) optical amplitude; b) optical phase.
field imaging and spectroscopy, by the group of Dimitri Basov [10]. With the new cryo-neaSNOM we also extend our s-SNOM to the cryogenic temperature range (<10-300 Kelvin) and open a complete new world for nanoscale optical microscopy and spectroscopy [Figure 1]. This technology enables for example the direct mapping of phase-transitions in strongly correlated materials or the detection of low-energy elementary excitations at the surface of solid-state systems.

2.2. Exciton polaritons in molybdenum diselenide

Molybdenum diselenide is a known van der Waals semiconductor which can be used as medium for excitonic transfer in nanophotonic circuits. With s-SNOM it is for the first time possible to observe the propagation of exciton polariton modes in real space [11]. A phenomenal propagation length of up to 12 µm at room temperature was found. The exciton polariton wavelength was revealed to be controllable by the waveguide thickness.

2.3. Phonon polaritons in hexagonal boron nitride

Also phonon polaritons in van der Waals crystals of hexagonal boron nitride could be observed in real space using s-SNOM [12]. Reading out the phonon polariton wavelength directly from the interference pattern near the crystal edges led to a dispersion relation that turned out to be dependent from the number of atomic layers. By designing a hyperbolic meta-surface based on nanostructured hexagonal boron nitride, concave wavefronts could be demonstrated by using an Au-nanorod as the phonon polariton launcher and the AFM tip as the near-field probe [13].

3. Conclusions

s-SNOM proves itself inevitable for the characterization of fundamental excitations in 2D-materials and metamaterials. Only with this technology, waves like surface plasmons, exciton polaritons and phonon polaritons can be observed in real space with 10-20 nm spatial resolution. Moreover, s-SNOM allows ultrafast spectroscopy on the femtosecond time scale, and even measurements at cryogenic temperatures. Hence, s-SNOM will ultimately play a major role in future investigations of photonic nanostructures.

Nanostructuring of Graphene Membranes with Focused Ion Beams: Towards 2D Metamaterials

Ivan Shorubalko

1Empa – Swiss Federal Laboratories for Materials Science and Technology, Dübendorf, Switzerland
*corresponding author, E-mail: ivan.shorubalko@empa.ch

Abstract

Nanostructuring of two-dimensional membranes with focused ion beams is demonstrated to be a promising technique for creating metamaterials. Few-nanometer-small structures with a down to ten nanometer period are demonstrated in graphene. Understanding the interaction between focused ion beams and freestanding 2D materials is crucial for exploiting the method towards novel metamaterials.

1. Introduction

One of the important physical length-scales in electronic devices/materials is the charge carrier mean-free path (MFP). Fabricating devices with a characteristic feature size smaller than MFP leads to ballistic transport mechanisms dominating the conventional diffusive transport picture [1]. Consequently, these devices are called ballistic devices and exhibit various novel electronic properties that may survive to the THz regime due to their nature. Ballistic artificial nanomaterials – engineered to have novel properties that may not be found in nature and classified as a type of metamaterials, Fig.1(a) [2]. These materials can be envisioned as THz rectifiers. Electrical rectification in graphene based individual nanodevices has been demonstrated at room temperature [3, 4]. MFP in such typical graphene material is of sub-100nm. A large part of graphene research is devoted to its nanostructuring or modification on the nanometer scale. Except standard electron-beam lithography many other different techniques have been proposed and explored over the last decade. Most advanced method to controllably create true-nanoscale structures and even individual defects in suspended graphene is its irradiation by high energy electrons in transmission electron microscope (TEM). Nevertheless, the throughput and practicality of TEM method are limited. Sputtering by energetic focused ion beams (FIBs) has been envisioned and to a large extend demonstrated as a powerful method to create nanostructures in graphene [5-8]. Here we report on pushing the limits of this technique in several aspects: resolution, reproducibility, homogeneity, and throughput. Essential understanding of the graphene (or any other 2D material) sputtering by FIBs can be done by rather simple binary collision theory (BCT). Periodic arrays of a million of few-nm-small pores with narrow size distribution can be fabricated in free-standing graphene. Such perforated ultrathin membranes already find their applications in the field of quick and energy efficient filtration [9].

2. Experimental/Theoretical Study

He- and Ga- FIB tools are used to irradiate and pattern free-standing graphene. Scanning (transmission) electron microscopy and He-ion microscopy (HIM) are used for high resolution imaging. Raman focal spectroscopy is used for defect characterization.

Figure 1: a) Scanning electron microscope image of an artificial functional material. The arrows indicate the typical electron trajectories. The devices operate similar to a bridge rectifier [2]. Triangles base is 200 nm large. b) Helium ion microscopy image of perforated graphene membrane with He-FIB, period is 30 nm. Inset shows a typical pore diameter distribution in nm. c) Triangular pore in graphene by He-FIB. Scale is 10 nm.

3. Discussion

Exposing free-standing graphene to the controlled He- and Ga-ions irradiation allows precise determination of the sputtering yield. Graphene shows to be semi-transparent for 10-30keV energetic He-ions. 99-97% of He-ions pass graphene without crating lattice defects. In contrast, large Ga-ions spatterarbon carbon atoms from graphene layer in 80-50% incidence cases, depending on kinetic energy 5-30keV.
Binary collision theory (BCT) explains well these experimental findings. Raman spectroscopy of damaged graphene reveals the defect formation mechanisms. He-ions create individual carbon vacancies until these defects overlap and amorphization occurs. Ga-ions can form mono and double vacancies as expected from BCT. Understanding the physics of the sputtering process allows to fabricate pores in graphene of only a few nm in diameter, ~2nm for He-beam and ~4nm for Ga. Eventually limited by ion beams diameters [8]. A million of nm-pore arrays are fabricated showing narrow pore diameter distribution, Fig.1(b). Pores as small as 10 nm and still resembling its triangular shape can be created in graphene, Fig.1(c).

4. Conclusions
Sputtering yields of free-standing graphene by He- and Ga-FIBs are experimentally determined. Defect density is measured by irradiation dose and compared to the extracted from Raman D to G peaks ratio. Binary collision theory is shown to be sufficient for explaining essential involved phenomena. Few-nm-small pores in graphene are demonstrated by He- and Ga-FIBs sputtering. Large-scale nanostructuring of graphene with small size-variation distributions is demonstrated. The method can be extended to other 2D membranes. Triangular (symmetry breaking) pores in graphene are be scaled down to 10 nm. These dimension length scales cross several physical length scales in typical 2D materials, such us: charge carriers and phonon mean free path. Presented study opens a way towards electrical rectifier metamaterials, frequency multipliers in THz range, phononic crystals and thermal rectifiers.

Abstract

The fabrication of complex periodic metallic nanostructures has been performed at a wafer scale by combining ‘Double’ Displacement Talbot Lithography (D2TL) and lift-off. Given the high flexibility and efficiency of D2TL, a broad range of periodic configurations can be achieved from one mask, which could facilitate applications in numerous fields, including metamaterials, nanoplasomics or nanophotonics.

1. Introduction

Periodic patterning is essential for many technologies that use plasmonic [1-2], or photonic nanostructures [3-4]. Among the various lithography techniques employed in research, and to a certain extent in industry, none of them combines a fast, cheap and flexible approach to fabricate those patterns.

In this work, we present an upgrade of a new high-throughput and fast lithography tool called Displacement Talbot Lithography [5]. By introducing lateral displacements, the creation of a variety of complex periodic nano- to micron patterns can be achieved over a large area (up to 100-200 mm). [6] Combined with a lift-off process, a broad range of periodic metallic nanostructure arrays have been achieved for the creation of meta-material structures.

2. Methods

2.1. D2TL patterning

Displacement Talbot Lithography (DTL) utilizes the periodic diffraction pattern on all space axes that results when a periodic mask is illuminated by a planar wave (Talbot effect). By displacing the wafer along the axis of illumination over integer spatial periods, the low depth of field is overcome [5]. In D2TL, by additionally moving the wafer perpendicular to the axis of illumination, the range and complexity of features achieved from a single mask is dramatically extended. Furthermore, a single periodic mask can be used to create a large number of different patterns by using different lateral displacements (Fig. 1).

Figure 1: A selection of SEM images showing the variety of patterns that can be achieved from using a hexagonal mask with 800 nm features on a 1.5 um pitch (top) with classical DTL using positive and negative photoresist, and (bottom), the large numbers of structures that can be realized with D2TL using the same mask and just positive resist.
2.2. Metallic structure lift-off

The transfer of the resist structures has been then performed thanks to a combination of Inductively Coupled Plasma etching (ICP) into a dielectric layer, and wet etching with low-dilution hydrofluoric acid (HF) to control the undercut profile. A metal deposition has then been realised via e-beam evaporation. The result of the patterns transferred in SiN and the one after the lift-off process are presented in Fig. 2.

Abstract

A unique freestanding nickel (Ni) metallic mesh based electromagnetic interference shielding film has been fabricated though the direct-writing technique and a subsequent selective metal electrodeposited process. The structured freestanding Ni mesh film demonstrates a series of advantages, including ultrathin thickness (2.5-6.0 \(\mu\)m) and ultralight weight (0.23 mg cm\(^{-2}\)), extraordinary optoelectronic performance, and outstanding flexibility that it can withstand folded, rolled up and crumpled into various shapes while keeping the conductivity constant. Experimental results show that the film yields an average electromagnetic interference shielding effectiveness about 40 dB with transparency of 92%.

1. Introduction

Electromagnetic radiation pollution, severely exacerbated by the development of modern electronics packed with highly integrated circuits, leads to harmful effects on sensitive precision electronic equipment as well as the living environment for human beings, promoting the research focus on novel high-performance EMI shielding. Significantly, with the development of modern electronics toward being flexible and integratable, the EMI shielding film must simultaneously provide high optical transmittance, excellent EMI shielding effectiveness (EMI SE), and meanwhile bendability even twistability which is imperative to adapt to complex shaped or foldable applications. The fabrication of an ultrathin transparent freestanding metallic mesh EMI film, breaking off the tradeoff of the transmittance and EMI SE has never been reported. It remains a significant technological challenge to develop metallic materials that exhibit all the above-mentioned desirable features simultaneously.

Herein, we demonstrate the realization of a freestanding, ultrathin, lightweight, mechanically robust, and transparent Ni metallic mesh-based EMI shielding film. The ultrathin freestanding Ni mesh contributes to excellent flexibility, folding or even attaching to three-dimensional shapes with ignorable degradation of the EMI shielding efficiency. It also allows a free permeation of gas and liquid molecules, such as oxygen, moisture, etc., showing excellent air permeability. This Ni mesh films are characterized with extraordinary optoelectronic properties: a transparency about 92\%-93\%, a sheet resistance of 0.24-0.7 \(\Omega\) sq\(^{-1}\), and a high EMI about 40 dB shielding efficiency in 8.2-12.4 GHz frequency range (X-band) for plane and crooked Ni-mesh films. Above all, the high-performance Ni-mesh EMI film processing excellent electrical conductivity, high EMI SE, outstanding transmittance and mechanical properties are promising EMI materials for practical applications.

2. Discussion

2.1. Sample preparation and characterization

The fabrication process of the freestanding Ni-mesh mainly includes four steps, which are illustrated in Fig. 1(a). First, a photoresist layer with a thickness of 9.6 \(\mu\)m was obtained by spin-coating onto a pre-cleaned ITO glass. Then, the patterned micro-trenches on the photoresist layer was generated by the laser direct-writing technique. Following on, the Ni metal was electrodeposited inside the predefined micro mesh grooves though the selective electrodeposition, and the deposition time was carefully controlled to obtain the Ni metallic mesh layer with a desired thickness. Thanks to the space confinement of the micro-grooves, the Ni mesh only grow inside them without a broadening in the linewidth. Lastly, the Ni mesh conductive films were finally accomplished after being peeled off from the ITO glass substrate. For all the obtained samples, the width of the Ni line is fixed on 5 \(\mu\)m with the thickness ranging from 2.5 to 6.0 \(\mu\)m. Therefore, the sheet resistance can be adjusted in a wide range while keeping the transmittance of the Ni mesh film almost unchanged.

The metallic mesh fabrication method can be scaled up to the large area, and a 10\times10\ cm\(^2\) Ni mesh film is obtained, as shown in Fig. 1(b). The freestanding Ni mesh film is completely transparent that the flower can be seen clearly through it. And meanwhile it exhibits excellent flexibility so that can be uniformly attached to complex shaped objects without any gap, such as the flower stem and the grape and even can stand upon the setaria viridis with sides dropping down naturally, which mainly attributes to its freestanding structure nature. Moreover, when the Ni mesh film was placed on the Albizia julibrissin, the flower filaments can even sustain their original state without any visible damage, delivering its ultralight features. For a 4.0 \(\mu\)m thickness Ni mesh film with an area of 10\times10\ cm\(^2\), it only weighs 23.1 mg [Fig. 1(c)] showing a density of 0.23 mg cm\(^{-2}\), while this lightweight Ni mesh still can sling a 100 g weight, more than 4000 times of the Ni mesh own weight.
When the weight was laid down, the Ni mesh film appears intact without any deformation, which was attributed to the firm texture of the Ni mesh.

Figure 1. (a) The schematic illustration of the fabrication process of the freestanding Ni mesh conductive film. (b) The characterizations of freestanding Ni metallic mesh: (i) large-scaled, (ii) high optical transparency, (iii), (iv) flexible and (v), (vi) lightweight properties. (c) (i) The weight of a scaled 10×10 cm² Ni mesh film with 4.0 μm thickness, (ii) a 100 g weight and (iii) the mechanical property of the Ni mesh film. (d) SEM images with different scale bar.

2.2. Experimental Results and Discussions

To evaluate the EMI SE of those freestanding Ni mesh films, a vector network analyzer in the frequency of 8.2-12.4 GHz (X-band) is employed. Figure 2(a) shows the measured EMI SE spectra of transparent freestanding Ni mesh films with different thicknesses in the X-band frequency range. The EMI SE of the Ni mesh films exhibit similar tendency, whose values decrease gradually along with the increasing frequency. The EMI SE values of the 6-μm-thick Ni mesh film decrease from 41 to 38 dB with the frequency increases from 8.2 to 12.4 GHz, whereas the values of the 2.5-μm-thick Ni mesh film decline from 37 to 35 dB. We illustrate that the Ni mesh film with increased thickness performs better in EMI shielding, attributing to the gradually increased electric conductivity. The simulated data further confirms our experimental results, as shown in Fig. 2(b), in which the electric conductivity corresponds to calculated ones at different thicknesses. Furthermore, to adapt to complex 3D objects, such as nonplanar and irregular surfaces, the influence of bending curvatures of freestanding Ni mesh films on EMI SE has been investigated. According to Fig. 2(c), it is apparent that the EMI SE value trend of spherical Ni mesh films with a curvature of 0.3 cm⁻¹ is in accordance with the complanate one. At the same frequency, SE is only 1 dB lower for the spherical Ni mesh film, in which the inappreciable gap can be ignored. In addition, as shown in Fig. 5(d), the EMI SE performance of the freestanding 4.0-μm-thick Ni mesh film with different curvatures of 0.45 cm⁻¹, 0.65 cm⁻¹, and 1 cm⁻¹ was also tested, respectively. At the same frequency, EMI SE value decreases slightly with the decrease of the curvature radius, and the overall difference between them is within 1 dB. Compared with the flat Ni mesh film, the decrease in EMI SE of the curved Ni mesh films is within 3 dB, which can fully meet the requirements of the EMI shielding in complex topography. It is noteworthy that the freestanding Ni mesh here can maintain the high mechanical stability after being bended for thousands of cycles, and simultaneously hold high EMI SE values, as depicted in Fig. 2(e). To make a comparison with the metallic shielding materials in the recently reported works [1-3], as presented in Fig. 2(f), where the EMI SE and the transparency properties of our freestanding Ni mesh films are all superior to those reported.

![Figure 2](image-url)

(a) The measured EMI SE of plane Ni mesh films in X-band, (b) the theoretically calculated EMI SE of plane Ni mesh films, (c) the EMI SE of spherical Ni mesh films. (d) The EMI SE curves of the Ni mesh film with a thickness of 4 μm with different curvatures. (e) The EMI SE variation of a 4.0 μm thick Ni mesh film with different bending cycles. (f) A comparison of the EMI SE versus transmittance characteristic of the measured sample with various flexible transparent EMI films in literature.

3. Conclusions

In conclusion, we demonstrate an ultrathin, lightweight, freestanding Ni mesh film that are fabricated by the direct-writing technique with a selective metal electrodeposited process, exhibiting EMI shielding efficiency ~40 dB in X-band and high mechanical flexibility (can be attached, folded, stretched, and crumpled into any shapes with almost no performance degradation). This freestanding metallic mesh structured electrode can be further explored or applied in various potential applications, such as conformal microwave antennas, transparent EMI windows, and wearable electronics.

Abstract

FIB nanofabrication has proven unique strengths by numerous applications in R&D prototyping [1]. Moreover the slow patterning speed of direct FIB milling itself (as compared to resist-accelerated lithography) can be overcome by the method of sketch & peel. With the help of a sketch-tape method isolated metallic structures can be created by milling only the outline of the design elements. Here we further investigate sketch & peel as well as its applications employing various ion species.

1. Introduction

Focused ion beam (FIB) systems are valuable tools for nanofabrication and rapid prototyping tasks in R&D by providing direct, resistless, and three-dimensional patterning. Although FIB milling in many cases is slower than a resist based process, the relative simplification of the overall nanofabrication approach helps to achieve scientific results faster. To extend the capabilities of FIB nanofabrication, the method of sketch & peel has been recently proposed for direct patterning of thin gold films [2]. With this method, FIB milling is able to create isolated metallic structures that are difficult to fabricate by conventional subtractive milling process. Considering that isolated metallic structures [3] are more favorable for investigating some optical properties but usually lead to unacceptable time-consuming processes by removing most of the gold layer, the sketch & peel method is supposed to be substantially useful for FIB nanofabrication applications. In this work we further investigate FIB sketch & peel method for nanopatterning of thin gold layers using various ion species. The combination of sketch & peel with high resolution milling is shown for examples of plasmonic patterns. Furthermore, we have employed continuous writing strategies based on a laser interferometer controlled stage movement for creating a seamless groove across extended distances. This enables the fabrication of mm sized patterns within minutes and at the same time nm features, still showing clean removal.

2. Sketch & peel method

Sketch & peel was first proposed by Y. Chen et al. for fast ion beam patterning of plasmonic structures on gold layers with Ga and He ions [2]. Instead of removing the layer material completely between the elements of a structure or array, the ion beam mills only the element outlines. The metal between these elements and outside the array can then be removed from the substrate by pasting and stripping a tape (figure 1).

Use of a low-adhesion layer is important for process reliability. Hence, no adhesive layer should be used between gold and substrate. Furthermore, the outline cut should be deeper than the metal layer thickness, to form a link between metal and substrate. Obviously the throughput gain mainly depends on pattern density and element size, but can be orders of magnitude higher than usual FIB milling.

3. Fabrication of large plasmonic arrays

Due to the high throughput of this process, large plasmonic arrays can be created with low beam currents and high resolution in a reasonable time. Furthermore, the elements inside these arrays can be combined with conventional low-dose and high-resolution cuts within the same milling step.

Figure 2 shows an example of such a combined process, with a 100 µm x 100 µm array of 10,000 bowties prepared on a silicon sample with 50 nm gold layer. Each single 300 nm bowtie is created by a surrounding deep outline cut and a final low-dose cut in the center to separate it into two triangles with sub-10 nm gaps. Here we used a beam current of only 1.7 pA Ga\textsuperscript{+}, resulting in 2 hours and 45 min process time. The gain in throughput is thus greater than a factor of 20 compared to conventional pure milling of the same array with the same beam current.

Another example of a plasmonic array is shown in figure 3. Here a 25 µm x 25 µm array of 625 gold nano-disks has been created by sketch & peel, including sinusoidal low-
dose cuts inside the disks. The complete pattern could be milled within a mere 25 min at 1.7 pA Ga+ beam current. This kind of nanoparticle arrays have been created earlier at Swinburne University using a mix and match process including EBL and FIB milling [4, 5].

Figure 2: Tilted SEM view of the inner part of a 100 µm x 100 µm bowtie array after peeling. The inlets show the bowtie design including low dose cut in the center and a single 300 nm gold bowtie with sub-10 nm gap.

Figure 3: Tilted SEM view of a 25 µm x 25 µm gold nano-disk array with 1 µm period. The inlet shows a single disk with 500 nm diameter including a sinusoidal low dose cross cut with 10nm gap.

Figure 4: 800 nm circles created with 4 different ion species and corresponding optimum line doses for successful sketch & peel.

5. Conclusions

Sketch & peel is a reliable method of extremely fast FIB patterning for low-adhesion metal layers. Elements with <100 nm to >1 mm in size can be created, whereas combination with high-resolution conventional milling enables sub-10 nm features. Due to the high throughput, an accurate laser interferometer stage and fixed-beam moving-stage writing modes are highly effective at creating even cm size patterns. Other low-adhesion layers than gold might be investigated in the future.

Abstract

The capability to fabricate variable-height structures with nanometre resolution is an answer to the ever-increasing demand for metasurfaces shape complexity. Here, we demonstrate that the shrinkage arising from the direct exposure of polymethyl methacrylate (PMMA) to an electron beam can be used to conveniently create structures with nanometre spatial resolution and realize variable height structures. Since the electron-beam can directly shape the PMMA, no additional fabrication steps such as development or lift-off are required. We employ direct-write electron-beam lithography (DW-EBL) to create spatial variations in the height of a Fabry-Perot (FP) cavity, resulting in a direct colour print without the need for pre-patternting that is necessary for some direct laser writing methods. In addition, the resolution and pixel size of the colour prints are limited by the electron beam. We also demonstrate colorimetric height measurements through image analysis of a DW-EBL patterned FP cavity. Finally, we fabricated blazed gratings which cannot be fabricated by conventional EBL methods without using development processes.

1. Introduction

With its high resolution and throughput, electron-beam lithography (EBL) has enabled the realization of metasurfaces, which require high spatial resolution [1–10]. The increasing demand for metasurfaces shape complexity requires additional degrees of freedom in fabrication, specifically the ability to achieve varying heights, which is not possible by the conventional EBL and its resists without multiple fabrication steps [11–13]. Although there are alternative fabrication routes such as grey-scale lithography [14], additive nanofabrication [15], liquid phase-focused electron beam-induced deposition (LP-FEBID) [16], and ion beam etching redeposition [17] which can achieve varying height structures and even more complex 3D patterning, these methods either lack the EBL resolution advantage, which is crucial to some metasurfaces, or need particular precursors, equipment, and additional processing steps. Moreover, variable-height patterns can be achieved by EBL through some resists without additional developing or lift-off. Our method circumvents the need for complex resists and fabrication processes and achieves complex topographies with the widely available PMMA.

Direct writing of structural colours offers numerous possibilities such as environmentally friendly and fadeless structural pigments, optical anti-counterfeiting, and camouflage [21–25]. However, direct laser writing, which is the most common method, often needs a prepared area. As an alternative, we used PMMA as the dielectric layer in a FP cavity and employed DW-EBL to realize stautred structural colours. Our approach does not need pre-patterning and benefits from the high EBL spatial resolution. The colours in a FP cavity are strongly dependent on the cavity length i.e., the PMMA layer’s thickness. Therefore, the colours from an optical micrograph can be used to determine structures height as was done by our image analysis and confirmed by AFM. Our method can be employed to directly obtain structure height information while directly patterning a surface, eliminating the need to carry out AFM measurements. Finally, we fabricated blazed gratings by EBL-DW, which otherwise cannot be realized by conventional EBL resists in a single step [2,26].

2. Results

The single-step fabrication method is illustrated in Fig. 1a. A 500 nm thick PMMA layer is sandwiched between two metallic layers to form a FP cavity. The bottom 100 nm thick Al layer acts as the back-reflector and the top 6 nm thick Ni layer acts as the partial reflector. Exposing the FP cavity to an e-beam results in local shrinkage of the exposed region, which results in a change in the FP resonance and the reflected colour. Since the optical cavity reflection properties and colours heavily depend on the polymer thickness, various colours would appear depending on the exposure dose, as shown in Figs. 1b and 1c. Thicknesses are measured by fitting the experimental reflection spectra to the simulation data and is further confirmed by atomic force microscopy (AFM) measurements.

A higher e-beam exposure dose results in larger thickness change as plotted in Fig. 1c. The rate of thickness change decreases with the increase of the dosage, and the thickness change reaches about 35% of the initial thickness for a maximum dose of 100 µs. The shrinkage mechanism of PMMA is illustrated in Fig. 1d. When the structure is irradiated by an e-beam, the PMMA mainly undergoes a backbone chain scission and ester group removal. In addition, large quantities of gases including CO, CO\textsubscript{2}, CH\textsubscript{2}, CH\textsubscript{4},OH, and other gaseous products are released [28–30]. Since most of the residue are either gaseous or volatile in the low-pressure e-beam chamber, they evaporate and as a result, the polymer undergoes a thickness change.
height variation of the multistep square obtained by analysing the optical image in (b). (d) AFM micrograph of the multistep square. The scale bars in (a) and (b) are 25 µm and 10 µm respectively. Optical micrographs in (a) and (b) are captured by a 20× objective lens.

The method is not limited to patterning FP cavities but can be employed to realize any pattern with variable heights on PMMA. Here we fabricated blazed diffraction grating to disperse light. Since the blazed grating has a variable-height profile, it cannot be fabricated by conventional e-beam resists in a single step i.e., resist developing step is still necessary. The blazed grating with sawtooth grooves is illustrated in Fig. 3a. The Optical and AFM micrograph along with gratings grooves profiles are shown in Fig. 3b-d. As can be seen from the AFM profile in Fig. 3c, the sawtooth profile can be achieved in a single step.

Figure 3a shows reflection spectra for x and y-polarized lights at the normal incident for a blazed grating. The diffraction efficiency η is shown for an x-polarized light at 20° tilted angle for blazed grating. As can be seen, the x-polarized and y-polarized lights are considerably different, which is expected. The maximum efficiency for the blazed gratings, has a maximum around the blue region.

3. Conclusions

Direct patterning of surfaces was demonstrated by direct write electron-beam lithography direct (DW-EBL). We showed through AFM and reflectance measurements that PMMA height can be tuned with nanometer precision by controlling the e-beam dose through AFM and reflectance measurements. Colour prints were fabricated by directly patterning a FP cavity. Our pixel size can be reduced to the sub-diffraction limit of visible light without significantly affecting the colours. DW-EBL for colour printing does not require surface pre-patterning, which is necessary for some of the direct laser printing methods. Since the colour reflected by the FP cavity depends on its height, we were able to

Figure 1: Direct E-beam patterning of a FP cavity. (a) Schematic of the direct electron-beam writing fabrication method. (b) Computer generated layout of patterns with varying exposure dose (colour coded), height change (colour coded), and the experimentally observed colours. (c) Thickness change vs. exposure dose for experiments and a double exponential function fitted to the experimental data. (d) Schematic of PMMA decomposition showing two main pathways (left) main chain scission, and (right) ester group removal. Optical micrographs are captured by a 20× objective lens (NA: 0.45).

The controlled thickness change by varying the exposure dose spatially can be employed to realize various patterns as shown in Fig. 2a shows optical micrograph of the A*STAR, NUS, and SUTD logos, as well as colourful letters spelling “PMMA” realized by direct e-beam patterning. Square pixels with a 200 nm size were used to realize these patterns.

In addition to structural colour applications, direct e-beam writing can be used to fabricate nanopatterns with variable heights, as shown in Fig. 2b. Structural colour can be used to deduce the feature height, eliminating the need for AFM measurements, as illustrated in Fig. 2c. The height map in Fig. 2c is plotted through analysing the optical image in Fig. 2b and correlating the colours in each pixel to the calculated heights in Fig. 1b. As can be seen, the height map deduced from the structural colours is in a good agreement with the AFM measurements in Fig. 2d.

Figure 2: Direct e-beam writing of structural colours and patterns. (a) A*STAR, NUS, SUTD logos, and colourful letters spelling “PMMA,” realized by direct patterning. (b) Optical micrographs of a multistep square. (c) A map of the height variation of the multistep square obtained by analysing the optical image in (b). (d) AFM micrograph of the multistep square. The scale bars in (a) and (b) are 25 µm and 10 µm respectively. Optical micrographs in (a) and (b) are captured by a 20× objective lens.

The method is not limited to patterning FP cavities but can be employed to realize any pattern with variable heights on PMMA. Here we fabricated blazed diffraction grating to disperse light. Since the blazed grating has a variable-height profile, it cannot be fabricated by conventional e-beam resists in a single step i.e., resist developing step is still necessary. The blazed grating with sawtooth grooves is illustrated in Fig. 3a. The Optical and AFM micrograph along with gratings grooves profiles are shown in Fig. 3b-d. As can be seen from the AFM profile in Fig. 3c, the sawtooth profile can be achieved in a single step.

Figure 3a shows reflection spectra for x and y-polarized lights at the normal incident for a blazed grating. The diffraction efficiency η is shown for an x-polarized light at 20° tilted angle for blazed grating. As can be seen, the x-polarized and y-polarized lights are considerably different, which is expected. The maximum efficiency for the blazed gratings, has a maximum around the blue region.

3. Conclusions

Direct patterning of surfaces was demonstrated by direct write electron-beam lithography direct (DW-EBL). We showed through AFM and reflectance measurements that PMMA height can be tuned with nanometer precision by controlling the e-beam dose through AFM and reflectance measurements. Colour prints were fabricated by directly patterning a FP cavity. Our pixel size can be reduced to the sub-diffraction limit of visible light without significantly affecting the colours. DW-EBL for colour printing does not require surface pre-patterning, which is necessary for some of the direct laser printing methods. Since the colour reflected by the FP cavity depends on its height, we were able to
infer the height map of an observed region by matching the reflected colour to its calculated height, which is in good agreement with AFM measurements. To further demonstrate the method’s viability to realize structures that require variable heights, blazed gratings were fabricated without any resist developing process. The proposed method minimizes the fabrication steps and complexity while offering variable height as a new degree of freedom for realizing metasurfaces.

Abstract

Time behavior of the Rayleigh-Lorentz invariant for a flux qubit resonator has been investigated in order to achieve better understanding of the resonator in quantum computing systems. We have analyzed the time variation of the Rayleigh-Lorentz invariant of the system and confirmed that such a variation is non-negligible especially when the parameters vary significantly. Through this analysis, we have studied the optimal evolution of the invariant that is necessary for adiabatic qubit-information detection with the qubit resonator.

1. Introduction

Adiabatic invariants of time-varying systems have attracted considerable interest from the early days of modern physics. A typical definition of an invariant is given by $I(t) = E(t)/\omega(t)$ where $E(t)$ and $\omega(t)$ are time-varying energy and angular frequency of the system, respectively. In 1895, Rayleigh [1] showed that $I(t)$ for a pendulum with a slowly varying length almost does not vary over time. Afterwards, Lorentz have rediscovered this consequence in the semiclassical regime and he have pronounced his discovery at the first Solvay Conference held in 1911. It is noticeable that such Rayleigh-Lorentz invariants are not exactly constants but approximately constants under the assumption that the change of parameters are very slow.

The study for the variance of Rayleigh-Lorentz invariants for specific systems may be interesting and provides insights for understanding the underlying mechanism associated with the invariants. The concept of such adiabatic invariants can be applied to analyzing various properties of mechanical and photonic systems, such as superconducting flux qubits, quantum control for adiabatic passage in atomic energy levels, and adiabatic quantum computation.

In this work, we will investigate the variance of the Rayleigh-Lorentz adiabatic invariant for a flux qubit resonator [2]. Flux qubit resonators are potential candidate for implementing quantum computation systems which are important in the field of quantum information science. If the adiabatic hypothesis relevant to Rayleigh-Lorentz adiabatic invariants holds, the initial eigenstate in the discrete spectrum of the Hamiltonian does not change over time. In order to process quantum information such as computing algorithms and the readout of the qubit state signals, a high-fidelity resonator is necessary. As an implementation of devices for such a purpose, flux qubit is an artificial two-level system that is a basic unit that stores quantum information. Typically, flux qubits are fabricated by superconducting circuits using nanotechnology facilities. The entanglement between flux qubit and a SQUID (superconducting quantum interference device) provides a protocol for measuring the quantum states [3]. By developing time variation of the Rayleigh-Lorentz invariant of the system, we study optimal evolution of the resonator needed for detecting qubit-informations with the resonator.

2. Dynamics for the time behavior of the invariant

We consider an extended Duffing equation [2, 4] that describes flux qubit resonators in quantum computation systems. We focus on the situation of weak Duffing non-linearity throughout this research. We have investigated the time evolution of $I(t)$ for several different values of the pumping angular frequency $\omega_p$. While $I(t)$ almost does not vary for the case of small values of $\omega_p$, it oscillates as $\omega_p$ becomes large. Sánchez-Soto and Zoido discovered similar oscillation of $I(t)$ for the system of lengthening pendulum [5]. We have also confirmed that $I(t)$ increases more or less as time goes by depending on the amplitude of the driving force. For large values of $\xi_0$, the increase of $I(t)$ over time is more rapid. From these analyses, we can confirm that, if the process of the change of the system parameters were too fast, $I(t)$ would not remain constant.

If the variance of the invariant has been minimized, the variation of the invariant would be very small enough that it can be negligible. Then, it is possible to achieve a reliable detection of states with high efficiency in quantum-limited metrology for quantum computing systems. One should bear this in mind when designing a flux qubit resonator.

3. Conclusions

Detailed analysis of quantum features of the flux qubit resonator can be fulfilled by means of the invariant quantity [6]. It has been confirmed that the Rayleigh-Lorentz invariant varies more or less over time. From the investigation of the time variance of the Rayleigh-Lorentz invariant for a flux qubit resonator, we have studied an optimal adiabatic evolution of the resonator which is necessary for efficient...
detection of qubit-informations.

From the investigation performed in this work, our understanding for the characteristics of the Rayleigh-Lorentz invariant of the system has been deepen. As Einstein pointed out, the slow variation of the potential strength in a time-varying oscillator is directly related to quantum mechanics. In a case that the potential varies sufficiently slowly over a cycle of oscillation, the state of the oscillator at a later time remains the same as the initial one.

Abstract

We demonstrate the inverse design, where the geometry of the structure is obtained for an on-demand response, of terahertz (THz) filters using Deep Learning. The filter response is achieved by using self-complementary metasurfaces. Our Deep Neural Network is first trained with thousands of synthetic data results obtained from electromagnetic (EM) simulations and tested on its ability to predict the geometry of the metasurface. The presented results allow the on-demand design of THz filters in a rapid and systematic manner.

1. Introduction

In recent years, terahertz technology has attracted considerable attention due to its potential applications. THz waves have the benefit of being able to penetrate visually opaque materials while being harmless to human body, having applications such as bio-sensing [1] and material characterization [2]. However, its further development is still hindered by the lack of devices that can effectively control and manipulate THz waves, such as modulators, filters and polarizers. In the THz frequency band, compared to other frequency bands, more active and passive components are still required for THz devices to become a mature technology used in industrial applications [3]. Currently, the design and optimization of THz filters have remained a time-consuming task where the Maxwell’s equations are solved iteratively until the desired response is achieved. For the case of inverse design, where the geometry of the structure is obtained for an on-demand response, common approaches are the use of evolution algorithms [4] and topology optimization [5]. However, those methods still remain time consuming and computationally demanding due to its random geometry approach [6].

In this work we demonstrate the inverse design of THz filters using Deep Learning. The filter response is achieved by using a self-complementary metasurface, two-dimensional arrays of artificial resonators and its complementary counterpart. Our Deep Neural Network is first trained with thousands of synthetic data results obtained from EM simulations and then tested on its ability to predict the geometry of the metasurface based solely on given filter responses.

2. Results and discussion

The metasurface chosen to realize the THz filter in this work was a self-complementary Jerusalem cross structure. The unit cell consists of a metallic Jerusalem cross and its complementary counterpart, as shown in Fig. 1. Self-complementary metamaterials are known for working as band-stop filters (BSF) for one linear polarization of the incident wave, while showing band-pass filter (BPF) response for the orthogonal polarization [7]. Also, due to Babinet’s principle, the resonance frequency for both polarization states should be at the same frequency [8]. Those characteristics of self-complementary metamaterials enables the design of a 2-in-1 filter, whose response can be easily switched between BSF and BPF by mechanically rotating the device by 90°, making this type of metamaterials a good option for designing filters in the THz frequency band.

Figure 1: Self-complementary metasurface unit cell using Jerusalem cross design. The length of the loading ends a, b, c and d were varied during the simulations, while the other parameters were fixed at \( l = 50 \mu m \), \( w = 100 \mu m \), \( e = 42 \mu m \), \( f = 40 \mu m \), and \( g = 5 \mu m \). The metal thickness and substrate thickness were 200 nm and 700 µm, respectively.
HFSS, a simulation software. The frequency range of interest in the simulations was from 0.01 to 2 THz and the transmission response was discretized into 400 data points. The set of synthetic data contains 20000 results obtained by varying the length of the loading ends a, b, c and d between 5 µm and 53 µm, in a way so that the loading ends do not cross each other. In the simulations, the substrate used was lossless Zeonor modeled with a relative permittivity of 2.56, while the metallic parts of the metasurface used gold modeled with a conductivity of 4.561x10^7 S/m.

The neural network has three hidden layers of 600, 2000 and 400 units, respectively. The number of units in the input layer was defined as 400 to match the number of discretization points of the synthetic data. The output layer, in a similar way, has 4 units representing the length of the four loading ends in the Jerusalem cross. The generated data was shuffled and split into training and test sets having 16,000 and 4,000 instances, respectively. The learning rate, which defines how quickly a network updates its parameters, utilized was 0.0005 and the dropout rate, a regularization technique to avoid overfitting, was fixed at 30%. The optimization algorithm and activation function chosen were Adam and Swish, respectively.

During the training process, the network weights are updated to minimize the error by comparing the network prediction with the labeled data in the training set. After the training process, the performance of the network is tested on a set of unseen data. In Fig. 3 we show an example design by the neural network developed in this work. By comparing the predicted and simulated spectra, we notice that it reasonably satisfies the target response, although with still some mismatch in the second resonance peak around 1.75 THz. Our proposed network can produce suitable geometric parameters to achieve the desired response, and we expect that, with increasing the training data, we can further improve its performance.

3. Conclusions

We propose a method for the inverse design of THz filters using Deep Neural Network. The filter response was obtained by using a Jerusalem cross-shaped self-complementary metamaterial. In this approach, the training process is a one-time cost and the design itself takes only a fraction of second, where it can be used as a fast prototyping tool. This work may be further expanded by varying more geometry parameters, increasing the number of feasible filter responses for the same basic structure.

Abstract

Metamaterial design, from RF to optical frequencies, can present a significant challenge to engineers. In this paper, several recent tools that can aid in the process of metamaterial synthesis are presented, and their relative advantages are discussed for various kinds of design goals.

1. Introduction

Over the past few years, research into metamaterials has expanded the Electromagnetics (EM) community’s understanding of their capabilities and led to the development of a tremendous range of unit cell designs with a host of properties and applications. Today’s designers have a wide range of metamaterial designs which can produce many different bulk properties, and which through minor modifications can be altered to meet their particular needs. However, designing metamaterials to achieve novel properties is still a great challenge, and has in some cases necessitated breaking away from the familiar canonical metamaterial shapes which are commonly employed [1]. In such cases, synthesizing new metamaterial designs can be assisted greatly by developing an automated inverse-design process which loops unit cell generation, evaluation, and analysis with powerful optimization techniques. In this paper, the impact that the choice of performance goals and optimizer have on the synthesized metamaterial unit cell topology are discussed.

2. Metamaterial Synthesis

While there is no exclusive form for metamaterial synthesis, the flowchart mapped out in Figure 1 presents a general inverse-deign process which combines optimization with unit cell generation, full wave evaluation, and effective parameter retrieval. The first stage in metamaterial synthesis is the design generator. This stage may take many forms depending on the evaluation tool used. However, one commonly used approach that is favored for its relative computational efficiency is that of a pixelated design [2, 3]. The choice of generator is further affected by fabrication considerations. For instance, in order for 3D metamaterials to be realized, it is either advantageous or necessary for the design to be contiguous.

Given an appropriate generator selection, the next stage of the synthesis pipeline is evaluation and analysis. While many different competing goals may affect which analysis tool is best suited for a given problem, EM simulators which, at a minimum, allow for periodic boundary conditions and S-parameter retrieval are sufficient to fulfill most needs. Depending on the intended behavior of the synthesized metamaterial, there are several possible values of interest that may be recovered from a doubly-periodic unit cell simulation. This process starts with the recovery of a design’s complex reflection and transmission coefficients. From these fundamentals, bulk effective parameters such as $\varepsilon$ or $\mu$ may be recovered and fed back to the optimizer in order to achieve a specific set of desired constituent material tensors. Secondary objectives like minimizing field enhancement or limiting the amount of a constituent material used may also be determined for the next stage, optimization, which can close the synthesis loop.

Optimization is the final stage of the synthesis procedure. At this stage, the various qualities of the generated designs may be considered together in order to guide the generator toward more optimal designs. While some design requirements may be captured by a single objective, others may be better understood by several, possibly competing objectives. Metamaterial synthesis, therefore, is a natural

Figure 1: Flowchart showing the metamaterial synthesis feedback loop. This automated process allows the rapid generation of metamaterials which fulfill certain design constraints while maximizing performance in desired goals.
application of Multiobjective Optimization (MOO), from which there are many powerful options to choose [4]. Each optimizer integrates with the generator in a different way to produce dissimilar metamaterial shapes as shown in Figure 2. Therefore, the choice of optimizer should be selected based on the problem constraints and fabrication methods available. The Genetic Algorithm (GA) is a good choice for designs based on pixelated planar structures on a substrate like those in Figure 2(a). Since this optimizer may be used in either single objective or multiobjective fashion, it covers the most general design formulation [5]. For cases where a higher degree of granularity is needed for proper evaluation, metamaterials may also be parameterized in 2D or 3D by Bezier surfaces [6]. These allow the indexing of complex structures for which a fully pixelated version like that shown in Figure 2(b) would overwhelm the capabilities of a GA. Being continuous in nature, Bezier surfaces are best optimized by a continuous single objective or multiobjective optimizer like the Covariance Matrix Adaptation Evolutionary Strategy (CMAES) or the Auto-adaptive BORG optimizer respectively [7, 8, 9]. Bezier surfaces may also be used in conjunction with the Multiobjective Optimization with Tolerance Analysis (MOTOL) which is a more recent optimizer that uses surrogate models to actively optimize fabrication tolerances [10]. MOTOL can be used to accommodate the inherent manufacturing inaccuracies of real system fabrication and improve the robustness of metamaterial designs. Finally, some designs may even demand extension into 3D and require that all features of the structure be contiguous. For such a need, the recent Multiobjective Lazy Ant Colony Optimization algorithm (MOLACO) is opportune [1]. MOLACO actually acts as both optimizer and generator, constraining designs to maintain continuous feature connection which makes it well suited for designing structures for additive manufacturing like in Figure 2(c).

3. Conclusions

Metamaterial synthesis is a general automated design methodology that can be used to generate unique metamaterials which fulfill numerous different or even competing design criteria. The tools outlined above offer powerful options for achieve a number of different structural or fabrication goals for the creation of innovative metamaterials.

Abstract

We present a circuit model for the spoof Surface Plasmon Polaritons (sSPP) waveguides for the terahertz band. The circuit model uses the theoretical calculation and optimization of the circuit elements in terms of the groove parameters. Here, we first simulate the sSPP waveguide by changing the groove dimensions that are the depth, aperture, and periodicity and extract the values of the circuit model parameters. Finally, we present the comparison of the proposed circuit model with the measurements.

1. Introduction

The surface plasmon polaritons (SPP) are electromagnetic waves that propagate along the metal and dielectric interfaces. These waves are strongly confined to the surfaces in the spectrum of ultraviolet and visible bands. However, as the spectrum shifts towards the terahertz and microwave bands, the metal surface behaves like a perfect electric conductor. However, surface waves that are named as the “spoof” surface plasmon polaritons are formed at the metal-dielectric interface that maintain high localization, showing a similar behavior to the SPP waves. In the literature, there are different examples of spoof surface plasmon polaritons. In [1], the sSPP structure is employed as an ultra-wideband filter. In other studies, it has been employed to form a frequency splitter and power divider [2, 3]. In addition to design and investigation of the sSPP devices, the circuit-modeling of the sSPP structure is also presented [4, 5].

In this paper, we present a circuit model for the spoof surface plasmon polariton waveguides at the terahertz regime. Here, the basic theoretical formulations given in [4] and [6] are used for finding the values of some of the circuit elements, where the values of the rest are found using optimization. Finally, the results of the proposed model are compared with the measurement results.

2. The Proposed sSPP Circuit Model

We first describe the design of sSPP waveguides in this section. The sSPP waveguides are composed of a coplanar waveguide (CPW) section, transition section, and delay line section as in shown in Fig. 1. The sSPP parameters are selected considering the insertion loss, return loss, and insertion phase response of the sSPP delay line section. We simulate different sSPP structures using ANSYS HFSS for understanding effects of the groove parameters on the behavior of the insertion loss, return loss, and the insertion phase sSPP delay line. Using these simulations, the parameters with the best insertion loss/insertion phase behavior are selected, where the groove depth, h, is 30 µm, aperture, a, is 10 µm, and periodicity, d, is 25 µm.

After deciding on the structure to be modeled, we examine the circuit model of the spoof surface plasmon polariton structure. This study is carried out using AWR Microwave Office, and the operating frequency range is selected between 0.26 THz and 0.3 THz. The effects of the coplanar waveguide, transition, and delay line sections are all considered in the proposed circuit model, as they have been included in the ANSYS HFSS simulations.
For the circuit modeling of the sSPP waveguide, a 16-period delay line section is designed, and the element values of each groove period, indicated by Fig. 2, are calculated using the formulas given in [4, 6]. For the circuit elements’ calculation, the other important parameter is the effective dielectric constant, which is given [7]. The calculations of $g_{c2}$, $g_{c3}$, $g_{l1}$, $g_{l2}$, and $g_{l3}$ are made by adapting the formulation in [4, 6] to the proposed circuit model for the terahertz band. The other element values, $g_{c1}$, R1, R2, and R3, are found using optimization, where the measurement results are used for comparison. The values of the circuit elements are given in Table 1.

In addition to the delay line section modeling, the transition and coplanar waveguide sections are also modelled. For CPW, the closed form coplanar waveguide formulation is used. The model of the transition is also designed using the same approach, however, the element values are found by optimization, where the measurement results are taken as the optimization reference. The results obtained by the proposed model are given in Fig. 3. The insertion loss and phase responses of the proposed model and measurement results exhibit similar behavior as shown in the graphs. The maximum least square error between the S-parameters of the circuit model and measurement results is found to be 0.01.

3. Conclusions

We presented a circuit model for the sSPP waveguide structures for the terahertz band, which targeted obtaining a minimum loss/maximum delay response. The proposed circuit model for a 16-section delay line showed good agreement with the measurement results between 0.26 and 0.3 THz. We believe that this model can be useful for the initial design of the sSPP waveguides, which will reduce the number of iterations and design time significantly compared to the full-wave electromagnetic simulations.

Abstract

An effective simulation approach for metalens design is demonstrated by combining multiple algorithms. Finite-Difference Time-Domain (FDTD) or Rigorous Coupled Wave Analysis (RCWA) algorithms are used to calculate the phase delay of various nano-cells, and then efficient beam propagation methods are used to trace the beam through the metalens or its phase mask. The test example shows that this multi-algorithm combined approach is accurate and efficient with reduced demand on computational memory and time.

1. Introduction

A metalens is a difficult structure to design and simulate, since its overall size is large with many nano-structures. To simulate the nano-structures, a rigorous algorithm such as FDTD must be used. However, FDTD is computationally expensive, requiring substantial computer resources. The largest metalens that can be directly simulated in most labs through FDTD is only tens of micrometers in diameter, much smaller than what is needed [1]. In practice, FDTD is not required for the entire structure. Simulations can be decomposed into simpler elements solved individually by different methods. In this paper, we propose an approach using a rigorous algorithm to calculate the phase shift of a single unit nano-cell, from which a phase mask is constructed. More efficient methods then simulate propagation. In addition to FDTD, RCWA is an alternative algorithm for simulating the nano-cell. For the propagation, two separate, efficient methods with respect to computational resources are used in cross validation.

2. Simulation flow

2.1. Simulation of the unit nano-cell

The phase of each unit nano-cell is critical to metalens performance. Approximate estimation based on the phase shift of the mode guided in an isolated nano-cell is not accurate [1] because it ignores resonances inside the nano-cell and interference from neighboring nano-cells. In our study, we used the FullWAVE (FDTD) and DiffractMOD (RCWA) tools from RSoft [2] to calculate the phase delay for nano-cells with certain lattice patterns. Shown in Figure 1 are the calculated phase shifts as functions of normalized diameter for the nano-pillar and nano-hole (left), and for rectangular and hexagonal lattices of nano-pillars (right).

![Figure 1: Phase shift of nano-pillar and nano-hole (left); for different lattices (right)](image)

It is obvious that nano-pillar creates positive phase shift while nano-hole gives negative phase shift. It is also shown that the lattice pattern makes little difference and what matters is the normalized diameter that is associated with the fill factor.

2.2. Layout of the metalens

Based on the phase delay curves shown in Figure 1, the diameter of each cell in a metalens can be determined according the designed phase shift at that particular point. Shown in Figure 2 is the layout of an ideal metalens. The phase profile of this metalens is shown in Equation 1.

\[
\psi(x, y, \lambda_0) = \frac{-2\pi}{\lambda} \left( \sqrt{x^2 + y^2 + F^2} - F \right),
\]

where \( \lambda \) is the wavelength and \( F \) is the focal length. The lens is designed with a focal length of \( F=200\mu m \), and a diameter of \( D=100\mu m \), for green light (\( \lambda=532nm \)).

![Figure 2: Layout of an ideal metalens built from nano-pillars](image)

To make the metalens manufacturable, the normalized diameters are chosen in the range of \([0.45, 0.85]\), which can
provide 360° phase shift. The phase mask of the above metalens was generated and is shown in Figure 3.

**2.3. Validation of BPM algorithm on a small structure**

BPM is an efficient method to simulate forward propagation without accounting for backward reflection. We first validated BPM against the more rigorous FDTD on a small metalens 20 µm in diameter and NA=0.25. The theoretical focal length is F=17.3 µm. Shown in Figure 4 on the left is the BPM simulation result with F=16.96 µm, and on the right is the FDTD result with F=17.14 µm. The comparison shows that BPM agrees very well with FDTD for this application.

For comparison the memory requirements for BPM were 0.19G and FDTD was 55G, and the respective simulation times were 1.5mins and 130 minutes.

**2.4. Validation of BPM algorithm on a larger scale structure**

A larger test structure is shown in Figure 2 with 100 µm diameter and F=200 µm. Shown in Figure 5 on the left is the BPM result with Gaussian input. The calculated focal length is F=200.1 µm. The memory and time required were 3.3GB RAM and 4 minutes on a desktop computer.

Because of memory requirements for FDTD, we validate BPM against another propagation algorithm, Beam Synthesis Propagation (BSP). BSP, due to its implementation, does not handle physical optics simulation of the nano-structures directly. Instead, it treats the metalens as a phase mask, as shown in Figure 3. The BSP result is shown in Figure 5 on the right. It confirms the smallest spot size obtained occurs at L=200 µm, in agreement with the BPM result. For this simulation, BSP takes approximately 3 minutes with 4 GB RAM on a laptop.

**3. Dispersion of the metalens**

Chromatic dispersion of the metalens is a well-known problem. Accurate modeling of the dispersion is the key step to design of an achromatic metalens. As shown in Figure 6, the nano-pillar under study behaves very differently for each RGB wavelength, even with some phase jumps for blue and green light caused by resonances in the nano-pillar.

Based on the above curves, we can generate phase masks for blue and red light. We then performed BPM simulation. The focal lengths predicted via BPM are 223 µm and 161 µm for blue and red light, respectively. We also did a separate simulation using the phase masks and Synopsys® CODE V® optical design software [3]. BSP was used to verify the focus positions of 223 µm and 161 µm. The RMS fit of the beam profile was approximately λ/100 in each case. Transverse field profiles at focus are shown in Figure 7.

**4. Conclusions**

We demonstrated an effective approach to design and simulate practical metalenses with rigorous FDTD or RCWA for nano-cell phase, and BPM or BSP for propagation through the metalens. The test examples shown demonstrate this is a viable approach, both accurate and efficient for computational resource requirements.
