On the other hand, the recent push toward multimode photonics opens one of the most prolific optical frontiers, with space-time beams offering enormous potential when coupled with OAM. Here, the goal is to structure not only the spatial transverse profile of the beam, but also the frequency, by tailoring the topological-spectral correlations of the light source. To this end, we structure femtosecond optical parametric amplified pulses using a Fourier space-time shaper based on flat diffractive axicons. The system offers complete control over the broadband topological content of the ultrashort pulses, with tuning of the topological-spectral correlations providing control over the chirality, orbital radius, number of intertwined helices and their dynamics, enabling new applications in ultrafast technology.

Photonic N00N-sates with spatially structured photons

Abstract: We study photonic N00N with spatially structured photons, i.e. quantum states where N photons are in a superposition between two orthogonal spatial modes. Using these states, we can show angular super-resolution measurements when implement through modes with a twisted transverse phase front. When realized with radially structured modes, the states allow us to study the Gouy phase anomaly in the quantum domain, its benefits in longitudinal sensing, and its fundamental importance in gaining a deeper understanding multi-photon quantum states.

Shaping the transverse structure of quantum light has attracted a lot of attention in quantum photonics ranging from fundamental studies to quantum information applications. A powerful way to describe any spatial structure in the paraxial limit are orthogonal transverse spatial modes e.g. Laguerre-Gauss modes. Amongst many other things, such modes show interesting features like a theoretically unbound quanta of orbital angular momentum (OAM) per single photon related to a twisted phase structure. Moreover, structured photons serve as a versatile testbed for the study of novel complex quantum states [1].

In this presentation talk, I will show some of the key areas of the application of structured photons in quantum photonics and introduce advanced schemes of spatial-mode modulation leading to the generation of photonic N00N states with transverse spatial modes. The latter describes quantum states where N photons are in an extremal superposition between two orthogonal modes, i.e $\frac{1}{\sqrt{2}}(|N0\rangle+|N0\rangle)$. Our results show that such states when realized with OAM modes, i.e. twisted N00N states, can be used to achieve super resolving angle measurements that scale with the photon number N as well as the OAM quanta, as shown in Fig. 1 a) [2].

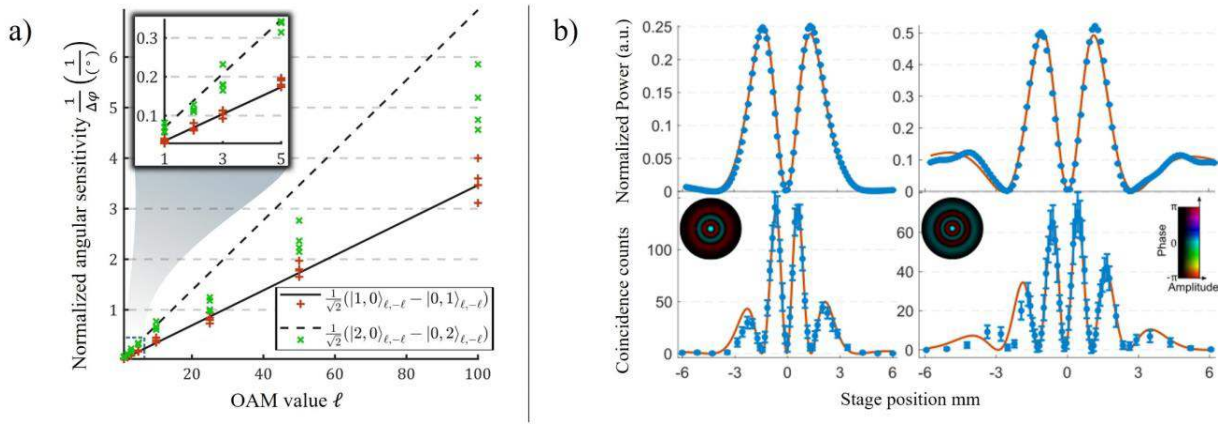

Fig. 1: a) Twisted N00N states show increased angular sensitivities for larger OAM values and for two-photons (green) compared to single photons (red). The plotted lines show the theoretically expected behavior. b) Experimentally recorded data of the Gouy phase's effect on radial mode superpositions between a Gaussian and radial mode of order 3 (left) and order 4 (right). The top row shows the classical behavior, the bottom row shows the effects of the quantum Gouy phase for N00N states using the same pair of modes for both cases.

In addition, we studied spatial mode N00N states in connection to a fundamental wave phenomenon, the so-called Gouy phase anomaly. It describes the anomalous phase delay of transversely confined waves when propagating through a focus. When probing it in quantum domain, i.e. when probing the quantum Gouy phase we find that it behaves different from classical light waves in terms of phase evolution as well as spatial mode order (see Fig.1 b). We further provided a few more insights, such as a nice corollary to Feng and Winful's proposition on the origin of the Gouy phase [3] by linking the speeding up of the quantum Gouy phase to an increasing spread in the transverse momentum of the state. Finally, our results show that radial mode NOON states can open up the possibility for supersensitive measurements of longitudinal displacement and highlight that the so-called photonic de Broglie wavelength is not sufficient for describing the behavior of photon number states [4].

Hence, the presented findings show an example of how engineering the quantum state and transverse-spatial profile of a set of photons can lead to quantum enhanced measurement precisions as well as gaining a deeper understanding of fundamental features of quantum light.

Novel Effects in Propagation and Absorption of Optical Vortices

Andrei Afanasev*

The George Washington University, Washington, DC 20052, USA

**corresponding author: afanas@gwu.edu*

Abstract: We present new theoretical results on twisted-light propagation and absorption by atomic matter. We demonstrate several effects arising due to the presence of the phase singularity on the propagating wave front: (a) Novel polarization states of optically polarized atoms (b) Enhanced quantum recoil, and (d)Nondivergent polarization features of divergent beams. Possible applications of the above effects will be discussed.

OCIS codes: (270.0270) Quantum Optics; (260.6042) Singular Optics; (050.4865) Optical Vortices

Ability of the twisted light to transfer combined optical spin and orbital angular momentum to atomic excitations was demonstrated experimentally with cold trapped ions [1]. Previously [2] we derived quantum selection rules that describe atomic transitions caused by twisted photons and in subsequent experiments [3] demonstrated dependence of angular-momentum selection rules on atom's position with respect to the phase singularity of the wave front.

The verified selection rules thus allow to predict optical polarization of atoms that absorb the twisted light [4]. We show that the longitudinal electric fields of the vortex play an important role especially in the case of anti-aligned spin and orbital angular momenta of the beam.

Next, we address the problem of determining the physically correct definition of the momentum and angular momentum densities in a spatially structured electromagnetic field, given that the expressions are not the same when one uses the canonical energy-momentum tensor instead of the symmetric Belinfante energy-momentum tensor in electrodynamics. This has important consequences for the interaction of matter with structured light, for example, with optical vortices and would give drastically different results for forces and angular momenta induced on small test objects. We show, with numerical estimates of the size of the effects, situations where the canonical and symmetrized forms induce very different torques or (superkick) recoil momenta on small objects or atomic rotors [5].

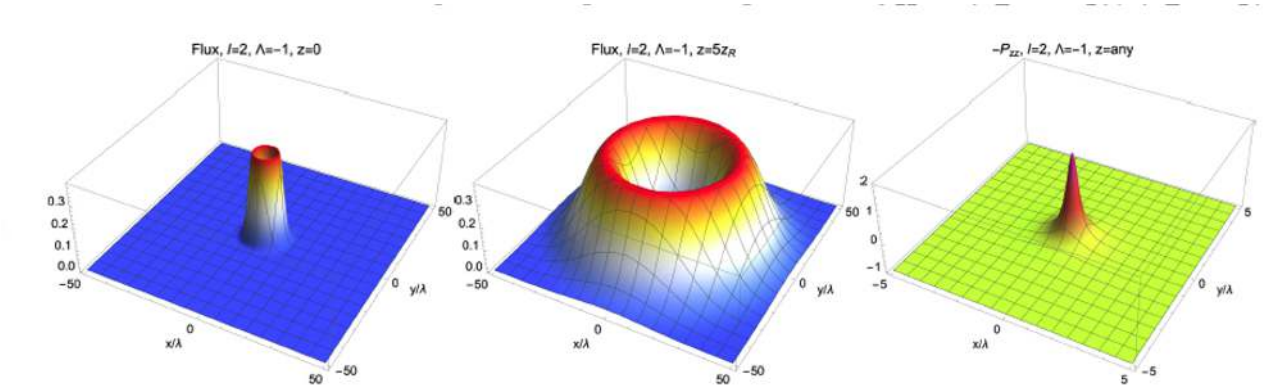

Figure 1. Non-diffractive behavior of polarization in an optical vortex beam (Laguerre Gauss) propagating in free space, having a topological charge l=2 and spin-helicity $\Lambda = -1$. Shown is the transverse-plane profile of energy density in beam's focus (z=0, left plot) that expands during propagation due to diffraction (z=five Raleigh lengths, middle plot), while the polarization parameter p_{zz} remains independent of propagation distance (right plot).

Finally, we demonstrate, both analytically and with simulations, that certain polarization features of optical vortex beams maintain constant transverse spatial dimensions independently of beam divergence due to diffraction. These polarization features appear in the vicinity of the phase singularity and are associated with the presence of longitudinal electric fields. The predicted effect may prove important in metrology and high-resolution imaging applications. In Figure 1, we compare transverse profile of the energy density for the optical vortex beam and a polarization parameter p_{zz} that measures relative contribution of longitudinal (along beam's axis) and transverse electric fields defined as [4,6]

$$p_{zz} = \frac{|E_\perp|^2 - 2|E_z|^2}{|E_\perp|^2 + |E_z|^2}.$$

The results of the calculation are shown in Figure 1, indicating a non-diffractive behavior of the polarization feature while the intensity profile of the beam expands during propagation because of diffraction. The demonstrated effect allows one to pinpoint the position of a phase singularity with subwavelength accuracy independently of the size of a beam spot.

Generation of Extreme-Ultraviolet structured fields with the seeded Free Electron Laser FERMI, and applications in atomic and molecular physics.

C. Callegari

Elettra – Sincrotrone Trieste, Italy
carlo.callegari@elettra.eu

Abstract: Free Electron Lasers are the most powerful light source presently available in the EUV and x-ray range; they allow the time-resolved study of atoms, molecules and condensed matter with chemical sensitivity. A seeded, modular design adds the possibility to generate fields with differing properties (wavelength, polarization, phase), and to combine them coherently. Applications range from sub-attosecond resolution in photoionization processes, to the generation and control of attosecond pulse trains, to the excitation or probing of chiral observables.

First demonstrated (and still of great practical interest) in the infrared [1], Free Electron Lasers (FELs) are of greatest interest where few or no alternatives are available to produce intense, ultrashort light pulses: at short wavelengths. Most of the existing FELs of the latter class are based on the Self Amplified Spontaneous Emission (SASE) process, with limited control on the longitudinal coherence properties of the pulse, much less on the precise structure of the pulse field [2]. The Free Electron laser FERMI in Trieste is based on a seeded design [3] that—along with the independent control of the resonant wavelength, phase, and polarization, of each radiator module—allows the generation and coherent superposition of fields with differing properties, such as wavelength [4], polarization [5], phase [6], and ultimately to the generation (with known limitations) of customized fields.

In this work I will summarize the technical aspects of generating such fields at FERMI, their limitations, and their main applications in the realm of atomic and molecular physics; I will then report on selected recent results concerning: the (post-processing) synchronization with an independent infrared field [7]; the study of photoionization processes by Optical Angular Momentum light beams [8]; the generation of exotic polarization states [9].

The results originate from the joint effort of many international laboratories and of a large number of researchers, whose work is gratefully acknowledged.

High efficiency interface between multi-mode and single-mode fibers

O. Korichi[1*], M. Hiekkamäki [1], and Fickler[1]

[1] Photonics Laboratory, Physics Unit, Tampere University, Tampere FI-33720, Finland
[*]corresponding author: Oussama.korichi@tuni.fi

Abstract: A new method for interfacing MMFs with SMFs is presented using a multi-plane light conversion scheme, achieving coupling efficiencies of 30% to 70%, for MMFs with core diameters up to 200 μ m, with only three phase modulations. We also investigate the influence of resolution on coupling efficiencies for field reconstruction and MPLC, and we show that commercial wavefront sensors and deformable mirrors can auto-correct in the kilohertz regime to establish an MMF-SMF interface.

Multi-mode fibers (MMFs) and Single-mode fibers (SMFs) are widely used in communication networks. Choosing to utilize either MMFs or SMFs depends on many factors. For example, in applications that require distances of up to 500 m - 600 m, MMFs are the practical choice in terms of cost. Beyond that, SMFs are necessary due to the modal dispersion in MMFs [1]. Hence, a device for efficiently interfacing an MMF with an SMF would be beneficial to optical telecommunication.

In this work, we present a method capable of achieving this interfacing between an MMF and SMF using a multi-plane light conversion scheme (MPLC) [2]. With our method, and discluding the losses in the optics, we demonstrate that only 3 phase modulations, realized with a single spatial light modulator (SLM), are enough to achieve MMF to SMF coupling efficiencies of 72% ± 7%, 60% ± 3%, 50% ± 4%, and 29% ± 3%, using MMFs with core diameters of 8.2 µm, 25 µm, 50 µm, and 200 µm, respectively [3].

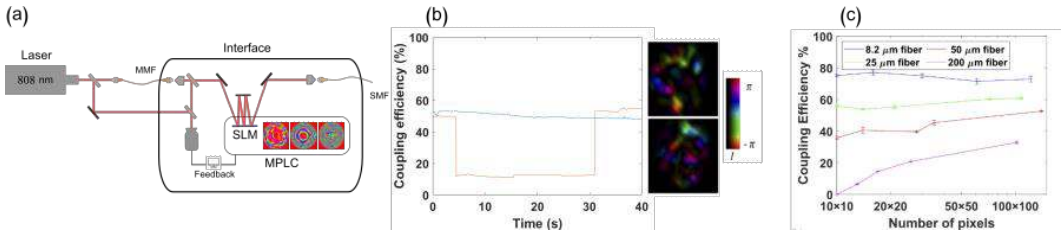

Fig. 1 (a) Sketch of the experimental setup for efficient MMF to SMF coupling using an MPLC implemented with an SLM. (b) Stability of coupling efficiency without disturbance (blue) and automatized correction after a strong deformation of an MMF with 50 µm of core diameter (orange). The insets on the right correspond to the complex field before (top) and after (bottom) the deformations (c) SMF coupling efficiencies after the mode transformation for different MMFs and resolutions of the reconstructed field. The efficiencies were obtained from 200 measurements within a time frame of 35 s, and the errors represent the standard deviation of the respective dataset.

In the experiment, we sent an 808 nm laser into an MMF and reconstructed the complex transverse amplitude of the output field from an interferogram [4]. We then used the obtained full field information to calculate the 3 phase modulation screens with wavefront matching [5]. The phase screens were optimized to transform the multi-mode field into the Eigenmode of the SMF, i.e., a Gaussian beam profile, such that the

transformed field could be efficiently coupled into the SMF (see Fig. 1a). Because the field reconstruction, as well as the mode transformation, were updated in real-time, the obtained coupling efficiency remains stable even if the output field of the MMF changes entirely, for example through strong deformation of the fiber (see Fig. 1b). We additionally tested the influence of the resolutions for both, the field reconstruction and MPLC system, on the coupling efficiencies. The former is shown in Fig. 1c. For both, we found that commercially available devices with increased speed and efficiency, such as wavefront sensors and deformable mirrors, would be enough to establish an MMF to SMF interface working in the kHz-regime.

The presented method might find applications in optical telecommunication and could also be adapted to correct for very strong atmospheric disturbances in long distance free space communication.

Thermal plasmonics and metamaterials for sustainable society

Quasi-resonance of surface plasmons for near-infrared sensitivity improvement of silicon image sensor

A. Ono[1,2*], T. Yoshinaga[1], K. Hashimoto[1], and N. Teranishi[2]

[1]Graduate School of Integrated Science and Technology, Shizuoka University, Japan
[2]Research Institute of Electronics, Shizuoka University, Japan

Abstract: We proposed quasi-resonant mode of surface plasmons with metal grating which diffracts incident photons to a large diffraction angle of nearly 90 degrees with high efficiency. The quasi-resonance of surface plasmons were applied to improve the near-infrared sensitivity of silicon image sensor. Metal grating was fabricated on the top of silicon sensor and the trench was embedded by a metal for the pixel separation. The diffracted light repeats reflection at metal-filled trench. The effective absorption length was extended in silicon.

The enhanced electric field by surface plasmon resonance has been applied in surface enhanced Raman scattering, fluorescence enhancement, photovoltaics, and so on. Most of the approaches in plasmonics have been considered to utilize the strong electric field enhancement on the metal surface. Here, we applied quasi-resonance of surface plasmons to improve the silicon absorption efficiency in near-infrared wavelength region [1, 2]. Silicon absorption efficiency is low in near-infrared wavelength region due to its band gap at the wavelength of 1100 nm. A thicker silicon absorption layer improves the absorption efficiency, but degrades the image recognition due to the crosstalk between pixels. Therefore, near-infrared sensitivity improvement for silicon image sensor without thick layer is one of the significant issues to be applied in time-of-flight imaging, night monitoring, and biological tissue imaging. Yokogawa *et al*. have been proposed and demonstrated extension of the effective absorption length in silicon using pyramid arrays and SiO_2 trench [3]. They improved 1.8 times sensitivity at 850 nm wavelength. Here, we proposed plasmonic diffraction to extend the effective absorption length in silicon. The target wavelength was selected at 940 nm, which was used for many applications in near-infrared sensing. Our proposed plasmonic image sensor was constructed by silver gratings on the silicon absorption layer and silver trenches for the pixel isolation (Fig.1).

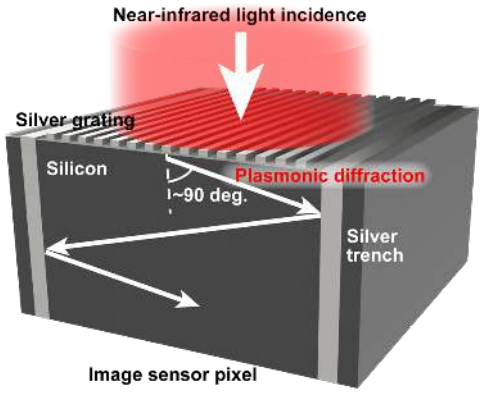

Figure 1. Schematic diagram of silicon based plasmonic image sensor with silver grating and silver trench

We found that near-infrared light incidence was diffracted with nearly 90 degrees in silicon side by silver gratings under the quasi-resonance of surface plasmons. The diffracted light propagates back and forth in silicon absorption layer by the reflection at the silver trenches. The effective propagation length was extended by this diffraction propagation, resulting in the absorption enhancement of the limited thickness of silicon absorption layer. Figure 2 shows the electric field intensity distribution of the cross-sectional view in silicon with silver grating on the top surface. In the silver grating period with 265 nm, width 230 nm, and height 85 nm, the incident near-infrared light was efficiently diffracted to the silicon side with high diffraction angle of approximately 80 degrees. The enhanced electric filed was observed at the interface between silver grating and silicon by surface plasmon excitation. In FDTD simulation, the diffraction efficiency was achieved to 49.7%. This plasmonic diffraction contributes to absorption enhancement because of the effective propagation length extension. By setting the silver trench as the isolation between pixels and the reflection mirror for the diffracted light, the incident photons were confined in silicon. Further devising the sensor configuration, we have clarified in simulation that absorption of silicon was enhanced to 53.5% in a limited thickness of 3 μm, which was an 8.2-fold enhancement compared to the bare silicon. Plasmonic image sensor dramatically improved the sensitivity in near-infrared and has a potential to be applied in near-infrared sensing.

Abstract: When a previously invisible physical quantity becomes observable, it opens the way to the discovery and elucidation of new physical phenomena. This has advanced science and technology, spread to various fields, and contributed to the development of society. Since the interaction between the optical magnetic field and matter is small, the optical magnetic field has not been observed. We have enabled optical magnetic field imaging by utilizing the magnetoelectric effect of single-gap split-ring resonator(SRR) that exhibits magnetic resonance at optical wavelengths.

Most of the optical responses in natural materials are caused by interactions with optical electric fields. Therefore, even if there is a place where the optical magnetic field is peculiarly strong, it cannot be detected directly. So, we have never seen the distribution of the optical magnetic field. If we can see the distribution of the optical magnetic field, what can we learn? For example, one would see the presence of loop currents (oscillating at high frequencies). Possibly, we may also see non-radiative electric quadrupole modes that occur in nanostructures. It may also contribute to elucidating the interaction between photons and phonons, which has recently attracted attention.

In our research, we proposed and demonstrated a method for observing the optical magnetic field distribution. We fabricated a large number of single-gap crescent-shaped gold SRRs with a diameter of around 100 nm on a glass substrate using Nanosphere Lithography.[1] White light was incident on a SRR arranged on the bottom surface of the prism in the arrangement shown in Fig.1(a). TE polarized light was incident at 45 degrees, which is the total internal reflection condition. The scattered light spectra of single isolated SRR are shown in Fig.1 (b). The spectral peak of the Ey polarization of the same component as the incident light was a wavelength of around 700 nm. This peak means the electric dipole in the same direction as the incident light was excited by the localized surface plasmon resonance of SRR. On the other hand, the scattered light of Ex polarized component different from the incident light appeared in the wavelength around 900 and 600 nm. In the case of

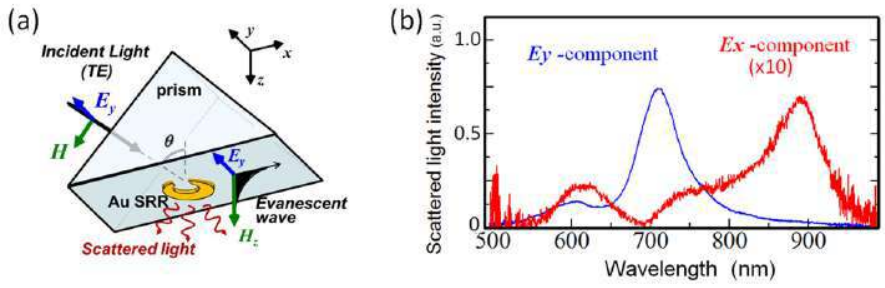

Fig.1 Experimental setup(a) and scattered light spectra of a single SRR(b)

oblique incidence, the incident magnetic field penetrates the single-gap SRR structure, and a magnetic resonance mode is excited in which a loop current flows in the ring of SRR. At that time, the loop current is thought to induce an oscillating current component perpendicular to the axis of symmetry, that is, an electric dipole in the x-direction due to the imperfect symmetry of the SRR structure, resulting in Ex-polarized scattered light. That is, when there is an optical magnetic field (Hy) perpendicular to the plane of the single-gap SRR, an electric dipole (x direction) perpendicular to the symmetry axis of the SRR is generated. Such a phenomenon is called the magnetoelectric effect.[2] We thought that this effect of single-gap SRR could be used for local magnetic field intensity monitoring and spatial distribution imaging. In order to demonstrate this, we fabricated a metasurface in which single-gap silver SRRs are densely arranged two-dimensionally[3] and photographed the scattered light intensity distribution at the magnetic resonance wavelength. For the optical magnetic field distribution used for the demonstration, interference fringes with a period of 367 nm created by two-beam interference were used. The interference fringes of the optical magnetic field and the optical electric field were designed so that the brightness was reversed. As a result of the experiment, Figure 2 was obtained, and the expected interference fringes were observed. This proves that optical magnetic field distribution imaging is possible.

Fabrication of metasurfaces for heat-shielding windows and 6G communications and investigation of the possibility of near-infrared reflection control by movable thin films

Y. Kanamori [1*]

[1] Tohoku University, Japan
[*]corresponding author: ykanamori@tohoku.ac.jp

Abstract: Metasurfaces for heat-shield windows which transmit visible wavelengths and reflect near-infrared (NIR) wavelengths for sun light were designed and fabricated. Transmittance of terahertz waves assumed for 6G communications was measured. Moreover, by combining the metasurfaces with movable thin-films, reflectance switchable filters that could change reflectance at NIR wavelengths whereas there was little change in visible wavelengths were designed. It can be expected to be used as smart glasses that control transmittance of the thermal wavelengths in summer and winter.

Metasurfaces have attracted attention as novel artificial materials having exotic optical characteristics academically, but also as practical usages [1-3]. Localized surface plasmon resonance on metasurfaces produces reflection peaks at the resonant wavelengths. Since the optical properties of metasurfaces depend on their shapes, or the refractive index of material existing within the surface plasmon polaritons distance range of metasurface, tunable metasurfaces based on micro-electromechanical systems technologies have been studied intensively in recent years [4,5].

In this study, visible-transparent and NIR reflective metasurfaces by designing their resonant wavelengths in the NIR region while maintaining high transmittance in the visible region are fabricated. The metasurfaces function as heat shielding filters and lead to energy saving. Moreover, by combining the metasurfaces with movable thin-films, reflectance switchable filters that can change reflectance at NIR wavelengths whereas there is little change in visible wavelengths are designed. It can be expected to be used as smart glasses that control transmittance of the thermal wavelengths in summer and winter.

Figure 1 shows a unit structure of metasurfaces. A cross-shaped Al structure is formed on an SiO_2 substrate. Here, l, w, h, and Λ are length, width, height, and period of the unit structure, respectively. h and Λ are fixed to be 60 and 450 nm, respectively. By making cross-shaped structures, there are no polarization dependence at a normal incident angle.

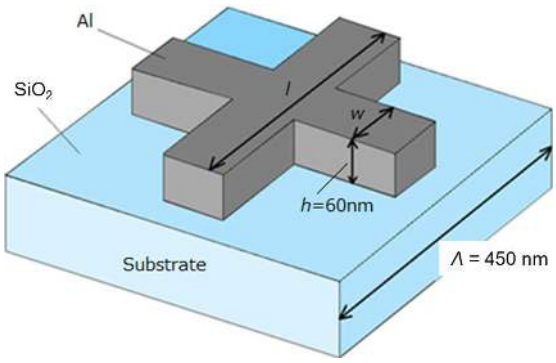

Figure 1: Unit structure of metasurfaces.

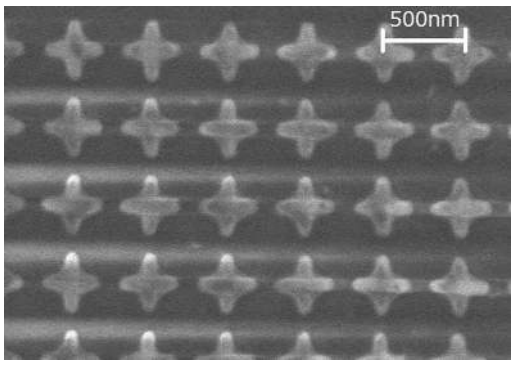

Figure 2: An SEM image of fabricated metasurface.

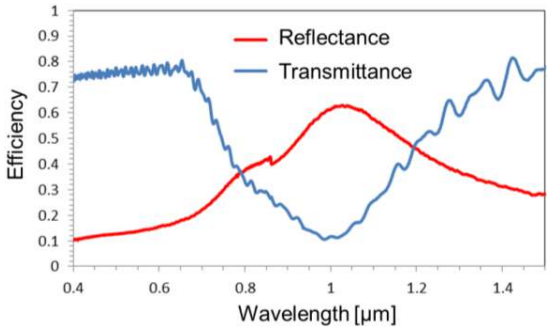

Figure 3: Measured spectra of the metasurface.

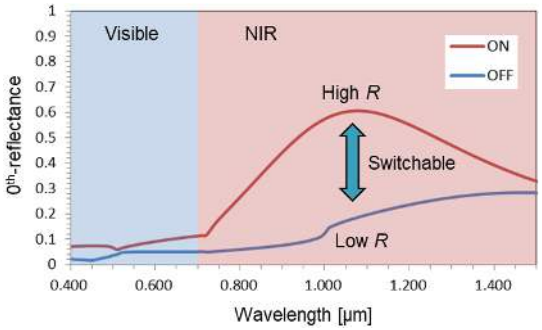

Figure 4: Calculated reflectance.

In fabrication, firstly, Al was deposited on a cleaned SiO_2 substrate, followed by electron beam lithography. Next, plasma etching was carried out. Finally, residual resist was removed.

A scanning electron microscope (SEM) photograph of fabricated metasurface is shown in Fig. 2. It is confirmed that the crossed structures which consist of Al are arranged on the SiO_2 substrate.

Figure 3 shows the measured transmittance and reflectance spectra of fabricated metasurface from visible to NIR wavelengths. At the visible wavelengths from 400 to 700 nm, uniform transmittance over 70% is maintained. At the NIR wavelengths larger than 700 nm in Fig. 3, the maximum reflectance of 62% is obtained at the resonant wavelength around 1.0 μm. In addition, high transmittance of terahertz wave (>50%) in the frequency range of 0.2-1 THz was achieved, which is suitable for applications in 6G communications.

Figure 4 shows calculated 0^{th}-ordered reflectance, based on rigorous coupled-wave analysis. ON and OFF indicated in Fig. 4 show high and low reflectance (R) at NIR wavelengths, respectively. By contacting a high refractive index plate consisting of silicon nitride on the metasurface, reflectance characteristics are switched from ON to OFF.

In conclusions, the metasurfaces that transmit visible wavelengths and reflect NIR wavelengths were designed and fabricated, successfully. The maximum reflectance of 62% was obtained at wavelengths around 1.0 μm, whereas uniform transmittance over 70% was maintained in the visible region. It was confirmed that reflectance in NIR region were switched from high to low one by contacting a high refractive index plate consisting of silicon nitride on the metasurface, on calculations. Si Plasmonic MEMS device for infrared sensing

M. Oshita, E. A. Abadi, T. Kan*

The University of Electro-Communications, JAPAN
*corresponding author: tetsuokan@uec.ac.jp

Abstract: When a metallic structure is formed on a semiconductor surface, the hot electrons in the metal excited by surface plasmon resonance (SPR) are extracted as an electric current. This method makes it possible to measure SPR by electric current in spacially limited situations. This sensing method can thus be integrated into MEMS (Micro Electro Mechanical Systems) to create attractive devices.

SPR is a collective resonance of free electrons on a metal surface in contact with a dielectric. When the light incident on a metal structure satisfies the SPR matching condition, the incident light couples to the free electron resonant vibration on the metal surface (Fig. 1(a)). Since the resonance mode changes depending on the metal geometry, a device can operate for specific wavelengths and polarizations. Furthermore, suppose the metallic structure is formed on a semiconductor. In that case, a Schottky barrier is formed at the metal-semiconductor interface, allowing hot electrons to be injected into the semiconductor and extracted as a current, enabling electrical readout of SPR (Fig. 1(b)). Furthermore, since the Schottky barrier height can be tuned lower than the silicon band gap, infrared detection becomes possible on a silicon device.

The authors have developed an infrared photodetector with metallic nanostructures embedded in Si. Copper nano blocks were embedded in the bottom of nanoholes on a silicon substrate (Fig. 1(c)). The block forms a Schottky junction with the surrounding silicon (Si), and hot electrons are injected into silicon by localized SPR induced by incident light irradiation. Copper forms a Schottky barrier of Φ_B = 0.65 eV with n-type silicon, so infrared photodetection is possible. In a device consisting of a 1000 nm periodic lattice of nanoholes with an

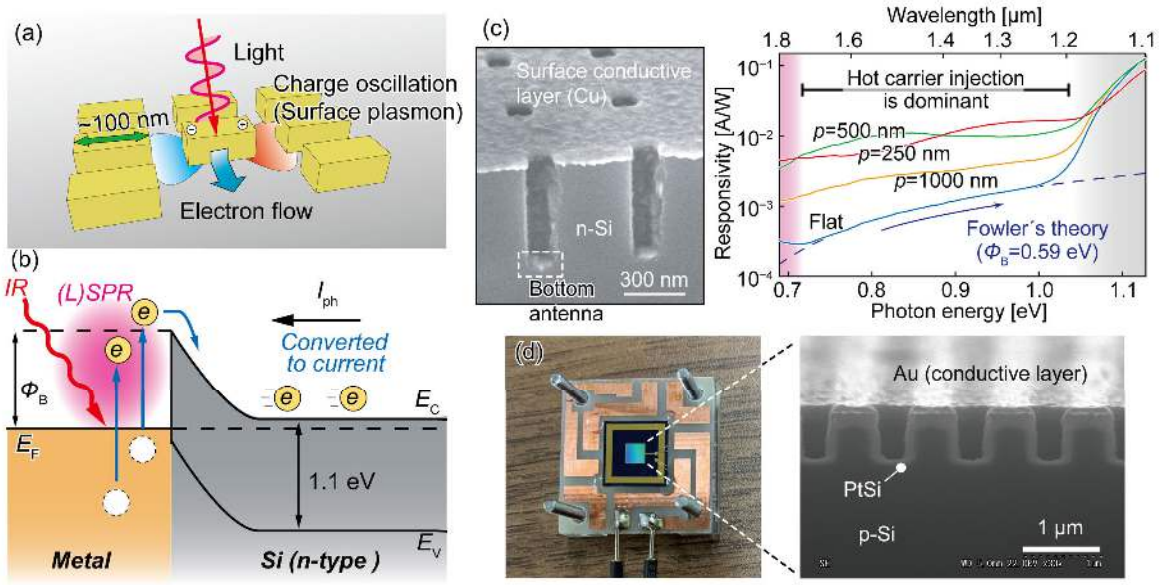

Fig. 1 Surface plasmon assisted infrared photodetection, (a) a device concept, (b) the Schottky barrier and photodetection mechanism, (c) buried nanoantennas for near-infrared photodetection[1], and (d) an mid-infrared photodetector[2].

aperture width of 150 nm, a sensitivity of more than 1 mA/W has been obtained down to a wavelength of 1.76 μm[1]. Furthermore, by changing the metal to a silicide (PtSi) presenting Φ_B = 0.28 eV with a p-type Si, it became possible to extend the measurable wavelength to mid-infrared, 3.4 μm[2]. Moreover, the spectrum measurement can be performed using a diffraction grating. Since SPR occurs at a unique angle of incidence for each wavelength on the grating, the angular current waveforms present peaks at a different angle depending on the wavelength (Fig. 2(a)). When the current is measured while scanning the incident angle, current waveforms become a superposition of each wavelength contribution composing the incident light (Fig. 2(b)). If the angular sensitivity spectrum for each wavelength is obtained in advance, the spectrum of the incident light can be reconstructed from this angular current waveform[3]. This measurement requires scanning the device angle relative to the incident light, and the angle scanning function can be integrated into a small device with MEMS technology[4]. Thus the spectral measurement is completed simply by irradiating light onto the small MEMS device. Integrating SPR with silicon MEMS can open up new fields of infrared sensing.

Abstract: High temperature stable thin film multilayers of metal and dielectric materials are important as selective emitters for thermophotovoltaics (TPV). We will present structured material systems from W, Ir, and HfO_2 and discuss degradation mechanisms.

Since the total radiated power of a thermal emitter scales with the fourth power of temperature, it is beneficial to realize structured material systems which not only provide selective emission, thus avoiding the emission of unwanted photons, but also stay stable at very high temperatures well above 1000 deg C. We are discussing the influence of phase stability of the dielectric constituent, agglomeration of the metallic constituent along with oxidation mechanisms and countermeasures to prevent such oxidation. In particular, Ir is promising as an oxidation-stable plasmonic material for TPV applications.

Spectrally selective infrared emitters enabled by 1D metamaterials

Yongkang Gong and Sang Soon Oh*

School of Physics and Astronomy, Cardiff University, Cardiff CF24 3AA, United Kingdom
*corresponding author: ohs2@cardiff.ac.uk

Abstract: We propose a new type of integrated and electrically controlled infrared emitter that exploits 1D dielectric/metallic multilayers. We design a multilayer system with a large photonic bandgap at the visible wavelengths and negligible reflection at the infrared wavelengths. Here, we experimentally demonstrate significantly enhanced emission at the broad infrared wavelengths of 1.4–14μm as well as strongly suppressed emission in the visible region.

Infrared (IR) emitters have been used for gas sensing in numerous applications such as detection of explosive or toxic gases, indoor/outdoor air quality monitoring, and medical diagnosis. Mid-IR thermal emitters based on metamaterials, especially with refractory metamaterials [1], have become popular due to their ability to generate thermal radiation with near-unity emissivity at arbitrary infrared wavelengths. We have recently demonstrated novel broadband and narrowband mid-Infrared metamaterial thermal emitters [2-4].

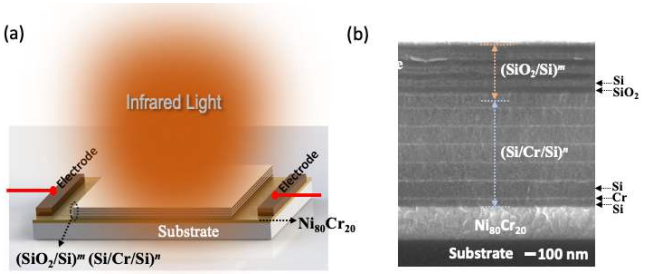

Figure 1 (a) Schematic of the IR emitter device (b) The thickness of each Si (SiO_2) layer in the $(SiO_2/Si)^m$ is 40 nm (100 nm), and the thickness of each Si (Cr) layer in the $(Si/Cr/Si)^n$ is 100 nm (4 nm); the number of periods m and n are 4 and 6, and the thickness of the $Ni_{80}Cr_{20}$ layer and the substrate is 300 nm and 0.5 mm, respectively. Adapted from Ref. [5].

In this work, we design a structure consisting of a 1D photonic crystal of and 1D metal/dielectric multilayer to suppress the emission at the visible wavelengths and enhance the emission at the infrared. As shown in Fig. 1, we stack $(Si/Cr/Si)^n$ and (SiO_2/Si) successively on top of a $Ni_{80}Cr_{20}$ nanolayer-deposited quartz substrate. After determining the thicknesses based of the transfer-matrix-method calculations, the designed structures have been fabricated using e-beam evaporation. Then, the emission property of the electrically heated devices was characterized using Fourier-transform infrared spectroscopy (FTIR) and grating spectrometer. Our experimental results show the averaged emissivity as high as ~0.81 over a broad infrared wavelength range of 1.4–14 μm and the averaged emissivity as low as ~0.07 at visible wavelengths of 0.45–0.75 μm.

We believe that the proposed high-efficiency thermal emitters will pave the way toward integrated infrared light source platforms for various thermal-photonic applications and provide a novel alternative for cost-effective, compact, low glare, and energy-efficient infrared heating.

Dynamic emissivity modulating thermoregulating fabric using metallic particles

M. G. Abebe[1*], G. Rosolen[1], and B. Maes[1]

[1]Micro- and Nanophotonic Materials Group, Research Institute for Materials Science and Engineering, University of Mons, 20 Place du Parc, B-7000 Mons, Belgium

Abstract: Maintaining comfort using photonic thermal management textiles can potentially decrease the energy cost for heating and cooling in residential and office buildings. We propose a thermoregulating fabric comprised of a high emissivity bottom layer and a metal-particle polymer composite on top to modulate emissivity and provide dynamic and passive thermal comfort. With detailed numerical modeling we demonstrate a wide dynamic ambient setpoint temperature window of ∼7.25 °C, with the wearer staying comfortable in the range between 18.5 and 25.75 °C. This thermoregulating performance indicates a vital energy-saving potential and paves the way to a more sustainable society.

As humanity starts to experience the consequences of climate change, addressing the global energy crisis provides us with a significant challenge. Surprisingly, more than half of our energy consumption goes to the heating and cooling of large empty spaces in residential and commercial buildings [1]. Therefore, passive personal thermal management, which creates a localized thermal regulation, can become critical to lower consumption and guarantee a sustainable future. Recently, micro-photonic driven local thermal management in textiles has captivated attention. Since radiative transfer accounts for around 50% of heat dissipation from the human body, a proper photonic thermal management strategy allows one to design passive temperature-regulating textiles. Previously we have shown a static state-of-the-art emissivity switch fabric design based on the Janus-yarn concept [2]. However, this fabric requires mechanical flipping to switch between cooling and heating modes.

Here we propose a metal-particle dynamic emissivity switch textile for dual-mode temperature regulation, using the fabrics' outer surface emissivity modulation. The fabric is constituted of a highly emissive bottom layer and a low emissive composite layer on top, which is thermo-mechanically dynamic (Fig. 1a). The top layer is made from a temperature-sensitive shape-memory polymer matrix with equal-sized metal particles (copper) uniformly dispersed, while the bottom layer is composed of carbon black. The proposed design operates in two modes, heating and cooling. When the ambient is cold, the fabric is in heating mode, and the polymer shrinks; thus, the volume fraction of the metal particles increases, resulting in high scattering and reflection, leading to a low effective emissivity of the fabric's surface [see Fig. 1a (I)]—subsequently, strong radiative heat emission to the ambient. When the ambient is hot, the fabric is in cooling mode; the polymer expands, allowing the low-emissive shape-memory polymer based top layer to stretch; as a result, the volume fraction of metal particles decreases [see Fig. 1a (II)]. This decrease substantially lowers radiation scattering and increases the fabric's emissivity, therefore facilitating more radiative heat transfer from the human body to the ambient. By introducing an optimized copper particle, one can achieve an effective emissivity contrast of about 0.65, which translates to a wide ambient setpoint window.

To model the fabric design, we first use electromagnetic wave theory (i.e., extended Lorenz-Mie solutions) to calculate the optical properties of a single metallic microsphere, such as scattering phase function, scattering

efficiency, and absorption efficiency. Second, we calculate the effective radiative properties of a particle cloud uniformly dispersed in a polymer matrix (effective scattering and absorption coefficients). Third, we investigate the radiative transfer analysis of a particulate medium using a collision-based forward Monte Carlo method. Finally, we implement the radiative parameters (emissivity) retrieved from the Monte Carlo calculations in the thermal model to retrieve the ambient setpoint temperature [3].

Figure 1b plots spectral emissivity for two specific cases, volume fraction f_v = 0.01 and 0.1, respectively, which we associate with the cooling and heating mode. In cooling mode (f_v = 0.01, blue line), we observe a very high spectral emissivity; therefore, the fabric is almost a perfect emitter for all the interesting wavelengths. In heating mode (f_v = 0.1, dark red line), the spectral emissivity is low over the entire human body emissivity spectral range (light blue background surface plot). It is clear that a low volume fraction results in high emissivity, and high volume fraction results in substantially decreased emissivity. This result is directly related to the metal particle cloud's effective scattering coefficient, which increases with volume fraction. The emissivity dependence on the volume fraction delivers the expected dynamic temperature regulation property of the proposed fabric. Heat transfer analysis shows that the design achieves a minimum setpoint of 18.5 °C to provide heating and the highest setpoint of 25.75 °C to provide cooling (Fig. 1c). The minimum setpoint corresponds to the emissivity of 0.27, where f_v = 0.1. On the other hand, the highest setpoint corresponds to an emissivity of 0.93, where f_v < 0.01.

Overall, we propose a dual-mode fabric design for personal thermal management using a multilayer approach by incorporating metallic particles to deliver emissivity modulation. The dynamic switching is achieved via a shape memory polymer matrix that responds to environmental changes. This design provides thermal comfort in a setpoint window of about 7.25°C.

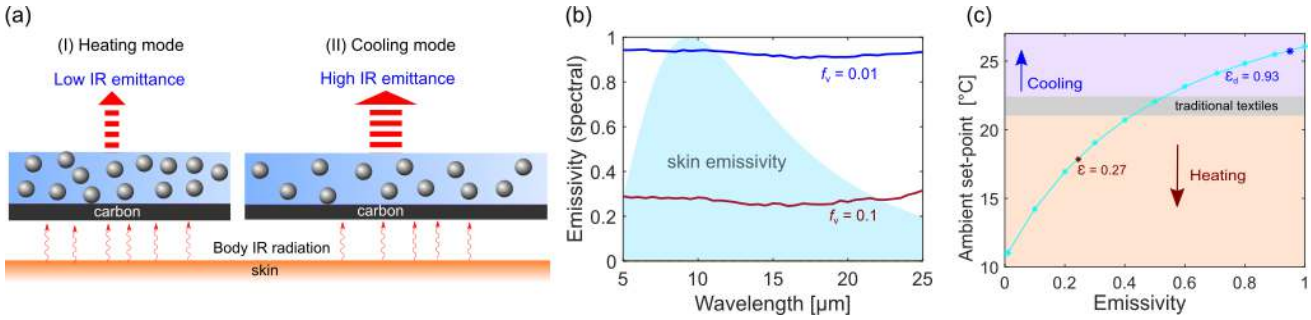

Figure 1. (a) Schematic illustration of fabric design working principle with dual mode operation. (b) Spectral emissivity for f_v = 0.01 and 0.1. (c) Ambient setpoint temperature of the design as a function of emissivity.

Abstract: Silicon microspheres with 2-3 μm in diameter, heated by means of a blue laser, at temperatures from 500 to 700 ºC emit light in the infrared with pronounced peaks that are associated with their Mie resonances. The emission occurs through the lowest order modes in the mid-infrared where the intensity can surpass the black body limit because the optical absorption cross section is larger than the geometric one.

The development of photonic circuitry in the mid-infrared constitutes a very promising technological niche, yet it is still in its infancy. In this context, light sources with appropriate performance are essential elements. Here, we show a light source based on a silicon microsphere and its thermal emission. The microsphere can reach a high temperature, near 700 ºC, when it is irradiated by a blue laser, λ = 405 nm, at a moderate power, P= 5mW. This process is relatively fast,[1] with characteristic excitation and decay times of the order of 10 μs, and it yields light radiation in the infrared with interesting spectral features. Instead of a broad emission, a silicon microsphere shows pronounced peaks that are associated with their Mie resonances. We have studied this phenomenon in two spectral regions of technological interest: in the mid-infrared where the fingerprint of most molecules appears, and in the near infrared, around the telecommunication wavelengths. Figure 1 shows such spectrum (black curve) in the mid infrared for a microsphere with 2080 nm in diameter, heated at 660 ºC.

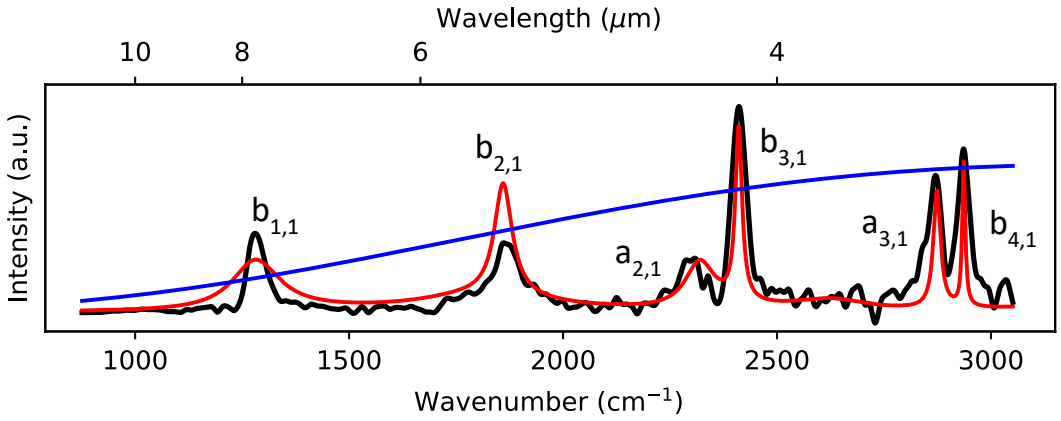

Figure 1: Measured thermal emission spectrum (black line) of a silicon microsphere with 2080 nm in diameter. The red curve corresponds to a fit to equation (1) with a fitted temperature of 660 ºC. The blue line is the calculated emission of a black body that has an area equal to the geometric projected area of the microsphere. The modes associated with each peak are indicated.[2]

The spectrum of figure 1 could be fitted (red curve) to the following equation:

$$I = \frac{2\pi hc^2}{\lambda^5 exp\left(\frac{hc}{\lambda kT}-1\right)}\, e \qquad (1)$$

that corresponds to the Planck equation of the black body emission modulated by the emissivity factor, *e*, where in this case *e* equals to the absorption efficiency of the microcavity defined by the particle. This allows identifying the resonances, that have been indicated besides their corresponding peaks with the usual nomenclature for transverse electric (b's) and transverse magnetic (a's) modes.[3] These are the lowest order modes. In addition, because the absorption efficiency is larger than one, the emission surpasses the Planck limit (blue curve) for the black body for some resonances.

Besides the mid-infrared, where the lowest order modes appear and where the sub-wavelength character in the three dimensions manifests, the light emission in the near infrared region shows as well pronounced peaks associated with Mie resonances. In this region we have found resonances with a quality factor of 400. In addition, we have demonstrated their wavelength tunability with temperature as figure 2 shows for a 3595 nm in diameter microsphere.[1]

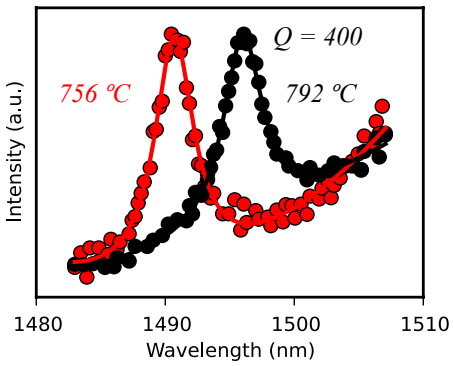

Figure 2: Measured $b_{10,5}$ resonance of a 3595 nm diameter silicon microsphere at two different indicated temperatures.[1]

Abstract: Metamaterials provide an accrued flexibility for tuning thermal emission but their resistance to high temperature is limited. So far, the few attempts to realize refractory metamaterial emitters relied on materials that are prone to oxidation which limits their operating temperature in air. In this work, we show how using innovative fabrication approaches and making the proper choice for associating a conducting and a dielectric material allows elaborating metamaterials with tunable emissivity that can operate in air at temperatures exceeding 1000°C.

At high temperature, thermal radiation accounts for a large part of the heat transfer. Therefore, the ability to tune thermal emission is paramount to improve energy efficiency when heating and cooling. It is also one of the keys for converting efficiently heat into electricity in a thermophotovoltaic system.

Electromagnetic properties of natural materials are mainly determined by their chemical composition. The metamaterial approach provides additional degrees of freedom for tailoring these properties by playing on the internal structure. This accrued flexibility is of particular interest for the design of thermal emitters: it allows full spectral control and impedance matching with free space, thereby maximizing the emission for a chosen wavelength range [1].

Unfortunately, most existing metamaterials rely on metals with a low melting point such as gold or silver. So far, the attempts to realize refractory metamaterial emitters relied either on refractory metals (e.g. Ta, Mo, W) or on nitrides (e.g. TiN, AlN, ZrN) [2, 3]. These materials do have high melting points but are prone to oxidation which limits their operating temperature in air [2, 4].

In 2013, Molesky et al. proposed a new approach to design selective emitters by engineering the poles and the zeros of the dielectric function of a hyperbolic metamaterial [5]. This theoretical paper served as a basis for several experimental implementations, the most successful one consisting of alternating layers of tungsten and hafnia [6], which were shown to be stable up to 1400°C under high vacuum [4]. However, in air the emitter still oxides and degrades above 1000 °C.

In this presentation, we will show how using innovative fabrication approaches and making the proper choice for associating a conducting and a dielectric material allows elaborating refractory metamaterials with tunable emissivity in the near infrared (NIR) that can operate in air at temperatures exceeding 1000°C.

Perfect Absorbers and Photothermal Control of Light by Single Crystalline Silicon Metasurface

J. Takahara[1,2*]

[1] Graduate School of Engineering, Osaka University, Japan
[2] Photonics Center, Graduate School of Engineering, Osaka University, Japan
[*]corresponding author: takahara@ap.eng.osaka-u.ac.jp

Abstract: Perfect absorbers (PAs) play crucial roles for energy saving towards sustainable society. Recently, all-dielectric PA metasurfaces have been demonstrated by degenerate critical coupling. In this talk, I present recent progress of our studies about single-crystalline silicon metasurface PAs operating from visible to near-infrared region by using electric/magnetic dipoles, quadrupoles excited in silicon Mie resonators. In addition, I demonstrate scattering control of light by photothermal effects in Huygens' metasurface.

A perfect absorber (PA) is one of the promising devices for energy saving towards sustainable society. This is because PAs achieve mutual energy conversion between heat and light with 100% efficiency [1]. In recent years, many kinds of plasmonic PAs have been proposed and demonstrated. Metal-free (non-plasmonic), all-dielectric PAs can be realized by degenerate critical coupling (DCC) [2]. In DCC condition, Electric Dipole (ED) and Magnetic Dipole (MD) modes in Mie resonator with mirror symmetry co-exist in Huygens' metasurface (HMS). In addition, radiative loss (γ) and intrinsic loss (ohmic loss) (δ) of two modes must be matched. For this reason, the wavelength of PA depends on δ of the material. We demonstrated that the wavelength of PAs can be tuned from visible to near-IR by controlling γ and δ by using embedded Mie resonators in silicon (Si) metasurface [3,4].

In this talk, I present recent progress of our studies about single-crystalline silicon (c-Si) metasurface PAs operating with wide-range of wavelength by DCC using electric/magnetic dipoles, quadrupoles excited in Mie resonators. In addition, I demonstrate scattering control of light beam by photothermal effect in the c-Si PA.

Figure shows schematic view of the PA based on embedded Si Huygens' metasurface and the concept of DCC. We are able to achieve PA at any wavelength in principle by tuning refractive index of surrounding dielectric medium (n) as well as intrinsic loss of a cap layer (e.g. amorphous Si (a-Si)), because DCC condition ($\gamma = \delta$) can be satisfied at any wavelength if the cap layer is lossy at the wavelength.

In addition, we propose and demonstrate experimentally all-optical switching device by using photothermal effect of the PAs of Huygens' metasurface. All-optical switching (on/off) effect can be observed in 1/10 power rather than the non-PA metasurface [5]. Photothermal effects in Mie resonators pave a new pathway to efficient all-optical switching in low power consumption.

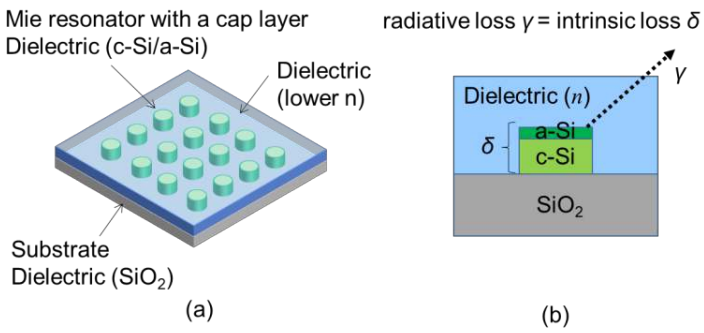

Figure (a) Schematic view of PA based on embedded Si Huygens' metasurface and (b) the concept of DCC.

Abstract: We demonstrate the plasmon-enhanced visible-light-driven hydrogen production from water using a polymer photocatalyst integrated with a TiN metasurface absorber. A 300 % increase in the hydrogen evolution rate was observed due to the LSPR that enhances the rates of light absorption, carrier separation, and hot-carrier transfer in polymer photocatalysts.

Broadband perfect absorbers in the visible region have attracted considerable attention in many fields, especially in solar thermophotovoltaic and energy harvesting systems. However, developing light absorbers with high absorptivity, thermal stability, and a broad bandwidth remains a great challenge. Here, we theoretically and experimentally demonstrate that a titanium nitride metasurface absorber exhibits broadband absorption with an average absorption of more than 92 % over a wavelength range of 400 nm to 750 nm. The increase in absorption is attributed to the localized surface plasmon resonance (LSPR). We demonstrate the plasmon-enhanced visible-light-driven hydrogen production from water using a polymer photocatalyst integrated with a TiN metasurface absorber, as shown in Figure 1. A 300 % increase in the hydrogen evolution rate was observed due to the LSPR that enhances the rates of light absorption, carrier separation, and hot-carrier transfer in polymer photocatalysts.[1] These results enable a new approach to preparing high-efficiency solar energy harvesting systems. The concept is extensible to other types of photocatalysts, such as 2D materials. In the end, we will also discuss the outlook for refractory metasurface in applications of solar energy harvesting systems.[1,2]

Abstract: A typical thermoelectric generators (TEGs) employ complex out-of-plane configurations, which often require additional thermal insulation components to preserve the temperature difference across the TEG. However, this can result in rigid and bulky configuration. In this study, we came up with a new TEG that is environmentally friendly and soft to the touch. It uses a pattern inspired by the stripes of a zebra to create a large temperature difference, making it a good option for future energy systems.

A thermoelectric generator (TEG) provides electrical power with thermal gradient. A key challenge in the development of TEG is making large temperature gradient through the device and miniaturization [1]. A conventional thermoelectric generator (TEG) involve a selective emitter with high IR emissivity to form the cool region at the TEG, while the bottom side is heated by ambient surroundings or solar energy with extended structures. However, a conventional TEG typically has the heating and cooling area in the direction of out-of-plane, matching the natural direction of heat flow, which requires additional thermal insulation components to preserve the temperature difference across the TEG [2]. Consequently, such TEGs can become bulky and complex, hindering their integration with other system components. Furthermore, As the size of the device reduces, so does its thickness, making it challenging to maintain a significant temperature differential between its upper and lower surfaces.

In this study, we present a novel approach for creating a large-area, in-plane thermoelectric generator (TEG) inspired by the zebra pattern, which maintains a significant temperature differential even in the horizontal direction. The TEG's heating region employs solar absorption, whereas the cooling region utilizes passive radiative cooling to optimize the temperature contrast between the two regions. Maintaining the temperature difference horizontally enables the TEG to be compact and stretchable. (Fig. 1A) The device is biodegradable, addressing the environmental impact. (Fig. 1B)

Fig. 1C illustrates an exploded view of stretchable, scalable, sustainable power scavenger using zebra pattern, consisting of a radiative modulator (top layer) and TEG (bottom layer). The proposed system comprises a microfiber membrane made of Poly(lactide-co-ε-caprolactone) (PLCL), which is coated with distinct patterns of poly(3,4-ethylenedioxythiophene)-poly(styrenesulfonate) (PEDOT:PSS) functioning as radiative heating and cooling elements. During the daytime, the TEG sustains the temperature gradient through infrared (IR) radiation and solar reflection in cooling region and IR reflection and solar absorption in the heating region. Even at night, the device maintains the temperature difference due to the cooling and heating regions responding oppositely to the IR radiation. (Fig. 1D)

To demonstrate the proof-of-concept, we measured the real-time outdoor power generation of the energy-harvesting system equipped with the radiation modulator, as shown in Fig. 2. The TEG produced a

maximum temperature gradient of approximately 17℃ between the black and white regions, resulting in a maximum power density of roughly 0.006 mW/m^2.

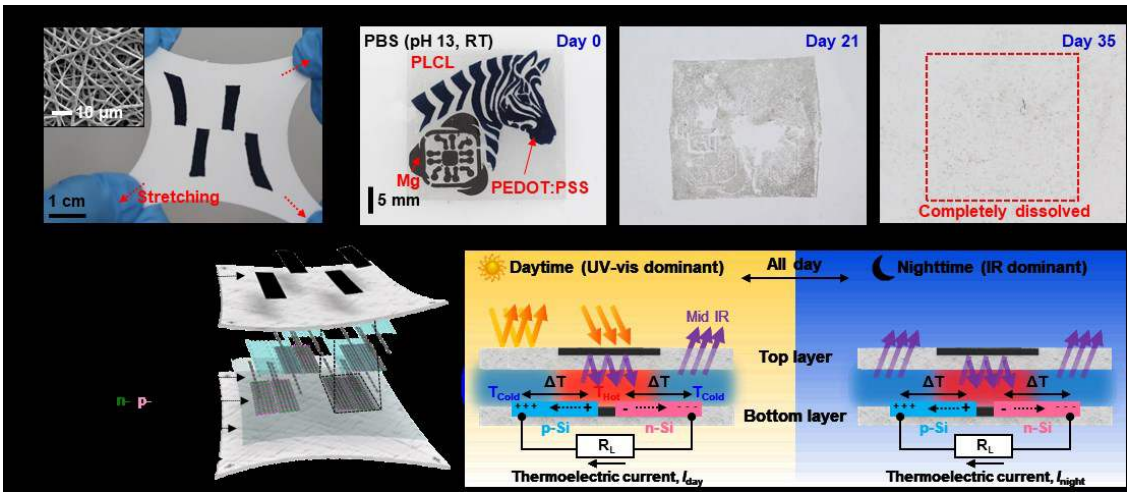

Figure 1. (A) A picture demonstrating stretching of a sustainable power scavenger using zebra-inspired in-plane radiative cooler/heater. The inset shows SEM image of the radiation modulator. (B) A series of dissolution images of a PLCL/PEDOT:PSS membrane and Mg film device, in PBS solution (pH 13) at room temperature. (C) A schematic view of (top layer) radiation modulator inspired by the stripes of a zebra and (bottom layer) thermoelectric generator (TEG) that are oriented in-plane direction of the device. (D) Cooling (white area) and heating (black area) mechanism of the device that sustain its temperature difference in two color region by 24 hours.

Realization of true perfect absorber metasurfaces

Y. Nishijima[1*]

[1] Department of Electrical and Computer Engineering, Graduate School of Engineering, Yokohama National University, 79-5 Tokiwadai, Hodogaya-ku, Yokohama, 240-8501, Japan

[*]corresponding author: nishijima-yoshiaki-sp@ynu.ac.jp

Abstract: We have realized true perfect absorption with midinfrared metasurfaces by numerical simulation and experimental measurements. To realize this feature, we noticed that the controlling of absorption and scattering in metasurface.

Realization of perfect absorption is desirable in the field of photo-thermal, photo-voltaic energy conversion. Especially radiation absorption in metal-insulator-metal (MIM) metasurface, which generally consist of a metal back-plate, dielectric layer, and a metal nano-structure, is currently applied for realizing a great variety of efficient photo-thermal energy converter designs. Such converters also show significant promise in the mid-infrared (IR) wavelength range, where they are used as both IR radiation sources as well as detectors, notably for applications in optical sensing of volatile organic compounds (VOCs)[1-3].

In most studies, the absorbance A exhibited by a MIM metasurface is among its most important properties implicitly treated as $A = I - R$, where I is total incident energy on the sample ($I = 1$ in the normalized presentation), whereas R is the reflectance. The metal back plate is understood as a reflector with negligible transmittance owing to its considerable thickness (Typically, thickness $t > 200$ nm of Au thickness is used as back ground metal). Hence, the scattered portion of radiation energy S is either ignored or not explicitly accounted for, since it is assumed to be incorporated in R or and is distributed among them[4].

However, the origin of plasmon resonance comes from scattering of light by metal nano structures. The absorption part will become the loss of the resonance. Therefore, it is natural to put the scattering as optical power balance equation as $I = A + R + T + S$. Due to a zero transmittance $T=0$ of the MIM metasurface, both R and S manifest as a backward reflection of light. Therefore, it is difficult to identify the true A and S from reflection measurement in experiments, it corresponds to the extinction, $Ext = A + S$.

One of the evidences of this scattering effects can bee seen in thermal radiation measurements. Figure 1 shows reflection spectra and thermal radiation spectra of MIM metasurface with different disc diameter. When the parameters of metasurface, such as thickness and permittivity of insulator layer, disc diameter, periodicity and resonance wavelength, metasurface realized perfect ant reflection R~0 (PAR). However, even such PAR condition, the radiation is reached around 60 ~ 70% and they did not reach to the perfect radiation (PR, Rad ~ 100%). According to the Kirchhoff's thermal law of radiation (absorption coefficient □ = radiation coefficient □), Absorption portion is directly equal to the radiation portion. Therefore, we concluded that PAR condition is not equal to the perfect absorption (PA), and the reflection measurements cannot identify PAR and PA.

In the presentation, we demonstrate the quantitatively analyzed the scattering effects by numerical modeling as well as fabrication and characterization of MIM metasurface. We observed the considerable effect backwards scattering has on the optical response of metasurface. Also, there is further room for improvement in removing the specular reflection of metasurface, guided by detailed FDTD analysis. Light scattering under

slanted incidence is the next required step for analysis of MIM response and can be achieved at a quantitative level using FDTD modeling. Also, we will show that it is possible to increase the PA and PR condition with using of nano-thin layers of metals with strong absorbance such as Cr, and high absorption plasmonic metal, AgAuCuPdPt high entropy alloy as new plasmonic materials.

Non-radiative cooling materials with high transparency

H. TT. Tam, M. Toma, and K. Kajikawa*

Tokyo Institute of Technology, Japan
*corresponding author: kajikawa@ee.e.titech.ac.jp

Abstract: Transparent non-radiative materials (non-RC) materials were investigated. The temperature reduction was measured for a glass plate covered with ITO, DMD, or Ag nanowire. It was found that the temperature reduction was negligible when exposed to the sky, whereas the samples were transparent in the visible wavelength region. The results show that these materials can be used for non-RC materials.

Radiative cooling (RC) releases heat into the universe through black-body radiation. This research field has recently attracted much attention because RC can refrigerate objects without using electricity [1]. However, there are some cases in which RC is a hindrance. For example, the surface of a car's windshield freezes on a sunny morning because the glass shows a relatively high RC performance. The windshield is sometimes covered with a cloth at midnight to prevent a freeze.

We investigated transparent "non-radiative materials (non-RC)" materials in this research. Glass plates coated with ITO (Indium Tin Oxide), DMD (dielectric/metal/dielectric: AZO(Aluminum-doped Zinc Oxide)/Ag/AZO), and AgNWs (silver nanowires) were examined. They are transparent in the visible region and have high reflectivity in the mid-infrared region. The RC measurements were performed in both in-house and in-field setups. The temperature reduction, $\Delta T = T_{amb} - T_{samp}$, was measured in both cases, where T_{amb} and T_{samp} are the temperatures of the ambient and the sample, respectively.

The temperature reduction measured in the field was negligible for ITO and DMD, whereas that for a glass plate was 1.5 K. The reduction for AgNW was 0.3 K, which is lower than that of a glass plate. These results show they can be used as non-RC materials.

New trends in opto-magnetism and magneto-optics

META 2023, PARIS - FRANCE, JULY 18 – 21, 2023

Twisted light affects ultrafast demagnetization

Abstract: High-intensity ultrashort laser pulses can destroy the magnetic order of ferromagnetic thin films on the femtosecond timescale. It is still an open question if the angular momentum of light can support this effect. For the material nickel, it has been shown that the spin of light only has a negligible influence. However, in our work, we experimentally demonstrate that photonic orbital angular momentum (OAM) affects the ultrafast demagnetization dynamics of a thin nickel film within the first hundreds of femtoseconds.

Optical fields can carry an orbital angular momentum (OAM) of $L = l\hbar$ with the OAM quantum number $l \in \mathbb{Z}$. Since its discovery in 1992 [1], there have been various applications of light with additional OAM, such as quantum entanglement, micromanipulation, communication, and microscopy [2].

Our research explores the potential impact of the OAM of light (often referred to as twisted light) on laser-induced ultrafast demagnetization of ferromagnetic materials. In this field, the question of how the angular momentum is conserved during the optically induced loss of magnetic order has not yet been fully answered. It has been shown that the spin angular momentum of light does not affect ultrafast demagnetization in ferromagnetic thin films such as Ni [3, 4]. However, pumping such a system with photons carrying OAM offers the potential to provide new insights, not only into the dissipation of angular momentum in the material but also into the interaction of optical OAM with matter in general.

We investigate ultrafast demagnetization of a thin nickel film induced by OAM light with time-resolved magneto-optic Kerr-effect measurements. We observed peculiar demagnetization dynamics that have so far not been observed for light without OAM: depending on the excitation geometry, the photonic OAM either supports (speeds up) or obstructs (slows down) the demagnetization process. Furthermore, we discovered that this effect occurs faster for higher OAM orders [5].

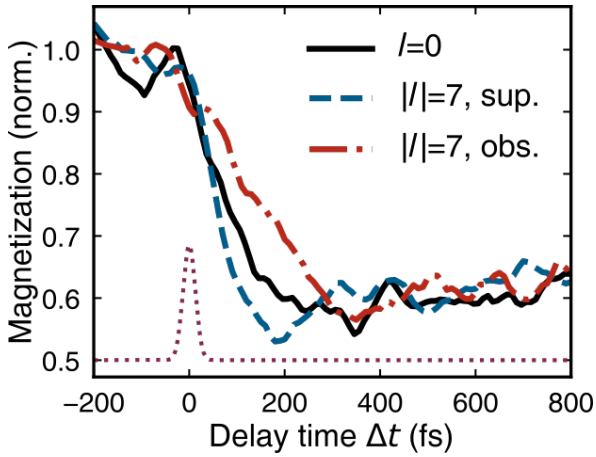

Figure 1: Demagnetization of the sample after irradiation of a pump pulse with $|l| = 7$ in the supporting (dashed line) and the obstructing (dash-dotted line) geometry in comparison to demagnetization with an $l = 0$ (solid line) beam. For better visualization, the data was smoothed. The dotted curve visualizes the pump pulse duration.

Magnetoplasmonics beyond metals: the case of plasmonic Transparent Conductive Oxide Nanocrystals

A. Gabbani[1*]

[1]Department of Chemistry and Industrial Chemistry, University of Pisa, Pisa, Italy

[*]corresponding author: alessio.gabbani@dcci.unipi.it

Abstract: In this contribution we show the potentiality of Transparent Conductive Oxide (TCOs) nanocrystals (NCs) for magnetoplasmonics, giving a proof-of-concept demonstration of their excellent performance in field-modulated refractometric sensing. Moreover, we demonstrate the ability of magneto-optical spectroscopy to accurately extract carrier parameters in this novel class of plasmonic materials, widely employed in plasmonics and optoelectronics.

Active modulation of the plasmonic resonance with an external tool enables a significant improvement of plasmon-based sensors and optical devices.[1] The use of magnetic fields to modulate plasmons presents several advantages: it is fast, easy to implement in devices, and fully reversible as it does not damage or modify the plasmonic material. However, achieving large magnetic modulation of the plasmonic resonance without broadening the optical response represents a great challenge in material choice for magnetoplasmonics, limiting the application in real-life devices. Indeed, noble metal nanocrystals (NCs) have sharp optical resonances, but weak magneto-optical signal, proportional to the cyclotron frequency (ω_C) [2]; on the other hand, nickel ferromagnetic nanodisks [3] or hybrid bimetallic nanostructures [4] have large magnetic modulation, while suffering from the high optical losses of the magnetic metal, thus broadening the plasmonic resonance.

To overcome such limitations, we propose a paradigm shift in material choice, employing plasmonic TCO NCs. Such NCs are able to support a plasmonic resonance in the infrared, due to the free carrier density introduced through aliovalent doping, and are promising materials for several optoelectronic applications spanning from smart windows[5] to infrared thermoplasmonics[6] and redox sensors[7]. Here, we employed two classes of TCOs NCs: Indium Tin Oxide (ITO) and F- and In^{3+} doped CdO (FICO), prepared by chemical synthesis with an average size around 10 nm. FICO NCs show up to 40-fold enhancement of the magnetoplasmonic response compared to Au NCs, detected through Magnetic Circular Dichroism (MCD). Such enhancement is due to the lower mass (m*) of free carriers in TCOs with respect to most metals, which in turn increase ω_C, combined with a reduced plasmon line width.[8]

Employing colloidal dispersions of TCO NCs in a proof of concept field-modulated refractometric sensing experiment we achieved a superior refractive index sensitivity with respect to metal-based magnetoplasmonic systems reported in the literature (Figure 1) [2-4]. Our approach challenges the current state of the art of plasmonic refractometric sensing [9], with the advantage of not requiring curve fitting but simply tracking a change in magneto-optical signal at a fixed wavelength. Considering that non-magnetic TCOs have been used in our work, a further improvement is potentially achievable incorporating TCOs in hybrid magnetic-plasmonic nanostructures, or introducing magnetic dopants in TCO NCs.

Finally, we demonstrate how the use of magneto-optical spectroscopy can be important to extract accurately free carrier parameters (density and effective mass) in this novel class of plasmonic materials. The latter is

quite important as carrier density in TCOs can be tuned across a wide range (from 10^{18} to 10^{21} carriers/cm^3), this affecting their optical and conductive properties. Indeed, conventional approaches to extract the carrier density rely on the fitting of the extinction spectrum, and the use of literature values of the carrier effective mass, which are generally measured independently on films or bulk materials.[10] Conversely, we propose a novel approach based on the simultaneous fitting of the extinction and MCD spectra to extract the carrier density and effective mass directly on the colloidal dispersion of the NCs. We believe that the proposed approach will contribute to shed light on the modification of free carrier parameters with synthetic or post-synthetic (photo-chemical or electrochemical) doping in plasmonic doped semiconductor NCs.

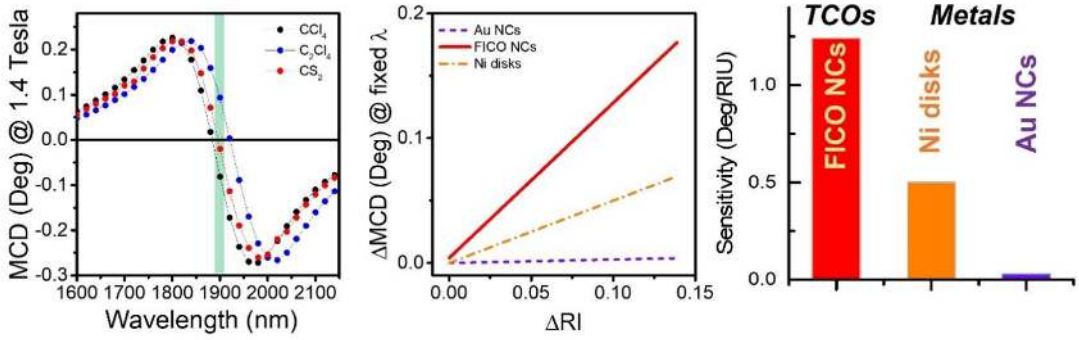

Figure 1: a) MCD of FICO NCs in three different solvents; b) MCD signal at fixed wavelength as a function of the solvent refractive index (RI) variation; c) RI magneto-optical sensitivity for FICO NCs compared with gold and nickel nanostructures.

Nanoscale and ultrafast magnetophotonics

A. Dmitriev[1]

[1]Department of Physics, University of Gothenburg, Gothenburg, Sweden
alexd@physics.gu.se

Abstract: Nanoscale magnetophotonics unites the concepts from magnetism (switching, storage, steering) with light (energy, information, photochemistry) at the nanoscale [1]. Our own exploration of this merger started some 10 years ago by conceiving nanoscale optical and magnetic antennas with magneto-optical properties dependent on optical resonances [2]. Today I highlight our recent work, were we employ plasmon nanoantennas to either funnel electromagnetic energy into ferrimagnetic films at the nanoscale assisting the demagnetization [3], or construct hybrid plasmon-ferrimagnet nanoantennas for that [4]. The produced architectures could also serve as the conceptually new high-resolution light incidence direction sensors or a platform with multistate demagnetization, potentially opening up for nanomagnetic neuromorphic-like ultrafast systems. We also show how adding nanoplasmonics allows to 'see' single molecule magnets with spectroscopy at ambient conditions [5]. Finally, I discuss a very intriguing prospect of 'spilling' materials properties (like electronic interband transition) outside the actual material by strongly coupling electronic and optical resonances in ferromagnetic Ni [6].

Magneto-Optical Light-Matter interactions in Weyl Semimetals

D. Cheskis[1*]

[1]Physics Department, Faculty of Natural Sciences, Ariel University, Israel

[*]corresponding author: dimach@ariel.ac.il

Abstract:

We present in this work is an experimental study of topological semimetals. This work was focused on studying the behavior of the type I $Co_3Sn_2S_2$ Weyl semimetals. Primarily, we are interested in magneto-optical measurements of these materials. Due to the effect of chiral anomaly, it is expected that the angle between electric and magnetic fields due to the term E*B [1] leads to the specific impacts in Weyl semimetals. In particular, it has been claimed that the chiral anomaly results in a charge imbalance between the Weyl nodes. In Weyl semimetals, the dielectric tensor receives a specific form [2] that allows observing chiral anomaly via magneto-optical Kerr effect. Such studies have been performed for Cd_3As_2 crystals under an external magnetic field, and the outcome of the chiral anomaly was measured by magneto-optical methods. We are demonstrating our first results for $Co_3Sn_2S_2$ crystals. To the best of our knowledge, such a study was not performed in these materials.

Abstract: The angular momentum transfer of circularly polarized light to a metal nanoparticle is studied using the time-dependent density functional theory in the real time formulation. It is found that the induced magnetic moment is maximal at the surface plasmon frequency of the nanoparticle, showing that it is a resonant plasmonic effect.

Transfer of angular momentum from helicity-controlled laser fields to a nonmagnetic electronic system can lead to the creation of magnetization [1]. The underlying mechanism in metallic nanoparticles is based on the inverse Faraday effect and has been studied using different theoretical approaches [2]. In this work, the dynamics using an orbital-based quantum-mechanical method within a many-body theoretical framework is investigated [3]. To this end, the real-time formulation of time-dependent, density-functional theory is used to study induced orbital magnetism in metallic nanoparticles excited by circularly polarized light. The nanoparticles are described by a spherical jellium model on a real-space grid. The polarized laser field gives rise to an angular momentum and, hence, a magnetic moment, which is maximum at the surface plasmon frequency of the nanoparticle, revealing that this is a resonant plasmonic effect. The primary contribution to the magnetic moment comes from surface currents generated by the plasmonic field, although some bulk contributions due to the quantum-mechanical nature of the system (Friedel oscillations) still persist. We compare several nanoparticles of K, Na, and Au having the same size and excited at their respective plasmon frequencies and show that the generated magnetic moment per energy pumped into the system is maximum for K and minimum for Au. A similar trend is observed for nanoparticles of the same chemical species but different sizes.

Optics and THz for ultrafast magnetization manipulation in ferro and ferrimagnetic systems

J. Gorchon[1]

[1]Institut Jean Lamour, CNRS, Université de Lorraine, 54000 France

Abstract: Controlling magnetization at ultrafast timescales has always been a major challenge and objective both for applications and fundamental aspects. In recent times, new methods that enable ultrafast magnetization reversal exploiting different stimuli, ranging from optics, to ultrafast on-chip current pulses, have been demonstrated. Moreover, some of these methods enable control of simple archetypal ferromagnetic systems. In this talk I will present some of these methods and will discuss various of the physical mechanisms playing a role.

Spin-transport, and the resulting spin-torques when spins are injected into a magnetic material, allow us to control the magnetization direction in magnetic devices electrically. We can use, for example, the spin-transfer torque effect [1,2] to reverse the magnetization of a magnet within nanoseconds. Such method has paved the way for applications such as spin-transfer-torque magnetoresistive random access memory (STT-MRAM). However, current-induced STT switching below a few hundred picoseconds with low power consumption while maintaining high thermal stability is challenging.

At our lab in IJL we are working on two different approaches to exploit spin transfer effects at ultrafast timescales. The first consists on using picosecond-wide charge current pulses (in the THz range) generated via photoconductive switches, to induce spin-orbit torques on magnetic layers [3,4]. The second approach focuses on the use of optical absorption to drive sub-picosecond spin currents in spin-valve structures [5,6] (see Fig1). We have recently shown, that both of these methods allow for ultrafast control of various archetypal out-of-plane magnetized ferromagnetic and/or ferrimagnetic layers. The mechanisms at play bridge concepts from ultrafast magnetism and conventional spintronics, enabling surprising dynamics.

Figure 1: A fully ferromagnetic spin-valve being excited by a femtosecond laser pulse can have its free layer reversed under no application of any magnetic field. We attribute the reversal to spin currents generated during the heating of the layers.

Amplification of magneto-optical activity via plasmonic modes hybridization

P. Vavassori[1,2*], Terunori Kaihara[1], and Pablo Rodriguez-Suarez[1]

[1]CIC nanoGUNE BRTA, Donostia–San Sebastian 20018, Spain

Abstract: We explore magnetoplasmonic-disk/plasmonic-ring nanocavities to achieve free-space light excitation and hybridization of multipolar modes. We show that the enhanced tunability and linewidth sharpening of Fano resonances in metasurfaces made of periodic arrangements of such hybridized magnetoplasmonic nanocavities produce a large amplification of the magneto-optical response together with the control of reflectance (Kerr configuration) and transmittance (Faraday configuration).

Magneto-optical (MO) effects are widely used in studying technologically relevant magnetic materials as well as to realize optical devices exploiting non-reciprocal propagation of light. The continuously developing field of magnetoplasmonics merges the concepts from plasmonics and magneto-optics to realize novel phenomena and functionalities for the manipulation of light at the nanoscale [1-4]. Owing to the intertwined optical and magneto-optical properties, magnetoplasmonics offers a versatile toolbox for actively tunable optical ultrathin surfaces and metasurfaces [5-7]. Enhancing magneto-optical effects is crucial for size reduction of key photonic devices based on non-reciprocal propagation of light and to enable active nanophotonics. Most studies focused on the amplification of the MO response produced by the excitation of localized dipolar plasmonic resonances (LPRs) in metallic magneto-plasmonic nanostructures. For a circular disk-like magneto-plasmonic nanoantenna, incident radiation of proper wavelength excites a primary LPR. When the nanoantenna is magnetized by the application of a magnetic field (H), a second LPR is induced by the inherent MO activity. This second MO-induced LPR (MOLPR) is driven by the primary LPR and is directed orthogonally to both H and the LPR. The ratio between the orthogonal radiating electric dipoles corresponding to the MOLPR and the LPR determines the magnetic-field induced polarization change of scattered light [1]. The amplitude of the electric dipole of the LPR is enhanced by the quality factor Q of the resonance with respect to the electric dipole induced in a continuous film. For typical metallic constituents Q can be up to 10 in the visible/near-infrared spectral range. Interestingly, the amplitude of the electric dipole of the MOLPR is enhanced by a factor Q^2 (i.e., up to 100) with respect to film or bulk magnetic material counterparts. This is because the MOLPR is a LPR resonance (Q-enhancement) not directly driven by the incident electromagnetic field but by the Q-enhanced primary LPR. This Q^2-enhancement of the MOLPR represents the limit for the maximum achievable amplification of the MO activity with respect to the film counterpart. However, polarization of re-emitted light is determined by the ratio between the MOLPR and LPR. Therefore, the simultaneous excitation of the LPR and MOLPR limits the maximum achievable enhancement of magnetic-field activated change in polarization to only a factor of Q, as observed experimentally [1-2], given that the LPR increases the reflectance. This Q-times enhancement of the MO activity represents a sort of fundamental upper limit that cannot be overcome using dipolar LPRs, hindering the practical applications of magnetoplasmonics to active nanophotonics and flat-optics

Recently, we disclosed and demonstrated an approach that exploits dark plasmons to achieve an unprecedented amplification of MO activity [8]. We designed and realized a symmetry broken

non-concentric magnetoplasmonic-disk/plasmonic-ring nanocavity fabricated by e-beam lithography. The broken symmetry enables the free-space light excitation of dark multipolar modes in the plasmonic-nanoring and their hybridization with the dipolar plasmonic resonance of the magnetoplasmonic nanoantenna. Such hybridization gives rise to a multipolar Fano resonance that, when excited, increases the reflectivity by a factor substantially lower than Q resulting in a large amplification of the magneto-optic response of the nanocavity, which is now approaching the Q^2-enhancement, namely the limit for the maximum achievable MO activity amplification. Such large amplification is explained as due to the peculiar and enhanced electrodynamics of the nanocavity, yielding to a large magnetically activated and radiant MOLPR driven by the intense but low-radiant multipolar Fano resonance mode [8]. It was anticipated in Ref. [8] that the concept proposed is general with prospects for even higher enhancements via optimization of the nanocavity design. In this study, we present a different nanocavity design that would allow overcoming several of the limiting constraints of the original design, that is a concentric arrangement of the noble-metal nanoring with an embedded hybrid noble-metal/ferromagnetic disk. In this design, an intense, sharp, and low-radiant Fano mode is produced by the hybridization of the dipolar mode of the disk and the dipolar bonding mode of the ring. The electrodynamics arising from the strong coupling between these two dipolar modes produces an exceptionally enhanced radiant MOLPR and allows for a broad control of the reflectance and transmittance to achieve a large amplification of the MO response both in reflection and transmission.

Abstract: We report magnetic helicoidal dichroism (MHD) in the interaction between XUV beams carrying orbital angular momentum (OAM) and magnetic vortices. It appears as a differential intensity profile of beams with OAM, reflected off magnetic structures with opposite curling sense. The results match theoretical predictions and confirm the potential of MHD for studying laser-triggered ultrafast dynamics in complex magnetic materials.

After finding many applications in the visible range, OAM beams with XUV wavelengths and ultra-short pulse duration, in the femtosecond to attosecond ranges, became available recently at high-harmonic generation (HHG) [3, 4] and free-electron laser (FEL) sources [6], widening considerably their application range. However, it has thus far found very scarce applications for magneto-optics, which rather harnesses the spin angular momentum of light to investigate and control magnetization, through the Faraday and Kerr effects [5].

Recently, we analysed theoretically the interaction of OAM beams with magnetic structures featuring non-uniform magnetization, in particular of XUV beams with magnetic vortices consisting of a curling in-plane magnetization [1]. We predicted that the far field intensity profile encodes the vortex symmetry in a way that depends on the sign and value of the topological charge ℓ, an effect deriving from the inhomogeneous modification of the

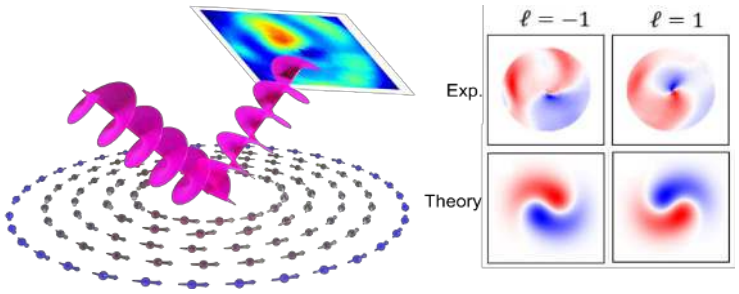

Figure 1. (Left) Experimental sketch for the observation of magnetic helicoidal dichroism. (Right panel) Differences between the images acquired for two opposite curling senses of the magnetic vortex, showing a typical 2D chiral structure, which depends on the incoming orbital angular momentum (top). Theoretical result (bottom).

regular reflectivity coefficients by the local magnetization. We named this effect Magnetic Helicoidal Dichroism (MHD). As for magnetic circular dichroism, MHD can be observed by inverting the sign of either the orbital momentum or of the magnetization, i.e. by switching the handedness of either the light helicoidal wavefront, or of the magnetic vortex.

In this contribution we report on the first experimental evidence of MHD (Fig. 1) obtained at the DiProI station of the FERMI free-electron laser source by measuring the scattered intensity from an Fe-Ni-alloy dot forming a magnetic vortex. The photon energy of the ˜100 fs long pulses was set to 52.8 eV (˜23 nm wavelength) in order to match the Fe 3p→3d core resonance, enhancing magneto-optical effects at XUV wavelengths and providing element selectivity. The scattered intensity data, collected as a function of ℓ and of the magnetic vortex winding sense, compared well to theoretical model predictions [2]. The match between theory and experiments confirms the potential of the new toolset provided by MHD for studying complex magnetic structures and, in particular, for addressing their laser-triggered ultrafast dynamics.

Understanding the interaction of OAM-light with a magnetic vortex has many potential interests. At the fundamental level, it allows to observe a new kind of dichroism, to study the role of photon spin-orbit coupling mediated by magnetization, as well as to explore new possibilities of angular momentum transfer between light and matter. In terms of applications, MHD in reflection can be exploited as a new spectroscopic tool joining the family of magnetic dichroism techniques. For their symmetry and size, magnetic vortices can be considered as an ideal benchmark sample to explore the interaction with OAM beams; moreover, given their rich dynamical response in the ultrafast domain, they are promising structure for light manipulation of the magnetization topology.

Ultrafast control of spins using resonant light excitation

D. Afanasiev

Radboud University, Nijmegen, The Netherlands
d.afanasiev@science.ru.nl

Abstract: I will discuss how light can be used to control magnetism: fundamental magnetic interactions, magnetic phase transitions, and highly nonlocal spin dynamics. I will particularly concentrate on nonthermal means to control magnetism when the photon energy of light is tuned precisely in resonance with optical resonance, e.g., lattice, orbitals, or electron excitation, carrying a direct impact on the ordered spins.

For many years, the central goal of condensed matter physics has been to understand and describe naturally occurring phenomena, both in macroscopic and microscopic terms. Over the past decades, a new paradigm emerged, which is to experimentally realize and control new states of matter that are not found in nature. Alongside answering fundamental scientific questions, control over and knowledge of potential ‘exotic’ phases also holds promise to create a new and radically different generation of data processing devices.

Ultrashort pulses of light are especially appealing in this sense as they allow to create strongly nonequilibrium transient states of matter with properties that are often not even available in the equilibrium. Light-induced superconductivity, metal-to-insulator transitions, and light-driven Floquet engineering are to name a few. Here I will discuss how light can be used to control magnetism: fundamental magnetic interactions, magnetic phase transitions, and highly nonlocal spin dynamics. I will particularly concentrate on nonthermal means to control magnetism when the photon energy of light is tuned precisely in resonance with optical resonance, e.g., lattice, orbitals, or electron excitation, carrying a direct impact on the ordered spins.

Structured ultrafast electric and magnetic fields by design

H. Petek[1*], A. Ghosh[1], S. Yang[1], and Y. Dai[1,2]

[1]University of Pittsburgh, USA
[2]Southern University of Science and Technology, China
[*]corresponding author: petek@pitt.edu

Abstract: We investigate the electric and magnetic fields in space and time when circularly polarized light interacting with a metal-dielectric interface is structured to generate single, periodic, and quasiperiodic topological vortex arrays. We image the space-time correlations of such fields by ultrafast photoemission electron microscopy. The structured fields interact with matter through electric dipole and magnetic dipole interactions. These interactions can overlap in space and time to drive magnetoelectric responses in topologically trivial and nontrivial matter.

The geometry of metastructures and circular polarization of light can generate topological plasmonic fields, that can have exotic interactions with matter as compared to plane wave optical fields.[1-5] By defining the orbital angular momentum of light, we design the spin-orbit interaction of surface plasmon polaritons leading to the plasmonic vortex generation. The structure of such fields varies according to the orbital angular momentum that is defined by geometry of SPP launching causing the fields to focus on $\lambda_{SPP}/2$ length scale (~250 nm). We generate movies of SPP fields as they evolve on sub-optical cycle time and sub-wavelength spatial scales by interferometric time-resolved two-photon photoemission electron microscopy.[6] Of particular interest is to image the spatial variation of isotropic (e.g. electric dipole) and bianisotropic (magnetoelectric) responses of matter within the fields of plasmonic vortices. The local field textures can locally observe and define time-parity conserving processes and break the time-parity conservation in materials that are exposed to their nearfield. Such fields are predicted to exist at the vortex that forms a plasmonic spin skyrmion texture (Figure 1). We will describe the magnetoelectric imaging of material responses by design of structured fields in plasmonic vortices.

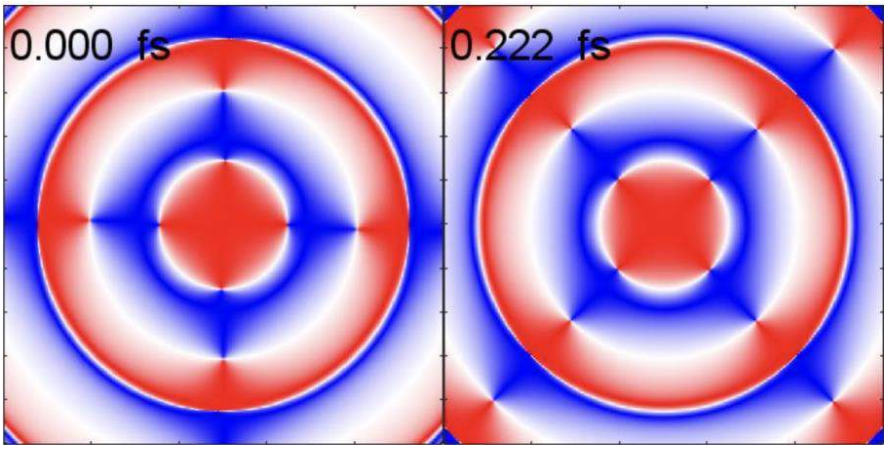

Figure 1. The calculated fields of a plasmonic skyrmion where blue and red designate instantaneous regions of isotropic and bianisotropic interactions, respectively. The two frames represent advance of 0.222 fs of 566 THz plasmonic field. The lateral dimension of the center meron (half-skyrmion; red) region is 260 nm.

Microwaves and millimeter waves applications of metamaterials and metasurfaces for the real world

META 2023, PARIS - FRANCE, JULY 18 – 21, 2023

Deep learning-driven all-optical operations utilizing metasurfaces

Zihan Zhao[1], Yue Wang[1], and Xumin Ding[1*]

[1] Advanced Microscopy and Instrumentation Research Center, School of Instrumentation Science and Engineering, Harbin Institute of Technology, Harbin 150080, China
[*]xuminding@hit.edu.cn

Abstract: In this paper, a novel compact trigonometric function operator based on the metasurface is proposed. Such an operator, which consists of a simple P-B (Pancharatnam-Berry) phase metasurface, can implement the four basic trigonometric operations (sine, cosine, tangent, and cotangent functions) at ultra-high speed with low power consumption, providing a feasible way to achieve a universal photonic computing chip.

Photonic computing has attracted great interest from researchers due to its remarkable advantages in terms of computing speed and power performance. Such an EM-wave-based computing strategy avoids analog-to-digital conversion and allows ultra-high-speed massively parallel operations, which has been proven to have great potential in temporal integration and differentiation[1,2], Hilbert transformation[3], spatial differentiators[4]. In recent years, the emergence and rise of metamaterials bring new developments to photonic computing, breaking through the limitations of traditional lens-based computing systems in terms of size and aberration. Compared to conventional Fourier-based optical computing devices, metasurfaces can achieve modulation of the EM profile within the sub-wavelength thickness, which facilitates the miniaturization of photonic signal processors in volume. The superiority of such a metasurface-based optical computing strategy has been demonstrated in various optical signal processing scenarios, such as spatial differentiation, integration, and convolution[5-7], Laplacian operation[8], image processing[9].

However, previous metasurface-based photonic computing systems mainly focus on spatial time and frequency domain operations, while lack of the solutions for optical function operations with specifc numerical inputs. As one family of the basic mathematical operations, trigonometric operations lie at the core position in the field of communication and signal processing. Conventional devices used to perform trigonometric operations, such as field-programmable gate array (FPGA) and digital signal processors (DSPs), are usually based on electronic components which result in low speed, high power consumption, and inevitable complexity. Nowadays, exponentially growing communication data and information need to be processed and stored in real-time, which poses a tough challenge to conventional electron-based operations. Therefore, a disruptive solution for numerical trigonometric operations is highly desired. To this end, we designed a trigonometric operator driven by an all-optical diffraction neural network, as shown in Figure 1. Here, different patterns of planar input light signals are designed as inputs to the network and the information is passed to the hidden layer which is mapped by a metasurface in the way of scattering. Finally, the output result will be presented on the output layer with the designed output pattern representing different values. Our design features several attractive advantages: Firstly, we achieve EM-based basic trigonometric operations under specific input values and the optimized visualized outputs allow clear and recognizable operation results. Besides, only one hidden layer is utilized in the diffractive neural network under the proposed composite input mode strategy, which considerably reduces the resources and time required to train the network and improves integration with other photonic systems. The proposed solution has been theoretically and experimentally verified to accurately perform the four

basic trigonometric operations and has great potential for applications in the field of ultra-high-speed signal processing and communication.

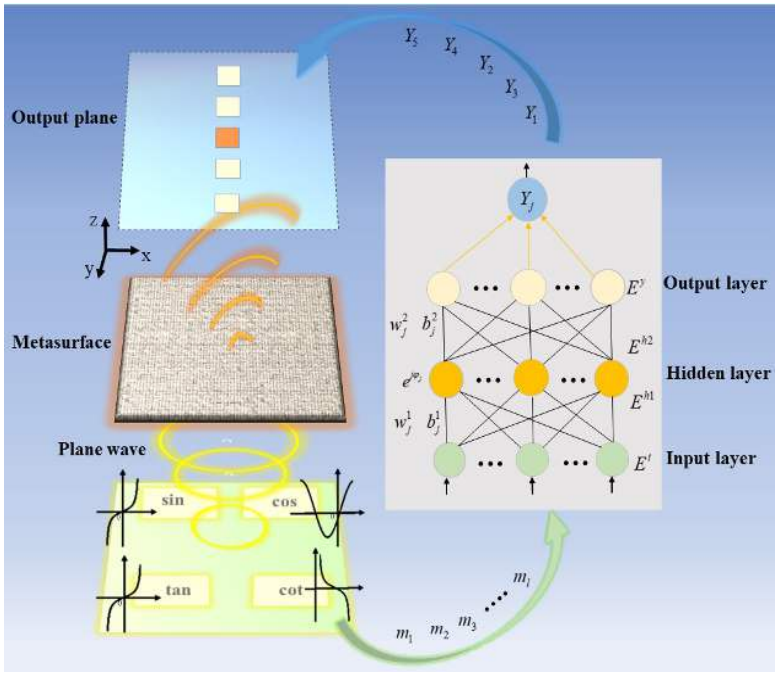

Figure 1. The conceptual representation of the designed optical trigonometric operator.

Abstract: Experimentally emulating the wireless test environments typically considered in signal processing can be challenging, especially for MIMO communications under Rician fast-fading if the K-factor is supposed to be adjustable. We demonstrate experimentally that electronic stirring of a reverberation chamber with a programmable metasurface conveniently enables the implementation of such channel conditions. We carefully characterize the precision with which a desired K-factor can be implemented simultaneously across multiple antenna pairs.

The signal-processing literature routinely assumes certain statistical properties of the wireless radio environment but experimentally emulating these conditions for real-life tests is often challenging. Consider the case of a wireless channel with fast Rician fading. In a single-input single-output (SISO) scenario, this can be emulated by pointing two horn antennas at each other inside a reverberation chamber; rotating a mode stirrer can yield different realizations and varying the horn antennas' separation can be used to adjust the Rician K-factor. However, note that the use of horn antennas implies that the unstirred field component is largely dominated by the line-of-sight (LOS) path, which is a special case of what happens in general, namely that the unstirred component includes the LOS path as well as significant multi-bounce paths that did not encounter the stirrer [1], [2]. In any case, this approach involving horn antennas does not trivially extend to multiple-input multiple-output (MIMO) scenarios, let alone to timely MIMO scenarios involving reconfigurable intelligent surfaces (RISs) that assist the wireless system. One possibility to emulate Rician fading for a MIMO scenario is to use omnidirectional antennas in combination with mechanical mode stirrers whose physical size would have to be adjusted every time that a different K-factor is supposed to be emulated. However, such an approach appears to be very cumbersome in practice.

A potential solution to overcome the above restrictions and limitations lies in the use of electronic stirring by partially reconfiguring the boundary conditions of the reverberation chamber with random configurations of a programmable metasurface. This idea was first proposed in [3] and the first experimental implementation of a programmable-metasurface stirred wireless channel was reported (in a context of wireless localization) in [4]. Subsequent work has characterized the statistical properties of the stirred field (i.e., *not* of the physical field which would be the sum of the unstirred and stirred fields) [5], by subtracting the unstirred field in post-processing. There has, to the best of our knowledge, not been any experimental study on implementing Rician fast fading with adjustable K-factor for generic wireless scenarios (involving MIMO, etc.), where the K-factor is adjusted by using only a subset of all available meta-atoms. Note that the programmable metasurface is used in order to setup the wireless test environment here, rather than as part of the wireless communications network that is under the wireless system engineer's control.

In this presentation, we report our experimental results on emulating fast-fading Rician conditions with electronically adjustable K-factor for a 4×4 MIMO wireless system based on omnidirectional dipole antennas. We carefully evaluate the K-factor [6], and how it depends on the number of utilized meta-atoms. We also check how for a given number of utilized meta-atoms the K-factor fluctuates across different antenna pairs. We find that these fluctuations are substantial, essentially because the unstirred component (since it is not dominated by the LOS) is itself a random variable. This phenomenon is not specific to our method of electronic stirring, but has seemingly not been clearly documented even in the case of mechanical stirring.

Abstract: We discuss the emerging field of reconfigurable and holographic metasurfaces for wireless.

In wireless communications, the term intelligent surface is referred to a planar metamaterial structure that is capable of generating an arbitrary current density distribution, so as to ensure the highest flexibility in generating a specified electromagnetic field and in shaping the propagation of the electromagnetic waves in large-scale networks. This presentation is aimed to report the latest research advances on analytical modeling, evaluating the ultimate performance limits, and optimizing intelligent surfaces for application to wireless communications, with focus on the synergies between electromagnetic and communication theories.

Metagratings for wavefronts manipulation: Theory and design

Z. Tan[1,2], J. Yi[1], B. Ratni[2], and S. N. Burokur[2*]

Abstract: Metagratings, structures composed of sparsely arranged load-impedance wires, are exploited to tailor and manipulate diffracted beams. Here, we focus on planar reflective-type metagratings where reflected diffracted orders are controlled.

Metagratings have been introduced in 2017 by Y. Ra'di et al. [1]. These structures consist of an array of wires arranged periodically and structured on a small scale with respect to the wavelength such that it is possible to introduce an effective linear (electric or magnetic) impedance. On the other hand, in the perpendicular direction, the distances are of the order of the wavelength. The properties of these wires are periodically repeated with a period generally greater than the wavelength, thus defining an elementary "supercell", which allows propagative diffracted orders.

By engineering judiciously the load impedance of the wires, the diffraction orders can be accurately controlled for various functionalities. Generally, the load impedance is a complex quantity, with a real part that can be active or lossy, and a reactive part that can be capacitive or inductive. Concerning the real part, we restrict ourselves to a positive or null value to avoid the complex realization of active circuits.

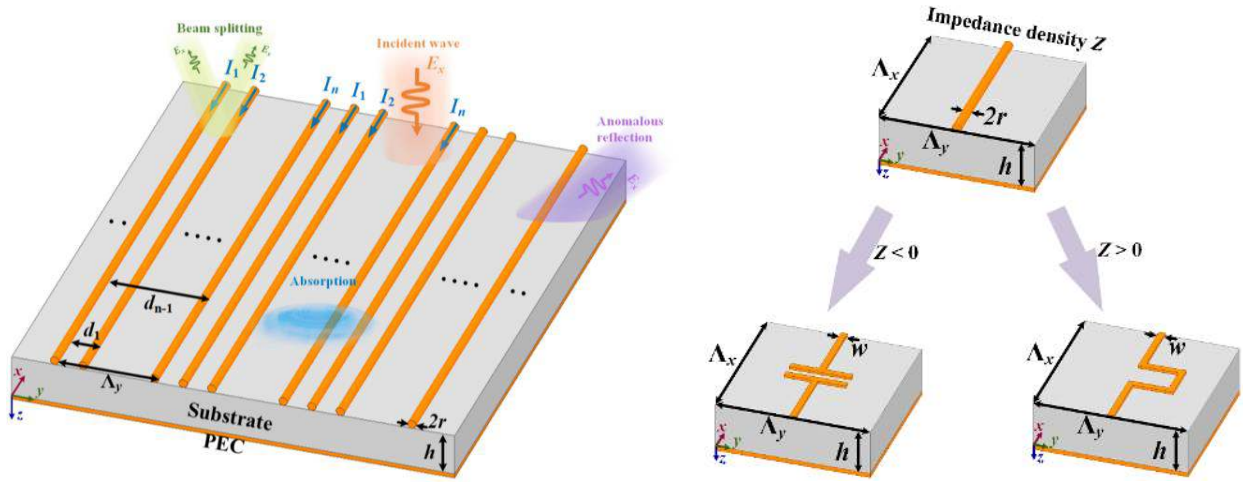

Figure 1. The physical system of the metagratings: a periodic array of cylindrical wires placed on a PEC-backed dielectric substrate. The array is illuminated by a TE-polarized plane wave. The elementary meta-atom of the metagrating is a cylindrical wire with a reactive impedance density *Z*. For negative *Z*, a microstrip capacitor is used and when *Z* is positive, a microstrip inductor is used to achieve the desired impedance density.

The schematic of a planar reflective-type metagrating is shown in Fig. 1. In the presence of the grounded

substrate, the excitation field takes the following form:

$$E_x^{exc}(y, z \le -h) = E_{inc}\left[e^{-ik_0(z+h)} + R_0 e^{ik_0(z+h)}\right] e^{-ik_0 \sin(\theta_{inc})y} \quad (1)$$

where $R_0 = \left[i\tan(k_s h) - \frac{\eta_0}{\eta_s}\right] / \left[i\tan(k_s h) + \frac{\eta_0}{\eta_s}\right]$ is the reflection coefficient of the incident wave, with $k_0 = \omega\sqrt{\mu_0\varepsilon_0}$, $\eta_0 = \sqrt{\mu_0/\varepsilon_0}$, $k_s = \omega\sqrt{\mu_s\varepsilon_s}$ and $\eta_s = \sqrt{\mu_s/\varepsilon_s}$. The radiated field in free space is then written as:

$$E_x(y, z \le h) = -\frac{k_0\eta_0}{2\Lambda_y} \sum_{m=-\infty}^{\infty} \frac{1+R_m}{\beta_m} \sum_{q=1}^{n} I_q e^{j\xi_m d_{q-1}} e^{-j\xi_m y} e^{-j\beta_m |z+h|} \quad (2)$$

where $d_{n\text{-}1}$ is the distance between n^{th} wire and 1st wire in one period ($d_0 = 0$), $\xi_m = 2\pi m/\Lambda_y$ and $\beta_m = \sqrt{k_0^2 - \xi_m^2}$ are the transverse component and longitudinal component of the m^{th} mode wavenumber in air, and $R_m = \left[j\tan(\beta_m' h) - \beta_m'/\beta_m\right] / \left[j\tan(\beta_m' h) + \beta_m'/\beta_m\right]$ is the reflection coefficient of the m^{th} mode, with $\beta_m' = \sqrt{k_s^2 - \xi_m^2}$.

Using the metagrating concept, functionalities related to antennas can be considered. For the implementation, considering that the imaginary part of the load-impedance density calculated can be positive or negative, microstrip inductor or capacitor structure are used to design the meta-atoms. The structure of the considered meta-atoms are shown in Fig. 1(b). For such simple microstrip structures, analytical formulations exist to calculate the load impedances. However, such analytical models have to be completed with a phenomenological scaling parameter by means of 3D full-wave simulations of an entire supercell. On the other hand, the LPA method described in [2], can also be applied to design metagratings in the "unit cell by unit cell" manner.

Using the above methodology, metagratings can be judiciously designed for different applications, such as beam steering, beam-splitting and absorbers [3-5], as schematically illustrated in Fig. 1(a).

Abstract: This summary presents the application of modulated metasurfaces in millimeter wave and sub-terahertz antenna systems. We succinctly show that by adopting metasurfaces as array element, one may mitigate some of the challenges found in large phased arrays with a limited field of view and concurrently enhance the gain bandwidth of modulated metasurfaces antennas with a single port.

The advent of future wireless networks beyond 5G has fostered the interest in millimeter and sub-terahertz (sub-THz) frequency bands, which will allow one to benefit from large unlicensed bandwidths and thus satisfy the need for higher data rates [1]. However, to make the most of such large bandwidths, one has to compensate the free space path loss (FSPL), which is proportional to the carrier's frequency and typically burdens the link budget as one approaches sub-THz bands [2]. Moreover, the generation of power at room temperature in the sub-THz gap is also challenging. Therefore, high-gain antennas radiating narrow pencil beams must be adopted. Typical architectures consist of scalar horns used as focal source for large reflector and lens systems [3]. Although efficient and wideband, such architectures are bulky and difficult to adopt in a paradigm that foresees the massive deployment of small cells. As opposed to electrically large reflectors and lenses, we target low-profile and light-weight architectures that can provide similar gains without imposing a toll on the relative bandwidth. This summary discusses the use of modulated metasurfaces (MTSs) [4]-[5] for the efficient transformation of guided modes into directive radiation in the millimeter-wave and sub-THz ranges.

In modulated MTSs, a dominantly transverse magnetic (TM) surface wave (SW) is typically excited on an inductive impedance plane. It has been shown that one can gradually radiate the SW power by periodically modulating such impedance boundary condition (IBC) [6]. This effect has been successfully exploited to design high-gain antennas capable of providing multiple beams [7], dual-polarization [8], and dual-band [9] operation [9]. Their main drawback is a relatively narrow bandwidth (BW) in gain, which has so far precluded their use for broadband applications (wideband sensing, 5G communications, etc.). The relative -3dB gain fractional BW ($\Delta f/f_0$, with f_0 being the center frequency and Δf the total BW) of modulated MTS antennas with circular shape is equal to [10],

$$B = \Delta f / f_0 = 1.2\left(v_g / c\right)\left(\lambda_0 / a\right) \tag{1}$$

where c is the speed of light in vacuum, a is the antenna radius, λ_0 is the free-space wavelength at f_0, and v_g is the SW group velocity at f_0. Practical values of $\Delta f/f_0$ may vary between 3.5% and 12% when the radius goes from $17\lambda_0$ to $5\lambda_0$ for v_g/c =0.5. On the other hand, the aperture gain G in absence of losses (directivity) is given by

$$G = \left(2\pi a / \lambda_0\right)^2 \left(a / \lambda_0\right) / \left(a / \lambda_0 + 2\right) \tag{2}$$

Combining the latter expressions the product between fractional bandwidth and gain can be approximately written as $G\times B$=47.37$(v_g/c)(a/\lambda_0)^2/(a/\lambda_0+2)$. On this basis, and assuming that v_g is fixed and according to (1), we

will show that one can increase the BW without impacting the gain (G) by dividing the total aperture into sub-apertures with smaller radius, each one fed by its own source. Second, grating lobes (repetitions of the main lobe related to the spacing between sources) can be avoided by the combined action of an aperiodic tiling of the aperture [11] and appropriately tailoring the element pattern of each sub-aperture. Compared to other approaches for broadband operation [12], the aperiodic tiling of the plane presents the advantage of allowing one to steer the beam over a limited field of view (FoV).

Perfect Control of Diffraction Patterns with Phase Gradient Metasurfaces

Yuxiang Wang,[1] Kuang Zhang[1],Guohui Yang, [1], Shah Nawaz Burokur and Qun Wu,[1]

[1]Department of Microwave Engineering, Harbin Institute of Technology, Harbin 150001, China

Abstract: Most studies on PGM focus only on single diffraction order. Multiple beams are still in the same order, and energy carried by different beams cannot be controlled. Here we propose a general method to perfectly control diffraction patterns based on a multi-beam phase gradient metasurface. An analytical solution for arbitrarily controlling diffraction beams is derived, the generation and energy distribution in high order diffraction beams can be achieved.

Considering a simple one-dimensional scenario where metasurface carries a spatial phase distribution along one direction located at $z = 0$ plane. When illuminated by a plane wave at an angle θ_{in}, the scattered beam will be composed of several diffraction orders, which are scattered in different directions. The response of the unit cells is the superposition of all beams. The intensity on the metasurface can be expressed as:

$$P_{meta}(x_i) = \left|R_{meta}(x_i)\right|^2 = \sum_{m=-n}^{n} \left|a_m\right|^2 + \sum_{\substack{p,\, q=-n \\ p\neq q}}^{n} \left|a_p\right|\left|a_q\right| \cos\left(2\pi\left(\frac{px_i}{L_p} - \frac{qx_i}{L_q}\right) + \phi_q - \phi_p\right) \tag{1}$$

where p and q represent arbitrary diffraction orders. We set the former term as unit energy and the latter term as 0. Obviously, it is satisfied for a single diffracted beam. Then, we consider the case when two diffracted orders are excited. When the period and number of the unit cells are same for both orders, the relationship between the diffracted orders and the discrete points is derived as:

$$\left|p - q\right| = \frac{s}{2}, \quad \phi_p - \phi_q = \frac{\pi}{2} + \pi b \tag{2}$$

where s is the number of unit cells in a period and b is arbitrary integer. The equation is only applicable for two beams with opposite diffractions. Since the equation does not limit the energy relationship between the beams, the energy of the different beams can be independently controlled. Fig. 1 shows the measured far-field energy distribution of two cases, which are +1st and -1st diffraction orders sharing an energy ratio of 1:2 and +2nd and -3rd diffraction orders sharing an energy ratio of 1:3. Both energy distributions of simulation and measurement show good agreement with the preset value, validating the proposed method that provides a new way to design multi-beam antennas and that has significance in wireless communication applications.

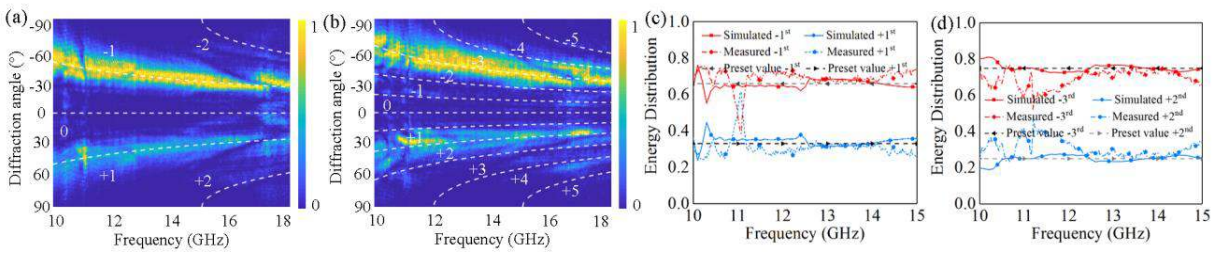

Figure 1. The measurement results, where (a) and (b) are normalized intensity of two cases, (c) and (d) are corresponding intensity comparison in the desired channels.

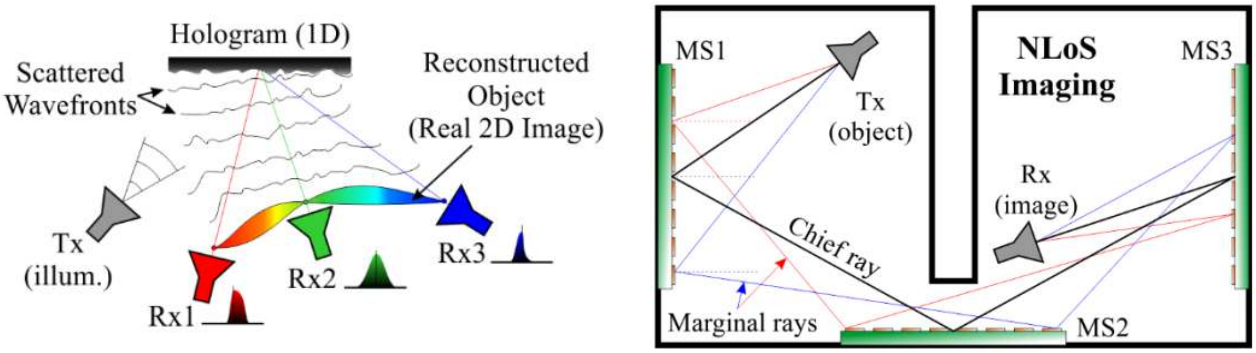
Abstract: We present our progress in developing tunable metasurfaces for microwave holographic imaging and for its application to wireless communications and virtual/augmented reality (VR/AR). Our methodology starts from the analysis of ideal metasurface apertures and moves to tunable static prototypes designed for fabrication with cost-effective techniques, e.g., 3D printing or conductive inks. We envision to translate the proof-of-concept study, and associated devices, to printed circuit board technology, implementing practical reconfigurable metaholograms for wireless communications and VR/AR.



The reconfigurable intelligent surface (RIS) archetype has recently gained traction, as an abstract electrically tunable aperture that can filter and manipulate the scattering of wavefronts in ways transcending the elementary geometric optics prescriptions, i.e., the standard laws of reflection and refraction. Metasurfaces (MSs), ultrathin sheets with subwavelength-sized resonators on their exposed face, are the physical implementations of RISs. Varactor or PIN-diode assembled printed-circuit boards (PCBs) are currently the go-to technology for microwave and mmWave band devices. This operation mode means that, by electrically tuning the microwave value of the loading element (varactor or diode), we can tune the equivalent reactance of a metasurface, i.e., tune its resonance to the desired frequency, polarization, and direction of scattering. This enables tunable functionalities such as perfect absorption, anomalous reflection (steering), focusing/imaging, and holography.

In this work we cast MSs as holograms [1], i.e., as devices storing phase and amplitude profiles that, when illuminated with a specific wavefront, can re-construct real images of the stored objects in 3D space, by coherent interference. For wireless communications, holography can be considered as the 3D extension of beam forming: In the latter we direct beams to desired directions in the farfield (so we have only two dimensions, the θ_{el} and φ_{az} angles), whereas in holography we can focus an arbitrary wavefront to any point or scatter/diffract it anywhere in 3D space, Fig 1(a). Envisioning widely deployed reconfigurable metaholograms, e.g., covering all the walls of a room, essentially implements a programmable wireless environment (PWE) in a rigorous and holistic way, i.e., overcoming the limitations of geometric optics approximations (neglect of near-field effects etc.). This framework enables us to design and optimize practical applications that are sensitive to power considerations and real-world "non-ideality", e.g., non-line of sight links, interference, obstructions, fabrication imperfections, fading, etc.

Back/front hauling of information for extended reality (XR) devices, a portmanteau for both virtual and augmented reality (VR/AR), is an application that stands to benefit from holographic metasurface imaging: Immersive interaction between remote users in an XR world is currently limited by latency, mostly imposed by

digital signal processing and by traversing multiple OSI (Open Systems Interconnection model) layers. To overcome this hurdle, we are developing a system where a PWE, enabled by reconfigurable metaholograms, can record the wavefronts scattered from the source object, in real-time, and then reconstruct (image) them in a remote location; the transmission happens at the speed of light, either over-the-air (for small distances) or over fiber (for larger distances). Reconfigurable metasurfaces play a twin role in this system: (i) on the source location, they operate as a distributed imaging lens, i.e., gathering all the rays scattered from the illuminated object, and focusing them onto a microwave imager; (ii) on the remote location, they operate as a distributed projection lens, i.e., scattering the reference beam in such a way so that a real 3D image of the source object is formed.

The aim/scope of our work can be broken down in three parts: Firstly, we develop the theoretical framework for holographic imaging in arbitrary environments, Fig. 1(b), assuming a set of ideal reconfigurable metasurfaces, both in the "imaging lens" and in the "projection lens" configuration; from this framework, we extract performance metrics related to sharpness and quality of object-image formation etc. Subsequently, we design and manufacture static but cost-effective metahologram boards, using additive manufacturing (3D printing) and/or conductive inks, for an experimental proof of concept. Lastly, we develop designs for reconfigurable boards in PCB technology [3].

(a) (b)

Figure 1. (a) Abstract off-axis holographic 2D projection by illuminating a reflective 1D hologram with the reference coherent source Tx. The real image of the reconstructed object is the twisted ribbon, where colors represent frequencies. In a wireless communications analogy, the hologram is focusing the broadband signal from Tx to three receivers, each at a different band. (b) Three MSs implementing a non-line of sight (NLoS) link by conjugate point-object/image formation on the Tx-Rx antennas; each of the three MSs aperture is custom phase-profiled, as can be seen by the anomalous reflections of the chief and marginal rays across MS1.

A Dual Polarized Metagrating to Manipulate Wavefronts

Abstract: Metagratings (MGs), which are sparse arrangements of subwavelength polarizable particles (meta-atoms), have demonstrated efficient realization of various electromagnetic functions in recent years. Here, we proposed a dual polarized metagrating which can independently control dual polarized waves.

The metagrating is derived from the periodic grating whose periodic constant is smaller than the working wavelength [1]. Unlike traditional grating, the period of metagrating is larger than the working wavelength. Based on the coupling behavior of periodic structure and the scattering modulation characteristics of the meta atoms, mg can improve the efficiency of the regulatory beam by using periodic Bragg scattering, thus avoiding the efficiency reduction and energy loss caused by the phase discretization of the metasurface.

Dual-polarized MG can effectively deflect *x* and *y* polarized incident waves, which is rarely seen in the literature and mainly depends on numerical optimization of the whole large period or typical MG design methods [2]. Based on the theory of line current [3] and referring to the structure of the metasurface, polarization-insensitive, dual-polarized cross-shaped structure metagrating is proposed which can independently control the *x*- and *y*-polarized wave.

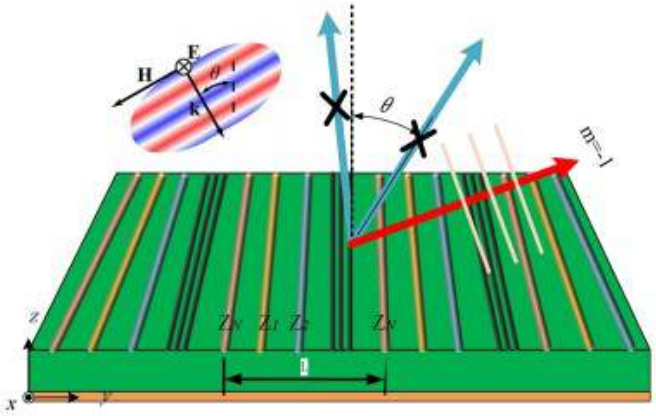

Figure 1. The physical system of the metagratings: a periodic array of thin loaded wires (represented by color cylinders) placed on a PEC-backed dielectric substrate. The array is excited by a TE-polarized plane wave, and has the functions of anomalous reflection.

Figure 1 shows the equivalent line current model of metagratings. When the plane wave illuminated on metagrating at the angle θ_{in}, its electric field expression is

$$E_x^{(in)}(y, z \le -h) = e^{-j\beta_0 z - jk\sin|\theta| y} \tag{1}$$

Since the period of the illuminated structure is L, the scattered field can be represented as a superposition of

plane waves:

$$E_x(y,z) = -\frac{k\eta}{4}\sum_{q=1}^{N}\sum_{n=-\infty}^{\infty} I_q e^{-jk\sin[\theta]nL} H_0^{(2)}\left[k\sqrt{(y-nL-(q-1)d)^2+z^2}\right] \tag{2}$$

Then, each polarization line current is excited in a thin wire characterized by its input-impedance Z_{in} and load-impedance densities Z_q. Ohm's law gives the relation between Z_{in}, Z_q and I_q:

$$Z_q I_q = E_q^{(exc)} - Z_{in} I_q - \sum_{p=1}^{N} Z_{qp}^m I_p \tag{3}$$

Thus, by setting up the specific impedance distribution of mg, the expected scattered electric field can be obtained.

In this paper, we design a cross structure mg which can respond to *x*- and *y*-polarized waves separately. The first MG has an impedance distribution of [-2.45j, -6.59j, -4.01j, -3.18j] along the *x* direction and the same impedance distribution along the *y* direction. It can realize single beam diffraction with different polarization wave incident. The second MG has an impedance distribution of [-2.45j, -6.59j, -4.01j, -3.18j] along the *x* direction and [-3.57j, -2.45j, -8.62j, -2.27j] along the *y* direction. It can realize single beam diffraction under *x*-polarized wave incidence and beam splitting under *y*-polarized wave incidence.

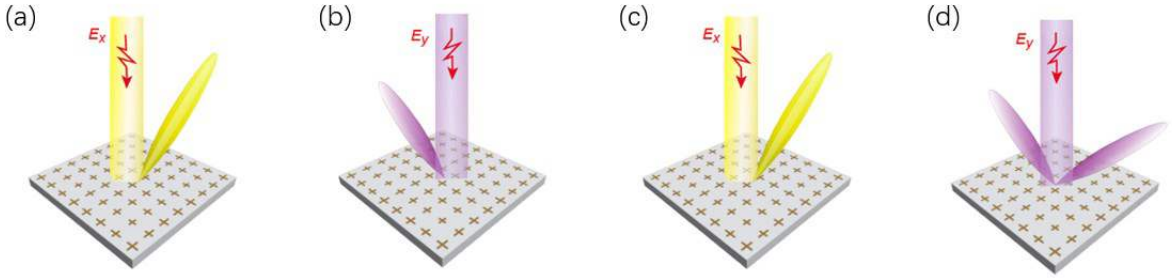

Figure 2. Functional diagram of two MGs. (a) The wavefront control for the first MG under *x*-polarized incidence. (b) The wavefront control for the first MG under *y*-polarized incidence. (c) The wavefront control for the second MG under *x*-polarized incidence. (d) The wavefront control for the second MG under *y*-polarized incidence.

The designed dual-polarized mg has great potential in multi-channel information processing, dynamic dual-polarized antennas and radar systems.

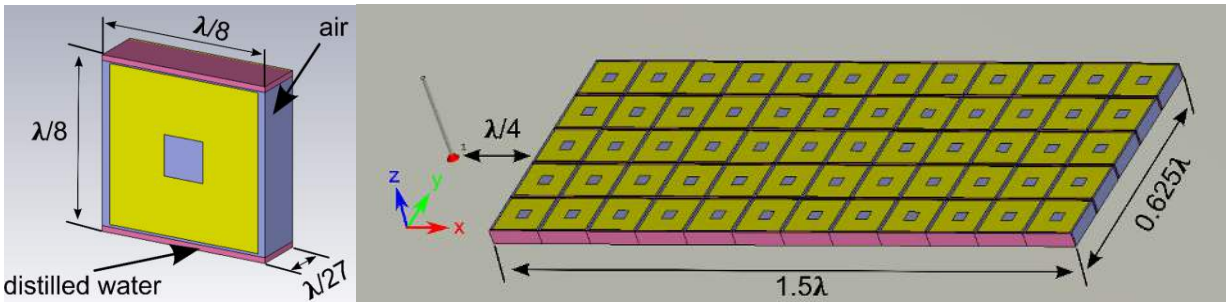
Composite based metasurface for surface wave excitation in HF band



G. Briand[1*], A. Barka[1], and S. N. Burokur[2]

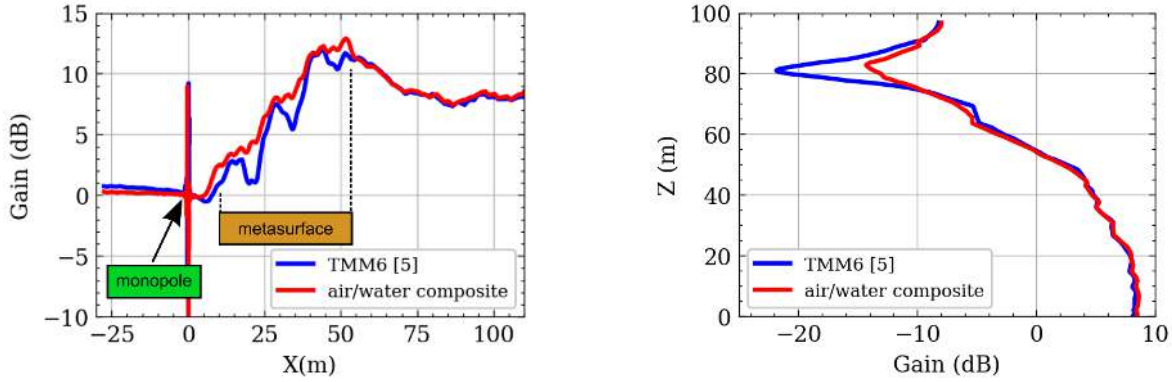
Abstract: This paper describes the design of a low profile inductive surface for High Frequency Surface Wave Radars (HFSWR) in HF-band. We discuss about reducing the thickness of the metasurface by designing an adapted dielectric support. The metasurface is then exploited to highly increase the electric field near the ground when illuminated by a quarter-wave monopole in TM polarization. This enhancement of the electric field is necessary in order to excite a surface wave.

Being able to detect ships up to 200 nautical miles, High Frequency Surface Wave Radars (HFSWR) constitute a major asset for maritime surveillance of Exclusive Economic Zone (EEZ), which is an area up to 200 nautical miles from coastal baseline where a sovereign state has special rights such as fishing and oil extraction exclusivity. ONERA, the French Aerospace Lab, has been developing radars (Graves, Nostradamus) and more specifically HFSWR for several years. First, an installation has been successfully tested [1], but interferences due to sky waves reflecting on ionosphere have been acknowledged [2]. Later, a metamaterial structure placed in front of the emitting antenna has been proposed in order to reduce ionospheric sky wave interferences and to increase the propagating energy near the ground in the forward direction [3, 4]. However, it has been observed that the structure is too high, typically $\lambda/10$ (3 m at 10 MHz), to withstand strong sea winds and due to regulation in protected natural area. A reduced profile metasurface of height $\lambda/30$ designed on a Rogers TMM6 substrate has been proposed and tested in the L-band at about 1.1 GHz [5]. Here, we make a step forward to design a new surface wave exciting structure that is compact and realizable in HF-band.

The metasurface is composed of resonant square metal rings printed on a dielectric substrate. The transposition of the previously designed L-band metasurface to the HF-band would require a very large size of the commercial Rogers TMM6 dielectric substrate, which is unrealizable in practice. Hence, it is highly desirable to find a natural material that has similar properties to the TMM6 substrate. We thus propose a composite material based on air and distilled water.



(a) (b)

Figure 1. (a) Unit cell designed using a composite dielectric material made of air and distilled water. (b) HF-band metasurface-based antenna.

Different designs of dielectrics, based on the shape of the composite and the materials used, can be considered. Their dielectric properties are obtained using the Nicholson-Ross-Weir parameter extraction method. An example of such design is made of 90% of air in distilled water to obtain an effective permittivity $\varepsilon_{eff} = 6$, see Fig. 1(a). An analytical study of the unit-cell using transmission line theory allows to tune the shape of the dielectric to get the desired inductive behaviour [5].

The performance of the metasurface is evaluated thanks to the vertically radiated electric field $E_{metasurface}$. The gain of the metasurface antenna is defined as $Gain = 20\log10\left(\frac{E_{metasurface}}{E_{inc}}\right)$, where E_{inc} is the amplitude of the electric field radiated by the monopole source. A gain enhancement of more than 10 dB (Fig. 2(a)) is observed at the extremity of the metasurface and most of the field is located at ground level (Z=0) (Fig. 2(b)), which is mandatory to excite a surface wave.

A Compact, Quad-Band, and Wideband Antenna Using Triple-Band AMC

Rafael Gonçalves Licursi de Mello*, Anne Claire Lepage, and Xavier Begaud

LTCI, Télécom Paris, Institut Polytechnique de Paris, 91120 Palaiseau, France
*corresponding author: E-mail: rafael.licursi@ieee.org

Abstract

We present a compact antenna with stable, unidirectional, high-gain radiation patterns to cover the standards 5G/4G/Wi-Fi 2.4/5/6E and X-band communications. The operating frequency bands are 2.4–2.7, 3.4–3.8, 5.17–6.45, and 8.0–12.0 GHz. The thickness is $0.09\lambda_l$ and the aperture size is $0.51 \times 0.65\ \lambda_l^2$, where λ_l is the wavelength at the lowest frequency. To achieve the desired performance, we exploit both the in-band and out-of-band operation modes of a triple-band artificial magnetic conductor (AMC) illuminated by a grooved bow-tie radiating element surrounded by a metal ring.

1. Introduction

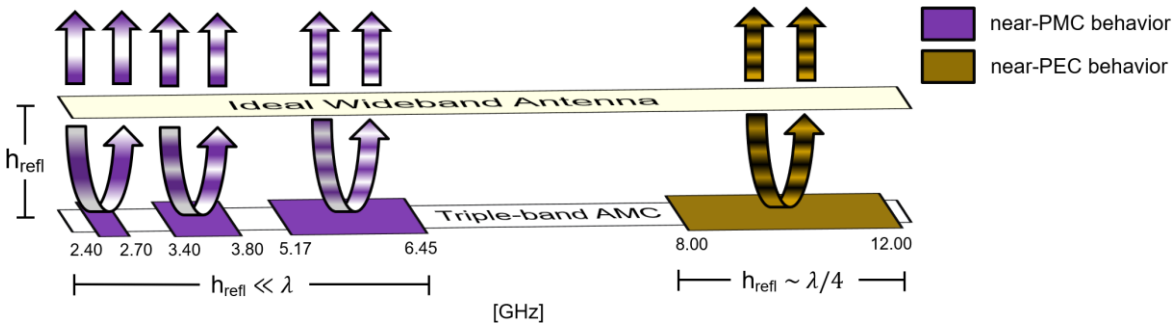
Modern Telecommunications are defined by the operation of multiple standards in parallel, which is pushing the employed components and systems towards a multiband and wideband technology. This paradigm represents a challenge in the antenna field because obtaining stable, unidirectional, high-gain radiation patterns in multiple, wide bands using a single antenna is not trivial.

In this work, we present a compact antenna with directive radiation patterns operating in the frequency bands 2.4–2.7, 3.4–3.8, 5.17–6.45, and 8.0–12.0 GHz appropriate to cover the standards 5G/4G/Wi-Fi 2.4/5/6E and X-band communications.

This quad-band antenna exploits both the in-band behavior of a triple-band artificial magnetic conductor (AMC), when it mimics a perfect magnetic conductor (PMC), and its out-of-band behavior, when it emulates a perfect electric conductor (PEC). This idea is represented in Fig. 1.

A wideband radiating element providing stable radiation patterns with maxima at each broadside direction in the addressed bands should be used as the radiating element. By choosing a spacing h_{refl} between the radiating element and the AMC that is about a quarter-wavelength distance in the highest band, which implies an electric distance much smaller than a wavelength for the lowest band, it is possible to achieve a stable, unidirectional, high-gain pattern in a triple-band operation with wide bandwidths covering the addressed standards.

In essence, this idea was already presented and validated in [1] with the design, fabrication, and measurement of a triple-band antenna with a dual-band AMC for the 5G/4G and Wi-Fi 2.4/5/6E standards. In [2], we extended the multiband reflection scheme to also handle the X-band, and the broadside gain of a spiral radiating element was considerably enhanced. The spiral radiating element is circularly polarized. Its current distribution follows a quasi-circular pattern and is not appropriate to illuminate an AMC with a cartesian arrangement [3]. For this reason, although [2] validates the multiband reflection scheme, the cross-polarization level and the flatness in the gain curve are not satisfactory.



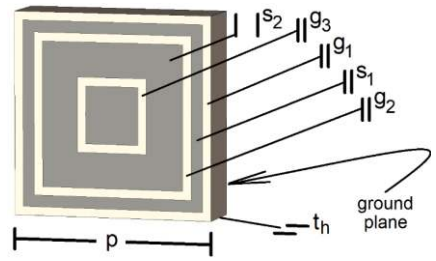


Fig. 1. Working principle: the triple-band AMC works as a near-PMC reflector around three resonances and as a near-PEC reflector far from resonances.

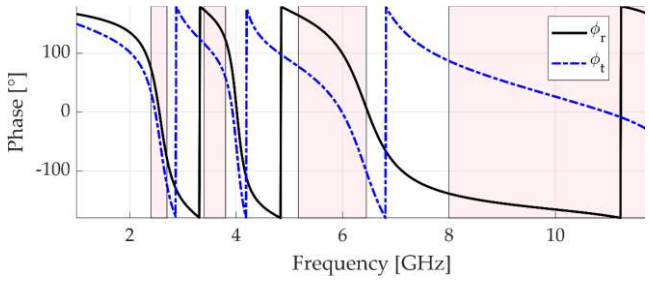
In this work, a grooved bow-tie radiating element [4], whose polarization is linear, is surrounded by a ring so that an appropriate bandwidth is achieved to cover the whole frequency range from 2.4 to 12.0 GHz. As such, the AMC can be properly illuminated by the radiating element in all the addressed bands. Results simulated with CST Studio Suite show that the proposed antenna provides unidirectional, high-gain patterns with maxima at the broadside direction associated to reasonable levels of cross-polarization and front-to-back ratios for all the addressed bands.

2. Materials and Methods

For the AMC, we use a unit cell with three square slots. This unit cell is designed to obtain the behavior of a perfect magnetic conductor (PMC) in three frequencies close to each other, where resonances occur with a reflection coefficient phase $\varphi_r = 0°$. Far from resonances, φ_r asymptotically goes to ±180° and a behavior close to the perfect electric conductor (PEC) is obtained. Fig. 2 depicts such unit cell.

Parameters

g_1	0.55 mm
g_2	0.30 mm
g_3	0.25 mm
s_1	0.25 mm
s_2	2.00 mm
t_h	4.90 mm
p	17.5 mm



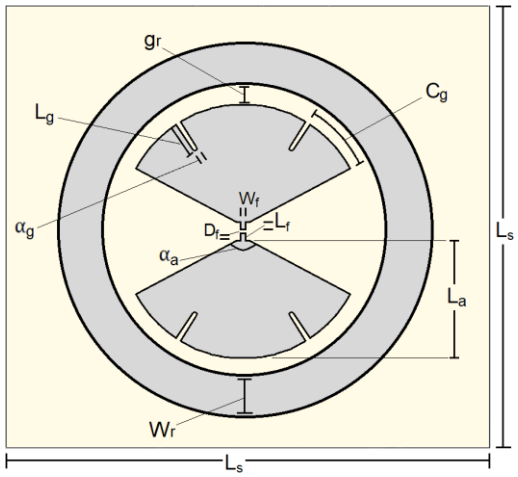


Fig. 2. Simulated unit cell, its parameters, and its reflection coefficient phase φ_r. The phase difference φ_t between the direct and reflected electric fields in the plane $h_{refl} =$ 7.5 mm is also shown.

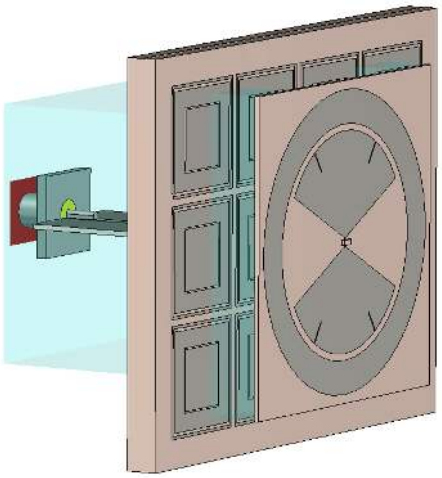
It was shown in [5] that constructive interferences occur between the direct and reflected electric fields at the broadside direction when $-120° < \varphi_t < +120°$, where $\varphi_t = \varphi_r + \varphi_p$ is the phase difference between both fields, $\varphi_p = -2kh_{refl}$ is the phase delay due to the round trip between the radiating element and the reflector, and k is the wavenumber.

We first design the AMC unit cell using a methodology similar to those of [1], to obtain the desired φ_t range in all the bands. The transient solver of CST Studio Suite is set for an infinite structure, using PEC and PMC boundary conditions, as proposed in [6]. A quarter wavelength at the central frequency of the highest band (10.0 GHz) is 7.5 mm. Fig. 2 also shows the parameters of this first unit cell, as well as its reflection coefficient φ_r and the phase difference φ_t between direct and reflected electric fields in a plane distance 7.5 mm from the unit cell. The substrate relative permittivity is $\varepsilon_r = 2.34$, and the loss tangent is $\tan\delta = 0.0013$. The addressed bands are colored, and the condition $-120° < \varphi_t < +120°$ is met in all of them.

Next, a radiating element presenting stable radiation patterns with maxima at each broadside direction in the addressed bands is designed. The element consists of a grooved bow-tie [4] surrounded by a metal ring (Fig. 3).



Parameters

ε_r	2.2	W_f	0.32 mm
$\tan\delta$	0.0009	D_f	0.76 mm
L_s	49.6 mm	L_g	3.7 mm
t_s	0.76 mm	α_g	0.69°
L_a	16.1 mm	C_g	30.0°
α_a	124.4°	g_r	2.0 mm
L_f	0.42 mm	W_r	10.0 mm

Fig. 3. Simulated grooved bow-tie with ring and its parameters.

The substrate presents a thickness $t_s = 0.76$ mm, relative permittivity $\varepsilon_r = 2.2$, and loss tangent $\tan\delta = 0.0009$. This antenna is first simulated alone with a discrete port whose reference impedance is $Z_{ref} = 151\ \Omega$. Its parameters are also shown in Fig. 3.

The AMC and the grooved bow-tie with ring are joined in a single device. As such, an optimization with full-wave simulations that consider the actual incidence of waves over the finite AMC can be done. The AMC has 3×4 unit cells, resulting in an aperture size of $62.9 \times 81.2\ \text{mm}^2$, that is, $0.51 \times 0.65\ \lambda_l^2$, where λ_l is the wavelength at the lowest operating frequency (2.4 GHz). A taper balun similar to the one used in [7] allows the feeding of the structure with a waveguide port over a 50-Ω SMA connector. Foam bricks ensure mechanical stability. The final structure is illustrated in Fig. 4.

New AMC parameters

g_1	0.52 mm
g_2	0.45 mm
g_3	0.25 mm
s_1	0.45 mm
s_2	2.75 mm
t_h	5.00 mm
p	18.3 mm

Fig. 4. Complete device with grooved bow-tie with ring and AMC. The AMC new parameters are also listed.

After the optimization, we used in the AMC unit cell the new parameters shown in Fig. 4. Further, a spacing $h_{refl} = 5.0$ mm was adopted. As such, the final device presents a total thickness 10.76 mm, which represents $0.09\lambda_l$. The balun in this work was used only to allow a future measurement of the structure in an anechoic chamber using a 50-Ω SMA connector. Hence, it was not considered in this calculation. In a real application, the feeding of the antenna would occur through a balun integrated in a board parallel to the antenna ground plane.

3. Results

The simulated results for the radiating element without and with the AMC are shown in Fig. 5. In terms of broadside realized gain, the introduction of the AMC provides an enhancement of up to 2.8 dB in the first band (2.4–2.7 GHz). In the second band (3.4–3.8 GHz), the improvement is up to 3.3 dB. In the third (5.17–6.45 GHz), it is up to 5.7 dB. On the other hand, in the fourth band (8.0–12.0 GHz), an enhancement of up to 4.2 dB occurs in the first half of the band, but a deterioration of up to 1.9 dB is seen in the second half, specifically from 10.5 GHz.

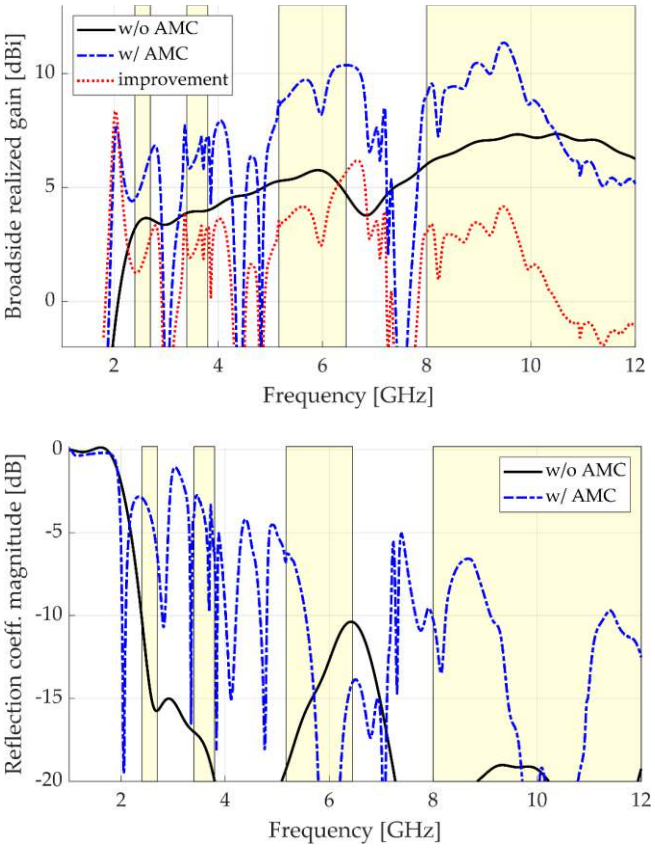


Fig. 5. Simulated broadside realized gain and reflection coefficient magnitude of the grooved bow-tie with ring, without and with the triple-band AMC.

Concerning the reflection coefficient, its magnitude is degraded in all the bands, which indicates that the proposed technique requires the design of a multiband impedance matching network. This network is considered out of the scope of this work to avoid losing focus on the advantages of the multiband reflection scheme.

Fig. 6 shows both E- and H-planes normalized radiation patterns of the grooved bow-tie with ring and AMC at the center frequency of each band. We can see that all the patterns are directive, with maximum radiation at the broadside direction. In the H-plane, the cross-polarization levels are -19.5, -23.1, -23.9, and -17.6 dB respectively for each band, whereas in the E-plane they are all negligeable. In the H-plane, the beamwidth is respectively 79°, 71°, 69°, and 43°. In the E-plane, the beamwidth is 80°, 69°, 54°, and 98°. The front-to-back ratios are 14.3, 26.3, 13.1, and 12.7 dB, respectively.

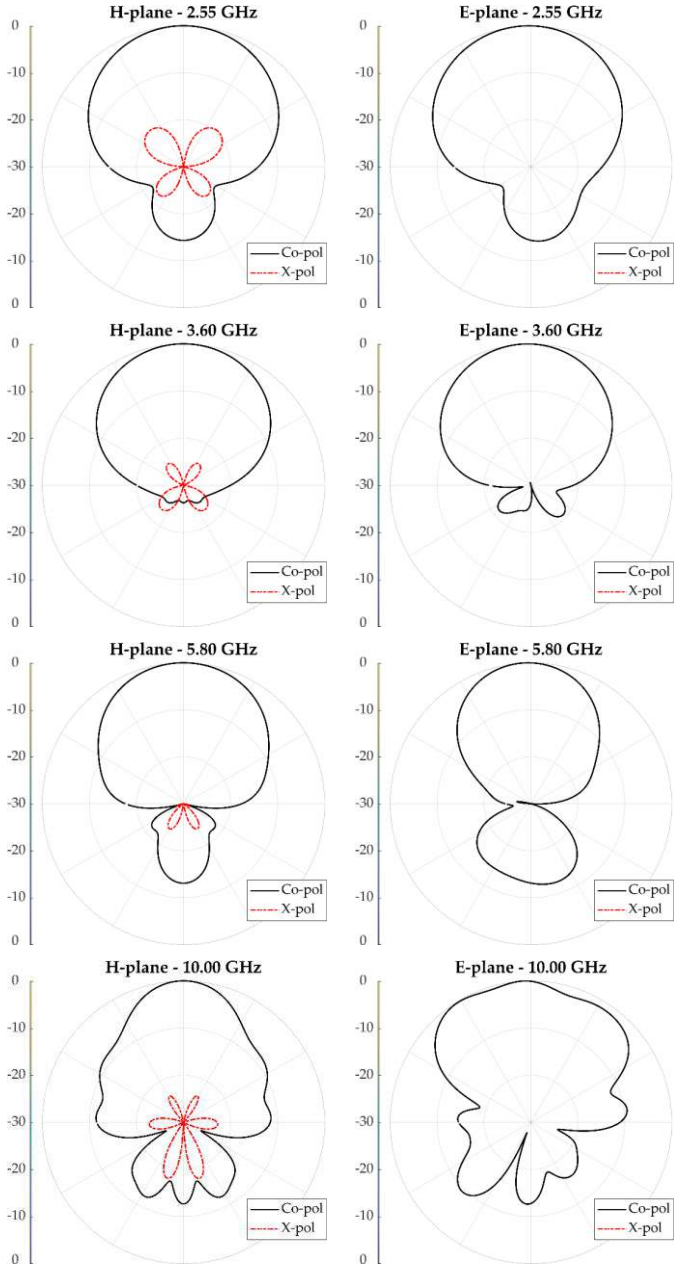

Fig. 6. Simulated normalized radiation patterns of the complete device in the center frequency of each addressed band.

4. Conclusions

We presented a compact, quad-band antenna with directive radiation patterns operating in the frequency bands 2.4–2.7, 3.4–3.8, 5.17–6.45, and 8.0–12.0 GHz appropriate to cover the standards 5G/4G/Wi-Fi 2.4/5/6E and X-band communications. Both the in-band and out-of-band operation of a triple-band AMC illuminated by a grooved bow-tie antenna shape surrounded by a ring were exploited to this end.

The results showed that the multiband reflection scheme enabled by the AMC provided a considerable improvement of the broadside realized gain in comparison to the radiating element alone, with unidirectional radiation patterns and reasonable levels of cross-polarization and front-to-back ratios in all the addressed bands.

The device is compact, with an aperture size of $0.51 \times 0.65\ \lambda_l^2$, and a thickness of $0.09\lambda_l$. However, the proposed approach requires a multiband impedance matching network to provide reflection coefficient magnitudes that could be acceptable in most of the applications.

Design and measurement of an oblique wide-angle metamaterial absorber for RF space applications

A.C. Lepage[1*], X. Begaud[1], O. Rance[1], K. Elis[2], and N. Capet[2]

[1]LTCI, Télécom Paris, Institut Polytechnique de Paris, 91120 Palaiseau, France

Abstract: The paper deals with the design, realization and measurement of a lightweight electromagnetic metamaterial absorber for space applications operating on the [2 GHz, 2.3 GHz] frequency band, under oblique incidence from 35° to 65°.

Nowadays the satellites are getting more and more multifunctional leading to the presence of numerous antennas on the platform. The latter are generally close to each other which may cause interference and thus degraded performances. One solution is to cover some critical areas of the platform with absorbing material [1,2]. However, these areas are generally illuminated with an oblique incidence over a wide angular range which makes the design of the absorber very challenging with the constraints of space applications.
Thanks to their numerous design parameters, metamaterial absorbers appear as a promising solution [3]. Thus it has been demonstrated that metamaterial absorbers enable low-profile and low-mass structures [3]. Some feature a wide angular range but are optimized at normal incidence [4-7]. The question of oblique incidence is addressed in [8]. But gathering oblique incidence and wide angular range remains challenging.
In the present scenario, as the position of the antennas is known, it is possible to divide the absorber surface into smaller parts, each one operating with respect to the incoming angle, and thus reducing the angular range as shown on Figure 1. This concept was first proposed in [9]. The geometry of the unit cell has been studied in [10-11].

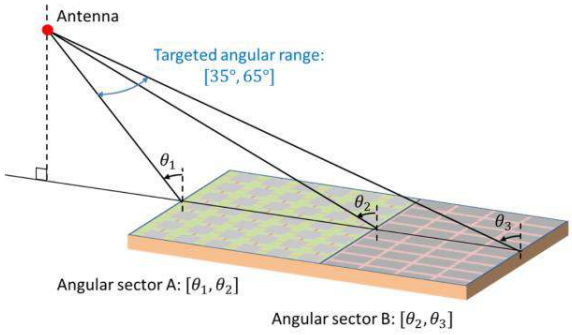

Figure 1: Concept of multi-sectoral absorber.

In this work, we present a sectoral metamaterial absorber for the angular range [35°, 65°] comprising two different sectors. A specific measurement setup has been developed to demonstrate that the whole structure effectively behaves as expected. Particular attention has also been paid on the post-processing of the measurements. Finally, the absorber achieves a measured reflection coefficient inferior to −11.5 dB, corresponding to an absorptivity above 0.965, over the 14% frequency band for [2 GHz, 2.3 GHz] for TE and TM polarizations over the targeted angular range.

Abstract: In this work, we propose transparent passive reflectors installed on windows to boost the millimeter wave signal quality in non-line-of-sight scenarios. The transparent passive reflectors are based on a structured metal mesh called NANOWEB, which exhibits exceptionally high conductivity and optical transmissivity. Ray tracing simulations were conducted for an L-shaped office building using commercial software. Numerical results showcase that NANOWEB-made reflectors can effectively eliminate dead spots, hence rendering them an appealing alternative to conventional opaque metallic reflectors.

Fifth generation (5G) cellular networks are expected to offer multi-gigabit data rates over the millimeter wave (mmWave) band, spanning from 24 to 40 GHz [1]. Despite the abundance of unutilized spectrum beyond the sub-6 GHz band, mmWave signals suffer from high propagation losses and are susceptible to obstruction. This can lead to poor radio coverage in non-line-of-sight (NLoS) scenarios, such as dense urban and indoor propagation environments [2]. To surmount this limitation, it is customary to deploy many base stations and active repeaters (i.e., network densification) in a geographical area.

On the other hand, the advent of metamaterials has recently led to the concept of smart reflecting surfaces, which can passively redirect the impinging signals toward desired directions [3]. Thus, reflecting surfaces could be a power-efficient alternative to typical active relays for coverage enhancement. To this end, transparent reflecting surfaces have attracted the interest of both academia and industry, mainly because they can cover windows and exteriors of buildings without blocking visible light. Existing transparent conductive films such as those made by indium tin oxide (ITO), however, have several drawbacks, including poor mechanical stability and low optical transmissivity versus electrical conductivity [4]. In this work, we rely on the conductive film called NANOWEB, which is a structured mesh of submicron metal wires [5]. This structure results in superior optical and electrical properties compared to other solutions, hence making it ideal for transparent reflectors of high efficiency.

For the performance assessment, we considered a realistic office environment with NANOWEB-made reflectors on its windows. Simulations were carried out by Altair's commercially available WinProp ray-tracing software. Extensive numerical results suggest that the use of passive reflectors can significantly improve the signal quality and achievable data rate in various NLoS locations at 28 GHz. Passive reflectors could therefore play a key role in the successful deployment of mmWave indoor networks, and our presentation will discuss multiple scenarios where their deployment can be beneficial.

Acknowledgements: This study is part of a joint project with Altair Engineering Inc., which has conducted the numerical simulations using its WinProp software.

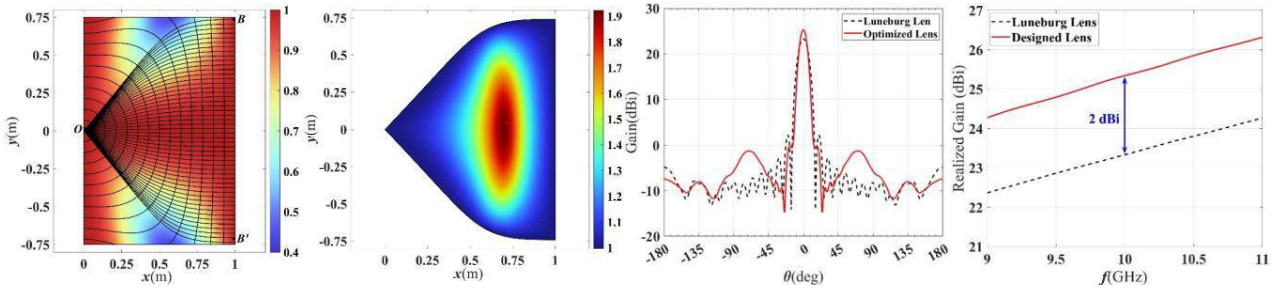
Abstract: In this paper, the phase function inside a graded index dielectric is directly defined using a closed-form formula to create a rotationally symmetric lens antenna. To maintain the refractive index within realistic limits, the refractive index is modified by the optical path rescaling method. An exemplar lens antenna provides a 2 dB improvement over the Luneburg lens at 10 GHz of the same length. The lens has a maximum refractive index of 2 and a side-lobe level of -25 dB.

All-dielectric lens antennas provide a low-loss, wide-band solution and aid in achieving excellent directivity while maintaining a compact structure. The rapid development of fabrication technology has brought graded index (GRIN) solutions to the spotlight. GRIN lens antennas provide good matching and have shown the capacity to give wide bandwidths. The Luneburg lens [1] is a standard GRIN lens capable of producing scanning directional beams. This lens is often large, and a low-profile lens antenna can be built for single-beam applications. Geometrical optics (GO) and Transformation optics (TO) are the two most prevalent GRIN lens antenna design methodologies in the literature. In the latest GO-based lens antenna design, a rectangular GRIN slab is positioned in front of a point source to progressively flatten the cylindrical phase fronts [2,3]. The two-dimensional (2D) refractive index is computed in such that a ray travelling down the optical axis arrives in phase at the aperture, with the ray entering the lens obliquely. The design formula is established on the assumption that rays within the slab propagate exclusively along the optical axis, which eventually results in a phase error [2,3]. Additionally, TO has been used in the design of lens antennas and the material complexity of the transformation-optical devices is dependent on the mapping utilized. It has been shown that employing a (quasi) conformal transformation yields a GRIN dielectric medium [4-6]. When improving directivity is the intention, reflections are an inherent part of TO. The aperture's refractive index is not uniform, and reflections occur at air-lens interface. Moreover, in regions of the design domain where the mapping expands the space, the refractive index falls below unity [5]. Recently, the optical path rescaling approach has been offered as a viable remedy for this flaw [6].



In the first step, we propose a mathematical formula for describing the phase function. This closed-form phase function formula satisfies the problem's constraints without making any unnecessary assumptions. It generates a refractive index of one at the source and the aperture, while producing a semi-circular phase front near the source and a flat phase front near the aperture.

Based on the principles of geometrical optics, the phase function of a region of space, defines the ray trajectories and the refractive index. The ray trajectories are aligned with the phase gradient and the refractive index is the absolute value of the phase gradient [1]. Now consider a 2D space within the x-y plane. Consider a point source radiating cylindrical waves from the coordinate system origin. Suppose a GRIN medium is located within $0 \leq x \leq 1$ that gradually flattens the cylindrical phase front emanating from the origin and traversing toward x=1. The phase function $S(x,y)$ of such device can be described as follows:

$$S(x,y)=rf(x)+x(1-f(x)) \tag{1}$$

where r equals $(x^2+y^2)^{1/2}$, and $f(x)$ is a suitable polynomial series. The above function must satisfy the boundary conditions of the problem. The refractive index should equal one near the source and near the aperture at x=1. Also, the phase contours should resemble cylindrical shapes near the source and should change to flattened contours near the aperture. It can be shown that having $f(x)=(2x+1)(x-1)^2$ in Eq. 1 satisfies these conditions. Figure 1(a) shows the phase function contours, the corresponding refractive index, and the ray trajectories for 50 rays. It can be seen from Fig. 1(a) that the refractive index for the regions above and below the optical axis is below one. This issue is resolved using the optical path rescaling method inside the *OAA'O* region [6]. The modified refractive index is depicted in Fig. 1(b) which is above one everywhere having a maximum value of less than two.

The designed lens antenna in Fig.1 (b) is simulated as a rotationally symmetric lens antenna in the X-band using CST. The Luneburg lens antenna with the refractive index formula of $n=(2-x^2-y^2)^{1/2}$ is chosen as the reference. Both lenses share the same length of 5 λ for λ=3 mm at the center frequency of 10 GHz. Both cases are aligned such that the optical axis is along the z-axis. The feed is a standard circular waveguide with a diameter of 23.83 mm, covering the 9–11 GHz range. The realized gain versus θ is plotted in the ϕ=0 plane for both cases in Fig. 1(c) at the center frequency of 10 GHz. The designed lens has side-lobe level (SLL) values of -25 dB compared to -21 dB for the Luneburg lens. The peak gain is increased from 23.3 dBi with the Luneburg lens to 25.4 dBi. The maximum realized gain value for both cases is plotted within the 9<f<11 GHz band in Fig.1 (d).

Abstract: We demonstrate the use of a space-time-coding digital metasurface operating in the microwave regime to experimentally generate various modes of time-varying orbital angular momentum (OAM) beams. By developing a time-domain field mapping technique, we are able to observe the generated time-varying OAM. Moreover, we explore an additional higher-order twist in the wavefront structure of time-varying OAM beams based on the flexible programmability of the metasurface. These proposed time-varying OAM beams hold potential for applications in communication and particle manipulation.

The orbital angular momentum (OAM) is the component of angular momentum of Electromagnetic (EM) waves that is associated with a helical or twisted wavefront, and the helical modes are characterized by topological charge l. The recent demonstration of extreme-ultraviolet beams with time-varying OAM realized by high harmonic generation has opened new opportunities for quantum excitation control and particle manipulation [1]. However, such an approach is not easily scalable to other frequency regimes and is not flexible enough for the exploration of other time-varying OAM modes. The recently proposed space-time-coding digital metasurface with powerful and flexible programmability of space-time modulation provides us an alternative approach to generate the time-varying OAM beams and further unlock their full potential [2].

In our work, we experimentally construct and observe time-varying OAM beams using a space-time-coding digital metasurface in the microwave regime. We divide the metasurface into 8 independent azimuthal sectors for reflection phase modulation. The space-time modulation scheme is designed as in Fig. 1(b), where the coding digits "1" to "8" represent the reflection phase from 0° to 315° in every 45° and the phase distributions at different time layers result in a time-varying topological charge $l(t)$. Then a time-varying OAM beam with topological charge $l(t)$ varying in $0,\ 1,\ 2,\ 3,\ 4(-4),\ -3,\ -2,\ -1$ periodically in time is generated as shown in Fig. 1(a). Due to the flexible programmability of the metasurface, we can generate different modes of the time-varying OAM beams by adding a time-dependent initial phase in each time layer. In Fig. 1(b), the designed zero phase (coding digit "1") positions marked by the black stars lead to a higher-order twist in the wavefront structure of the time-varying OAM beam. Such a higher-order twist can be described by a winding number w and regarded as an additional degree of freedom in constructing the time-varying OAM beams, which can be used in structured light construction, information encoding, and the rotational Doppler effect.

For experimental demonstration of the time-varying OAM beams generated by the space-time-coding digital metasurface, we directly map the time-varying OAM field including amplitude and phase patterns at various instants of time. A scanning probe and a reference probe are used to measure the time-domain scattering parameters at different positions in the near field. The results from the reference probe can be used to align the time-domain signals probed at different positions. After the synchronization process, we obtain the measured near-field amplitude and phase patterns of the time-varying OAM beams at different instants of time in one period as seen

in Fig. 1(c), showing the time-varying topological charge $l(t)$ in consecutive integer values. The change of OAM is clearly observable in the phase patterns as the spiral fringes vary in time. In addition, the OAM spectrum analysis is performed using OAM mode decomposition on the measured field patterns, demonstrating the high mode purity of the generated time-varying OAM and the designed higher-order twist in the wavefront structure.

In summary, we have experimentally generated time-varying OAM beams by a space-time-coding digital metasurface in the microwave regime. Different modes of time-varying OAM beams can be generated by designing a high-order twist in wavefront structure. We develop a time-domain field mapping technique to dynamically map the time-varying OAM field patterns and evaluate them by performing the OAM spectrum analysis. Our proposed time-varying OAM beams provide new routes in in communication and particle manipulation

A Non-Interleaved Bidirectional Janus Metasurface with Full-Space Scattering Channels

Guanyu Shang[1], Zihan Zhao[1], and Xumin Ding[1*]

[1] Advanced Microscopy and Instrumentation Research Center, School of Instrumentation Science and Engineering, Harbin Institute of Technology, Harbin 150080, China
[*]xuminding@hit.edu.cn

Abstract: Our metasurface with broken mirror symmetry can fully exploit four independent information channels under opposite propagation directions. A series of proof-of-concept is constructed to validity of our methodology, and the simulations and experimental results further show that the proposed non-interleaved bidirectional metasurface can provide an attractive platform for various applications, ranging from structured light conversion, optical imaging, multifunctional optical information processing and others.

Metasurface, composed of two-dimensional artificial meta-atoms, offers the complete control of light, including amplitude [1-3], phase and polarization [7-9] within a platform of various merits such as thinness, easy fabrication and low loss, compared to conventional optical elements. A plethora of exciting applications are demonstrated, such as optical vortex beam generation, energy absorption beam deflection and all-optical image processing, just to name a few. The demand to process the increased information loads with more compact devices in modern optics calls for multifunctional metasurfaces. For instance, the transmission-type metasurface can perform the multiplexing of wavelength, polarization, angle and angular momentum of light, thus enriching the information processing capabilities. Recently, the capacity limit of a single transmissive metasurface as characterized with the Jones matrix has been demonstrated[36], which leads to a natural question of whether one can further add more capacity atop it. To answer this, we note such claims only hold true under the assumption of a metasurface working in half-space, either in reflection or transmission sides, while leaving full-space scattering channels overlooked.

Herein, we demonstrate a transmission-reflection-integrated Janus metasurface, supporting independent functions in both reflection and transmission channels with different incident directions at the same frequency. Importantly, meta-atoms with multilayer composites have broken mirror symmetry, which allows different transmission performances propagating in opposite directions for our demonstrated extreme wave manipulations. Besides, all meta-atoms contribute to the scattering, thus free of segmented or interleaved arrangement (Figures 1a and 1b) and suggesting the full utilization of the metasurface. As a proof of concept, for the forward and backward propagations of the y-polarized incidence, co-polarized reflection and cross-polarized transmission channels in two directions can be independent control and produce four different holographic imaging effects with broken mirror symmetry (Figure 1c). Moreover, protected by reciprocity, the reflected cross-polarized component can show the same holography with the transmitted cross-polarized component when propagation direction changes, suggesting six concurrent operation channels in our designs. Our Janus metasurface with the integration of multifunctional channels in full spaces suggests a new regime of meta-devices with high function capacity and compactness, of great potential in information encryption, optical anti-counterfeiting and others.

Reconfigurable Intelligent Surface as MIMO

S. Droulias[1*] and A. Alexiou[1]

[1]Department of Digital Systems, University of Piraeus, Piraeus 18534, Greece

[*]corresponding author: sdroulias@unipi.gr

Abstract: The Reconfigurable Intelligent Surface (RIS) is often treated either as a collection of point scatterers with properties similar to antennas in an equivalent MIMO communication link or as a continuous radiating surface, which is subsequently discretized. In this work we investigate the connection between the two approaches, we analytically find the factor that renders them equivalent and we demonstrate our findings with examples of RIS elements modeled as antennas with commonly used radiation patterns and properties consistent with antenna theory.

A Reconfigurable Intelligent Surface (RIS) redirects and possibly modifies the properties of incident waves, with the aim to restore non-line-of-sight communication links. Usually, the RIS is treated as a continuous radiating surface or sheet that locally satisfies the boundary conditions, ensuring that an incident plane wave is reflected towards the desired direction [1,2]. Alternatively, due to the inherently discrete nature of the RIS elements, it is more natural to treat the RIS as a planar distribution of scatterers and, in particular, point scatterers that bear the properties of conventional antennas, such as gain and directivity [3-5]. Because the former approach involves a continuous radiating sheet of infinite extent that is subsequently discretized, the question is how well the local RIS elements retain the properties prescribed by the continuous infinite radiating sheet upon discretization and what is the effect of the finite RIS size. Because the latter approach involves the collective response of individual scatterers, therefore by definition implementing a finite-sized RIS, the question is how well the properties of the individual antenna-like scatterers can reproduce the actual field radiated from the RIS.

In this work, we demonstrate the equivalence between the two approaches. We analyze each approach separately and we find the connection between the two, on the basis that they must both account for elements with the same properties, i.e. polarizabilities, guaranteeing the same scattered wave. We investigate how the properties of the continuous sheet are related to the properties of point scatterers that bear characteristics consistent with the antenna theory, and we discuss commonly used models in recent theoretical works. We find that, overall, the treatment of the RIS as point scatterers may overestimate the scattered field and, therefore, a correction factor must be taken into account. By analyzing the correction factor by means of realistic radiation patterns, we demonstrate how the RIS performance is affected by design properties of the RIS elements, such as gain, directivity and inter-element coupling, and we discuss the implications on the predicted power at the receiver.

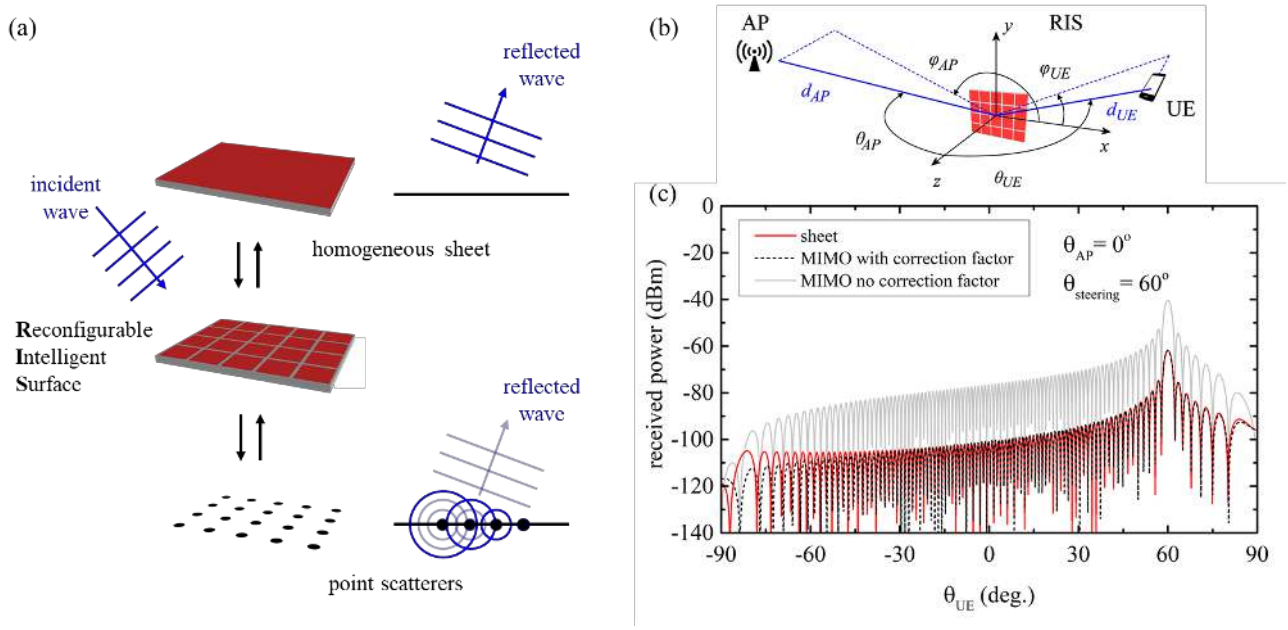

Figure 1. RIS as sheet and MIMO. (a) Schematic representation of a RIS steering an incident wave towards a prescribed direction. The RIS can be analyzed as a homogeneous radiating sheet or, equivalently, as a distribution of point scatterers that bear the properties of conventional antennas. (b) System model of RIS-aided link, illustrating the positions and relative angles between the Access Point (AP), RIS and User Equipment (UE). (c) Equivalence between the sheet and MIMO model for RIS elements modeled as antennas with radiation pattern $U_0(\theta,\varphi) = \cos^2\theta$ and properties consistent with antenna theory. The AP transmitts a TE-polarized wave with amplitude 1 V/m, which impinges normally on a lossless RIS ($\theta_{AP} = 0^o$). The RIS steers the wave on the xz plane at angle $\theta_{steering} = 60^o$, maximizing the received power when $\theta_{UE} = 60^o$. Without the correction factor (solid gray line) the antenna model overestimates the analytically predicted power (solid red line); the sheet-MIMO equivalence is restored upon incorporating the correction factor (dashed black line). The RIS is operating at 150 GHz and consists of 250×250 elements with periodicity $\lambda/5$, forming a reflecting surface of total size 10 × 10 cm^2. The received power is calculated at distance 20 m from the RIS, as a function of the angle θ_{UE} that marks the UE position.

Cross-wavelength Metasurface Based on Carbon Nanotubes

Jin Zhang[1*], Peng Liu[1], and Zhipei Sun[1]

[1]QTF Centre of Excellence, Department of Electronics and Nanoengineering, Aalto University, FI-02150 Espoo, Finland.

Abstract: Multifunctional metasurfaces have garnered significant interest from both academia and industry in the past decade. However, achieving cross-wavelength functionalities remains a challenge due to the strong dispersion of passive materials. In this study, we propose a novel concept of cross-wavelength metasurface that integrates various functionalities with multispectral channels. As proof of concept, we demonstrate optical transparency, Thz diffusion and microwave selectivity simultaneously in a carbon nanotube based metasurface through a laser micromachining technique.

Metasurfaces, which are a new class of subwavelength ultrathin flat components, have brought disruptive innovations to the electromagnetic and nanophotonic fields[1]. Despite of the maturing developments of customized metasurfaces in specific scenarios, limited working wavelength and fixed wave-manipulation emerge as the common defects. To overcome these challenges, cross-wavelength metasurfaces with multispectral capability have been proposed to expand the engineering space for processing concurrent tasks in different channels . However, the interaction of nanostructures between long and short wavelength has not been fully underutilized, resulting in a vacuum region in the terahertz band between microwave and optical regions. To our knowledge, a real cross-wavelength multifunctional metasurface has not been achieved thus far.To address this, we propose a new mechanism for achieving multi-functionalities across the whole frequency band, including microwave, THz and optical region, using interacted layered metasurfaces based on carbon nanotubes (CNT). T The conceptual features of the designed metasurface are pictorially depicted by covering the window of a car (Fig. 1A), offering the challenging compatibility for optical transparency, THz diffusion and microwave selectivity simultaneously. The schematic view in Fig. 1B shows that it is composed of a five-layered stack including a CNT coding array as the top layer, a 175μm-thick transparent polycarbonate spacer as the second layer, a CNT patch structure as the third layer, a 2mm-thick transparent quartz substrate as the fourth layer, and the CNT fishnet structures as the bottom layer. The CNT is made of transparent double-walled carbon nanotubes doped by AuCl3. This selection of materials ensures high transmission of visible light in the assembled metasurface.

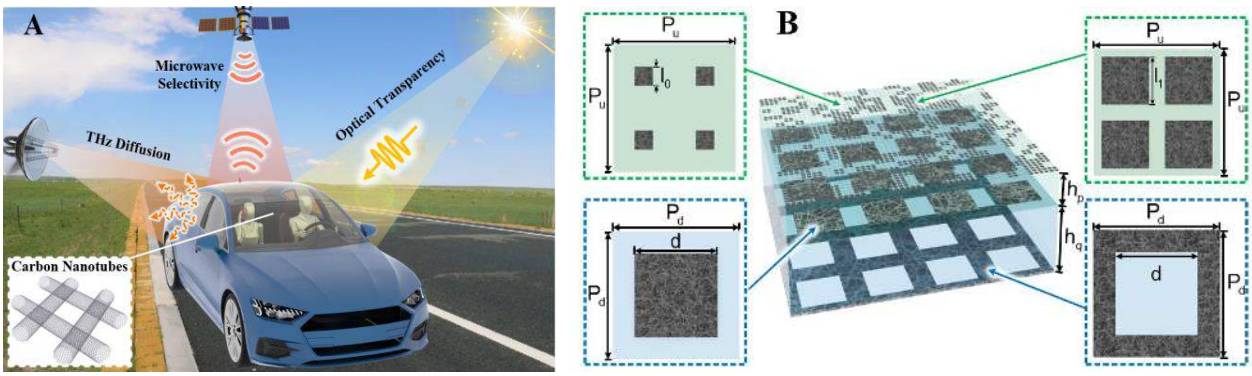

Figure 1 (A) Conceptual features and (B) schematic depiction of the cross-wavelength metasurface.

We start the design by engineering the electromagnetic response for microwave selectivity. Figure 2A gives a schematic representation of the unit cell of proposed metasurface and its physical mechanism can be demonstrated by the equivalent circuit model (ECM) shown in Figure 2B, where Z_p and Z_f represent the characteristic impedance of the CNT patch and fishnet structures, respectively. We plot the reflection and transmission spectra in Figure.2C, which shows the good agreement between simulated and calculated results. It is seen that the reflection amplitude was minimized to about -45 dB, while the transmission reached its maximum value at 7 GHz. This demonstrated that the proposed metasurface formed a selective electromagnetic window in the microwave region, which only allowed the transmission of EM waves at specific frequencies and reflected other noise waves. Next, we demonstrated the performance of the proposed metasurface in terms of THz diffusion, as shown in Figure 3. The metasurface was divided into three parts: the THz coding array providing 1 bit phase random distribution, the polycarbonate (PC) and quartz layers acting as dielectric layers, and the CNT patch/fishnet structures reflecting all the incident THz waves. By optimizing the metasurface using genetic algorithm, we were able to achieve diffuse scattering, as shown in Figure 3B and C, thereby demonstrating the effectiveness of the design.

Abstract:
We have experimentally studied the charge-spin cooperative dynamics of two-electron states in a GaAs double quantum dot (DQD), which are driven in a nonequilibrium phonon environment created by a nearby QD-based phonon source. The spin-flip rates increase remarkably, which is explained by the simultaneous action of the spin-orbit and electron-phonon interactions. Furthermore, we found the imbalance of the occupation probabilities between antiparallel/parallel spin states, which is explained by the thermal nonequilibrium of the phonon environment in the DQD.

Thermodynamics in quantum mesoscopic systems has long been studied as one of the central concepts in solid-state physics. In particular, temperature gradients over mesoscopic structures have realized various kinds of thermodynamic functions such as heat engines and heat valves, which are useful for improvements of thermoelectric conversion and heat control by electrical means in mesoscopic devices. For the demonstration of a heat engine in nano-structure devices, a semiconductor quantum dot (QD) is recognized as one of the best platforms because a dot can be coupled to the multiple electron reservoirs with the different electron temperatures. However, none of QD-based heat engines discussed in previous studies is driven by heat reservoirs at different lattice temperatures. This is probably because a lattice temperature gradient over a few hundred nanometer distances, order of a QD size is technically difficult to be created. A QD-based local phonon source has already been utilized to study phonon-assisted electron tunneling in the Coulomb blockade QD but not yet the effects of thermodynamics [1].

In this work, we concentrated on both the charge and spin dynamics of two-electron states in a GaAs lateral double QD (DQD), that are driven by a nonequilibrium phonon environment created by a QD-based phonon source located at the one side of the DQD (see Fig. 1(a) for the sample geometry) [2]. Note that the maximum energy of the phonon is determined by the applied bias voltage as eV_{PS}. The DQD is adjusted in such a way that the ground states of the (1,1) and (0,2) charge states are resonant, and the possible spin states in the resonant DQD are depicted in the diagram in Fig. 1(b). To discuss the phonon-induced charge-spin dynamics at a single electron level, we implement a real-time charge sensing technique using a nearby QD, which is combined with the Pauli spin blockade effect of a DQD. Thereby, we count the number of the spin-flip tunneling events in the two-electron DQD set in the spin blockade regime under phonon radiation. Our experimental results show that the spin-flip rate remarkably increases when the irradiated phonon energy exceeds the lowest excitation energy in the DQD (see Fig. 2(a)). The increase in the spin-flip rate can be explained by the phonon-mediated inter-dot tunneling process and the intra-dot spin-flip process involving the excited states (see Processes I and II illustrated in Fig. 2(b), respectively). Furthermore, we discovered the significant imbalance in the occupation probabilities between the antiparallel and parallel spin configurations of the (1,1) charge state (see Fig.

2(c)). These experimentally observed behaviors of the spin dynamics are successfully reproduced by our recent theoretical calculations, which take into account the spin-orbit and electron-phonon interactions in the DQD under the nonequilibrium phonon environment. Our theoretical calculation indicates that the imbalance of the occupation probability between parallel and anti-parallel spin configurations shown in Ref. [2] is created not just by the phonon temperature increase but the phonon temperature gradient in the DQD system.

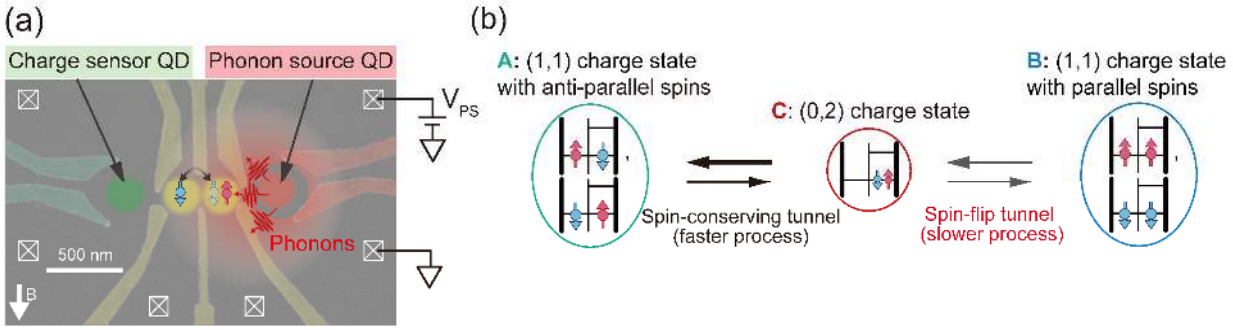

Fig. 1. (a) Geometrical configuration of our GaAs DQD sample. The DQD is formed on the two yellow circles, and the charge sensor is placed on the left green circle. The phonon source locates on the right red circle, on which the DC bias voltage V_{PS} is applied. (b) Transition diagram in a resonant two-electron DQD. States A and C (B and C) are connected by the spin-conserving (spin-flip) tunneling processes.

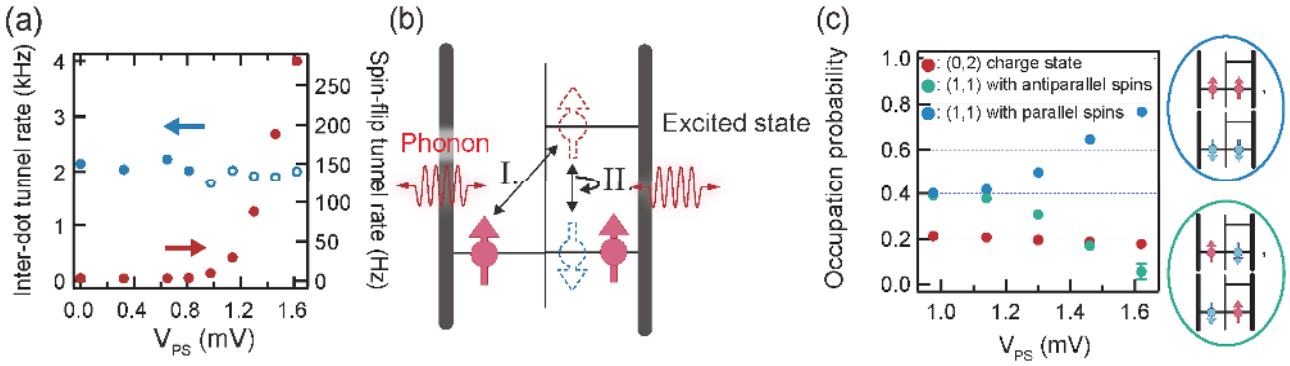

Fig. 2. (a) Spin-conserving inter-dot tunnel rate from state C to A (blue) and the spin-flip tunnel rate from state B to C (red) plotted as a function of V_{PS}. (b) Energy level diagram in a DQD, which explains the phonon-induced spin-flip tunneling process involving the excited state. (c) Occupation probabilities of the (0,2) charge state and anti-parallel and parallel spin states of the (1,1) charge state, plotted by red, green, and blue dots, respectively. For the (1,1) charge state, as V_{PS} is larger, the occupation probability of parallel spin configurations increases, while that of anti-parallel spin configurations decreases.

Abstract: Electronic and phononic coherence has been studied in an n-type GaAs crystal using transient reflection measurements with relatively phase-locked femtosecond pulses at 90 K. The interference fringes due to electronic and phononic coherence are observed in the coherent phonon amplitude as a function of pump-pump delays. The collapse and revival feature was observed in electronic coherence and well represented in the theoretical calculations. The electronic decoherence time was estimated to be 23 ±0.3 fs.

Quantum coherence, which enables a superposition state, is one of the most important features of quantum mechanics. Quantum coherence persits in an isolated system but disappears rapidly in condensed matter. Quantitative values of the decoherence time and the decoherence mechanism in condensed matter are still well understood. We are investigating the quantum coherence, in particular electronic and phononic coherence, in semiconductors by developing ultrafast quantum-path interferometry.

We have studied quantum interference (electronic and phononic coherence) between electron-phonon coupled states in n-type GaAs (001) excited by relatively phase-locked femtosecond pulses through changes in transient reflectivity. The sample is doped with Si at a donor concentration of 1.0×10^{18} cm^{-3} and placed in a cryostat. The pulse width is approximately 60 fs (full width at half maximum). The central energy of the pulse is 1.55 eV, slightly above the GaAs bandgap. The delay (τ) between two pump pulses was controlled with a step of approximately 300 attoseconds by using a home-built Michelson-type interferometer. At the fixed τ, a reflectivity change as a function of a pump-probe delay (T) shows a damped oscillation with ~114 fs and ~128 fs spacing, which are attributed to the longitudinal optical (LO) phonon at 8.8 THz and the LO phonon-plasmon coupling (LOPC) at 7.8 THz, respectively [1]. The 8.8 THz oscillation represents phononic coherence, and the decoherence time is estimated from its decay behavior to be 3.4 ps at 90 K. The amplitude of the LO phonon is determined from the Fourier transformed spectrum.

The LO phonon amplitude ($A(\tau)$) as a function of the pump-pump delay τ shows fringes with ~2.7 and ~114 intervals in the parallel polarized condition (Fig. 1 (a)). The sample temperature is set to be 90 K. The fast and slow fringes are due to electronic and phononic coherence, respectively. The electronic coherence continues longer than the pump-pulse duration and exhibits a collapse and revival feature characteristic of the impulsive stimulated Raman scattering (ISRS) pathway [1]. At 45 degrees condition (Fig. 1 (b)), both the fast and slow fringes are observed and the additional splitting feature is found on the fast fringe pattern [2]. On the other hand, in the perpendicularly polarized condition (90 degrees, Fig. 1 (c)), only the slow fringe is observed [3].

We have constructed a simple quantum mechanical model for the generation of LO phonons by double-pulse excitation [4]. In the model, the system consists of two electronic bands and a harmonic oscillator for phonons.

The Raman tensor is used for the electron-phonon coupling. We use a dipole interaction between the system and optical pulses (classical electric field) and the rotating wave approximation. The time evolution of the system is calculated via a quantum master equation with second order perturbation. Theoretical calculations using ISRS paths give good agreement with the experimental data for three polarized conditions. The fast fringe corresponding to the electronic coherence is due to the ISRS path in which photo-excitation and de-excitation are induced by pump 1 and 2, respectively. On the other hand, the slow fringe corresponding to phononic coherence is due to interference between coherent phonons induced by each pump 1 and pump 2 (photoexcitation and de-excitation occur within one pulse). In addition, the calculation predicts that the splitting in the collapse and revival feature of electronic coherence at the 45-degree condition depends on the electronic decoherence time. From the splitting, the electronic decoherence time is estimated to be 23 ±0.3 fs in n-GaAs at 90 K.

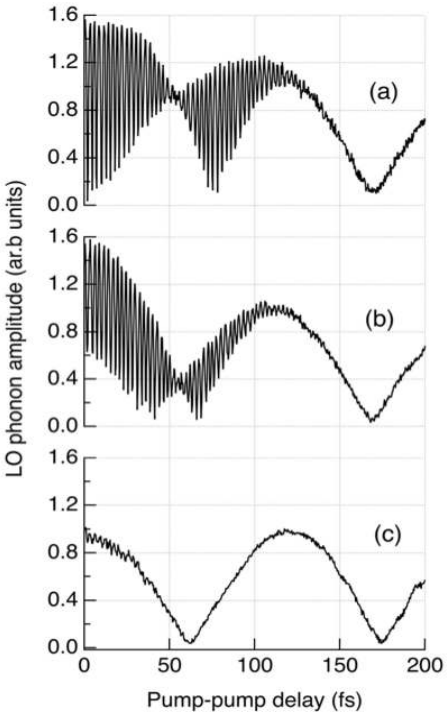

Fig. 1 LO phonon amplitude as a function of pump-pump delay at relative polarization angle of (a) 0, (b) 45, and (c) 90 degrees. Sample temperature is 90 K.

Abstract: Many molecular, quantum-dot, and optomechanical nanocavity-QED systems demonstrate strong nonlinear interactions between electrons, photons, and phonon modes. We show that such systems can be described by a universal model in the vicinity of the nonlinear resonance involving all three degrees of freedom. We solve the nonperturbative quantum dynamics in the strong-coupling regime, taking into account quantization, dissipation, and fluctuations of all fields. Strong coupling at the nonlinear resonance leads to tripartite quantum entanglement and distinct emission spectra.

Nonlinear optical interactions acquire qualitatively new features in the strong-coupling regime of cavity QED, especially when utilizing an extreme field localization achievable in nanophotonic cavities. The dynamics becomes especially interesting when the strong coupling regime is realized at the nonlinear resonance between three or more degrees of freedom. One possible example where it can be realized is a molecule or an ensemble of molecules in a plasmonic nanocavity, when molecular vibrations modulate the electron transition frequency. This coupling is typically introduced via the Huang-Rhys theory and is often used to describe not only molecules but also the effect of phonons on the coupling of a quantum dot or an optically active defect to the cavity field. When the strength of such a nonlinear three-wave interaction is higher than the dissipation rates, entangled electron-photon-phonon states of GHZ type are formed. Another route to the nonlinear resonance is cavity optomechanics, where mechanical oscillations of a cavity parameter modulate the frequency of the photon cavity mode. We show how these very different physical models of electron-photon-vibrational coupling can be mapped onto the universal parametric Hamiltonian, independently on the specific physical mechanism of coupling. When solving for the quantum dynamics we include the effects of dissipation and fluctuations for all degrees of freedom. The effects of the phonon reservoir lead to qualitatively new features and rich multi-peak structure in both photon and phonon emission spectra at the nonlinear resonance that are not present in the standard Rabi oscillations regime.

Abstract: Periodic subwavelength silicon patterning opens new degrees of freedom to control the propagation of light and sound in silicon photonic circuits. In this invited presentation, we will show our most recent results on leveraging silicon nanostructuration for optomechanical and nonlinear applications.

Brillouin scattering, i.e. the nonlinear interaction between optical and mechanical fields inside a material, has generated great scientific interest for its numerous applications in communications, sensing and quantum technologies. However, efficient Brillouin interactions require simultaneous confinement of optical and mechanical modes. Such optomechanical confinement is challenging in SOI waveguides due to a strong phonon leakage towards the silica cladding. On the other hand, the absorption of the silica cladding for wavelengths above 3.5 μm limits the use of the silicon-on-insulator (SOI) technology in the mid-infrared.

Since their first demonstration in silicon photonics [1,2], subwavelength-grating metamaterials [3, 4] have been used as a powerful tool for overcoming performance limitations of conventional silicon photonic devices. Furthermore, periodically patterning silicon with a subwavelength pitch opens new degrees of freedom to control the propagation of light and sound in silicon photonic circuits with unprecedented flexibility. In this invited presentation, we will show our most recent results on the use of subwavelength nanostructuration to control photons and phonons in integrated silicon waveguides [5,6]. We will also present the supercotinuum generation in the near-IR and mid-IR with suspended silicon waveguides [7].

These results open exciting new perspectives to exploit nonlinear and optomechanical effects with scalable silicon photonics technology, having great potential for applications in optical and wireless communications, radar, sensing, metrology and quantum technologies.

Abstract: Nano-optomechanical systems (NOMS) are developed to explore the ultimate limits of sensitivity in mass sensing. Fabricated using silicon-on-insulator and typical integrated photonics process flows, we use NOMS chips for directly sensing miniscule mass levels in gas chromatography and in mass spectrometry as well as for performing sub-millidegree resolved temperature sensing. We have a vision for achieving single atomic mass unit mass sensitivity resolution in air and room temperature.

Nano-optomechanical systems have been deployed as the mass sensing element in niche applications of mass spectrometry [1] and gas chromatography [2]. Using racetrack optical resonators in silicon-on-insulator coupled to doubly clamped mechanical beams, we were able to demonstrate that the intrinsic sensitivity of a thermomechanically limited NOMS resonant sensing system is independent of mechanical damping [3]. We have explored the nonlinearity limitations in NOMS, both taking advantage of it for optomechanical spring effect sensing [4], and designing around it to extend the linear range of device operation [5, 6]. Taking advantage of optomechanical numerical modeling that combines the coupling of two optical field colors and mechanical response, we were able to locate and exploit a null in optomechanical nonlinearity at a specific optical cavity detuning in order to increase linear operation range in one of our NOMS devices. The increased linear range led to our most recent demonstrated sensitivity level of 83 yg (yocto = 10-24) or about 50 atomic mass units [7]. Our current project develops slot-mode waveguides with photonic crystal cavities and phononic crystal mechanical elements for enhancement in both optical and mechanical quality factors. This will enhance the optomechanical coupling and the frequency stability which will allow size-down-scaling of cantilever beams and the potential of single Dalton mass sensitivity levels.

Abstract: We demonstrate single-crystal diamond optomechanical crystal cavities that support ~ 200 THz optical modes co-localized with high-frequency 10 GHz acoustic modes. Their measured optomechanical coupling $g_0/2\pi > 200$ kHz is extracted through optomechanical back action measurements.

Cavity optomechanics integrates mechanical resonators within optical cavities, enhancing the coupling of light and the motion of mechanical resonator [1]. Mechanical resonators interact with a wide range of physical systems, making them a critical element of sensing and quantum transduction technologies by connecting a mechanical degree of freedom to other physical systems. The performance of these systems is enhanced by integrating mechanical resonators directly within optical cavities, which confine photons and phonons to small mode volumes.

Diamond is a promising material for hybrid quantum systems due to its extraordinary optical, thermal, and mechanical properties and the presence of accessible colour center defects for spin-qubit applications. Optomechanical crystal (OMC) devices fabricated from diamond can be used as quantum transducers that bypass the need for spin-optical transitions.

Thanks to advances in diamond nanofabrication techniques, cavity optomechanical devices can be realized from single crystal diamond (SCD). OMC cavities fabricated using angle etching [2] and membrane thinning [3] have enabled coherent optomechanical coupling to mechanical resonances with frequencies of 5.5 to 9.5 GHz. Here we use quasi-isotropic etching for the first time to fabricate OMC cavities in single-crystal diamond, and show that they confine optical and high-frequency mechanical modes coupled via radiation pressure. Using these devices, we characterize the optomechanical coupling to 10.2 GHz modes - the highest frequency acoustic mode measured in SCD to date.

Diamond optomechanical crystal demonstrated in this work is designed to support co-localized optical and mechanical modes, and unlike previously studied angle-etched devices, have rectangular cross-section and was fabricated using a quasi-isotropic etch process adopted from Khanaliloo *et al.* [4]. Simulated normalized transverse electric (TE-like) field of the localized optical mode and mechanical displacement profiles of the mechanical breathing modes are shown in Fig. 2(a).

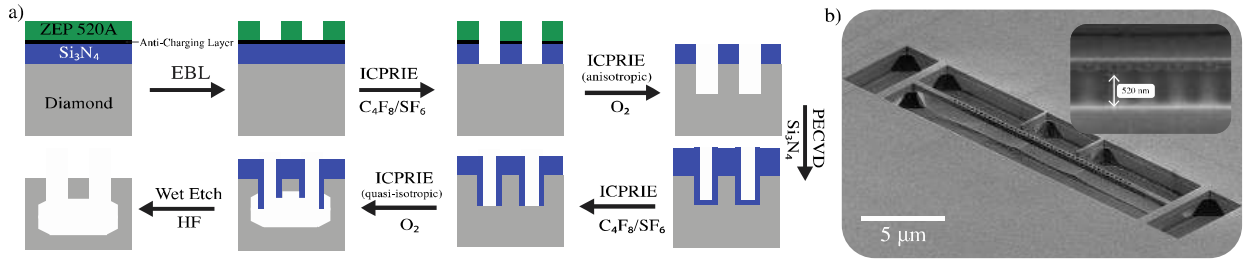

Figure 1. Fabricated diamond optomechanical crystals. (a) Fabrication process flow using high temperature plasma quasi-isotropic undercut etch. (b) Tilted scanning electron microscope (SEM) images of 1-dimensional OMC defined by air holes and zoomed-in view of the defect region (inset).

In the experimental setup, light is coupled into the OMC via a dimpled fibre taper. The transmitted light from the device is split into two outputs for optical and mechanical spectroscopy measurements. Figure 2(b) displays both the optical transmission and measured mechanical spectra as a function of input laser wavelength. A Lorentzian fit of the optical spectrum gives a measured total optical decay rate of 10.16 GHz corresponding to an optical Q-factor of $Q_O = 3.05\times10^4$ centered at $\lambda_0 = 1575.25$ nm. Mechanical spectroscopy was performed by analyzing the RF spectrum of the photodetector light using a real-

time signal analyzer (RSA). As the laser is tuned onto the side of the optical resonance, thermomechanically driven motion of the mechanical mode at 10.178 GHz with quality factor of $Q_m = 9.05\times10^2$ is transduced.

To characterize optomechanical coupling, Fig. 2(c) plots the measured mechanical linewidth of the mechanical breathing mode, collected under laser detuning $\Delta = \pm\omega_m$ as a function of the intracavity photon number (n_{cav}). The mean value extracted from the Γ_{red} and Γ_{blue} data yields an intrinsic mechanical linewidth of $\Gamma_i/2\pi = 11.25$ MHz. Figure 2(d) demonstrates the calculated optomechanically induced damping $\Gamma_{OM} = \Gamma_{red} - \Gamma_i$, plotted versus intracavity photon number (n_{cav}). A linear fit yields $g_0/2\pi = 229.9$ kHz. With a blue-detuned input field by the mechanical frequency and sufficiently high power, the effective mechanical line-width, Γ_m, goes to zero, and we are able to excite the mechanical mode into self-induced oscillations (i.e. phonon lasing) shown in Fig. 2(e).

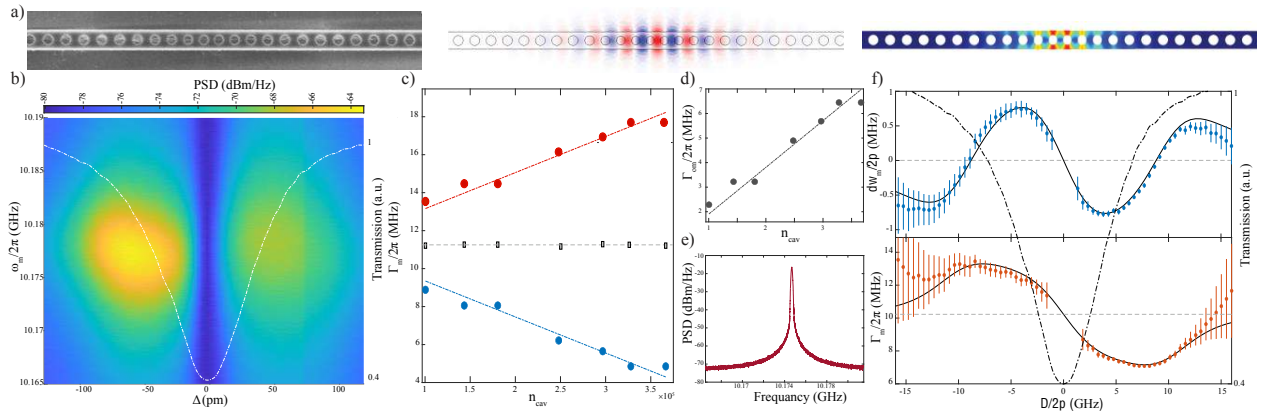

Figure 2. Diamond OMC optical and mechanical spectroscopy of the acoustic breathing mode. (a) Top-view SEM image of the device, normalized optical mode, and mechanical displacement profile of the mechanical mode. (b) The acoustic breathing mode's power spectral density (PSD) and normalized optical transmission (white path) plotted versus input laser detuning from the optical cavity resonance. (c) Measured mechanical linewidths at $\Delta = \pm\omega_m$ plotted versus n_{cav}. (d) Calculated optomechanically induced damping (Γ_{OM}). (e) Self-induced oscillation (i.e. phonon lasing) of the mechanical mode. (f) Optically amplified mechanical loss and spring shift in mechanical frequency measured as a function of laser detuning. Large error bars in regions far from cavity resonance are due to low amplitude mechanical mode resulting from the low number of cavity photons, yielding more uncertainty in the fit.

The optically amplified mechanical loss rate and optical spring shift in the mechanical frequency were also measured as a function of laser detuning. Figure 2(f) displays the experimentally derived optical damping and springing curves for the diamond OMC acoustic breathing mode. Estimates for the intrinsic mechanical damping of $\Gamma_i/2\pi = 10.23$ and 10.18 MHz and the single-photon optomechanical coupling rate of $g_0/2\pi = 192.0$ and 195.8 kHz can be extracted from this data.

In summary, we reported demonstration of a high-frequency diamond OMC cavity fabricated using quasi-isotropic etching. Optomechanical coupling in these devices will allow cooperativity > 1 for an intracavity photon population on the order of 10^5. The demonstrated device is a promising platform for reaching much larger cooperativities by operating at cryogenic temperatures where mechanical dissipation will decrease. The high-frequency mechanical mode of this device makes it less susceptible to decoherence due to its low thermal phonon population. These features open the door to demonstrating quantum optomechanical applications.

Abstract: Departing from traditional optomechanics, the integration of microwave circuits offers substantial nonlinearities that can be effectively harnessed for enhanced coupling between microwave and mechanical systems. In this work, we show that a mechanical system can be strongly coupled to a microwave circuit, enabling cavity cooling with one microwave photon in average. In addition, the strong Kerr non-linearity of the circuit can be leveraged to further increase the cooling efficiency compared to what is achievable with a linear system. Since mechanical systems can also be efficiently coupled to optical fields, mechanical interfaces can be used to realize transduction of quantum information between the microwave and optics domains.

Applications of phonon-electron devices for microwave frequency signal processing

Matt Eichenfield

Sandia National Labs, USA
*corresponding author, E-mail: eichenfield@arizona.edu

Abstract

Devices that allow controllable interactions between electrons and phonons—acoustoelectric devices—have undergone a resurgence of interest in the last 8 years due to rapid advanced in heterogeneous integration of piezoelectric materials and semiconductors. Here, I will describe some of the novel devices and systems that are emerging from this field. I will discuss my group's work demonstrating devices such as phononic amplifiers, mixers, switches, and others. Finally, I will discuss the prospects of these devices for insertion into wireless technologies both existing and future, as well as novel applications.

Photonic Implementation of Non-Adiabatic Holonomies for Quantum Computing

V. Neef, J. Pinske, M. Heinrich, S. Scheel, A. Szameit*

Institute for physics, University of Rostock, Albert-Einstein-Str. 23, 18059 Rostock, Germany
*corresponding author: alexander.szameit@uni-rostock.de

Abstract: We present the experimental realization of non-adiabatic holonomies in integrated quantum optics. Implementing quantum gates solely by means of non-Abelian geometric phases increases stability and reduces the need for quantum error correction. We use femtosecond laser-written waveguides and to realize topologically protected single-qubit gates as well as gate sequences, and verify their performance by means of heralded single-photon measurements. Our findings pave the way towards a holonomic architecture for quantum computers.

Implementing quantum gates as non-Abelian holonomies, a class of topologically protected unitary operators, is a particularly promising paradigm for the design of intrinsically stable quantum computers[1]. In contrast to dynamical phases, which record the passage of time, the geometric phase accumulated by a quantum system propagating through a Hilbert space $\mathcal{H}$ depends exclusively on its path. A famous example of such a quantity is the Berry-Pancharatnam phase[2,3], which is Abelian and belongs to the one dimensional unitary group $\mathrm{U}(1)$. In general, however, geometric phases can exhibit arbitrary dimensionality. Wilczek and Zee introduced the idea of multi-dimensional, non-Abelian geometric phases – so called holonomies[4]. Anandan later lifted the requirement of adiabaticity to create truly time-independent holonomies[5]. Non-adiabatic holonomies rely on a subspace $\mathcal{H}_{\mathrm{geo}}$ of the Hilbert space which is spanned by states $\{|\Phi_k\rangle\}_k$ fulfilling $\langle\Phi_k|\widehat{H}|\Phi_j\rangle = 0$, where $\widehat{H}$ is the system's Hamiltonian. Restricting the propagation to $\mathcal{H}_{\mathrm{geo}}$ ensures parallel transport and, thus, a purely geometric phase (see Fig. 1a). Crucially, the states $\{|\Phi_k\rangle\}_k$ are no longer instantaneous eigenstates of the Hamiltonian[6,7].

Quantum optics constitutes a particularly versatile platform for quantum information processing and the construction of non-adiabatic holonomic quantum computers: Not only does it readily enable the desired integration and miniaturization, the bosonic nature of photons also conveniently allows for multiple excitations of the same bosonic mode[8,9].

Our system consists of three waveguides (L, C, R) fabricated by femto-second laser direct inscription[10]. In this planar geometry, direct coupling between the outer channels L and R is effectively suppressed, while each of them interacts with the central site C via the couplings κ_{L} and κ_{R}, respectively. Pairs of indistinguishable photons from a Type-I SPDC source allow for heralded coincidence measurements with a set of avalanche photo diodes (APDs). Exciting the three-waveguide structure with a single photon creates a two-dimensional geometric subspace $\mathcal{H}_{\mathrm{geo}}$. Under a cyclic evolution through $\mathcal{H}_{\mathrm{geo}}$ a two-dimensional non-adiabatic holonomy $\widehat{U}$ can therefore be realized. Parametrizing the couplings[6,7] as $\kappa_{\mathrm{L}}(z) = \Omega(z)\sin\left(\theta/2\right)\mathrm{e}^{\mathrm{i}\phi}$ and $\kappa_{\mathrm{R}}(z) = \Omega(z)\cos\left(\theta/2\right)$ with constant weights (defined through θ and ϕ) and an envelope function $\Omega(z)$, the cyclicity condition simplifies to $\int_{z_{\mathrm{i}}}^{z_{\mathrm{f}}}\Omega(z)\,\mathrm{d}z = \pi$. The resulting holonomy[11]

$$\widehat{U} = \begin{pmatrix} \cos\theta & -\mathrm{e}^{-\mathrm{i}\phi}\sin\theta \\ -\mathrm{e}^{\mathrm{i}\phi}\sin\theta & -\cos\theta \end{pmatrix}$$

belongs to the group $\mathrm{U}(2)$ and acts as a single-qubit gate for the dual-rail encoded qubit $|0\rangle_{\mathrm{logic}} = |1_{\mathrm{L}}0_{\mathrm{R}}0_{\mathrm{C}}\rangle$,

$|1\rangle_{\text{logic}} = |0_L 1_R 0_C\rangle$. A dense subset of the symmetry group can be created using two successive non-commuting holonomies[8,11]. Interestingly, and in contrast to the adiabatic approach, real-valued couplings ($\phi = 0$) already suffice to realize such non-commuting holonomies. As a proof of principle, we experimentally realize two prominent quantum gates, Pauli-X and Hadamard, up to a global phase. Figure 1b depicts the waveguide structure for the Hadamard gate ($\theta = 3\ \pi/4$), where $\Omega(z)$ was chosen such that the waveguides L and R approach C along a cosinusoidal path, followed by a straight section, and finally are separated once more by another cosine segment. To ensure a smooth transition to a standard fiber array, additional cosine-shaped fanning sections were implemented at the beginning and end of the chip. Due to its inherent symmetry, no fanning section is needed for the Pauli-X gate ($\theta = \pi/2$). The measured probabilities of the Hadamard gate are depicted in Fig. 1c. We find an average fidelity between theoretically expected probabilities and measurement of $\bar{F} = (99.2 \pm 0.2)\%$ for the Hadamard gate and $\bar{F} = (99.1 \pm 1.0)\%$ for the Pauli-X gate, showcasing the high accuracy of our quantum-optical realization of non-adiabatic holonomic quantum gates. We experimentally prove the non-Abelian nature of the quantum gates and realize the *QP penny flipover*[12], a quantum algorithm from quantum game theory. Our findings pave the way towards universal holonomic quantum computing.

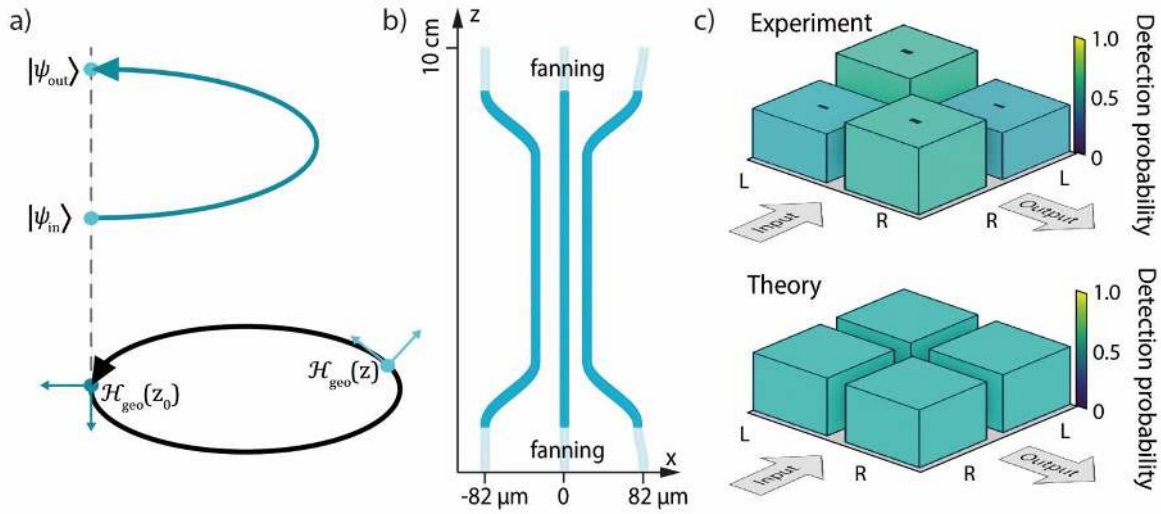

Figure 1: a) Schematic illustration of a non-adiabatic holonomy. The geometric subspace $\mathcal{H}_{\text{geo}}$ (spanned by non-dynamical states) is time dependent (bottom layer). In input state $|\psi_{\text{in}}\rangle$, prepared inside the initial geometric subspace, will be transformed into an output state $|\psi_{\text{out}}\rangle$, that also lies inside the initial geometric subspace. **b)** Waveguide-based implementation of the non-adiabatic holonomic Hadamard gate. **c)** Experimental results and theoretical predictions for the probability distributions of a Hadamard gate.

Quantum explorations and applications of phonon-electron interactions

Matt Eichenfield

Sandia National Labs, USA
*corresponding author, E-mail: eichenfield@arizona.edu

Abstract

Interactions between electrons and phonons are being vigorously explored for their utility in RF signal processing, sensing, and more. However, these devices are almost entirely unexplored in the quantum regime. Here, I will describe our recent work theoretically and experimentally exploring quantum electron-phonon interactions and how they can be applied to fundamental studies of materials and quantum information science.

Abstract: We review recent progress on the experimental observation of light thermalization to the Rayleigh-Jeans equilibrium in multimode optical fibers. We develop a nonequilibrium thermodynamic description of light thermalization on the basis of the wave turbulence theory by taking into account the impact of disorder (weak and strong random mode coupling), which is inherent to light propagation in multimode optical fibers. The analysis reveals that weak disorder increases the rate of thermalization to equilibrium, whereas strong disorder can inhibit light thermalization.

Different studies on wave turbulence revealed that purely classical waves can exhibit a process of condensation that originates from the thermalization of the waves toward the Rayleigh-Jeans (RJ) equilibrium distribution [1,2]. Although this phenomenon of condensation of classical waves differs from the quantum Bose-Einstein condensation, the underlying mathematical origin is formally analogous because of the common singular behavior (vanishing denominator) of the equilibrium Bose distribution for quantum particles and the equilibrium Rayleigh-Jeans distribution for classical waves [1]. However, the observation of condensation of optical waves in a conservative (e.g., cavity-less) configuration is hindered by the prohibitive large propagation lengths required to achieve RJ thermalization. Recently, the observation of the RJ condensation and thermalization of light waves has been reported in multimode optical fibers [3-5].

The experiments are based on a phenomenon of spatial beam cleaning recently discovered in multimode optical fibers [6-8]. As a matter of fact, light propagation in multimode optical fibers is affected by a structural disorder of the material. We have formulated a wave turbulence kinetic description of the random waves that account for the presence of structural disorder. The theory unveils a significant acceleration of the process of thermalization and condensation that is induced by the disorder [9]. This fast process of condensation can explain the effect of spatial beam cleaning as a consequence of the macroscopic population of the fundamental mode of the fiber.

Our experiments in multimode fibers evidence the transition to light condensation: By decreasing the kinetic energy ('temperature') below the critical value, we observe a transition from the incoherent thermal RJ distribution to wave condensation [3]. The experimental results show that the chemical potential reaches the lowest energy level at the critical value of the energy to condensation, which leads to the macroscopic population of the fundamental mode of the optical fiber. The condensate fraction across the transition to condensation is in quantitative agreement with the RJ theory. We have also characterized the thermodynamics [10] of classical

condensation through the analysis of the specific heat: In opposition to quantum Bose-Einstein condensation, the heat capacity takes a constant value in the condensed state and tends to vanish above the transition in the normal state [3]. More recently, RJ thermalization has been extended to non-Hermitian optical lattices [11] or by including the conservation of orbital angular momentum [12-13].

We will present recent developments about the development of a wave turbulence theory accounting for the impact of strong disorder [14]. The theory unveils the interplay of disorder and nonlinearity. It reveals that a nonequilibrium process of condensation and thermalization can take place in the regime where disorder effects dominate over nonlinear effects. We validate the theory by numerical simulations of the nonlinear Schrödinger equation and the derived kinetic equation, which are found in quantitative agreement without using adjustable parameters. Experiments realized in multimode optical fibers with an applied external stress evidence the process of thermalization in the presence of strong disorder [14].

Finally, we report the recent observation of Rayleigh-Jeans thermalization to negative temperature equilibrium states through its propagation in a multimode optical fiber [15]. The bounded energy spectrum of the optical fiber enables negative temperature equilibriums with high energy levels (high order fiber modes) more populated than low energy levels (low order modes). Our experiments show that negative temperature speckle beams are featured, in average, by a non-monotonous radial intensity profile [15]. Bringing negative temperatures to the field of optics opens the door to the investigation of fundamental issues of negative temperature states in a flexible experimental environment [10].

Thermalization of weakly non-integrable Josephson junction networks

Gabriel M. Lando

Center for Theoretical Physics of Complex Systems, Institute for Basic Science, Daejeon 34126, Korea

February 17, 2023

Statistical mechanics is, in many ways, considerably more general than either classical or quantum mechanics: as long as one knows how to write a partition function, the statistical formalism can be applied. A cornerstone assumption for such generality is the ergodic hypothesis, which allows us to average over ensembles of similarly prepared systems rather than time. This is definitely not true for integrable systems, in which motion is always confined to lower-dimensional submanifolds and, therefore, thermalization is never achieved. It is then natural to wonder how thermalization is suppressed as a system approaches an integrable limit: Is integrability reached through an universal mechanism? How long does it take? Does it happen isotropically?

In this talk I will expand on results previously published by our group, namely that there appear to be two main pathways towards integrability, each with markedly distinguishable features. While previous investigations were focused on abstract discrete unitary maps, I will present results obtained for one- and two-dimensional networks with hundred(s) of coupled Josephson junctions. Such a generalization from maps to high-dimensional Hamiltonian systems is quite a formidable computational task, some aspects of which I will also briefly expose in the presentation.

Diffusion without Spreading of Wavepackets in Nonlinear Lattices with linear Anderson Localization

Serge AUBRY
Laboratoire Léon Brillouin, CEA Saclay, 91191-Gif-sur-Yvette, France
*serge.aubry91@gmail.com

Abstract:
We discuss the long time behavior of a finite energy wave packet in nonlinear Hamiltonians on infinite lattices at arbitrary dimension, exhibiting linear Anderson localization. Early numerical studies suggested a subdiffusive behavior of the wave packets in such models. However, strong arguments both mathematical and numerical, suggest for infinite models that small amplitude wave packets may generate stationary quasiperiodic solutions (KAM tori) almost indistinguishable from linear wave packets. The probability of this event is non vanishing at small enough amplitude and goes to unity at amplitude zero. Most other wave packets (non KAM tori) are chaotic (as well as in finite size systems).

We propose a modified Boltzmann statistics for wave packets based on the Arnold diffusion conjecture (recently partially proven) which should be valid in generic models. The consequence is that the probability that a chaotic wave packet spreads to zero amplitude is zero. It must always remain focused around one or few chaotic spots which wander randomly over the whole system and generate subdiffusion. Moreover, it can be rigorously proven in a large class of so-called Ding Dong models (where the nonlinearities are replaced by hard core potentials) that spreading is impossible for any initial wave packet despite subdiffusion has been also numerically observed in some of these models.

Thermodynamics and pressure of composite multimoded optical systems

N.K. Efremidis[1,2*] and D.N. Christodoulides[3]

[3]Ming Hsieh Department of Electrical and Computer Engineering, University of Southern California, Los Angeles, California 90089, USA.
[*]corresponding author: nefrem@uoc.gr

Abstract: We investigate the thermodynamic behavior of composite optical systems. Each component is associated with a different color or polarization and the components are coupled via nonlinear interactions. In a manifestation of Le Chatelier's principle, we find that depending on the type of the nonlinearity, such systems thermalize to different final states. In addition, we compute the partial optomechanical pressure of each component, whereas the total pressure is the direct sum of the partial pressures (Dalton's law).

A thermodynamic theory for optical systems has recently been developed [1]. It predicts that optical systems can reach thermal equilibrium in the form of a Reyleigh-Jeans distribution. This theory can have important consequences in multimoded optical settings explaining, for example, phenomena, such as beam self-cleaning in multimode fibers [2,3]. The resulting Rayleigh-Jeans distribution can also be derived using a grand-canonical approach [4,5], and can be extended to include additional system parameters [5]. Such parameters are particularly important, in the formulation and derivation of the actual optomechanical pressure that is applied under thermal equilibrium conditions [6].

Here, we examine the statistical mechanics of composite optical settings using a grand canonical statistical approach. In principle, we can have Γ different components, that can be different colors or different polarizations. For simplicity, we assume that each component has the same number of supermodes M. The linear systems are then coupled through their nonlinear interactions to a single nonlinear Hamiltonian. The linear part of the Hamiltonian can be written as

$$H = \sum_{l=0}^{M} \sum_{\gamma=1}^{\Gamma} \frac{\varepsilon_\gamma^{(l)} n_\gamma^{(l)}}{\omega_\gamma}$$

where γ denotes the component associated with frequency ω_γ, and $\varepsilon_\gamma^{(l)}, n_\gamma^{(l)}$ is the propagation constant and the power occupation number of the lth mode of the γ component. The number of power conservation laws depends on the type of the nonlinearity. For example, in the case of two components, a cubic nonlinearity results to self-phase and cross-phase modulations and thus to two conservation laws $N_\gamma = \sum_l n_\gamma^{(l)}, \gamma = 1,2$. On the other hand, for second harmonic generation, due to the power exchange between the fundamental and the second harmonic, we have only one conservation law $N = \sum_\gamma \sum_l n_\gamma^{(l)}$.

Interestingly, independently of the number of power conservation laws, the system has a unique temperature.

However, for each power conservation law, an associated chemical potential gives rise to a different Rayleigh-Jeans distribution. Thus, depending on the type of the nonlinearity, the same initial condition can get thermalized to a different final state, depending on these conservation laws. A resulting Le Chatelier's principle determines the equilibrium state for the partial power of each component. We also compute the optomechanical pressure that is applied to the system. In particular, for each the pressure due to the γ component can be written as

$$p_\gamma = -\sum_{l=1}^{M} \frac{n_\gamma^{(l)} M}{\omega_\gamma} \left(\frac{\partial \varepsilon_\gamma^{(l)}}{\partial L} \right)_M$$

where L is the transverse size of the system. The total optomechanical pressure is the sum of the partial pressures a manifestation of Dalton's law.

Controlling optical thermalization via spectral engineering: A Kinetic Equation Approach

T. Kottos*

Wave Transport in Complex Systems Lab, Department of Physics, Wesleyan University, USA
*corresponding author: tkottos@wesleyan.edu

Abstract: We utilize a kinetic equation approach together with a nonlinear scaling theory for the analysis of optical thermalization in multimode nonlinear photonic networks. We show that spectral engineering, either via band-gap design or via disorder, molds the thermalization process and the formation of the thermal states. Further isomorphisms with the theory of spin networks reveals the existence of optical phase transitions of the thermal equilibrium states, which resemble a paramagnetic to ferromagnetic and to a spin-glass phase transition.

In physics, one often encounters problems involving a great number of interacting modes. Such problems naturally arise in statistical mechanics, hydrodynamics, matter-waves, and more. An emerging framework is in photonics, where light propagation in non-linear or disordered multimode optical structures have recently attracted a lot of attention. On the fundamental side there are many unanswered questions associated with the energy exchange between the modes and the role of the underlying spatio-temporal complexity, originating from the disorder, the network topology, the complex nonlinear intermodal interactions and mode-dependent losses. Brute force computational attempts to answer these questions are either impossible (due to the large number of degrees of freedom involved) or unsatisfactory as far as the understanding of the underlying physics that dictates the energy redistribution. At the same time, there is a pressing need from modern technologies to develop theoretical tools that will allow us to tailor the intermodal energy exchange and harvest it to our advantage. If this endeavor is successful, it will give rise to a next generation of high-power light sources, high-resolution imaging schemes, and high-speed telecommunication systems.

A prominent photonic framework where the above fundamental questions are interlinked with technological developments appear in the multi-core fibers (MCFs) and multi-mode fibers (MMFs). These systems have recently been exploited as alternatives to single mode fibers – the latter experiencing information capacity limitations, imposed by amplifier noise and fiber non-linearities. What makes multicore and multimode fibers attractive is the possibility to utilize the multiple cores/modes as extra degrees of freedom in order to carry additional information -- thus increasing the information capacity of a single fiber. Of course, MCFs and MMFs also suffer from the above-mentioned challenges (e.g. disorder-induced or/and nonlinearity-induced mode mixing). It is, therefore, imperative to develop theories that take into consideration the role of band-structures of an underlying linear structure, the potential presence of disorder and their interplay with non-linearities in the modal mixing and provide a quantitative description of light transport in such multimode photonic systems.

We have addressed these questions, by implementing a kinetic equation (KE) approach together with a newly developed scaling theory, to the optical beam propagation in such multimoded nonlinear settings. Our analysis is able to highlight the importance of spectral engineering and band-gap structures, disorder, and connectivity between the nodes of the optical nonlinear network. We have found that an engineered band-gap dispersion leads to an optical beam thermal state that is described by a generalized Rayleigh-Jeans distribution. Its formation is controlled by the size of the underlying band-gap of the linear system. The KE allows us also to evaluate the relaxation times towards

such thermal states. In case that disorder is introduced into the linear structure, the thermalization process is hindered. We have developed a universal one-parameter scaling theory that predicts an exponential suppression of the relaxation rate for increasing disorder. The one-parameter scaling variable that controls the relaxation rate, describes the resilience of spatially localized modes to form "localization" clusters against non-linear interactions which tends to desegregate them. Finally, we have shown that appropriate connectivity of the underlying linear system might lead to the presence of various phases of the optical thermal state that share similar features as the paramagnetic, ferromagnetic and spin-glass phase encountered in spin systems.

We acknowledge partial support from Simons Foundation grant no MPI 733698.

Recent Advances in Non-Hermitian Photonics: Topological, Disordered and Quantum systems

The bosonic skin effect: boundary condensation in asymmetric transport

L.Garbe*, Y.Minoguchi, J.Huber, P.Rabl

Vienna Center for Quantum Science and Technology, Atominstitut, TU Wien, 1040 Vienna, Austria
*corresponding author: louis.garbe@tuwien.ac.at

Abstract: We study the incoherent transport of bosons through a one dimensional lattice with different left and right hopping rates, modelled by the asymmetric simple inclusion process (ASIP). In this unusual transport scenario, the density profile acquires a zigzag pattern near the boundary, with particle distribution alternating between thermal and Bose-condensed distributions. Furthermore, we show that the onset of this phase is closely related to the non-Hermitian skin effect and coincides with an exceptional point in the spectrum of density fluctuations.

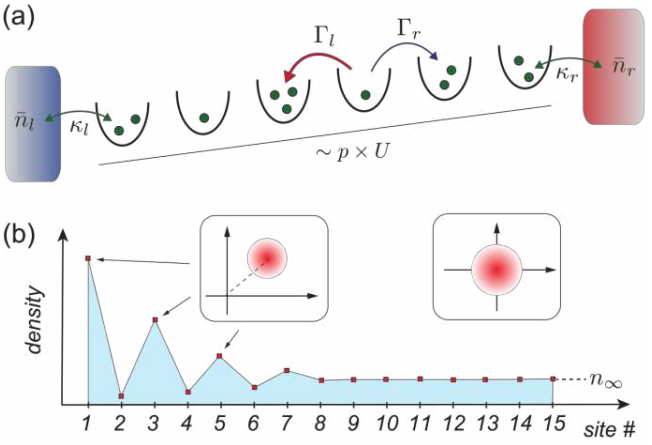

Fig 1 : (a) Sketch of our model. (b) The density acquires a zig-zag pattern, with a number distribution alternating between thermal and coherent.

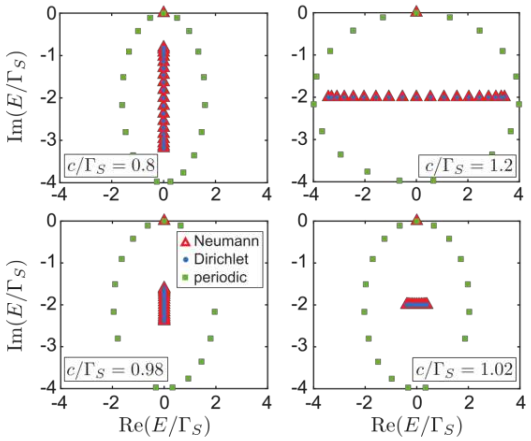

Fig 2 : Excitation spectrum of density fluctuations. The onset of the zig-zag phase coincide with an exceptional point.

We consider bosons hopping through a lattice, according to the following Lindbladian:

$$\mathcal{L} = \Gamma_r D[\hat{a}^\dagger_{p+1}\hat{a}_p] + \Gamma_l D[\hat{a}_{p+1}\hat{a}^\dagger_p]$$

with different left and right hopping rates. In this model, the probability for a boson to jump on a site already occupied is *enhanced* by bosonic bunching. This is an exemple of a so-called *inclusion* process, or ASIP. This non-linear, asymmetric transport leads to an unusual phase, where the population shows a *zig-zag pattern* near the boundary. Remarkably, although the transport is purely incoherent, every other site enters a *Bose-condensed state*, with a coherent particle distribution breaking a U(1) symmetry. We show that this boundary condensation is closely related to *the non-Hermitian skin effect*, and coïncide with an exceptional point in the excitation spectrum of density fluctuations. This effect thus establishes a direct connection between quantum transport, non-equilibrium condensation phenomena and non-Hermitian physics, which can be probed in cold-atom experiments or in systems with long-lived photonic, polaritonic or plasmonic excitations.[1]

Abstract: We discuss nontrivial physics in boson sampling dynamics generalized to the non-unitary regime. We discover novel dynamical transitions characterized by the distinguishability of photons, which is also relevant for sampling complexity. We especially show that parity-time (PT) symmetry breaking affects the complexity of sampling the probability distribution. In particular, for a PT-broken phase, a notable dynamical transition that the boson distribution becomes distinguishable in the long time occurs, indicating the easiness of sampling bosons.

Extended Nielsen-Ninomiya theorem and non-Hermitian topological phenomena

Masatoshi Sato

[1]Center for Gravitational Physics and Quantum Information, Yukawa Institute for Theoretical Physics, Kyoto University, Kyoto 606-8502, Japan
msato@yukawa.kyoto-u.ac.jp

Abstract: The Nielsen-Ninomiya theorem is a fundamental theorem on chiral fermions in lattice systems. In this talk, I report an extension of the theorem in open systems, which includes the original Nielsen-Ninomiya theorem in a special limit. In contrast to the original theorem, which is a no-go theorem for bulk chiral fermions, the new theorem permits them due to bulk topology intrinsic to open systems. I will also report on applications of our theorem and predict a new type of topological phenomena.

Abstract: In a Hermitian system, bound states have quantized energies while free states form a continuum. We demonstrate how this principle can fail in non-Hermitian systems. Certain non-Hermitian systems with imaginary momentum and Landau-type vector potential host eigenstates that we call "continuum Landau modes" (CLMs), featuring gaussian spatial envelopes and a continuum of complex energies. CLMs could be realized in 1D and 2D photonic or acoustic lattices, and have interesting behaviors such as rainbow trapping and wave funnelling.

Introduction A quantum particle in an infinite continuous space can have two kinds of energy eigenstates: the bound states with quantized energies, or spatially extended free states with continuous energies. This property has been mathematically proven based on certain assumptions, one of which is that the Hamiltonian is Hermitian [1]. Over the past two decades, there has been much progress in realizing non-Hermitian Hamiltonians, particularly in the context of photonic lattices and other synthetic structures [2,3]. Could we use such ideas to engineer non-Hermitian Hamiltonians that violate the standard dichotomy between bound states and free states? Here, we discuss non-Hermitian Hamiltonians that have localized energy eigenstates, which we call "continuum Landau modes" (CLMs), at every complex energy E. These CLMs arise from a mapping to the zero modes of a continuous family of Hermitian 2D Dirac models [4].

Continuous and Discrete Model Consider the non-Hermitian 2D Hamiltonian

$$\mathcal{H} = s_x\left[-i\frac{\partial}{\partial x} - By\right] + is_y\left[-i\frac{\partial}{\partial y} + Bx\right] \tag{1}$$

here $s_{x,y} = \pm 1$. It has eigenstates of the form

$$\psi(x,y) = C\exp\left[-\tau|\boldsymbol{r} - \boldsymbol{r_0}|^2 + i\,\boldsymbol{q}\cdot\boldsymbol{r}\right] \tag{2}$$

where C is a normalization constant, $\tau = -s_x s_y B/2$, $\boldsymbol{q} = (q_x, q_y)$ is an arbitrary real vector, and $\boldsymbol{r_0}$ is some function of $\boldsymbol{q}$ and the eigenenergy E. If $\tau > 0$, the wavefunctions are normalizable regardless of $\boldsymbol{q}$ and E, with characteristic length $l \sim B^{-1/2}$. For each $E \in C$, there is a continuum of bound states centered at different $\boldsymbol{r_0}$. We call these eigenstates CLMs as they are related to zeroth Landau level (0LL) modes of massless 2D Dirac fermions [4]. CLMs of a given energy E have a one-to-one map with the 0LL modes of a given Hermitian Dirac Hamiltonian, whose gauge is determined by E. The CLM eigenstates are thus uncountable because the gauge can be continuously varied.

The 2D lattice in Fig. 1(a) exhibits CLMs in its long-wavelength limit. The Hamiltonian is

$$\mathcal{H} = \sum_r \left[B(y - ix)a_{\boldsymbol{r}}^\dagger a_{\boldsymbol{r}} + t_x\left(a_{\boldsymbol{r}-\hat{x}}^\dagger a_{\boldsymbol{r}} + h.c.\right) + t_y\left(a_{\boldsymbol{r}-\hat{y}}^\dagger a_{\boldsymbol{r}} - h.c.\right)\right] \tag{3}$$

where $a_{\boldsymbol{r}}^\dagger$, $a_{\boldsymbol{r}}$ are creation and annihilation operators at $\boldsymbol{r} = (x,y)$(the lattice constant is set to 1, thus $x, y \in Z$), and $t_x, t_y \in R$ are hopping coefficients. $\mathcal{H}$ is manifestly non-Hermitian. In a slowly-varying envelope approximation, we find that the envelope function obeys $H_{\boldsymbol{k}}\Psi_{\boldsymbol{r}} = E\Psi_{\boldsymbol{r}}$, where to first order in spatial derivatives,

$$H_k = E_k^0 - \left[-i\mu_k\frac{\partial}{\partial x} - By\right] + i\left[-i\nu_k\frac{\partial}{\partial y} - Bx\right] \tag{4}$$

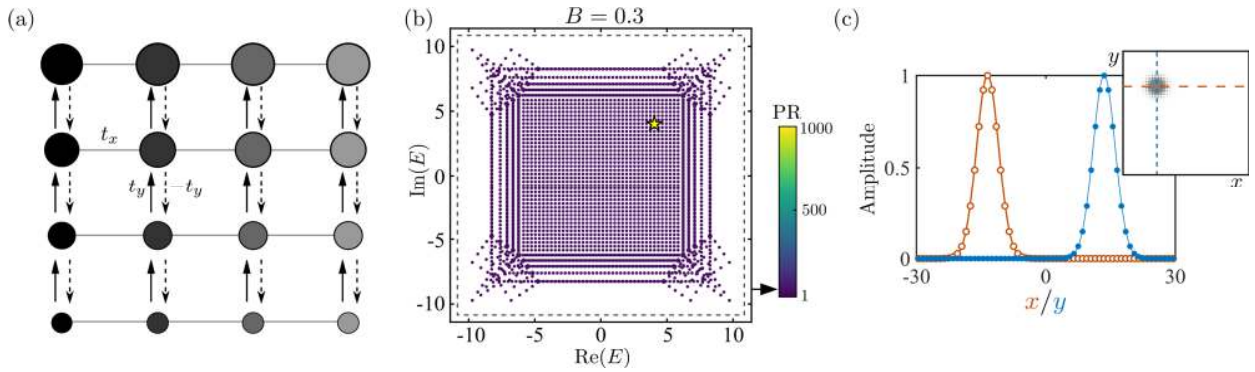

Figure 1: (a) Schematic of a square lattice with reciprocal hoppings along x (gray lines), nonreciprocal hoppings along y (black arrows), and onsite mass $m_{x,y} = B(y - ix)$ (size and darkness of the circles indicate the real and imaginary parts). (b) Complex energy spectrum for a finite lattice of size 60 × 60 with open boundary conditions, with $t_x = t_y = 1$ and $B = 0.3$. The color of each dot corresponds to the eigenstate's participation ratio (larger for less localized states). (c) Wavefunction amplitude for the eigenstate marked by a yellow star in (b). Hollow and filled circles respectively indicate the variation with x and y, along lines passing through the center of each gaussian; solid curves show the CLM predictions. Insets show the distribution in the 2D plane.

where $\mu_{\boldsymbol{k}} = 2t_x \sin k_x$ and $\nu_{\boldsymbol{k}} = 2t_y \cos k_y$. For $B/\mu_{\boldsymbol{k}} < 0, B/\nu_{\boldsymbol{k}} > 0$, there exist CLMs similar to the continuous case. If the lattice is infinite, they form a continuous set over $E \in C$. If the lattice is finite, the CLMs reduce to a band in a finite area of the complex plane, as shown in Fig. 1(b). All the eigenstates are localized, as shown in Fig. 1(c). CLMs can also occur in 1D lattices, we show one of these lattices can serve as a rainbow trap [5], whereby the response to an excitation is concentrated at a position proportional to the frequency. Another lattice can act as a wave funnel [6], concentrating an input excitation onto a boundary over a wide frequency bandwidth.

Summary Non-Hermitian Hamiltonians can violate the usual distinctions between quantized bound states and the continuum of free states. Such systems could be realized on the same platforms (e.g., photonic lattices) already being used to study other non-Hermitian phenomena. It would be interesting to explore other Hamiltonians that cause similar violations, and the physical consequences thereof.

Non-orthogonality of Bogoliubov modes and the laser linewidth

I. Amelio[1,2*], I. Carusotto[3]

[1]Center for Nonlinear Phenomena and Complex Systems, Université Libre de Bruxelles, Belgium

Abstract: The non-orthogonality of Bogoliubov modes accounts for both Henry and Petermann broadening mechanisms of the laser linewidth. Applications to exceptional points, (disordered) topological lasers and polariton condensates are discussed.

For a generic semi-classical laser dynamics in the complex Ginzburg-Landau form, in Ref. 1 we develop a Bogoliubov approach for the computation of the laser emission linewidth. The main ingredients are the Goldstone mode and how fluctuations are projected into this mode, keeping into account the non-orthogonality with the other modes.
Our method provides a unifying, geometric perspective of the treatments by Henry and Petermann: both broadening mechanisms are ascribed to the non-orthogonality of the Bogoliubov modes, which live in a space with doubled degrees of freedom.

We then illustrate a few applications. Even before we discussed the general theory and its geometrical aspects, the method was in fact used to compute the diverging Petermann factor at the exceptional point of a phonon laser (Ref. 2).

Then, in Ref. 3 we developed the approach in full generality to study the Petermann factor of topological lasers. Since the edge mode of a 2D Harper-Hofstadter model is also present at the Hamiltonian level, when saturable gain is introduced and the system lases, the distortion of the the edge mode can be very small and the Petermann factor close to 1. This is a fundamental result, demonstrating that topological lasers can emit in a highly coherent manner. When disorder is considered, our formulas also hold and the linewidth will decrease for small systems. Notice that for very long edges, Bogoliubov theory eventually breaks down and Kardar-Parisi-Zhang physics sets in and disorder can increase coherence!

Finally, the method allows to study the interplay of drive-dissipation, interactions and spatial inhomogeneity typical of polariton condensates (Ref. 1). The traditional theory of the Henry and Petermann factors (the latter comes from a linear analysis of the system close to threshold) is found to fail dramatically in the presence of sizable polariton-polariton interactions, which deform the condensate shape. In particular, also in a strong confining potential, the intrinsically multi-mode nature of the density fluctuations has to be considered in order to describe quantitatively Henry-like phase diffusion.

Non-Hermitian quantum optics in cold atomic ensembles

Georgios A. Siviloglou* and J. F. Chen

Southern University of Science and Technology, Shenzhen, 518055, Guangdong, China
corresponding author: siviloglouga@sustech.edu.cn

Abstract: In this talk, we will introduce a quantum non-Hermitian interface between photons and atoms. A tunable interaction between photonic and magnonic modes is established, and probing non-Hermitian dynamics at the single quantum level is achieved. We demonstrate experimentally quantum interference between two distinct bosonic excitations, and that their tendency to bunch together can be altered by hermiticity.

In an ideal quantum memory, single photons can be stored as single quanta of atomic spin coherence and, in turn, coherence can be converted back to photons. This conversion can be represented by a linear and unitary beamsplitter operation which mixes two different bosonic modes. If the beamsplitting operation can become non-Hermitian, as in the case of a cold atomic ensemble [1], photon bunching can be switched to antibunching.

In our experiments, we demonstrate that controlling the dissipation in an atom-photon interface alters the statistics of quantum interference [2]. The degree of hermiticity is controlled by the detuning of two lasers interacting in laser cooled gas of atomic rubidium. The standard Hong-Ou-Mandel dip is thus reversed, and, in stark contrast, a bump of enhanced coincidence is observed as shown in Figure 1.

Abstract: While light waves propagating through inhomogeneous media are typically subject to scattering, non-Hermitian settings allow for these processes to be suppressed by an appropriately tailored complex refracted index. Along these lines, we leverage the additional degrees of freedom presented by gain and loss in optical mesh lattices to observe photonic constant-intensity waves and induced transparency.

When light waves propagate through inhomogeneous media, local scattering and subsequent interference affect both amplitude and phase, giving rise to complex speckle patterns. It has recently been proposed that these distortions can be suppressed by generalizing the initial Hermitian medium to a non-Hermitian system by judiciously adding gain and loss [1,2] (Fig. 1a). While the viability of the underlying concept has been demonstrated for acoustic waves [3], we here present the first all-optical realization in photonic mesh lattices implemented via coupled fiber-loops [4].

Fundamentally, a complex inhomogeneous medium is defined by two degrees of freedom at each point: The real part of the refractive index, and its imaginary part encoding local amplification or damping. In conjunction, both components of the complex refractive index govern the phase and amplitude of propagating waves. Harnessing the tunability of these parameters allows one to synthesize inhomogeneous media in which any distortion due to scattering and subsequent interference is entirely cancelled. Along similar lines, our conceptual framework enables us to tailor the optical properties of non-Hermitian systems to support the propagation of waveforms with (in principle) any desired intensity distribution. To experimentally observe these features, we employ pulse propagation of light in coupled optical fiber-loops (Fig. 1(b) top) [5]. The time-multiplexed pulse dynamics readily map onto a mesh lattice with one spatial and one temporal dimension (Fig. 1(b) bottom), while the desired non-Hermitian characteristics of the lattice sites are implemented with phase- and amplitude modulation that directly address the real and imaginary part of the optical potential for any given lattice site, respectively.

In this vein, we demonstrate here for the first time an optical realization of constant-intensity waves [6] (Fig. 1c) with preserved amplitudes and phases during the propagation through potentials with static disorder. The stark difference between conventional Hermitian systems and our tailored complex inhomogeneous media demonstrates the efficiency of our technique, which is fundamentally based on the direct relation between the wave solution and the medium's optical characteristics [2]. Similarly, any desired propagation pattern can be preserved in an inhomogeneous environment by a time-dependent potential, e.g. for the discrete diffraction pattern known from quantum random walks [7] (Fig. 1d). We anticipate our findings to drive future developments in scattering-free wave propagation or phase-amplitude selective transmission, e.g. for secure communications.

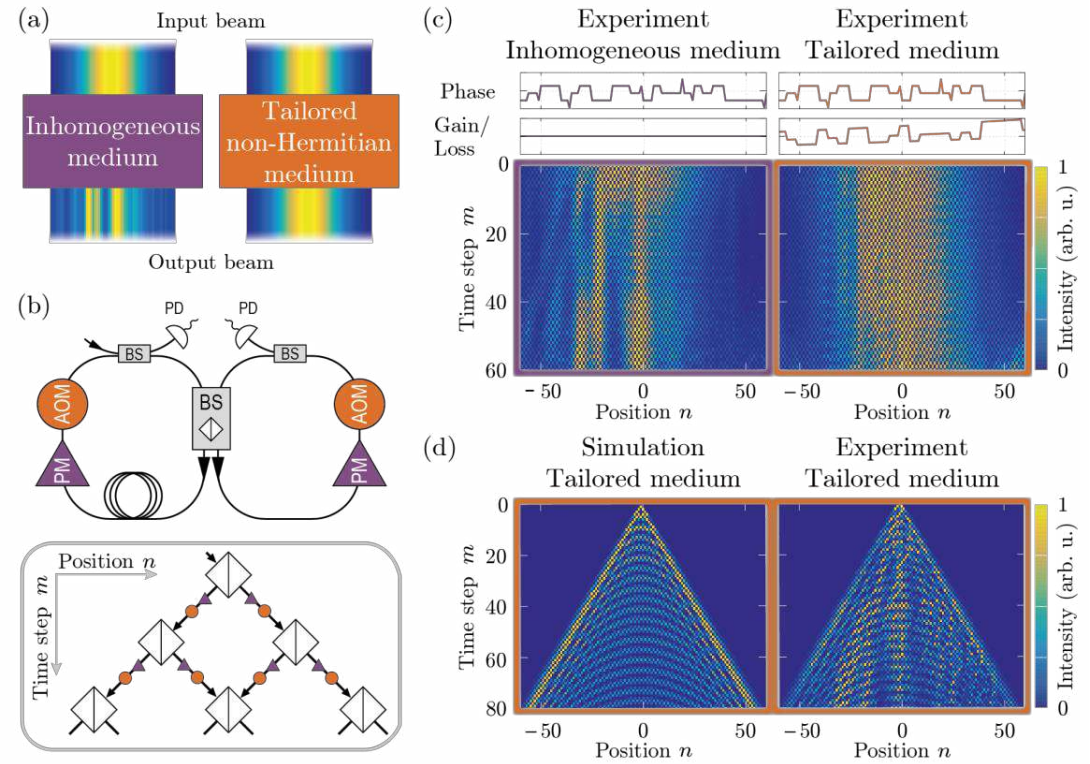

Figure 1: (a) Wave packet distortions in inhomogeneous media can be suppressed by tailored non-Hermiticity. (b) Fiber-loop-based optical mesh lattices employ phase-modulators (PM), beam splitters (BS) and acousto-optical modulators (AOM) in each loop to control the complex potential landscape (top). The time-multiplexed light evolution is recorded by photo detectors (PD) can be mapped onto a 1D lattice (bottom). (c) Compensation of scattering and diffraction for a Gaussian envelope by a time-independent tailored medium (right) versus a conventional inhomogeneous medium (left). (d) Simulation (left) and experimental data (right) of the compensation of scattering for discrete diffraction associated with a homogeneous lattice in an inhomogeneous setting.

Observation-dependent enhancement and suppression of two-photon coincidences by tailored losses

M. Ehrhardt*, M. Heinrich, and A. Szameit

University of Rostock, Institute for Physics, Albert-Einstein-Str. 23, 18059 Rostock, Germany
*corresponding author: max.ehrhardt@uni-rostock.de

Abstract: We investigate the Hong-Ou-Mandel interference of photon pairs in birefringent waveguides with polarization-dependent losses. Depending on the detection basis, we show seamless tunability all the way from enhancement to full suppression of indistinguishable photons.

The Hong-Ou-Mandel (HOM) effect [1] is perhaps the most well-known consequence of two-photon interference, where a pair of indistinguishable photons interferes destructively on a balanced beam splitter. As a result, the photons bunch together in either one of the two output ports, ideally reducing the coincidence rate to zero. Notably, the introduction of non-trivial losses can change this behavior in various ways. For example, parity-time symmetric conditions in an optical coupler have been shown to systematically shift the conditions for fully destructive quantum interference from balanced to unbalanced [2]. Similarly, a lossy beam splitter can actually cause an enhancement of coincidence rates for indistinguishable photons (compared to distinguishable photons), represented by a peak in the HOM experiment [3-5], that is generally associated with fermionic anti-bunching behavior.

In our work, we experimentally demonstrate that bosonic HOM dip characteristics are retained even in the case of a loss-induced peak. To this end, we implement nontrivial losses in a birefringent waveguide via coupling the waveguide to a reservoir (Fig. 1A) with polarization-dependent hopping rates $c_{H/V}$ for horizontal and vertical polarization, respectively. The target waveguide itself represents a polarization coupler [6] that performs polarization oscillation with the rate $\Delta\beta$ (mismatch between horizontal/vertical propagation constants), periodically transferring intensity between the diagonal $|D\rangle$ and antidiagonal $|A\rangle$ polarization states, respectively. Fig. 1B shows the influence of the sink: In addition to the global loss rate of $2\overline{c}$, the difference in the polarization-dependent coupling $\Delta c=c_H-c_V$ to the sink (exemplified in Fig. 1C) yields an imaginary part of the hopping rate. In our experiments, we launch photon pairs with one photon in the state $|D\rangle$ and the other one in the state $|A\rangle$. The experimental setup (Fig. 1D) is used to record the resulting HOM pattern in different observation bases as shown in Fig. 1E: The observed peak with a visibility of 0.541±0.009 in AD-basis is seamlessly transformed into a dip with a visibility of 0.93±0.05 in the horizontal/vertical (HV)-basis by rotating the observation basis.

In conclusion, we presented a nontrivial loss implementation in a polarization coupler. This system serves to combine intrinsically bosonic statistics of the two-photon input state and an enhanced survival probability of indistinguishable photon pairs [7]. As consequence, switching between HOM pattern with dip and peak characteristics is enabled by changing the observation basis.

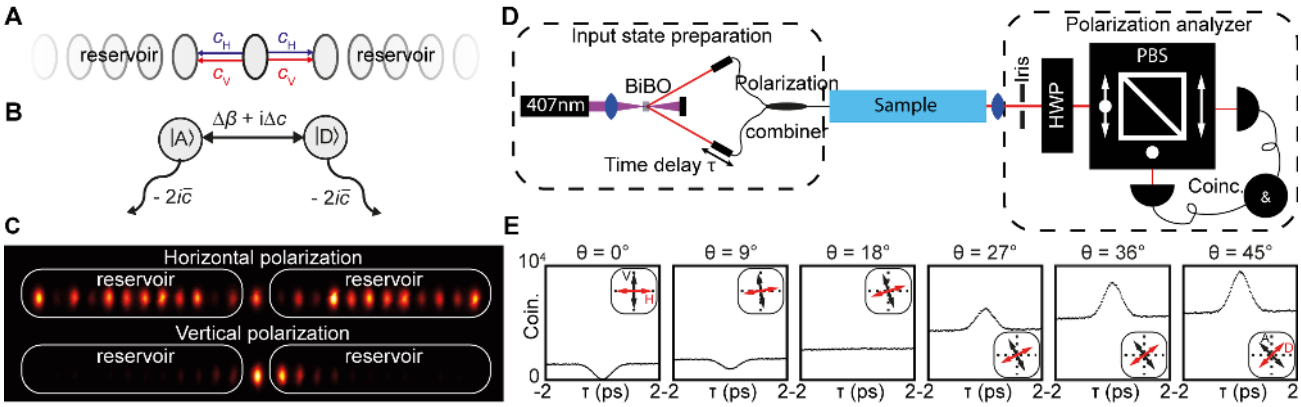

Figure 1. HOM experiment in a lossy polarization coupler. (**A**) A birefringent optical input and target waveguide is coupled to two sinks consisting of a long linear array of tightly coupled waveguides. Polarization-dependent coupling strengths c_H and c_V between the horizontal and vertical (fast/slow principle) axes of the main waveguide and the first waveguide of the sink implement (**B**) a non-trivial loss distribution for photons launched and observed diagonally $|D\rangle$ and antidiagonally $|A\rangle$ towards the HV-frame of reference. (**C**) Intensity distribution of the output after z=15 cm observed with a CCD camera when the central waveguide is illuminated at λ=814 nm. For an excitation in the horizontal polarization only 4.5% intensity remain in the main waveguide, whereas 48.3% remain for the vertical polarization. (**D**) Photon pairs are created via spontaneous parametric down conversion and coupled into a polarization combiner that launches one photon in the state $|A\rangle$ in the main waveguide whereas the other one is launched in the state $|A\rangle$. After the subsequent propagation in the sample, the remaining photons in the target waveguide are analyzed with a polarization beam splitter (PBS). The photons detected with Avalanche photo diodes at the PBS' transmitting and reflecting port, record coincidences in the horizontal/vertical (HV) and antidiagonal/diagonal (AD) polarization basis adjusted via the half-wave plate's (HWP) principal axes orientation. (**E**) HOM patterns recorded in different polarization bases.

Compressibility and fluctuations of an optical quantum gas

J. Schmitt

Institute of Applied Physics, University of Bonn, Wegelerstr. 8, 53115 Bonn, Germany
email: schmitt@iap.uni-bonn.de

Abstract: Quantum gases of atoms, exciton-polaritons, and photons provide a test bed for many-body physics under both in- and out-of-equilibrium settings. Experimental control over dimensionality, potentials, or the coupling to reservoirs offers wide possibilities to explore phases of matter, for example, by probing susceptibilities, as the compressibility. For gases of material particles, studies of the mechanical response are well established; for optical quantum gases, they have so far remained elusive. In my talk, I will discuss experimental work demonstrating a measurement of the compressibility of a two-dimensional quantum gas of photons in a box potential inside a dye-filled microcavity, from which we obtain the equation of state for the optical medium [1]. Upon entering the quantum degenerate regime, the density response to an external force sharply increases, hinting at a highly compressible Bose gas. In other recent work, we have demonstrated a non-Hermitian phase transition of an open photon Bose-Einstein condensate, which is revealed by an exceptional point in the fluctuation dynamics [2, 3].

Stability of Non-Hermitian Hamiltonians with Different Periodicities Using Floquet Theory

Avadh Saxena[1], Julia Cen[1], and Yogesh N. Joglekar[2]

[1]Theoretical Division, Los Alamos National Lab, USA
[2]Department of Physics, Indiana University-Purdue University Indianapolis, USA

By using Floquet theory Hermitian Hamiltonians with time-periodic coefficients can be readily analyzed. They have been extensively used for engineering Floquet Hamiltonians in standard quantum simulators. When generalized to non-Hermitian Hamiltonians, time-periodicity provides important means to engineer the landscape of Floquet quasi-energies across the complex plane. Here, we study two-level non-Hermitian Hamiltonians with coefficients that have different periodicities by invoking Floquet theory [1]. Both parity-time or PT-symmetric and anti-PT (or APT)-symmetric Hamiltonians are considered. Using analytical as well as numerical calculations we obtain the regions of stability, defined by real Floquet quasi-energies and contours of exceptional point (EP) degeneracies. We then extend our analysis to investigate the phases that accompany these cyclic changes. Our results demonstrate that time-periodic, non-Hermitian Hamiltonians generate a truly rich landscape of stable and unstable regions, particularly when compared with single-drive models.

Abstract: Due to the local nature of the nonlinearities in nonlinear photonic topological insulators, attempts to describe its topology using traditional band structure approaches are not suitable. Here, we propose to use the so-called spectral localizer, which allows us to define local topological invariants such as a local Chern number. Using the nonlinear Haldane model with on-site Kerr terms, we show that the soliton can creates topological interfaces inside the lattice.

In recent years, photonic topological insulators (PTIs) have gained substantial interest due to their promise to improve current photonics devices with their topologically protected edge states **[1]**. At high optical power, it becomes natural to consider nonlinear PTIs. However, the topological characterization of the solitons, so far, has been relying on a band structure formalism **[2]**, which does not fully account for the nonlinear phenomena due to the local nature of the nonlinearities. Here, we present a general framework for classifying topological solitons using local markers that is applicable to topology of any dimension in the ten Altland-Zirnbauer classes **[6]**. As these local markers can be calculated entirely from the system's real-space properties, and without projecting into an occupied subspace, they can be directly applied to non-linear systems. Finally, we illustrate this general framework using a Haldane lattice with on-site Kerr terms.

Compared to traditional topological descriptions that rely upon a system's Bloch eigenstates to characterize its topology, the spectral localizer takes an operator-based approach. This approach can be seen as the real-space analogue to topological quantum chemistry, namely by looking for obstructions that prohibit continuing the system to an atomic limit **[3]**. For a two-dimensional system, the localizer can be defined as **[4]**:

$$L_{\lambda=(x,y,E)}(X,Y,H) = \begin{pmatrix} (H-E) & \kappa(X-x)-i\kappa(Y-y) \\ \kappa(X-x)+i\kappa(Y-y) & -(H-E) \end{pmatrix}, \quad (1)$$

where H is the Hamiltonian matrix considered, X, Y are the position operators that are diagonal matrices indexing the position of the sites, and $\lambda = (x, y, E)$ is to be seen as an input for the local probing of the topology in space (x,y) and energy (E). κ is a hyperparameter that makes the units consistent between the position and Hamiltonian matrices. The localizer framework shares similar features as the band structure approach. Indeed, its spectrum $\sigma(L_\lambda)$ can heuristically be understood as a real-space, local analogue of the bulk bands. For the 2D system in class A **[6]**, the spectral localizer can be used to find the local Chern number **[4]** defined as:

$$C_{L,\lambda} = \frac{1}{2} sig(L_\lambda(X,Y,H)), \quad (2)$$

where $sig(M)$ is the signature of the matrix M, i.e., the number of positive eigenvalues minus the number of negative ones, and for which the local Chern number can only change through a gap closing of the localizer spectrum, namely when $\min(|\sigma(L_\lambda)|) = 0$. The topological robustness can then be represented by its localizer gap $\Delta L_\lambda := \min(\sigma(L_\lambda))$.

As an example for describing the topology in nonlinear PTIs, we consider the nonlinear Haldane lattice **[5]**, with the lattice geometry as shown in Fig. 1(a). The lattice is characterized by a (next) nearest neighbor coupling

t_1 ($t_2/t_1 = 0.5$), an inversion-symmetry-breaking on-site term $M/t_1 = 0.3 * 3\sqrt{3}$, a time-reversal-symmetry-breaking Haldane flux $\phi = \pi/2$, and on-site Kerr terms $g|c_n|^2$ with $|c_n|^2$ being the intensity at the given site n. Given the above parameters, the linear lattice (g = 0) is in the topologically non-trivial phase which is given by the condition $|M/t_2| < 3\sqrt{3}\,|\sin\phi|$. Here, we consider a nonlinear mode ψ_{NL} [Fig. 1(a)] obtained by numerical continuation of the linear mode at energy $E/t_1 = 1.28$, by first increasing the Kerr coefficient $g/t_1 = 0 \rightarrow 3$, then by increasing the total power $\|\psi_{NL}\|^2 = 1 \rightarrow 7.8$. The obtained nonlinear Hamiltonian matrix $H(\psi_{NL})$ is then used to calculate the localizer [Eq.1-2] at $E/t_1 = E_{NL}/t_1 = 1.028$. Figure 1(b) plots the local Chern number obtained across the whole lattice, directly revealing the real-space picture of the topology of the system. There is a topological interface at the edge of the lattice as expected from the lattice being in the topological non-trivial phase. However, the system also reverts to a trivial topological phase in two locations in its interior where the strength of the soliton results in strong on-site energies, yielding another pair of topological interfaces. This shows the topological nature of the obtained soliton, which is self-sustained by the topological edge states created at the topological interface. By looking at the localizer spectrum $\sigma(L_\lambda)$ [Fig. 1(c)], one can also quantify the robustness of the topological soliton to be $\Delta L_\lambda/\Delta E = 2.7\%$, with ΔE being the bulk band gap in the linear lattice. This shows that the nonlinear mode is weakly protected in case of perturbation $\|\delta H\|$ of the order of 2.7% of bulk band gap.

To conclude, using a real-space picture of the topology of the system, we demonstrate the topological origin of a given soliton mode as well as its topological robustness against disorder.

This work is part-funded by Sandia National Laboratories (SNL). SNL is managed and operated by NTESS under DOE NNSA contract DE-NA0003525.

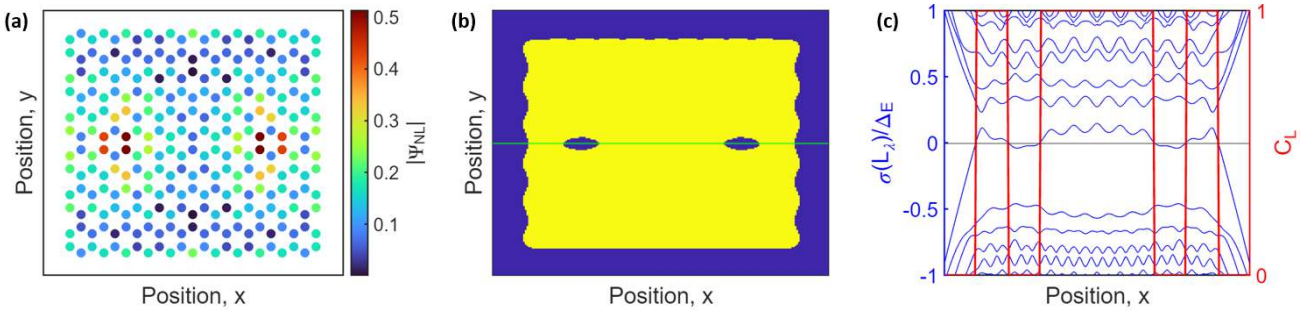

Figure 1: (a) Field profile of the soliton $|\psi_{NL}|$. (b) Local Chern number C_L across the lattice (and outside the lattice). Yellow (purple) region correspond to $C_L = 1$ ($C_L = 0$). (c) Spectrum of the localizer normalized to bulk band gap $\sigma(L_\lambda)/\Delta E$ and the local Chern number C_L along the green line in panel (b). For panels (b) and (c), $E = E_{NL} = 1.028t_1$ and $\kappa = 2.2$ has been used.

Experimentally realizable *PT* phase transitions in reflectionless quantum scattering

M. B. Soley[1*], C. M. Bender[2*], and A. D. Stone[3]

Abstract: We demonstrate theoretically that *PT*-symmetry behaviors could be measured in fundamental Schrödinger quantum mechanics via standard cold-atom experiments. Whereas *PT* symmetry-breaking has previously only been measured for classical wave equations or open quantum systems with complex potentials and inherent information loss, we identify spontaneous *PT*-symmetry breaking in a novel family of purely real, experimentally realizable quantum potentials, $V(x)=-|x|^p$ for real p. The results encourage the search for quantum *PT* symmetry behaviors and the development of quantum *PT* symmetry technologies.

PT (parity-time reversal) symmetry has seen great success in optics, with applications from lasing and sensing to wireless power transfer. Despite *PT* symmetry's promise in quantum mechanics, the only quantum *PT*-symmetry experiments have been for open systems with complex potentials, which entail inherent information loss. We introduce a novel class of purely real potentials ($V(x)=-|x|^p$ for real p truncated to constant energy beyond the region $-L\leq x\leq L$) that makes *PT* symmetry experimentally realizable in fundamental quantum mechanics. We show these potentials make possible the measurement of quantum *PT* symmetry behaviors, including spontaneous *PT*-symmetry breaking, in standard cold-atom experiments with programmable traps [1].

In particular, we consider the curious case of weakly bound states in upside-down *PT*-symmetry potentials. Upside-down *PT*-symmetry potentials of the form $V(x)=-x^p$ for $p=2,4,6\ldots$ at first appear not to support bound states, as the potentials tend towards minus infinity at large distances from the origin. Yet, consideration of the complex Schrödinger equation indicates the potentials in fact support an infinite set of weakly bound states [2,3,4]. Straightforward implementation of the potential in fundamental Schrödinger quantum mechanics is not possible, as the potentials are both infinite-length and unbounded in energy. In contrast, the aforementioned novel class of potentials are finite in length and bounded in energy, and therefore are amenable to elementary quantum scattering experiments. Inspired by ref. [3], we hypothesize that reflectionless states in these potentials reproduce the weakly-bound states for sufficiently large L. We identify these states by applying the general theory of reflectionless scattering mode (RSM) theory from optics [5,6] to quantum mechanics for the first time.

We find the novel class of potentials reproduces the eigenvalues and eigenstates of the upside-down *PT*-symmetric potentials to high accuracy. The RSM energies agree with the analytic eigenvalues with up to 7-8 digits to arbitrarily high energy and are robust to various models of experimental error over wide ranges of noise strengths. Likewise, the RSM wavefunctions exhibit all the expected behaviors of the eigenstates, including a symmetric probability density, oscillatory behavior, and subexponential decay.

Importantly, we find the novel class of potentials enables measurement of spontaneous *PT*-symmetry breaking in fundamental quantum mechanics for the first time. Previously, spontaneous quantum *PT*-symmetry breaking has been seen for the analytic continuations of the upside-down *PT*-symmetric potentials, $V(x)=x^2(ix)^\varepsilon$ and $V(x)=x^4(ix)^\varepsilon$ [2,4]. However, these potentials are inherently complex except at even integer values of ε. Instead,

we consider the novel class of purely real potentials for varying p. We find the class in fact exhibits all phases of *PT* symmetry: The fully-broken phase appears for $p \leq 2$, a mixed phase appears for $2<p<4$, and an unbroken phase appears for $p \leq 2$. In addition, the quantum phase transitions are accompanied by a "smoking-gun" of *PT*-symmetry breaking: the reflection coefficient transitions from a quadratic to quartic reflection coefficient lineshape at clear exceptional points.

Preliminary results indicate that implementation of the proposed quantum system is well within reach of today's experimental cold-atom approaches. The required energy and length scales are commensurate with readily reachable ultracold temperatures for Bose-Einstein condensates of alkali atoms, and the potentials can be readily produced with techniques such as Digital Micromirror Devices (DMD) and holographic methods. These results suggest the proposed system can be straightforwardly implemented in cold-atom experiments with programmable traps and calls for further search for *PT* symmetry behaviors in fundamental quantum cold-atom systems.

Abstract: Starting from an open quantum system description of driven-dissipative arrays of cavities, I show how to restore the bulk-boundary correspondence for the most paradigmatic class of non-Hermitian lattice Hamiltonians, namely those involving a single complex band, and how this links to topological amplification.

Non-Hermitian (NH) lattice Hamiltonians display a unique kind of energy gap and extreme sensitivity to changes of boundary conditions—the so-called NH skin effect. Due to the NH skin effect, the separation between edge and bulk states is blurred and the bulk-boundary correspondence in its conventional form breaks down [1]. Despite considerable efforts to accommodate the NH skin effect into a modified bulk-boundary correspondence, a formulation for point-gapped spectra has remained elusive.

In this contribution, I will show how to restore the bulk-boundary correspondence for the most paradigmatic class of NH lattice models, namely single-band models without symmetries [2]. This is achieved by presenting an alternative route to the classification of NH topological phases, where the focus is shifted (i) from effective NH Hamiltonians to NH Hamiltonians obtained from the unconditional dynamics of driven-dissipative arrays of cavities, and (ii) from the eigen-decomposition to the singular value decomposition as the main tool for studying their bandstructure.

The class of NH Hamiltonians that reveal the bulk-boundary correspondence are unconditional NH Hamiltonians which do not neglect quantum jumps altogether but instead retain a contribution from fluctuation-dissipation processes by averaging over the quantum state of the system. Concretely, the desired NH Hamiltonian is implemented in one-dimensional driven-dissipative cavity arrays, in which Hermiticity-breaking terms—in the form of non-reciprocal hopping amplitudes, gain and loss—are explicitly modelled via coupling to (engineered and non-engineered) reservoirs. I will show that this approach introduces extra constraints to the NH Hamiltonian, neglected so far, which determine the following major changes to the topological characterization: First, the complex spectrum is not invariant under complex energy shifts, which removes the arbitrariness in the definition of the topological invariant. Second, topologically non-trivial Hamiltonians are only a strict subset of those with a point gap; this implies that the NH skin effect does not have a topological origin. Third, topological phase transitions are accompanied by the closure of a real-valued gap, defined in terms of the singular values.

I will then show how to reinstate the bulk-boundary correspondence in terms of the singular value decomposition, instead of the eigen-decomposition, and explain its physical significance. The NH bulk-boundary correspondence takes the following simple form: *An integer value* $\nu \in \mathbb{Z}$ *of the winding number defined on the complex spectrum of the system under periodic boundary conditions corresponds to* $|\nu|$ *exponentially small*

singular values associated with singular vectors that are exponentially localized at the system's edge under open boundary conditions and vice versa; the sign of ν *determines at which edge the vectors localize*. Non-trivial topology manifests as directional amplification with gain exponential in system size, which is the hallmark of NH topology [3]. I will explain the physical relevance of this peculiar behaviour.

Non-Hermitian dispersive hydrodynamics and Riemann problems

Sathyanarayanan Chandramouli[1*], Nicholas Ossi[1], Ziad H. Musslimani[1] and Konstantinos G. Makris[2,3]

Abstract: Dispersive hydrodynamics (DH) is the study of nonlinear dispersive wave dynamics in fluid-like media. A fundamental problem in DH corresponds to studying the dynamics of a Riemann problem: a step-like initial condition connecting two constant amplitude states. Constant-intensity waves can exist in non-Hermitian optical media (while generally absent in Hermitian inhomogeneous environments). Thus, we can define and study the notion of non-Hermitian dispersive hydrodynamics and its associated Riemann problems in both ordered and disordered optical media for the first time.

The last decade or so has witnessed an intense interest in the general area of dispersive hydrodynamics and its associated Riemann problems [1]. Central to this effort is the investigation into the structure and formation of dispersive shock waves. Much of the research done along these lines has revolved around nonlinear wave propagation inside a homogeneous and conservative medium, where the total power or integrated density is time-independent. Extensions to scenarios involving weak dissipation have however been proposed and studied, with the KdV-Burger's equation being a prototypical test bed model. On the other hand, certain nonlinear wave phenomena (such as DSW) can occur in a spatially non-uniform media, as is the case, for example, in Bose-Einstein condensate flows [1] and optical waveguide arrays [2] and resonant fluid flows over variable topography [3], to name a few. Often, the interplay between dissipation and inhomogeneity lead to the formation of novel multi-scale wave excitations (for example, in polariton condensate flows: [4]). Generally speaking, in inhomogeneous media (conservative or dissipative) plane waves of constant amplitude are no longer viable. This in turn leads to the fundamental question as to how one can formulate and study dispersive hydrodynamics through the lens of Riemann problems. An equally important related issue is the effect of non-Hermiticity (that manifests itself in the gain-loss distribution) on wave breaking. In this paper, leveraging on the new concept of non-Hermitian constant intensity waves, originally proposed in [5] (additional references [6],[7]), we develop a general framework within which non-Hermitian dispersive hydrodynamics and its associated non-Hermitian, Riemann problems can be studied.

Our starting point is the NLS equation with external Wadati potential

$$i\psi_t + \frac{1}{2}\psi_{xx} + \frac{1}{2}(w^2(x) - iw'(x))\psi - |\psi|^2\psi = 0 - - - (1),$$

where $w(x) = \theta'(x)$. Eq. (1) supports a one-parameter (ρ_0) family of constant intensity solutions of the form

$$\psi_{CI}(x,t) = \sqrt{\rho_0}e^{i(\theta(x) - \rho_0 t)} - - - (2)$$

Eq. (1) also governs the dynamics of a dispersive "fluid", which can be seen by considering the polar representation

$$\psi(x,t) = \sqrt{\rho(x,t)}\exp\left(i\phi(x,t)\right), \text{ where } u(x,t) = \phi_x - - - (3),$$

that when inserted into (1) yields the system

$$\rho_t + (\rho u)_x = \rho w'(x) - - - (4)$$
$$(\rho u)_t + (\rho u^2 + \mathsf{P} + R)_x = w'(u + w)\rho - - - (5)$$

This system with reaction terms thus governs wave intensity and momentum dynamics in active media with gain

and loss. Here, $\mathsf{P} \equiv \rho^2/2$ and $R \equiv -\frac{1}{4}\rho(\ln\rho)_{xx}$.These hydrodynamic equations possess source terms that are proportional to the imaginary and real parts of the external potential respectively. These additional new terms give rise to a host of new nonlinear wave patterns that do not exist in bulk media. This hydrodynamic system also conserves a “modified" hydrodynamic momentum density

$$\big(\rho(u-w)\big)_t + \big(\rho(u-w)u + \mathsf{P} + R\big)_x = 0 \quad ---(6)$$

while also admitting constant intensity hydrodynamic backgrounds (Eq.(2)).

Within this setting, we thus formulated for the first time a three-parameter family of (non) centered Riemann problems for Eq. (1) that connect two exact and modulationally stable CI states

$$\psi(x,0) = \begin{cases} \sqrt{\rho_0^{(1)}}\exp(i\theta(x)), & \text{as } x < x_0, \\ \sqrt{\rho_0^{(2)}}\exp(i\theta(x)), & \text{as } x > x_0, \end{cases} \quad ---(7)$$

where x_0 (the location of the step) is an additional parameter influencing the dynamics of the non-centered Riemann problems. The long-time evolutions of these non-Hermitian Riemann problems reveal rich dynamics [8], particularly due to the loss of space-translational and reflection symmetries.

Abstract: Robustness against defects and disorder is one of the most appealing properties of topological insulators. However, such topological resilience typically collapses when the level of disorder is beyond the magnitude of the band gap. Here, we address this problem by exploring the anomalous topological insulator in non-reciprocal scattering networks, whose edge transport survives strong disorder, and even thrives in the absence of periodicity in very amorphous cases. We experimentally confirm such exceptional robustness on microwave scattering networks.

Topological framework for directional amplification in driven-dissipative cavity arrays

C. C. Wanjura[1*], M. Brunelli[2], and A. Nunnenkamp[3]

Abstract:
We present a unifying framework based on non-Hermitian topology to understand non-reciprocity and directional amplification in driven-dissipative cavity arrays. Specifically, there is a one-to-one correspondence between non-trivial non-Hermitian topology defined on the spectrum of the dynamic matrix and regimes of directional amplification, in which the end-to-end gain grows exponentially in system size. The distance between complex spectrum and origin (size of the point gap) determines the amount of tolerated disorder which makes topological, directional amplification extremely robust against disorder.

Directional amplification, in which signals are selectively amplified depending on their propagation direction, has attracted much attention as key resource for applications, including quantum information processing. Recently, several, physically very different, directional amplifiers have been proposed and realized in the lab. Here, we present a unifying framework based on non-Hermitian topology to understand non-reciprocity and directional amplification in driven-dissipative cavity chains [1-2].

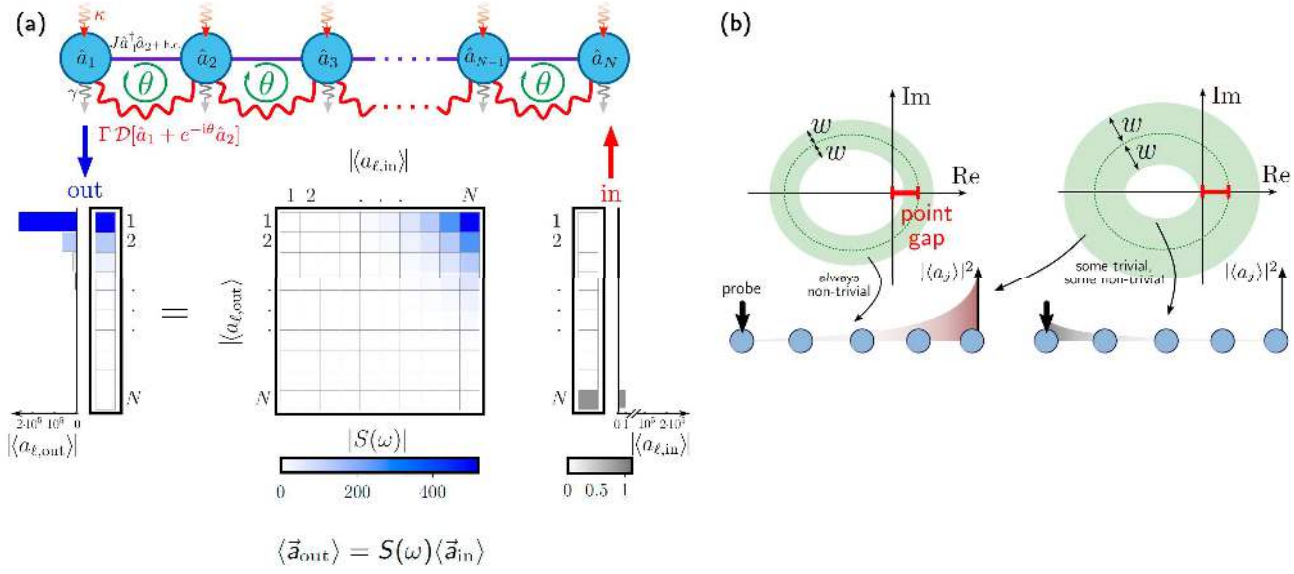

Figure 1. Topological, directional amplification in a driven-dissipative chain. (a) In topologically non-trivial regimes, input signals are amplified from one end to the other but suppressed in the reverse [1]. (b) The amount of tolerated disorder w is set by the distance of the complex spectrum from the origin (size of the point gap) [2]. If the disorder strength is smaller than the size of the point gap, any disordered realization will display directional amplification and the robustness is guaranteed; if the disorder strength exceeds the size of the point gap, robustness against disorder is not guaranteed and the directional amplification may be lost.

We consider translational-invariant bosonic systems in which nearest-neighbours are coupled through bi-linear Hamiltonian terms and non-local dissipators [1], e.g. Figure 1 (a). All modes are subject to decay and possibly incoherent pumping. The system is furthermore coupled to input-output waveguides at rate γ which allows to probe the scattering response of the system. This gives rise to equations of motion of the form $\langle \dot{a}_j \rangle = \sum_\ell H_{j,\ell} \langle a_\ell \rangle - \sqrt{\gamma} \langle a_{\ell,\mathrm{in}} \rangle$ in which $\langle a_\ell \rangle$ denotes the mean cavity field of the ℓth mode, H is the non-Hermitian dynamic matrix and $\langle a_{\ell,\mathrm{in}} \rangle$ the probe field incident on the ℓth site. The scattering matrix $S(\omega) = \mathbb{I} + \gamma(\mathrm{i}\omega\mathbb{I} + H)^{-1}$ encodes the system response to this probe relating input to output fields $\langle a_{j,\mathrm{out}} \rangle = \sum_\ell S_{j,\ell}(\omega) \langle a_{\ell,\mathrm{in}} \rangle$. $|S(\omega)|^{\mathrm{T}} \neq |S(\omega)|$ implies non-reciprocity, since transmission in forward and backward direction differ, while $\left|S_{j,\ell}(\omega)\right| > 1$ implies amplification with the gain $\mathcal{G}(\omega) \equiv |S(\omega)|^2$.

We define a winding number as topological invariant on the complex spectrum $H(k)$ of the dynamic matrix under periodic boundary conditions in reciprocal space which counts the number of times $H(k)$ encircles the origin. Moving from periodic to open boundary conditions, we have shown that there is a one-to-one correspondence between a non-zero winding number and regimes of directional amplification, in which the end-to-end gain grows exponentially with the number of cavities [1]. Specifically, we derived an analytic expression for the scattering matrix in topologically non-trivial regimes [1]

$$S(\omega) \cong \overbrace{\sqrt{\mathcal{G}(\omega)} \sum_{j,\ell} f(j,\ell)\, |j\rangle\langle\ell|}^{\text{directional amplification}} + \overbrace{\begin{pmatrix} \text{PBC} \\ \text{background} \end{pmatrix}}^{\ll \mathcal{G}(\omega)} + \begin{pmatrix} \text{exponentially} \\ \text{small correction} \end{pmatrix}$$

in which the gain $\mathcal{G}(\omega) \propto e^{\alpha N}$ ($\alpha > 1$) grows exponentially with the number of sites N. The function $f(j,\ell)$ shapes the scattering matrix leading to a dominant matrix corner resulting in directional end-to-end gain, see Figure 1 (a). The transmission in the reverse direction, the reverse gain $\bar{\mathcal{G}}(\omega)$, is exponentially suppressed, $\bar{\mathcal{G}}(\omega) \propto e^{-\alpha N}$, and at the exceptional point $\bar{\mathcal{G}}(\omega) = 0$ exactly. Parameter regimes achieving directional amplification can be elegantly obtained from a topological 'phase diagram' [1].

Realistic systems are always subject to disorder. However, we have shown that topological, directional amplification is extremely robust against disorder [2]. Indeed, the separation between the complex spectrum and the origin (the size of the point gap) determines the amount of tolerated disorder, see Fig. 1 (b). Furthermore, we have shown that the zero reverse gain associated with exceptional points remains exactly zero in the presence of arbitrary on-site disorder.

On a practical level, our work unifies existing proposals for both phase-preserving and phase-sensitive directional amplifiers and provides a guiding principle for the design of novel multimode directional amplifiers that can be implemented with state-of-the-art platforms such as superconducting circuits, optomechanics, photonic crystals and nanocavity arrays. On a fundamental level, our framework predicts immediate physical and observable consequences for a topological invariant closing the gap between theory and experiment since non-Hermitian winding numbers are otherwise difficult to extract.

Abstract: Coordinate transformations have been a powerful tool for design of metamaterial optical structures during the last 15 years [1]. In this talk I will discuss our recent research about theoretical methodologies for creating non-Hermitian transparent materials [2], invisibility cloaks [3], and light confinement [4], by coordinate transformations and mapping of electromagnetic field solutions.

Waves typically propagate very differently through homogeneous medium than through an inhomogeneous medium such as complex dielectric structures. In the first part of the talk I will present the surprising result that wave solutions in two-dimensional free space can be mapped to a solution inside a suitably designed non-Hermitian potential landscape, such that both solutions share the same spatial distribution of their wave intensity [2]. This protocol naturally enables the design of structures with broadband unidirectional invisibility for which outgoing waves are indistinguishable from those of free space.

In disordered media, multiple scattering prevents the application of conventional approaches for the design of light fields with desired properties. This is because any local change to such a medium typically affects these fields in a non-local and complicated fashion. By modifying the above theoretical methodology we devised a procedure for tailoring an inhomogeneous 1D Hermitian dielectric index distribution that allows us to control the intensity profile of an incoming light field purely locally, that is, with little or no influence on the field profile outside of a designated region of interest [4].

Transformation of coordinates is a versatile tool to mold the flow of light, enabling a host of astonishing phenomena such as optical cloaking with metamaterials. Moving away from the usual restriction that links isotropic materials with conformal transformations, we have shown how nonconformal distortions of optical space are intimately connected to the complex refractive index distribution of an isotropic non-Hermitian medium [3]. Remarkably, this insight can be used to circumvent the material requirement of working with refractive indices below unity, which limits the applications of transformation optics. We apply our approach to design a broadband unidirectional dielectric cloak, which relies on nonconformal coordinate transformations to tailor the non-Hermitian refractive index profile around a cloaked object. Our insights bridge the fields of two-dimensional transformation optics and non-Hermitian photonics.

Graph parity-time symmetry for bipartite graphs and system stability analysis

H. Benisty[1,2*], L. A. Moreno-Rodriguez[3] C. T. Martinez-Martinez,[4] and J. A. Mendez-Bermudez,[3]

Abstract: We investigate the eigenvalues of random matrices depicting a set of gain and loss systems that are coupled to each other, forming a bipartite graph that exhibits parity-time symmetry. It has significance for complex systems e.g. in the sense of May's instability and the consequences of the "circular law" of eigenvalues distribution and disordered nanolasers. Regions of real spectra in (connectivity, gain/loss) space are outlined. A new feature is a simple angle dependence of eigenvalue distribution in a parametric plane.

Random matrices and their eigenvalues are known as a key tool for stability analysis of large systems, since R.E. May well-known proposal in 1972, that large systems become unstable as the disc occupied by the relevant eigenvalues grows and pushes some eigenvalues in the unstable part of the complex plane in a marginal stability analysis. On the other hand, a renewed approach to open coupled systems has taken place with parity-time symmetry, whereby coupling could force eigenvalues to be real (in the unbroken phase) in spite of uncoupled elements having gain and loss, provided that parity-time (PT) symmetry holds (gain <–> loss under a space symmetry).

Combining earlier knowledge from binary bipartite networks [1], studies on random graphs with gain and loss [2], and studies of non-bipartite PT-symmetric graphs [3], we address here the case of bipartite graphs having parity-time symmetry. Fig.1(a) gives an example of size N=10 (5+5 nodes), and the PT-symmetry holds due to the same topology of edges for 12345 and ABCDE, causing the adjacency matrix in Fig.1(b) to exhibit a pattern with two anti-diagonal N/2 block matrices transposed of each other. The two parameters are the connectivity (fraction of nonzero edges) α and the gain-loss parameter γ on the diagonal.

The relevance to real system with multiple gain and loss elements is emerging in nanophotonics [4]. More generally, the issue of the stability of specific complex systems ensuring e.g. those ensuring transfer of energy from one subgraph to the other could benefit from these studies.

The typical results that we have explored are the fraction of eigenvalues that are real (or imaginary) as a function of N, α and γ, Fig.1(c), for which relatively simple but nontrivial laws emerge, requiring fractional power laws. See ref. [5] for more details.

Another kind of result of possible interest is the eigenvalue distribution density, not in the complex plane, but in the [γ,Re(λ)] plane: It appears to be a combination of what the circular law would predict along the ordinate, Re(λ) at $\gamma=0$ here, and a simple trigonometric function of the local angle of this plane, thus $\psi = \mathrm{atan}(\mathrm{Re}(\lambda)/\gamma)$.

We thus hope to get a set of analytical tools as well as other accurate parametric trends by numerical studies, so as to pave the way to the understanding of a broad series of complex open system with a view to their stability criteria.

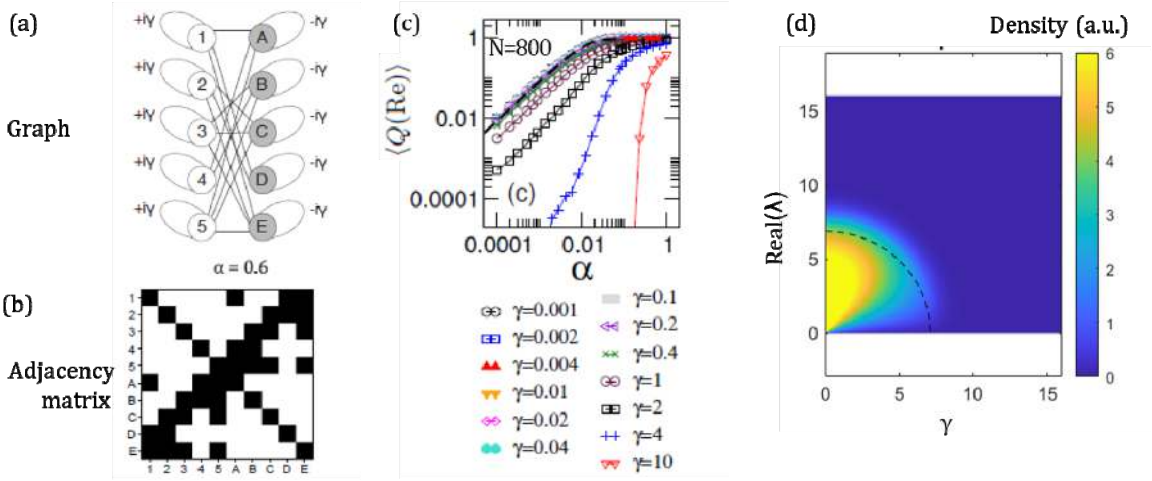

Fig.1 (a) Example of bipartite graph of size 10 with 5 gain + 5 loss elements, with PT symmetry with connectivity α=0.6; (b) corresponding adjacency matrix (1=black) ; (c) fraction of real eigenvalues vs $\log_{10}(\alpha)$ for several γ values; (d) statistical density distribution of eigenvalues in the [γ, Re(α)] plane for a large matrix, with a circle law indicated.

Abstract: We address the problem of the optimal design of first-order Parity-Time symmetric Bragg grating for the distributed feedback laser diodes operation. It is shown that the optimal design grating is not the exceptional point where the perfect unidirectional reflectivity condition is met. It is rather the design corresponding to the broken Parity-Time symmetry phase where the reflection asymmetry is still playing in important role. We also present experimental results on the electrically injected DFB lasers based on such design.

The advent of Parity-Time symmetry in photonics benefited from an important interest to this topic that sparkled a plethora of experimental demonstrations of related physical effects. This work represents an attempt to apply the concept of PT-symmetry to practical mature complex devices, in particular to the design and fabrication of an electrically injected single frequency DFB laser. The main interest of applying the concept of PT-symmetry to DFB lasers is to take advantage of two characteristics that improve the single-frequency behavior by the simultaneous presence of index modulation and losses. Fig. 1 represents the principle of complex coupling with gratings made up of physically separate components which are seen as two (complex) additive contributions by the mode of the waveguide. The presence of the index-modulated grating ensures a lower threshold injection current, while the presence of losses improves the laser emission mode discrimination mechanism and makes single-frequency operation more robust [1,2]. Moreover, according to several theoretical works, the one-way reflection characteristic of the Parity-Time symmetry should make the laser more robust with respect to online optical feedback.

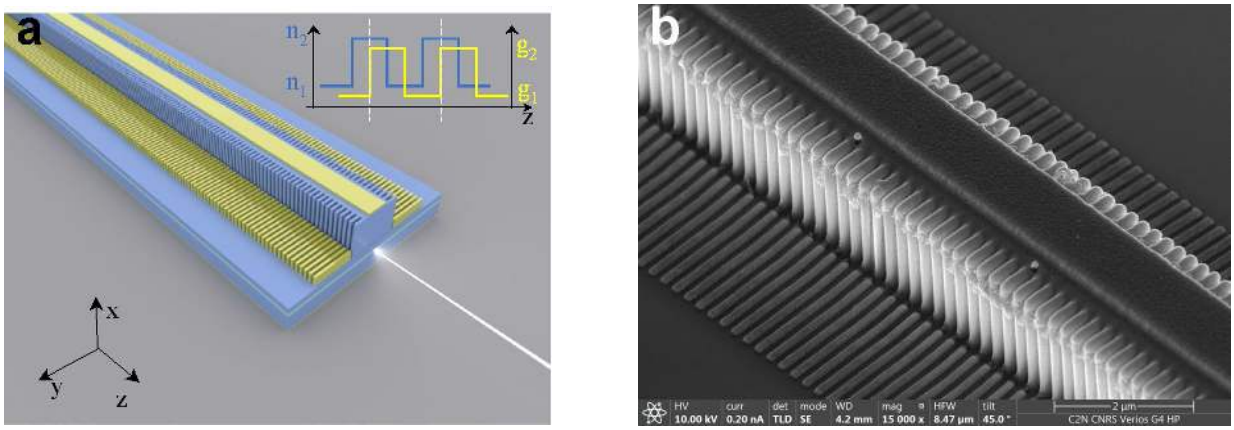

Fig.1. a) Sketch of PT-symmetric DFB laser, blue (dielectric) and yellow (metallic) gratings are shown; the inset depicts the condition for PT-symmetric potential. b) SEM side view of a fabricated first-order broken PT-symmetry DFB laser.

Our modeling results show that optimal operation of these complex coupled DFB lasers requires careful management of the imaginary part of the index profile to avoid excessive losses leading to increased threshold current and reduced power. It turns out that, as a rule, the modulation of the imaginary part of the index profile must be approximately three to four times lower compared to the modulation of the real part of the index profile. Such a complex index profile Bragg grating corresponds to the PT-symmetry broken condition (the associated added imaginary terms being off-diagonal). Nevertheless, the asymmetry in the reflection coefficient leading to the appearance of an additional narrow-band gain discrimination mechanism [1] still plays a beneficial role leading to more robust single-frequency operation. An additional improvement of this mechanism allowing to decrease even more the threshold current and to increase the emitted power could be obtained by using an AR/HR coating whose asymmetry is matched to that of the Bragg grating with a complex profile [2].

Experimental results for electrically injected uncoated DFB lasers with a first order PT-symmetry broken Bragg grating are shown in Fig. 2. As can be seen, the threshold current is less than 20mA while the output power at 100mA injection current is about 13mW. This presents a very noticeable improvement over the third-order PT-symmetry-broken DFB lasers that we reported earlier [1]. Further improvement in output power can be achieved by increasing the injection current up to 300 mA, but this requires mounting the fabricated lasers on heat sink mounts. Work along this direction is ongoing.

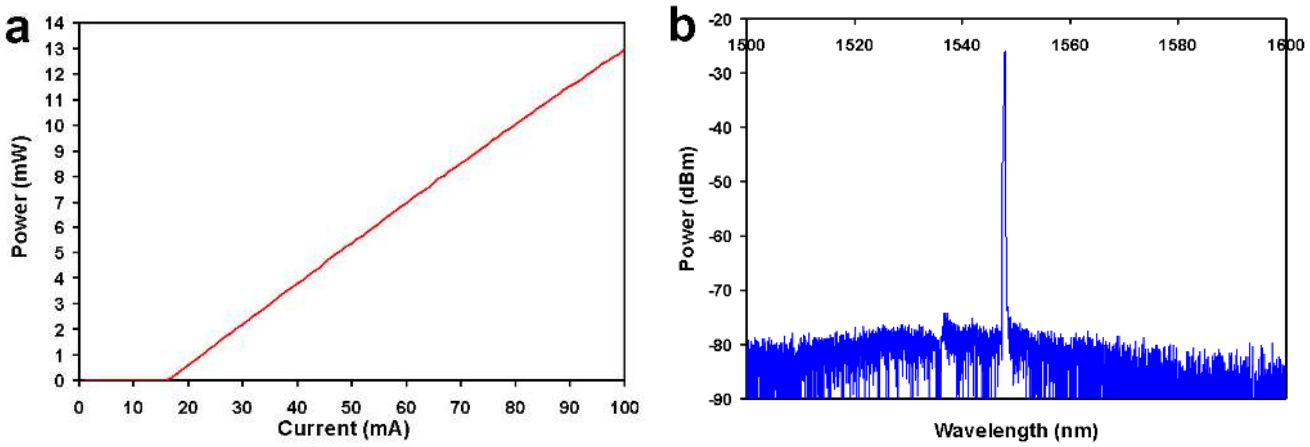

Fig. 2 Typical a) Light–current characteristic; b) Emission spectrum for first-order broken PT-symmetry DFB lasers.

Experimental observation of lasing over Anderson-localized modes at exceptional points using quantum echoes

Sushil Mujumdar[1], **and Krishna Joshi**[1]

[1]Nano-optics and Mesoscopic Optics Laboratory, Tata Institute for Fundamental Research, Mumbai, India
[*]corresponding author: mujumdar@tifr.res.in; sumujumdar@gmail.com

Abstract: We report experimental observation of Anderson-localized lasing modes in quasi-one-dimensional disordered systems over exceptional points. The non-Hermitian system comprised linear arrays of coupled microresonators in which a lasing material provided gain, while free-space scattering in the open system provided loss. Using a probabilistic search over a massive sample space of Anderson-localized modes, we identified exceptional points by tracing the vanishing quantum echo between coupled modes. The spectral lineshape analysis confirmed a second-order exceptional point.

Exceptional points[1] are intriguing spectral degeneracies in non-Hermitian systems at which two or more eigenvalues coalesce simultaneously with the coalescence of associated eigenfunctions. EPs signify singularities at which the eigenvalues and eigenfunctions of non-Hermitian matrices cannot be described analytically[2]. This seemingly abstract construct has been demonstrated to bear a significant impact on the performance of photonic systems. Hitherto, typical photonic systems operated at exceptional points involved coupled resonators or coupled waveguides, whose parameters are chosen with prior knowledge of the systemic behavior. One of the parameters, usually gain or loss, is then tuned gradually to hit a magnitude where the PT symmetry is broken. Such a process, however, is untenable in a mesoscopic disordered system, wherein the physical configuration is randomly organized, and is apriori nondeterministic. Therefore, hitherto, despite theoretical proposals[3], there are no experimental reports of exceptional points in disordered or localizing systems.

Our approach involves a statistical route towards EPs, in which we realize a massive sample space of about 15000 Anderson localizing configurations. This is enabled by our experimental setup wherein a linear array of coupled microresonators realized in a dynamic manner is periodically interrogated by a pulsed laser, wherein every individual laser pulse illuminates a different configuration. The diagnostic apparatus was built to *simultaneously* measure the spatial, spectral and temporal signatures of modes for every configuration. The temporal measurements played a critical part of revealing quantum echoes representing oscillations of energy between the coupled modes, akin to Rabi oscillations in two-level systems[4]. This measurement is vital because it sifts out coupled modes from various accidental spectral peaks that mimic a doublet. Subsequent analysis of the vanishing quantum echo, accompanied by simultaneous coalescence of eigenvalues and eigenvectors leads to the identification of exceptional points. Further, spectral lineshape analyses confirm the second-order nature of these exceptional points[5].

Level statistics and Anderson localization transitions of non-Hermitian systems with exceptional points

Chen Wang[1]*

[1]Center for Joint Quantum Studies and Department of Physics, School of Science, Tianjin University, Tianjin 300350, China

*corresponding author: physcwang@tju.edu.cn

Abstract: In this talk, I will discuss some recent progress in the understanding of level statistics of non-Hermitian Hamiltonians. These include 1) Poisson level statistics of extended states of non-Hermitian metals [1]; 2) A new universal level spacing distribution, which displays linear level repulsion, for exceptional points of disordered non-Hermitian systems [2].

Open systems are described by non-Hermitian Hamiltonians and have drawn increasing attention in recent years due to their academic interest, importance, and relevance to reality. Unlike Hermitian Hamiltonians, whose eigenenergies are real, the eigenenergies of non-Hermitian Hamiltonians are, in principle, complex numbers. The real parts of eigenenergies are interpreted as quasi-particle energies, and the imaginary parts are the inverse of quasi-particle lifetimes.

It is known that the level-spacing distribution for random Hermitian Hamiltonian is a fundamental quantity that reveals the underlying physics. For example, level repulsion is a general principle in Hermitian quantum physics, which prevents two extended states from having the same energy and gives rise to the well-known Wigner-Dyson distributions for the normalized nearest-neighbor energy-level spacing [3]. Differently, for non-Hermitian systems, a pioneering work by Grobe, Haake, and Sommers shows that the nearest-neighbor level spacing distributions are the so-called Ginibre distributions, where the three Gaussian Ginibre (orthogonal, unitary, and symplectic) ensembles display a universally cubic level repulsion [4].

We revisit the level statistics of non-Hermitian systems by focusing on a different question: What is the distribution of the quasi-particle energies, i.e., the real part of eigenenergies, of extended states? To this end, we first show that an Anderson localization transition can happen in either preserved time-reversal-symmetry or broken disordered non-Hermitian Hamiltonians. Then, we find that the nearest-neighbor quasi-particle energies follow the Wigner-Dyson distribution if the non-Hermiticity is much smaller than the mean level spacing of quasi-particle energies. If the meaning level spacing of the quasi-particle energies is much smaller than the non-Hermiticity, we observe a universal Poisson distribution, which is universally true for the Anderson insulators whose energy eigenstates do not overlap with each other. Our results thus provide a unified picture for recently discovered “level attraction” in various systems and a theoretical basis for manipulating quasi-particle energy levels.

Besides, we also study the level statistics of complex eigenenergies of some non-Hermitian systems with exceptional points. The widely accepted Ginibre distributions are no longer applicable in our models. In the symmetry-protected or symmetry-broken phases, where the eigenenergies are real or come in complex-conjugate pairs, respectively, the nearest-neighbor level spacing distributions follow the Wigner-Dyson distributions. Here, time-reversal symmetry plays a

significant role in determining the degree of level repulsion. Near the exceptional points, we observe some new distributions, which depend on symmetries for small sizes but become a universal distribution for large sizes. In both cases, they display a universal linear level repulsion rather than the universal cubic level repulsion of the Ginibre distributions.

In conclusion, the general Wigner-Dyson distribution of energy level spacing of extended states in Hermitian systems is replaced by the Poisson distribution for quasi-particle level spacing of non-Hermitian disordered metals. This is a surprising result since Poisson distribution is only valid for highly localized states in Hermitian systems. Furthermore, the level repulsion of states near exceptional points is universally linear, rather than the cubic level repulsion of the Ginibre distributions. This recent progress shows that the level-statistics problem for non-Hermitian systems is far from fully solved.

Abstract: Sensors typically detect small perturbations by measuring their effects on a physical observable in the linear response regime. As it turns out, once linear resonse is abandoned, new opportunities emerge. A prominent example is resonant systems operating near Nth-order exceptional point degeneracies (EPD), where a small perturbation $\varepsilon \ll 1$ activates an inherently sublinear response $\sim \varepsilon^{1/N} \gg \varepsilon$ in resonant splitting. Here we propose an alternative sublinear optomechanical sensing scheme that is rooted in Wigner's cusp anomalies (WCA), first discussed in the framework of nuclear reactions: a frequency-dependent square-root singularity of the differential scattering cross section around the energy threshold of a newly openened channel, which we use to amplify small perturbations. WCA hypersensitivity can be applied in a variety of sensing applications, besides optomechanical accelerometry focused on in this talk. Our WCA platforms are compact, do not require judicious arrangement of active elements (unlike EPD platforms), and if chosen, can be cavity free.

Emergence of non-Hermitian dynamics in a quantum gas leading to a self-driven topological pump

A.Baumgärtner

[1]ETH Zürich

The time evolution of a driven quantum system can be strongly affected by dissipation. Although this mainly implies that the system relaxes to a steady state, in some cases it can lead to the appearance of new phases and trigger emergent dynamics. In our experiment, we study a Bose-Einstein condensate dispersively coupled to a high finesse optical resonator. The cavity is populated by scattering photons from a transverse drive illuminating the atoms. The sum of the drive and the self-consistent intracavity field provides a topological band structure. When the dissipative and coherent timescales are comparable, we find a regime of persistent oscillations where the cavity field does not reach a steady state: The emergence of an exceptional point. In this regime the atoms experience a potential that periodically deforms itself, even in the absence of an external time-dependent drive. Consequently, the dynamic lattice triggers topological pumping [1]. We show complementary measurements of the light field and of the atomic transport, proving the connection between the non-stationarity and the topological pumping and further investigate the emergence of the dynamics with various spectroscopic techniques.

Non-Hermitian microresonators at an Exceptional Point

Riccardo Franchi[1*], Stefano Biasi[1], and Lorenzo Pavesi[2]

[1]Nanoscience Laboratory, Department of Physics, University of Trento, 38123 Trento, Italy

Abstract: In this work, we present a new integrated structure operating at an exceptional point consisting of an infinity-shaped microresonator twice coupled to a bus waveguide. Its improved sensing performance is reported as well as its high variability of output spectra. Finally, an experimental method for individually exciting supermodes of resonant Hermitian and non-Hermitian structures is presented.

The study of non-Hermitian systems has found great interest in recent years. In particular, the discovery of PT-symmetric non-Hermitian systems [1] and the special non-Hermitian degeneracies called exceptional points (EPs) have stimulated the study of new systems. The features of exceptional points have been used in various applications through the realization of devices such as sensors, unidirectional lasers, unidirectional reflectors, and non-reciprocal optical components exhibiting a violation of the Lorentz reciprocity theorem. In these realizations, integrated optics may be the disruptive technology thanks to the advantage of miniaturization and the ease of implementation of loss, gain and asymmetric coupling.

Here, we report the study of a new integrated device called the infinity-loop microresonator (ILMR) [2]. The ILMR operates at an EP and consists of an infinity-shaped waveguide twice coupled to a bus waveguide. Its shape allows high tunability of the transmission and reflection spectra as a function of the two couplings with the bus waveguide while remaining at an EP. We show how this device is able to increase the sensitivity to a backscattering perturbation compared to a standard microring resonator. In addition to increasing the sensitivity due to the characteristic square root EP trend [3], using both the transmission spectrum and the sum of the transmission and reflection spectra, the ILMR is able to avoid the region of insensitivity typically found at small perturbations. Finally, an experimental method for individually exciting the supermodes of a Hermitian or non-Hermitian resonator system is presented. It is based on a simultaneous and coherent excitation of a system from both sides. By properly tuning both the intensity and the relative phase between the two input fields, one can directly measure the real and imaginary parts of the eigenvalues from the output spectrum [4]. This allows the quality factor of a resonant system to be defined even in the presence of a resonant doublet.

Abstract: In this contribution we focus on topological defects that are local kinks or obstructions in an order parameter field where domain walls, superconductor vortices or dislocations are few of many prominent examples. Topological bound states can form around these defects much in the same way edge and surface states bind to one- and two-dimensional interfaces, respectively. Here, we discuss both numerical and experimental advanced in the context of topological acoustics, where a man-made lattice hosting a topological nontrivial phase is realized with added real-space lattice distortion and non-Hermiticity.

Abstract: Non-Hermiticity exhibits an excellent platform to achieve new insights in physics and technology. Here we discuss the influence of non-Hermitian environments on emission properties of a dipole. Using the perturbation theory, we reveal that resonant energy transfer between donor and acceptor molecules strongly enhances at the exceptional point. Our results are essential for nanooptical applications including light energy transport and signal processing on a chip.

Introduction

Parity-time (PT) symmetry and non-Hermiticity is a remarkable tool for tailoring light-matter interaction. It has been already achieved advantageous behaviors in scattering, lasing, coherent perfect absorption, wireless power transfer, etc. Therefore, this topic is under a close attention from the photonic community.

Non-Hermitian physics initiated by Bender and Boettcher [1] in relation to quantum mechanics was extended to optics due to possibility to associate a Hamiltonian with an optical system [2,3]. The optical non-Hermitian Hamiltonians including PT-symmetric ones then can have real eigenvalues. By changing system's parameters one is able to reach an exceptional point, in which sets of both eigenvalues and eigenvectors coalesce. The physics in vicinity of exceptional points is rich and can be analyzed from mode, topology and symmetry points of view. Many prospective applications of non-Hermitian systems as CPA-lasing and sensing are related to the behaviors near exceptional points [4]. In the particular case of a PT-symmetric system exceptional points separate PT-symmetric and broken-PT-symmetric states. Here we deal with some nanophotonic issues, namely, resonance energy transfer and spontaneous emission of dipoles interacting with non-Hermitian systems. In order to describe the system in vicinity of higher-order exceptional points we develop the appropriate perturbation theory.

Results

We consider a generic system described by the non-Hermitian Hamiltonian as a sum of unperturbed and perturbed parts [an example of such a system is shown in Fig. 1(a)]. The unperturbed Hamiltonian corresponds to that at the exceptional point, while the perturbed Hamiltonian is proportional to the small perturbation parameter ε. In the perturbation series for eigenvalues and eigenvectors the leading terms are proportional to $\varepsilon^{1/n}$, where n is the order of the exceptional point. Owing to the perturbation the degeneracy available at the exceptional point is lifted and we can generally determine the eigenvalues in two non-Hermitian phases corresponding to $\varepsilon<0$ and $\varepsilon>0$ [5]. We demonstrate such a behavior in Fig. 1(b) for PT-symmetric system possessing a second-order exceptional point at $\varepsilon=0$. Green's function as a Mittag-Leffler expansion can be also presented through the perturbation parameter ε. The Green function is indispensable for finding the local density of states and resonance energy transfer.

Using the perturbation theory, we can find the eigenfrequencies of the modes and compare the results with a numerical simulation. The degenerate eigenfrequency of unperturbed modes is generally a complex number $\omega_0 = \omega_0' + i\omega_0''$, the imaginary part of which determines decaying properties (both radiation and non-radiation) of the modes. When the decay is small, the local density of states and, therefore, the Purcell factor can increase at the

exceptional point [6]. Otherwise, the exceptional point does not affect the local density of states. It was confirmed in numerical and analytical calculations of the Purcell factor for the system of two coupled PT-symmetric rectangular waveguides [7]. The resonant energy transfer in a non-Hermitian system can be characterized by a spectral function $T(\omega)$ maximizing at the exceptional point. As it is seen in Fig. 1(c), the spectral function rapidly grows with the order of exceptional point. The increase of $T(\omega)$ with the order n is shown in [5] as a result of numerical simulation for mirror-assisted system of coupled resonators.

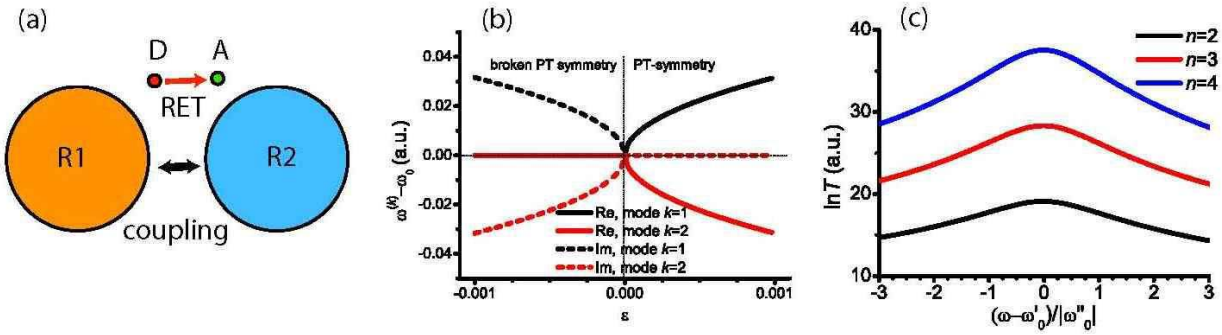

Figure 1. (a) Non-Hermitian system of coupled resonators to enhance resonance energy transfer (RET) between donor (D) and acceptor (A) molecules. (b) Departure of the eigenfrequencies $\omega^{(k)}$ of modes k from the degenerate frequency ω_0 as function of the perturbation parameter ε (order of exceptional point n=2). (c) Frequency dependence of spectral function $T(\omega)$ of the RET for different orders n of exceptional points.

To sum up, exploiting the developed perturbation theory near a higher-order exceptional point we have determined the closed-form frequency dependences of the local density of states and resonance energy transfer. Our results may find application for tailoring response of non-Hermitian systems at the nanoscale.

A Hermitian Bypass to the non-Hermitian Quantum Theory

Tanmoy Das
Department of Physics, Indian Institute of Science, Bangalore 560012

tnmydas@iisc.ac.in

Conservation laws are an idealization of real-world problems, and hence the demand to develop non-Hermitian (NH) quantum theory is growing. The NH quantum theory suffers from various ill-defined properties and singularities. Here we construct a unified approach, applicable to all NH operators, by constructing a Hilbert space of a suitably designed Hermitian operator and expanding the NH Hilbert space on this basis. This way, the singularities are transported to the expansion parameters while the basis states remain well-defined. We developed a well-defined time-independent quantum theory of the generic NH Hamiltonians and exhibited several representative examples and applications.

Abstract: Semiconductor lasers and laser arrays emit temporally unstable and low spatial quality beams associated to intrinsic dynamical spatiotemporal instabilities. We propose the simultaneous modulations of refractive index and gain-loss generating non-Hermitian potentials as a stabilization mechanism. The proposed spatiotemporal modulations are introduced by directly acting on field and carriers. The stabilization is based on the stabilization of specific stationary solutions or on field localization. Stabilization is shown for VCSELs, EELs and EEL arrays.

Semiconductor lasers, like Vertical-Cavity Surface Emitting Lasers (VCSELs) and Edge Emitting Lasers (EELs) with flat mirrors lack from transverse mode selection to guarantee a Gaussian mode emission, developing turbulent behaviors and unstable emitted beams. The instability is primarily due to the intrinsic modulation instability (MI) of the homogeneous solution and is dramatically enhanced by nonlinear destabilizing effects such as self-focusing and filamentation when pump power is increased.

Periodic non-Hermitian potentials were proposed for the control of turbulence by changing the dispersion relation to suppress the MI in some general models and specifically in optical systems where such potential corresponds to simultaneous periodic modulations of refractive index and gain-loss [1]. Aside, Parity-Time (PT) symmetries that includes phase-shifts between the real and imaginary parts of the potential have been proposed for the light control [2]. More recently, periodic space-time potentials with temporal PT-symmetry, have been applied in general models like the Complex Ginzburg-Landau Equation (CGLE) for the turbulence reduction and stabilization of the homogeneous solution [3,4].

Here, we summarize two different manners for the stabilization of laser emission with non-Hermitian potentials differing from the usual stabilization of the homogeneous solution. The first is the non-homogeneous but stable laser emission in new transverse solutions generated by the introduction of a transverse non-Hermitian periodic modulation with in-phase real and imaginary parts. This technique stabilizes specific new stationary solutions emerging when the modulation amplitude is large enough. We analytically and numerically investigate such stabilization way in general models like the CGLE and in VCSELs, see Fig.1 a [5].

The second is based on the symmetry breaking of the coupling in the transverse direction induced by non-Hermitian potentials with a phase-shift between real and imaginary parts. The induced coupling asymmetry achieves its maximum for phase-shifts corresponding to PT-symmetries. The combination of such potentials with axial symmetries lead to field concentration and stabilization. Such non-Hermitian potentials with radial symmetry in VCSELs can induce unidirectional inward radial mode coupling allowing to an axial concentration of the energy generated in the whole active region, avoiding turbulent behavior and generating narrow bright beams even below threshold [6]. The stabilization of EELs and EEL arrays by field localization involves a

transverse multimode field in a long cavity and showing temporal dynamics. Taking advantage of the different time scales of the cavity round trip time and carrier's relaxation time a 2D+1 spatiotemporal model for these class B lasers is developed to characterize the stabilization by field localization [7,8]. Temporal stabilization with spatially redistributed light emission can be achieved in EEL arrays by particular shifts between electrodes (green) and laser waveguides (brown), see Fig.1 d.

Abstract: We present an experimental study of optical time-refraction in single-cycle time-interfaces. Specifically, we study the propagation of a probe pulse through a sample undergoing large refractive index changes induced by an intense ultra-short modulator pulse. © 2023 The Author(s)

Large and fast modulations of the macroscopic electromagnetic (EM) properties of materials can have far reaching consequences [1–6]. Unlike low amplitude modulation or slow modulation in time, in cases where the macroscopic response is large and fast enough - even a single "step" modulation can result in dramatic changes [7].

When a wave propagating in a medium experiences a sudden change in the real part of the refractive index $\boldsymbol{n(t)}$, it undergoes two fundamental process - time refraction, and time reflection [8]. In this process of temporal modulation of the EM properties of the medium, the energy of the propagating wave ("probe") is not conserved, but when the medium is homogeneous the wave momentum (wave-vector) is conserved. Consequently, when the refractive index is increased abruptly the spectrum of the wave undergoes a red-shift, and when the index is decreased the spectrum undergoes a blue-shift. broadband frequency translation through time refraction has been recently observed in experiments [9,10], but time-reflection was thus far demonstrated only with water waves [11] and very recently with microwaves [12]. The lack of energy conservation in such time-modulated EM media implies the scattered wave may even be more energetic than the incident one [13], and can lead to tremendous amplification of waves by the modulation. Such time boundaries may also be used for applications such as antireflection temporal coatings [14], extreme energy transformations [15], inverse prisms [16], temporal aiming [17] and fundamental physics as well [18–22]. Concatenating several time-modulations periodically can lead to the formation of wide momentum gaps and the system functions as a Photonic Time-Crystal (PTC) [2,3,23,24]. The gaps in momentum of a PTC, where the temporal frequency is complex, can lead to broadband parametric amplification, and can interact with the emission of radiation by free electrons [25], atoms [4] and classical dipoles [4]. All of these rely on the ability to induce time-interfaces: very large changes in the EM properties of materials occurring at single-cycle rates.

Here, we explore the physics of time-refraction induced by a large 1-2 cycles modulation of the EM properties in Epsilon Near Zero (ENZ) materials.

Conventional nonlinear optics enables material response that is instantaneous but very small in the optical regime, and hence cannot be used for our purpose. On the other hand, recent progress with transparent conductors enables large optically-induced response in the optical regime. Thus, to induce significant time-refraction in the single-cycle regime, we create a moving time-boundary that occurs as fast as the time-period of the propagating wave, with a refractive index change of the order of $\boldsymbol{\Delta n \sim 0.5}$. Crucially, the material remains relatively transparent despite the huge relative index change, which allows us to explore new physics. The time-refraction we observe exhibits two frequency shifts induced by the index modulation. The first is a red-shift from the instantaneous rise in the refractive index. We demonstrate, for the first time, that this large refractive index change can occur within the single cycle regime. We do that by varying the duration of the modulation pulse between 30fs down to 6fs, and observe the corresponding decrease in the response time directly. The second frequency shift we observe is the blue shift associated with the relaxation (decrease) of the refractive index of the material back to its original value. We observe a large blue shift of a duration similar to that of the red shift. This implies that the relaxation process of the electrons back to their original energies (bottom of conduction band) occurs within ultrashort time scales, contrary to the expected relaxation of hot electrons in transparent conductors, which relies on coupling to phonons and takes hundreds of femtoseconds.

It is essential to analyze the transmitted pulse measurements of Fig.1B as a function of the modulator width. In Fig. 1C we plot the wavelength shifts of the mean wavelength vs. modulator-probe delay. These wavelength shifts show clear dependence on the modulator width both in rise time and in the magnitude of the red-shift. This conforms with the understanding that the refractive index change occurs because the material absorbs the modulator light, which excites conduction electrons to higher energies in the conduction band. Since absorption is an induced transition process, it is fundamentally instantaneous, hence it was expected that the rise of the refractive index would follow the accumulation of energy absorbed in the material. That is

$$\frac{d}{dt}\Delta\varepsilon(\mathrm{t}) \approx \mathrm{I_{mod}}(\mathrm{t}) - \frac{1}{T_{Decay}}\Delta\varepsilon(\mathrm{t}), \qquad \mathrm{n(t)} = \mathrm{Re}\left\{\sqrt{\varepsilon_{I_{mod}=0} + \Delta\varepsilon(\mathrm{t})}\right\} \tag{1}$$

Where $I_{mod}(t)$ is the time-dependent intensity of the modulator pulse in proper units, $\varepsilon_{I_{mod}=0}$ is the ambient (unmodulated) permittivity of the TCO slab and t=0 is defined when the modulator starts entering the sample. Since in our setup we probe the index change with a probe pulse, the refractive index response appearing in our measurements is a convolution of the index response and the temporal envelope of the probe pulse. In Fig. 1D we present the amount of refractive index change occurring within a single

cycle of the temporal period of the probe, as calculated from the mean wavelength shift shown in Fig. 1C and described by Eq. 1. For the shortest modulator width, we estimate that the refractive index of the sample is varied by ~0.12 within a single cycle of the probe wave.

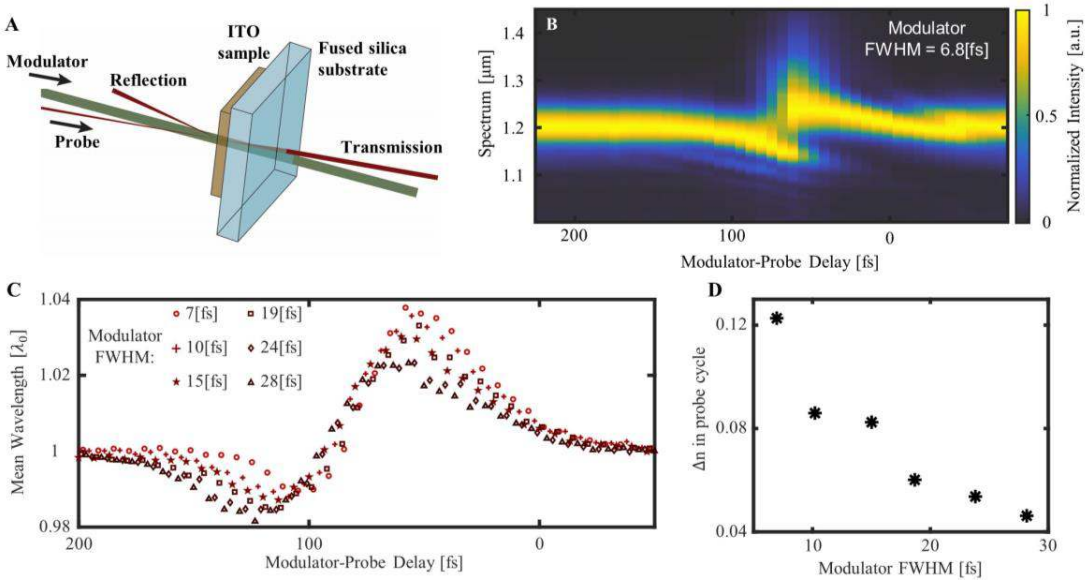

Figure 1: (A) Schematics of the modulator – probe setup. The modulator is a pulsed optical beam at 800nm (mean) wavelength, compressed to different pulse widths through a hollow core fiber system, illuminating a 700 micrometers diameter region of the sample. The probe beam is a 40fsec pulse at mean wavelength of 1200nm. The modulator and probe are synchronized to arrive at the TCO sample at controlled delays. The intensity and spectrum of the transmitted probe and the intensity of the reflected probe are measured. (B) Spectrogram of the probe pulse transmitted through the sample, for modulator pulse of the temporal width (FWHM) of 6.8[fs]. Negative delays (right side of the plot) correspond to the probe pulse passing through the sample before the modulator arrives. Each spectrum of the spectrogram is normalized individually. (C) Mean wavelength of the transmitted probe pulse vs modulator-probe delay, for different modulator pulse widths. Zero delay is arbitrarily set when 20% red-shift change is achieved for each modulator width. The rise time for red-shift appears to decrease with the modulator width, while the maximal shift increases. (D) The maximal refractive index change occurring within a single cycle of the probe temporal period vs the modulator width. Each data point is obtained using eq.1 and fitting the rise of the red-shift in Fig. 1C to erf function convolved with the probe envelope.

To conclude, we experimentally studied a new regime in which a pulse propagates in a material whose refractive index undergoes very large variations (~0.5) on the single cycle time scale while maintaining transparency. We find that the response time to large index variations can be extremely fast (few femtoseconds), and, unexpectedly, the relaxation seems to be on similar time scales. Our findings, especially the very fast relaxation of the variation in the refractive index in ITO, pave the way for observing new phenomena involving time refraction and reflection, photonic time crystals, and many other effects related to time boundaries.

Statics and Dynamics of non-Hermitian Many-body Localization

Arijeet Pal

University College London, UK
*corresponding author: a.pal@ucl.ac.uk

Abstract: Many-body localized phases retain memory of their initial conditions and have been shown to exist in disordered interacting systems with unitary dynamics. The stability of the localized phase due to the breakdown of unitarity is of relevance to experiments when coupling to the environment. Motivated by this, we investigate the impact of non-Hermitian perturbations on many-body localization in the interacting Hatano-Nelson model which breaks unitarity via asymmetric hopping. We study the impact on eigenstates and dynamics due to the non-Hermiticity.

Abstract: Reflectionless (RL) states that are eigenfunctions of a non-Hermitian operator enable reflectionless coupling of light to a scattering sample. Here, we first observe exceptional points of RL states obtained by tuning the scattering strength in symmetric scattering samples. Then, instead of using wavefront shaping techniques, we will show that we can design anti-reflection structures for perfect transmission through disordered medium for any incident wavefront.

The transmission of waves through disordered media is ordinarily frustrated by multiple scattering within the medium. The average transmission is typically small when the sample length is much larger than the transport mean free path. However, as illustrated by the existence of open channels with perfect transmission, it is possible to find states of no reflection at the input at specific frequencies even in random media. In this talk, we will first discuss the related concept of reflectionless (RL) states [1,2]. Similarly to the poles of the scattering matrix, RL eigenvalues are eigenvalues of a non-Hermitian operator based on the wave equation. For this operator, the incoming channels are modelled with gain and outgoing channels with losses. When a RL eigenvalue is tuned to the real axis, a state with zero reflection and therefore perfect transmission in non-absorbing samples is obtained. Interesting properties arise in symmetric samples because the reflectionless operator is parity-time symmetric. Two real RL eigenvalues can coalesce at an exceptional points (EP) when the scattering strength is tuned symmetrically [2]. We experimentally observe such EPs in a multimirror Fabry-Perot system and then a complex cavity [3]. A clear signature of an EP is the broadening of the reflection lineshape. Our theoretical work are fully confirmed by measurements in the microwave range.

Using the framework of RL states, we will show that the transmission through an obstacle can be greatly enhanced by positioning new scattering elements in front or behind it. A symmetric disorder placed on each side of a barrier can indeed enhance transmission through the barrier over a broad frequency range [4] as a result of the PT-symmetric property of the RL operator. Finally, we will demonstrate that a structureless medium can even be made fully transmitting to all incoming wavefronts at a single frequency by placing a customized complementary medium in front of it [5]. The matrix generalization of the critical coupling condition between the two structures leads to the presence of a high-order diabolic point of RL states. Unlike open channels that are restricted to properly engineered wavefronts, any incoming wave is fully transmitted when the anti-reflection structure is placed. The design of the anti-reflection structure is realized numerically and the results are verified

experimentally. We render electromagnetic waveguides fully transmitting in spite of several dozen scattering elements being placed inside of them.

Abstract: Higher order exceptional points (sensitivity) and topological protection (robustness) are two antagonistic effects. We examine their interplay on the prototypical non-Hermitian SSH lattice in terms of pseudospectra theory and its geometric features.

In the context of non-Hermitian topological photonics, we examine the interplay between robustness (due to topology) and sensitivity (due to non-Hermiticity) in the prototypical system of a non-Hermitian Su-Schrieffer-Heeger (NHSSH) lattice around the underlying exceptional points (EPs) [1,2]. In order to systematically examine the lattice sensitivity, we provide a mathematical framework ideal for non-Hermitian systems, that is the complex and structured pseudospectra theory [3,4,5,6,7,8]. In particular, we consider three different lattices, namely an infinite, a finite and a hetero structure of two NHSSH lattices (see Fig. 1). The intricate relation between the lattice symmetry and the symmetries of the perturbations is revealed based on pseudospectra [3,4]. Our starting point is the prototypical SSH model, in the context of coupled mode theory. More specifically, the lattices that we consider are schematically depicted in Fig. 1. The coupling constants are denoted by c_1 and c_2 for intra- and inter-cell coupling, respectively. The global gain-loss amplitude of each waveguide channel is described by the parameter γ, and thus making the whole system non-Hermitian. Regarding the case of an interface SSH lattice, we consider two SSH chains that are connected with an extra channel at the interface that has a tunable gain/loss amplitude γ_0.

In the vast majority of previous studies, the sensitivity of a non-Hermitian system under external perturbations was analyzed using the semi-analytical techniques based on perturbation theory, for systems of usually small number of waveguides. For lattices of our type such an approach is rather problematic and is not easily applicable, since we do have to use different versions of perturbation theory depending how close we are at the underlying EPs, and with very limited types of perturbation strengths. Therefore we introduce an alternative and general computational framework based on pseudospectra [3].

Our results for the three NHSSH lattices, are shown in Fig. 1. The red dots represent the spectrum and the yellow dots the corresponding pseudospectra. As we can see, the corresponding pseudospectra are extended patterns on the complex plane, and their size is related to the sensitivity of the lattice. In particular, the eigenstates close to the gap closing point are most sensitive and these away from that gap are more robust. The geometrical size of the main lobe of the complex pseudospectrum as a function of the perturbation strength ε has a square-root and cubic-root dependence, that are characteristics signatures of the EP2 and EP3, respectively, for small values of the perturbation strengths.

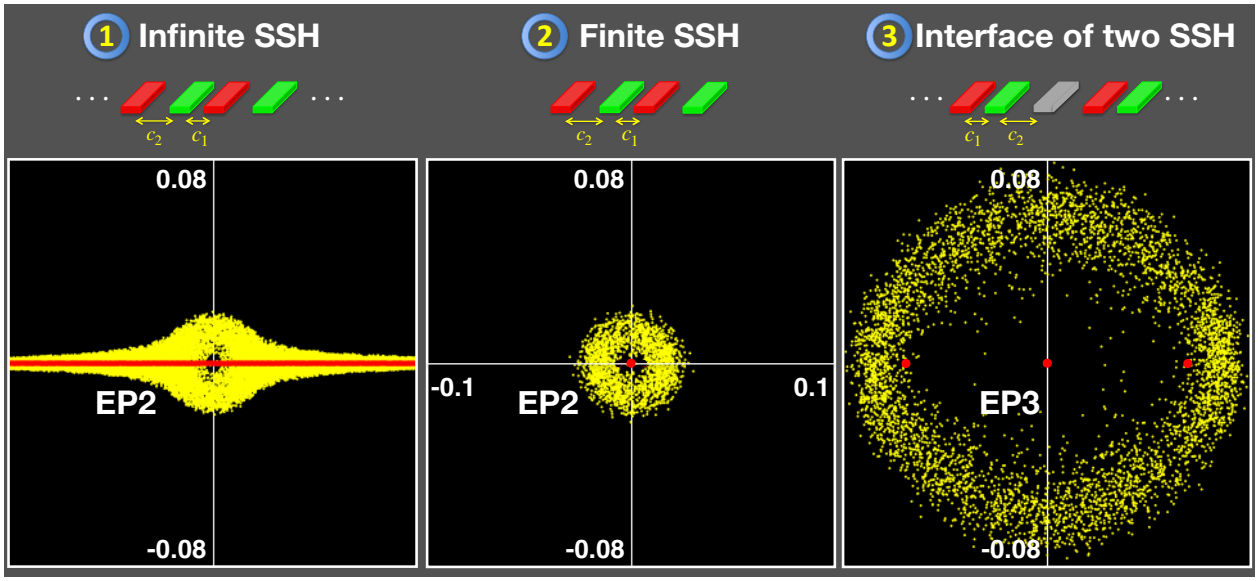

Figure 1: Complex unstructured pseudospectra around the EPs of the three NHSSH lattices: infinite (left), finite (center, N=80) for $\gamma = 2$, and interface (right, N=81) for $\gamma = 2.0159$ and $\gamma_0 = 0$. In all cases $c_1=3$ and $c_2=1$. On the top row the red, green and gray colors illustrate the gainy, lossy, and neutral waveguide, respectively. On the bottom row, the modes that form the EPs (conventional spectra, red dots) and corresponding 0.0001-pseudospectra (1000 realizations-yellow dots), for the three lattices are presented on the complex plane. We have to note here that in the interface lattice, at the red dot at [0,0] three eigenvalues coalesce. We do not show the edge states of the finite SSH, which are located at [0, ± 2i] and the associated perturbations of the order $\varepsilon/2$.

In conclusion, our results highlight the fundamental question of the interplay between ultrasensitivity and topological protection in the unique framework of pseudospectrum theory and may provide insight for the study of other lattices of non-Hermitian topological physics.

Physical limitations on the observability of non-Hermitian effects in passive systems

H. Schomerus[1] *

[1]Department of Physics, Lancaster, University, UK
*corresponding author: h.schomerus@lancaster.ac.uk

Abstract: I contrast fundamental limitations on the physical observability of non-Hermitian effects in passive and active non-Hermitian systems. While active systems suffer from noise, passive systems are limited by causality, which can be reformulated in terms of constraints on the experimentally observed density of states. Applied to paradigmatic effects, it turns out that signatures of exceptional points and the non-Hermitian skin effect become hidden.

Active elements appear to be critical in experimental realization and observations of paradigmatic non-Hermitian phenomena, such as the non-Hermitian skin effect and the squared-Lorentzian line shape at an exceptional point. As such systems consume energy and suffer from noise that violates the exact implementation of topologically relevant symmetries, passive realizations appear desirable. Here, I establish fundamental limits on this objective that relate constraints from causality to the experimental protocol of determining the density of states [1]. In the density of states, the non-Hermitian skin effect turns out to be completely hidden, while the squared Lorentzian only appears as a background effect of limited contrast (Fig. 1).

Theoretically, the key insight is utilizing an appropriately generalized time-delay operator to link the causality constraints with the experimental protocol to determine the density of states. Practically, the constraints can then be formulated directly in terms of the microscopic model, as earlier established via spectral considerations [2]. Conceptually, the strong link between a fundamental concept and a key experimental observable provides a new perspective on analogous constraints on the spectral features and response in active and passive non-Hermitian systems [3-7].

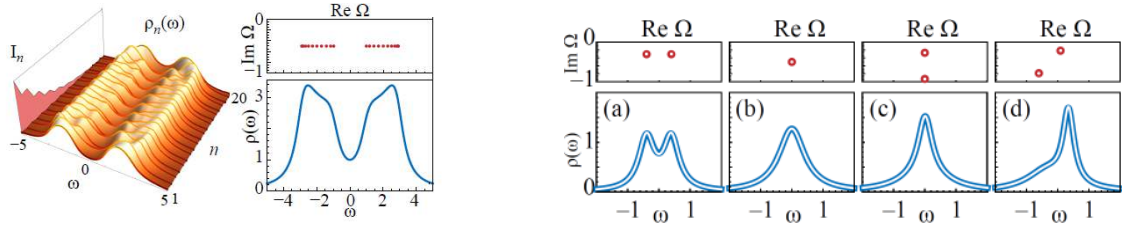

Fig. 1 Left: Local and global density of states ρ in a non-reciprocal non-Hermitian system with open boundaries. The eigenfunctions display the non-Hermitian skin effect (see intensity profile I_n), but this is not reflected in the local density of states. Right: Density of states of a passive system passing through an exceptional point. In striking contrast to active systems, right at the exceptional point (second panel) the density of states is a normal Lorentzian. For both systems, the red dots show the position of states in the complex frequency plane.

Pseudomagnetic suppression of non-Hermitian skin effect

Abstract: Inspired by previous work on magnetic suppression, we demonstrate that a pseudomagnetic field can also suppress non-Hermitian skin effect using a two-dimensional tight-binding lattice. By increasing pseudomagnetic field, the skin modes are pushed into the bulk, accompanied by the reduction of skin topological area and the restoration of Landau levels. Our results provide a new route to localization control and could be useful in classical wave devices that are able to host non-Hermitian skin effect but inert to magnetic fields.

Nontrivial point gap topology that is unique to non-Hermitian physics has led to the non-Hermitian skin effect (NHSE), where most of eigenstates accumulate at the boundaries. Contrary to NHSE, pseudomagnetic fields (PMFs) which are constructed from spatially varying artificial gauge fields can induce Landau levels and associated bulk-localized modes in magnetic-free systems. Considering both localization mechanisms, how will NHSE and PMF interact if they are present in a single system? Recent theoretical studies show that magnetic fields can lead to a suppression of the NHSE: with an increasing magnetic field, the skin modes are gradually pushed into the bulk [1, 2]. Compared to magnetic field that interacts with charged systems, current platforms for realizing the NHSE are mostly magnetically inert. This separation in physical systems poses a challenge in utilizing the competition between the NHSE and magnetic field.

Instead of a real magnetic field, we show that a PMF can also suppress the NHSE in this work. As illustrated in Fig. 1, we construct a two-dimensional lattice model with both NHSE and a PMF, induced by nonreciprocal hoppings and inhomogeneous hoppings, respectively. The NHSE can occur in either x or y direction, depending on directions of nonreciprocal hoppings. The PMF is applied via y dependent J_1 hoppings, thus generating a spatially uniform PMF that is directly proportional to η:

$$J_1(y) = J_2 + 2t\cos\left[\frac{1}{2}\left(\frac{\pi}{2} - \frac{2\pi y}{N_y}\eta\right)\right], \tag{1}$$

When NHSE is along x-direction, we demonstrate the suppression via calculation of skin topological area S_1, which is the weighted sum of winding number $w(E_0)$ in the complex energy E_0 plane:

$$w(E_0) = \frac{1}{2\pi i}\int_{-\pi}^{\pi} dk_x \frac{d}{dk_x}\log\det\left(\mathcal{H}(k_x) - E_0\right), \tag{2}$$

As shown in Fig. 2, the reduction of S_1 signifies the overall weakening of $w(E_0)$, therefore elucidating the suppression of NHSE from its topological origin.

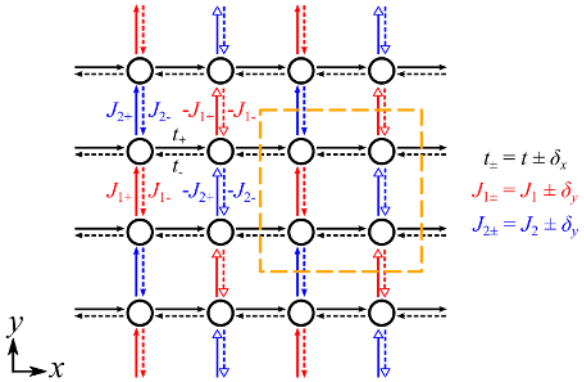

FIG. 1. Illustration of the lattice model. The solid and dashed arrows denote hoppings along opposite directions, with the colors indicating different hopping strengths. Due to the presence of negative hoppings, there is a π gauge flux per plaquette. The yellow dashed box denotes the unit cell.

On the other hand, by starting from y directional NHSE, we demonstrate the suppression via calculations of skin mode profiles and Landau level spectrum as depicted in Fig. 3. The suppression is prominent for energies within the first few Landau levels, where the effective theory of the PMF stays valid. In addition to the transition from skin mode to Landau mode, the zero-energy eigenstate even shows a sublattice polarization that captures the states of different origins at distinct sublattices, thus highlighting its uniqueness in PMF systems.

As a result, our model can be directly mapped to realistic physical settings in photonic, acoustic and circuit systems, therefore paving a novel way to localization control for classical wave devices. In future works, it would be desired to further apply the tunable skin modes found here to various classical wave devices, especially in optical systems where active control of localization and nonlinear effects can be studied.

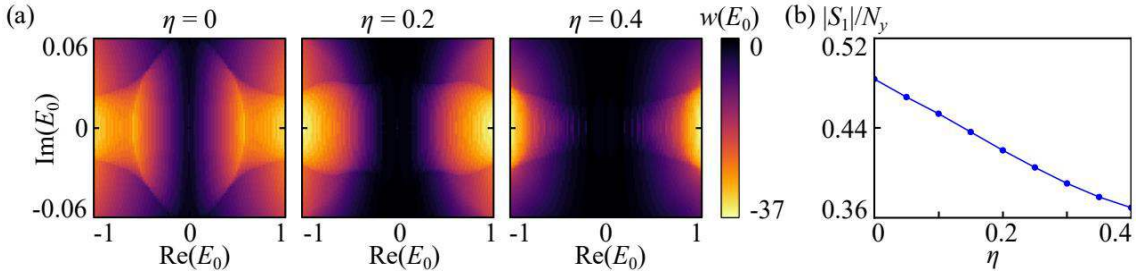

FIG. 2. (a) Plots of winding number $w(E_0)$ against PMF indicator η in the complex reference energy plane [Re(E_0), Im(E_0)] at (δ_x, δ_y) = (0.05, 0). The color indicates the magnitude of winding number $w(E_0)$ obtained from a strip of N_y cells along y direction, but infinite along x direction. (b) Skin topological area per unit cell S_1/N_y as a function of PMF indicator η, computed in a similar supercell as panel (a).

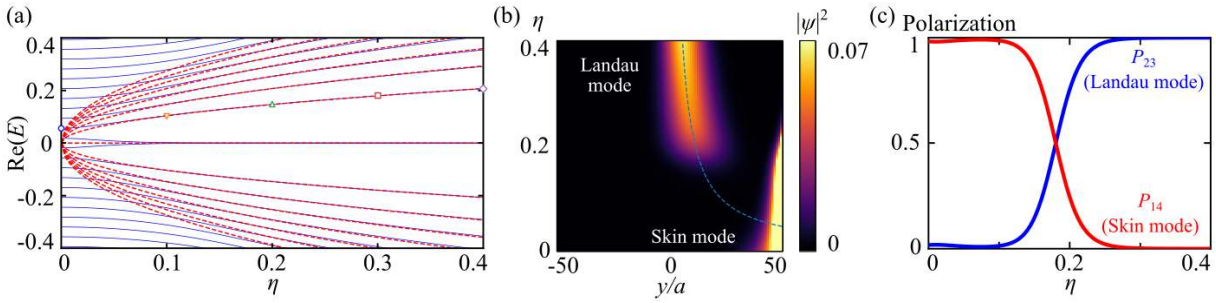

FIG. 3. (a) Real part of the energy spectrum as a function of η at the $k_x = \pi/2$ valley and fixed non-Hermitian components (δ_x, δ_y) = (0, 0.05). Landau levels of lower orders in the Hermitian limit are included as red dashed lines that agree with computed spectrum at large PMFs. (b) Spatial variation of the eigenstate characterized by zero energy at different PMFs with fixed δ_y, showing a transition from skin mode to bulk-localized zeroth Landau mode as theoretically predicted by its center (blue curve). (c) Sublattice polarization of the eigenstate in panel (b). P_{14} and P_{23} quantify the probability distributions which concentrate at each pair of the sublattices respectively, at the same time quantifying the dominance of skin mode and Landau mode at different η.

Probing the spatial and temporal decay of quasimodes in non-Hermitian Vogel spirals via localization maps

Abstract: We investigate the temporal and spatial properties of the quasimodes of non-Hermitian Vogel spiral planar arrays. The analysis of the localization maps reveals that optical quasimodes with three types of spatial decay coexist in these deterministic aperiodic structures: exponential, Gaussian and power-law decay. On average, the Gaussian ones are found to be the most spatially and temporally localized. In addition, our results provide the first direct demonstration of critical quasimodes in Vogel spirals.

Aperiodic metamaterials, whose structural order lie in between periodic and disordered media, have emerged as an alternative photonic platform [1-3]. Among them, Vogel spirals stand out as prominent examples due to being generated by simple, deterministic mathematical rules and to their unusual optical properties [1,2,4]. They consist of planar arrays of scatterers (*e.g.*, dielectric or metallic nanoparticles) whose positions in polar coordinates are given by $r_n = a_0\sqrt{n}$, $\theta_n = \alpha n$, where $n = 1, 2, 3, ...$ The scaling factor a_0 determines the average interparticle separation, while the divergence angle α allows interpolating the structural properties between short-range correlated amorphous systems and uncorrelated random ones.

Remarkably, a transition to light localization has been predicted to occur in non-Hermitian (*i.e.*, open) Vogel spiral arrays [4], despite the fact that Anderson localization of light for randomly distributed dipoles does not occur in 3D [5]. In this work we investigate the spatial and temporal localization properties of Vogel spirals. Their quasimodes ψ_n are obtained using the Green's matrix method [2,4,5]. The spatial decay of the quasimodes are characterized by the localization maps [6]. The analysis consists of calculating their normalized participation ratios $q_n = \mathrm{PR}_n/N$ and structural entropies, which are defined as

$$S_{str_n} = -\sum_{i=1}^{N}|\psi_n(i)|^2 \ln|\psi_n(i)|^2 - \ln \mathrm{PR}_n \quad (1)$$

The relation between these two quantities allows us to predict the existence of quasimodes of arbitrary types of spatial decay by comparing the results to the corresponding references curves [6]. Furthermore, we access information regarding the temporal localization of each quasimode by determining its normalized decay rate g_n, that quantifies modal overlap [5].

In Figure 1 the localization maps for four types of Vogel spirals (*i.e.*, different divergence angles α) are shown. The maps reveal that these arrays support a rich variety of localized quasimodes. In particular, we verify the coexistence of modes with exponential, Gaussian, and power-law decay, as indicated by the reference

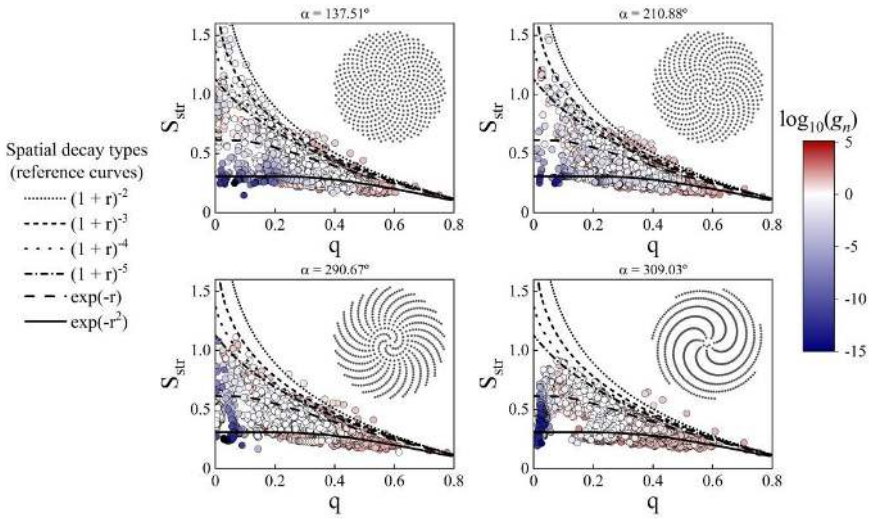

Figure 1. Localization maps: structural entropy S_{str} as a function of the normalized participation ratio q of all quasimodes of different Vogel spiral arrays (depicted in the insets) with $N = 5000$ point scatterers and optical density $\rho\lambda^2 = 30$. The maps are color coded according to the $\log_{10}$ values of the normalized decay rate g_n.

curves. Modes with exponential decay are usually associated with Anderson localization in disordered systems, but here we show that they can also exist in deterministic aperiodic Vogel spirals. Nonetheless, we find that, on average, the quasimodes with Guassian decay are not only the most spatially localized (smallest participation ratios) but also the most temporally localized (smallest decay rates, for which $g_n \ll 1$). In addition, the localization maps show that quasimodes with power-law decay do exist in Vogel spirals, with a broad range of spatial extents. These modes, known as critical modes, typically exist in aperiodic systems and were believed to occur in Vogel spirals, but had not been directly demonstrated so far [1,2,4].

Abstract: An efficient strategy to design localized modes in photonic structures is to use the interplay of constructive and destructive interference in periodic photonic lattices. Here, we show experimentally that in lattices of lossy resonators, the addition of external optical drives with a controlled phase enlarges the possibilities of manipulating interference effects and allows for the design of novel types of localized modes with footprints down to a single site.

The engineering of localised modes in photonic structures is one of the main targets of modern photonics. An efficient strategy to design these modes is to use the interplay of constructive and destructive interference in periodic photonic lattices. This mechanism is at the origin of defect modes in photonic bandgaps, bound states in the continuum and compact localised states in flat bands. In this presentation we show that in lattices of lossy resonators made of coupled semiconductor micropillars, the addition of external optical drives with controlled phase enlarges the possibilities of manipulating interference effects and allows designing novel types of localised modes [1]. We show that light can be localised down to a single site of a photonic lattice in a fully reconfigurable manner. We use the technique to engineer dissipative solitons in topological gaps [2].

The localized modes reported here are fully reconfigurable and have the potentiality of enhancing nonlinear effects and of controlling light–matter interactions with single site resolution

Non-Hermitian Spin-Hall Effect in Topological Metasurfaces

Abstract: We demonstrate that, for suitable trapping one-dimensional Dirac potentials, there exist guided modes exhibiting spin-dependent field distributions, which may give rise to their different coupling efficiency to the radiative continuum or light-matter coupling properties. For leaky open Dirac metasurfaces this should manifest in different transport and radiative properties of modes of opposite spin – the non-Hermitian spin-Hall effect. We use silicon nanophotonic metasurfaces that support pseudo-spin degree of freedom as a testing platform to experimentally confirm such spin-dependent non-Hermitian properties of spin-full photonic Dirac waveguides.

The Dirac equation is a paradigmatic model that describes a range of intriguing properties of relativistic spin-½ particles, from the existence of antiparticles to Klein tunneling. However, the Dirac-like equations have found application far beyond the original scope and have been used to comprehend the properties of graphene and topological phases of matter. In the field of photonics, the opportunity to emulate Dirac physics has also enabled topological photonic insulators. In this work, we demonstrate that judiciously engineered synthetic potentials in photonic Dirac systems can offer physical properties beyond both the elementary/quasi-particles' and topological realms. Specifically, we introduce a new class of optical "Dirac waveguides", whose guided electromagnetic modes are endowed with pseudo-spin degree of freedom. When combined with the ability to engineer synthetic gauge potentials acting on it, the pseudo-spin enables control over the guided modes which is unattainable in conventional optical waveguides. In particular, we use silicon nanophotonic metasurfaces supporting pseudo-spin degree of freedom as a testing platform to predict and experimentally confirm a spin-full nature of the photonic Dirac waveguides. We also demonstrate that, for suitable trapping potentials, the guided modes exhibit spin-dependent field distributions, which gives rise to their distinct transport and radiative properties. Thereby, the Dirac waveguides manifest spin-dependent radiative lifetimes – the non-Hermitian spin-Hall effect – and open new avenues for spin-multiplexing, controlling characteristics of guided optical modes, and tuning light-matter interactions with photonic pseudo-spins.

The demonstrated pseudo-spin-dependent trapping and guiding of light opens a completely new direction for applications of photonic pseudo-spins, beyond topological concepts. We anticipate that the spin-full nature of the modes will find its use in on-chip quantum photonic devices where quantum information could be encoded by a photonic pseudo-spin. The spin-dependent field distributions and quality factors of the modes can also be used for selective (e.g., polarization dependent) control of

light-matter interactions on a photonic chip, which envisions novel design principles of polaritonic, active, and nonlinear photonic devices.

Figure 1. Higher order exceptional points in photonic lattices

Dimitrios Kaltsas[1,2], Ioannis Komis[2,3], and Konstantinos G. Makris[1,2]

Abstract: Higher order exceptional points (HEPs), are unique characteristic degeneracies of non-Hermitian systems. We provide a systematic method for constructing infinite optical lattices that exhibit HEPs. The spectral properties-sensitivity of these lattices around HEPs is investigated in terms of pseudospectra theory, along with the topological character of the corresponding bands. Recent results concerning conservation laws in non-Hermitian systems and their relation to HEPs, will also be presented.

Open systems under the effect of dissipation and/or amplification, are effectively described by non-Hermitian Hamiltonians. One of their most important features is the existence of unique non-Hermitian degeneracies [1] or exceptional points [2], where two or more eigenvalues and eigenvectors coalesce for particular values of the system's parameters. One special class of non-Hermitian Hamiltonians are these that respect parity-time (PT)-symmetry. In the past years, in the context of non-Hermitian photonics [3] various PT-symmetric systems with higher order exceptional points have been experimentally demonstrated and used to design ultra sensitive sensors [4]. However these exceptional points are usually studied in finite lattices of few elements. In the first part of the talk, we will present a systematic methodology of constructing infinite one-dimensional optical lattices that exhibit higher order exceptional points. The appropriate gain-loss distribution is determined analytically for HEP's of various orders. In the second part of our talk, we will present the pseudospectra [5, 6] of the associated infinite lattices around the HEP's and relate them to the lattice's sensitivity to external perturbations. At the end, we are going to discuss recent results regarding the existence of conservation laws in non-Hermitian systems.

Let us start by considering one dimensional trimerized lattices, that are described by the following 3-by-3 bulk momentum Hamiltonian of the form:

$$H=\begin{bmatrix} i\gamma & t_1 & t_2 e^{ik} \\ t_1 & 0 & t_1 \\ t_2 e^{-ik} & t_1 & -i\gamma \end{bmatrix} \qquad (1)$$

This matrix describes a three-cell periodic lattice where γ, t_1, t_2 are real and k is the Bloch wavenumber $k \in [-\pi, \pi)$. For, $k=\pi/2$ the three values of the propagation eigenvalues λ are equal to zero and the eigenvectors coalesce. Indeed we can show that this is an HEP of order three, meaning EP3. Note that although we only consider the bulk momentum Hamiltonian that exhibits an EPN with N=3, this method can be generalized to derive a lattice with an EPN from a suitable N-by-N bulk momentum Hamiltonian.

Our computational results for N=3, and coupling constants $t_1=1$ and $t_2=2$ are shown in Fig.1. In particular the real and imaginary parts of the three bands versus the gain-loss amplitude, γ are shown in Fig.1 (a), (b), respectively. We have also analyzed the sensitivity of the system to external perturbations by using pseudospectra methods [5, 6]. More specifically, by adding a random matrix E such that $\|E\| < \varepsilon$ -where $\| \cdot \|$ denotes the norm of the matrix- to the bulk momentum Hamiltonian, and calculating the union of all the resulted spectra, we get a pattern in the complex plane, called pseudospectrum (Fig.1(c)). The blue dots are the pseudoeigenvalues of an ensemble of 1000 perturbed bulk momentum Hamiltonians, for $\varepsilon = 2 \cdot 10^{-3}$. The red dots are the actual eigenvalues that form the EP3. Finally, in Fig. 1(d) we numerically evaluate the pseudospectral abscissa A_ε, that provides a measure of the sensitivity of the lattice for different values of ε [6]. The slope of the linear fit is $\approx 1/3$, which is a characteristic signature of an EP3 [2, 4]. We have also

extended our methodology to higher orders and thus constructing lattices that exhibit EP4 and EP7.

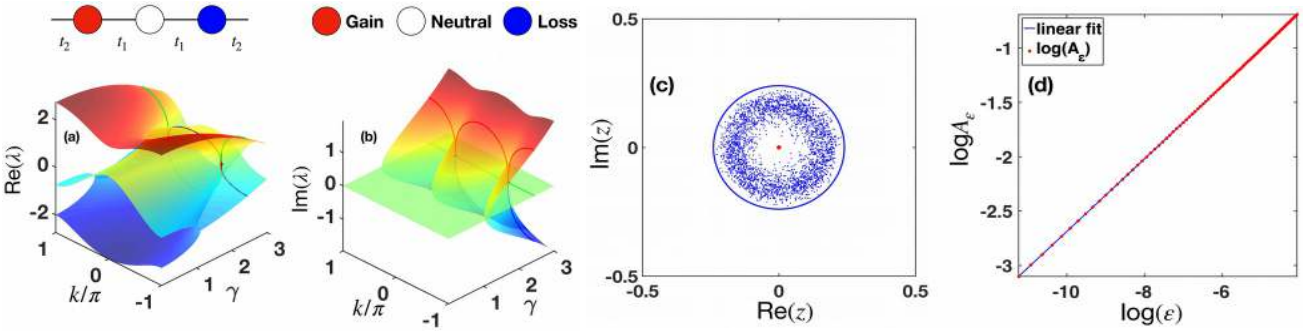

Figure 1: Bandstructure and sensitivity of the system. The values of the coupling coefficients have been chosen to be t_1=1 and t_2=2. (a), (b) Real Re(λ) and imaginary Im(λ) part of the three bands vs the Bloch wavenumber k/π and vs the gain/loss amplitude γ, respectively. (c) The red dots are the exact three eigenvalues that form the EP3 in the complex plane. The blue dots denote the pseudospectrum for $\varepsilon = 2 \cdot 10^{-3}$. The solid blue line is the pseudospectrum calculated by a singular value decomposition method [6]. (d) Pseudospectral abscissa A_ε for different values of ε, in logarithmic scale. The slope is 1/3, as is expected for an EP3.

In conclusion, we have introduced a systematic method [7] to construct infinite optical lattices that exhibit EPs of higher order. In particular, we have considered trimerized and tetramerized non-Hermitian lattices that exhibit EP3 and EP4, respectively. Our methodology is quite general and can be applied to even higher orders (we have numerically verified our method up to N=7). Notice that the corresponding finite lattices with periodic boundary conditions, exhibit the same HEPs, thus making our results relevant to experimental realizations. Our novel complex lattices are directly related to non-Hermitian optics and topological physics, since on the one hand they can be used to implement ultra sensitive sensors and on the other hand, can be used to identify new topological phases in the complex plane.

Metasurfaces for Nonlinear and Ultrafast Nanophotonics

META 2023, PARIS - FRANCE, JULY 18 – 21, 2023

Broadband control of topological-spectral correlations in space-time beams

Abstract: We introduce shaping and characterization methods for femtosecond space-time beams with broadband correlations between their topological charges (up to L=80) and spectral frequencies (covering nearly 50% of the visible spectrum).

The synthesis of ultrashort wave packets with simultaneously tailored spatial and temporal properties has seen tremendous advances in recent years [1], following progress in both wavefront and pulse shaping. This is part of a more general trend towards multimodal photonics [2], in which more and more degrees of freedom of light are combined together to attain unprecedented light fields. In the realm of space-time beams, of particular interest are wave packets carrying orbital angular momentum (OAM) with a topological charge ℓ. Many fascinating demonstrations of these beams have appeared so far, including time-varying OAM beams [3, 4], spatiotemporal optical vortices with transverse OAM [5], light coils [6, 7], and revolving-rotating beams [8]. Most of these schemes, however, were limited to small topological charges and/or narrow spectral bandwidths. By changing the geometry of our Fourier space-time synthesizer and fabricating custom grayscale optical phase plates, we demonstrate here the shaping of space-time wave packets with correlations between a wide band of topological charges, with values up to $\ell = 80$, and spectral frequencies covering nearly 50% of the visible spectrum. The broadband nature of these correlations brings unprecedented capability in the tailoring of OAM-carrying space-time beams on a femtosecond scale.

We characterize [9] this new family of space-time beams both by means of an established technique based on axis interference and cross-correlation, as well as by introducing a spatially-resolved spectral method. The latter relies on the combination of two interferometers, a temporal one based on the translating-wedge-based identical pulses encoding system (TWINS) [10] and a spatial one based on off-axis interference. This provides a temporal interferogram for every pixel of the camera from which we can obtain spectral interference images and carry out off-axis digital holography. As a result, we obtain a hypercube with the intensity and phase of the spectral components of the shaped femtosecond pulse. This allows us to experimentally characterize the topological-spectral correlation, which is observed to closely follow our design.

With our technique we can generate both separable and nonseparable space-time beams carrying OAM. The first one corresponds to a separable pulsed vortex, in which all spectral frequencies carry the same topological charge, $\ell = 40$. On the other hand, the second light field can have the profile of a light coil [6] (or helical wave packet) and exhibit an azimuthally-dependent pulse arrival time. We use this technique to generate a variety of space-time beams with both linear and nonlinear topological-spectral correlations. The former allow us to control the chirality, orbital radius, intertwining and multiplexing of helical wave packets,

while the latter allow us to manipulate their dynamics. We foresee that our space-time shaping method will find its use in several applications allowing: the transfer of OAM to matter, such as in Raman-active media at the core of laser- plasma accelerators; the imaging of ultrafast electronic processes, thanks to the mapping of time to space carried out by these wave packets; and the increase of the capacity of optical communication channels, thanks to OAM-frequency division multiplexing.

Abstract: We experimentally demonstrated the near-infrared to visible imaging, based on the third-order generation processes, by designing a silicon membrane metasurface supporting symmetry-protected bound states in the continuum.

Nonlinear nanophotonics has been attracting tremendous attention due to its vast applications in sensing, optical microscopy, and quantum photon source generation. Nonlinear metasurfaces have been recognised as a potential substitute for commercial infrared (IR) imaging and spectroscopy detectors because of their superiority of being ultra-compact and containing fewer components for signal conversion [1]. Here, we propose silicon membrane metasurfaces with smaller unit-cell sizes (Fig. 1a) to enhance local light confinement and to increase the conversion efficiency and spatial resolution of the third-harmonic generation (THG) in IR imaging applications [2].

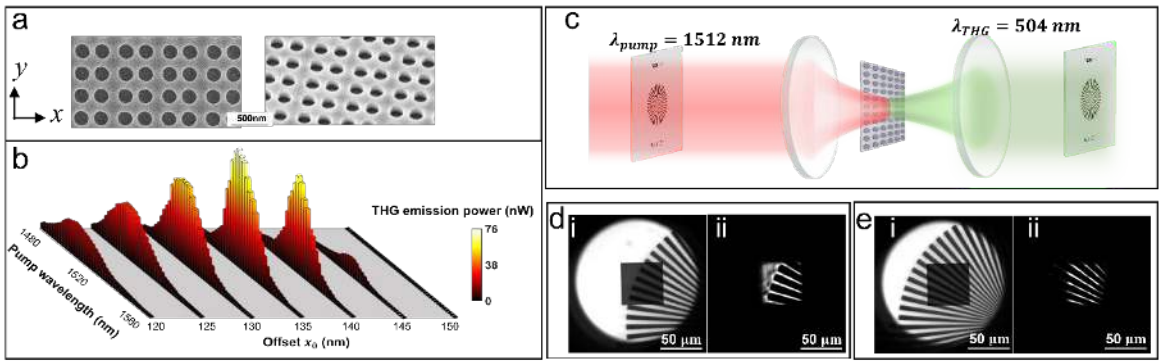

Fig. 1 (a) SEM image of the fabricated metasurface sample. (b) Experimentally measured THG spectra of the samples with different offset x0. The offset x0 is defined as the distance from the center of one hole to the midline of the unit (with a dimer hole) along the x direction. (c) Schematic of THG imaging based on Si membrane metasurfaces. The near-IR signal passes through the target, then is converted into the visible signal via the metasurfaces, forming the target image on the CCD camera. (d, e) The images of the target and the metasurfaces under (i) white light source illumination. (ii) Transformed visible images of the target via membrane metasurfaces under NIR light illumination.

We theoretically and experimentally demonstrate the formation of different types of bound states in the continuum (BIC) from silicon dimer-hole membrane metasurfaces to achieve nanoscale light manipulation with strong electromagnetic field confinement. By tuning the gap between the two holes, the symmetry-protected BICs can be transformed into quasi-BICs with a tuneable Q-factor, which can directly affect the conversion efficiency (see Fig. 1b). We experimentally obtained a significant THG enhancement near the resonance, leading to a conversion efficiency of 3.6×10^{-6} under a pump peak intensity of 1.0 GW/cm^2. Importantly, compared to classical metasurfaces composed of the periodic arrangement of nanoparticles, our silicon membrane metasurface supports resonances with a smaller unit-cell size and a larger mode volume, providing a powerful platform for nonlinear imaging applications. Figures 1c-e demonstrate the ability of THG imaging with our designed metasurface. Under a pump at a wavelength of 1512 nm, an image of the NBS 1963A resolution target is formed by the focal lens onto the metasurface (see Fig 1c). The pattern of the overlapping area between the image of the target and the metasurface, shown in Fig. 1d and e, can be clearly converted to visible images at a wavelength of 504 nm. The quasi-BIC metasurface significantly boosted the THG emission intensity as compared to the silicon slab area (the dark background), where our camera can detect no sizeable nonlinear emission.

In summary, we experimentally demonstrated the conversion of the invisible image to the visible based on the THG process with the designed silicon metasurface. Our results suggest a new paradigm for realising efficient nonlinear photonics metadevices and extending the applications of nonlinear nanoscale photonics to new types of imaging technologies.

Abstract: We demonstrate experimentally that a strongly enhanced generation of spatially entangled photon pairs can be achieved from metasurfaces supporting nonlocal double resonances at the signal and idler wavelengths, and reveal that multiplexed metagratings featuring different orientations allow the engineering of bi-photon polarization states and optically controllable generation of arbitrary polarization qutrits. Furthermore, leveraging the exceptional capabilities of the metasurface, we present a combined quantum ghost and scanning imaging protocol allowing 2D imaging with a 1D detector array.

Quantum entanglement underpins a broad range of fundamental physical effects [1] and serves as an essential resource in various applications. In optics, the most common source of entangled photons is based on the spontaneous parametric down-conversion (SPDC) process in quadratically nonlinear materials. Dramatic enhancements of nonlinear light-matter interactions were achieved in nanofabricated structures with subwavelength thickness known as metasurfaces [2], which are also bringing advances to the field of quantum optics [3, 4]. The generation with metasurfaces of photons entangled in spatial and polarization degrees of freedom and their applications are currently active research topics.

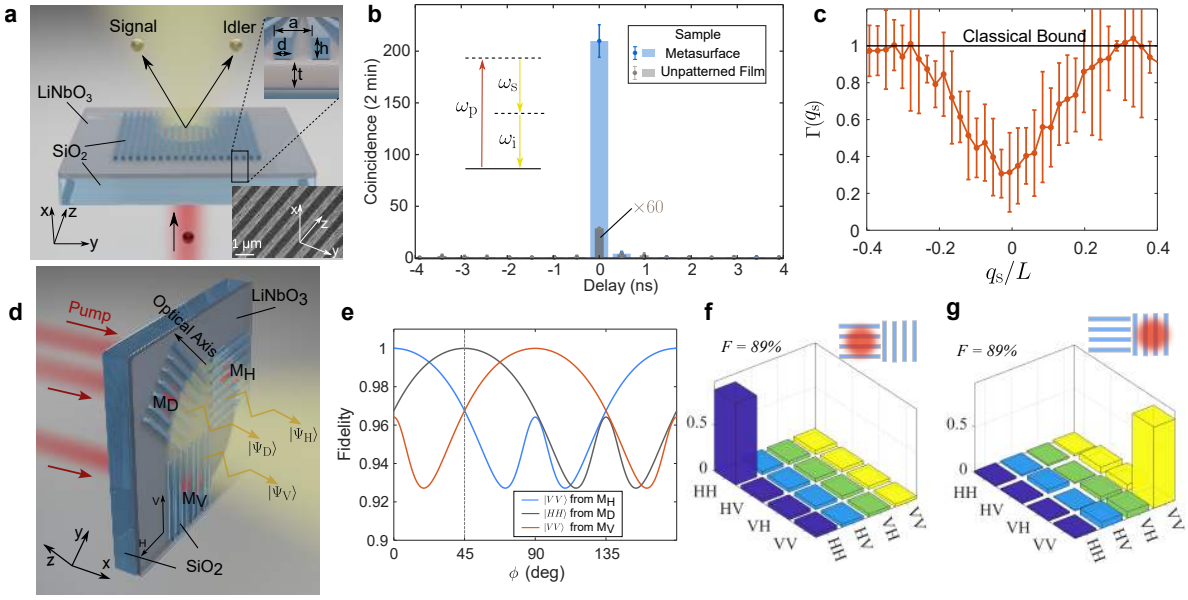

Fig. 1. a Sketch of spatially entangled signal and idler photons generation from a $LiNbO_3$ thin film covered by a SiO_2 metagrating and pumped by a continuous laser. Inset shows the SEM image of the metasurface. **b** Coincidence histograms of SPDC from metasurface and unpatterned film. **c** Violation of Cauchy-Schwartz inequality for values below the classical bound. **d** Sketch of generation of polarization-entangled photon pairs with multiplexed metagratings (M_H, M_V, and M_D) in a metasurface. **e** Fidelity of polarization states generated from metagratings vs. optical axis orientation angle ϕ. **f-g** Experimentally reconstructed density matrix of polarization state from metagratings M_H and M_V.

Here we report the experimental generation of spatially entangled photon pairs through SPDC from a metasurface incorporating a lithium niobate nonlinear thin film of 300 nm thickness [5], see Fig. 1**a**. We measure the correlations of photon pairs and identify their spatial anti-bunching through violation of the classical Cauchy-Schwartz inequality [Fig. 1**c**], witnessing the presence of multi-mode entanglement. Simultaneously, the photon-pair rate is strongly enhanced by 450 times as compared to unpatterned films [Fig. 1**b**] due to high-quality-factor resonances.

Additionally, we present an original approach for engineering photon polarization states with a nonlinear metasurface and preparing polarization Bell states and qutrits with arbitrary amplitude and phase, thereby overcoming the fundamental limitation of an unpatterned nonlinear crystal. We develop a single metasurface incorporating multiplexed linear metagratings with different orientations, as sketched in Fig. 1**d**. Since each metagrating selectively

enhances the generation of photon pairs that are linearly polarized along the grating direction (see Fig. 1**e**), one can produce desired polarization states by controlling the grating orientation, unrestricted by the form of quadratic susceptibility tensor in unpatterned nonlinear materials. As an example, we fabricate two orthogonal metagratings oriented at $\pm 45^\circ$ from the optical axis of $LiNbO_3$. The experimental reconstruction of the density matrix confirms the polarization state engineering of photon pairs with metagrating orientations (Fig. 1**f**-**g**).

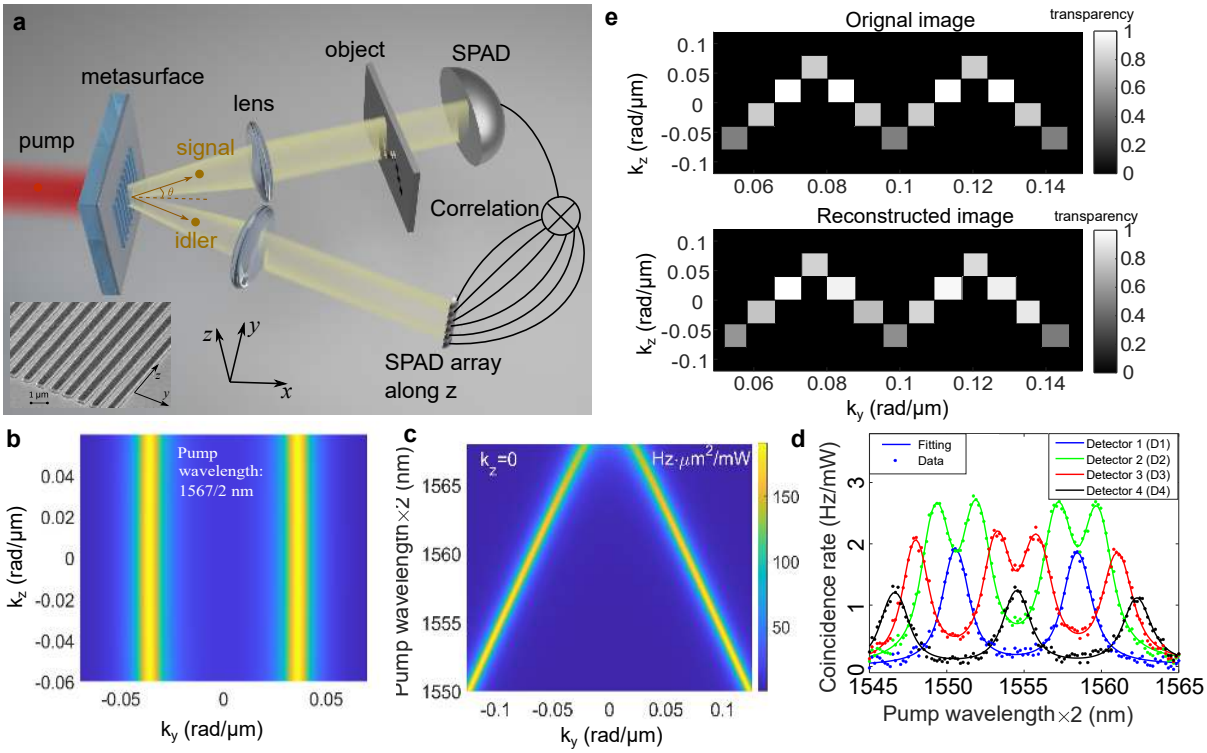

Fig. 2. a Quantum imaging system based on nonlinear lithium niobate metasurface photon-pair source. **b** Simulated emission pattern of photon pairs at a pump wavelength of $1567/2$ nm. **c** Predicted tunability of the photon emission along k_y via the pump wavelength. **d** Simulated coincidences with a four-detector array in the 'idler' arm, for the 'M' shape object in the 'signal' arm. **e** Comparison of the original (top) and reconstructed (bottom) object images.

Furthermore, using the unique benefits of the fabricated metasurface shown in Fig. 1**a**, we reveal, for the first time to our knowledge, the practical potential of quantum imaging, facilitating an efficiently combined ghost and all-optical scanning imaging protocol. The schematic setup is represented in Fig. 2**a**, where the metasurface generates spatially entangled signal and idler photons, featuring two unique properties: (i) the photon emission is narrow in y- yet broad in z-direction (Fig. 2**b**) and (ii) the emission angle in y-direction can be all-optically scanned by simply tuning the pump beam wavelength (Fig. 2**c**). Using these features, we can image an object placed in the 'signal' arm. A single-photon bucket detector and a 1D array of detectors are put in the 'signal' and 'idler' arms respectively, allowing ghost imaging in the z-direction and all-optical scanning in the y-direction. Considering an 'M'-shape object as an example, we simulate the correlations between the 1D detector array and the bucket detector across a range of pump wavelengths (Fig. 2**d**). We use the correlations data to perform the full reconstruction of the 2D object image, which closely reproduces the original pattern (Fig. 2**e**). We also verified that the reconstruction is robust under experimental conditions [5], accounting for measurement noise and fabricated metasurface dimensions.

These results pave the way towards miniaturization of various quantum devices by incorporating ultra-thin metasurfaces functioning as room-temperature sources of quantum-entangled photons, opening the door to various applications including quantum imaging.

Abstract: We have demonstrated an electrical-driven micro-electro-mechanical (MEMS) empowered dynamic optical metasurface platform for dynamic polarization control with high modulation efficiencies and fast speed by leveraging the commercially available piezoelectric MEMS technique.

Metasurfaces have attracted increasing attention due to their unprecedented capabilities of molding classical light, thus promising potential applications in integrated photonics with ultracompact footprints and multiple functionalities [1]. Despite significant progress, most existing metadevices to date are passive and lack real-time dynamic modulation post-fabrication. Therefore, it is highly desirable to realize tunable metasurfaces with functionalities actively controlled by applying external stimuli, which are promising for more intelligent and adaptive systems. In this talk, I will talk about a piezoelectric MEMS-empowered dynamic metasurface waveplate with high polarization conversion efficiencies (~ 75%), broadband operation (~ 100 nm near the operating wavelength of 800 nm), fast responses (< 0.4 ms) and full-range birefringence control that enables complete encircling Poincaré sphere along trajectories [2].

Abstract: Subwavelength resonators can enhance nonlinear optical response of laser-excited semiconductors by several orders of magnitude, provide ideal conditions for accessing and exploring qualitatively new physics beyond the perturbative regime, and serve as nanoscale sources for nonlinear frequency conversion. Nonperturbative generation of higher harmonics can be observed in a single subwavelength resonator supporting bound states in the continuum excited by an ultrashort mid-infrared laser beam. Our experimental observations are supported by numerical simulations based on nonperturbative model for electronic excitation.

Since decades, the optical physicists have been interested in quadratic and cubic nonlinear optical responses of materials and the methods to enhance and to control over the nonlinearity. High-intensity ultrashort laser pulses in ultraviolet/near-infrared wavelength range suited well for this purpose, albeit the high-order harmonics were mainly generated in laser-induced plasmas in gases and ablation plasma plumes, but not in bulk solids. The observation of non-perturbative high-order spectra, spanning up to the 25th harmonic, in ZnO bulk crystal by applying high-intensity mid-infrared laser [1] has opened new opportunities, as well as encouraged for new theoretical insights to describe the electronic excitation and harmonic generation beyond perturbation theory.

Simultaneously, subwavelength nanostructures were extensively used to enhance further the nonlinear optical response, starting from plasmonic gratings and bowtie antennas to confine the electric fields at the nanoscale and directing towards semiconductor nanostructures of high refractive index, supporting high-Q resonances, exhibiting comparable nonlinearity but having lower absorption losses. A considerable improvement of nonlinear conversion efficiency was provided by resonant metasurfaces, consisting of periodic arrangement of meta-atoms, supporting Mie, collective lattice and Fano resonances, and, most recently, bound states in the continuum [2].

Recent experiments on high-order harmonics benefit from both state-of-the-art concepts, exploring the ultrashort excitation of resonant semiconductor nanostructures with high-intensity mid-infrared laser pulses [3-5]. However, the sizes of the metasurfaces have remained relatively large in the two lateral dimensions. A novel concept to overcome this limitation by using a single subwavelength AlGaAs resonator, hosting quasi-bound states in the continuum mode, has been proposed in our recent work, enabling to generate harmonic spectra up to the 7th harmonic [6]. High-order harmonics show clear signatures of non-perturbative behavior such as weaker power law scaling than expected from the perturbative theory.

We support our findings by implementing a full-vector Maxwell-based approach with a nonlinear current, describing the response of photo-excited carriers. The calculated high harmonics spectra are enhanced by several

orders of magnitude comparing to the unstructured sample, non-resonant geometry or off-resonant laser irradiation conditions. Our simulations indicate that the nanoscale confinement of electron plasma inside subwavelength resonator is at the origin of pronounced non-perturbative odd harmonics. We have analyzed the contributions of the photo-excited carriers (non-perturbative origins) and of the cascaded frequency mixing of 2nd and 3rd harmonics alone (perturbative origins) and reveal that in our settings the odd-order harmonics are favored over the even-order harmonics.

Combining metaphotonics and nonlinear optics, extending to quantum optics of semiconductors to describe both optical and electronic properties beyond the perturbative regime, would be a next challenging step, opening up new perspectives for selective control over the generated harmonics and their polarization state and for ultrafast optical switching and resonance tuning at the nanoscale.

Abstract: High refractive index metasurfaces represent a promising research area of nanophotonics and light–matter interaction at the nanoscale. In this work, we report our recent progress concerning tunable nonlinear dielectric metasurfaces. We discuss the main physical phenomena enabling the dynamic control of the nonlinear process and compares the temporal dynamics of the different adopted approaches.

Dielectric and semiconductor nanostructures emerged as excellent candidates for nanophotonic applications. The possibility to engineer their radiated fields and the capability to govern the polarization of the emitted light with very low losses compared to metallic nanodevices, in the near-infrared and visible region of the electromagnetic spectrum, have gained significant attention in the nanophotonic community [1].

In this regard, the resonant enhancement of the fields inside semiconductor resonators has been already proved to enhance nonlinear frequency generation. III-V semiconductors such as Gallium Arsenide (GaAs) or Aluminum Gallium Arsenide (AlGaAs) show remarkably high even-order susceptibilities due to the broken central symmetry in their crystal structures. Notably, AlGaAs exhibits a direct gap which increases with the Aluminum molar fraction, enabling two-photons absorption free operation around the third communication window. As a result, efficient harmonic generation of the second order from AlGaAs nano-platforms was recently demonstrated in different static scenarios [2]. However, in several applications including modulators, tunable imaging and active beam shaping, a reconfigurable behavior of the emitted nonlinear signal is desirable.

In this work, we will discuss several promising approaches to dynamically tune the emitted nonlinear signal coming from AlGaAs metasurfaces, including liquid crystal infiltration and exploitation of opto-thermal effects [3, 4]. Finally, we will discuss our newest achievements concerning difference frequency generation in such kind of platforms [5].

Abstract: Thin films of artificially designed materials, e.g. by nanostructuring, are enticing systems for the generation of photon pairs by nonlinear frequency conversion. They can enable control of many properties of the generated photons, as the polarization, spectrum, and propagation direction. The talk will discuss recent results, in particular steps towards the control of the polarization degree of freedom.

Photon-pairs have evolved as a critical resource for quantum technologies, and many applications in quantum communication, imaging, sensing and computing are based on using such quantum states with judiciously designed properties. For many applications, sources of photon pairs are still based on bulk nonlinear crystals, which due to the need for phase matching enable efficient generation only in limited parameter ranges. In the last years, it was demonstrated that also thin films of second-order nonlinear materials can serve as sources of photons pairs by spontaneous parametric down conversion (SPDC), without the need to achieve phase matching [1]. Structuring these films into resonant metasurfaces enhances the generation efficiency while providing a large number of degrees of freedom for controlling the properties of the generated pairs through the geometry of the nanoresonators [2, 3].

For controlling the polarization of the generated pairs, with the aim of realizing polarization-entangled photon pairs, in particular resonant structures made from III-V semiconductors seem promising [4], as their nonlinear tensor couples all polarization components. The talk will discuss recent experiments and simulations that highlight this potential in sum-frequency generation, a classical inverse process to SPDC, which allows to accurately predict the properties of the photon-pairs generated in SPDC.

Alternatively to using the geometry of resonant metasurfaces to control the polarization properties of photon pairs, one can also use materials with specifically chosen nonlinear tensor structures to achieve particular states. One material class with very peculiar nonlinear properties are transition metal dichalcogenides (TMDC), which tensor structure only couples the two in-plane polarization due to the two-dimensional nature of the layered material. Recently, TMDCs became available that conserve the second-order nonlinearity also for crystals with thicknesses in the range of several tens of nm, such that efficient nonlinear interactions can be achieved [5]. I will discuss our progress towards photon-pair generation in such materials.

Abstract: Flat optics has been recently unveiled as a powerful platform to perform data processing in real-time, and with small footprint [1, 2, 3]. So far, these explorations have been limited to linear optics, while arguably the most impactful operations stem from nonlinear processing of the incoming signals. In this context, here we add a new twist and depth to analog optical computing: we demonstrate that nonlinear phenomena combined with engineered nonlocality in flat-optics devices can be leveraged to synthesize Volterra kernels able to perform complex operations on incoming images in real-time.

Metasurfaces have already introduced a paradigm shift for nonlinear optics enabling stronger nonlinearities in thin films and manipulation of the nonlinearly-generated wavefront [4, 5, 6]. In this framework, here we show that it is possible to exploit nonlocal nonlinearities as a powerful tool for analog computing with light waves. We show that using nonlinear nonlocality in flat optics we can realize analog image processing with previously not accessible functionalities. By exploring the simple scenario of a uniform χ_2 thin sheet, we demonstrate edge detection operation with exciting potentials. In our proposed nonlinear flat-optics solution, the non-resonant nature of the nonlinear interaction involved in image processing allows edge detection over a broadband spectrum with ultra–high contrast and superior resilience to noise.

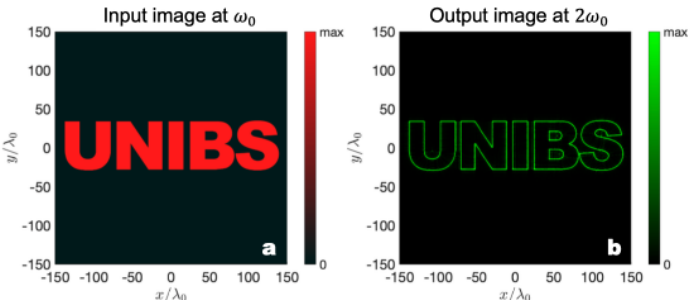

Figure 1: Edge detection with a nonlinear thin film

Our results indicate that Volterra kernels of nonlinear nonlocal flat optics can open new opportunities in applications such as image processing, item recognition for computer vision, and high-contrast, high-resolution microscopy.

Abstract: Light can interact with nanostructured materials giving rise to several physical phenomena, including enhanced electric fields, generation of high energy carriers and heat dissipation. These effects can be manipulated by engineering such materials into optical metasurfaces where the shape, material and arrangement of the meta-atoms, the metasurface building blocks, can be modified depending on the application. This talk reports recent results where nanoscale optical metasurfaces are utilized in diverse systems, targeting extreme electromagnetic energy focusing, light rectification or steam generation.

Conductive nanoparticles interact with electromagnetic radiation through highly confined electronic oscillations named plasmons. Following a series of events, plasmons decay, losing their energy to electron-hole pairs and, eventually, to the particles' lattice as heat, increasing their temperature [1].

Plasmonic oscillations display large field enhancements that can be utilized to redirect radiation at nanoscale locations. Recently we have implemented an optothermal design where metallic bowties antennas connected to a heat sink funnel electromagnetic energy into small thermally insulated and poorly absorptive reactors. Thanks to the antenna plasmonic properties and reactor insulation, the system displayed dramatic thermal gradients, even leading to the reactors melting while leaving the antennas at relatively lower temperatures. The concept paves the way to realizing photothermally asymmetric systems where absorbing elements stay cool while electromagnetically hidden structures heat up [2].

The approach shows particular promise because the capability to generate heat in subwavelength regions can lead to thermal hot spots, improving the efficiency of nonlinear processes. For example, we have shown how water desalination is a nonlinear optical process benefitting from high-temperature regions of limited size with respect to homogeneous thermal landscapes, both achievable with the same input power, showing how light absorption engineering can positively affect thermal processes [3].

In this context, we have recently demonstrated how topologically optimized dielectric metasurfaces can

attain extremely large field enhancements in ultra-confined regions, potentially improving the efficiency of nonlinear optical processes, even at the cost of rejecting part of the input power [4]. Besides light steering, a critical requirement for photothermal processes is the efficient light-heat conversion at the base of the temperature increase. By utilizing arrays of TiN nanocavities, we have achieved the dissipation of about 90% of the solar spectrum within ~250 nm only thick substrates [5], paving the way to ultrathin optothermal devices.

There are applications, however, where heat dissipation is detrimental, and hot carriers should be harnessed before their thermalization. We have shown how the spatial distribution of out-of-equilibrium carriers excited by plasmon decay can be utilized, before their decay, to control the optical properties of nanostructures at the ~ps timescale [6,7]. Additionally, we proved that tapered conical nanoantennas could be fabricated in a point-contact metal-insulator-metal configuration to increase the hot electron extraction process close to the visible by orders of magnitude [8]. While the efficiency of such a light rectification process remains low, our work points to the key role that hot carrier management plays in energy applications.

Abstract: Quantum optical metasurfaces are outperforming their bulk counterparts in terms of multifunctionality. In this talk, I show how quasi bound states in the continuum resonances in semiconductor metasurfaces can be used to engineer entangled photons in several degrees of freedoms, such as frequency and direction of emission.

Optical metasurfaces are playing an essential role in the development of subwavelength-scale devices with multifunctional operation. By exploiting high quality factor resonances, such as quasi bound states in the continuum (qBIC), metasurfaces can enhance nonlinear effects such as harmonics generation, or spontaneous effects like photoluminescence emission from quantum dots. Another promising direction for qBIC resonant metasurfaces in quantum optics is the spontaneous emission of entangled photons. One way to generate entangled photons is via spontaneous parametric down-conversion (SPDC), where a higher-energy photon splits into two lower-energy photons (called signal (s) and idler (i)) upon interaction with a second-order nonlinear material. The three interacting photons (pump, signal and idler) fulfill energy conservation. Here, I am going to discuss our new results on photon pair generation via SPDC driven by qBIC resonances in quantum optical metasurfaces (QOM).

In the first work, we used symmetry-broken GaAs metasurfaces featuring two quasi-BIC resonances in the IR infrared range, as shown by the white light transmittance in Figure 1A (top and central panels). These resonances have different multipolar contributions. The resonance at 1359.4 nm is of electric dipole (ED-qBIC) origin, and resonance at 1429.4 nm has a magnetic dipole (MD-qBIC) electric field distribution [1]. When the QOM is pumped at 725.4 nm, it emits frequency-degenerate photon pairs in the forward direction, as shown in Figure 1A (bottom panel). The outer peaks (see yellow vertical lines) correspond to an SPDC process driven by the ED-qBIC resonance, and the inner peaks (see blue vertical lines) to another SPDC process driven by the MD-qBIC resonance. Because of energy conservation, the QOM emits one photon of a pair at the resonance wavelength (either ED- or MD-qBIC), and the conjugate sister photon is emitted at the wavelength that conserves energy given the pump wavelength. By adjusting the pump wavelength or the resonance wavelength, the QOM can emit frequency-degenerate or non-degenerate photon pairs [1]. This multicolor emission of photon pairs is scalable with the number of resonances in the QOM. For further details see Ref. [1].

In the second work, again we exploited quasi-BIC resonances in GaP metasurfaces. The QOM under study exhibits a resonance at 1184 nm, as shown by the white light transmittance in Figure 1B (top). A principal difference between the GaAs and GaP metasurfaces is that in the former, the resonances appear as peaks in the white light transmission spectrum, while in the latter, the resonance appears as a dip in the spectrum. We pumped the GaP metasurface with a laser centred at 594 nm, and measured the spectrum of the photon pairs emitted in the forward-backward directions, i.e., we collected one photon of the pair in the forward direction, while its conjugate photon is detected backwards, in this way, we perform forward-backward two-photon correlation measurements.

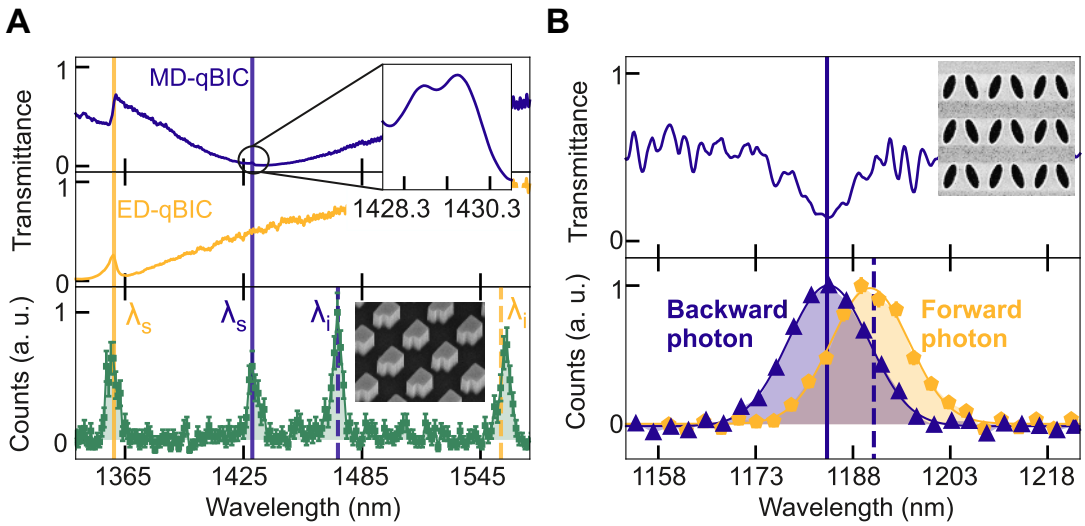

Figure 1. (**A**) White light transmittance (top and central panels) measured in the GaAs metasurface (inset in the bottom panel shows a scanning electron micrograph (SEM)), featuring two qBIC resonances (blue and yellow solid vertical lines). The bottom panel shows the spectrum of the photon pairs emitted by the QOM. The dashed vertical lines indicate the wavelength of the partner photons to the ED-qBIC (yellow) and MD-qBIC (blue) resonant photons. (**B**) White light transmittance (top panel) measured in the GaP metasurface (inset shows an SEM) showing a qBIC resonance at 1184 nm (solid vertical line). The blue and yellow points in bottom panel show the spectrum of photons emitted in the backward and forward directions, respectively. The dashed vertical line indicates the wavelength of the conjugate photon to the resonant one.

The yellow and blue points in Figure 1B (bottom) show the spectrum of the photon emitted in the forward and backward direction, respectively. The QOM metasurface emits frequency non-degenerate photon pairs, where the photon generated by the resonance is emitted in the backward direction, while its conjugate photon is emitted in the forward direction, that is, the QOM demultiplexes the emission of the photon pair, both in direction of emission and wavelength. For further details see Ref. [2].

In summary, our works show that metasurfaces are promising platforms for quantum optical applications. Both features shown here cannot be achieved in standard bulk crystals. The QOMs not only generate photon pairs but also engineer their spectral and spatial properties. The GaAs QOM can be used for the generation of linear graph states [1], while the GaP QOM can be used in applications where heralding one of the photons is crucial.

Stimulated Emission Tomography of Spontaneous Four Wave Mixing from a Metasurface

J. Yang[1], P. Dichtl[1], J. Florez[1], N. Gemmel[1], S. D. Gennaro[1], X. Xiao, C. C. Phillips[1], A. Clark[1,2], and R. F. Oulton[1*]

Abstract: We apply stimulated emission tomography (SET) to assess the ability of individual nanoantennas and their metasurface arrays to generate correlated photon pairs via spontaneous four-wave mixing (SFWM). Following the SET framework, we characterize SFWM by studying four-wave mixing (FWM), producing maps of joint spectral density (JSD) to characterize the bi-photon state. Although a much weaker process than parametric down conversion, SFWM from metasurfaces produces similar photon production rates, and brings the advantage of wider choice of nonlinear materials.

Plasmonic and dielectric nanoparticles have been used extensively for nonlinear optical frequency mixing in recent years due to their broadband field enhancement and the large ultrafast nonlinearities they offer [1,2,3]. Through careful design of the particle resonances and shapes, bespoke nonlinear optical responses can be achieved, such as a second-order response in a non-centrosymmetric arrangement of Au nanoparticles. The control of the nonlinear output can be maximised when arranging the nanoparticles in a metasurface for harnessing the power of designer 'flat optics' with capabilities such as frequency- and polarisation-dependent routing of photons. However, while many proof-of-principle studies have been published on classical coherent frequency mixing of multiple beams, the practical aspects of spontaneous photon pair generation rates in metasurfaces and a comparison with conventional photon pair sources is rarely addressed.

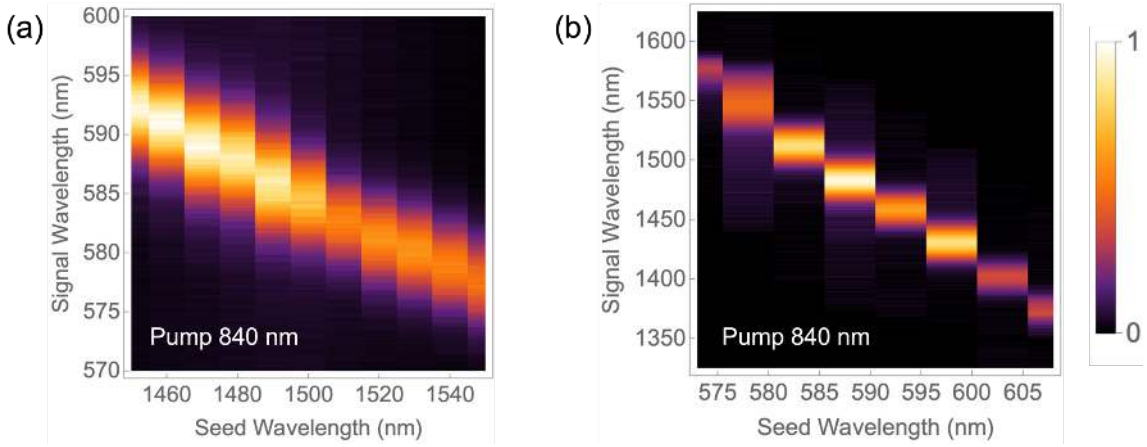

Figure 1. Joint Spectral Density maps for (a) up-conversion and (b) down-conversion Four Wave Mixing spanning 580 nm to 1500 nm.

Here, we apply the Stimulated Emission Tomography (SET) technique to frequency mixing in plasmonic nanoantennae to quantify their expected performance as novel wavelength-agile correlated photon pair sources. Introduced by Liscidini and Sipe [4], SET conveniently enables characterises photon pair generation by studying the corresponding stimulated process, thus bridging the gap between nonlinear optics and quantum optics. We first introduce our sample [5] and setup and explain how the numbers of stimulating and generated photons are determined in our experiment. Next, the classical frequency mixing efficiencies and the estimated spontaneous photon pair generation rates are presented. Below the damage threshold of the particles, we find a generation efficiency for spontaneous parametric down conversion approaching 1 photon pair per second per nanoparticle. This analysis is followed by a characterisation of Joint Spectral Density (JSD), (example shown in Fig. 1) allows us to quantify the spectral entanglement of the biphoton output. Here, the SET technique provides increased spectral resolution, limited only by the spectral width of the stimulating beam, compared to an SPDC experiment with spectrally resolved coincidence measurements. Our sample does not yet offer the ability to directly detect spectrally correlated photons, however, with our experimental capabilities we would be able to easily characterise any of a variety of candidate nonlinear metasurfaces. The paper closes with perspectives on applications as wavelength-agile pair sources for quantum imaging in previously inaccessible wavelength ranges.

Abstract: The aim of this work is to exploit the negative electron affinity of the surface of hydrogenated diamond combined with the excitation of conduction band electrons to induce emission of electrons following the interaction with visible light. Diamond is a very wide band gap semiconductor and therefore interacts weakly with visible light. However, we show that by combining plasmonic nanoparticles with diamond it is possible to excite electrons into the conduction band of the diamond through a multistep process involving at least two visible light photons.

Combining plasmonic metal nanoparticles with wide bandgap semiconductor materials has been demonstrated to be an effective way to sensitise these materials to sub bandgap light.[1] This is often used as a strategy improve the photocatalytic properties of these materials.

In this work we focus our efforts on diamond as it has the very interesting property of having a negative electron affinity at its surface when it is hydrogenated. The result is that when electrons are excited into the conduction band in the vicinity of a diamond/vacuum or, indeed, a diamond/water interface they are ejected from the diamond into the vacuum or water. This property can lead to numerous useful applications such as a cold cathode or as a clean source of solvated electrons. The problem is that diamond has a band gap of 5.5 eV and therefore this process only works with VUV light ($\lambda < 213$ nm).

We have fabricated two separate systems based on the combination of plasmonic nanoparticles with diamond which show that the exciting the plasmonic resonance of the metal nanoparticles can lead to a strong enhancement of the emission of electrons from the diamond surface. The process is demonstrated using an array of nanoparticles embedded below the surface of a thin film of diamond for the emission of electrons into vacuum using visible light. The increased electron emission efficiency was verified by photoemission and photoconducibility measurements. Initial attempts with Aluminium as the plasmonic material were not successful[2] while successive fabrication using silver showed the required properties. The results allow us to hypothesise metasurfaces with properties which could optimise the efficiency of the process. Furthermore, a second system involving nanodiamonds coupled with gold nanoparticles in acqueous solution has been shown to be source of solvated electrons following interaction with visible light. In this case the presence of solvated electrons was verified by using an ultrafast pump-probe experiment in which a visible light pump was used to

excite the plasmon resonance of the gold nanoparticles while the white light probe was used to optically detect the formation of the solvated electron in the first picoseconds after the excitation.

Based on the details of the above measurements we propose a mechanism to explain the results which initially involves the excitation of an electron into empty defect states followed by a second step in which the electron is excited from the defect state into the conduction band.

Abstract: We demonstrate ultra-fast all-optical switching based on the implementation of a metasurface-based laser dichroic mirror design. The crystalline silicon metasurfaces with 100 nm thickness on sapphire substrates are fabricated using established processes in Si-semiconductor industry. Under weak-pump excitation, relative transmittance changes of up to 100% are possible for characteristic times ranging from 25 to 120 ps. A carrier-driven absolute amplitude modulation of over 72% is observed at 102-120 ps relaxation times. A CW 1030 nm laser's beam modulation for free space communication is verified in a laboratory environment.

Novel optical switching [1,2] and wavelength conversion[3]based on optical-metasurfaces have showed a lot of promise for ultra-fast modulation of light. However the total transmission modulation in such all-optical processes has remained low so far, in the range of a few percentages. High-quality factor metasurfaces made of robust materials are necessary to boost the modulation contrast to the levels (70-90 %) necessary for practical use for wireless and free space communication. Here, we show an incredibly high-contrast and quick-responding of transmission modulation of the silicon optical metasurface. The interference of a radiative electric dipole and a non-radiative, asymmetric bound-state in the continuous (BIC) channel results in a kink-type transmission response in our metasurface design[4]. With a few tens of picoseconds of temporal response, we show absolute transmission modulation of over 72% that is driven by carrier injection in the crystalline silicon metasurface.

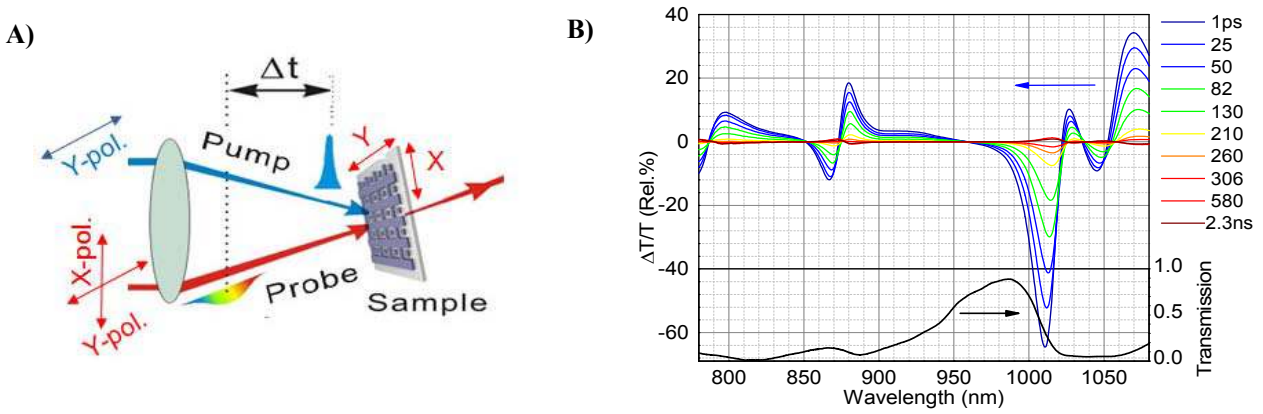

Figure 1. A) Schematic of the ultra-fast time-modulation based on a pump-probe Q-boosting time variant resonator. B) Transmission spectrum (black curve) and relative transmission modulation after pumping with 41 kW pump power and intensity of 1GW/cm^2 .
The metasurface is fabricated from a crystalline silicon on a sapphire substrate. It has periodicity of 500 nm and a thickness of 100 nm,

Figure 1. The metasurface is characterised via pump-probe spectroscopy, Fig.1(a), where a 170 fs pump beam at 520 nm excites the sample and generates free carriers in the silicon. A broad-spectrum probe beam is used to test the metasurface transmission at different time delays. The relative and absolute change of transmission spectra at different delay are depicted with coloured curves on Fig. 1(b). The two kinetics of the positive and negative maximum, Fig. 1(d), show that the relaxation of the induced charge carriers is predominantly characterized by a time constant about 102 ps (at 108nm) and 120 ps at 1012 nm respectively. Transmission spectra with a pump-probe delay of +3ps with and without pump, respectively are shown on Fig.2B. The highest depth of modulation (purple, differential spectrum) is -72% at around 990 nm. The modification of a CW 1030 nm laser's beam for free space communication has been verified in a lab setting using the same sample.

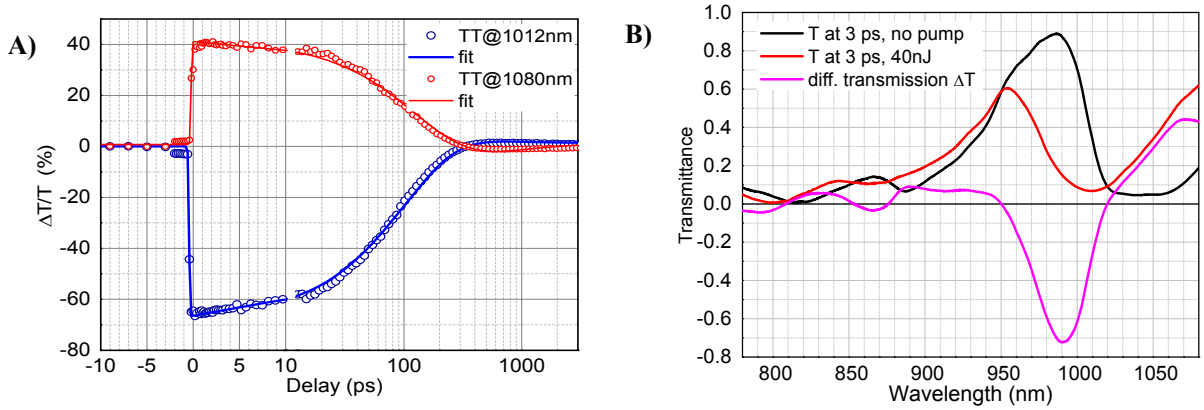

Figure 2. A) Transient dynamics at wavelengths of 1012 nm (blue circles) and 1080 nm (red circles). The time response for relaxation of the carrier injection obtained from exponential fit (solid lines) is 120 ps. B) Transmission spectra at pump-probe delay of +3ps with no pump (black) and with 245 kW pump power and intensity of 6 GW/cm^2 (red curve). Differential spectrum (purple) shows maximal depth of modulation of -72% at ca. 990nm

In summary, we demonstrate a record-high ultra-fast transmission modulation in silicon metasurfaces with BIC kink-type high-Q transmission. Our results open new opportunities for all-optical high-contrast switching in resonant metasurfaces.

Two-Dimensional Electronic Spectroscopy of Strong Exciton-Surface Plasmon Polariton Coupling

Christoph Lienau[1]

[1]Institute of Physics and Center for Nanoscale Dynamics (CeNaD), University of Oldenburg, 26129 Oldenburg
*corresponding author: christoph.lienau@uol.de

Abstract: Strong exciton-plasmon-couplings are investigated using two-dimensional electronic spectroscopy, revealing Rabi oscillations of polariton cross-peaks and accessing two-quantum excitations. Coherent population oscillations between excitons that are strongly and weakly coupled to the plasmonic field are demonstrated.

The creation of hybrid light-matter systems due to strong coupling is of major current interest for material science and to steer chemical reactions [1–3]. Of special interest are dipolar interactions between molecular excitons (X) and plasmonic resonators, such as surface plasmon polaritons (SPP) [4]. Sufficiently strong coupling to vacuum field fluctuations allows for the coherent flow of energy between X and SPP, i.e. Rabi oscillations, forming new hybridized upper (UP) and lower (LP) polariton states.

Here, we explore these strong coupling phenomena and especially their dynamics for the first time using two-dimensional electronic spectroscopy (2DES). We demonstrate strong coupling by revealing coherently oscillating cross-peaks" in the 2DES and demonstrate a new coherent transport phenomenon: Plasmon fields drive coherent exciton population oscillations between distant two distant exciton sites.

For this, we investigate the polariton dynamics of a prototypical system for X-SPP coupling, a periodic gold slit array coated with a 10-nm-thick squaraine-based J-aggregated thinfilm (Fig.1a) [5, 6]. The linear reflectivity of the sample shows an avoided crossing between UP and LP branches of the dispersion relation arising from strong X-SPP coupling (Fig. 1b) and an additional, angle-independent UX peak, usually explained by "uncoupled" excitons sitting outside the regions of high field-enhancements.

To probe the coherent dynamics of the system we performed a series of 2DES experiments at different angles of the dispersion relation. Fig.1b-c show the results for an angle of incidence of $\theta = 27°$. Dispersive resonances at the UX and LP energy, arising from a blue-shifted excited state absorption, give access to two-quantum excitations of the coupled system. The extracted one- and two-quantum dispersion relations are depicted in Fig. 1e. Dynamics of diagonal and cross peaks show pronounced Rabi oscillations, whose corresponding energy matches the 2DES peak splittings. The analysis of the data (Fig.1f) reveals that the dynamics of the strongly coupled system are not only governed by the anticipated UP-LP Rabi oscillations. Most prominently, the observed oscillations match the peak splittings between the UX and LP, thus indicating that the "uncoupled" excitons play a major role in the coherent dynamics.

Our findings can be understood by considering the effect of of SPP fields on the excitons distributions. For this, it is important that the relevant in-plane components of the SPP fields, driving the coupling to the excitons, are strongly enhanced inside the slits, yet have a finite value in between the slits. Thus, only those excitons residing indside slits can undergo strong X-SPP coupling, enabled by sufficiently strong local field enhancements. Those "uncoupled" excitons that sit between the slits, instead, couple only weakly couple to the same SPP mode. Hence, their energetic positions are basically unaffected by X-SPP coupling even although they can still exchange energy with the plasmon field. This is a three-level scenario that is reminiscent of lambda-type systems in atomic physics for which coherent, light-driven population transfer processes are already known. In our case, we demonstrate that the plasmon drives coherent population oscillations between the strongly-coupled excitons,

spatially confined to the slit regions and spatially distant "uncoupled excitons" that reside between at slits, separated by a few hundreds of nanometers from the two strongly-coupled excitons. It is this coherent populations transfer that gives rise to the pronounced Rabi oscillations probed in 2DES. We further support this conclusion by quantitative density matrix and Frenkel exciton model simulations.

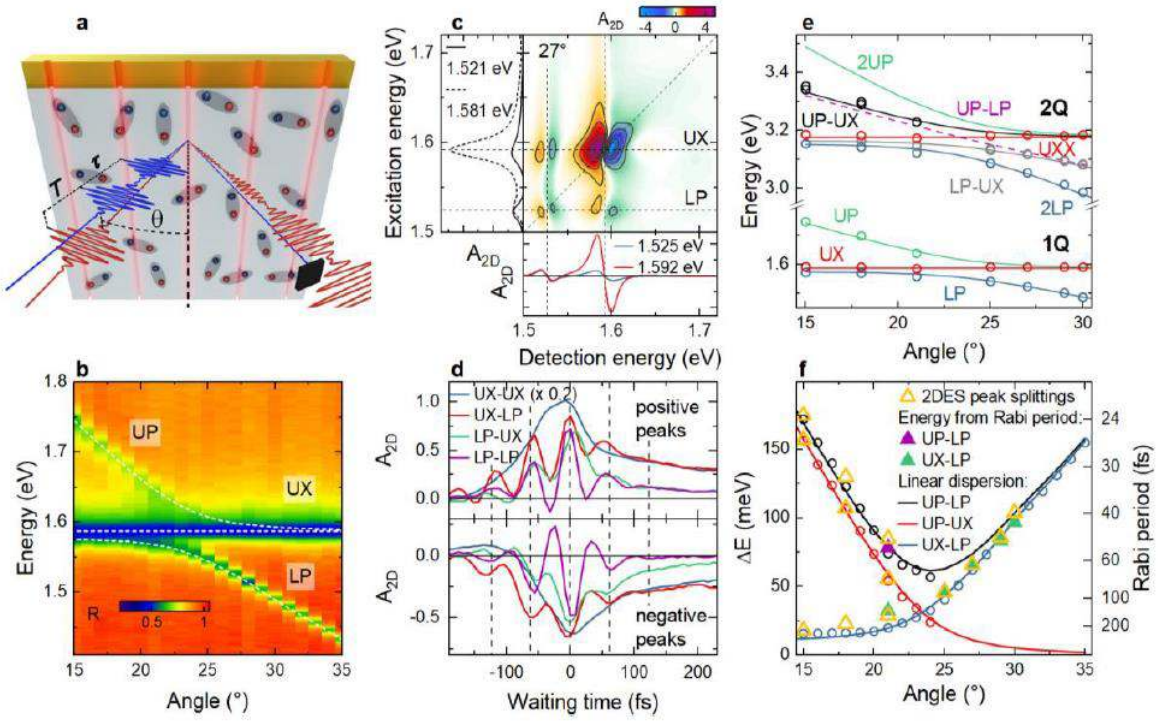

Fig. Sample geometry of the J-aggregate coated gold slit grating. b) Angle-resolved linear reflectivity (θ) of the strongly coupled X-SPP system. "Uncoupled" excitons (UX) appear 1.6 eV. c) Absorptive 2DES map at waiting time 0 fs and θ = 27°. Dispersive peaks arise from the superposition of one-quantum transitions and excited state absorption into two-quantum states. d) Peak dynamics in c) showing pronounced Rabi oscillations with a period of ~65 fs, matching the UX-LP energy splitting. e) One- and two-quantum dispersion relations f) Energetic splittings from the linear (circles) and 2DES measurements (triangles). The observed Rabi periods do match the energy difference between UX and LP and reflect coherent population oscillations between locally distant exciton sites driven by the plasmon field.

Our 2DES study thus not only provides the first observation of coherent Rabi oscillations due to strong couplings but also indicates a new pathway for coherent, plasmon-driven long-distance energy transfer in hybrid nanostructures.

Abstract: We achieve all-optical switching of the upconverted light in periodic dielectric metasurfaces through a $\omega + 2\omega$ pump scheme. Exploiting the pump pulse phase as tuning knob, upconversion is switched between diffraction orders with efficiency >90%. Polarization of the pump beams and of the emitted light can is also employed to route the upconverted light among different sets of diffraction orders. We envision the proposed approach as an effective approach to upconvert and steer telecom photons into visible detection paths.

Frequency upconversion of near-infrared photons to the visible range is strategical for information technology, as it can provide an alternative for the read out of telecom signals using efficient silicon-based detectors. Light upconversion is a nonlinear process mediated by matter that consists in the interaction of either energy-degenerate photons, such as in second-harmonic and third-harmonic generation (THG), or photons with different energies, such as in sum-frequency generation (SFG). We recently investigated frequency upconversion in both plasmonic and dielectric nanoantennas [1,2]. Thanks to the adopted dual-beam pump scheme, where an ultrashort pulse (ω) at telecom wavelength (λ = 1551 nm) impinges on the sample along with its frequency-doubled replica (2ω), THG and SFG are degenerate in energy. This, along with coherence, enables the interference between the processes. Yet, we found that in individual nanoantennas symmetry plays a major role in enhancing/suppressing the interference between SFG and THG. By tuning the relative phase between the two

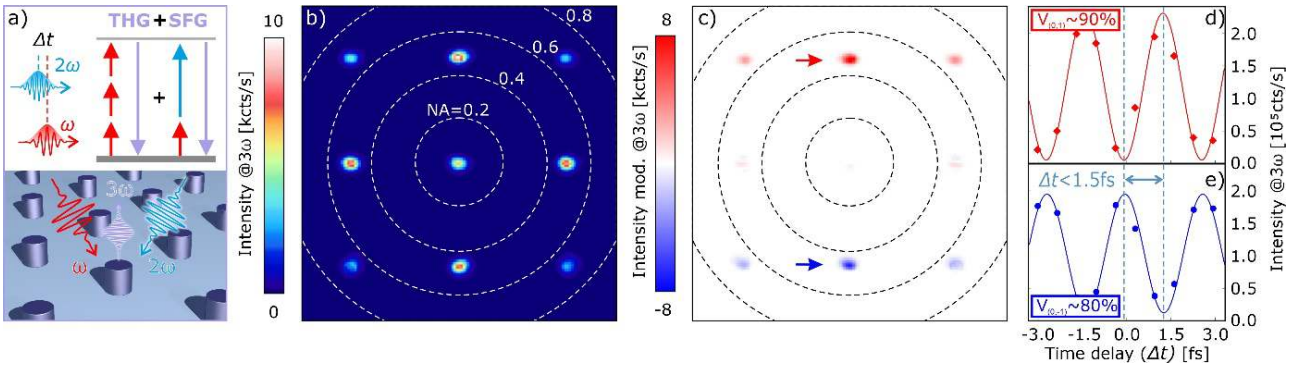

Fig. 1 a) Scheme of the dual beam pumping for upconversion (top) and pictorial description of the AlGaAs metasurface excitation and emission. b) Back focal plane (BFP) map of the upconverted light (SFG+THG) emission by the metasurfaces. The first order diffraction lobes appear at a NA=λ/p = 517 nm/1100 nm = 0.47, where p is the array periodicity. c) Modulation of the upconversion evaluated as the difference between the BFP maps acquired at about 1.5 fs delay between the pump pulses (see dashed lines in panels d and e). d) and e) Upconversion intensity of the (0,1) and (0,-1) orders of the metasurface (red and blue arrows, respectively) demonstrating switching with visibility V up to 90% and switching times of about 1.5 *fs*.

impinging pulses, we performed all-optical switching of upconverted light with efficiency > 50% in asymmetric plasmonic antennas [2].

Optical metasurfaces are rapidly emerging as flexible, ultrathin and multi-functional platforms to manipulate light [3]. Recently, they were also applied to efficient nonlinear light conversion and steering [4]. Here, by applying the above dual-beam pump scheme to a periodic AlGaAs metasurfaces (Fig. 1a), we attain all-optical switching of the upconverted telecom photons in the visible range as in [1,2]. This is attained thanks to the symmetry-breaking induced in the detection and obtained by tuning the metasurface diffraction with respect to the meta-atom nonlinear emission in the Fourier plane. Using the relative phase between the pump pulses as a tuning knob, we could steer the upconverted radiation among different metasurface diffraction orders (see Fig. 1b and c) with an efficiency up to 90% (see Fig. 1d). This is attained by engineering the nonlinear emission of the individual meta-atoms along with the metasurface diffraction in the Fourier space to maximize the interference between SFG and THG in specific *k*-space directions. We also demonstrate that the polarization state of both pump and emission allows to reconfigure the switching between different sets of diffraction orders.

Notably, we reach an overall conversion efficiency $\beta = P^{3\omega}/P^{2\omega}P^{\omega} > 10^{-5}W^{-1}$ at relatively low pump peak intensities (10 MW/cm^2). The proposed approach can be envisioned as an all-optical method to route upconverted telecom photons into various detection channels. The combination of the interferometric and nonlinear character of the emitted light could be also extremely appealing for applications to nonlinear sensing.

Abstract: Efficient ultrafast reconfiguration of the second-harmonic generation of AlGaAs nonlinear nanoantennas operating at 1550 nm telecom wavelength, is achieved by ultrafast interband photoexcitation with femtosecond visible pulses. The combination of broadband transient transmittivity, time-revolved second harmonic generation, and nonlinear optics nanoscale modeling, allows to track the ultrafast modulation of the second harmonic signal, into the nanoscale charge carrier dynamics at the base of a giant permittivity change at the semiconducting band edge.

Strong non-linear optical effects can be demonstrated, exploiting the enhancement of light-matter interaction in subwavelength nanostructures based on media with high nonlinear susceptibility. High-refractive index dielectrics are promising material platforms for nonlinear nanophotonics in the visible and near-infrared ranges. They enable large field enhancement via multiple Mie scattering resonances, that can be tuned controlling the geometrical parameters of the nanoantennas. Remarkably, dielectrics nanoantennas benefit from reduced Ohmic losses compared to metallic nanostructures.

Conventional semiconductors have been explored for fabricating nonlinear dielectric nanoantennas operating both in transmission and in reflection configuration. Amongst these, GaAs is particularly promising because of the direct near-infrared bandgap of the material (1.422eV/872nm at room temperature), enabling efficient excitation with visible light. Moreover, fine-tuning of the semiconducting bandgap can be achieved by controlling the Al and Ga concentration in AlGaAs.

Here, we discuss the ultrafast control of the linear and nonlinear optical response of dielectric nanoantennas based on AlGaAs, exploiting photoexcitation with femtosecond visible pulses [1-2].

First, we investigate the transient optical response of $Al_{0.18}Ga_{0.82}As$ nanopillars with multiple Mie resonances. To this aim, we apply a combination of broadband transient reflectivity measurements and nonlinear optics nanoscale modeling, to follow the simultaneous modulation of four distinct resonances in the range 650-1150 nm, after the above bandgap photoexcitation with a 400nm pump pulse, see Figure 1a-b [1].

We observe a build-up of the transient reflectivity signal, which is attributed to the ambipolar diffusion of the photo-generated electron hole pairs inside the nanopillar. While, the relaxation dynamics exhibi a picosecond component driven by the interplay of intraband transitions, i.e. the Drude plasma response, and the Pauli blocking of interband transition induced by the pump absorption.

Remarkably, the investigated dynamics of the dielectric nanoantennas preside over large permittivity modulation, which is expected to affect the nonlinear optical response of the nanoantennas.

Here, we propose an efficient configuration for ultrafast control of the second harmonic generation (SHG) of the AlGaAs nanoantennas, see Figure 1c-d, exploiting the giant modulation to the dielectric permittivity expected at the semiconductor band edge, after photoexcitation with femtosecond visible pulses.

We demonstrate intense (up to 6%) modulation of the SHG of $Al_{0.18}Ga_{0.82}As$ nanopillar [2] by the time-resolved SHG experiment, with the fundamental at 1500nm telecom wavelength, and the second harmonic signal at 775 nm, at a pronounced scattering resonance. A control pulse at 500nm, is used to photo inject charge carriers and induce an intense modulation of the dielectric permittivity. Interestingly, the photoexcitation, can either quench or enhance the SHG signal depending on the nanopillar radius. The SHG shows buildup dynamics which we attribute to the ambipolar diffusion of the photogenerated electron−hole pairs, occurring in a few picoseconds. The efficient nonradiative recombination of the carriers, which in the nanopillar is favored by the the higher surface-to-volume, is then driving the decay of the SHG signal, in a few tens of picoseconds.

In conclusion, we demonstrate the active control of the reflectivity and of the second-order nonlinearities of dielectric nanoantennas by ultrafast optical excitation, opening intriguing application perspectives for light manipulation in ultra-compact configurations. The understanding of the nanoscale dynamics, appears crucial for the design of novel nonlinear nanophotonics devices based on optically reconfigurable multiresonant nanoantennas. Large modulation of other nonlinear optical effects is expected, including difference-frequency generation for spontaneous parametric down conversion, to be exploited in optically controlled nanosource of entangled photons, for quantum applications.

Abstract:
In the last decade, Titanium Nitride has emerged as an alternative plasmonic material to noble metals, thanks to its refractory properties and a carrier-lattice thermalization time much faster (< 100 fs), with respect to e.g. gold (~ 1 ps). In this work, we provide a numerical model to unfold TiN ultrafast nonlinear optical response, on a broad spectral range. The calculations are validated on a 200 nm-thick TiN film on glass.

Titanium Nitride (TiN) has gained notable interest in the last decade due to its refractory nature, CMOS- and bio-compatibility, interband losses lower than gold in the visible range, and a tunable permittivity when varying the synthesis parameters [1,2]. Regarding TiN transient optical response, the electron-phonon coupling in this material was found to be much stronger than in typical plasmonic media, such as noble metals. Indeed, the relaxation of out-of-equilibrium hot electrons following ultrafast photoexcitation takes place in less than 100 fs, one order of magnitude faster than, e.g., in gold (~ 1 ps) [3,4]. However, a comprehensive study of TiN nonlinear optical response upon excitation with fs-pulses is still missing. This represents a major lack when thinking about exploiting TiN as a new material for ultrafast plasmonic devices.

In this work, starting from the inhomogeneous Two-Temperature Model [5], we first assess the carrier and lattice temperature increase following the ultrashort photoexcitation of a 200 nm-thick TiN film. Then, considering one interband transition and an isotropic and parabolic band structure, we connect the increase in the carrier temperature to the variation of the interband contribution to the material's permittivity. For what concerns the modulation of the intraband (Drude) part of the permittivity, we prove it to be due both to the increase in the carriers' scattering with phonons and to the onset of thermoelastic effects in the TiN film. To validate the theoretical calculations, we perform ultrafast pump-probe spectroscopy on a 200 nm-thick TiN film on glass by monitoring its transient reflectivity, with ~ 100 fs temporal resolution, 500 nm pump and broadband (320 -550 nm) probe. The main results are shown in Figure 1 a)-d). The theoretical calculations are able to accurately reproduce the experimental pump-probe measurement. Our model also enables us to disentangle the interband and Drude contributions to the permittivity variation, and we demonstrate that the modulation of interband transitions plays a key role in TiN nonlinear optical response. Indeed, without considering it, we completely miss the ultrafast features (< 150 fs) in the transient reflectivity ($\Delta R/R$), as shown in Figure 1e)-f).
As such, thanks to the combination of ultrafast pump-probe spectroscopy measurements and semi-classical modelling, we are indeed able to unfold the origin of the ultrafast nonlinearities in TiN. Moreover, our model

represents a powerful tool to make predictions on TiN transient response of more complex structures, such as TiN nanostructures and metasurfaces. This paves the way for the engineering and development of new TiN devices for ultrafast plasmonics applications, such as the all optical modulation of light.

Abstract: Sub-picosecond polarization control is a fundamental functionality for several applications, from information encoding to probing of chemical systems such as chiral molecules. We present an all-optically reconfigurable AlGaAs metasurface, showing giant dichroism modulation upon investigation via ultrafast pump-probe spectroscopy. By combining modelling of carriers excitation and relaxation processes with full-wave electromagnetic simulations, we can attribute the relevant transient features to pump-induced band-filling effect, opening a gain region in the spectral range of a sharp resonance of the structure.

Active control of light polarization in the THz speed regime is a highly desirable and challenging goal in Photonics. Indeed, the ability to master this functionality would allow the development of novel free-space optical links for telecommunications [1], as well as the implementation of innovative techniques to manipulate material processes [2] or to probe polarization-sensitive systems as chiral molecules [3] in a time-resolved fashion. To this aim, all-optical paradigms present several advantages, also having the potential to exceed the fundamental limitations of electronics, and have been employed on a variety of platforms [4,5,6]. Metasurfaces are the ideal candidates for the implementation of devices working in such schemes; as planar collections of nanoresonators, compactly arranged, they are both tunable and convenient for integrated applications.

Within this context, we present an anisotropic metasurface of AlGaAs nanowires on top of a GaAs-AlOx substrate, working in reflection. Anisotropy in the metasurface plane entails a strongly dichroic optical response in static conditions, which is in fact evident in the unperturbed reflection spectra for the two in-plane polarizations. We experimentally demonstrate a giant modulation of such dichroic properties via ultrafast pump-probe spectroscopy, using a low-moderate level of excitation (pump fluence ~70 $\mu J/cm^2$) with respect to values reported in literature: specifically, we obtain a peak value of differential reflectivity of almost 470% for probe polarized along the periodicity direction ('TM'), with comparatively negligible, yet remarkable modulation (up to ~60%) for probe polarization parallel to the wires ('TE').

To provide a clearcut interpretation of these results, we construct a modelling approach based on a segregated, multi-step procedure [7,8]. We first consider the physical processes presiding over relaxation of

electron-hole pairs photogenerated in the semiconductor nanowires, by employing the so-called three-temperature model (3TM). The latter is a rate equation model which describes the evolution of internal degrees of freedom: electron-hole pairs density in the skin depth of the nanustructure and in its bulk, and lattice temperature.

In turn, each of these quantities is responsible for a transient modification of permittivity, $\Delta\varepsilon$, through three mechanisms: a Drude effect, accounting for intraband transisitions; band-filling, relative to interband transitions and consisting of a saturation of absorption channels at photon energies near the AlGaAs bandgap; thermo-optics processes. Permittivity variation then entails a modified optical response with respect to unperturbed conditions, which we describe with full-wave electromagnetic simulations.

Our modelling strategy is able to capture the transient dynamics of the optical signal qualitatively and quantitatively. Moreover, it reveals that a pivotal role is played by band-filling effect, dominating $\Delta\varepsilon$ near the AlGaAs bandgap (~750 nm), so that the resulting modulated permittivity $\varepsilon + \Delta\varepsilon$ presents a *negative* imaginary part in a narrow spectral band comprised between 735 nm and 750 nm. This is the fingerprint of the opening of a gain window, precisely in the region of a resonant mode of the structure for the TM polarization. It is specifically this interplay of phenomena which enables the surge of the huge differential reflection signal.

These results unveil a new promising route to employ direct-gap semiconductor platforms for the ultrafast control of light polarization near the bandgap region; they pave the way for the design of novel resonant structures, specifically engineered to exploit the band-filling induced gain window.

Abstract: Steering the polarization of light at an ultrafast speed is a crucial functionality for a plethora of applications, including free-space optical links for high-speed information processing and recording. Nonlinear metamaterials have recently been developed for ultrafast manipulation of light polarization by all-optical means (i.e., upon excitation by a femtosecond control pulse). Here, we demonstrate strong birefringence features in a reconfigurable, anisotropic AlGaAs metasurface, achieving more than 90° rotation of the polarization ellipse at a few picosecond timescales.

One of the fundamental characteristics of light is its polarization state. Controlling light polarization on the ultrafast timescale may enable a wide range of applications in numerous systems, ranging from chemical complexes, spin precession to lattice vibrations [1,2,3]. The state-of-the-art polarizing components (i.e., polarizers and waveplates) are either passive or suffer from the intrinsic limits of electronic (GHz) modulation speed [4]. To achieve dynamical polarization control in the THz speed regime, one promising approach involves the design of reconfigurable and all-optical schemes utilizing anisotropic thin nanostructures such as metamaterials, in which optical pumping could induce a transient modulation of static dichroism and birefringence [5].

Within this framework, we present an anisotropic AlGaAs nanowire metasurface fabricated on top of a GaAs-AlOx substrate, operating in reflection mode. We experimentally demonstrate remarkably efficient ultrafast birefringence features via ultrafast pump-probe spectroscopy Specifically, we observed up to 90° rotation of the polarization state around the 750 nm wavelength, sitting near the bandgap of the AlGaAs, and up to 120° rotation at 790 nm.

For the realization of the ultrafast transient birefringence experiment, the polarimetric pump-probe data are recorded using polarized probe pulses and controlling the polarization outcome at the detector. Specifically, the incident pump beam (400 nm) is linearly polarized perpendicular to the nanowires, while the polarization of the broadband probe beam is rotated 45° clockwise with respect to the pump polarization by utilizing a combination of a half-wave plate and a linear polarizer, illuminating the sample almost at a normal incidence (θ = 7°). At the detection, to determine the polarization state of the reflected probe beam, we utilized a quarter-wave plate and a fixed polarizer which is set to the same transmission axis of the first polarizer used for the input probe beam, i.e. at 45° with respect to the pump polarization. The fast-axis of the quarter-waveplate is aligned parallel with the wires and then rotated to a different angle (β) for each set of measurements. The reflected probe intensity is then recorded as a function of probe wavelength and the time delay between pump and probe pulses. The 2D differential reflectivity maps for the two different angles (β) of the quarter-waveplate ($\Delta\beta$ = 60°) are

depicted in figure 1, indicating strong modulations of the polarization components around 750 nm spectral region associated with the rotation of the polarization ellipse.

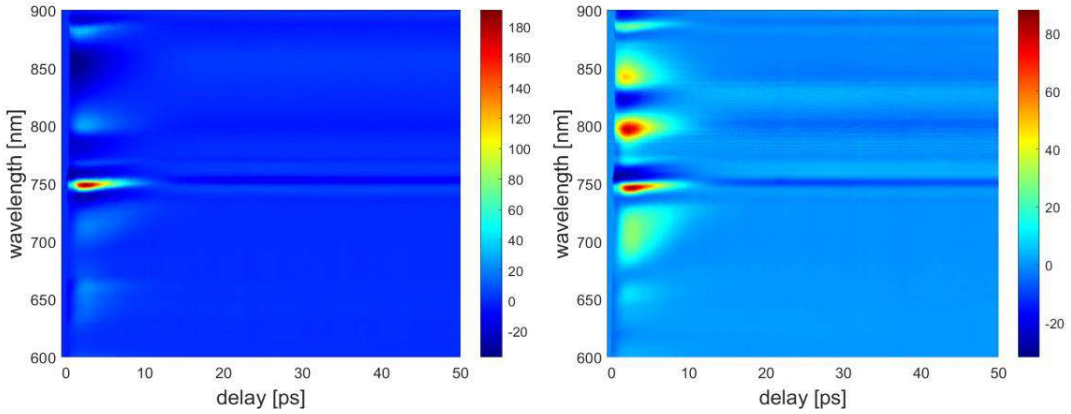

Figure 1: Pump-probe transient reflection maps recorded at different angular positions of quarter waveplate ($\Delta\beta = 60°$).

By using these sets of dynamic and static reflection measurements, we can retrieve the Stokes parameters of the probe light reflected by the metasurface and reconstruct the corresponding polarization ellipses as shown in figure 2. We observed complex dynamics within the spectral window near the bandgap (750 nm) and at longer wavelengths (790 nm).

Our results indicate in a clearcut way the potential of direct-gap semiconductor platforms for all-optical birefringence modulation and pave the way for the development of high-performance, reconfigurable metasurfaces, featuring extended-state birefringent resonances for the ultrafast control of light polarization.

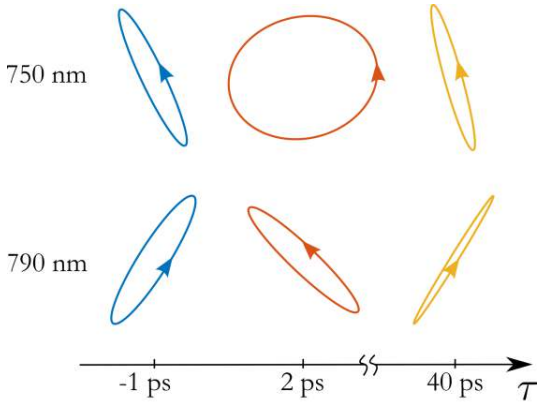

Figure 2: Dynamical polarization ellipse reconstruction at two different wavelengths evaluated for three selected pump-probe delays.

Abstract: We report on the development of an analytical expression for the description of the artificial third-order nonlinearity induced in an amorphous-silicon based metasurface, which takes into account the polarization states of the interacting light fields. Based on this model, we retrieve the tensorial values of the nonlinear susceptibility by measuring the third harmonic generation efficiency of a dielectric metasurface composed of rectangularly-shaped amorphous silicon elements.

Introduction

Recently, dielectric metasurfaces, two-dimensional arrays of subwavelength elements, called meta-atoms, have been extensively employed to tailor nonlinear interactions without being restricted by phase-matching requirements[1]. It has been shown that dielectric metasurfaces can enhance the nonlinear conversion efficiency when compared to a film of the same material with the same thickness[2]. Despite this interest, a complete description of the artificial nonlinearity in meta-atoms is still missing. In this work, we derive an analytical expression to describe third-harmonic generation (THG) via the artificial third-order nonlinearity originating from the meta-atom symmetry, with an emphasis on the polarization states of the fundamental and generated third-harmonic fields. By exploiting this description, the tensor elements of the artificial nonlinearity of a test-bed amorphous silicon (a-Si) metasurface are experimentally retrieved from the THG conversion efficiency. The presented theoretical analysis and experimental results allow for the design of functional nonlinear metasurface devices for various applications, from nonlinear imaging to novel sources of nonclassical light.

Theory and experimental characterization

The sample under test is an array of rectangular blocks, which belongs to the orthorhombic crystal class, also referred to as C_2 (twofold in-plane rotational symmetry)[3]. The nonlinear polarization density, P, of the THG process is proportional to the third-order susceptibility matrix, $M^{(3)}$, of the corresponding crystal class. In our case, the incident light is polarized along the x-y plane and propagates in the z-direction (i.e., $E_z = 0$). As such, the z polarization can be omitted, so that $M^{(3)} = \begin{pmatrix} \chi_{11} & 0 & \chi_{18} & 0 \\ 0 & \chi_{22} & 0 & \chi_{29} \end{pmatrix}$. Using Ansys Lumerical® software, we designed an a-Si metasurface (on a silica substrate) so that no dipole resonances would occur close to our input wavelength, i.e., λ_f = 1596 nm. The geometric parameters obtained from this numerical study are as follows: L = 420 nm, W = 160 nm, H = 425 nm, and D = 520 nm (see inset of Fig 1b). The sample was then fabricated via e-beam lithography and characterized by means of a tunable femtosecond pulsed-laser source. The THG power was measured using a silicon-based photodiode paired with a lock-in amplifier. The setup (see Fig. 1a) also included a THG imaging module, comprising focusing lenses. We measured the metasurface linear transmission in the telecom band (see Fig. 1b) for input horizontally- (H) and vertically-polarized (V) light. The metasurface shows a high

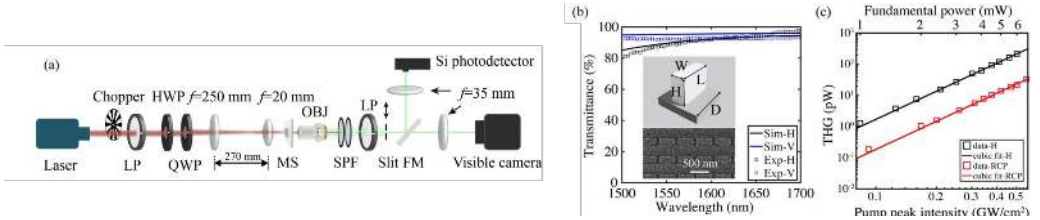

Figure 1. (a) Experimental setup for the characterization of the metasurface. LP: linear polarizer, HWP: half-wave plate, QWP: quarter-wave plate, MS: metasurface, SPF: short-pass filter; OBJ: objective, FM: flip mirror. (b) Simulated (solid curves) and measured (squares) linear transmittance for horizontal (with respect to the meta-atom long axis, black curve) and vertical (blue curve) input light. In the inset, a scanning electron microscopy image of the metasurface is shown, together with a schematic of a meta-atom. (c) Powe scaling measurements. Solid lines represent cubic fit curves while square markers are associated with the experimental data for horizontally- (black) and circularly- (red) polarized input light.

measured and simulated transmittance (> 92%), which confirms its off-resonance response at the target fundamental wavelength. We also investigated the dependence of the THG power on the fundamental peak intensity in the case of horizontally- and circularly (right handedness, RCP) polarized lights (see Fig. 1c). Both measurements show a good agreement with a cubic fit, as expected from the THG process. Finally, we retrieved the nonlinear tensor elements by quantifying the THG conversion efficiency for various input polarizations: 1) H-polarized fundamental light (η_{P1}); 2) V-polarized light (η_{P2}); 3) RCP light with an output linear polarizer set to H (η_{P3}) and V (η_{P4}). The conversion efficiency is evaluated as the ratio between the intensities of the THG and fundamental beams. The corresponding tensor elements could be found via the following relationships:

$$\chi_{11} = G\sqrt{\eta_{P1}};\ \chi_{22} = G\sqrt{\eta_{P2}};\ \left|\frac{\chi_{11}-3\chi_{18}}{2\sqrt{2}}\right| = G\sqrt{\eta_{P3}};\ \left|\frac{\chi_{22}-3\chi_{29}}{2\sqrt{2}}\right| = G\sqrt{\eta_{P4}}, \quad (1)$$

Where $G = \frac{2\varepsilon_0 c\lambda_f\sqrt{n_{3\omega}n_{\omega}^3}}{\sqrt[4]{3}\pi l I_{\omega} sinc\left(\frac{\Delta kl}{2}\right)}$, ε_0 is the vacuum dielectric permittivity, c the vacuum speed of light, l the meta-atom thickness, Δk the wave-vector mismatch, $n_{3\omega}$ and n_{ω} the refractive indices at ω and 3ω, respectively, and I_{ω} the input beam intensity. The retrieved tensor elements are hence estimated to be: $\chi_{11} = 7.9 * 10^{-18}\, m^2/V^2$; $\chi_{22} = 7.42 * 10^{-19}\, m^2/V^2$; $\chi_{18} = 4.67 * 10^{-19}\, m^2/V^2$; $\chi_{29} = 1.38 * 10^{-18} m^2/V^2$. It is worth stressing that, for a uniform a-Si film, $\chi_{18} = \chi_{29} = \chi_{11}/3$, and that THG is forbidden for circularly polarized light (see Eq. 1), while $\chi_{11} = \chi_{22}$. This further highlights the artificial nature of THG in the metasurface.

In conclusion, we have developed a mathematical description for the THG process in rectangularly-shaped meta-atoms and estimated their artificial optical nonlinearity by taking into account their geometrical features and symmetry. We have also designed and fabricated an a-Si metasurface to characterize its THG properties and retrieve the values of its artificial susceptibility tensor. The presented model represents a useful and convenient approach to develop novel metasurface platforms for nonlinear photonic manipulations.

Abstract: A metasurface of Gallium Phosphide on glass with a robust design enables high-quality factor (Q) modes, arising from the concept of quasi bound states in the continuum (QBICs). The high enhancement of the incident electric field is used to compute the nonlinear second harmonic (SH) fields in a non-perturbative approach, yielding a theoretical maximum conversion efficiency of 0.5%. Preliminary experimental results will be presented.

Bound States in the Continuum (BICs) are inaccessible modes with eigen-energies embedded in the radiation continuum. The phenomenon was first introduced in quantum mechanics, but its formalism can be expanded to many systems with wave-like behavior, such as the interaction of light with structures in the nanoscale. In principle, a BIC cannot be coupled to external radiation. A symmetry-protected BIC, however, can be accessed by adding a defect that breaks a certain symmetry, thus becoming a quasi-BIC or QBIC [1]. Because of its conception as a purely bound state, periodic structures, like metasurfaces, were a starting point for its study with electromagnetic waves. Many designs have been proposed and experimentally studied in recent years [2], with quality factors in the range of 10^2 to 10^5.

In this work, we propose a novel design [3] of a GaP metasurface with a very high-quality factor and a robust design. Its properties come from the relatively large dimensions of the added defect and its behavior when increasing the asymmetry. In figure 1A, the unit cell composing the metasurface can be seen in the top panel, and a schematic showing the electric field's direction at the resonance is shown. The design consists of two elliptical cylinders with an extra cylinder that acts as a coupler to form the QBIC. When the coupler is at the positions marked with an 'x' (or the dashed sections at the bottom of 1A), the system has reflection symmetry in the y-direction. When the coupler is then displaced a distance Δy, a QBIC can be excited. In general, for small asymmetries the quality factor of the resonance depends on the inverse square of the asymmetry parameter. In figure 1B we show how the relationship holds for displacements up to 40 nm with a coupler diameter of 80 nm. It is also interesting to note how the quality factor does not monotonically decrease, and a region of stability appears between the two extremes. This is a novel behavior in QBIC dielectric metasurfaces and shows that it is possible to obtain strong resonances (Q between 10^3 to 10^5) without fine-tuning the geometry.

To check the performance of the metasurface in nonlinear applications, we computed the SHG efficiency for a selected geometry with a Q of 4×10^5, whose electric field distribution can be seen in the top inset of figure 1B. The simulations were done with non-perturbative approximations, two extra terms were added to the linear polarization inside the material, pump depletion and optical Kerr effect, which depend on the second and third-order nonlinear susceptibilities, respectively. These terms are relevant because of the high-intensity fields that arise even with low excitation powers (1 to 10 mW to excite a large area of 10 to 30 μm^2). In these conditions, the SH fields and the intensity-dependent refractive index are no longer negligible. The theoretical maximum efficiency with all effects considered is 0.5 %, which is higher than the previously reported value of

0.2 % [4] in the same regime and shows further room for improvement from the maximum achieved experimentally of 2×10^{-5} % at similar pump intensities [5].

Figure 1C shows some preliminary samples fabricated using this design on silicon. GaP metasurfaces are currently being made and experimental results will be presented. We believe that the presented metasurface would bring new record-breaking efficiencies for nonlinear light generation processes.

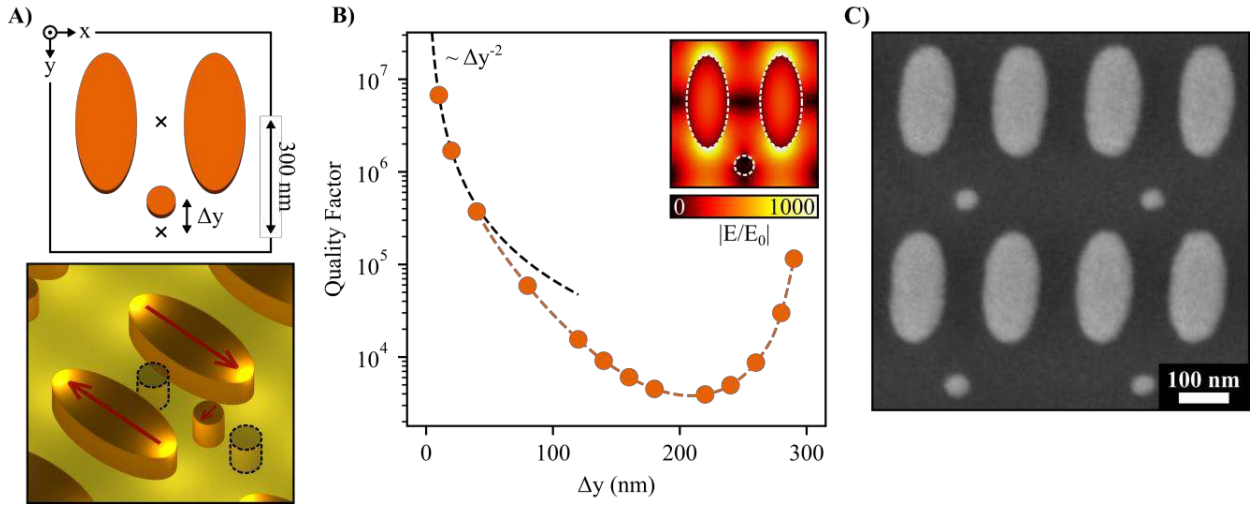

Figure 1. A) In the top panel the unit cell conforming the metasurface can be seen. A schematic of the electric field's direction at the resonance is shown at the bottom. B) Quality factor of the mode as a function of the coupler displacement. In the top inset the electric field enhancement for Δy = 40 nm. C) SEM image of fabricated metasurface with a coupler diameter of 40 nm

Ultrafast modulation of surface plasmon dispersion in metallic bilayers by hot non-equilibrium electrons

A. Avdizhiyan[1*], A. Stupakiewicz[1], and I. Razdolski[1]

[1]Faculty of Physics, University of Białystok, Poland
[*]corresponding author: a.avdizhiyan@uwb.edu.pl

Abstract: Employing back pump-front probe spectroscopy to Fe/Au bilayers, we investigate an indirect manipulation of the surface plasmon dispersion at the remote Au/air interface. The absorption peak of the surface plasmon resonance experiences a shift at the femtosecond timescale, highlighting the role of hot nonequilibrium electrons for ultrafast plasmonics.

Active plasmonics, a rapidly developing branch of modern nanophotonics, aims at controlling collective excitations of free charges at metallic interfaces. Its growth is fueled by the quest for light localization and manipulation at the nanoscale, opening pathways to novel optical devices [1]. Conventional ways of modulation of the surface plasmon dispersion entail the use of femtosecond laser pulses which are operative on the ultrashort timescale [2]. However, direct irradiation of the plasmonic interface with high-power optical pulses inevitably leads to significant heating, resulting in an increased energy dissipation.

In this work, we employ an indirect optical excitation to control the surface plasmon dispersion at a remote interface. As a model system, we use a Fe/Au metallic bilayer in which an efficient laser-induced injection of spin-polarized non-thermal electrons was demonstrated [3]. In a back pump-front probe experimental configuration with 50 fs temporal resolution, we study the impact of the pump-induced hot electron injection from Fe on the surface plasmon dispersion at the Au/air interface. A plasmonic grating at the Au surface enabled the excitation of a propagating plasmon-polariton mode with a free-space probe radiation. The thickness of the Au layer is sufficiently large (70 nm in total: 35 nm solid Au and 35 nm grating depth) to exclude the direct optical excitation of the electrons in Au in the vicinity of the surface. The grating periodicity of 460 nm results in the excitation of the surface plasmon-polariton at an incidence angle of 45 degrees around 790 nm wavelength. The reflected probe radiation is registered with a spectroscopic camera allowing for the wavelength-resolved analysis of the plasmonic impact of the laser-induced hot electron injection.

The main result of our work is presented in Figure 1. It is seen that the pump-induced injection primarily results in antisymmetric variations of the optical reflectivity around the plasmon resonance at few hundred fs pump-probe delays. On the contrary, symmetric variations are suppressed. As such, we conclude that the injection of non-thermal electrons mainly results in a shift of the resonance, while leaving the quality factor unperturbed. This is a striking contrast to the direct laser irradiation which often results in deteriorating of the resonance quality factors due to the ultrafast heating of the electronic subsystem. Further, the lifetime of the effect resides on the subpicosecond timescale, in agreement with the estimated lifetime of the non-thermal electron population in Au. We then discuss physical mechanisms of the electron dynamics resulting in the plasmon resonance shift upon non-thermal electron injection. Our results demonstrate high promise of the novel

approach towards ultrafast active plasmonics based on non-thermal electrons.

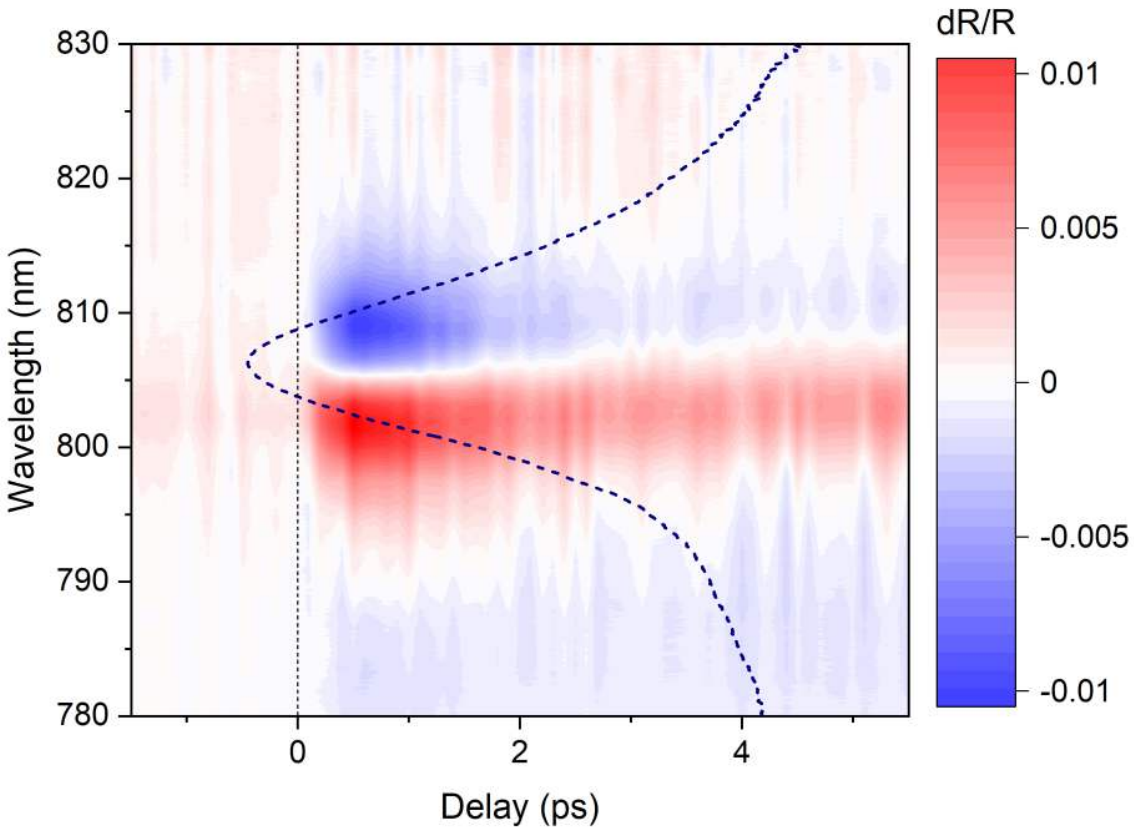

Figure 1. SPP back pump – front probe spectroscopy of a Fe/Au bilayer with a plasmonic grating. The figure shows variations dR/R by wavelength from the delay time between the pumping and probing pulses. The dashed line indicates the resonant surface plasmon-polariton excitation in the equilibrium state (at negative delays).

Abstract: We present a theoretical study of the interactions between confined acoustic phonons and localized surface plasmons (LSPs) in the framework of acoustic Raman scattering. By using the Fermi golden rule we introduce a new physical quantity, the Raman energy density (RED), which is a local quantity that serves as a tool for the study of resonant Raman scattering mediated by LSPs in nanoparticles. The RED represents the electromagnetic energy density excited by the Raman probe and modulated by the phonons.

Most of the studies focusing on metallic nanoparticles consider them as static bodies at rest. However, localized surface plasmons (LSPs) can be temporally modulated by acoustic vibrations, also known as acoustic phonons, naturally present in the nanomaterial and surrounding environment. Very recently, there has been a renewed interest on the modulation effect of the LSPs by (opto)mechanical modes and elastic waves [1-6]. Such high-frequency (GHz-THz) modulation can be used to increase detection and sensing accuracy of nano-objects and molecules. For instance, these vibrating nanoparticles, acting as simple optomechanical nanoresonators, can be seen as nanoscale analogs to quartz crystal microbalances. Acoustic-phonons Raman scattering is a very effective, high-precision, and non-invasive technique for nanometrology. It uses the acoustic vibrations as local probes to determine sizes and distances at the nanoscale with very high accuracy. However, the effectiveness of this technique is directly related to the knowledge of the interaction mechanisms between electrons (plasmons) and phonons (acoustic vibrations). Therefore, it is necessary to know what are the vibrational modes sustained by a given nanostructure (amplitude, frequency, symmetry) and know how they interact with the LSPs to completely determine the Raman efficiencies and selection rules.

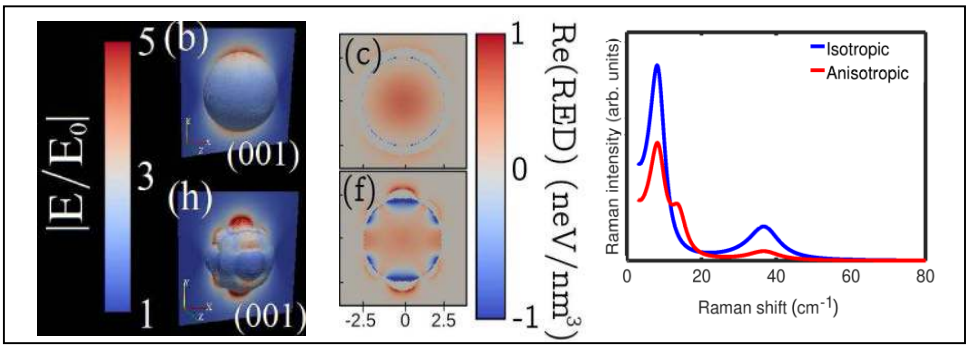

Fig. 1 Left: Isotropic (l=0) and Anisotropic (A_{1g}) breathing acoustic mode of a AuNP modulating the near electric field induced par the dipolar localized surface plasmon (LSP). **Center**: Raman energy density (RED) resulting from the interaction of the l=0 and A_{1g} vibration mode with the dipole LSP. **Right**: Calculated acoustic Raman spectra for the isotropic and anisotropic nanoparticles.

Here, we investigate the dynamic properties of metallic nanoparticles by focusing on the interaction between confined acoustic vibrations and LSPs (**Fig. 1, left**) [5, 7]. The dynamic properties of LSPs are responsible for the transient optical absorption modulation, that can be observed in time-resolved transient absorption experiments [6], and for the acoustic SERS effect [4], We describe the resonant Raman scattering process using a new approach based on a single direct acousto-plasmonic interaction process described by Fermi golden rule [7]. Within this framework, we introduce a new physical quantity, namely, the Raman energy density (RED; **Fig. 1, center**). Similarly to the Raman-Brillouin electronic density (RBED) introduced in semiconducting nanostructures [8, 9], the RED allows for studying and monitoring the acousto-plasmonic Raman scattering in the near-field. We modeled the acousto-plasmonic interaction by implementing vibrational dynamics (resonant ultrasound method, RUS), into electrodynamic calculations (discrete dipole approximation, DDA). We used this methodology to compute the acoustic Raman spectra (**Fig. 1, right**) and investigate the interaction between LSPs and (an)isotropic acoustic vibrations, thus leading to the full determination of Raman efficiencies and selection rules. We show that the RED (**Fig. 1, center**), which can be mapped in the near-field for each vibration mode, correlates the far-field Raman scattering (**Fig. 1, right**) to the local acousto-plasmonic hot spots (**Fig. 1, left**), provides a deeper understanding of the Raman scattering process (*e.g.*, Raman selection rules), and serves to study the acousto-plasmonic coupling of complex nanostructures.

Heat transfer modelling in the crossover regime between conduction and radiation

M. Gómez Viloria[1], P. Ben-Abdallah[1], and R. Messina[1*]

[1]Laboratoire Charles Fabry, Laboratoire Charles Fabry, Institut d'optique,

CNRS, UMR 8501, Université Paris-Saclay, 91127 Palaiseau, France

[*]corresponding author: riccardo.messina@institutoptique.fr

Abstract: We analyze the heat transfer between two metals separated by a vacuum gap in the extreme near-field regime, in which tunneling photons, phonons and electrons are expected to play a role. We quantify the relative contribution of these carriers with respect to the separation distance and the applied bias voltage. Our results emphasize some inconsistencies in recent experimental results about heat exchanges in extreme near-field regime and set a roadmap for future experiments.

The theoretical framework of Fluctuational ElectroDynamics (FED) [1] describes the near field radiative heat transfer for separation distances below the thermal wavelength (some microns at ambient temperature). In this distance regime the heat flow between two solids at different temperatures can exceed the far field limit by several orders of magnitude, in particular when the bodies exchanging heat support surface resonant modes, such as surface phonon-polaritons or surface plasmons [2].

At even smaller distances, in the so-called extreme near field (distances in the nanometer range and below) the physics is expected to change radically. Interestingly, two recent scanning thermal microscopy (SThM) experiments [3,4], approaching gold tips to gold substrates, reached apparently opposite conclusions. While one of them shows large deviations from FED for separation distances of few nanometers, the other one shows no deviations from FED even at sub-nanometer gaps, where acoustic phonons and electrons are expected to contribute as further channels to the heat exchange.

Here we introduce a theoretical framework to investigate the heat transfer mediated by photons, phonons and electrons between two metallic bodies. We quantify the role of electron tunnelling currents [5] by paying attention to the role played by the shape of the electronic barrier in the presence of electron-electron screening interactions [6,7]. Using an approach based on the elastic theory [8-10], we address the role of acoustic phonons coupled through the van der Waals and the electrostatic forces. Finally, we employ FED [1] to study the role played by photons, by taking into account the contribution of non-local effects [11,12].

This theoretical work allows us to outline the relative weight of the different carriers with respect to the separation distance, and to highlight the crucial role played by the external bias voltage on the heat flux carried by the three types of carriers [13]. We also demonstrate that depending on the sign of this bias, electrons can either heat up the cold body or pump heat from it by Nottingham effect.

Strategies to Tailor Thermal Properties of Metamaterials: Perforation and Amorphisation

K. Termentzidis[1]

[1]CETHIL Laboratory UMR5008, CNRS, INSA of Lyon, France
[*]corresponding author: konstantinos.termentzidis@insa-lyon.fr

Abstract: The rapid development of fabrication techniques enables the elaboration of new class of materials with tailor thermal properties. The thermal metamaterials are intelligently designed artificial structures with which one can engineer heat energy as the thermal conductivity becomes an extrinsic property. Here several theoretical and experimental examples of thermal metamaterials using the strategies of perforation and amorphisation will be presented.

The thermal conductivity of pristine bulk materials is an intrinsic physical property of the material and it cannot be controlled. With the nanostructuration, one can design materials with extrinsic thermal properties. The so called thermal metamaterials enable us to manipulate heat flow, with aim to propose thermal functional devices [1]. Among them, Phononic Crystals (CR) rise interesting fundamental questions and promising applications in thermal management and thermoelectricity. Recently, important new physical insights proposed in the literature concerning heat flux manipulation based in new phenomena such as: coherent effect, hydrodynamics, phonon focusing, thermal shielding, concentration, or even inversion [2]. Here, the impact of purposed amorphisation, perforation and the existence of native oxides (that arise on samples in presence of air) located at the membranes surfaces or around patterned holes on the thermal conductivity will be analyzed using atomistic simulations.

When the characteristic sizes of metamaterials with perforated holes, or amorphous inclusions are of the order of the mean free path of the heat carriers, here the phonons, all structural details should be taken into account. In this regime, the heat flux becomes very sensitive to atomic scale engineering as the creation of holes, the neck distances, the alignment of holes, the orientation of defects and surfaces/interfaces [3,4,5]. The aformentioned PC are considered 2D nanostructures. Adding complexity, there are also three-dimensional (3D) metamaterials as nanowire networks. These nanostructured materials are potential metastructures for nanoelectronics and thermoelectric applications. The 2D and 3D nanowire networks are a new class of nanoarchitectured materials have interesting physical properties due to their low mass density and their high surface-to-volume ratio. We will show that the thermal conductivity of these networks decreases in increasing the distance between the nodes [6]. This effect is much more pronounced in 3D networks due to increased porosity, surface-to-volume ratio, and the enhanced backscattering at 3D nodes compared to 2D nodes. We propose a model to

estimate the thermal resistance related to the 2D and 3D interconnections in order to provide an analytic description of thermal conductivity of such nanowire networks; the latter is in good agreement with molecular dynamic results. The backscattering processes in the nodes increase the thermal resistance by a factor of 5 compared to simple nanowires.

Nanostructures for Photocatalysis - From regular to dendritic Architectures

Christin David

Friedrich-Schiller Universität Jena, Institute of Condensed Matter Theory and Optics, 07743 Jena, Germany
Abbe Center of Photonics, 07745 Jena, Germany
*corresponding author: christin.david@uni-jena.de

Abstract: We discuss the opportunity to design switchable nanostructures for enhanced selectivity in photocatalytic reactions. While we can tailor regular nanostructures in active metasurfaces to manipulate light in the desired way, irregular nanostructure platforms as obtained from self-organized growth of dendritic nanoarchitectures offer a high density of hot-spots with a wealth of spectral features. We present numerical calculations assessing optical and thermal properties of such structures as well as estimating light-induced electron transfer mechanisms to nearby molecules.

Complex nanostructured matter is of great interest for spectroscopy, biochemical sensors, microscopy and (photo-)catalysis [1]. They show high tunability of spatial and spectral properties, boosting energy conversion efficiency with high local fields or improving absorption through directional scattering. Surface roughness poses a major challenge to theoretical methods aiming at accurately describing realistic experimental situations [2].

We study the structure-performance relationship in nanostructured architectures for nanophotonic applications from regular thin-walled TiO2 and TiN nanotubular pillars [3, 4] to self-organized dendritic structures made from gold [5]. The possible enhancement of reaction and transport rates due to a large surface area, strong electron confinement and short diffusion paths make them highly interesting for energy conversion platforms [6,7]. A further advantage for use in bionanotechnology, catalysis and related fields is the biocompatibility of the employed materials. Self-assembled nanostructures are favorable with view to their fabrication costs in a highly competitive industry.

The emergence and density of hot-spots is studied in dendritic structures and applied in SERS and photoreduction experiments on methylene blue (MB) [5]. Interestingly, a high hot-spot density does not guarantee a high catalytic yield but is more favorable in SERS measurements. For the catalytic experiments, a uniform distribution of similar hot-spots through more homogeneous feature sizes yields better results. We support experimental findings with numerical calculations using Boundary Element Method (BEM) for dendritic structures, Fourier Modal Method (FMM) for regular structures and also give an overview over our most recent contributions to modeling optical response from rough and irregular nanostructures [2-5]. Furthermore, we consider local temperature effects [8] and calculate electron transition rates from local dipole-dipole coupling as well as electron injection [9].

Smart Sensing and Spectroscopy using Thermal Emission

Yuzhe Xiao[1]

[1]Department of Physics, The University of North Texas, USA
[*]corresponding author: yuzhe.xiao@unt.edu

Abstract:

Thermal emission is a ubiquitous phenomenon where hot objects radiate energy as electromagnetic waves. I will first introduce a new metrology method—depth thermography—that can measure the temperature distributions of an object at different depths, based on the light thermally emitted from that object. Then, I will introduce a new spectroscopic technique—Planck spectroscopy—that measures the spectral emissivity of an object using only a temperature-controlled stage and a detector, without any wavelength-selective components such as prisms, gratings, or interferometers.

Nanophotonic scintillators for enhanced x-ray detection and imaging

Charles Roques-Carmes[1,2]

[1]Research Laboratory of Electronics, Massachusetts Institute of Technology, Cambridge MA 02139, USA
[2]Ginzton Laboratory, Stanford University, Stanford University, Stanford CA 94305, USA
[*]corresponding author: chrc@mit.edu

Abstract: Scintillators are materials that emit light in the form of spontaneous emission when pumped by high-energy particles, such as x-rays. We demonstrate that several concepts in nanophotonics, such as out-coupling and Purcell enhancements, can enhance and shape scintillation light. We then discuss possible applications of such "nanophotonic scintillators" (consisting in the integration of scintillator materials into nanophotonic structures) in enhancing the resolution and detection efficiency of x-ray imaging systems.

Bombardment of materials by high-energy particles (e.g., electrons, x- and γ-ray photons) often leads to light emission, known generally as scintillation. Scintillation is ubiquitous and enjoys widespread applications in many areas such as medical imaging, x-ray non-destructive inspection, night vision, electron microscopy, and high-energy particle detectors. A large body of research focuses on finding new materials optimized for brighter, faster, and more controlled scintillation. Recent results have proposed scintillation enhancement relying on photonic effects, either by enhancing the rate of spontaneous emission [1, 2], or through improved light extraction [3].

Here, we develop a general framework based on integrating nanophotonic structures into scintillators to enhance their emission, which we coin "nanophotonic scintillators" [4]. To start, we develop a unified and *ab initio* theory of nanophotonic scintillators that accounts for the key aspects of scintillation: the energy loss by high-energy particles, as well as the light emission by non-equilibrium electrons in arbitrary nanostructured optical systems. This theoretical framework allows us, for the first time, to experimentally demonstrate nearly an order-of-magnitude enhancement of scintillation in x-ray-induced scintillation, through improved light extraction from bulk scintillators. Our theory also allows the discovery of structures that could eventually achieve orders-of-magnitude scintillation enhancement and shaping of scintillation's optical properties (e.g. angular, spectral, polarization), in addition to the end-to-end imaging optimization of nanophotonic scintillators integrated into imaging systems [5]. We show that inverse-designed nanophotonic scintillators could enable the development of a new class of brighter, faster, and higher-resolution scintillators with tailored and optimized imaging performances.

A multimode quasi-normal mode framework for nonlinear harmonic generation with 2D materials

Thomas Christopoulos[1,2*], Emmanouil E. Kriezis[1], and Odysseas Tsilipakos[2*]
[1]School of Electrical and Computer Engineering, Aristotle University of Thessaloniki, GR-54124 Thessaloniki, Greece
[2]Theoretical and Physical Chemistry Institute, National Hellenic Research Foundation, GR-11635 Athens, Greece
[*]corresponding authors: cthomasa@ece.auth.gr, otsilipakos@eie.gr

Abstract: In this work, we present a multimode framework for linear and nonlinear modal calculations in non-Hermitian systems comprising 2D materials. The framework is based on the ability to appropriately expand both the linear and nonlinear responses of a resonant cavity in terms of the supported quasi-normal modes. Through numerical simulations, we find that the proposed framework is efficient and extremely accurate, even when complex contemporary photonic systems incorporating 2D materials are involved.

Non-Hermitian cavities, i.e., resonant systems with radiation leakage and resistive loss, support quasi-normal modes (QNMs), whose properties are not as well-defined as those of normal modes supported by Hermitian systems. QNMs exhibit interesting but cumbersome properties, with the most notable being the unphysical spatial exponential divergence of the field components outside the resonant cavity, complicating the process of their normalization. Lately, the study of QNMs has produced very interesting results by providing the appropriate normalization needed to regularize this mode divergence [1-2]. In effect, this important fact led to the development of elegant techniques to reconstruct the full linear spectrum of a system using the QNMs it supports [3]. However, the study of expansions that additionally include nonlinear interactions received much less attention [4-5]. Additionally, although the methods presented thus far cover a wide range of material configurations (dielectric and plasmonic scatterers and metasurfaces, photonic crystals, etc.), none has focused on the contemporary family of 2D materials (e.g., graphene, transition metal dichalcogenides, black phosphorus, etc.) which, among others, possess unique nonlinear properties. In this work, we present such a complete methodology, beginning from the careful introduction of 2D materials in the linear QNMs framework through their natural representation as infinitesimally thin layers and subsequently progressing to additionally include their nonlinear properties through the demonstration of the third harmonic generation effect [5]. We also rigorously take into account material dispersion by expanding the established finite-element method using appropriate surface auxiliary fields [3,5]. Thus, we successfully provide with the proper normalization that correctly captures the full complexity of 2D materials including infinitesimal thickness, dispersion, loss, and anisotropy, applicable either in linear or nonlinear systems.

The developed nonlinear multimode framework is validated through two indicative resonant structures comprising graphene [Fig. 1(a)], i.e., the most prominent 2D material. Graphene supports tightly confined surface plasmons in the THz regime, whose tight confinement further enhances its inherent strong nonlinear response. The first example that is examined consists of a single graphene strip lying on a glass substrate. The second is a metasurface made of periodically arranged graphene strips on a metal-backed substrate to operate in reflection. The response (both linear and nonlinear) of the two systems is studied using the developed QNMs framework and validated through (nonlinear) full-wave simulations. The results of Fig. 1(b-e) show that excellent agreement is achieved between the two methods both in the linear and nonlinear regimes and even under oblique incidence.

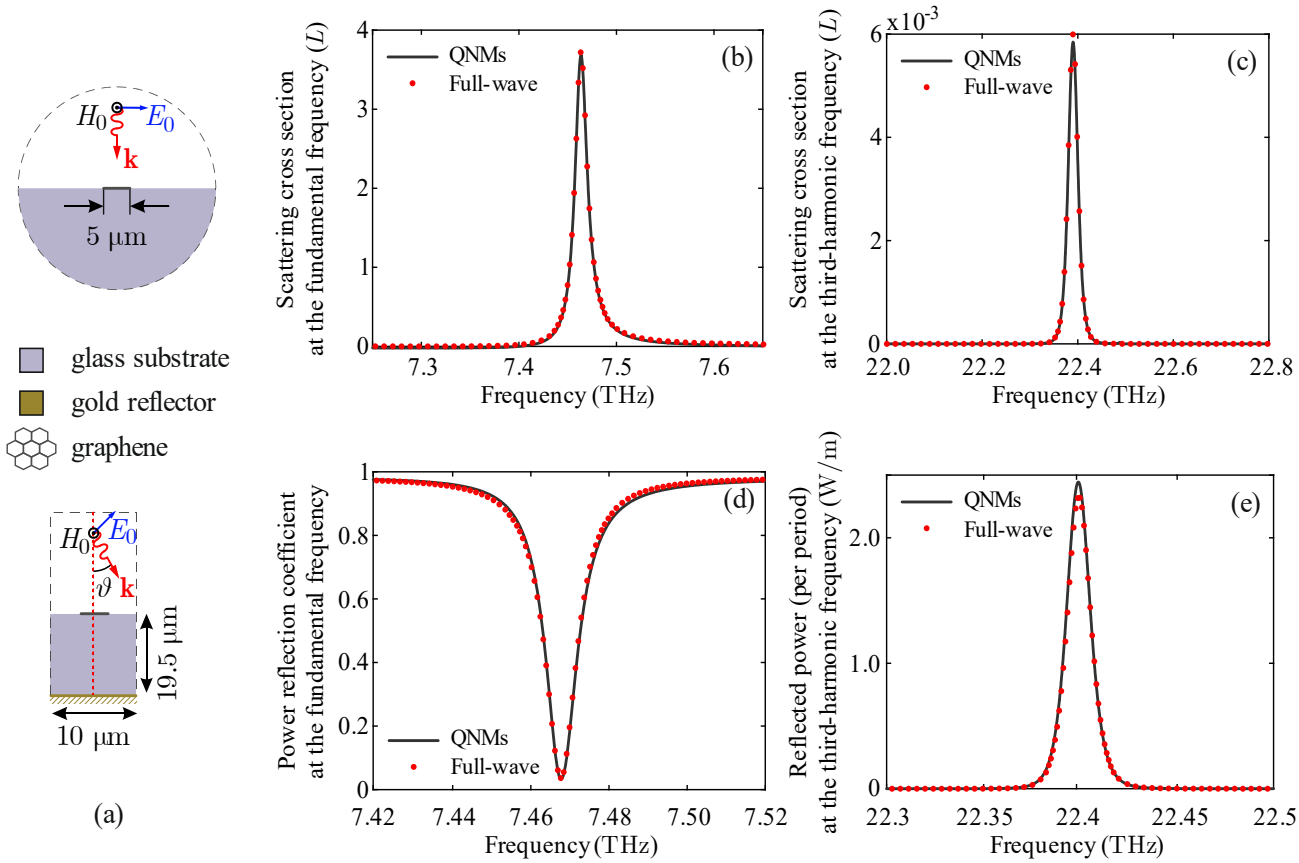

FIGURE 1. (a) The two considered structures comprising graphene on a glass substrate. (b) Linear and (c) nonlinear response (scattering cross-section) of a single graphene strip under normal incidence. (d) Linear and (e) nonlinear response (power reflection coefficient and reflected power, respectively) of a graphene metasurface under oblique incidence ($\theta=20^o$). QNM expansion (solid lines) and full-wave simulations (red point markers) show excellent agreement in both cases.

Green's tensor inverse design of light-matter interactions

R. Bennett[1]

[1]University of Glasgow, United Kingdom
[*]corresponding author: robert.bennett@glasgow.ac.uk

Abstract: Effective designs for photonic elements are usually found through a combination of intuition, symmetry and previous experience. By contrast, inverse design allows (locally) optimal geometries to be algorithmically discovered, often leading to much higher performance than structures designed by hand [1]. Originating in fluid dynamics, inverse design techniques are finding new applications across quantum optics and (nano-) photonics. In this talk I will outline a very general approach towards inverse design that concerns itself only with the electromagnetic dyadic Green's tensor of a particular scattering geometry [2]. Significant reductions of computational overhead are achieved by using the adjoint method, which is naturally built into the formalism through the symmetry properties of the Green's tensor. This approach allows inverse design methods to be applied to a whole family of surface-dependent light-matter interactions in a unified and consistent way, opening up new routes to optimisation of, for example, Casimir-Polder forces, resonant energy transfer [2], environment-induced coherence [3], helicity structures [4], dielectric cloaks [5] and non-local response of metasurfaces [6], among others.

[*]Corresponding author: Youssef.jeyar@umontpellier.fr

Abstract: We present a numerical approach for the solution of EM scattering from a dielectric cylinder partially covered with graphene. It is based on a classical Fourier-Bessel expansion of the fields inside and outside the cylinder to which we apply the ad-hoc boundary conditions in the presence of graphene. Due to the singular nature of the electric field at the ends of the graphene sheet, we introduce auxiliary boundary conditions to better take this reality into ac- count. The result is a very simple and very efficient method allowing the study of diffraction from such structures.

1 Introduction

Diffraction of electromagnetic waves from circular cylinders is rather a simple and classical problem [1]. In this situation, the incoming and outgoing fields can be represented in terms of circular waves expressed through Fourier-Bessel expansions. All the channels are independent from each other because of the circular symmetry and homogeneity of the cylinder. However, when this cylinder is partially covered with a sheet of graphene, this breaks the symmetry and homogeneity at the level of the surface and then all the channels can be mixed up thus leading to interesting physical phenomena. Under this situation, the boundary conditions lead to an algebraic system linking the outgoing amplitudes of the fields to the incoming ones. This system may be singular in the case of transverse magnetic polarization (TM: the magnetic field is parallel to the direction of invariance of the cylinder). This is due to the singularities of the tangential component of the electric field at the ends of the graphene sheet. One way of solving this issue is to use a supplementary expression of this field right at the level of the circumference of the cylinder in terms of Local Basis Functions (LBFs) able to reproduce the singularities [2].

2 Results

Figure 1 shows the geometry of the diffraction problem where a plane wave (wavelength λ) is impinging on a circular cylinder (radius R and dielectric permittivity ε_r) partially covered by a graphene (conductivity σ). As already said in the introduction, this problem of diffraction can be solved through the expansion of the fields in terms of Fourier- Bessel modes. This will be called the classical method. It turns out that under TM polarization there are some singularities of the tangential electric field that cause slow convergence of the computations. This problem is handled through the introduction of LBFs that possess the same singularities of the field.

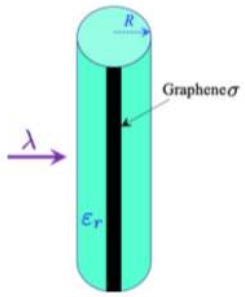

Figure 1. Sketch of the diffraction problem under consideration: an electromagnetic plane wave hits the covered dielectric cylinder under classical diffraction.

Figure 2 shows the scattering efficiency versus the wavelength, obtained with the classical method and with the LBFs method. It can be clearly seen that the LBFs method converges rapidly as compared to the classical one. For the LBFs method the number of modes necessary to achieve convergence (stabilization of the fourth digit for example) is very low about: 40 modes contrary to the classical method where even more than 150 modes do not give the same results.

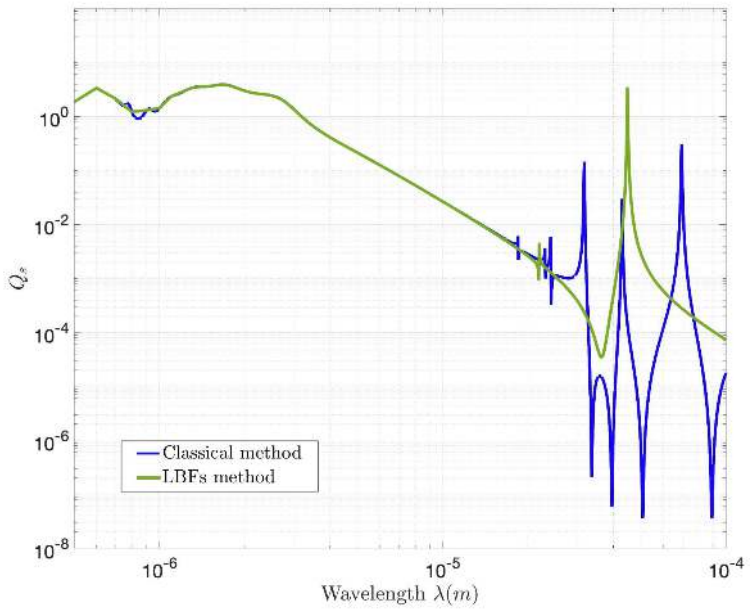

Figure 2. Scattering efficiency *Qs* of cylinder of radius $R = 0.5\mu m$ and permittivity $\varepsilon_r = 3.9$ immersed in air, a graphene sheet of chemical potential $\mu = 0.5$ eV and $T = 300$ K

Improving Photonic Crystal Waveguide Simulation Efficiency: A Journey from 3D approaches to Deep Neural Networks

C. F. Schwahn[1], S. A. Schulz[1]

[1]SUPA, School of Physics and Astronomy, University of St Andrews, St Andrews, UK
*corresponding author: sas35@st-andrews.ac.uk

Abstract: In this paper, we summarize the historical and recent contributions of our group to the development of accurate and efficient simulation and design methods for Photonic crystal waveguides. This will look at the use of ensemble average properties for the calculation of propagation loss, 2-dimensional approximations and finally optimization and machine learning techniques. Here we demonstrate the same accuracy as full 3D simulations with a 7-orders of magnitude reduction in the calculation time, to the sub-ms per design range.

The properties of slow light Photonic crystal (PhC) waveguides are fully controlled by their design parameters, such as the lattice period, hole radius or shifts of individual rows of holes [1]. Thus designing such devices seems like a straightforward task – all that needs to be done is to solve Maxwell's equations using appropriate boundary conditions and the appropriate refractive index distribution. However, this picture belittles the complexity of this task.

To accurately predict the properties we would need to solve Maxwell's equations with a deep-subwavelength resolution – typically 10 or more grid points per wavelength – in 3D, resulting in simulations that take multiple CPI/GPU hours per device. Combined with the fact that we need to optimize over a large design space (e.g. figure 1 indicates a 7-dimensional design space) the device design quickly becomes prohibitively complex, severely limiting the use of PhC waveguides.

During this talk, I will focus on both historical and recent developments in the field of PhC waveguide simulations, resulting in highly accurate and efficient simulation methods. We will consider the 7-dimensional design space shown in figure 1. It consists of the hole radius of the background lattice (r_0), row-wise variations of the hole radius of the first three rows (r_1-r_3) and row-wise shifts of the first three rows of holes perpendicular to the waveguide (s_1-s_3).

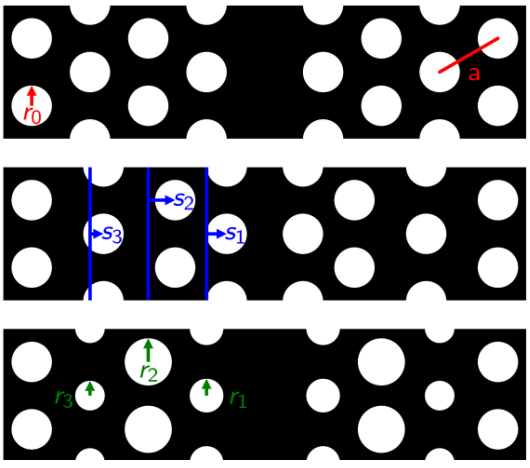

Figure 1: Schematic of a Photonic crystal waveguide with 7 design parameters (r_0, r_1, r_2,

The historical overview will begin with the traditional approach of solving Maxwell's equations or simplified wave equations in 3D [2], before moving on to 2-d approximation methods, that reduce the design space and hence grid volume [3]. These methods have enabled optimization methods [4] and eventually machine learning approaches [5,6]. These latest developments allow us to simulate the optical properties of PhC waveguides not in CPU hours but on a sub-ms timescale. This paves the way

towards the rapid and fast exploration of the design space. Our Neural Network based approach has an absolute mean error of only 0.3% compared to the MIT Photonics Band solver (better than the accuracy achieved with modern fabrication methods), with a 7-orders of magnitude reduction in the simulation time.

Modeling and Applications of Nonlocal Asymmetric Metasurfaces

K. Achouri[1*], S. Boroviks[1], and O. JF Martin[1]

[1]Swiss Federal Institute of Technology in Lausanne (EPFL), Switzerland
[*]corresponding author: karim.achouri@epfl.ch

Abstract: The concept of nonlocal metasurfaces has recently emerged to overcome the limitations of local metasurfaces in terms of efficiency and diversify their functionalities. To better exploit the potential of nonlocal metasurfaces, we have developed a general modeling framework that includes nonlocal interactions. Based on this model, we show the connection between nonlocality and the metasurface spatial symmetries. Finally, we provide several examples highlighting the advantages and related applications of nonlocal metasurfaces.

Nonlocality in electromagnetism, often alternatively called spatial dispersion, refers to an extended distance between an excitation and the response that it induces in a nonlocal medium. In practice, most conventional optical or electromagnetic media are spatially local due to the simple nature of their structure. However, this is generally not the case of metamaterials and metasurfaces that often exhibit non-negligible nonlocal interactions between their complex scattering particles [1,8].

Historically, these nonlocal interactions have often been considered undesirable as they were considered detrimental in many applications due their strong dependence on the direction of light propagation. However, it now appears that nonlocality presents a major advantage which is that, in contrast to temporal dispersion, it is not restricted by causality. While temporal dispersion must obey the Kramers-Kronig relations implying that a change in the response of a medium leads to an increase of its loss, nonlocal effects may be leveraged without inducing additional loss and thus do not impair the efficiency of the system. This suggests that highly efficient operations may be performed with nonlocal metasurfaces.

In this work, we present a general approach for modeling nonlocal metasurfaces. This modeling approach is based on the concept of the generalized sheet transition conditions that have been extensively used to design dipolar metasurfaces [2]. We will show how this model may be extended to include multipolar contributions, which includes nonlocal effects. We will also discuss how nonlocal interactions are intimately related to the spatial symmetries of the lattice and scattering particles of metamaterial structures [3].

Finally, we will present several examples of metamaterials where nonlocal interactions play an essential role. A selection of such examples is illustrated in Fig. 1. The case of perfect (i.e., fully efficient) refraction and reflection is depicted in Fig. 1a, where such operations respectively require bianisotropy (a type of nonlocal response) or nonlocal energy transport [2,4]. In Fig. 1b, we show that an asymmetric plasmonic metasurface may be used to generate asymmetric second-harmonic generation [5]. This unconventional effect stems from nonlocal interactions in both linear and nonlinear regimes. The last example shown in Fig. 1c shows that a longitudinal optical torque may be induced by illuminating a helical-shaped nanoparticle with a normally incident plane wave [6,7]. In this case, note that the particle is *not* geometrically chiral, however it nonetheless exhibits a pseudochiral response that originates from multipolar nonlocal effects [3,6,7].

An overview of spatial spectral methods with complex-plane deformations for the representation of waves in homogeneous and layered media without absorbing boundary conditions

R. J. Dilz[1*] **and M. C. van Beurden**[1]

[1]Eindhoven University of Technology, The Netherlands
[*]corresponding author: r.dilz@tue.nl

Abstract: The prevention of reflections from the edge of the computational domain is a challenge in computational electromagnetics. Although ways exist to absorb/negate such reflections, we recently proposed an entirely different strategy. Based on a representation in the spectral domain, we analytically represent waves on the entirety of space, but with accuracy focused only on a certain region. Therefore, we can employ formulations without worrying about boundary conditions. We show several examples of this technique, including simulations in layered media.

In the past, several methods have been developed for the computation of electromagnetic fields that employ a Fourier transform of the spatial dimension(s). An important reason for employing the spectral domain is that the Green function for electromagnetic scattering can be expressed easily in it. Especially for layered media this is true, since an analytical expression for the Green function is only available in the spectral domain, and a spatial-domain Green function can only be computed through tedious Sommerfeld integrals [1]. Additionally, spatial derivatives are more easily represented in the spectral domain.

Examples of computational methods include the Fourier Modal Method [2], which uses (truncated) analytic expressions within layers and then couples these layers with each other by employing the layer-boundary conditions. Another example is the spectral domain volume integral equation in [3]. Here, analytical expressions for reflection and transmission coefficients are employed to incorporate the boundary conditions. However, both these methods have in common that they are usually employed for periodically repeating structures.

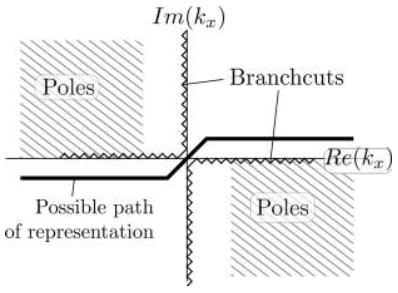

Figure 1: Typical locations of poles and branch cuts for layered media

One reason that spectral-domain methods are usually employed for periodically repeating scatterers is that employing a simple Fourier-series discretization then leads to simple and fast algorithms. However, the generalization to aperiodic scatterers is challenging. Absorbing boundaries can help to mitigate waves that travel over the unit-cell-boundary [4], but these can lead to numerical instabilities. Fully aperiodic discretization methods that are compatible with Fourier transforms exist, e.g. Gabor frames [5] and Hermite-interpolations [6]. Still the behavior of both Green function and fields are difficult, since radiation/guided waves can extend to infinity in the spatial domain. In the spectral domain, this is represented by branch cuts and poles.

In Figure 1 we indicate the location of such poles and branch cuts for a typical reflection coefficient of a layered-medium stack – a function that is typically required to be represented in a computational method for layered media. As long as the full stack is made of passive materials, the poles and branch points will always be a certain range away from the origin, and will not exceed a range from the origin on the real k-axis. To efficiently discretize this singular behavior is hard, especially when using discretizations that are meant for continuous functions, such as is the case with discretizations that work well in both spatial and spectral domain.

We solve this issue by representing electromagnetic fields and Green functions on a deformed contour in the complex plane [6,7,9]. This contour then circumvents the poles and branch cuts, so that all desired quantities can be properly discretized. However, the contour does represent fields in the numerically unstable regions of the complex plane that represent gain-media. In [8, Chapter 9] we have shown that a stable representation can always be reached, when the deformation contour is chosen smartly, depending on the size of the simulation domain. Several formulations for complex-plane path deformations have been developed.

We will show the current status of our ongoing research and show some examples of cases relevant to the meta-materials community.

Effect of top metallic contacts on radiation transfer and conversion efficiency for near-field thermophotovoltaics

K. Austry[1], **Y. Jeyar**[1], **M. Luo**[1], **B. Guizal**[1], **R. Messina**[2], **R. Vaillon**[3], **and M. Antezza**[1,4]

[4] Institut Universitaire de France, 1 rue Descartes, F-75231 Paris Cedex 05, France

Abstract: Design of the metallic contact grid at the front side of thermophotovoltaic cells is critical. In particular, in the near field, the effect of this metallic grid can be tremendous both in terms of optical and electrical (resistive) losses. However, this effect has been theoretically either discarded or studied by means of extremely simplified models (like shadowing methods, consisting in just ignoring the fraction of the cell surface covered by metal).

Our study, based on a rigorous approach, investigates the real influence of the front metal contact grid. By modelling this grid by a metallic grating, we show that it can significantly affect the electrical power generated by the cell. Quantitative and qualitative analyses indicate behaviors which are quite different from those predicted by previous simplistic approaches.

By using the fluctuational electrodynamics framework, we first solve the full electromagnetic problem of a metallic grating in the presence of a cell and an emitter. Then we derive the emitted/absorbed radiation in the nanophotonic structure (including all multiple electromagnetic wave reflections involving the grating, the cell and the emitter) and electrical power production in the thermophotovoltaic cell.

Similarly to a previous work [1], we consider a doped-silicon emitter at 800 K which irradiates on an indium arsenide p-n junction cell kept at 300 K. A gold grating is set above the cell spaced at 100 nm from the emitter in order to observe the influence of the height of this body on the emitter-cell near-field heat transfer (see Fig. 1).

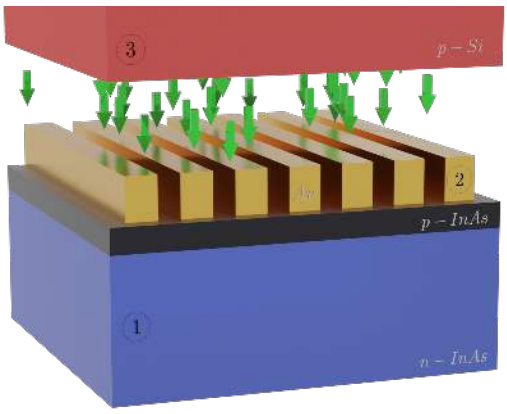

Figure 1: The configuration studied is a doped-silicon emitter which irradiates at 800 K on a TPV cell made of indium arsenide, kept at 300 K and covered by a gold grating.

A plane-wave decomposition is carried out for the incoming and outcoming waves of each body in a stationary regime. With the scattering matrix approach [2,3,4], we are able to compute the reflection and transmission coefficients in order to determine the net heat flux absorbed and the electrical power generated by the cell, in this three-body configuration.

Near-field regime allows evanescent waves to contribute, and this happens here in the presence of a grating which opens new heat transfer channels. To tackle the grating periodicity, we use a Fourier modal method (FMM) to evaluate the reflection and transmission coefficients. We need high-order Fourier modes in order to face the abrupt transition of the dielectric permittivity at the metallic-vacuum interfaces within the grating. To reach a faster convergence when calculating the grating reflection and transmission coefficients, we combine the FMM with the adaptative spatial resolution (ASR) [4]. By performing a change of coordinates, this method allows to densify the sampling around the critical region of the grating and get convergence much more rapidly. This is a crucial ingredient in order to have a fast and reliable converging code that must perform a three-dimensional integral over the mode quantum numbers, necessitating evaluation of millions of reflection and transmission matrices.

We first show that the presence of a grating increases the generated electrical power with respect to a cell without grating, and this for grating heights smaller than 1 micron. We also show that the previous over-simplified theoretical method considering a simple shadowing effect underestimates the generated electrical power by around one order of magnitude.

Concerning the TPV conversion efficiency, it is defined as the ratio of the electrical power generated by the cell to the net radiative power absorbed by the cell and the grating. We find that the presence of the metallic grating can reduce the TPV efficiency in a considerable way.

Our results suggest that rigourous approaches considering properly the impact of a metallic contact grid at the front of cells in near-field thermophotovoltaic devices are absolutely required in order to make accurate predictions of both electrical power and conversion efficiency.

Inverse design of dispersive optical nanostructures and tunable metasurfaces

Antonio Calà Lesina[1*]

[1]Hannover Centre for Optical Technologies, Institute for Transport and Automation Technology (Faculty of Mechanical Engineering), and Cluster of Excellence PhoenixD, Leibniz University Hannover, 30167 Hannover, Germany
[*]corresponding author: antonio.calalesina@hot.uni-hannover.de

Abstract: Inverse design techniques hold the promise to uncover free-form nanophotonic structures in 3D with shapes beyond human intuition and novel optical functionalities. This talk focuses on our recent work on large-scale topology optimization of dispersive materials, anapole states in plasmonic nanostructures for transparent metasurfaces and metamaterials, and inverse design of tunable metasurfaces while accounting for the tuning mechanism.

Advances in computing capabilities and numerical methods, such as the finite-difference time-domain (FDTD) and finite-element methods (FEM), have recently empowered the design of nanophotonic devices [1]. By exploring large design spaces one can find solutions to complex optimization problems, but also discover new conceptual free-form designs. However, exploring large parameter spaces is computationally challenging. Techniques such as parameters sweep or stochastic optimization methods, e.g., genetic algorithms, are only suitable to handle problems with few design parameters, and therefore only useful when a good initial guess is known. Deep learning algorithms are emerging as a promising option for nanophotonics inverse design, but they require prohibitively large data sets for training. Topology optimization (TopOpt) is a robust inverse design technique which produces solutions far beyond human intuition and other optimization methods. Typically, TopOpt problems are solved using gradient-based optimization methods, where the gradient of the objective function with respect to the design variables is computed using efficient techniques such as the adjoint method, which only requires two simulations [2].

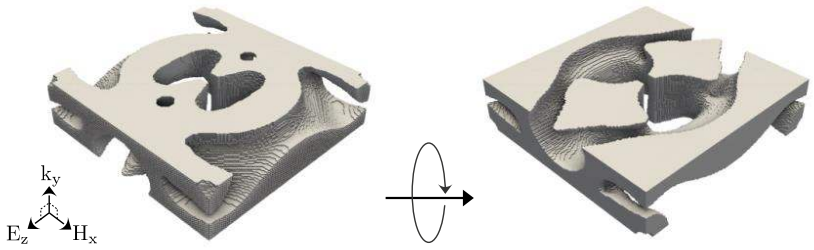

Figure 1: High-index dispersive dielectric nanostructures designed via topology optimization [credit: J. Gedeon].

My team develops and maintains an in-house parallel 3D FDTD Maxwell solver, which has been used for over a decade on supercomputers in Italy, Canada and Germany. The solver is parallelized with the message passing interface (MPI) and exhibits nearly linear scalability tested up to 16k cores [3]. Our software allows us to simulate large-scale devices that are intractable with commercial (Ansys Lumerical FDTD) and open-source (MEEP) software packages. Performing free-form optimization employing high-performance computing (HPC) has revolutionized many engineering disciplines, where new conceptual designs were obtained [4]. My team is focusing on TopOpt techniques combined with HPC to address the urgent need both in research and industry to make the numerical tools for the inverse design of large-scale free-form nanophotonic systems in 3D more scalable and efficient. In my talk, I will present our recent results on the inverse design of large-scale nanostructures and

metasurfaces in 3D, focusing on:

- Time-domain topology optimization of 3D metallic and dielectric dispersive nanoantennas with broadband optical response. A high-index dielectric nanostructure optimized in 3D for broadband field enhancement is presented in Fig. 1.
- Novel plasmonic nanostructures with anapole states for highly packed transparent metasurfaces and metamaterials, which may find application in nonlinear optics, lasing and sensing.
- Inverse design of tunable metasurfaces, where the tuning mechanism is taken into account during the optimization process.

Energy Efficient Back-to-Back Neural Networks to Design Photonic Devices

Ergun Simsek

Department of Computer Science and Electrical Engineering,
University of Maryland Baltimore County, Baltimore, MD 21250, USA
simsek@umbc.edu

Abstract: By solving the drift-diffusion equations on nonuniform spatial and temporal grids, where the broadband modulations are defined with window functions, the computation time can be reduced by two orders of magnitude. This significant reduction enables the simulation of thousands of photodetectors within a few hours, allowing for the creation of a large database. This dataset is then used to train energy-efficient back-to-back neural networks that can successfully design photodetectors based on the desired phase noise, quantum efficiency, and bandwidth.

Photonic and optoelectronic devices, which are typically designed with numerical solvers, exhibit complex and nonlinear behavior. Machine learning algorithms can help design these devices more efficiently, but they require a large amount of data to learn and make accurate predictions. Therefore, a fast numerical solver is essential to create a large enough dataset.

In this work, we achieve this goal by developing a new drift-diffusion equation solver that is two orders of magnitude faster than traditional solvers, allowing us to study both group IV and III-V photodetectors. The significant reduction in simulation time was made possible by implementing non-uniform time-stepping [1] and utilizing window functions as broadband modulations [2].

In [3], we demonstrate two important findings regarding the prediction of photodetector performance metrics with neural networks. Firstly, traditional fully-connected neural networks can predict these metrics with a high level of accuracy (97%). Secondly, neural networks that are designed based on the physical principles and characteristics of the photodetectors can achieve even higher prediction accuracy (99%) while using fewer neurons and consuming less energy. The neural network architecture depicted in the left half of Fig. 1 uses multiple layers to pair the parameters of each photodetector layer, inform the decoder network about the interfaces separating the layers, mimic the current transport among neighboring layers, and teach the decoder about the specific order and bi-directional interactions between these paired inputs. Additional layers are then used to perform the regression of the device performance metrics.

In this work, we employ a similar strategy to design an energy-efficient back-to-back neural network. The encoder network is identical to the one used in our previous study [3], while the decoder network is almost a symmetric copy, with the exception that clustering is performed in the last neural network layer instead of regression. In this direction, each parameter is allowed to be one of the 201 pre-defined unique values. For instance, there are 201 unique thickness values that can be assigned to each photodetector layer, ranging from 10 nm to 2000 nm in increments of 10 nm. Similarly, there are 201 doping levels that can be assigned to these layers, which are logarithmically distributed between 10^{14} cm^{-3} and 10^{19} cm^{-3}.

The encoder network is asked to determine the parameters of the designs for phase noise levels ranging from –170 dBc/Hz to –180 dBc/Hz, quantum efficiency between 0.1 and 0.2, and bandwidth between 5 GHz and 20 GHz. These designs are subsequently analyzed using a solver for drift-diffusion equations. The resulting metrics are found to be very similar to the desired metrics.

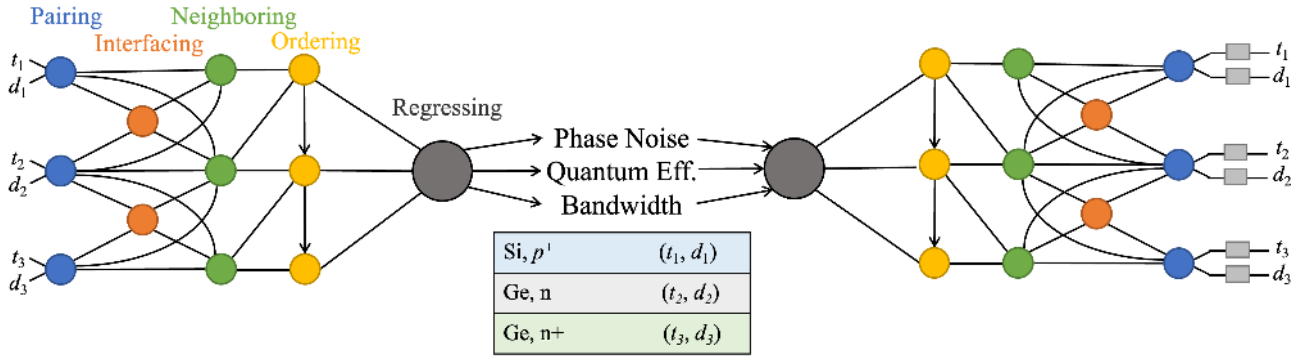

Figure 1 An illustration of energy-efficient the back-to-back neural network specifically designed (i) to learn from device parameters (layer thicknesses and doping levels) to predict performance metrics (phase noise, quantum efficiency, and bandwidth) and (ii) to design a photodetector for the desired set of device metrics. In the middle, a 3-layer Si-Ge photodetector is illustrated, where t_i and d_i are the layer thickness and doping levels for the i^{th} layer, where i = 1, 2, 3.

In order to comprehend the reasoning behind the proposed back-to-back neural network's successful device design capabilities, we conducted an investigation into the relationship between the inputs and outputs. At the conference, we will discuss this in detail and elaborate on our findings. Briefly, we were able to identify the influence of each design parameter on the device's performance metrics. Additionally, we noticed that phase noise, quantum efficiency, and bandwidth result in almost a flat surface in three dimensions, as illustrated in Figure 2. This provides a clear visualization of the trade-offs and limitations that are present.

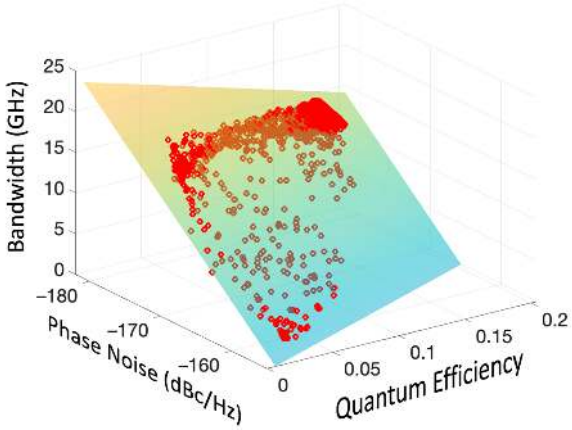

Figure 2 Phase noise, quantum efficiency, and bandwidth of the Si-Ge photodetectors form almost a flat surface.

The Fourier Modal Method simplified for crossed subwavelength gratings

B. Guizal[1*]

[1]Laboratoire Charles Coulomb (L2C), UMR 5221 CNRS- Université de Montpellier, F-34095 Montpellier, France
[*]corresponding author: brahim.guizal@umontpellier.fr@institution.edu

Abstract: We present a simplification of the Fourier Modal Method (FMM) for crossed gratings with subwavelength heights. We show that in this case it is possible to compute the scattering matrix of the structure without solving the eigenvalue problem which is the most expensive computational part of the FMM algorithm. This approach is very efficient and thus suitable for periodic metasurfaces.

The Fourier Modal Method[1] is one of the most versatile and efficient methods for modeling diffraction from gratings. This is why it is suitable for modeling metasurfaces based on crossed binary gratings. The problem with this approach is that for metallic structures, it is necessary to truncate the Fourier series representing the fields to a high order implying the use of large matrices (especially in the case of crossed gratings). This is very demanding from the computational point of view because the heart of the FMM is based on the solution of an eigenvalue problem. This later has a cost scaling with the third power of the dimension of the matrices in play. This can be a severe limitation and hinder the use of the FMM.

On the other hand, an interesting class of metasurfaces is made of gratings with subwavelength heights. In this special case, it is possible (via a Taylor series expansion of the phase propagation matrix) to simplify the FMM is such a way that it is no longer needed to solve any eigenvalue problem. This proves to be very efficient in reducing the computational cost.

After recalling the principle of the FMM and the details of the corresponding algorithm, I will show how the assumption of subwavelength height leads to a simplified scattering matrix where there is no need to solve any eigenvalue problem. Numerical examples will be presented to support this new algorithm.

Enhanced and Tunable Kerr effect on InSb/graphene hybrid magnetoplasmonic structure at Terahertz waves

M. Ben Rhouma[1*], K. Edee[2], and B. Guizal[3]

Abstract: In this work, we propose a novel hybrid magneto-plasmonic structure based on graphene and doped InSb to enhance the magneto-optical Kerr effect at terahertz frequencies. The structure is composed of a 1D periodic doped InSb inlayed between a metallic backgate and a dielectric/doped graphene sheet . By computing the optical response of this structure, we show an enhanced and large Kerr rotation in a wide range of THz frequencies compared to that induced by a single graphene sheet and/or a doped magnetized InSb .

Magneto-optical (MO) effects such as Faraday and Kerr effects are phenomena referring to changes in the polarisation state of light after interacting with a magnetic material and describe the interaction between optical and magnetic materials, which plays a fundamental role in the technological applications, such as optical isolators and magnetic sensors. The ability to enhance MO effects is then crucial for designing several devices. One way to achieve that is to combine plasmonics and magnetics to give rise to the magnetoplasmonics field which became, recently, an active topic of research.

Graphene magneto-plasmonics, the research area that combines magnetic and plasmonic properties of graphene, has attracted considerable interest in recent years, thanks to the unique and unusual properties of the surface magnetoplasmons supported by graphene [1]. These properties have been exploited to design many tunable plasmonic nonreciprocal devices in the terahertz regime which became attractive for its benefits in various applications such as medical imaging, biological studies, space exploration, communications and security. Doped InSb has been recently exploited in magneto-plasmonic devices for the terahertz range as a potential MO material and showed interesting magneto-plasmonic properties in this frequency range. In this work, we propose to combine the interesting properties of both materials in the THz regime by hybridizing their surface magnetoplasmons which give rise to a large and enhanced magneto-optical effect. The studied structure consists of a 1D periodic doped InSb inlayed between a metallic backgate and a dielectric/doped graphene sheet and an external static magnetic field can be applied. We compute the magneto-optical spectra with the Polynomial Modal Method (PMM) and study the magneto-optical Kerr effect on such structures. We show an enhanced and large Kerr rotation in a wide range of THz frequencies compared to that induced by a single graphene sheet and/or a doped magnetized InSb. It is found that the underlying mechanism is due to the hybrid plasmonic waveguide guided modes resulting from the strong coupling between the graphene surface magneto-plasmons (GSMP) and the surface magneto-plasmons across the InSb. Moreover, calculation results demonstrate that this large Kerr rotation can be tuned by optimizing the graphene properties and structure parameters such as the graphene fermi level and the applied magnetic field. Our findings may offer a promising way in the design of new THz magneto-optical devices.

Ray Tracing Model for Non-Rotationally Symmetric Geodesic Lens Antennas with Full Beam Scanning Range in the Azimuthal Plane

S. Clendinning[1*], O. Zetterstrom[1], F. Mesa[2], and O. Quevedo-Teruel[1]

[1]Division of Electromagnetic Engineering and Fusion Science, KTH Royal Institute of Technology, Sweden

Abstract: This presentation discusses a ray tracing model developed to determine the radiation pattern of geodesic lens antennas with non-rotationally symmetric footprints, where the geometry of the lens is defined using spline functions. The shape of this footprint and lens height profile can be modified by changing parameters in the defined functions. The code features a significant modification to work previously published by the authors to account for the non-rotationally symmetric design. The model runs significantly faster than commercially available software.

Lenses are very useful when integrated with antennas as they can be used to manipulate a wave front propagating through the lens to have attractive features. This manipulation is dependent on the shape of the lens, the refractive index profile or both. Graded refractive index (GRIN) lenses that are rotationally symmetric, for example the Luneburg lens, are of high interest as they are capable of beam scanning over a large range. The Luneburg lens is particularly of interest as it can generate a planar wave front from a point source [1-5]. This planar wave translates to a directive beam, which is a feature desirable for 5G/6G, satellite communications or radars. An inherent disadvantage of rotationally symmetric lenses is their size. This can be reduced through the introduction of a mirror plane, reducing the lens size by half but also reducing the scanning range by half [2], or by introducing a compression along a single axis [3]. A further reduction in profile size (that maintains scanning range) can be achieved by defining the profile footprint with a desired shape then applying a modified GRIN to this.

The GRIN medium can be implemented using a range of techniques such as with dielectrics [1] or a quasi-periodic structure such as metallic pins [4]. Another option is to use the geodesic form where the graded refractive index is replicated using parallel curved metallic plates [3, 5]. The plates follow a height profile that replicates the optical path length that the wavefront traverses and the Poynting vector direction at the lens aperture that is present in the GRIN equivalent. In a geodesic Luneburg-like lens, the height profile (z) is a function of the lens radius (ρ) and follows approximately the hyper-elliptic form,

$$z = h_0(1 - \rho^p)^{\frac{1}{q}} \qquad (1)$$

where h_0, p and q are design parameters which modify the profile shape [3]. There are no known closed-form expressions to determine the required height profile for non-rotationally symmetric cases analytically, and hence a convenient strategy must be used to optimize the height profile in these cases. Geodesic lenses can be modelled using commercial software, e.g. in CST Microwave Studio, however this is often computationally expensive. This is particularly problematic when optimizing the profile or exploring new arrangements (such as non-rotationally symmetric cases) where many simulation runs are required, thus motivating the development of

a ray tracing model. We will present an example of a non-rotationally symmetric case designed using a ray tracing model, which has been verified using full wave simulations. This code follows a similar technique to works previously reported by the authors, however a significant modification has been applied into how the lens is meshed and how the lens is fed.

The ray tracing model to be presented can be broken into 3 steps. Firstly, geometric optics is used to determine the trajectory of rays through the lens. The outline of the lens footprint is defined using a spline function. It is this step that differentiates this presentation from our previous work [3, 5]. The desired height profile is then applied and meshed using polar coordinates. As a result of Fermat's principle and the homogenous refractive index profile between the conductive plates, the shortest physical distance (the geodesic) is equivalent to the optical path taken by the rays. The python library *gdist* is used in conjunction with the mesh to determine the ray trajectory through the lens [3]. The second step assumes that power is conserved along each ray tube to approximate the amplitude distribution at the lens aperture (ray tube theory). As an adequate assumption of the E-field pattern of the source is imposed, an additional comparison of the ray separation close to the source and at the lens aperture provides the amplitude distribution at the aperture. The radiation of the lens aperture is then assumed to be equivalent to that of an array of radiating dipoles (one for each ray) with amplitudes following this amplitude distribution obtained from ray tube theory. The excitation phase of each dipole is given by the travelled optical path length for the corresponding ray. The number of dipoles/rays must be sufficient for the result to converge. The final step combines the contribution of each of these 'target-dipoles' to generate the far-field radiation pattern using Kirchhoff's diffraction formula.

The resulting ray tracing model is capable of calculating a far-field radiation pattern that fits well with those determined from full-wave simulation, however with a significantly shorter run-time. This allows for the exploration of structures that would be highly inconvenient to investigate using commercial software only.

Numerical methods for topological polaritonics

I. Septembre[1*], C. Leblanc[1], D. D. Solnyshkov[1], and G. Malpuech[1]

[1]Institut Pascal, Université Clermont Auvergne, CNRS, INP, France
[2]Author Affiliation, Country
[*]corresponding author: ismael.septembre@uca.fr

Abstract: Exciton-polaritons represent an exciting platform for the implementation of topological photonics. In the field of polaritonics, we use the paraxial approximation which allows mapping the Helmholtz equation to the Schrödinger equation. We use this to model microcavities with or without patterning and observe topological effects. We use this in polariton waveguides and demonstrate polariton Bose-Einstein condensation.

Exciton-polaritons are part-light, part-matter quasiparticles that can be described in the simplest case using the strongly-coupled oscillator model.

First, I will present our works on guided polaritons. We use FEM (Finite Element Method) calculations to compute the dispersion of photonic modes in a photonic crystal hosting unidirectional topological interface states. We show that a triangular photonic crystal slab has the same topology as a staggered honeycomb photonic crystal slab but with a giant advantage in the calculation time and experimental feasibility. The coupling of the photonic modes to the excitonic resonance can be made by two methods. The first one can be fully implemented in FEM calculations by taking into account the excitonic resonance in the dielectric permittivity tensor. The second one is more efficient and consists in calculating the photonic modes and then using the coupled oscillators model. We then show that FDTD (Finite-Difference Time-Domain) calculations can simulate the propagation of topological interface states between two photonic crystals with different symmetries, and we probe their unidirectionality [1].

Thanks to the large quantization wavevector in the growth direction, photonic modes in the microcavities can be described using the paraxial approximation. Interacting polaritons are thus described by the non-linear Schrödinger equation (also called the Gross-Pitaevskii equation), which is simpler to solve than Maxwell equations. This is a very powerful tool, which allows simulation of the spatial dynamics and even the relaxation of macroscopically populated states of exciton-polaritons and their Bose-Einstein condensation. Continuing our study of the topological structures, we use the photonic dispersion of a photonic crystal to demonstrate Bose-Einstein condensation of exciton-polaritons. The photonic mode is tuned to a bound state in the continuum leading to a dispersion of the radiative losses which are null at the bound state and grow quadratically with the wave vector. This loss profile facilitates reaching the condition for polariton Bose-Einstein condensation, as demonstrated using the non-linear Schrödinger equation taking into account the dispersion of real and imaginary parts of the photonic modes calculated by FEM and the strong coupling with the exciton.

In the last part, I will elaborate on our works on microcavities. We first describe the phenomenon of Andreev reflection on a polaritonic superfluid (analogue of optical parametric oscillations with a phase-conjugating mirror), using the non-linear Schrödinger equation [2,3]. We then show that it is possible to simulate numerically the Gross-Pitaevskii equation to observe parametric amplification of topological interface states [3]. We study numerically the possibility to form a polaritonic analogue of a multi-terminal Josephson junction using the Bogoliubov-de Gennes formalism derived from the non-linear Schrödinger equation [4]. We

show that it can lead to topological singularities (Weyl nodes) in arbitrary large, and we study both 3D and 4D parameter space that we can approximate by an effective Hamiltonian which facilitates the calculations.

Analyzing Invisibility using a Nonlinear Eigenvalue Formulation

Zitao Mai and Ya Yan Lu*

Department of Mathematics, City University of Hong Kong, Hong Kong
*corresponding author, E-mail: mayylu@cityu.edu.hk

Abstract

For some incident plane waves, the waves reflected by a lossless periodic structure may be identical (in the far field) to the waves reflected by a perfectly electric (or magnetic) conductor. The periodic structure is thus invisible with respect to these incident waves. We propose an efficient method for computing such special incident waves, based on a nonlinear eigenvalue formalation and a contour-integral method.

1. Introduction

When a time-harmonic plane wave impinges upon a periodic structure (such as a diffraction grating), reflected and transmitted waves are generated. Mathematically, this leads to a boundary value problem (BVP), where the frequency and the wavevector of the incident wave are given. If the periodic structure is lossless and backed by a perfectly electric (or magnetic) conductor (PEC or PMC), there are only reflected waves. If there is only a single propagating diffraction order, the reflected wave in the far field is a plane wave with a fixed wavevector. In some cases, the (far field) reflected wave of the periodic structure is identical to the wave reflected by a PEC (or PMC) for the same incident wave. In that case, the periodic structure is *invisible* with respect to the incident wave. For a given periodic structure, it is of interest to find all such incident waves. The standard approach is to search the frequency and wavevector of the incident waves iteratively, but it is not efficient and unreliable.

For a linear operator A, the standard eigenvalue problem $Av = \lambda v$ is linear, if A does not depend on the eigenvalue λ. We formulate the invisibility problem for periodic structures as a nonlinear eigenvalue problem (NEV)

$$A(\omega)v = 0, \tag{1}$$

where A is an operator depending on the angular frequency ω and a wavenumber β, but we consider β as given and ω as the unknown eigenvalue, such that Eq. (1) has a nonzero solution v. When A depends on ω analytically, the NEV can be solved by the contour-integral method [1,2]. An important advantage of the contour-integral method is its robustness. All eigenvalues inside a contour (in the complex plane of ω) are determined, and no initial guesses are needed.

2. Theory

We consider a lossless 2D structure given by a dielectric function $\epsilon(x, y)$ that is invariant in z, periodic in x with period L, and bounded between $y = 0$ and $y = h$. The structure is on a PEC (or PMC) given in $y < 0$, and the medium above (i.e., $y > h$) is air. For a transverse electric (TE) incident wave

$$u^{(i)} = e^{i[\alpha_0 x - \beta_0 (y-h)]}, \quad y > h, \tag{2}$$

where α_0 is real, $\beta_0 = \sqrt{k_0^2 - \alpha_0^2}$ is positive, and $k_0 = \omega/c$ is the free space wavenumber, the wave reflected by the periodic structure can be written as

$$u^{(r)} = \sum_{m=-\infty}^{+\infty} R_m e^{i[\alpha_m x + \beta_m (y-h)]}, \quad y > h, \tag{3}$$

where $\alpha_m = \alpha_0 + 2m\pi/L$, $\beta_m = (k_0^2 - \alpha_m^2)^{1/2}$. If k_0 satisfies $k_0 < 2\pi/L - |\alpha_0|$, then for all $m \neq 0$, β_m is pure imaginary. In that case, $u^{(r)}$ is asymptotically a single plane wave $R_0 e^{i[\alpha_0 x + \beta_0 (y-h)]}$ as $y \to +\infty$. For the same incident wave, if there is a PEC (or PMC) at $y = h$, the reflected wave is exactly $R_* e^{i[\alpha_0 x + \beta_0 (y-h)]}$, where $R_* = -1$ or 1. If $R_0 = R_*$, then the periodic structure is invisible with respect to this incident wave.

The governing equation for the total field u is the Helmholtz equation $\partial_x^2 u + \partial_y^2 u + k_0^2 \epsilon(x,y) u = 0$. In the rectangular domain Ω given by $0 < x < L$ and $0 < y < h$, if u at $y = h$ is known, we can solve the Helmholtz equation with a PEC (or PMC) boundary condition at $y = 0$, and quasi-periodic conditions $u(L,y) = e^{i\alpha_0 L} u(0,y)$ and $\partial_x u(L,y) = e^{i\alpha_0 L} \partial_x u(0,y)$, and we can evaluate the y derivative of the solution at $y = h$. This leads to a linear operator Λ_0 satisfying

$$\left.\frac{\partial u}{\partial y}\right|_{y=h} = \Lambda_0 u|_{y=h}. \tag{4}$$

On the other hand, from Eq. (3), we can define an operator Λ_1, such that $\partial_y u^{(r)} = \Lambda_1 u^{(r)}$. More precisely, Λ_1 is a linear operator satisfying $\Lambda_1 e^{i\alpha_m x} = i\beta_m e^{i\alpha_m x}$ for all m. Moreover, since $u = u^{(i)} + u^{(r)}$ for $y > h$, and $u^{(i)}$ is given in Eq. (2), we have

$$\left.\frac{\partial u}{\partial y}\right|_{y=h} = \Lambda_1 u|_{y=h} + f, \tag{5}$$

where f is related to $u^{(i)}$. Combining Eqs. (4) and (5), we obtain

$$(\Lambda_0 - \Lambda_1) u|_{y=h} = f. \tag{6}$$

The above is a reformulation of the diffraction problem as a linear equation for total field u on the line segment given by $y = h$ and $0 < x < L$. To impose the invisibility condition $R_0 = R_*$, we notice that

$$u(x,h) = (1 + R_*) e^{i\alpha_0 x} + \sum_{m \neq 0} R_m e^{i\alpha_m x}. \tag{7}$$

Therefore, we have a linear functional B satisfying

$$B u|_{y=h} = \frac{1}{L} \int_0^L u(x,h) e^{-i\alpha_0 x} dx = 1 + R_*. \tag{8}$$

We can re-write Eqs. (5) and (8) as

$$\begin{bmatrix} \Lambda_0 - \Lambda_1 & -f \\ B & 0 \end{bmatrix} \begin{bmatrix} u|_{y=h} \\ 1 \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \end{bmatrix}. \tag{9}$$

If the interval $(0, L)$ is discretized by N points, then $u|_{y=h} = u(x,h)$ becomes a column vector of length N, Λ_0 and Λ_1 are approximated by $N \times N$ matrices, B is approximated by a $1 \times N$ matrix, f is approximated by an $N \times 1$ matrix, and the right hand side in Eq. (9) is a column vector of length $N + 1$. This leads to the NEV Eq. (1), where A is an $(N+1) \times (N+1)$ matrix.

3. Conclusion

The NEV Eq. (1) can be solved by the contour-integral method which is robust and efficient. In a previous work [3], we have formulated diffraction anomalies, such as zero reflection, zero transmission and total absorption, as NEVs, and applied the contour-integral method. In this paper, we formulate an invisibility problem as an NEV and demonstrate the efficiency of the approach by numerical examples.

Local-rational models for the adaptive frequency sampling of nanophotonic simulations

F. Ferranti*[1], D. Peumans[2]

Abstract: Electromagnetic (EM) simulation tools are necessary tools for the design of nanophotonic devices (or systems). The frequency-domain behavior of these devices can become quite complex, for example due to delay phenomena, and the presence of multiple (anti-)resonances. Performing EM computations with an EM solver can be a computationally complex task that is time-consuming and resource demanding. Complementary time- and frequency-domain EM solvers exist that provide insight and understanding into optical and EM phenomena.

In this work, we focus on frequency-domain EM solvers. The computation of the device's behavior at each frequency (wavelength) sample of interest can be computationally expensive. Undersampling potentially leads to an inaccurate description of the EM behavior, as valuable behavior characteristics such as (anti-)resonances and coupling effects can be partly identified or even missed. On the other hand, oversampling leads to a waste of computational resources.

Adaptive frequency sampling (AFS) algorithms can be used to prevent under/oversampling by automatically selecting a minimal set of frequencies, in such a way that each frequency sample contains as much valuable information as possible about a nanophotonic device's behavior [1]. This work investigates a novel AFS algorithm based on a local rational modeling (LRM) technique. LRM techniques [2] can greatly mitigate issues associated to the model order selection when rational models are used to drive the AFS process. By only focusing on a small sub-band around a specific center frequency, the local dynamic variations can be more easily modeled by a low-order model. Once all the local rational models are obtained after the first iteration, consecutive iterations only need to update the models around those frequencies that are affected by the inclusion of new frequency samples. LRM techniques are also suitable for parallel computing. Numerical results will be shown during the talk to validate this novel AFS technique.

Abstract: We study the light emission mechanisms of coatings and gratings made of ZnO nanowire (NWs) elaborated with a soft chemistry approach, Fig. 1(a-c). The latter architecture relies on the photo-imprinting of a sol-gel ZnO-based photosensitive seed layer combined with the subsequent localized hydrothermal growth of ZnO NWs [1]. Standard and angle-resolved photoluminescence measurements performed on both kinds of structures reveal that the grating structuration increases the NWs emission by a factor up to 2 and directionally extracts the red radiation of light. Our electromagnetic simulations based on an effective model theory and on the resolution of the eigen modes highlight that the NWs ribbons act as coupled microcavities that boost the ZnO emission thanks to light localization and diffractive mechanisms. The photoluminescence of the ZnO NWs is also simulated with a semi-classical approach based on Maxwell-Bloch equations and the finite-difference time-domain (FDTD) algorithm [2], Fig. 1d. The light extraction efficiencies for NWs coatings and gratings are calculated when a structural disorder is included to reproduce the random aspect of the set of NWs.

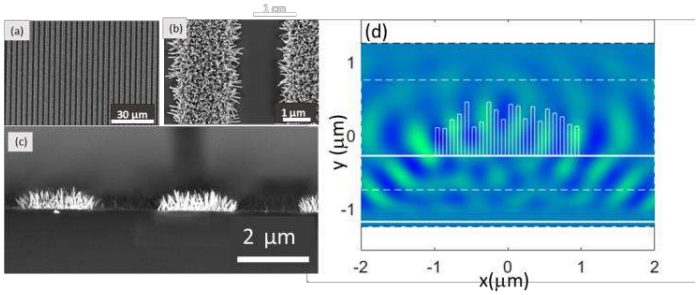

Figure 1: (a-c) SEM images from a top and perspective view of ZnO NWs grating on a quartz substrate. (d) Map of the emitted electric field calculated around 600 nm with the FDTD algorithm.

Our numerical study shows that the optical properties of these structures result from a competition between the structural disorder and the periodic structuring. These specific features could be exploited in applications where specific spatial extraction is useful such as anti-counterfeiting marking.

Keywords: Time-varying materials, relativity, momentum, arrow of time

Recently, time-varying media has risen as a new paradigm in photonics [1], which implicitly allows waves to experience *longitudinal acceleration*. However, such accelerating waves are *not* a solution of the standard wave equation. To study such waves rigorously, we have derived the accelerating wave equation in 1+1 dimensions,

$$\frac{\partial^2 f(x,t)}{\partial t^2} = c(t)^2 \frac{\partial^2 f(x,t)}{\partial x^2} - \dot{c}(t)\frac{\partial f(x,t)}{\partial x}, \tag{1}$$

where $f(x,t)$ is the wave, $c(t)$ is the time dependent speed of the wave, and $\dot{c}(t)$ is the acceleration. If we choose c_0 as the (constant) vacuum speed of light, and write the speed variations as a modulation to the vacuum speed, such that $c(t) = c_0/n(t)$, we can find the general plane wave solution to the accelerating wave equation as in

$$f(x,t) = A\exp(i\omega t' - ikx) + B\exp(i\omega t' + ikx). \tag{2}$$

Here, A and B are amplitude coefficients and $k = \omega/c_0$ is the wavenumber. Moreover, we have defined an *intrinsic* time for the electric field as $t' = \int n(t)^{-1}dt$, which is the time experienced by the wave. Intriguingly, this is fully equivalent to the definition of proper time in general relativity [2]. In other words, if we allow waves to accelerate, they exhibit properties that have natural parallels in the theory of relativity, such as *time dilation* and *length contraction*. To test this framework, we investigated simple refraction problems, as well as the more exotic disordered photonic time crystal [3]. Our results are entirely consistent with earlier studies, and our formulation can be used to model time-varying materials, as well as material interfaces *without* boundary conditions (i.e. our solutions are analytical and continuous over the whole domain).

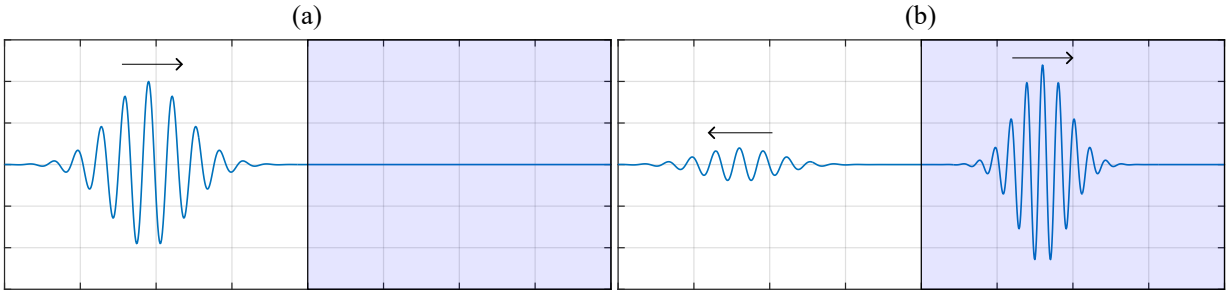

Figure 1: Electric field at an interface, as seen in the laboratory frame. (a) Gaussian pulse incident on a dielectric, travelling from left to right (indicated by right pointing arrow), (b) the reflected pulse (leftarrow) and the transmitted pulse (right arrow). This pulse was analytically simulated with continuous functions. The wavenumber of light does *not* change inside the dielectric, but rather, the pulse experiences length contraction.

Lastly, we have gained important new insight into two long-standing problems in physics: the Abraham–Minkowski controversy and the arrow of time. To be more specific, by considering the effects of longitudinal acceleration, the Abraham–Minkowski controversy can be solved without dividing the overall momentum to wave and material portions. Moreover, the accelerating wave equation allows only solutions with a positive time, thus establishing a preferred temporal direction and shedding light on the microscopic arrow of time. Note that this is distinct from the thermodynamic (macroscopic) arrow of time.

Deep Learning and Optimization for Efficient and Robust Nanophotonic Design

S. D. Campbell, R. P. Jenkins, P. L. Werner, and D. H. Werner

The Pennsylvania State University, Department of Electrical Engineering, University Park, PA 16802 USA
*corresponding author: sawyer@psu.edu

Abstract: Nanophotonic device design requires efficient full-wave solvers and optimization techniques. To this end, deep learning shows promise for improving both forward- and inverse-design aspects of such problems. Meanwhile, multiobjective and topology optimization approaches have proven successful in realizing highly performant freeform nanophotonic devices with tailored functionalities. Combining deep learning with advanced optimization techniques gives designers beyond state-of-the-art tools for realizing extremely efficient nanophotonic device design cycles.

Deep learning (DL) techniques have seen tremendous interest in recent years within the greater electromagnetics and optical communities for their potential to accelerate both forward- and inverse-design problems [1], [2]. Several studies have trained deep neural networks (DNNs) to act as sophisticated surrogate models (*i.e.*, black boxes) to replace the forward modelling component in nanophotonic design problems. This can lead to tremendous time savings by eliminating the need for expensive full-wave simulations (*e.g.*, those based on FDTD or FEM methods). To this end, we developed a cascaded two-stage DNN based on U-Net and CNN (convolutional neural network) topologies to assist in the multiobjective optimization of nanophotonic meta-devices that are resilient to common fabrication uncertainties during E-beam lithography and other conventional manufacturing techniques [3]. At the same time, we have developed techniques that enforce minimum size constraints including for both positive and negative features (*i.e.*, widths and gaps/voids) which can be directly integrated with our freeform metasurface synthesis techniques and DNN framework [4].

Meanwhile, optimization techniques exist in parallel to DL and are equally important to nanophotonic design [5]. Generally, these algorithms are judged according to their convergence statistics with particular emphasis on the number of iterations required to meet a desired cost (or fitness) value and the variance of final cost values achieved when starting from random seeds. To this end, topology optimization (TO) is an extremely popular gradient-based technique for freeform nanophotonic device design. TO is commonly employed to simultaneously adjust the permittivity of each voxel in an array that comprises the space where the nanophotonic structure may exist [6], [7]. Since we usually desire binary (*i.e.*, two-material, usually dielectric and air) 2.5D planar nanophotonic devices, the permittivity gradients in vertically-aligned voxels are often averaged so as to maintain a fixed permittivity throughout. Meanwhile, binary-coercion techniques are employed to enforce adjacent voxel pillars to a fixed permittivity value. However, these compromises can degrade convergence behavior which can lead to inefficiencies if many trials are needed to achieve a desired performance goal. To improve upon these compromises, we demonstrated how the multi-gradient can lead to a better choice of gradient to follow than conventional averaging and accelerate TO convergence two-fold [8].

Abstract: We present a symmetry-broken nanophotonic waveguide platform with embedded quantum dots (QDs) that enables both Purcell-enhanced emission and strong chiral coupling.

The confinement of the light in nanophotonic waveguides enables chiral coupling between the spin of the quantum emitter and the helicity of the waveguide mode with a near-unity directionality to left- or right-propagating modes. We present a symmetry-broken waveguide platform with embedded quantum dots (QDs) that enables both Purcell-enhanced emission and strong chiral coupling. We observe record high Purcell factors for both non-chirally-coupled and chirally-coupled quantum dots emitting in the slow-light spectral region of a glide-plane photonic crystal waveguide (PCW).[1] For the non-chirally-coupled dot, we use a quasi-resonant phonon-sideband excitation scheme to eliminate slow internal relaxation and achieve an extremely large radiative decay rate of 17±2 ns^{-1} (60±6 ps lifetime), corresponding to a 20±2 fold Purcell enhancement. We also observe chiral routing of spin-carrying photons from a QD near a chiral point with a 5±1 fold Purcell factor, substantially outperforming previous demonstrations with nanobeam[2], nanofiber[3], and PCWs[4-6]. Together, these results constitute significant progress towards reaching the threshold for scalable chiral networks relying on chiral quantum optics.

Abstract: We developed a neural network-based inverse-design technique for the design of single-material multilayer optical devices. Such devices are made of one material and the growth parameters are varied to achieve different refractive indices at each layer. The inverse design method explored is computationally efficient and capable of designing devices consisting of several hundred layers. If systemic fabrication imperfections are introduced during training the resulting designs account for the non-idealities of the growth process while still yielding sufficiently high performance.

We demonstrate a neural network based inverse design technique based on a differentiable analytical solver for the design of single-material multilayer planar film devices [1]. Such devices are created by varying the growth conditions of a single monolithic film during its growth. This results in controllable variations of the refractive index allowing for multilayer devices such as filters, anti-reflective coatings, and a variety of other optical devices to be realized [2,3]. As there is only one material in the device there are no multi-material interfaces leading to superior mechanical, optical, and thermal properties [2,4,5]. However, modelling the growth conditions, particularly dynamic growth conditions, is challenging. In this work as can be seen in the figure (adapted from [1]) the "Online Optimizer" is a fully connected neural network which is trained to take a seed multilayer film stack and modify it to produce an optimized film stack. In the first stage of the optimization, we bypass the growth and ellipsometry and assume that the growth was perfect. The analytical solver used (Transfer Matrix Method) is differentiable, as a result the training of the neural network can be done by backpropagating the error between the target and realized spectra through it. This contributes to dramatically improving the convergence of the method and allows for efficient design even for devices with several hundred layers. The training of the "Online Optimizer" is repeated until the error between the designed stack transmission spectra and target spectra converges to a minimum. Similar neural network based design methods have been recently explored for metasurfaces, and multilayer films with discrete materials [6–8].

Additionally, as mentioned previously, imperfections during the growth, multilayer effects, and other non-ideal factors will be present as imperfections in any experimentally realized device. Even minor imperfections in layer thicknesses and refractive indices can dramatically affect the resulting transmission and reflection spectra of the device. To account for this a second stage of training is initiated taking the optimized neural network as a starting point. In the proposed method, the design produced by the neural network is experimentally grown with in situ ellipsometry providing information as to the deviation in both thickness and refractive index of each grown layer. The measured stack is then simulated using the analytical solver. This allows for backpropagation through the solver to update the neural network weights. The result of this second stage of training is that the retrained neural network will produce material stacks which are designed to compensate for systemic errors occurring during the growth of the device. The efficacy of this approach was explored by simulating a variety of possible fabrication imperfections and demonstrating that the resulting design after training perfectly compensated for the simulated imperfections.

In summary, in this work we explored a neural network based inverse design technique capable of producing highly optimized single-material multilayer film devices with arbitrary target transmission/reflection spectra. Furthermore, we developed a method for utilizing this architecture to optimize the growth of these devices to compensate for the complex systemic imperfections introduced during growth. We believe this approach provides a path for the design and optimization of complex single material multilayered devices.

This work is supported by the US Department of Energy (DOE), Office of Science through the Quantum Science Center (QSC), a National Quantum Information Science Research Center and National Science (ML Algorithm Development) Foundation award 2029553-ECCS and Purdue ECE Elmore Emerging Frontiers Center "The Crossroads of Quantum and AI."

Efficient Design of 2D Slanted Gratings using Polynomial Modal Method

K. Edee[1*], G. Granet[1] and P. Bonnet[1]

[1] Université Clermont Auvergne, INP, CNRS, Institut Pascal, F-63000 Clermont-Ferrand, France
[*]corresponding author: kofi.edee@uca.fr

Abstract: We present an efficient approach to design 2D gratings using the polynomial modal method (PMM). The PMM is a rigorous modal method based on orthogonal and modified polynomials, as proposed by [1]. By utilizing the covariant form of Maxwell's equations, we accurately account for boundary conditions. We demonstrate the effectiveness of our method through several relevant numerical examples.

Slanted gratings, which exhibit a non-vertical profile, have garnered significant attention due to their unique electromagnetic properties and potential applications including optical communication, sensing, and energy harvesting , polarization control, and enhanced light-matter interactions [1-3]. These non-standard grating structures, where the grating patterns profile are intentionally tilted or exhibit a slanted profile, can manipulate the polarization state of incident light and introduce specific diffraction characteristics that are unattainable with conventional gratings. Accurate calculation of the electromagnetic diffraction in slanted gratings is essential to optimize their design and improve their performance in practical implementations.

Traditionally, Fourier modal method (FMM) also called, rigorous coupled-wave analysis (RCWA) [4-8], and finite-difference time-domain (FDTD) methods [9] have been used to investigate the electromagnetic properties of grating structures. However, these methods can be computationally demanding and may not always provide an efficient solution, particularly for complex or high-aspect-ratio slanted gratings. Therefore, alternative approaches that offer improved computational efficiency and accuracy are desirable for studying the electromagnetic field behavior in these structures.

Here, we present a polynomial modal method-based [10-13] approach to solve the 2D slanted grating problem. This method is based on orthogonal and modified polynomials.
To meticulously account for boundary conditions, the covariant form of Maxwell's equations is used. The resulting metric tensor is no more diagonal, making it intricate to apply factorization rules in the FMM/RCWA framework. Nonetheless, the PMM does not require these rules, simplifying the computation process.

We use the PMM to design 2D gratings and demonstrate its efficiency through several pertinent numerical examples. These examples reveal that the PMM can accurately predict the diffraction efficiency and other properties of the designed gratings while reducing computational complexity in comparison to traditional methods.

Abstract: We simulate a structured GaN waveguide with EigenMode simulation (EME) and optimize the geometrical parameter of this structure in order to control its emission energy. Those simulations reveal the impact of the decrease of GaN thickness on the Rabi splitting and the photonic gap as well as the optimal filling factor range in order to have large photonic gap. These results contribute to the realization of photonic crystal laser ridge at room temperature.

Polariton in microcavities are one of the main actual research field in polaritonics. The recent development of waveguide polariton lasers open a new range of possibilities in optoelectronics. Wide gap semiconductor such as ZnO and GaN are used in order to maintain the strong coupling regime up to room temperature thanks to their strong exciton binding energies (E_X=25 meV for the GaN) and large oscillator strength [1]. Polariton laser at room temperature has already been demonstrated in a ZnO waveguide in a cavity formed by cracks [2]. Recently, H.Souissi *et al.* demonstrated a CW polariton laser in a GaN ridge with distributed bragg reflectors [3]. The study of this Fabry-Perot cavity reveals unconventional properties compared to conventional ridge lasers, such as the loss of reciprocity between the loss and gain process in the cavity and the diminution of the pump size required to operates in the laser regime (15% of the cavity length). Similarly, polariton laser has also been evidenced in GaN/AlGaN microrings [3].

Yet, in the GaN ridge laser [3,4], competition between the laser emission and the relaxation of the condensate along-side the lower polariton branch leads to a quick increase of the threshold with the temperature as well as a significant redshift of the laser emission. This phenomenon is worsened by the absence of ground state in GaN waveguide [3]. The implementation of a photonic crystal onto a waveguide (Fig 1a) could overcome this difficulty and provide a solution to have a better control over laser emission.

Indeed, based on the result of EigenMode Expansion (EME) Simulation [5], we proposed a design of structured waveguide composed of an etched TiO_2 surface, a GaN Core and an AlGaN lower cladding, in which we reveal the formation of a potential minimum in the waveguide dispersion (upper blue curve Fig 1b). By comparison, the dispersion of a GaN planar polariton waveguide has no ground state (orange and green curve, with or without TiO_2 top cladding, Fig. 1b). The dispersion in a 1D photonic crystal slab is simulated with dispersive TiO_2 and GaN refractive indices which take into account the excitonic effect with an Elliott-Tanguy model [1]. The optimization of the geometrical parameters is of a paramount importance in order to obtain a

large Rabi splitting, manifestation of the strong coupling regime, as well as a large photonic gap, allowing an effective selection of the lasing polariton mode. GaN thickness decrease induces a diminution of the Rabi splitting (blue curve Fig 1c) and an increase of the photonic gap (black curve Fig 1c). The variation of the filling factor (ff) leads to an optimal ff range of 60 to 85% (Fig 1d), preserving an 80 meV Rabi splitting as well as a 30 meV photonic bandgap. For a laser emission at 3.44 eV [3], a 69nm period is required, which imposes an etching width of the TiO_2 surface between 10 and 30 nm in order to have a reasonably large photonic gap, which is very challenging in terms of technological realization. This photonic crystal waveguide design is a step towards the experimental realization of low threshold GaN laser operating in the strong coupling regime at room temperature.

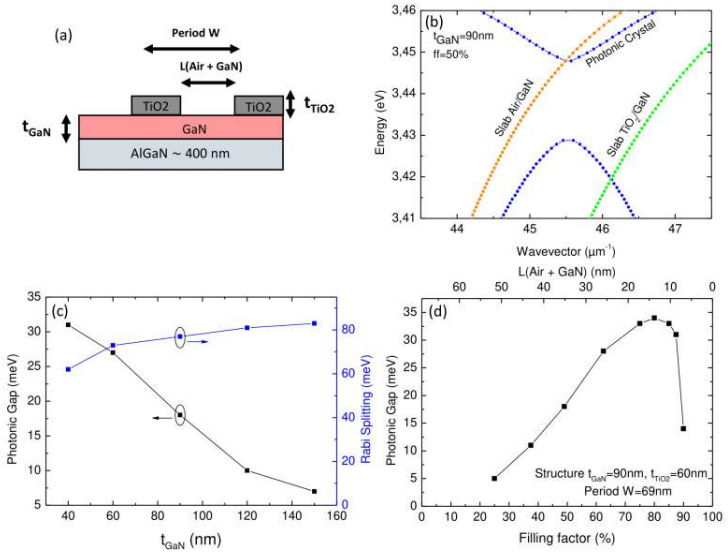

Figure 1: (a) Photonic crystal waveguide (ff = 1 – L(Air+GaN)/W), (b) Polariton dispersion for a given set of parameters (t_{GaN}=90nm, f_{TiO2}=60nm, W=68.9nm, ff=50%), (c) Rabi splitting vs GaN thickness vs Photonic Gap, (d) Photonic gap vs of the filling factor

Abstract: In this talk, we discuss the computational aspects of the quantum hydrodynamic theory (QHT). We review the theoretical basis of the QHT and discuss the numerical methods used to solve the QHT and discuss the challenges associated and applications.

A reliable way to theoretically describe and numerically model optical properties of plasmonic nanostructures with different length scales requires methods beyond classical electromagnetism. In this context, it becomes very important to develop simulation techniques to take into account quantum microscopic features at the scale of billions of atoms.

The quantum hydrodynamic theory (QHT) is a powerful approach to study the behavior of plasmons in metallic nanostructures, as it incorporates the nonlocal behavior of the electron response by including the electron pressure, electron spill-out and tunneling effects [1, 2]. This method allows to explore light-matter interactions in extreme scenarios in which microscopic features can strongly affect the macroscopic optical response. However, the QHT requires solving a set of coupled partial differential equations in region that goes from a fraction of a nanometer to few microns, which makes it computationally challenging.

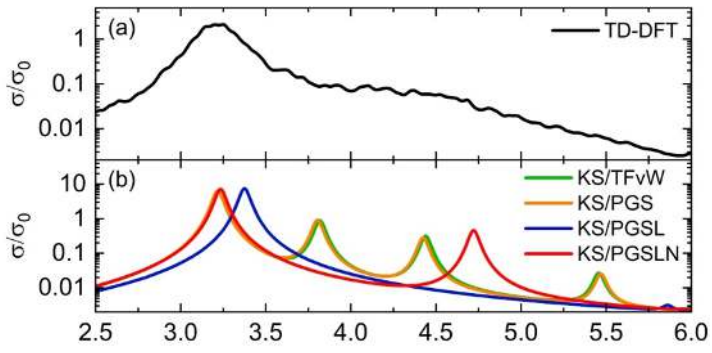

Figure 1: Na jellium sphere with $N_e = 1074$ electrons: absorption cross section normalized to σ_0 geometrical cross section as obtained from (a) TD-DFT, and (b) several QHT approximations.

In this talk, we discuss some of the computational aspects of the QHT. We first review the theoretical basis of the QHT and explore some applications, including photon emission [3], strong-coupling [4] and nonlinear optics [5]. We describe the numerical methods used to solve the QHT and discuss the challenges associated with simulating plasmonic systems. Finally, we point out the limitations of conventional functionals in QHT and propose possible corrections [6,7]. We introduce a more general QHT method accounting for kinetic energy contributions depending on the Laplacian of the electronic density, thus, beyond the gradient-only dependence of the Thomas-Fermi and von Weizsäcker functional (see Figure 1).

Radiative heat exchange driven by acoustic modes between two solids at the atomic scale

M. Gómez Viloria*, R. Messina, and P. Ben-Abdallah

Laboratoire Charles Fabry, Institut d'Optique, CNRS, UMR 8501,

Abstract: When two solids are separated by a vacuum gap of smaller thickness than the wavelength of acoustic phonons, the latter can tunnel across the gap. We show that the acoustic modes in polar crystals can also significantly contribute, at atomic scale, to the nonlocal optical response of the material. We investigate the radiative heat transfer between two slabs of polar materials separated by vacuum gaps of atomic thickness and highlight the strong contribution of these modes at cryogenic temperatures.

In the near field (for separation distances smaller than the thermal wavelength, of the order of some microns at ambient temperature), the radiative heat flow between two solids at different temperatures can exceed the blackbody limit by several orders of magnitude. Furthermore, at the atomic scale, close to contact, the vibrational modes of the crystal lattice are expected to play an important role in the heat exchange. While the contribution of acoustic phonons tunneling due to Van der Waals forces and electrostatic interactions near the surface has been investigated [1–5], the radiative contribution of the acoustic modes has been neglected so far. Under the local assumption (wavevector $\mathbf{k} \approx 0$), optical modes are independent from the acoustic modes, and are the sole responsible for the thermal radiation for distances larger than a few nanometers. However at subnanometer distances, the electromagnetic response of solids is nonlocal ($\mathbf{k} \neq 0$) and both acoustic and optical modes are coupled, contributing together to the radiative heat exchange. In order to demonstrate the role of this contribution, we calculate [6] the nonlocal dielectric permittivity of magnesium oxide (MgO) using molecular dynamics. In conjunction with fluctuational electrodynamics calculations, we are able to highlight the role of radiation between two solids produced by acoustic modes compared to the expected results from the local theory. We show that this additional contribution can become the dominant channel for radiative heat exchanges at atomic scale in the cryogenic regime (below 100 K). Since the acoustic vibration modes can be excited with the help of piezoelectric transducers, our work opens the possibility to the control of radiative heat exchanges at atomic scale using external mechanical actuation.

Abstract: The generation of vortex beams is a field of research with an important impact on both fundamental and applied physics. [1] In this work, we show our recent results on the generation of second-harmonic vortex beams with a dielectric nonlinear optical metasurface.

Recently, the rise of interest for nanophotonics and flat-optics [2] has spurred the demonstration of meta-holograms that can create Laguerre-Gauss beams with ultrathin devices. [3] Flat optics also showed its potential in the nonlinear regime. [4] Plasmonic MS were the first to perform wavefront shaping in connection with second harmonic generation (SHG), albeit with low conversion efficiency and huge dissipation in the near-infrared (near-IR) range. [5] Later, based on silicon-on-insulator (SOI) platform, nonlinear wavefront shaping was demonstrated with third-harmonic-generation (THG), based on the $\chi^{(3)}$ of silicon. [6]

Here we generate second harmonic (SH) beams carrying non-zero orbital angular momentum (OAM) via a dielectric $\chi^{(2)}$ metasurface, with SH generation and phase control being achieved at the level of single meta-atoms. The related lookup-table-based meta-hologram has a fork-like phase profile that steers a vortex beam of topological charge |5| in the first diffraction order, with good agreement between analytical and experimental results. The optical vortices studied experimentally in this work are characterized in three dimensions, by following the related singularity along a straight line perpendicular to the metasurface. However, it is also possible to generate more complex beam topologies. More precisely, we can shape light beams into several zero-intensity loops that are knotted or linked [8,9].

Abstract: We discuss how DNA templates can be engineered as smart building materials to associate quantum emitters and plasmonic resonators and to maximize light-matter interactions at room temperature.

Light-matter interactions in condensed media at room-temperature are fundamentally limited by electron-phonon coupling. For instance, while the excitation cross-section of an isolated atom, or of a single quantum emitter at cryogenic temperatures, can reach one half of the wavelength of light squared (meaning that more than 50% of incoming photons will interact for a diffraction-limited excitation); this value is reduced by 6 orders of magnitude for a fluorescent molecule or for a colloidal quantum dot at room temperature because of homogeneous phonon broadening. In order to render the exceptional optical properties of single quantum systems (such as single-photon emission and nonlinearities) efficiently accessible at room temperature and in condensed media, it is essential to enhance and optimize these interaction cross-sections.

Over the last decade, gold nanostructures have shown amazing promise towards this goal thanks to their ability to enhance optical fields by several orders of magnitude in deeply sub-wavelength volumes. However, the nanoscale dimensions of these field enhancements mean that it is extremely difficult to address them in a controlled and reproducible way. To this end, we exploit DNA molecules to create plasmonic resonators with a control over both their nanoscale dimensions and their chemical environment. Using this strategy, we were able to enhance single-photon emission from fluorescent molecules by more than two orders of magnitude in a weak-coupling regime [1,2] and to reach a strong-coupling regime between a plasmonic resonator and 5 organic molecules (figure 1), albeit with low reproducibility [3]. We propose the DNA-based assembly of dimers of plasmonic nanocubes in order to provide reproducible single-molecule strong coupling [4] and to make the coherent interaction of light with single quantum emitters feasible at room temperature.

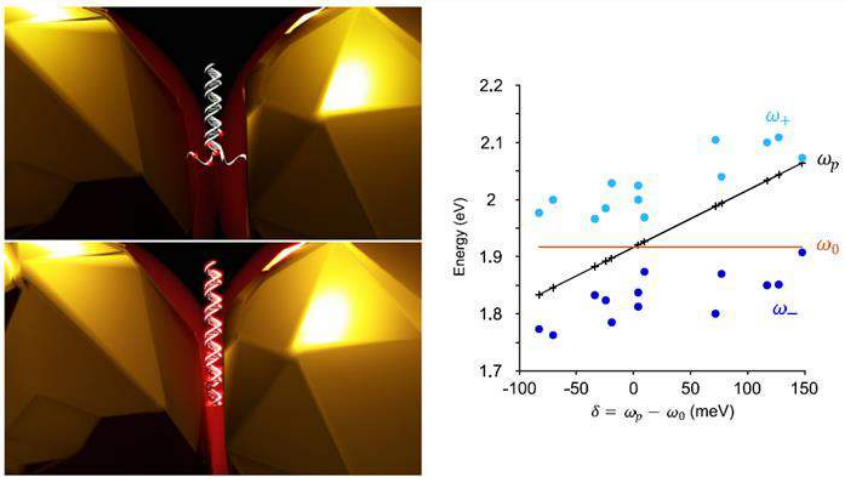

Figure 1: Representation of 5 fluorescent molecules placed in the hotspot of a gold particle dimer using DNA and distribution of eigenenergies in strongly coupled nanostructures exhibiting an anti-crossing behavior.

DNA origami assembled nanoantennas for manipulating single-molecule spectral emission

M. Sanz-Paz[1*], F. Zhu[1], N. Bruder[1], K. Kolataj[1], M. Pilo-Pais[1], A. Fernandez-Dominguez[2], and G. P. Acuna[1]

Abstract: Optical antennas have been widely used for manipulating single-molecule emission properties, including intensity and decay rates, and thus for affecting lifetime, polarization, spectrum, or directivity. Here, we make use of DNA origami as a breadboard to precisely position a single emitter in the vicinity of a single gold nanorod and study their interaction with high accuracy. We show, that we can affect the spectrum of a single fluorophore depending on its relative position and spectral overlap with the gold nanorod.

Optical nanoantennas can affect the decay rates of nearby emitters by modifying the local density of photonic states around them [1,2]. In the weak-coupling limit, and according to the Fermi's Golden Rule, the emission spectrum of a dye is given by the energy of all the possible radiative transitions weighted by the probability of each of them to occur. By engineering the resonance of a nanoantenna, one can selectively enhance specific vibronic transitions of a dye molecule, thus shaping its emission spectrum [3]. Since interactions between emitters and nanoantennas are known to be position dependent, we make here use of DNA origami [4,5] to precisely place an individual dye at different positions around a gold nanorod. We show how this relative position between the nanorod and the emitter affects the emission spectrum of the latter [6]. In particular, we observe the appearance of a second fluorescence peak whose wavelength and intensity are correlated with the fundamental plasmonic resonance of the nanorod, which we extract from its photoluminescence spectrum [7] and will depend on the nanorod's dimensions. This second peak results from the selective enhancement of transitions to different vibrational levels of the excitonic ground state, whose energies are in resonance with the plasmonic one. Finally, we show how this reshaping of the fluorescence spectrum can be used to experimentally determine the wavelength-dependent radiative decay rate enhancement.

Sketch of the experimental configuration, showing the fluorescence emission reshaping experienced by a single fluorophore in the presence of a nanorod, in a way that depends on the dimensions of the latter.

Abstract: DNA nanotechnology allows for nm precision positioning of moieties, be these organic dyes, or inorganic nanoparticles. Using this we can study and exploit energy transfer beyond the classic FRET limit in manners that are not available with other methodologies. Using DNA bricks and organic dyes we have demonstrated point-to-plane transfer and its r^{-4} dependence we also exploited DNA origami for positioning of semiconductor quantum dots and plasmonic gold nanoparticles to investigate nanosurface energy transfer (NSET).

The most common use of Förster resonance energy transfer (FRET) is the interaction of a single dipole-dipole pair, i.e. between a single D(onor) and A(cceptor). In this case the FRET efficiency decays with the D-A distance (r_{DA}) to the sixth power. This makes FRET a powerful tool for determining nanoscale changes in position or orientation. Yet, similar dipole-dipole interaction mechanisms can be imagined in much more complex systems, such as interactions where the dipole of a D is interacting with an A surface, which can be either molecular or continuous. In these cases the mathematical models can change drastically, for example changing the r_{DA} dependence from r^{-6} to r^{-4}. To undertake molecular energy transfer studies, nm control of positioning is required due to the large changes in efficiency on that scale. DNA nanotechnology provides that capability through well-characterized bioconjugation strategies in combination with designable and modular 2-D and 3-D nanostructures.

Through the use of DNA bricks 3-D nanostructures which incorporate five two-dimensional planes with each controllably having 1 to 12 copies of five different D, A, or intermediary organic dyes we were able to access clear signatures of sheet regime FRET, also described as point-to-plane transfer (See Figure 1), which accesses r^{-4} transfer efficiencies.[1] Nanostructure characterization, steady-state and time-resolved spectroscopic data, along with molecular dynamics modeling and numerical simulations, allowed us to compare experimental energy transfer efficiencies to theoretical expectations.

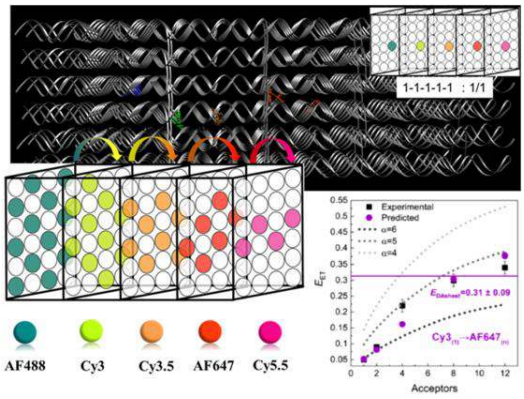

Figure 1: (Top) Chimera schematic of DNA brick with a single dye per plane. (Bottom) Cartoon demonstrating the variation of dyes that can be placed in each plane. Comparison of experimental and theoretical prediction of energy transfer as a function of the number of acceptors in a plane. Adapted from Reference 1.

In a complimentary approach, we are utilizing 2-D DNA origami to look at the energy transfer between a QD and a single dye A and compare that with a single gold nanoparticle (AuNP) A. We utilize a histag peptide-peptide nucleic acid hybrid approach to efficiently conjugate the QD to the DNA origami (See Figure 2).[2] The intent is to distinguish between the traditional FRET mechanism of energy transfer and nanosurface energy transfer (NSET), also known as dipole–metal plane coupling, that is theorized to occur between a QD and AuNP.[3] We aim to deposit the structures into films which can then be cryogenically cooled down to as low as 4 K to vary the transfer efficiency without varying the r_{DA} which should allow us to distinguish whether r^{-6} (FRET) or r^{-4} (NSET) or something in between is occuring.

Abstract: The DNA origami technique has emerged as one of the most versatile bottom-up nanofabrication methods. In this talk I will discuss our recent results related to application of DNA origami for fabrication of plasmonic systems with novel stimuli and optical responses. Specifically, we will present fabrication of i) light-responsive dynamic plasmonic assemblies with easily regulated steady out-of-equilibrium states[1]; ii) chiral plasmonic systems with visually detectable reconfigurable optical activity; iii) metal shells with tailored complex morphologies and optical responses within near-infrared transparency window(s).

Colloidal Silicon Nanospheres as Building Blocks for Photonic Applications

H. Sugimoto[1*]

[1]Department of Electrical and Electronic Engineering, Graduate School of Engineering at Kobe University, Japan
[*]corresponding author: sugimoto@eedept.kobe-u.ac.jp

Abstract: Low-loss optical nanoantennas made of high index dielectrics have attracted much attention as an alternative to plasmonic antennas that often suffer from losses of noble metals. Here, we develop Mie resonant crystalline Si nanospheres in the size range of 100-300 nm dispersible in solution. Monodisperse colloidal Mie resonators not only exhibit vivid colors but also act as colloidal metamaterial (i. e., meta-fluids) that have advantages in solution-based fabrication of thin film optical devices. In addition, colloidal dispersions of Si nanospheres enable the formation of functional nanoantennas for enhanced light matter interactions using printing and self-assembly technologies.

Dielectric nanoparticles exhibit electric and magnetic Mie resonances and provide opportunities for manipulating and enhancing the light-matter interactions. The dielectric nanoantennas have been usually fabricated by electron beam lithographically on the solid substrate and thus the applicability of the solution based assembly techniques have been limited compared to the plasmonic counterparts since gold and silver colloids that are commercially available.

In this talk, we present development of colloidal dispersion of perfectly spherical silicon nanoparticles dispersible in alcohol by thermal disproportionation of silicon monoxide at very high temperature (>1450°C) followed by chemical etching. We also developed monodisperse silicon nanoparticles by applying density gradient centrifugation process for the size separation.[1-4] Figure 1a shows the solution in which different sized silicon nanoparticles are dispersed. The solutions exhibit bright scattering colors depending on nanoparticles sizes. TEM image in Fig. 1b shows the monodisperse silicon nanoparticles with highly spherical shapes. In addition, Figure 1c demonstrates high crystallinity of the particle. We show fundamental properties of the silicon nanoparticles including directional scattering and fluorescence enhancement by exploiting magnetic Purcell effect of Mie resonances.[5-7]

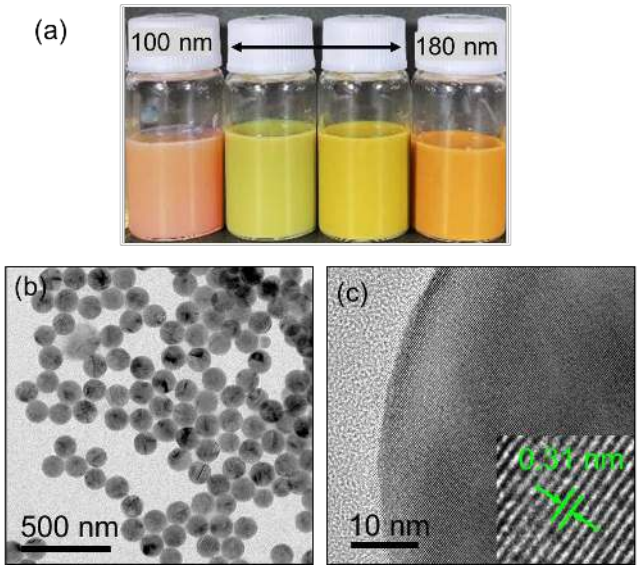

Figure 1. Dual nanoantennas. Helicity of incident light is preserved at Kerker condition of dielectric nanoantennas.

In this work, we also introduce the assembly of the silicon nanoparticles.[8] By properly assembling high index nanoparticles, the optical response can be tailored via the near field coupling between nanoparticles. The coupling provides accessible electric and magnetic hot spots in an assembly, and modulates the directionality of the light scattering. We develop a process to fabricate linear and zigzag arrays of silicon nanoparticles by using a

template assisted capillary assembly method. From angle and polarization resolved scattering spectroscopy, we show that coupling of the electric dipole and magnetic dipole resonances between nanoparticles strongly modifies the scattering spectra. The results demonstrate the potential of the silicon nanoparticles for development of functional optical nanoantennas by employing further sophisticated assembly techniques by using DNAs.

Abstract: Aptamers are artificially engineered DNA sequences which can change their conformation upon the binding of their specific target. Aptamers immobilized inside of a nanopore regulate ionic flux through target recognition, as the conformation switch rearranges the corona of charge density within the orifice. Gaining mechanistic insight into these dynamic nano-systems would enable the development and tailoring of new methods for small-molecule sensing. We have explored the link between aptamer conformation and signal modulation both experimental and theoretically.

Summary: In this work, we immobilized dopamine-specific aptamers inside of nano-scaled orifices. We then demonstrated that the binding of dopamine modulates the ionic flux antipodally when compared to the target specific response of nanopipettes functionalized with serotonin specific aptamers [1], even though both neurotransmitters have the same charge. We identified the opposite conformational changes upon analyte capture as being responsible for the distinctive signal behaviors, supported by combining experimental quartz crystal microbalance with dissipation monitoring results with theoretical finite element method and molecular dynamic simulations. Our investigations improve our understanding of the complex interactions occurring in confined nanoscale environments and have the possibility of driving further innovations in bioinspired nanopore technologies for small molecule sensing.

Abstract: Plasmon-enhanced fluorescence provides an attractive avenue toward single-molecule studies, providing high sensitivity and superior signal-to-noise ratio. I will describe our recent efforts in this field, focusing on the use of plasmon-enhanced fluorescence to reveal single-molecule DNA dynamics on microsecond timescales and in real-time.

Biomolecules such as DNA are at the basis of all processes in living organisms. These molecules exhibit intra- and intermolecular interactions on timescales from nanoseconds to hours. Understanding such mechanisms is key to solving problems in many fields including diagnostics and molecular biology. Typically, these mechanisms are studied using single-molecule fluorescence,[1] a powerful technique that allows for the observation of real-time biomolecular dynamics while revealing spatial and temporal heterogeneity. However, the brightness and photon budget of the required fluorophores are limited by saturation and bleaching, prohibiting direct observation of sub-ms processes in most cases.[2] Methods based on optical tweezers have better time resolution, but are not force-free.[3]

In this work, we optimize the size and shape of nanoantennas based on gold nanorods[4] to harvest millions of photons per second from a single fluorophore coupled to the antenna. This provides superior signals compared to free space fluorophores, and dramatically increases the signal-to-noise ratio at short timescales. Using methods based on DNA-PAINT,[5] we study the dynamics of very short complementarity regions and Holliday junctions in real-time with microsecond integration times.

Abstract: We develop a colorimetric sensing platform compatible with single-molecule detection by assembling gold-nanosphere dimers on a Y-shaped 3D DNA origami that acts as a nanoscale actuator in response to specific stimuli.

DNA origamis are a flexible platform to produce nanostructures that shift their morphology when interacting with specific target molecules, such as DNA/RNA strands, proteins, or specific cations [1]. To translate the conformational changes of a DNA origami in colorimetric information, we exploit the nanoscale dependence of plasmon coupling between two gold nanospheres. Dark-field microscopy allows us to monitor such nanoscale distance changes on a color camera [2,3]. The design of our Y-shaped 3D DNA origami (Fig. 1-a) features an active site, whose conformation can be tuned by hybridizing specific DNA single strands (Fig. 1-b), and two arms on which gold nanospheres are attached. The overall morphology of the hybrid nanostructure is governed by the geometry of the DNA origami but also by steric and electrostatic repulsion between gold nanospheres. We observe that the difference in conformation of the active site is only visible in the optical response of the nanostructures for high ionic strengths, when these steric and electrostatic repulsions are reduced.
One-step colorimetric sensing of DNA single strands is achieved at high ionic strengths by using a strand displacement reaction (Fig. 1-c). These measurements are carried out both by performing single-nanostructure scattering spectroscopy (Fig. 1-d) and by monitoring the hue of single dimers in dark-field images (Fig. 1-e), obtaining similar statistical responses. These results open exciting perspectives for the colorimetric sensing of individual DNA strands on a color camera.

Slowing down microwave photons in a superconducting quantum metamaterial

A. V. Ustinov*

Physics Institute, Karlsruhe Institute of Technology, Germany
*corresponding author: ustinov@kit.edu

Abstract: Progress in quantum information processing leads to a rising demand for devices to control the propagation of electromagnetic wave pulses and to ultimately realize a universal and efficient quantum memory. While in recent years significant progress has been made to realize slow light and quantum memories with atoms at optical frequencies, superconducting circuits in the microwave domain still lack such devices. We present an overview of our recent experiments with arrays of eight frequency-tunable superconducting qubits coupled to a one-dimensional waveguide.

Waveguide quantum electrodynamics offers a wide range of possibilities to effectively engineer interactions between artificial atoms via a one-dimensional open waveguide. While these interactions have been experimentally studied in the few qubit limit, it is relevant to demonstrate the collective properties of such systems for larger arrays of qubits in a metamaterial configuration. We will present our recent results of experimental study a metamaterial made of eight superconducting transmon qubits with local frequency control. By consecutively bringing the qubits to a common resonance frequency we observe the super- and sub-radiant states, as well as the emergence of a bandgap [1].

Making use of the quantum nonlinearity of qubits coupled to the mode continuum of a waveguide, we demonstrate formation of a transparency window in the bandgap region of the ensemble. We also experimentally demonstrate slowing down electromagnetic waves in this qubit array. Time-resolved experiments show electromagnetic wave group velocities reduced by a factor of about 1500 in the single-photon regime [2]. We analyze two complementary approaches, one relying on dressed states of the Autler–Townes splitting and the other based on a tailored dispersion profile using the qubits frequency tunability. Depending on the method used, the speed of light can be controlled with an additional microwave tone or an effective qubit detuning.

Our findings demonstrate high flexibility of superconducting circuits to realize custom band structures and open the door to microwave dispersion engineering in the quantum regime.

This work has received funding from European Union’s Horizon 2020 Research and Innovation Programme under Grant Agreement No. 863313 (SUPERGALAX).

Quantum Analogues of Dissipative Circuit Elements

A. M. Zagoskin[1]

[1]Department of Physics, Loughborough University, UK
*a.zagoskin@lboro.ac.uk

Abstract: Quantum analogues of non-dissipative circuit elements, that is, structures which can exist in a coherent superposition of states with different values of inductance or capacitance, are readily realized using superconducting qubits. Here I show the possibility of the existence of quantum analogues of dissipative circuit elements, which demonstrate superpositions of states with different resistances or memristances.

A circuit containing a superconducting quantum bit can demonstrate a quantum contribution to its (inverse) inductance [1] or capacitance [2] dependent on the qubit state. One can therefore speak of full quantum analogues of inductance and capacitance, that is, non-dissipative circuit elements which can be in a superposition of states with different values of these parameters [3].

Figure 1 (reproduced from [3]). A quantum point contact in a 2D electron gas controlled by a qubit near the pinching point can be considered as a 1D conductor interrupted by a scatterer. The transparency of the contact is controlled by the quantum state $|j\rangle$ *of the qubit.*

The situation may seem qualitatively different for quantum analogues of dissipative circuit elements (resistors and memristors) [4]. Indeed, the dissipation inherent in these elements would seem to destroy all quantum coherence between the superposed states, so that the best one can hope for is observing random fluctuations between two values of resistance or memristance [5,6].

The discussion of coherent superposition of states in quantum memristors requires a more technical approach (see Ref.[7]). Here we restrict ourselves to the case of quantum resistors and argue that quantum superpositions of states with different resistances are possible, e.g., in the situation of Fig.1. Here the region which determines the conductance is spatially separated from the regions where the corresponding dissipation occurs. Therefore the superposition lifetime can exist at least on the scale of the electron travel time $\tau \sim l/v$. The actual lifetime of a superposition can exceed this minimum for small enough voltages across the system, since the decoherence rate of the qubit controlling the point contact is (see [8]) $\Gamma = -\frac{eV}{h}\ln|t_0 t_1^* + r_0 r_1^*|$.

Here $t_{0,1}$ and $r_{0,1}$ are the transmission and reflection amplitudes of the contact in the corresponding quantum states. The quantum conductance of the system is thus

$$\hat{G} = \frac{e^2}{h}\left(|t_0|^2|0\rangle\langle 0| + |t_1|^2|1\rangle\langle 1|\right) = G_0|0\rangle\langle 0| + G_1|1\rangle\langle 1|,$$

similar to the expressions for quantum inductance and capacitance.

The realization of fully quantum analogues of all four classical circuit elements will simplify the design and advance the development of quantum metamaterial-based devices, such as detectors, antennas and neural networks.

I am grateful to C. Huggins, A. Balanov, S. Saveliev and P. Navez for stimulating discussions. This research was supported by the European Union's Horizon 2020 Research and Innovation Program under Grant Agreement No. 863313 (SUPERGALAX).

Improved Method for Characterizing Resonance Quality Factor in Superconducting Resonators

Martin Weides
James Watt School of Engineering and Centre for Quantum Technology, University of Glasgow, Glasgow, G12 8QQ, UK
Martin.Weides@glasgow.ac.uk

Abstract: We present a study on tunable Fano-type resonances in a superconducting coplanar cavity coupled to multiple artificial atoms [1,2]. By applying bias current through nearby control lines, the shape of the measured cavity transmission can be continuously tuned, exhibiting Fano-type resonances with a dispersive shift that can be observed as a peak or a dip. We demonstrate how the heating of the environment can invert the line shape of the cavity, and how this Fano-peak inversion is possible due to a tunable interference between a microwave transmission through a background and through the cavity. We also discuss how the background transmission can be accounted for by Jaynes-Cummings type models via modified boundary conditions.
Additionally, we investigate the characterization of material losses in superconducting resonators, using a combination of simulation and experiment to determine the reliability of a fitting algorithm for separating internal and coupling quality factors of the resonance quality factor [3,4]. We propose a novel measurement protocol to reduce fitting errors and mitigate the influence of the measurement background on fit results.
Our findings provide insights into the tunability and manipulation of Fano-type resonances in superconducting quantum devices and can be generalized for other resonance systems beyond superconducting resonators.

Abstract: To obtain high performance THz-waves emitting devices made by single crystals of high temperature superconductor $Bi_2Sr_2CaCu_2O_{8+\delta}$(Bi2212), an understanding of the device characteristics based on the material characteristics would be an important issue. In principle, electric characteristics of the intrinsic Josephson junctions (IJJs) constructed in Bi2212 crystals strongly depend on the crystal conditions such as carrier concentrations, crystal defects, quality of atomic scale of Josephson junctions. We have studied material and device characteristics of Bi2212 crystals prepared with different annealing conditions.

THz-waves emitters based on the ac Josephson effect have been developed using a single crystal of high-T_c superconductor $Bi_2Sr_2CaCu_2O_{8+\delta}$ (abbreviated as Bi2212)[1]. Single crystals of Bi2212 consist of insulating Bi_2O_2 layers and superconducting CuO_2 layers stacking alternately along the crystallographic *c*-axis and these stacks are known as intrinsic Josephson junctions (IJJs)[2]. THz-waves can be obtained by processing Bi2212 single crystals into mesa structures and applying dc bias voltages across the IJJs[1]. It is noted that the device characteristics are summarized in the several review papers[3]. Most previous research has primarily focused on their emitting characteristics, although some studies have investigated the device characteristics of emitters under different annealing conditions and substitution effects. Recent advancements in knowledge and fabrication techniques have enabled us to study the device characteristics connected with the material properties of the compound. In this study, we prepared Bi2212 crystals with different oxygen contents δ, and compared the crystal characteristics and device characteristics in order to obtain further understanding of the role of excess oxygen δ for the device.

$Bi_{2+x}Sr_{2-x}CaCu_2O_{8+\delta}$ single crystals prepared with nominal composition ratios of Bi/Sr = 2.15/1.85 (x = 0.15) were grown using a floating zone furnace. The grown crystals were cut into square shapes with several mm^2. Then, to adjust oxygen contents δ of the crystals, they were annealed either under 0.2%-O_2 gas flow at 650°C or under N_2 gas flow at 600°C. At the end of the annealing process, the crystals were quenched to stabilize oxygen contents in the crystals. To fabricate a Bi2212 crystal chip for a THz-emitter, a wet etching method was used[4]. After that, these chips were assembled as Bi2212 THz-waves emitters using a sandwich structure developed in our group[5].

As for the characterization of the fabricated crystal chips, X-ray diffraction was performed with ω and θ-2θ scan to evaluate the homogeneity of the crystals and the lattice constants. A four-circle diffractometer was used at BL-4C in Photon Factory, High Energy Accelerator Research Organization (KEK). The incident X-ray energy was set to be 8.8 keV through a Si(111) double-crystal monochromator.

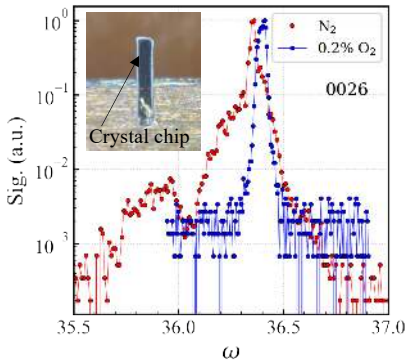

Fig.1 ω scan plot for the crystal chips. Inset displays an optical photograph of the sample.

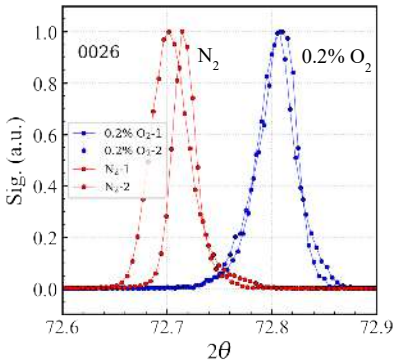

Fig. 2 θ-2θ scan plot for the crystal chips.

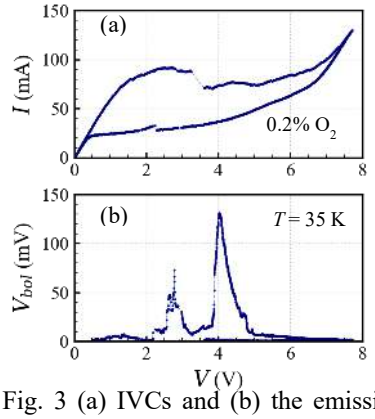

Fig. 3 (a) IVCs and (b) the emission intensities detected by the bolometer at 35 K.

As for the characterization of the Bi2212 THz-emitters, the fabricated devices were mounted on a cold finger of a helium-flow type of cryostat (Oxford Instruments, CF1104) equipped with optical windows. The electrical characteristics of the devices were measured using a conventional two-terminal method. An InSb hot-electron bolometer (HEB) (QMC Instruments, QFI/2BI) was used to detect the electro-magnetic waves from the devices.

The inset of Fig. 1 displays an optical photograph of a 0.2%-O_2-annealed crystal chip with the dimensions of ~65×390×6 μm^3. Figure 1 shows typical ω-scan plots measured around 0026 for the 0.2%-O_2-annealed and the N_2-annealed samples. The data were normalized by the values of the maximum peak intensities of the scans. In this case, the curve profile suggests that the crystal homogeneity of the 0.2%-O_2-annealed sample is higher than that of the N_2-annealed one. It is noted that the curve profile seems to depend on the crystal chips. Figure 2 shows the θ-2θ scan plots measured around 0026 for the samples. We measured two samples for each annealing conditions. The plot indicates that the lattice constant of the c-axis becomes longer with decrease of the oxygen contents of the crystal. The difference of the lattice constant and the carrier density would be reflected in the device characteristics. For the device characteristics, a clear THz emission was only observed from the 0.2%-O_2-annealed crystal chip. Figure 3 (a) and (b) display the current-voltage characteristics (IVCs) and the applied bias voltage dependence of the emission intensities detected the bolometer (V_{bol}) for the 0.2%-O_2-annealed one at 35 K. The clear emission is observed at around 4 V (35 mA). In the conference, we will discuss relationships between the device and material characteristics in detail.

Abstract: We will present experiments on ultrastrongly coupled, strongly subwavelength resonators in arrays down to single element. We will discuss the limitations of the planar resonators approach when employing extremely subwavelength gaps and we will present the new developments towards single-object, few electrons ultrastrongly coupled systems.

Sub-wavelength electromagnetic field localization is a central theme in photonic research, as it allows sensing capabilities as well as increasing the light-matter coupling strength. Recently, the strong and ultrastrong light-matter coupling regime [1] in the THz range with split-ring resonators coupled to magnetoplasmons [2] has been widely investigated, achieving successive world-records for the largest light-matter coupling ever achieved. Ever-shrinking resonators have allowed to approach the regime of few electrons strong coupling, in which single-dipole properties can be modified by the vacuum field [3].

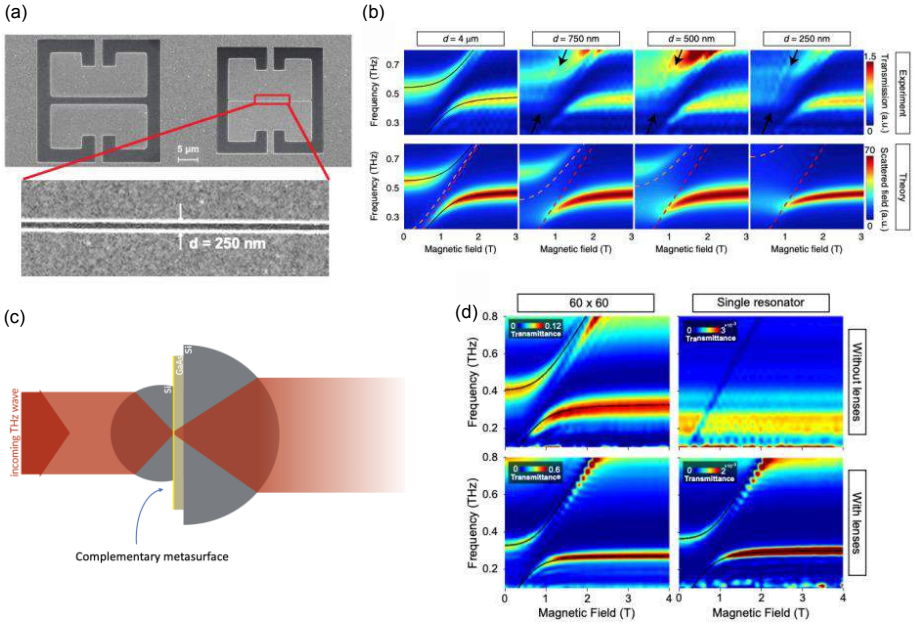

Figure 1: (a) SEM image of two cSrr , one with 2um gap and one with 250-nm gap. (b) Top row: transmission of cSrrs coupled to the Landau level transition in 2DEG versus magnetic field for four different gap sizes, d. black arrows indicate an additional feature that corresponds to $f = 1.6 \times \omega c/2\pi$, and the black solid lines are fitted LP and UP. bottom row: the calculated scattered field for different gap feature sizes, d (same as the gap sizes of the experiment results). (c) Schematic of the immersion lenses setup. (d) Transmission measurements without (top row) and with the aSIL configuration (bottom row) for a 2D array of 60 × 60 cSRRs (left column) and a single resonator (right column). The black solid lines are the fitted LP and UP using the Hopfield model.

Using our Landau polariton platform [2], we will discuss, using theoretically and experimentally, the existence of a limit to the possibility of arbitrarily increasing electromagnetic confinement in polaritonic systems. Strongly sub-wavelength fields can excite a continuum of high-momenta propagative magnetoplasmons [4] when planar resonators with sub-micrometric gaps are employed (Fig.1 (a)). This leads to leading to the emergence of nonlocal polaritonic effects, as certain polaritonic features disappear and the system enters in the regime of discrete-to-continuum strong coupling(Fig.1b). Particularly, the upper branch progressively disappears as the resonator's gap is reduced. Theoretical analysis including non-local effects displays that the frequency of the polaritonic resonances becomes complex, as the continuum of plasma waves irreversibly absorbs photons, even neglecting intrinsic plasmonic and photonic losses. The physics is akin to the one found in Landau damping, where in our case energy is dissipated generating plasma waves and not free electron–hole pairs.

We will as well discuss experiments reporting spectroscopy of a single, ultrastrongly coupled, highly subwavelength complementary resonator (cSRR) operating at 300 GHz. By using a combination of immersion lenses (Fig.1 c, asymmetric Silicon immersion lens aSIL) and THz-TDS , we unravel the linewidth dependence of planar metamaterials as a function of the meta-atom number indicating quenching of the superradiance. On these grounds, we investigate ultrastrongly coupled Landau polaritons at the single resonator level (Fig.1 d) [5], reaching ultrastrong coupling normalized ratio $\frac{\Omega}{\omega} = 0.6$. We will as well discuss the THz spectroscopy of micron-sized, exfoliated 2D materials.

Abstract: To engineer the ultrastrong light-matter interaction between Josephson plasma waves (JPWs) and terahertz (THz) radiation for manipulation of cavity quantum electrodynamic (cQED), we propose an array of deeply subwavelength micro-cavities composed of high-temperature superconductor BSCCO. We confirm the ultrastrong coupling of the JPWs and THz radiation by observing anti-crossing behaviour in the reflection spectra of the array in the superconducting regime. The proposed metamaterial could be useful in the development of THz cQED, coherent emitters, sensitive detectors, and tunable bolometers.

Terahertz (THz) radiation has become increasingly important for both practical applications such as high-speed wireless communications and fundamental scientific research, such as studying superconducting condensates in layered high-temperature superconductors. $Bi_2Sr_2CaCu_2O_{8+\delta}$ (BSCCO) is a particularly important high-temperature superconductor (HTS) due to its intrinsic Josephson junctions (IJJs), which are the building blocks of coherent and continuous solid-state THz IJJ emitters [1]. The Josephson plasma waves (JPWs), resulting from the coupling of the c-axis Josephson current with electromagnetic (EM) waves, have diverse applications, from slowing down light to converting continuous THz radiation into short pulses in the nonlinear regime [2]. The strong-light matter coupling between the JPWs and THz EM waves can be beneficial for boosting the radiated power of IJJ emitters.

This paper proposes an array of microcavities, each composed of a high-temperature superconducting BSCCO thin film sandwiched between two silicon films. The substrate of the cavity arrays is a layer of gold with a thickness of 500 nm, and each cavity is covered with a thin layer of gold (200 nm thick), as shown in the inset of Figure 1 (a). The BSCCO thin film is a c-axis oriented superconductor with a c-axis dielectric function of $\varepsilon_c(\omega) = \varepsilon_\infty\left(1 - \omega_p^2/\omega^2\right)$ where $\varepsilon_\infty = 12$. The cavity array has a subwavelength spacing of P=100 μm, and the distance between two gold patches is kept constant at 1200 nm.

Here, the THz wave is normally incident on the structure. Above the transition temperature (T_c), the Josephson plasma frequency ω_p is zero and approaches a value of 0.67 at T=20 K. For a cavity width of w=67.3 μm, the cavity resonance frequency $f_c = c/2w\sqrt{\varepsilon_{eff}}$ is equal to the Josephson plasma frequency. ε_{eff} is the effective permittivity of the cavity. The reflection spectra of the device show a single dip at a frequency of 0.67 THz for this cavity width (as shown in Figure 1 (b)). However, when a BSCCO film with a thickness of 225 nm is inserted into the cavity, two dips are observed in the reflection spectra. The frequency splitting between these two dips is 0.29 THz.

Three weak, strong, and ultrastrong coupling regimes between THz EM waves and Josephson plasmon can be

defined. The splitting in resonance frequency is representative of strong coupling. The minimum value of splitting (so-called Rabi frequency) between two dips is obtained by tuning the cavity frequency (i.e. cavity width) around the value of Josephson frequency [3]. The coupling is in the ultrastrong regime when the normalized Rabi frequency, which is the Rabi frequency divided by cavity frequency, is not negligible compared to one. Our study shows that the normalized Rabi frequency is 0.29 for a BSCCO thickness of 200 nm, indicating ultrastrong coupling. It increases to 0.87 for a BSCCO thickness of 800 nm [3].

Further study on the thermal characteristic of the normalized Rabi frequency shows that this quantity is not dependent on temperature below T_c. However, approaching T_c leads to weak coupling, and no splitting is observed. Overall, our proposed array of microcavities demonstrates ultrastrong coupling between JPWs and THz EM waves, which can be beneficial for boosting the radiated power of coherent emitters and the development of sensitive BSCCO THz detectors.

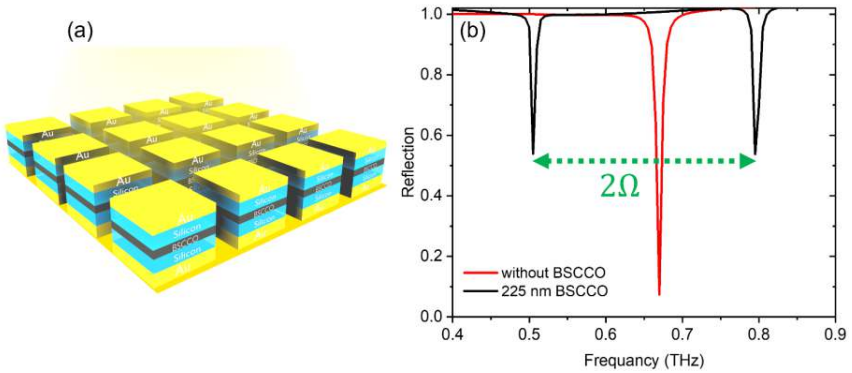

Figure 1: (a) Array of subwavelength microcavities composed of gold/silicon/BSCCO/silicon/gold layers. (b) The reflection spectra of the device with a cavity width of w=67.3 μm. when there is no superconductor (red line) and a superconductor with a thickness of 225 nm is between two silicon films. Here the temperature is T=20 K where $\omega_p = 0.67$ THz.

Abstract: We consider a Josephson Junction with nanoengineered pillars connecting its two banks. Josephson vortices are generated by the applied magnetic field applied and are driven by the applied current flowing through the junction. If pillar is large enough, the vortices cannot pass through it and go around it, forming a loop behind. The evolution of the loops depends on the Josephson coupling and external conditions and usually results in multiple creations and annihilations of the loops.

Mutual interaction of vortices and Josephson plasma waves in Josephson structures offers an unprecedented level of control of electromagnetic field waves, which are in much needed THz frequency range [1]. Josephson vortices can be used to generate THz radiation [2], to form tuneable photonic crystals [3], to guide THz waves [4, 5], or to manipulate them [6] utilizing natural nonlinearity of Josephson junctions or even to generate a quanta of THz radiation [7]. Therefore, superconducting THz devices can provide an alternative to more conventional THz systems.

Here, we discuss how nanoengineered single Josephson junction can be used to generate Josephson vortex loops. Creation and annihilation of such loops can be used as to emit THz radiation. Moreover, when loops are created, they can be stable inside the junction as they trapped by pillars connecting superconducting banks of the junction. Therefore, the system can be used as a storage of THz radiation (THz battery) or as a memory element for computing at THz frequency range.

To simulate creation and annihilation of Josephson loop, we used time-dependent Ginsburg Landau equations with Josephson coupling at the junction [8]. Superconducting banks of the junction are also connected by cylindrical pillars made of the same materials as the banks or superconducting material with slightly different superconducting critical temperature, which helps us to switch on and off barrier provided by superconducting pillars. Detailed of our extended simulations are published in [8] where different evolution and annihilation of Josephson vortex loops are considered.

Figures 1 (a-h) show the simples possible case of a simulated 4 pillar sample at steady state creation-annihilation cycle of Josephson vortex loop. In Fig. a, a vortex shown by dark blue colour enters the sample with two vortex loops trapped by the right column of the pillars. The current pushes the vortex to go round the two pillars, which initially had with no loops Fig. 1 b-d. The two vortex loops formed behind the vortex (Fig. 1 e) when it passes the left two pillars and approaches the right two pillars pushing the vortex loops at the right pillars, as a result, collapsing these loops (Fig. 1f). Them the vortex circumvents the right pillars (Fig. 1 g) and escapes the sample, leaving two new vortex loops formed arounf the right pillars (Fig 1h), while the new vortex entering the sample forces the two loops at the left pillars to collapsed. This process continues if the applied current is constant, however, if the current is switched of at moment shown in Fig. 1e, the system relaxed at the state Fig. 1j with four loops and the vortex trapped between pillars. However, if the current is switched of at the moment (h), the system is relaxed to the state (i) with four pillars and no vortex

between loops. Switching the system at other time moments can result in diverse vortex-loop configurations. These states can be used both for computational memory and storage of THz radiation energy.

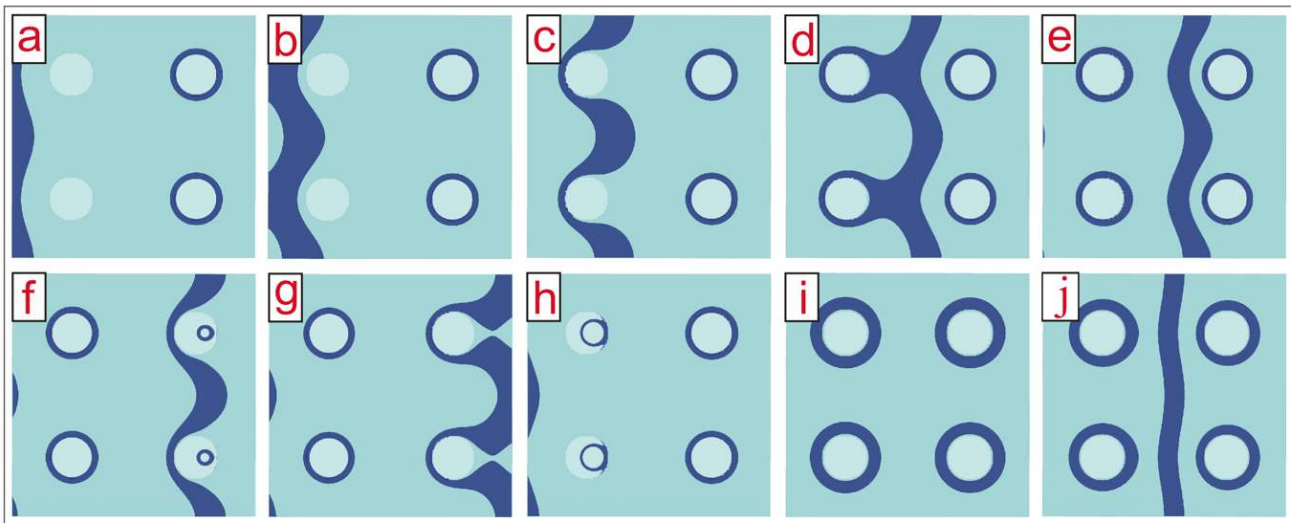

Figure 1: (a-h) Evolution of vortices and vortex loops at a constant applied magnetic field and DC current; (i) and (j) represent the steady states of the system if the applied current is switched off at the moment (h) and (e), respectively.

Quantum electrodynamics of non-demolition detection of single microwave photon by superconducting qubit array

P. Navez

Loughborough University, Epinal Way Loughborough, Leicestershire LE11 3T, UK

Summary

Single particle detection is one of the most fundamental issues in quantum me-chanics as it addresses the question of quantum measurement. An accurate quantum description of a detector would avoid the use of the Born's rule (or von Neumann postulate) about the probabilities of different outcomes, leading to the controversial interpretation of the collapse of the wave packet or the Schrodinger's cat. In addition, it leads to applications standing from precise weak microwave signal measurement to the detections of axions, that are hypo-thetical particles predicted in the standard model of elementary particles and which become photons when passing through a magnetic field.

In this talk, we apply consistently the formalism of quantum electrodynamics and we developed a comprehensive theoretical framework describing the inter-action of single microwave photons with an array of superconducting transmon qubits in a waveguide cavity resonator [1]. In particular, we analyse the effects of microwave photons on the array's response to a weak probe signal exciting the resonator. The study reveals that a high quality factor cavities provide better spectral resolution of the response, while cavities with moderate quality factor allow better sensitivity for a single photon detection. Remarkably, our analysis showed that a single-photon signal can be detected by even a sole qubit in cavity under the realistic range of system parameters. We also discuss how quantum properties of the microwave radiation and electrodynamical properties of resonators affect the probe response of qubits' array and, how the interaction between the qubits improve the detection by reaching a noise level close the Heisenberg lowest bound limit [2]. Our results provide an efficient theoretical background for informing the development and design of quantum devices con-sisting of arrays of qubits, especially for those using a cavity where an explicit expression for the transmission or reflection is required.

Our results is used for the interpretation of the experiments done within the EU-SUPERGALAX consortium. Preliminary measurements show the influence of an external power on the transmission spectrum [3] in accordance with the theory [1].

Modelling hot carrier generation in large metallic nanoparticles

Johannes Lischner[1*]

[1]Department of Materials, Imperial College London, United Kingdom
[*]corresponding author: j.lischner@imperial.ac.uk

Abstract: Localized surface plasmons in metallic nanoparticles give rise to very strong light absorption. The decay of these excitations results in the generation of energetic or "hot" electrons and holes which can be harvested and harnessed for applications in photovoltaics, photocatalysis and light sensing. To optimize hot carrier production in devices, a detailed theoretical understanding of the relevant microscopic processes, including light-matter interactions, plasmon decay and hot electron thermalization, is needed. In my talk, I will describe a material-specific theory of hot-carrier generation in metallic nanoparticles which combines a classical description of the electromagnetic radiation with large-scale atomistic quantum-mechanical simulations. I will present results for hot carrier distributions in spherical nanoparticles of gold, silver and copper and discuss the relative importance of interband and intraband transitions as function of nanoparticle size. Finally, I will describe results for more complex systems, such as core-shell nanoparticles or "reactor" systems in which small catalytic nanoparticles are adsorbed to a larger plasmonic nanoparticles.

Dynamic plasmonics and optics with organic conducting polymers

Magnus Jonsson

Organic Photonics and Nanooptics group, Laboratory of Organic Electronics, Department of Science and Technology, Linköping University, Sweden

E-mail: magnus.jonsson@liu.se

Abstract: My group is interested in developing novel ways to control light and heat using organic materials like conducting polymers and cellulose. Applications include tuneable nanooptical metasurfaces, reflective color displays and energy-regulating optical materials. In particular, we recently introduced conducting polymers as a new materials platform for dynamically tuneable plasmonics.[1] By contrast to static nanoantennas made of traditional metals, the optical response of the polymeric antennas can be repeatedly turned off and on again by varying the redox state of the polymer, which reversibly switches the material between optically metallic and dielectric states in the near infrared and infrared ranges.[1-4] I will then demonstrate how the same type of conducting polymers offers novel means for forming dynamically tuneable structurally colored materials,[5,6] with anticipated use for reflective labels and electronic readers in color. If time allows, I hope to also introduce our latest works on radiative cooling, including electrical tuning at ambient conditions, structurally colored cooling systems, and integration with ionic thermoelectric devices.[7-9]

Surface Susceptibility Synthesis of Spatially Dispersive Metasurfaces

J. Dugan[1*], T. J. Smy[1], F. Monticone[2], and S. Gupta

[1]Carleton University, Canada
[2]Cornell University, USA
[*]corresponding author: jordandugan@cmail.carleton.ca

Abstract: We propose a simple method to synthesize and obtain a zero thickness sheet boundary condition of a spatially dispersive (SD) metasurface to achieve desired wave transformations operations specified in the spatial frequency domain. We demonstrate the proposed method by synthesizing a space-plate as an example, using zero-thickness sheet description of a Huygens' metasurface in terms of angle-dependent surface susceptibilities.

Recently, there has been a lot of interest in nonlocal, or spatially dispersive metasurfaces, where the induced polarizations on the unit-cells are strongly dependent on the fields over an extended region across the surface. These surfaces have found applications in wave-based computing [1] as well as in shrinking optical systems [2], for instance, thereby greatly expanding the wave transformation capabilities compared to what is currently beenachieved using purely local metasurfaces. Recently, a computationally efficient method for modeling these surfaces has been proposed whereby the metasurface is modeled as a zero thickness sheet characterized by angle-dependent surface susceptibilities and the fields around the surface satisfy the generalized sheet transition conditions (GSTCs) [3]. If these surface susceptibilities take the form of a rational polynomial, they can be implemented as spatial boundary conditions in standard numerical methods [4]. While these works have focused on the field analysis of SD metasurfaces, the focus of this paper is the synthesis of surface susceptibilities to achieve desired field transformations in the spatial frequency domain. This is in contrast to synthesis methods currently restricted to local metasurfaces only [5]. To demonstrate the procedure to synthesize a 2D metasurface in the y − z plane to achieve a desired reflection R(k_y) and transmission T(k_y) response, let us assume TE Polarization, and a Huygens' metasurface configuration, which consists of orthogonal tangential electric and magnetic susceptibilities only. These susceptibilities, assuming the surface is described by the GSTCs, take the following form:

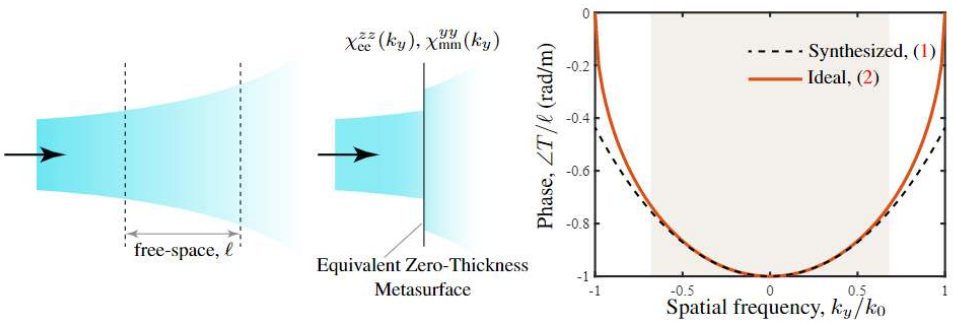

Figure 1: Phase response of a free space body of length ℓ and of the synthesized space-plate in the spatial frequency domain, where the space-plate is represented as an equivalent zero thickness sheet model.

$$\chi_{\mathrm{ee}}^{zz}(k_y) = \frac{2j\sqrt{k_0^2 - k_y^2}\left(-1 + R(k_y) + T(k_y)\right)}{k_0^2\left(1 + R(k_y) + T(k_y)\right)} \approx \frac{\sum_{m=0}^{\infty} a_m\, k_y^m}{\sum_{n=0}^{\infty} b_n\, k_y^n} \tag{1a}$$

$$\chi_{\mathrm{mm}}^{yy}(k_y) = \frac{-2j\left(1 - T(k_y) + R(k_y)\right)}{\sqrt{k_0^2 - k_y^2}\left(1 - R(k_y) + T(k_y)\right)} \approx \frac{\sum_{m=0}^{\infty} c_m\, k_y^m}{\sum_{n=0}^{\infty} d_n\, k_y^n}, \tag{1b}$$

where k_y is the transverse wave vector, and the surface susceptibilities are to be approximated as rational polynomial functions for simple integration with standard numerical full-wave solvers. This is achieved by inverse Fourier transforming the GSTCs with the incorporation of (1), which converts the polynomial terms to spatial field derivatives, and thus the corresponding spatial boundary conditions. To apply this method, consider a metasurface to compress free space (also known as a space-plate), as illustrated in Fig. 1. Such an ideal surface has zero reflection (i.e., R = 0) and a transmission coefficient given by:

$$T(k_y) = \exp\left(-j\ell\sqrt{k_0^2 - k_y^2}\right), \tag{2}$$

where ℓ is the length of free space we are attempting to compress. This needs to be substituted in (1) to obtain the surface susceptibilities to construct the zero thickness sheet boundary condition. To obtain the desired polynomial form of the susceptibilities, T (ky) can be expressed in an alternate all-pass filter form as

$$T = \frac{1 - j\xi}{1 + j\xi}, \quad \text{where } \xi = -\tan\left(\frac{-j\ell\sqrt{k_0^2 - k_y^2}}{2}\right) \tag{3}$$

This all-pass form ensures the magnitude of the transmission response ensures unity magnitude for all k_y. Taking a 2nd order Taylor expansion of ξ with respect to k_y, substituting T into (1) and then taking a 2nd order Taylor expansion of the radical terms yields the final set of rational polynomial susceptibilities that can now be integrated into standard numerical methods. Fig. 1 shows one example, where we see that in the paraxial regime, the phase shift produced by the synthesized susceptibilities provides an excellent match with the ideal space-plate response with the quality of the match deteriorating for large values of k_y. In future works, we will integrate the synthesized susceptibilities in the full-wave numerical solvers to demonstrate their operation directly in the space-domain, as well as explore the mapping between the synthesized susceptibilities and the physical unit cell structures to practically implement the synthesized SD metasurfaces. The proposed synthesis method thus represents an important theoretical technique to analyze SD metasurfaces and evaluate their fundamental performance limits.

Abstract: We use single particle spectroscopic imaging and statistical analysis to assess the plasmonic enhancement of NIR-to-visible upconversion luminescence (UCL) from single β-$NaYF_4:Yb^{3+}:Tm^{3+}$ upconverting nanoparticles (UCNPs) coupled to random arrangements of Ag nanowires supported on glass substrates, termed nanowire composites (NWCs). By examining the effects at the single particle level, and accumulating a statistical sampling of single particle emitters, both on and off the plasmonic substrates studied, we obtain a statistical description of UCL emission enhancement in the Tm-doped UCNPs and map out the statistical distribution of excitation and luminescence enhancement on the plasmonic substrates. We use both wide field and confocal scanning spectroscopic imaging of single UCNPs on and off the plasmonic substrates in combination with energy and time resolved spectroscopy, and compare these results to a coupled rate equation analysis to elucidate the energy transfer upconversion enhancement mechanisms. The results obtained are compared to Finite Difference Time Domain (FDTD) calculations of the fields near the plasmonic substrate.

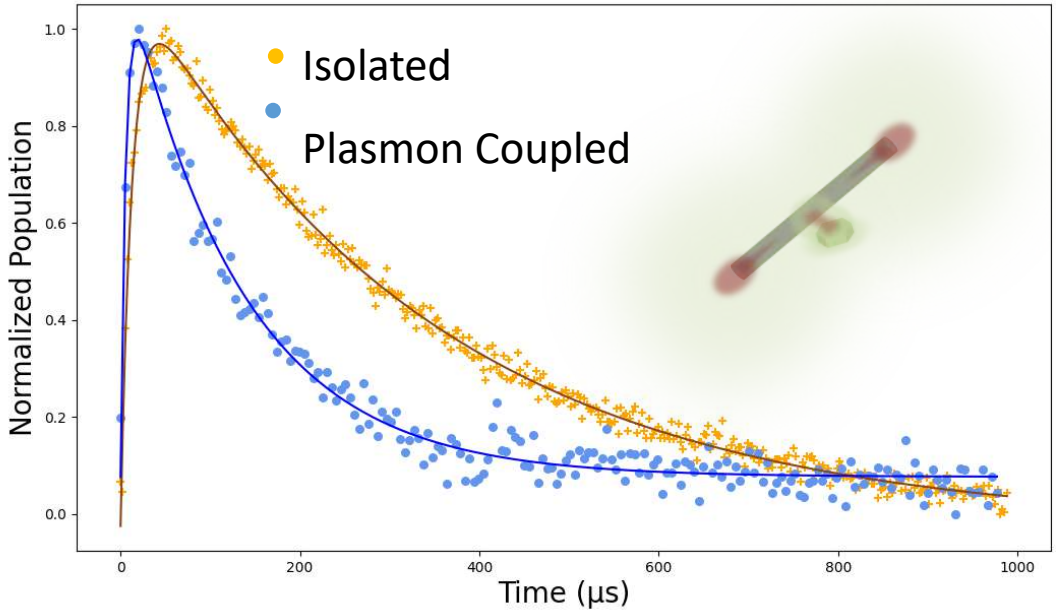

Figure: Single particle luminescence decay of isolated and plasmon-coupled upconverting nanoparticle.

Topological Trapped-Rainbow and Nonreciprocal Guides Beyond the Time-Bandwidth Limit

Konstantinos Baskourelos and Kosmas L. Tsakmakidis
Section of Condensed Matter Physics, Department of Physics, National and Kapodistrian University of Athens, Greece
Author e-mail address: ktsakmakidis@phys.uoa.gr

Abstract: Topologically protected wave transport has recently emerged as an effective means to address a recurring problem hampering the field of 'slow light' for the past two decades: Its keen sensitivity to disorders and structural imperfections. With it, there has been renewed interest in efforts to overcome the delay-time–bandwidth limitation usually characterizing slow-light devices, on occasion thought to be a 'fundamental limit'. Our talk will overview latest developments and point out important new functionalities that overcoming the limit can enable.

1. Introduction

It has recently been realized[1-3] that nonreciprocity and topology – both, important even in the usual light regime of integrated optoelectronic and photonic structures – are particularly crucial in the slow- and stopped-light regime, with a number of recent works having elucidated that they both play a key role for attaining prolonged *and* broadband (i.e., T-B unlimited) light localization in topological, terminated[1] or 'rainbow trapping'[4], structures (see Fig. 1). In the latter approach, use can be made of the concept of synthetic dimensions.

A synthetic dimension in graded 'rainbow trapping' structures can be constructed[4] by exploiting a translational degree of freedom – e.g., inside the unit cell of a two-dimensional chirped photonic crystal waveguide. The translational grading (tapering) gives rise to a nontrivial topology in the synthetic dimension, which in turn results to robustly localized (stopped) surface states where different frequencies are localized at different positions along the guide ('rainbow principle', see Fig. 1c).

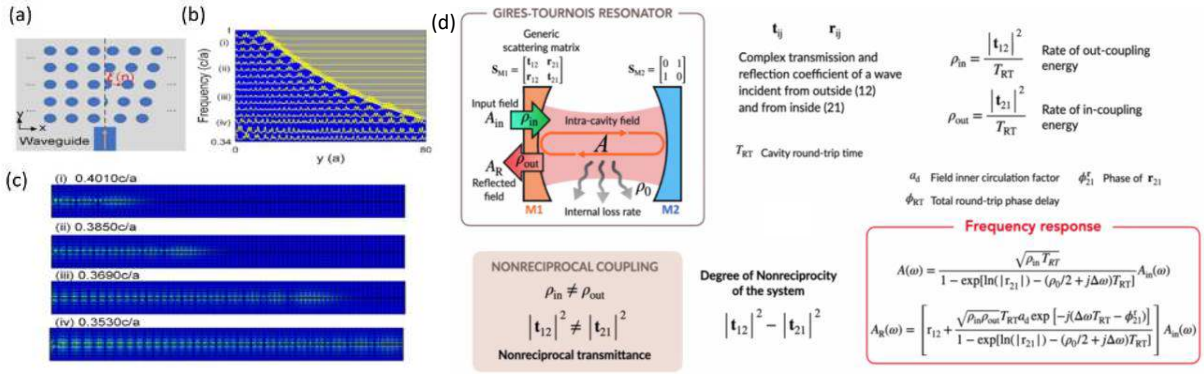

Fig. 1. (a) Schematic diagram of a topological 'trapped rainbow' structure, with light coupled-in using a dielectric waveguide. (b) Normalized energy density distributions along the interface shown in (a). The blue and gray parts are regions of existence and nonexistence of interface modes. (c) Different light frequencies are rigorously stopped and trapped at different positions along the topological guide of (a). (d) General schematic of a nonreciprocal cavity, along with the main definitions used for the analysis of its time-bandwidth product and intra-cavity power.

Such ‘topological trapped rainbows’ can rigorously stop and localize states of different frequencies at different positions along a topological waveguide, controlled by the tuning of the spatial modulation of the states’ group velocity. For photonic crystal structures, in particular, the operation frequency as well as the bandwidth of the topological trapped rainbow can be tuned by controlling the band gap of the photonic crystal, and is completely decoupled from the storage (stopping) time. This topological principle can be applied to photonic crystals of any symmetry and material composition, so long as a complete band gap exists.

In terminated topological structures forming nonreciprocal cavities[1-3], on the other hand, wave propagation is halted by the use of a terminating metallic layer (not by reducing v_g to zero), where back-reflections and scattering are prevented owing to the topological design of the structure.

2. Enabled applications and outlook

As has recently been established[5], the degree to which the limit can be exceeded exactly corresponds to the degree to which light power increases inside a device. Thus, devices operating beyond the limit will be uniquely positioned to enhance optical nonlinearities or achieve ultrafast active control. The nonlinear interactions can here be greatly enhanced due to the compression of the local energy density as a *broadband* pulse is decelerated inside the device.

The enhancement of nonlinearities can be large enough to produce measurable effects due to single-photon input fields[6-9] – an effect already well-established even for T-B limited slow-light devices. There is a principal way a single-photon nonlinearity could here be useful: As a source of single (e.g., Foch-state) photons with controllable spatio-temporal characteristics.

Further envisaged applications of beyond-the-limit slow and stopped light, the regime where the density of states and the Purcell factor dramatically increase[6], would be ultralow-light-level all-optical switching, enhanced chiral nanobiosensing, optical micro-combs, and enhanced spontaneous emission rates – appealing for fast light-emitting diodes (nano-LEDs), with an ultimate goal of attaining spontaneous emission rates faster than around 50 GHz, so that LEDs could become faster than lasers[7]. All devices relying on strong light-matter interactions would benefit from the above regime because, as explained before, the degree to which the T-B limit is exceeded exactly corresponds to the degree to which power inside a device increases[5], thereby potentially enabling unprecedented capabilities in the fields of metamaterials, nanophotonics and nonlinear optics – both, classical and quantum ones.

From synthesis to assembly: a Silicon based metasurface fabrication

Juan Xin[1], Wajdi Chaabani[1], Julien Proust[1] and Jérôme Plain[1*]

Abstract: In this study, we present a simple method to fabricate silicon nanoparticles from wafer chips. This technique allows to obtain nanoparticles of relatively homogeneous size and showing Mie resonances in the visible range. The second result that we will present is an assembly technique based on the use of the capillarity force and allowing the obtaining of metasurfaces from silicon nanoparticles.

There are many ways to fabricate nanoparticles allowing to have optical properties at nanometric scales. For example, top-down approaches based on electron lithography have as main drawbacks the cost and time of fabrication. On the other hand, bottom-up approaches are less expensive but do not allow easy organization to obtain metasurfaces. Thus, it is necessary to combine the two types of approaches to associate a low-cost synthesis technique with a lithography technique.

In our synthesis technique, we simply grind bulk silicon to obtain nanoparticles[1]. This technique allows us to obtain in solution Si nanoparticles with a diameter ranging from 80 nm to about 250 nm. By centrifugation steps, it is possible to obtain a final mean size of about 120 nm ± 20 nm. Dark field and corresponding SEM images are shown for individual nanoparticles in Figure 1.

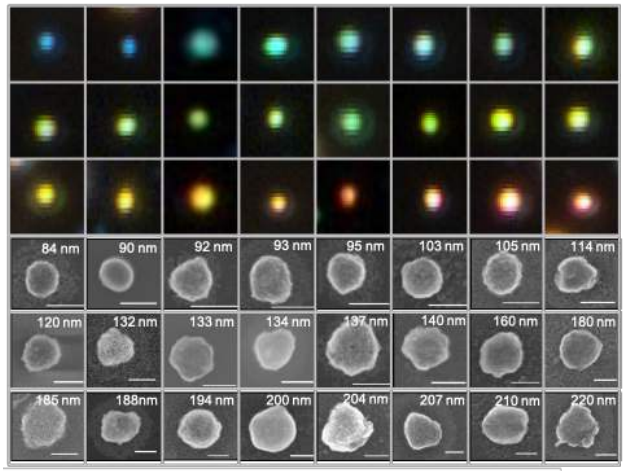

Figure 1. Up. Dark field images of Si nanoparticles. Down. Corresponding SEM images.

The second step allows to deposit the nanoparticles in a pattern obtained by electronic lithography. This technique, based on the assistance of capillary forces, allows to obtain large surfaces from a colloidal solution of nanoparticles. Figure 2 shows nanoparticles of two different sizes distributed on a complex pattern.

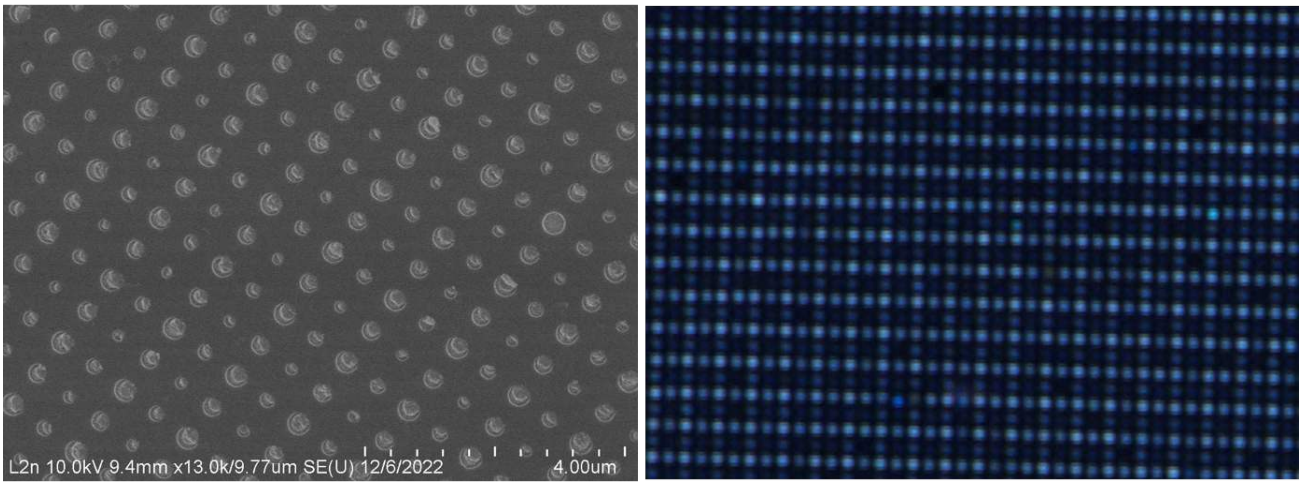

Figure 2. Left. SEM images of Si nanoparticles arranged on a complex pattern. Right. Corresponding Dark field images of Si based metasurface.

We have demonstrated that it is possible to organize naonaoparticles obtained in solution on a surface using a technique that is relatively simple to implement and compatible with all nano-lithography techniques.

Abstract:
Periodically corrugated Au/α-Al_2O_3 plasmonic substrates were used for surface enhanced Raman spectroscopy of thiophenol molecules. The results showed a strong dependence of the intensity of the Raman peaks of thiophenol molecules on the value of the period of corrugation and the angle between the polarization of the laser beam and the corrugation vector.

The dielectric-metal interface is a system that enhances the response of light-exited molecules when deposited on metallic surface. This enhancement can be observed in Raman light scattering as the surface enhanced Raman scattering (SERS) effect. A plasmonic substrate consisting of periodically-corrugated sapphire surface coated with a thin layer of metal creates a periodic modulation in the surface plasmon resonance (SPR) of the material. It results in the formation of surface plasmon polaritons (SPPs) that can be tailored to specific wavelengths of light. This modulation can also result in the formation of a photonic bandgap [1,2]. Results of our studies showed an additional effect of the corrugation on Raman spectra collected from organic molecules deposited onto corrugated metallic surface.

The Raman spectroscopy was used to investigate the effect of corrugation on the SERS (Fig. 1a) of organic molecules (thiophenol) deposited onto the plasmonic substrate (Au on M-cut α-Al_2O_3). The substrate consisted of periodically-arranged sapphire rows coated with a 10 nm-thick gold layer (Fig. 1b). Periods of nanostructures were ranging from 170 nm till 450 nm. The 785 nm laser wavelength was used to illuminate the thiophenol.

The sample was rotated and an angle between laser polarization and the corrugation vector was determined (Fig. 1a and 1d). Collected Raman spectra of thiophenol revealed several characteristic peaks (Figure 1c).

Analysis of the results showed the existence of dependencies of thiophenol Raman peaks intensities:

1. on the angle between the direction of polarization and the corrugation vector (Fig. 1d.),
2. on the period of corrugated substrate (Fig. 1d.).

The results showed that the strongest Raman intensity is observed along the corrugation vector, whereas the smallest intensity is in the direction perpendicular to the corrugation vector. Moreover, Raman intensities increase with the period of corrugation up to 270 nm. For larger periods, the intensity decreases. Such behavior could be explained with the use of the model discussed in Ref.3 showing that at selected frequencies a SPP damping changes nonlinearly as a function of corrugation dimensions.

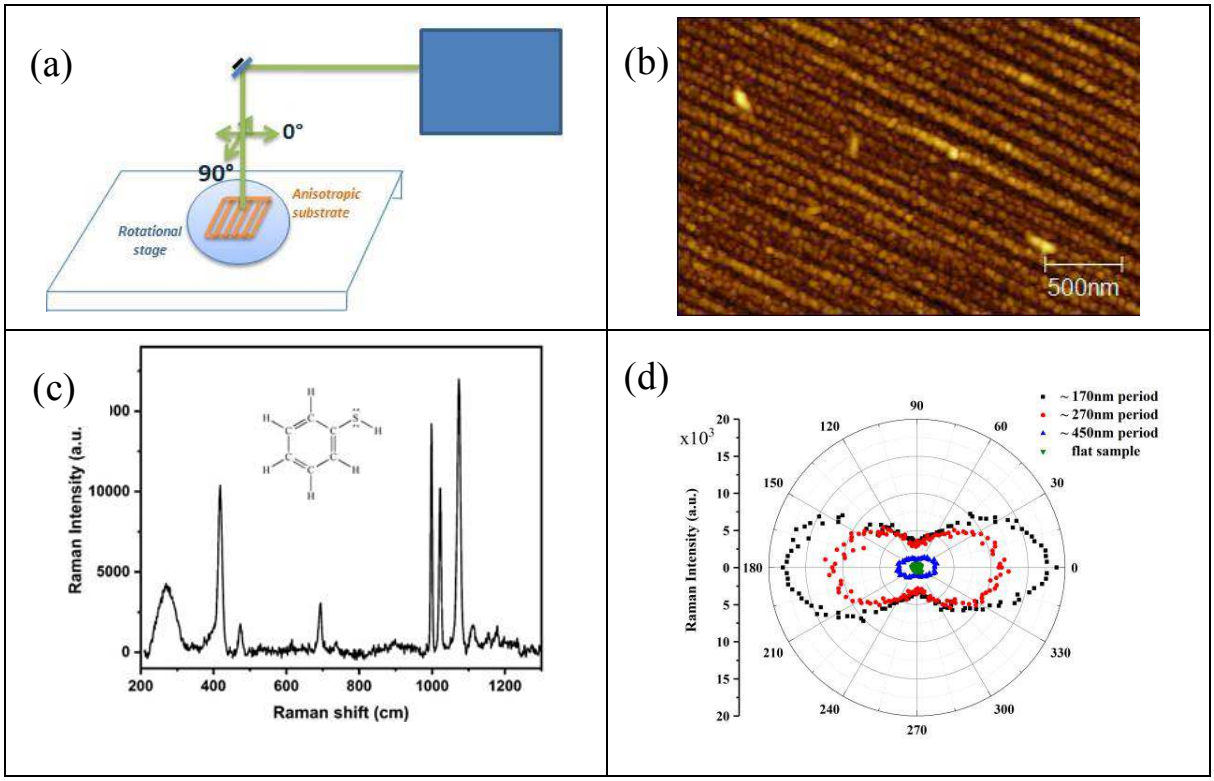

Figure 1. Schematic of measurements geometry (a). Raman spectrum of thiophenol (b). AFM image of corrugated sapphire coated with a 10 nm-thick Au layer (c). Period and angle dependency of Raman intensity of the thiophenol peak at 1072 cm^{-1} (the angle was determined between the corrugation direction and the laser beam polarization) (d).

Abstract: Bird-window collisions often lead to the death of the bird and damage to the window. However, many animals, including birds, can perceive UV light. Many species have hence developed visual communication in this wavelength range, for instance, thanks to photonic structures. Such structures allowed us to design a new UV-reflecting multilayered coating for bird-safe glazing, through a bioinspiration approach. This coating was optimised for bird and human visual perception.

Every year, billions of birds collide with windows, often resulting in their death, as well as in significant material damage. Some manufacturers developed UV-reflective coatings for bird-safe glazing. These coatings are often visible to the human eye over a wide range of viewing angles. In addition, the bird perception of these glazings is usually not considered in depth when developing such selectively reflective devices. However, many animal species, including birds and insects, have developed a wide variety of photonic structures active in the UV due to their perception of light in this range of the electromagnetic spectrum [1]. These structures, optimised during evolution by natural selection, allow us to elaborate new concepts of optimised coatings for selective reflection in the UV and to develop bird-safe glazing through a bioinspiration approach [1]. We developed a bird-safe coating for flat glass panels and polymers that exploits the difference of light perception between humans and birds. This coating consists of a periodic multilayer of metal oxide layers deposited on soda-lime glass substrates by Physical Vapour Deposition (PVD) with patterns. The optical response of the multilayer was numerically designed in terms of morphology and material composition, through a multi-objective optimisation, using human and avian colour perception models. Such a coating deposited on a window makes the window bird-safe, while preserving the aesthetics of the window. The deposited pattern is invisible to human eyes but strongly reflects in the UV range.

Cross-reactive plasmonic arrays as optical tastebuds

Justin R. Sperling [1], William J. Peveler [2], Alasdair W. Clark* [1]
[1]James Watt School of Engineering, University of Glasgow, Glasgow, United Kingdom
[2] School of Chemistry, University of Glasgow, Glasgow, United Kingdom

Abstract: We present a cross-reactive nanoplasmonic sensor capable of identifying and classifying complex liquid mixtures. Analogous to biological tastebuds, our plasmonic sensor shows promise in a variety of industrial applications as a simple, rapid quality control measure.

There are a variety of analytical tools that are used in the beverage industry for quality control. Typically, these tools are large, expensive, and are not compatible with real-time, in-line monitoring (e.g. gas chromatography mass spectrometry). On the other end of the scale are human tasters who can be trained to recognize impurities within batches of product, but who, due to the nature of human taste, are prone to giving inconsistent scores. As such, there is the need for simple, real-time sensory tools that can be deployed within production facilities as quality control systems; tools which, ideally, could also provide "taste" scores analogous to those provided by human testers. Here, we present a nano-scale optical tastebud system that may fit these requirements.

Our artificial tastebud arrays are composed of millions plasmonic nanostructures, each approximately 100nm x 100nm. Made from Au and Al, these tastebuds provide a plasmonic response (a colour shift in their resonance condition) that is highly dependent on the refractive index of their immediate surroundings. Through specific surface modification we segregate, within the nanoscale sensing volume of the structures, the molecular components of the liquids introduced to the tastebuds. By modifying different arrays of tastebuds with different chemical groups, we can ensure each array probes a different family of components within the liquid. By comparing the resonance shifts from each array we generate a unique statistical score for each mixture. We believe that this development may lead to both portable and in-line devices for applications in beverage production, counterfeit detection, and environmental monitoring.

Effective refractive index determination and light propagation mechanisms in natural scattering media

D. T. Meiers[1*] and G. von Freymann[1,2]

[1]Physics Department and Research Center OPTIMAS, RPTU Kaiserslautern-Landau, 67663 Kaiserslautern, Germany
[2]Fraunhofer Institute for Industrial Mathematics ITWM, 67663 Kaiserslautern, Germany
[*]corresponding author: dmeiers@rptu.de

Abstract: We present a new mixing rule for calculating the effective refractive index beyond the limit of small particles; a restriction found in common effective medium approaches such as the Maxwell-Garnett or Bruggeman theory. Subsequently, these findings are used to distinguish the diffusive and coherent portion of light transport in ultrathin, strongly scattering white beetle scales. It is shown that weakly localized random photonic modes contribute about one third of the overall scattered light, revealing their significance for the brilliant whiteness.

1. Introduction

The interaction of electromagnetic waves with disordered media is ubiquitous in nature, which can be for example observed as vivid structural coloration of various insects, fishes, algae etc. [1]. However, due to the random local arrangements a full description of the light transport on the microscopic scale is in general impossible and an effective medium approach is used instead. Such a description requires the determination of an effective refractive index, which is often done applying the Maxwell-Garnett (MG) or Bruggeman (BG) theory. While both theories are simple to use, they are restricted to grains much smaller than the wavelength of light, which is infrequently fulfilled for natural disordered materials. Using finite-difference time-domain (FDTD) simulations, we systematically investigate the effect of the sphere size on the effective refractive index. Based on the simulation results a new mixing rule is derived, which is capable to correctly describe the effective refractive index of sphere packings composed of large particles [2].
In addition, it is shown that this mixing rule can be also applied for interconnected random structures such as the complex chitin network found in the scales of the white beetle *Cyphochilus*. These scales are of particular interest, since they belong to the strongest scattering structures based on low refractive index materials. While previous studies related the strong scattering to solely diffusive light transport [3], here we find a significant contribution of coherent light scattering by using time and spatially resolved coherent light scattering spectroscopy measurements and accompanying simulations [4].

2. Results

Applying the condition that the forward scattering amplitude of a spherical region of the composite medium vanishes once the background index matches the effective refractive index, FDTD simulations are used to investigate the influence of the sphere size. For dielectric spheres embedded in a dielectric host, it is found that for small sphere sizes the results of the MG theory are obtained. However, with increasing sphere size the results start to deviate from the MG theory, with larger discrepancy at higher refractive index contrasts. In all cases it is observed that a parabola can be fitted to the results in good accordance. Finding a simple empirical formula for

the coefficients of the parabola yields a new, simple mixing rule for large particles. This mixing rule clearly outperforms the prediction of the MG and BG theory, as shown in Fig. 1a.

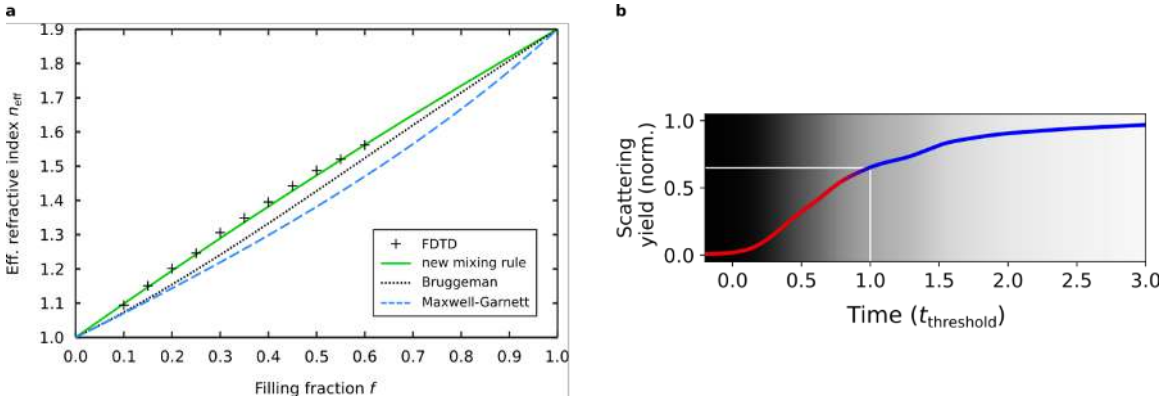

Figure 1: **a**, Comparison of the predictions of the new mixing rule for large particles, the MG and the BG mixing rule with the effective refractive index of a sphere packing, yielded by FDTD simulations. The sphere packing is composed of spheres with a refractive index of 1.9 and a sphere diameter of 380 nm which is not small with respect to the used wavelength of 700 nm. Adapted from [2].**b**, Accumulated scattering yield of the white beetle scales over time. The threshold time $t = 1$ marks the point where the scattering behavior changes from diffusive (red curve) to weak localization assisted (blue). The background shading represents the color impression of the scale over time. Adapted from [4].

Using the mixing rule to determine the effective refractive index of the beetle scales, typical lifetime of diffusive transported light inside the scales is calculated. It is found that this lifetime matches well with the point where the transport behavior changes qualitatively as observed in experiments and simulations. Thereby, the transport at early times is dominated by diffusion while for late times leakage from weakly localized random photonic modes is mainly contributing to the scattered light. Since the portion of this coherent light scattering phenomenon is about one third of the total scattered light, coherent light scattering plays a crucial role for the efficient scattering exhibited by the scales as well as their brilliant whiteness. This can be also discerned in Fig. 1b, revealing that the scales would rather appear gray than white if the coherent light transport would be missing.

Abstract: Currently, there is no coating system that can repel dust, is resistant to UV radiation, and can withstand subzero temperatures to deter serious surface, operational and bodily threats in defense, space, and planetary missions. Such risks not only affect the crew but also damage equipment, on-board instruments, sensors, thermal switches, lens, solar and electronic panels. In this talk, we will present a case study of an optically transparent, solid- and liquid-repellent 'omniphobic' coating (SLRC) developed in our lab with exceptional mechanical durability that can tackle dust mitigation issues for a wide range of solids (regolith, dust, debris, ice etc.). Anti-static, anti-reflective, UV-resistant and dust-repellent features have been designed displaying extreme-low adhesion of solids and liquids. Such SLR coatings are instrumental for a wide range of applications, including photonics.

Bio-inspired surface nanopatterning using Femtosecond Lasers and its Applications

Chunlei Guo

University of Rochester, USA

Cuttlefish-eye inspired vision systems with high-quality imaging capabilities

Young Min Song

[1]Electrical Engineering and Computer Science, Gwangju Institute of Science and Technology, Gwangju 61005, Korea
[*]corresponding author: ymsong@gist.ac.kr

Abstract: We discuss the development of an artificial vision system inspired by the unique vision system of cuttlefish. The system compensates for uneven vertical light distribution and reduces incident lights from the top of its vertical field of view using a W-shaped pupil. The high-density belt-like pixel region of a cylindrical silicon photodiode array allows for high-acuity imaging in the region of interest. A flexible carbon nanotube polarizing film integrated into the surface of the array enables polarization-sensitive imaging, resulting in an artificial vision system that achieves high contrast and acuity under uneven light conditions.

Artificial vision is crucial for mobile robotics, particularly for self-driving cars that need to monitor their environment and detect objects to avoid collisions. High contrast and acuity imaging systems are necessary for these applications, but limited image contrast under vertically uneven illumination conditions can hinder object detectability. While drivers can physically mitigate these issues, software-based approaches are necessary for artificial vision systems. However, processing the large amount of visual information required demands high computational power and energy consumption, requiring appropriate hardware solutions.

Inspired by vision systems in nature, such as those found in aquatic and amphibious animals, various artificial vision systems have been developed [1-5]. These bio-inspired systems have unique features that enable high-performance imaging, but none have yet achieved high contrast and acuity under highly noisy conditions caused by randomly polarized sunlight. In this context, the cuttlefish, which have evolved to have a high-acuity vision system optimized for vertically uneven illumination and to detect polarized light, inspire a high-performance artificial vision for mobile robotics [6].

The unique eye structure of the cuttlefish, consisting of a W-shaped pupil, a single spherical lens, and a curved retina with a high-density belt-like photoreceptor region and polarization-sensitive photoreceptors, enables high-contrast and high-acuity vision under vertically uneven illumination conditions. Inspired by these features, an artificial vision system has been developed that compensates for uneven vertical light distribution, enables high-acuity imaging in the region of interest, and maintains an average degree of polarization for polarization-sensitive imaging. By integrating these optical and electronic components, the developed system can balance uneven light distribution while achieving high contrast and acuity, making it a promising candidate for high-performance artificial vision in mobile robotics.

Abstract: Due to the scarcity of blue colour exhibited by natural organisms, highlighting the underlying this colour mechanisms is always very impactful for the understanding of the natural world. In this research, the colour of the blue rounded spots occurring in the skin of *Taeniura lymma* stingray was unveiled by a combination of experimental and numerical techniques. Our results demonstrated that this blue colour arises from coherent scattering in quasi-ordered photonic structures occurring in the skin of this stingray.

Blue is often described as the rarest colour in natural organisms [1]. Elucidating the underlying mechanism(s) giving rise to such a hue is always very impactful for the understanding of the natural world in which human beings live. In this research, the colour of the blue rounded spots occurring in the skin of the bluespotted ribbontail ray *Taeniura lymma* was unveiled by a combination of experimental and numerical techniques. Histological observations were carried out with optical, fluorescence and transmission electron microscopies. Optical characterisations were performed by spectrometry and microspectrofluorimetry. Numerical simulations were based on two-dimensional fast Fourier transforms of electron micrographs of the observed structures and Benedek's theory relating Fourier transform of spatial variation in refractive index to the intensity of coherent scattering [2]. Our results demonstrated that the blue colour of this ray arises from coherent scattering in quasi-ordered photonic structures occurring in the skin of this animal. This type of structures made of collagen fibres is mostly unknown in marine species. In addition, structural blue colours had never been reported in elasmobranches.

Abstract: In this report, we introduce a non-planar repeated dewetting approach to fabricate gold nanoislands (NIs), uniformly distributed on the wide and highly curved surface of tapered fiber (TF). Through-TF measurements show that the device can achieve a limit of detection in aqueous solution of 10^{-7} M for rhodamine 6G and 10^{-5} M for serotonin and dopamine at near-infrared wavelengths. We envision our technology as a first step towards the unexplored frontier of in-vivo label-free plasmonic neural interface.

Optogenetics has stimulated the development of optical neural interfaces. However, the field largely replies on exogenous fluorescent indicators, which is an indirect way to investigate the biological system and may even alter the native state of the system[1]. Thus, the neuroscience field would highly benefit from label-free approaches to investigate the central neural systems. Surface-enhanced Raman spectroscopy (SERS) is a promising, highly sensitive and label-free approach to detect biomolecules. However, bringing SERS into the deep brain regions requires a specific design to integrate plasmonic structures with minimally invasive neural probes that provide enough sensitivity to detect neurochemicals in a physiological environment.

Here, we introduce a novel non-planar repeated dewetting approach (npRDW)[2] to obtain uniformly distributed gold nanoislands (NIs), decorated along and around the entire highly curved surface of a tapered optical fiber (TF). The fabrication approach is schematically shown in Figure1a. The SEM inspections (Figure1b) of the fabricated NIs-TF device show a uniform NIs coverage until the very tip. The experimental configuration for measuring the limit of detection (LOD) through the tapered fiber (TF) is schematically shown in Figure1c. The results show the NIs-TFs probe have a LOD of 10^{-7} M for aqueous solutions of rhodamine 6G (R6G), and 10^{-5} M for serotonin and dopamine in the near-infrared region. The obtained LOD for neurotransmitters surpasses the current report for SERS-active TF detecting dopamine employing the same configuration (excitation and collection field guided in the same waveguide) by two orders of magnitude[3], and is compatible with the upper bound level of concentrations for neurotransmitters, measured to be in the tens of μM range for both dopamine and serotonin[4,5]. We believe that the highly sensitive SERS detection of the NIs-TFs probe offers opportunities to explore neurotransmitters' dynamics in vivo.

Abstract: In recent years, various nanoengineered structures have been suggested as substitutes for chemical colorants. Nevertheless, many suffer from limited color-palette, angle sensitivity, and are incompatible with industrial production requirements. Here, we introduce a technique for structural coloring that overcomes these constraints by exploiting the hybridization of self-assembled nanoparticles with an ultrathin cavity. Our technique provides a flexible foundation for producing an ultralight plasmonic paint that is eco-friendly and large-scale compatible, bridging the gap between proof-of-concept and industrial applications.

Demonstration of purely structural color based large scale butterflies and paints – A subwavelength plasmonic cavity formed by a self-assembly of metallic nanoislands on top of an oxide-coated mirror, generates color by selectively absorbing certain wavelengths and strongly back-reflecting other..

Summary: Commercial paints rely on the use of molecules that selectively absorb photons matching their electronic transitions. However, these chemicals have low resolution, are environmentally unstable, and can be toxic and polluting. In recent times, nanostructured materials have been suggested as potential alternatives for coloring. These engineered materials control the scattering and reflection of incident light to create color without the need for harmful chemicals. Nevertheless, they often lack saturation, offer a limited color palette, are difficult to integrate with industrial standards, and suffer from severe angle and polarization sensitivity.

Here, we report an approach to structural coloration that exploits the plasmonic resonances that arise naturally from the interaction of light with a random array of metallic islands at visible frequencies. These self-assembled nanoislands, grown using conventional thin film techniques, are placed near a mirror to create a strong hybridization of localized plasmon and subwavelength cavity modes. This results in a single resonance with minimal angular and polarization dispersion and over 90% reflectance at certain wavelengths. Crucially, the optical response of these nanostructures can be easily adjusted across the entire visible spectrum through simple changes in geometrical parameters to achieve a full color range. Fabricating the structures through large-scale techniques we produce stand-alone paints that are ready to be transferred onto any substrate. Remarkably, the platform offers full coloration with a single layer of pigment, with an unbeatable surface density of 0.4 g/m^2, making it the lightest paint in the world. Overall, our plasmonic structural color provides a non-toxic, fade-resistant, and environmentally friendly coloring solution that bridges the gap from proof-of-concept to real-world industrial applications.

Abstract: We review the accomplishments and motivations behind the development of plasmonic structural colors, overview the highlights of recent works, and provide a perspective on this field's colorful and bright future going forward. In particular, for perspective, we will review the current application space for plasmonic colors, from displays to sensors. Furthermore, we provide a overview on the different manufacturing processes of various plasmonic color films proposed to produce products at industrial scales.

The development of plasmonic structural colors began centuries ago, with plasmonic colors being used in stained glass. These beautiful vibrant colors result from localized surface plasmon resonances of nanoparticles embedded in the glass. The fact that the some of the oldest stained-glass windows in the world found in the Bavarian Augsburg Cathedral were constructed in approximately 900 years ago and still retain their original beautiful colors speaks to many of the advantages of plasmonic colors [1]. They can be constructed to be extremely durable, made of common environmentally friendly materials, and produce a variety of beautiful colors.

As nanofabrication techniques became common, various engineered nano-plasmonic antenna designs became common. These resulted in an explosion in the variety of plasmonic structural color systems, including, gratings [2] and periodic arrays of metallic nano-antenna [3], subwavelength nanohole arrays [4], surface relief metasurfaces [5], and hybrid nanohole/disc arrays [6], and dye free plasmonic structural paints [7].

Additionally, unlike stained glass, plasmonic nano-antenna systems can be engineered to exhibit very particular responses to their environment, this has led to a large number of tunable metasurfaces based on a number of physical processes, including polarization tuning [5,8], electrical tuning [9,10], temperature tunability [11], one-time laser tuning [12], chemical tuning [13], mechanical tuning [14], and finally the rapidly developing field of micro/nano-electromechanical (MEMS/NEMS) tunable colors [15]. MEMS/NEMS and electrical tunability is envisioned to allow for a future of bright, wide-angle visible, high-resolution retro-reflective displays. Since retro-reflective displays use light from the environment for illumination, they are in principle more energy efficient than current light-emitting display technologies, such as liquid crystal or light-emitting diode displays. They are also in principle more visible in direct sunlight. Indeed, many of the possible applications of such displays have been pioneered by e-ink display technology.

Additionally, the same sensitivity to the environment that allows for tunability has also resulted in various applications for colorimetric sensing. Plasmonic structural colors can also be made sensitive to refractive index environment, angle, and strain allowing for sensitive colorimetric sensing of all of these quantities [8,14,16,17]. There are a variety of other applications of the inherently high resolution, tunability, and robustness of plasmonic structural colors in various fields such as security, information storage, steganography, and other areas where plasmonic colors can prove to be an effective solution [18].

Plasmonic structural colors colors are part of a visually striking field, and in this work we will overview

some of the most exciting past achievements in this field, recent and present research, and provide a view on future work in this field. We will emphasize the exploding application space for such plasmonic colors and overview common manufacturing techniques and how they can be applied to solve problems at scale across the application space now and in the future.

Abstract: Acoustic transmission through arbitrary arrangement of scatterers possesses Rayleigh reciprocal symmetry with respect to switch of emitter and receiver at points *A* and *B*, $p_A(\mathbf{r}_B) = p_B(\mathbf{r}_A)$. Velocity field does not possess the same reciprocal symmetry if the system of scatterers does not have reflection symmetry (*P* symmetry). Here we show that in a viscous fluid lack of reciprocal symmetry for velocity leads to different dissipated energy for forward and backward propagation, thus making acoustic propagation truly nonreciprocal.

Wave propagation in a viscous fluid is an irreversible process since it is accompanied by entropy production. While viscous dissipation breaks time-reversal symmetry (*T* symmetry), which is the necessary condition for nonreciprocity, it is commonly believed that viscosity is not a factor for nonreciprocity. This is due to the fact that reciprocity of pressure is compatible with viscosity. The velocities obtained from the Navier-Stokes equation in general case form a vortex field. The vorticity, however, does not contribute to pressure, which depends only on the potential part of the field of velocities, $p(\mathbf{r}) \sim \nabla \cdot \mathbf{v}$, as it follows from the linearized continuity equation. Therefore, the Rayleigh reciprocal symmetry for pressure remains valid even in a viscous fluid. Asymmetry in velocity field, $\mathbf{v}_A(\mathbf{r}_B) \neq \mathbf{v}_B(\mathbf{r}_A)$ cannot be a manifestation of nonreciprocity in *ideal* fluid since fluid dynamics is time reversible. If now the viscosity factor is "switched on" different distribution of velocities in the forward and backward propagation generates different amount of dissipative losses. As a result, the difference in intensities $I_A(r_B) - I_B(r_A)$ acquires a truly nonreciprocal dissipation-induced part. Of course, if the distribution of scatterers between points *A* and *B* is mirror symmetrical the viscous losses become equal. Then, propagation of sound becomes reciprocal while remaining irreversible. Thus, broken *PT* symmetry is the necessary condition for acoustic nonreciprocity.

Numerical simulations were performed for a rigid cylindrical scatterer of diameter 6.35 mm imbedded in a fluid with viscosity η and density ρ, Fig. 1. The upper half of the cylinder (along arc DAC) is not flat. It is covered by square tips of size σ. This roughness breaks *P* symmetry but it does not affect much the scattering cross-section if $\sigma \ll \lambda$. At the same time, it strongly affects the velocity field within the narrow boundary layer $\delta = \sqrt{2\eta/\rho\omega}$ where dissipation occurs. The emitter and receiver were placed 5 mm away from the center at the symmetrical points *A* and *B*. Numerical solutions using the Navier-Stokes equation were obtained for $\sigma = 10$ and 100 μm at frequency 565 kHz that corresponds to the wavelength in water $\lambda = 2.6$ mm. Viscosity of the fluid was changed from 0 to $\eta = 60\,\eta_{water}$. Nonreciprocity for pressure is characterized by $\Delta_p = \frac{2(p_A(B) - p_B(A))}{p_A(B) + p_B(A)}$, which is plotted as a function of normalized viscosity η/η_{water} in Fig. 1a. The numerical values for Δ_p presented in Fig. 1a are very small for both amplitudes of roughness and they do not grow with viscosity. This suggests that pressure remains reciprocal even in a very viscous fluid. The graph in Fig. 1b clearly demonstrates that nonreciprocity $\Delta_v(\eta)$ for modulus of velocity, which exists even for acoustic mode in ideal fluid $\eta = 0$, grows

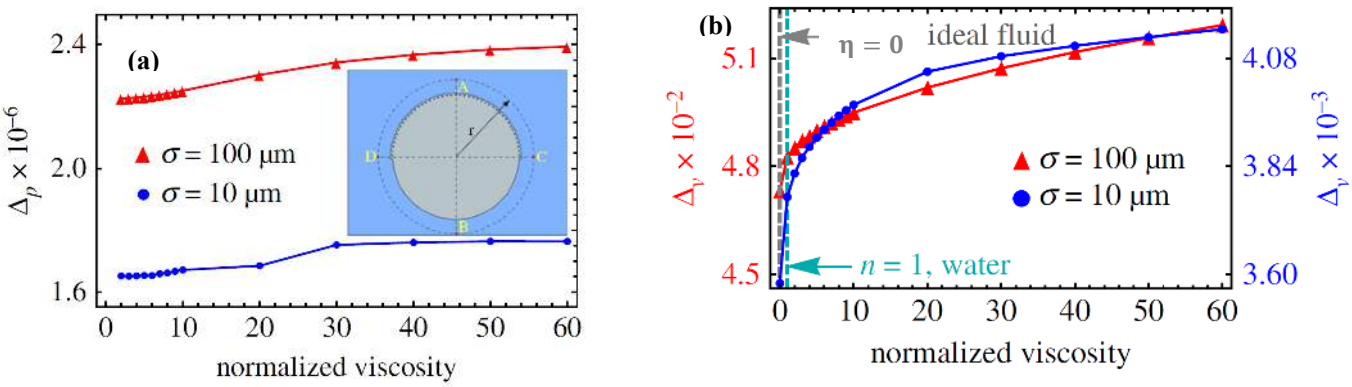

Fig. 1. Nonreciprocity for (a) pressure, Δ_p and (b) modulus of velocity versus normalized viscosity η/η_{water}. The left (right) vertical axis in (b) is for roughness $\sigma = 100$ (10) μm. The graphs demonstrate reciprocal behavior of pressure and strongly nonreciprocal behavior of velocity [1].

fast with η. The difference $\Delta_v(\eta) - \Delta_v(\eta = 0)$ is the part of nonreciprocity caused solely by viscosity. This part scales as $\sqrt{\eta}$ according to the scaling of viscous losses in the boundary layer δ.

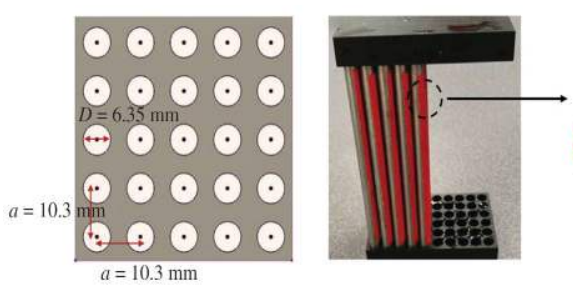

Fig. 3. The cross-section view of the phononic crystal. Rough part of cylindrical surface is highlighted in red.

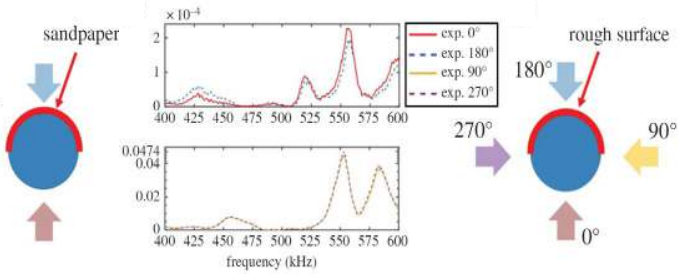

Fig. 4. Experimental transmission spectra along asymmetric (upper panel) and symmetric (lower panel) directions.

A phononic crystal used for experimental demonstration [1] of the effects of asymmetry and non-reciprocity is shown in Fig. 3. Stainless steel rods (D = 6.35 mm) were arranged in a square lattice with period a = 10.30 mm. Half of the cylindrical surface of each rod was covered by a sandpaper representing a scatterer with broken P symmetry (σ = 1.36 μm) along the direction 0° ↔ 180°. The measure of non-reciprocity does not remain constant in Fig. 4 (upper panel) but changes and even alternates its sign with frequency. At the same time, all the spectra measured along the P-symmetric direction 90° ↔ 270° are reciprocal (lower panel). Nonreciprocal transmission through a phononic crystal with strongly asymmetric scatterers was experimentally measured in Ref. [3].

This work was supported by the National Science Foundation under EFRI grant no. 1741677.

Spectral response at hierarchically-constructed exceptional points

Jan Wiersig*

Institut für Physik, Otto-von-Guericke-Universität Magdeburg, D-39016 Magdeburg, Germany
*corresponding author: jan.wiersig@ovgu.de

Abstract: Non-Hermitian degeneracies, so-called exceptional points, have attracted considerable attention in photonics, plasmonics, and acoustics. One way to implement exceptional points of higher order is the scheme of hierarchical construction. We derive explicit formulas for the spectral response at such higher-order exceptional points.

At an exceptional point (EP) of order n exactly n eigenvalues and the corresponding eigenstates of a non-Hermitian Hamiltonian coalesce [1]. Several peculiar and counterintuitive properties of such non-Hermitian degeneracies have been studied in particular in optics and photonics [2]. EPs exhibit a strong spectral response to perturbations: when a Hamiltonian $\hat{H}$ at an EP of order n and eigenvalue E_{EP} is subjected to a perturbation,

$$\hat{\mathcal{H}} = \hat{H} + \varepsilon \hat{H}_1 \,, \tag{1}$$

then the resulting energy (or frequency) splittings are generically proportional to the n-th root of the small perturbation parameter $\varepsilon > 0$ [1]. These splittings are considerably larger than the linear splittings at conventional degeneracies. Importantly, for fixed order n the resulting splittings still depend on the perturbation and the internal structure of the EP. Their contributions can be separated for generic perturbations in the inequality [3]

$$|E_j - E_{\mathrm{EP}}|^n \le \varepsilon ||\hat{H}_1||_2 \, \xi \,, \tag{2}$$

where E_j are the eigenvalues of the perturbed $n \times n$ Hamiltonian matrix (1), $||\cdot||_2$ is the spectral matrix norm, $\xi := ||\hat{N}^{n-1}||_2$ is the spectral response strength, and $\hat{N} := \hat{H} - E_{\mathrm{EP}}\mathbb{1}$ is the traceless part of the unperturbed Hamiltonian.

An EP with large ξ has potentially a strong response to perturbations which makes it attractive for sensing applications [4]. However, this comes at a price, namely the delicate fine tuning of experimental parameters, in particular for higher-order EPs. A robust method to obtain higher-order EPs is the hierarchical construction [5]. In this scheme two subsystems with $n \times n$ Hamiltonians $\hat{H}_{\mathrm{a}}$ and $\hat{H}_{\mathrm{b}}$, each at an EP of order n with the same eigenvalue E_{EP}, are coupled in a unidirectional way,

$$\hat{H} = \begin{pmatrix} \hat{H}_{\mathrm{a}} & 0 \\ \hat{K} & \hat{H}_{\mathrm{b}} \end{pmatrix} . \tag{3}$$

For a generic $n \times n$ coupling matrix $\hat{K}$ the Hamiltonian of the composed system $\hat{H}$ has an EP of order $2n$.

We generalize this scheme to include also two EPs of different order n_{a} and n_{b} and determine the spectral response strength of the resulting EP of higher order $n_{\mathrm{a}} + n_{\mathrm{b}}$ to be [6]

$$\xi = ||\hat{N}_{\mathrm{b}}^{n_{\mathrm{b}}-1} \hat{K} \hat{N}_{\mathrm{a}}^{n_{\mathrm{a}}-1}||_2 \,, \tag{4}$$

with $\hat{N}_{\mathrm{a}}$ and $\hat{N}_{\mathrm{b}}$ being the traceless parts of $\hat{H}_{\mathrm{a}}$ and $\hat{H}_{\mathrm{b}}$. The spectral response strength ξ can be written in terms of the spectral response strengths ξ_{a} and ξ_{b} of the two subsystems as

$$\xi = \xi_{\mathrm{a}} \xi_{\mathrm{b}} |\langle \widetilde{j_{\mathrm{b},n_{\mathrm{b}}}} | \hat{K} | \psi_{\mathrm{EPa}} \rangle| \,. \tag{5}$$

Here, $|\psi_{\mathrm{EPa}}\rangle$ is the eigenvector of $\hat{H}_{\mathrm{a}}$ and $|\widetilde{j_{\mathrm{b},n_{\mathrm{b}}}}\rangle$ is the normalized last Jordan vector of $\hat{H}_{\mathrm{b}}$. Equation (5) provides a

possibility to design the unidirectional coupling in order to maximize the spectral response at the resulting higher-order EP. For fixed properties of the original lower-order EPs and fixed total coupling strength, measured e.g. by $||\hat{K}||_2$, the coupling matrix $\hat{K}$ can be chosen such that $|\langle\widetilde{j_{\mathrm{b},n_\mathrm{b}}}|\hat{K}|\psi_{\mathrm{EPa}}\rangle|$ is maximized. We also derive an easy to calculate upper bound

$$\xi \leq \xi_\mathrm{a}\xi_\mathrm{b}||\hat{K}||_2 \,. \tag{6}$$

Figure 1 shows as example the unidirectional coupling of a parity-time ($\mathcal{PT}$) symmetric dimer to a $\mathcal{PT}$-symmetric trimer. The parameters are chosen such that the former is at an EP of order $n_\mathrm{a} = 2$ and the latter at an EP of order $n_\mathrm{b} = 3$. The two subsystems are coupled in a unidirectional manner from the gainy cavity of the dimer to the gainy cavity of the trimer resulting in an EP of order $n_\mathrm{a} + n_\mathrm{b} = 5$. Such a scenario can be realized experimentally by replacing the single-mode cavities by microrings supporting clockwise and counterclockwise traveling modes and couple them via a conventional optical waveguide [6]. The spectral response strength of the dimer (trimer) is $\xi_\mathrm{a} = 2g_\mathrm{a}$ ($\xi_\mathrm{b} = 4g_\mathrm{b}^2$) [3]. From Eq. (4) or (5) one calculates

$$\xi = \sqrt{8}|k|g_\mathrm{a}g_\mathrm{b}^2 \,, \tag{7}$$

which shows how the coupling strengths have to be chosen in order to obtain a strong spectral response at this hierarchically-constructed EP of order 5.

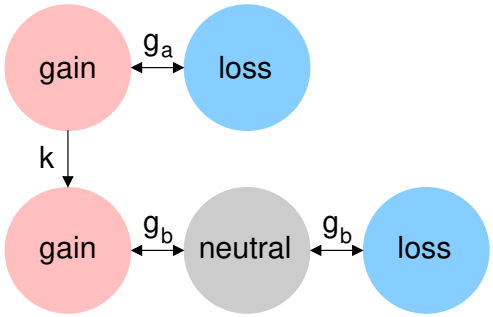

Figure 1: Illustration of the unidirectionally-coupled $\mathcal{PT}$-symmetric dimer and trimer at an EP of order 5. Each disk represents a single-mode cavity. The cavities are coupled horizontally in a symmetric fashion with coupling strengths $g_\mathrm{a} > 0$ and $g_\mathrm{b} > 0$. The vertical coupling is unidirectional with strength $|k|$.

We have presented an explicit formula for the spectral response strength of hierarchically-constructed higher-order EPs. The response strength is a measure of the quality of the EP and is relevant for the design of EP-based devices. We have related this quantity to the spectral response strengths of the individual subsystems. The analysis presented here also serves as a first step towards a more general theory of mode coupling at and near EPs.

Efficient analysis and design of edge states

H. Schomerus[1] *

[1]Department of Physics, Lancaster, University, UK
*corresponding author: h.schomerus@lancaster.ac.uk

Abstract: I describe an efficient approach that allows to design edge states at arbitrary energies. In this approach, edge states are mapped onto unstable fixed points of a non-linear map, which can be directly determined from microscopic coupled-mode descriptions. The approach can make effective use of topological symmetries, but also applies to non-Hermitian and nonreciprocal systems.

Edge and interface states are central to our understanding of topological systems. I show how one can directly determine interface configurations that support edge states at a given energy or frequency. In paradigmatic systems, the underlying equations can be approached analytically, allowing, for instance, to determine a symmetry-breaking edge potential that fixes an edge state in a Su-Schrieffer-Heeger (SSH) chain at a predetermined energy (see Fig. 1). As shown in Fig. 2, the approach also applies to higher-dimensional edges, allowing to design unconventional edge dispersion relations in the complex energy plane.

The design framework rests on a simple real-space renormalization approach that reformulates the quantization condition of these states as a powerful fixed-point condition [1]. Using these fixed points, one then directly obtains the required interface data. Besides its practical utility, this approach provides a completely novel perspective on the formation of such states, clearly separating the roles of symmetries in the bulk and at the interface. As the approach holds for non-Hermitian and non-reciprocal systems, it also gives novel insights into the non-Hermitian skin effect. Conceptually, the approach also highlights the interplay of left and right eigenstates, whose separate roles features physically, e.g., in sensors.

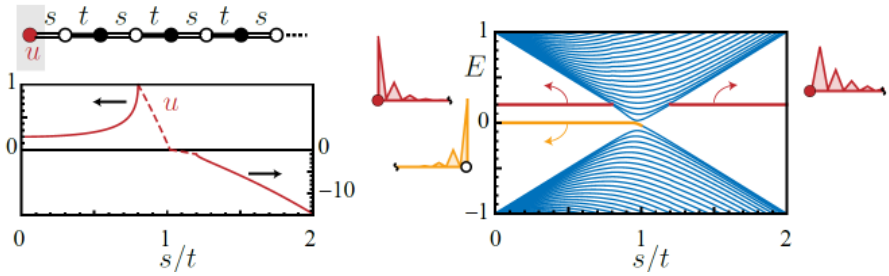

Fig. 1 Design and implementation of a symmetry-breaking edge state in a Su-Schrieffer-Heeger (SSH) chain, illustrated here for target energy E=0.2. This is achieved by using a symmetry-breaking edge potential u, which can be determined analytically (left panel). Implemented in a finite chain (right panel), the desired edge state (red) appears whenever its energy is inside the gap, possibly coexisting with a conventional edge state at the other edge (yellow).

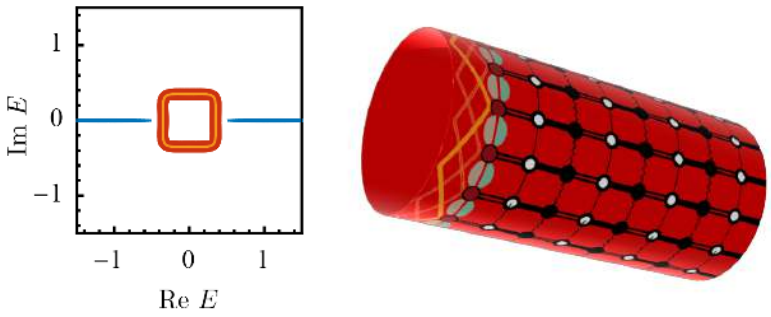

Fig. 2 Design and implementation of a dispersion relation approximating a square in the complex energy plane. The target dispersion is shown in yellow, the actually obtained dispersion is shown in red (with additional extended bulk states shown in blue). The sketch on the right illustrates the implementation of the system on a cylinder. The edge is configured with couplings that follow from a simple condition. The bulk consists of ladders made out of SSH chains.

Abstract: Topological zero-modes are known to be localized at the interface between two structures with different topology. Here using the degree of non-Hermiticity and using non-unitary and yet similarity transformation we lift this property and design zero-modes that are not necessarily localized. Our proposed approach paves the way for designing topologically protected states that potentially could be used for far field imaging and sensing.

The study of the topological system is by now well-established and both Hermitian and non-Hermitian systems are addressed fairly in the literature [1]. The major concept in topological lattices is the existence of a so-called zero-mode that its eigenenergy is robust against disorder and its corresponding field distribution is mainly localized at the interface of the lattice. Specifically, in 1D localization occurs at the edge and in 2D while along the interface of the edge of the structure, the topological mode can provide transport, perpendicular to the edge the topological state is localized. This localization creates a barrier for practical applications of topological modes as in many systems the mode requires to be extended. An example of such an application is far-field sensing and imaging.

Thus, it is essential to find a universal approach that allows for engineering the shape of topologically protected zero-modes. Here we will show that using a similarity transformation we can engineer a non-Hermitian structure and obtain a topologically protected zero-mode with any desired field distribution. It is important to notice that the actual lattice with an engineered topological state might not have any obvious symmetry that allows describing the topological properties of the system. Furthermore, although the engineered structure is non-Hermitian, its spectrum remains real as its corresponding Hamiltonian is obtained from acting a similarity transformation on the Hamiltonian of a Hermitian topological system. Despite the existence of the real spectrum, the non-Hermiticity of the engineered Hamiltonian can lead to the skin effect in the engineered structure such that all the bulk eigenmodes become exponentially localized on one side of the structure.

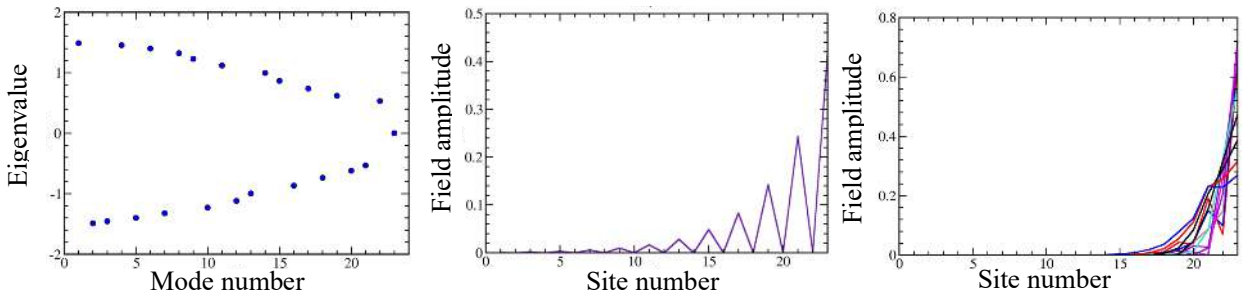

Figure 1. (a) Spectrum of the engineered lattice, (b) Flipped zero mode, (c) Skin states.

An example of engineered zero-mode is given in Fig. (1b) in which a flipped edge state is depicted. The engineered lattice with N number of sites has a non-Hermitian Hamiltonian that is given by non-unitary and yet

similarity transformation $H = AH_{SSH}A^{-1}$ in which H_{SSH} is a $N \times N$ matrix associated with the Hamiltonian of a system that is given by the well celebrated Su-Schrieffer-Heeger (SSH) Hamiltonian and is expected to have an edge state localized at the left side of the lattice. Furthermore, A is a $N \times N$ diagonal matrix. The diagonal element a_{nn} $(n = 1, \ldots, N)$ of A is given by the $a_{nn} = f_n$ with $f_n = f_{n-1} + f_{n-2}$, $f_1 = 1$ and $f_2 = 2$. We note that, a_{nn} is generated by the Fibonacci sequence. The similarity transformation that we used here makes sure that the two Hamiltonian H_{SSH} and H have the same spectrum even H is a non-Hermitian Hamiltonian. The spectrum of H is shown in Fig.(1a). As expected, we observe that both Hamiltonians have a zero-mode. However, the mode profile associated with the zero-mode of the Hamiltonian H_{SSH} is localized at the left side as we mentioned before while H has a zero-mode profile that is localized at the right side of the engineered lattice. We further, observe that the spectrum of the non-Hermitian Hamiltonian H depicts the so-called skin effect in which all the extended states are localized at one side of the lattice. This is shown in Fig.(1c).

By choosing a different function rather than the one we used in the previous example we can obtain other desired zero-modes not only in 1D but even in 2D. Figures (2a,b) are examples of such engineered zero-mode profiles. Specifically, in Fig. (2a) we have a zero-mode that is extended [2] all over the lattice while Fig.(2b) shows a zero-mode localized in the center of a 2D lattice.

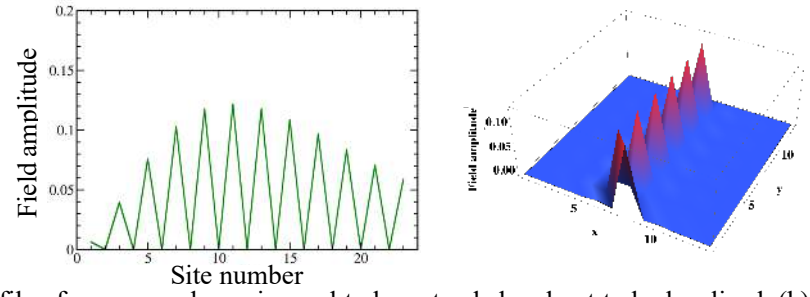

Figure 2. (a) Field profile of a zero-mode engineered to be extended and not to be localized. (b) Mode profile of a zero-mode associated with a 2D engineered structure that is localized at the center of the lattice and not at the edge.

Conclusion: We have shown that using a similarity transformation we can tune the shape of a zero-mode such that is no longer necessarily localized at one edge. This idea is not limited to 1D and can be extended to 2D as well. Our results can pave the way for designing topological devices that are working based on specific mode profiles, this includes far-field imaging, switches, gates, etc.

Abstract: We extend the standard coupled waveguide system with balanced gain and loss for PT-symmetry, in order to exploit and tailor the exceptional points. First, we place an electric dipole source between the waveguides, to create a contrast between wave propagation on both sides of the dipole by controlling its polarization. Secondly, we study the influence of chirality on the guided modes, by inserting a chiral material in the waveguide gap. We observe a strong chiral impact at degeneracies, and interesting avoided crossings at exceptional points arise.

Parity-time (PT) symmetry is the focus of various research projects due to its unique properties. [1] A standard photonic structure for PT-symmetry concerns coupled waveguides, one made of a gain material and the other with an equal amount of loss. The imaginary part of the refractive index in the waveguides defines the gain/loss parameter γ, that determines the operating regime: PT-symmetric when the two modes propagate without gain or loss, and PT-broken when one mode is amplified and the other decays. The transition between these two regimes occurs at the exceptional point (EP). On the one hand, we tailor an electric dipole source to the features of PT guided modes to create a contrast between wave propagation on both sides of the dipole. [2] On the other hand, we study the influence of chirality on these modes by inserting a chiral material in the gap between the waveguides.

Coupling a circularly or elliptically polarized electric dipole to a single waveguide can lead to directional excitation of waveguide modes. [3] This directionality is lost if the dipole is at the center of coupled waveguides but can be restored by taking advantage of the unique characteristics of PT modes. We place an electric dipole in the center of the air layer separating two PT-symmetric slab waveguides (fig. 1(a)). This setup is numerically simulated using an eigenmode expansion Maxwell equations' solver (CAMFR).

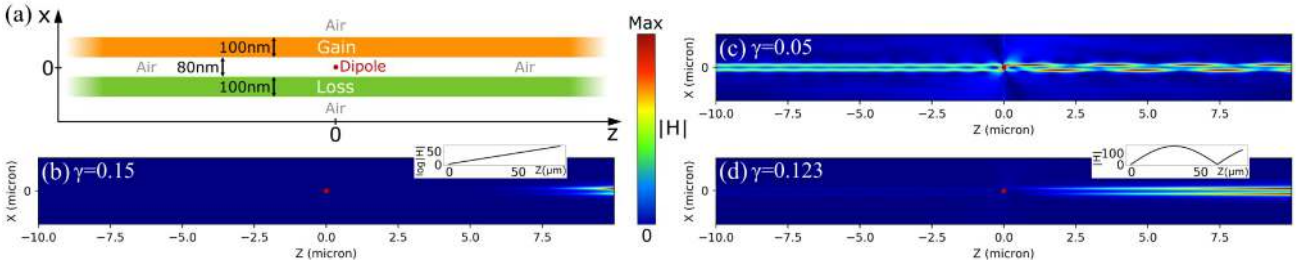

Figure 1 - (a) PT-symmetric coupled waveguides, infinite in the z direction. The dipole is at the red dot. (b-d) Magnetic field absolute value in the structure for various γ. The insets show the value at x=0. The value of the gain/loss parameter at the EP for our structure is γ_{EP} = 0.123.

For each γ, we search for the electric dipole that excites only one mode on one of the sides of the dipole. In the PT-broken regime ($\gamma > \gamma_{EP}$=0.1231 – fig. 1(b)), we choose to cancel the gain mode on the left, making the field considerably smaller than on the right side, as the gain mode on the right increases the field

exponentially. In the PT-symmetric regime ($\gamma \leq 0.1231$ – fig. 1(c,d)), one of the two propagating supermodes of the structure is removed on the left which produces a uniform field profile, while exciting both modes on the right causes a beating (fig. 1(c)). As γ increases, the beating pattern on the right side elongates until γ reaches the EP, where it is infinitely long (fig. 1(d) shows a close situation). Moreover, each of these contrasts can be switched between left and right by adapting the dipole polarization, which can be useful in integrated photonics applications.

Instead of a dipole, we then introduce a chiral material in the gap between PT-symmetric rectangular waveguides (fig. 2(a)). We simulate this setup with the finite element method using the SimPhotonics software, a Matlab Toolbox developed at the Laboratoire Charles Fabry. The gain/loss parameter is varied to explore the different regimes. The width of the gap is tuned to obtain desired features in the mode dispersion. We observe that chirality has the most effect on the modes when their dispersions cross, i.e., when they are degenerate. When the gap is narrow and achiral, the fundamental modes cross: a quasi-TM mode and the quasi-TE symmetric mode. An anticrossing appears between these modes when chirality is introduced in the gap (fig. 2(b)). An intermediate situation can be obtained for medium gaps: the TM-mode crosses the EP for an achiral gap, so chirality prompts a trimodal interaction that generates a complex, hybrid dispersion (fig.2(c)). For a larger gap, the quasi-TM mode crosses the antisymmetric TE-mode of a PT fork, leading to a `symmetry recovery' zone (an `inverted' EP, fig.2(d)).

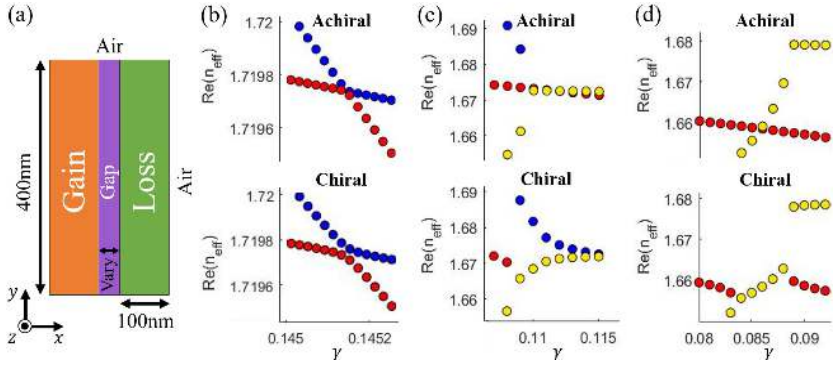

Figure 2 - (a) PT-symmetric rectangular waveguides and chiral gap, infinite along *z*. (b-d) Dispersion with an achiral (top) or chiral (bottom) gap, with width (b) 12nm, (c) 32nm, or (d) 44nm.

In the end, by using an adequate dipole coupled to PT-waveguides, a contrast in the mode excitation can be obtained between both sides, which can be exploited in integrated photonic structures. Furthermore, introducing a chiral material in the gap results in noticeable and rich avoided crossing patterns, which could be exploited in integrated chiral sensing applications.

Abstract: When a non-Hermitian system is tuned around a loop in Hamiltonian parameter space, its complex eigenvalues trace out a braid that depends only on how the loop encloses the space of exceptional points (EPs). While in principle adiabatic loops could be used to execute braid operations, long-time dynamics is dominated by gain-loss imbalance and adiabatic evolution breaks down. We discuss experimental progress speeding up adiabatic operations encircling EPs by optomechanically tuning two nearly-degenerate vibrational modes of a SiN membrane.

Abstract: In the context of non-Hermitian photonics we present recent results regarding structured wavefronts that are maximally transmitted through a complex medium. We investigate dissipative optical lattices with gain and non-Hermitian multimode optical fibers. In both cases we present a unified framework of description that reveals the common features of these optimal states. Connection to Anderson localization, scattering eigenchannels, phase conjugation and imaging will be also discussed.

Dissipation due to the inherent material losses has been always considered as an obstacle. However, based on the notion of parity-time (PT)-symmetry, that was recently introduced in the context of optical physics [1], such synthetic structures can utilize loss as an advantage in many applications [2,3]. Here in the context of non-Hermitian optics, we introduce the concept of non-Hermitian power eigenchannels [4] based on singular value decomposition of the associated propagator [5,6].

The first part of the talk is devoted to dissipative waveguide arrays with sparse gain with symmetric or not coupling coefficients. The effect of uncorrelated disorder and noise, is systematically investigated. In this case, despite the Anderson localization of all eigenstates, the system exhibits counter-intuitive propagation by quantized jumps between states located around distant sites [7, 8]. Such a novel effect was recent experimentally demonstrated in optical fiber loop networks. The relevance of this type of transport to the corresponding power eigenchannels will be discussed.

In the second part of the talk, we will present recent results regarding maximally transmitted states in non-Hermitian multimode fibers. Connections to phase conjugation and imaging applications will also be presented.

Our methodology can be applied to any non-Hermitian system that contains complex elements with loss-gain, or exhibits an asymmetry induced non-Hermiticity and thus exploits the meaning of wave transport in complex open systems.

Switching between topological edge states in nanophotonic structures using phase-change materials

G. Veronis[1], Y. Huang[2], and Y. Shen[3]

[1]Lousiana State University, USA
[2]Central South University, China
[2]Sun Yat-Sen University, China

Abstract: We introduce non-Hermitian plasmonic waveguide-cavity structures based on the Aubry-Andre-Harper model to realize switching between right and left topological edge states using the phase-change material $Ge_2Sb_2Te_5$ (GST).

We introduce non-Hermitian plasmonic waveguide-cavity structures based on the Aubry-Andre-Harper model to realize switching between right and left topological edge states using the phase-change material $Ge_2Sb_2Te_5$ (GST). We show that switching between the crystalline and amorphous phases of GST leads to a shift of the dispersion relation of the optimized structure so that a right topological edge state for the crystalline phase, and a left topological edge state for the amorphous phase occur at the same frequency. Thus, we realize switching between right and left topological edge states at that frequency by switching between the crystalline and amorphous phases of GST. We also find that the right and left topological edge states in the optimized structure are robust in the presence of disorder. Topological edge states in one-dimensional photonic systems are important for applications in sensing, nonlinear optics, and optical diodes. Our results could lead to the development of compact reconfigurable photonic devices based on such topological edge states.

Exceptional-point sensing with a quantum interferometer

Abstract

We demonstrate the existence of exceptional points (EPs) in dual-beam SU(1,1) interferometers and show EPs are linked to both high signal and low noise. For a multistage variant, EPs of the overall input-output matrix form multiple bands of high signal-to-noise ratio (SNR) which separate into two phases by EPs of the transfer matrix of a repeating unit. Our investigations demonstrate the possibility of EP sensing in lossless nonlinear quantum systems and the significance of EPs in quantum interferometers.

1. Introduction

Recently, non-Hermitian systems and EPs have attracted many attention for their implementation in the quantum realm. For instance, chiral quantum state conversions have been experimentally observed in a cold atom system [1]. Regarding the regime of quantum EP sensing, the way to setup a quantum EP sensor is still unclear. Nevertheless, it has been suggested to use lossless (Hermitian) systems with nonlinear interactions (e.g. a parametric amplifier), instead of material gain and loss, to construct non-Hermitian dynamics so that the quantum noise can be much smaller to tackle current problem of noise in EP sensors. Meanwhile, nonlinear interactions in parametric amplifiers are already useful in constructing quantum interferometers which raises the question of whether these lossless interferometers can also capture a quantum EP.

2. EP in quantum interferometers

An example SU(1,1) dual-beam interferometer is shown in fig. 1(a) where parametric amplifiers (PAs) are used to replace the beam splitters in the classical Mach–Zehnder interferometer. The observables quadrature amplitudes before and after this interferometer are therefore related by [2]:

$$\begin{pmatrix} \hat{X}_2^+(\theta_{\text{out}}) \\ \hat{Y}_2^+(\theta_{\text{out}}) \end{pmatrix} = S(\phi) \begin{pmatrix} \hat{X}_0^+(\theta_{\text{in}}) \\ \hat{Y}_0^+(\theta_{\text{in}}) \end{pmatrix}, \qquad (1)$$

where $\hat{X}_n^+(\theta) = \frac{1}{\sqrt{2}}(\hat{a}_n^\dagger + \hat{b}_n^\dagger)e^{i\theta} + \frac{1}{\sqrt{2}}(\hat{a}_n + \hat{b}_n)e^{-i\theta}$ and $\hat{Y}_n^+(\theta) = \hat{X}_n^+(\theta + \pi/2)$. By tuning the parameters within the interferometer $S(\phi)$ can exhibit EP. Furthermore, if we choose $\theta_{in} + \theta_{out} = \pi/2$, this matrix $S(\phi)$ has an analogy to scattering matrices in PT-symmetric systems, for instance, EP occurs as zero at an off-diagonal element of $S(\phi)$, reminiscent of unidirectional zero reflection. To quantify the sensing performance of this EP sensor we evaluate the noise and signal-to-noise ratio in Fig. 1 (b) and (c), with respectively. Here the noise is given by the quantum fluctuations $\Delta^2\hat{Y}_2^+ = \langle \hat{Y}_2^{+2} \rangle - \langle \hat{Y}_2^+ \rangle^2$ and the signal is given by

$$\text{SNR} = \frac{\left(\frac{d}{d\phi}\langle \hat{Y}_2^+ \rangle\right)^2}{\Delta^2\hat{Y}_2^+}.$$

We found that the noise is preserved as the white dashed line (indicating EP condition) and the solid black line (indicating noise preserving condition) completely overlaps with each other. For SNR in Fig. 1(c), we observe the SNR is generally higher in the low noise region near EP lines. Compared to the original sensing scheme for the interferometer [3], our EP scheme has an SNR ratio of approximately 90% of the highest theoretically possible value.

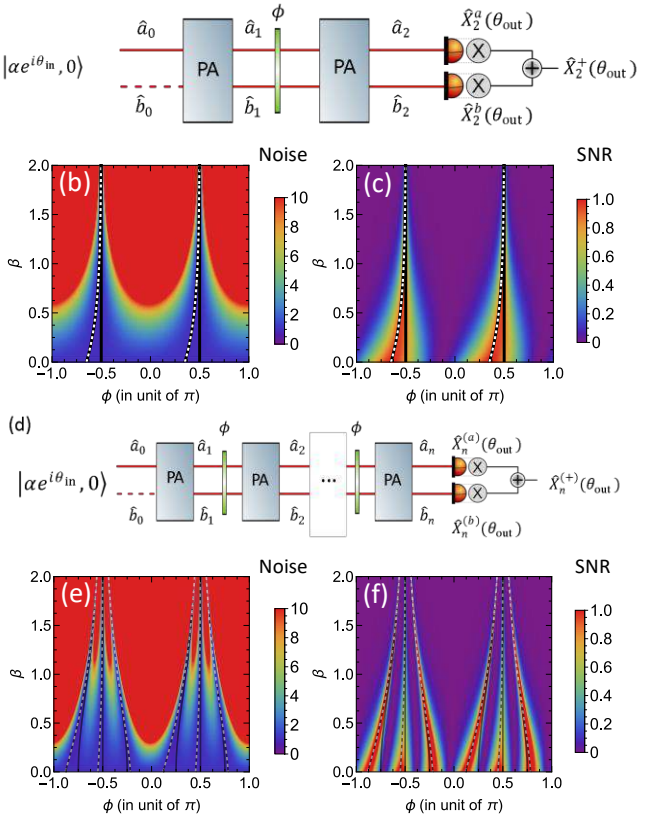

Figure 1. (a) Schematic of a dual-beam SU(1,1) interferometer. (b) noise and (c) SNR of this interferometer when measuring $\hat{Y}_2^+(\theta_{out})$ with an input coherent state $|\alpha e^{i\theta_{\text{in}}}, 0\rangle$. Here $\theta_{out} = 0.425\pi$ and $\theta_{in} = \pi/2 - \theta_{out}$. Black curves denote the noise is being preserved in the interferometer, i.e. $\Delta^2\hat{Y}_2^+ = \Delta^2\hat{Y}_0^+ = 1$. White dashed curve represents the EP. SNR are normalized by

$2|\alpha|^2 e^{4\beta}$ (d) Schematics of a multistage dual-beam SU(1,1) interferometer. (b,c) same as (a) with 4-stages i.e., totally 4 PAs. SNR are renormalized by $|\alpha|^2 n^2 e^{4\beta}$ for n stages interferometer

A variant of multistage dual-beam SU(1,1) interferometer is shown in fig. 1 (d) with increased numbers of PAs. We also found that the noise is preserved here and SNR is generally higher near EP lines indicate our EP sensing scheme extends to the multistage setting. Fig. 2(a) shows the eigenvalues of the transfer matrix U_{unit} of a single repeating unit consisting of one phase object and one PA as

$$U_{unit} = \begin{pmatrix} G & g \\ g & G \end{pmatrix} \begin{pmatrix} \exp(i\phi) & 0 \\ 0 & \exp(-i\phi) \end{pmatrix}.$$

where $G = \cosh\beta$ and $g = \sinh\beta$ with β controlling the gain of PAs, ϕ is the phase objected to be sense. this matrix indeed undergoes a phase transition at EP and two phases directly affect the SNR in Fig. 2(b) which shows the SNR for n-stage interferometers. Here SNR forms two phases separated by the EPs of U_{unit}. One phase has highly oscillating behaviour in SNR when U_{unit} is in the PT-symmetric phase ($\lambda_1 = \lambda_2^*$). While SNR has no such oscillations when U_{unit} is in the PT-broken phase ($\lambda_1 = 1/\lambda_2$).

3. Conclusion

We presented a dual-beam SU(1,1) interferometer as a platform for obtaining a quantum exceptional point (EP) We found out the signal is amplified while the quantum fluctuation noise is preserved at this EP. Numerical results showed that the sensitivity in terms of signal-to-noise ratio (SNR) will attain its maximum around the quantum EP of the overall input-output relation matrix. Additionally, our investigation of a multistage variant of the SU(1,1) interferometer indicate that the EP sensing scheme extends to this setting since the preserving property is universal across the number of stages. Finally, we have found that the EP of the overall input-output relation matrix for an increasing number of stages separate into two phases, which are identified by the EPs of the transfer matrix of a single stage.

Landau-Zener transitions through a pair of higher order exceptional points

E. M. Graefe[1*], S. Malzard[1,2], and R. Melanathuru[1]

[1]Department of Mathematics, Imperial College London, United Kingdom

Abstract: We study the Landau-Zener type transition probabilities between the asymptotic states of a PT-symmetric non-Hermitian N-level Landau-Zener with two exceptional points of order N. The system is Hermitian for asymptotically large times, and has purely imaginary eigenvalues between the exceptional points. The transition probabilities show a characteristic binomial behaviour, which, in the adiabatic limit, are given by the ratios of binomial coefficients. This behaviour can be understood via the eigenvector structure, despite the breakdown of adiabaticity typical for non-Hermitian systems.

We consider a non-Hermitian N-level generalisation of the Landau-Zener scenario, described by a time-dependent Hamiltonian of the form

$$\hat{H} = -2\alpha t \hat{J}_z + 2\mathrm{i}\gamma \hat{J}_x \ ,$$

Where $\alpha, \gamma \in \mathbb{R}$ and $\hat{J}_j$ denote angular momentum operators. In an N-dimensional representation, this system has N-th order exceptional points at $|\alpha t| = |\gamma|$. At large positive and negative times the eigenvectors are the standard angular momentum basis. We consider the asymptotic relative (re-normalised) populations of the eigenstates at $t \to +\infty$ assuming the system was in an eigenstate at $t \to -\infty$. Using the SU(2) structure of the system we derive an analytic expression for these populations, and show that in the adiabatic limit $\alpha \to 0$ they are given by

$$P_{jk} \to \frac{1}{2^n} \binom{n}{k} \ .$$

We show how this can be understood from the overlaps of the adiabatic eigenvectors close to the exceptional point.

Abstract: In this paper, we analyze dispersion curves of guided modes in a two-layer $\mathcal{PT}$ symmetric slab waveguide. It is shown that the total number of cutoff points and dispersion curves is always finite. As the imaginary part of the dielectric constant is increased, the lowest dispersion curve always exists but other dispersion curves degenerate into points on the light line and then disappear. Interestingly, the dispersive curves are not always tangential to the light line.

We consider a two-layer $\mathcal{PT}$ symmetric slab waveguide surrounded by air as shown in Fig. 1 [1]. The structure is perpendicular to the z axis, the relative dielectric function ε has a nonzero imaginary part and satisfies $\varepsilon(z) = \overline{\varepsilon}(-z)$. The transverse electric (TE) guided mode has an electric field component $E_x = \mathrm{Re}[u(z)\exp(i\beta y - \omega t)]$, where β is the propagation constant, $\omega = k_0 c$ is the angular frequency, and k_0 is the free space wavenumber [2]. We consider real β, k_0 and $|\beta| > k_0$. The dispersion curves are connected with the light line at the cutoff points [3, 4].

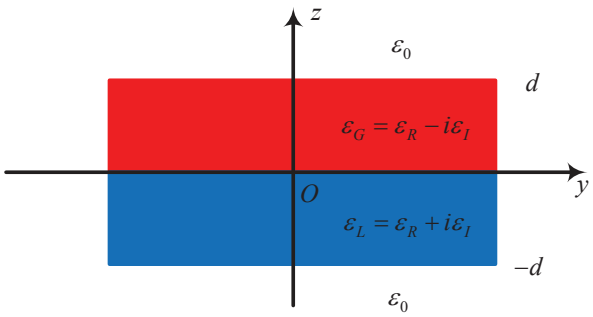

Figure 1: A two-layer $\mathcal{PT}$ symmetric slab waveguide with thickness $h = 2d$ surrounded by air. ε is the relative dielectric constant and $\varepsilon_0 = 1$. ε_R and ε_I are constants.

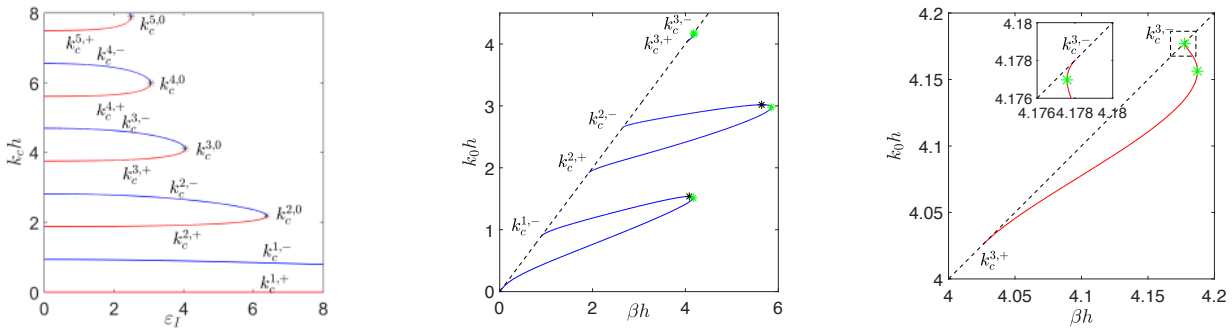

Figure 2: Left: The cutoff wavenumbers for different ε_I. Middle: The dispersion curves for $\varepsilon_I = 4$. Right. Two second order EPs $dk_0/d\beta = \infty$ exist in the 3rd dispersion curve for $\varepsilon_I = 4$. Green * represent EPs.

As shown in Fig. 2 for $\varepsilon_R = 12.25$, each dispersion curve originates from two dispersion curves of the slab waveguide with $\varepsilon_I = 0$. The total number of cutoff points is finite for $\varepsilon_I > 0$. This implies that the number of dispersion curves is also finite as shown in the middle panel of Fig. 2. On the 3rd dispersion curve, there exist 2 exceptional points (EPs) satisfying $dk_0/d\beta = \infty$ as shown in the right panel of Fig. 2.

From Fig. 3, we can see that the lowest dispersion curve exists for any ε_I. As ε_I is increased, all other dispersion curves will degenerate into points and then disappear. At a special value of ε_I, the dispersion curve is not tangential to the light line. This is a distinguished feature of the $\mathcal{PT}$ symmetric waveguide.

On each dispersion curve, there could exist 2 exceptional points (EPs) satisfying $dk_0/d\beta = \infty$ as shown in the panel (b) of Fig. 3. But as ε_I is increased, they merge into a third order EP and then disappear as shown in panels (b) and (d) of Fig. 3.

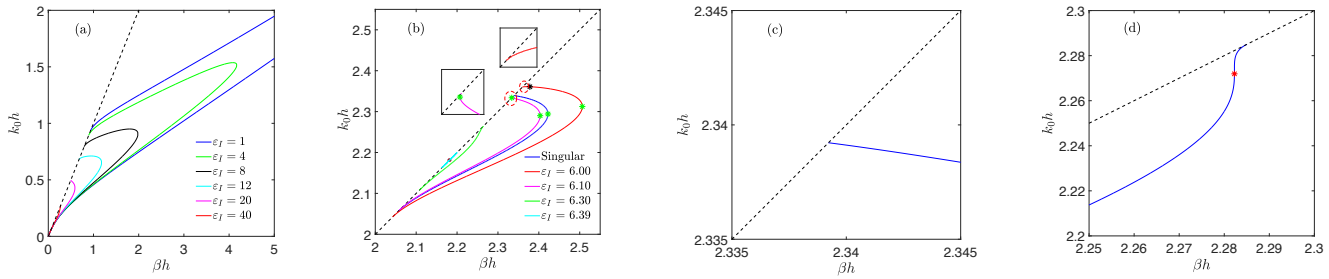

Figure 3: (a). The lowest dispersion curve for different ε_I. (b). The 2nd dispersion curve for different ε_I. (c). The local behavior of the 2nd dispersion curve when the dispersion curve is not tangential to the light line. (d). The 2nd dispersion curve when a third order EP appear. The third order EP is denoted by red *.

Abstract: In PT-symmetric systems, losses dramatically alter the quantum correlations of interfering photons. We study lossy directional couplers with increasing loss values beyond the PT-symmetry breaking point and observe the impact of this transition on the two-photon dynamics. Upon entering the PT-broken phase, the visibility of the Hong-Ou-Mandel interference decreases.

With their conceptual description of Parity-Time (PT) symmetry [1] , Bender and Boettcher inaugurated a new field of studies with fascinating implications on topology [2] and exceptional point dynamics [3], to name a few. Typically, PT-symmetric Hamiltonians exhibit real eigenvalues below a certain threshold, whereas above, the PT-symmetry is spontaneously broken as the eigenvalue spectrum becomes complex. Entirely passive configurations based solely on differential losses [4] allow the physics of PT symmetry to be faithfully carried over to a quantum-optical context [5] and explored therein [6]. Here we study the ways in which the relative proportion of losses systematically impacts the characteristics of quantum correlations between interfering photons by analyzing the two-photon correlations in PT-symmetric directional couplers.

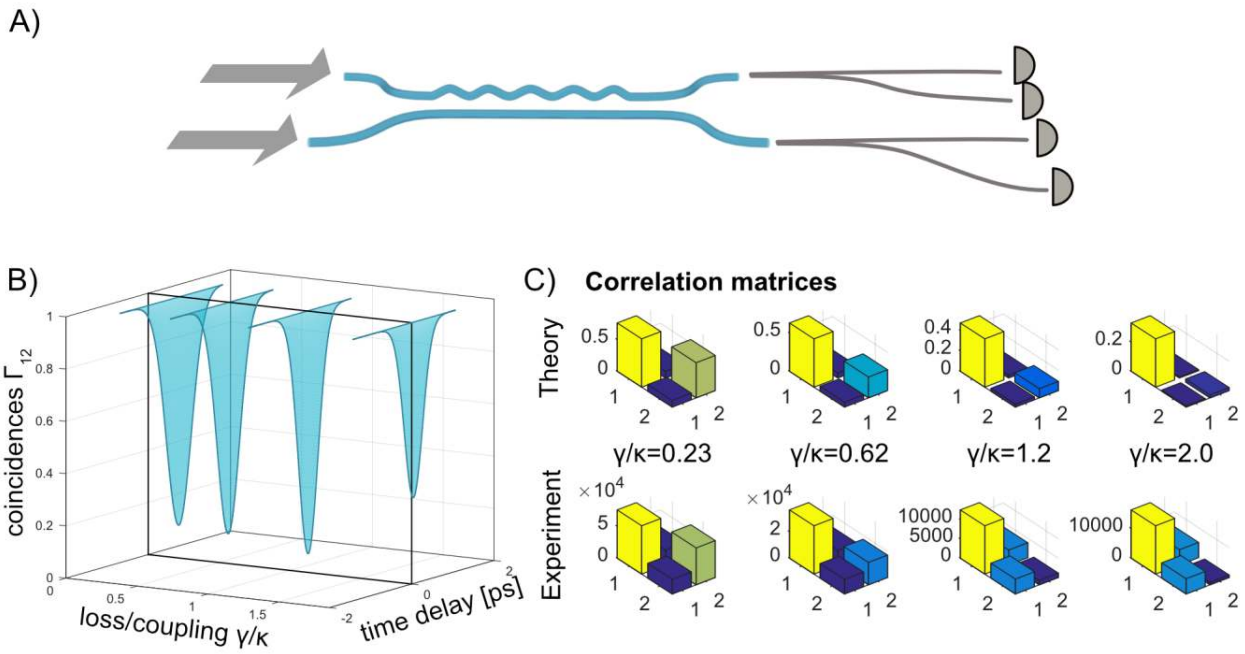

Figure 1. A) Indistinguishable photon pairs are launched into the waveguide structure of the PT-symmetric coupler, the output is routed through 50/50 fiber beam splitters and detected using avalanche photo diodes. B) Hong-Ou-Mandel dips measured in PT-symmetric couplers for increasing loss, up to PT-symmetry breaking. C) Measurement of the full correlation matrix for the PT-symmetric couplers and corresponding analytical solution of the two-photon correlation.

Our system (Fig.1 A)) consists of two waveguides whose interaction is described by a coupling coefficient κ. As one of the waveguides exhibits a loss γ, the PT symmetry breaking threshold is found at $\gamma = 2\ \kappa$. For our studies, we implemented a set of such lossy couplers with fixed coupling coefficient and identical interaction lengths for different loss values, ranging from the conventional Hermitian case ($\gamma = 0$) up to and above the PT-symmetry breaking point at $\gamma/\kappa = 2.0$. We probed these systems by injecting pairs of indistinguishable photons, followed by coincidence measurements with click detectors to record the two-photon correlation matrices at the output, as shown in the lower row of Fig. 1 C). Based on our experimental parameters and the analytical solution of the full correlation matrix [6], the theoretical curves depicted above are retrieved. Subsequently, we tuned the time delay between the incident photons to record the corresponding Hong-Ou-Mandel interference curves in Fig. 1B).

Our studies show that increasing losses in the PT-symmetric coupler gradually decrease the visibility of the quantum interference in a Hong-Ou Mandel experiment, potentially below the value of 50%, without actually impacting the quantum nature of the system. This also manifests itself in a systematic reshaping of the correlation matrix (Fig. 1C)).

Abstract: We studied the exceptional chains (ECs) in non-Hermitian systems and the symmetries that secure their stability. By assigning orientations to exceptional lines (ELs), we analyzed the robustness of ECs via establishing a source-free principle for ELs. The principle leads to the discovery of three mechanisms for stabilizing the junction of ELs. The observation of these exotic ECs is demonstrated through numerical simulations in photonic crystals and experimental observations in coupled active oscillators.

In 3D non-Hermitian systems, the EPs can form stable exceptional lines (ELs) or more striking geometric features such as knots and links in the momentum space without any symmetry. However, as another typical EL configuration, the exceptional chains (ECs), formed by several connected ELs, have a fundamental difference from other EL morphologies, i.e., the existence and stability of ECs demand symmetry protection. We revealed that the complex eigenenergy braiding around an EL can assign a positive orientation to the EL. Via generalizing the Fermion doubling theorem of EPs to arbitrarily oriented and closed surfaces, we establish the source-free principle of the directed ELs, implying that if several ELs flow into a junction, the same number of ELs must outflow from the junction. As an immediate application, this principle, when combined with certain non-Hermitian spatiotemporal symmetries, can ensure the robust formation of ECs from several directed ELs.

We also uncover that by incorporating the Hermitian-adjoint into account as a new dimension, the non-Hermitian crystalline systems are generalized, and we propose three symmetry-based mechanisms that can stabilize different types of ECs with distinct local morphologies and topological features. In addition, we designed non-Hermitian photonic crystals (PCs) to illustrate our ideas of symmetry-protected ECs. Through numerical simulations, three typical ECs are observed in the PCs, hence confirming the applicability of our theory for general full-wave systems.

Our theory also applies to other systems such as mechanical oscillators. We designed and implemented a non-Hermitian mechanical model to exhibit ECs in a three-dimensional synthetic parameter space while being protected by symmetries.

In short, we established the source-free principle of directed ELs and showed that the source-free principle together with symmetry constraints are two crucial conditions for the formation of ECs. Based on this idea, a comprehensive theory has been developed to construct ECs of diverse local morphologies. Furthermore, we experimentally observed the symmetry-protected EC in crafted nonreciprocally coupled mechanical oscillators.

Abstract

We develop an approach to map the quantum optical scattering of linear dissipative metasurfaces to Liouvillian dynamics, based on the effective Hamiltonian of the metasurfaces in a fictitious time. Our approach enables us to specify the generalized eigenspace of the Liouvillian superoperator, allowing us to analytically obtain the input-output relationship of the density matrix and the photon transition probabilities. This work facilitates the straightforward modeling of non-Hermitian metasurfaces in the quantum regime, directly from the specification of classical scattering matrix.

1. Introduction

The capability of manipulating scattering from metasurfaces enables many applications including quantum tomography, and entangled state preparation [1, 2]. Classically, non-Hermitian and topological systems are already under active research using metamaterial structures as building blocks [3] making non-Hermitian or lossy metasurfaces a possible candidate as a versatile platform in quantum optics.

2. Scattering at EP by Lindblad moment equation

Starting from a classical scattering of a linear dissipative metasurface given by scatting matrix S, one can describe the input-output relationship of density matrices by adding loss channels to the system as in the left route in Fig. 1. We find another equivalent method as shown in the right route in fig. 1 by mapping the input-output relationship to an equivalent Liouvillian dynamics evolve in fictitious time τ given by

$$\frac{d\hat{M}(\tau)}{d\tau} = \mathcal{L}'\hat{M}(\tau) = -i\left(\hat{H}_{\text{eff}}\hat{M}(\tau) - \hat{M}(\tau)\hat{H}_{\text{eff}}^{\dagger}\right) \quad (1)$$

with the effective Hamiltonian operator $\hat{H}_{\text{eff}}$ defined as:

$$\hat{H}_{\text{eff}} \triangleq \Sigma_{ij}(i\log(S))_{ij}\hat{a}_i^{\dagger}\hat{a}_j$$

where moment matrix $\hat{M}$ is equivalent to density matrix on another basis [4]. With this equation, we first design a bianisotropic metasurface with two gold bars in a unit cell that can capture a classical EP in Fig. 2 (a). Classical EP happen at $\Delta\gamma = 0$ as shown in Fig. 2 (b-c). The quantum EP of this metasurface is probed using Eq. (1). Using this approach all photon transition probabilities can be obtained analytically in terms of classical scattering matrix elements. For example, the photon transition probabilities at EP ($\Delta\gamma = 0$) for pure state input are summarized in Fig. 2 (d). Figure 3 (a,b) shows the evolution of the eigenvalues of $\mathcal{L}'$ when $\Delta\gamma$ scans across the classical EP at $\Delta\gamma = 0$ and at this moment all eigenvalues of $\mathcal{L}'$ all degenerate indicating that Eq. (1) promotes the classical EP at S to quantum EP in $\mathcal{L}'$.

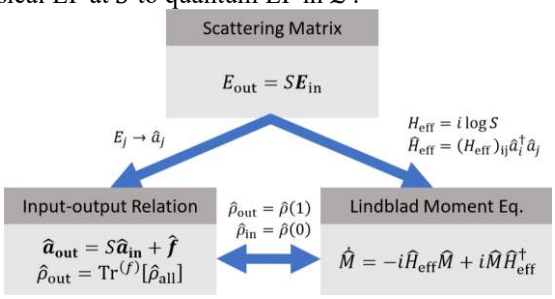

Figure 1. The left route is the standard dilation approach with ancilla modes added to represent absorption channels. The right route is the mapped Lindblad moment equation propagating photon moment matrix from fictitious time $\tau = 0$ to 1.

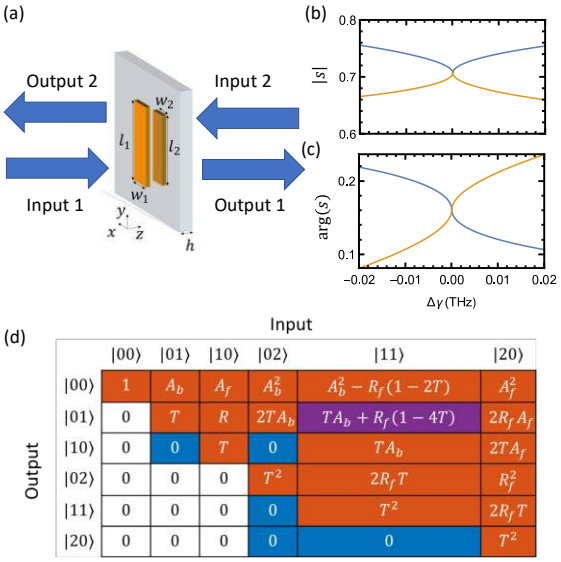

Figure 2. (a) Schematic of a classical EP capturing metasurface. (b,c) Eigenvalues of scattering matrix S of matersurface in (a) when extra material loss $\Delta\gamma$ is added. The two branches are colored as blue and orange. At $\Delta\gamma = 0$ there is an EP where two eigenvalues coalesce. (d) Photon transition probabilities at EP in terms of scattering matrix elements with transmission $T = |t|^2$, forward reflection $R_f = |r_f|^2$, forward absorption $A_f = 1 - T - R_f$ and backward absorption $A_b = 1 - T$ here the metasurface give unidirectional zero reflection $r_b = 0$ at EP.

The generalized eigenspace is summarized in Fig. 3(c), where each block represents a set of general eigenmatrices with the same eigenvalue. The squares represent individual general eigenmatrices, and multiple squares are grouped together to form a row, indicating they belong to the same Jordan chain. The arrows in Fig. 3(c) illustrate the flow of data, such as the density matrix or moment matrix decomposed into the eigenbasis, during propagation at quantum EPs. When the representation is changed from $\hat{\rho}$ to $\widehat{M}$ or vice versa, the data flow is shown by the blue arrows. Propagation of the moment matrix $\widehat{M}$ is governed by the Lindblad moment equation in Eq. (1), and the flow of data is indicated by the blue arrows. An example of propagating the state $\hat{\rho} = \frac{1}{2}(|2,0\rangle + i|1,0\rangle)(\langle 2,0| - i\langle 1,0|)$ is provided in Fig. 3(d), where the color represents the decomposition coefficient in the eigenbasis for the input and output $\hat{\rho}$ and $\widehat{M}$.

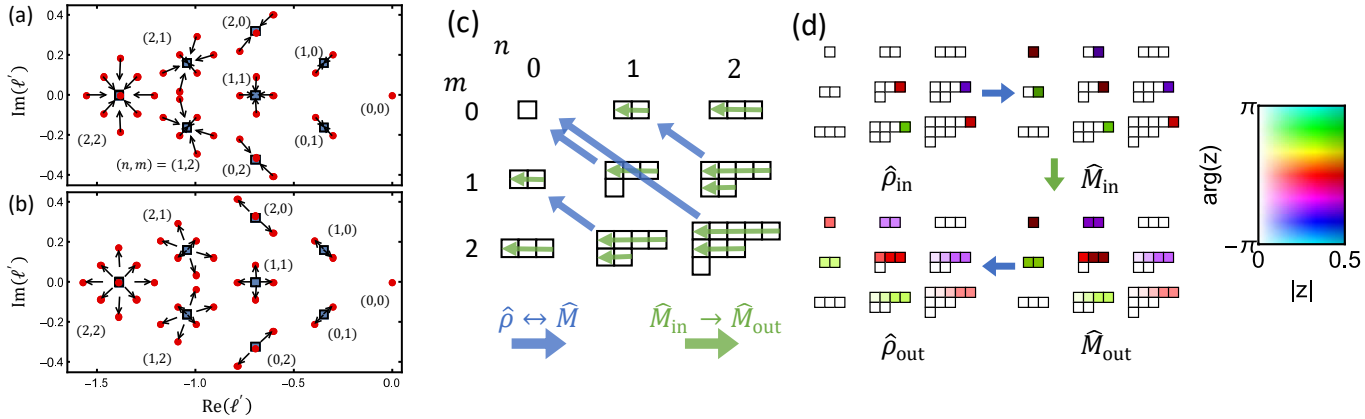

Figure 3. (a,b) The eigenvalues ℓ' of the Liouvillian superoperator $\mathcal{L}'$ as red dots for (a) $\Delta\gamma = -0.009$ THz, (b) $\Delta\gamma = 0.009$ THz, and blue squares for $\Delta\gamma = 0$ in both (a) and (b). Arrows represent the trajectory of the eigenvalues when $\Delta\gamma$ is increasing. (c) The flow of information when states are propagating at EP in the eigen-moment basis. Blue arrows represent the effect of changing representation $\hat{\rho} \leftrightarrow \widehat{M}$. Green arrows represent the effect of propagation $\widehat{M}_{in} \rightarrow \widehat{M}_{out}$. (b) States transformation of input $\hat{\rho} = \frac{1}{2}(|2,0\rangle + i|1,0\rangle)(\langle 2,0| - i\langle 1,0|)$. The colors in each square represent the complex coefficient of the corresponding eigen-moment in decomposing either density matrix $\hat{\rho}$ or moment matrix $\widehat{M}$.

3. Conclusion

In this work, we have established a model for quantum scattering from a lossy metasurface as a Lindblad master equation in a fictitious time. This approach enables us to form a complete eigen-moment basis to describe the propagation of the photon density matrix through a change of representation. The numerical examples presented in this study provide insight into the characterization of quantum scattering from a bianisotropic metasurface for a single polarization. These investigations pave the way for future studies on passive parity-time symmetric metasurfaces in the quantum optical regime.

A Coherent Perfect Absorber for Arbitrary Wavefronts

Y. Slobodkin[2†], G. Weinberg[2†], H. Hörner[1†], K. Pichler[1], S. Rotter[1*] and O. Katz[2*]

[1]Institute for Theoretical Physics, Vienna University of Technology (TU Wien), Austria

[†]These authors contributed equally to this work

Abstract: The concept of a 'coherent perfect absorber' (CPA) as a time-reversed laser is well-known in the domain of non-Hermitian photonics. However, conventional CPAs are usually limited to perfectly absorbing only a single, carefully shaped wavefront (`mode'). Apart from the correctly matched input wavefront, all of the possibly many other modes are only weakly absorbed. We have now overcome this limitation by creating a 'massively degenerate coherent perfect absorber' (MAD-CPA) that can absorb any complex input field with near-perfect efficiency.

It is easy to achieve efficient light absorption with thick materials. But thin materials with a low absorption factor are much less effective at transforming incident radiation into other forms of energy, such as heat. One method of addressing this problem is embedding the weak-absorbing material into a resonant structure. At the 'critical coupling condition', where the coupling strength to the resonator is balanced with the internal dissipation, the incoming field is perfectly absorbed, with no energy reflected back from the resonator. However, there is a severe limitation to this method: the incoming field must have a judiciously shaped wavefront in order to satisfy the critical coupling condition [1, 2]. In other words, only a single incoming wavefront, or spatial mode, can be "coherently perfectly absorbed". Although this allows for interference-based control of the absorption process, other modes are only weakly absorbed due to the different interference patterns they produce.

We can successfully demonstrate both in theory and by experimental implementation how to eliminate this constraint on the number of perfectly absorbed modes in a coherent perfect absorber (CPA) [3]. Our multi-mode CPA for arbitrary wavefronts is based on the notion that "coherent perfect absorption" is equivalent to time-reversing a laser operating at the first lasing threshold. Therefore, to achieve a device that can completely absorb *any* combination of incoming modes through interference, it is necessary to create a time-revered laser that emits *all* of these modes simultaneously. It turns out that such a laser already exists, and is known as a 'degenerate cavity laser'. The degeneracy of modes in such a cavity is based on the special feature that the field on either one of the two outer cavity mirrors is self-imaged onto itself after one cavity round-trip. This achieved by placing two convex lenses inside the cavity, the first lens one focal length after the input coupling mirror, and the second lens three focal lengths after the input coupling mirror. The total length of the cavity is four focal lengths, and it is therefore often referred to as '4f-cavity' (Fig. 1). With this configuration, we can ensure coherent perfect absorption of any combination of modes, regardless of their relative phases (Fig. 2). This robust absorption mechanism promises to be highly advantageous for numerous potential applications.

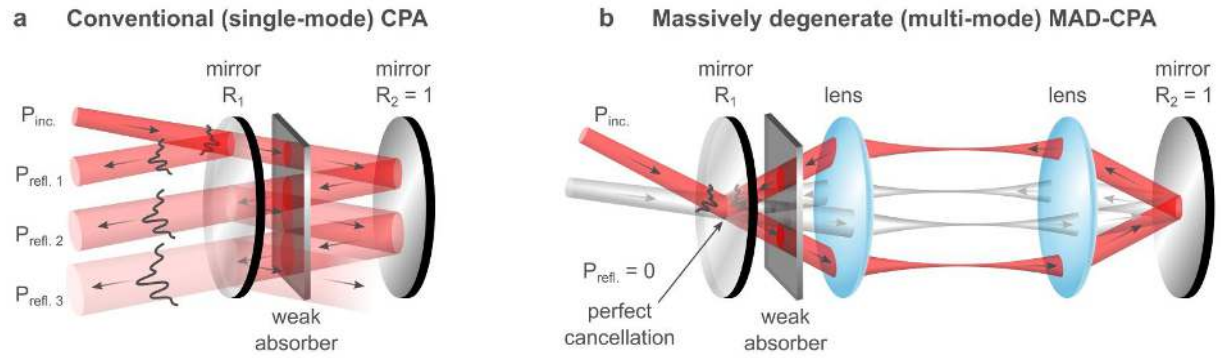

***Figure 1**: **Concept of a massively degenerate coherent perfect absorber (MAD-CPA) capable of absorbing arbitrary wavefronts.** **(a)** In a conventional CPA, a weak absorber is positioned between two flat mirrors. While destructive interference can lead to perfect absorption of a normal-incident plane-wave, any other incoming mode, such as the tilted beam shown, results in multiple reflections that cannot destructively interfere. **(b)** In contrast, the multi-mode MAD-CPA can perfectly absorb any complex incident wavefront. This is accomplished by placing the weak absorber in a degenerate (self-imaging) cavity, which is realized in this case by a conventional cavity with two lenses arranged telescopically. In such a degenerate cavity, any complex input field incident on the front cavity-mirror (R1) is self-imaged onto itself after each cavity round-trip. All reflections from the multiple cavity round-trips show perfect destructive interference with the outer reflection from the front cavity-mirror (as shown for two incoming beams at different angles), leading to perfect absorption of light in the weak absorber.*

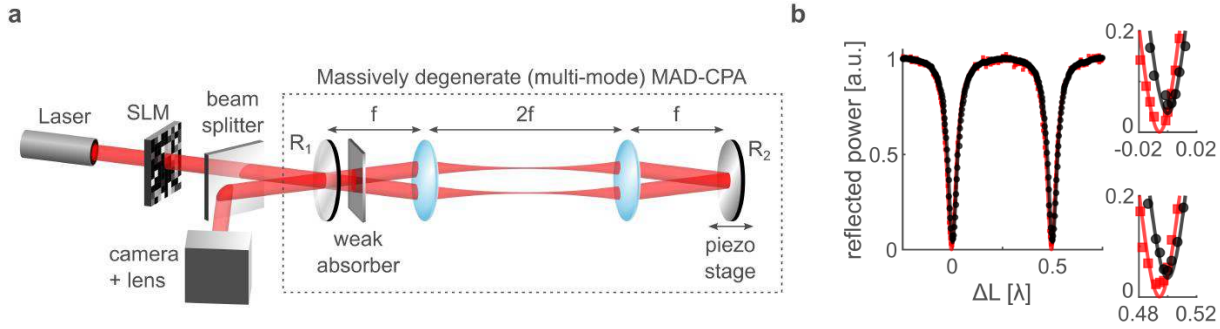

***Figure 2:** **(a)** Setup: Complex input fields are injected into a degenerate cavity that contains a critically-coupled weak absorber, using a computer-controlled SLM, illuminated by a wavelength-stabilized laser. The spatial intensity distribution of the reflected light is measured by a camera. Coherent perfect absorption is achieved by tuning the cavity length to be resonant with the laser wavelength. **(b)** Experimental results for a speckled Yin-Yang symbol with over 1000 modes as the complex input field. The back-reflected power is plotted as a function of cavity length, with black dots indicating the total reflected power and red squares representing the reflected power of one individual mode. The numerical prediction for the total reflected power of a 100-mode input, considering the residual reflection of the lenses, is shown with black and red lines.*

Photon production in cavity: Quasinormal modes as a tool for quantum dynamics

M. Federico[1*] and H. R. Jauslin[1]

[1]Laboratoire Interdisciplinaire Carnot de Bourgogne, CNRS – Université de Bourgogne, UMR 6303, BP 47870, 21078 Dijon, France

[*]corresponding author: maxime.federico@u-bourgogne.fr

Abstract: We discuss the construction of a model using quasinormal modes (QNMs) to describe the production of single-photons inside a leaky cavity. Our approach is based on the fact that photon's dynamics is given by Maxwell's equations. By taking advantage of this property, we construct a hybrid basis made of truncated QNMs inside the cavity and completed with any other basis outside. The completeness allows to write a quantum Hamiltonian interacting with an emitter expressed with creation-annihilation operators directly on QNMs.

Single-photons are of great interest in the race towards quantum technologies since they can be used as qubits. Their production on demand is already well mastered experimentally, for instance through cavity quantum electrodynamics schemes [1]. However, the theoretical models describing such systems are often based either on normal modes or on a continuum of modes [1,2]. These two approaches feature some drawbacks: normal mode models require the addition of phenomenological parameters to let photons escape from the cavity while a continuum of modes prevents to consider only a finite number of modes to describe the interaction with an emitter. We thus want to develop a third option (see Figure 1) using the concept of quasinormal modes (QNMs) [3,4] that are particular solutions of the wave equation with outgoing boundary conditions. They are promising objects since they form a discrete set and already contain the information about the interface of the resonator.

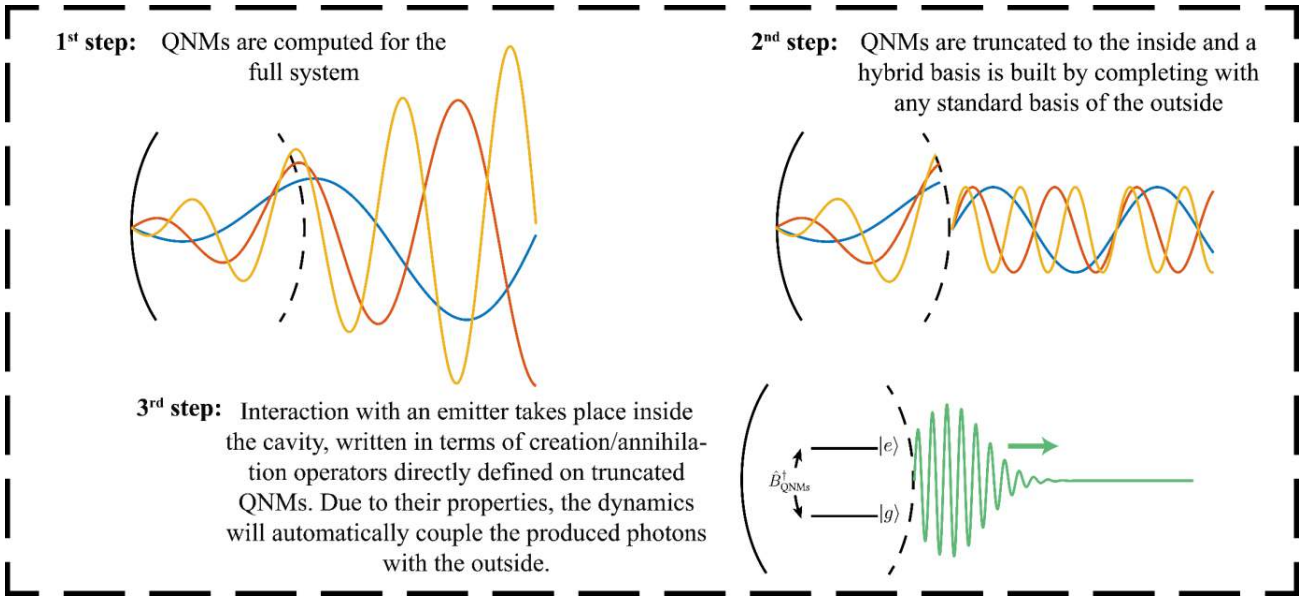

Figure 1: Schematic showing the step-by-step construction of a quantum model using quasinormal modes to describe photon's production in leaky cavity.

To be able to use QNMs (that are classical solutions of the wave equation), to describe photons (that are quantum excitations of the electromagnetic field), we want to take advantage of the particular description of photon's dynamics. Indeed, although they are quantum objects, photons are carried by classical solutions of Maxwell's equation i.e. if one considers a single-photon (described by the action of a bosonic creation operator onto the vacuum state of a Fock space $\mathbb{F}(\mathcal{H})$ as $|1_\psi\rangle = \hat{B}_\psi^\dagger|\emptyset\rangle$, where ψ is any element of the one-quantum subspace $\mathbb{F}_1 = \mathcal{H}$), the time evolution of such state is given by $|1_\psi(t)\rangle = \hat{B}_{\psi(t)}^\dagger|\emptyset\rangle$, where $\psi(t)$ is a solution of the classical Maxwell equations [5]. And since Maxwell's equations can be rewritten in terms of a wave equation, QNMs could in principle be used to describe the dynamics of a single-photon. The only constraint about the classical solution is that it should belong to the one-quantum subspace $\mathbb{F}_1$ i.e. to the Hilbert space of square integrable functions $\mathcal{H}$.

A well-known property of QNMs, which causes some difficulties, is that they diverge for positions far from the cavity [3,4], meaning that they cannot belong to $\mathcal{H}$. However, one can take advantage of the particular setup in which they are used that is, in our case, a cavity embedded either in vacuum or in a passive dielectric medium such as an optical fiber that collects the produced photons. Indeed, for these media, the dynamics given by Maxwell's equations is known and is very simple: a translation outward the cavity at the speed of light in the medium. One therefore only needs to use QNMs inside the cavity at initial time since the dynamics for later time will be directly given by the translation outward the cavity of the QNMs at the interface. Moreover, QNMs are known to form a complete basis inside the cavity [3,4] which allows us to construct a hybrid basis made of QNMs inside and of any other basis of $\mathcal{H}$ outside. Such a basis can then be used in the quantum formalism to have a quantum description using the concept of QNMs but without following the Green function quantization nor defining regularized QNMs outside the cavity [6].

The power of this model lies in the use of truncated QNMs which are thus automatically in $\mathcal{H}$. Then, the interaction with a single emitter can be described as a coupling with QNMs only because everything happens within the cavity. Finally, the dynamics will naturally link the inside with the outside due to the leakage properties of QNMs. Such model drastically reduces the dimensionality of the problem since one can choose only QNMs that are resonant with the single-emitter and for the outside part, the model will create only states that are propagating outward the cavity.

Abstract: I will give an overview over the most important inverse design techniques techniques, will discuss respective drawbacks and advantages, while discussing also potential dangers and risks, that come with data-driven techniques in a general picture. Particular focus will be spent on the neural adjoint method and its variations.

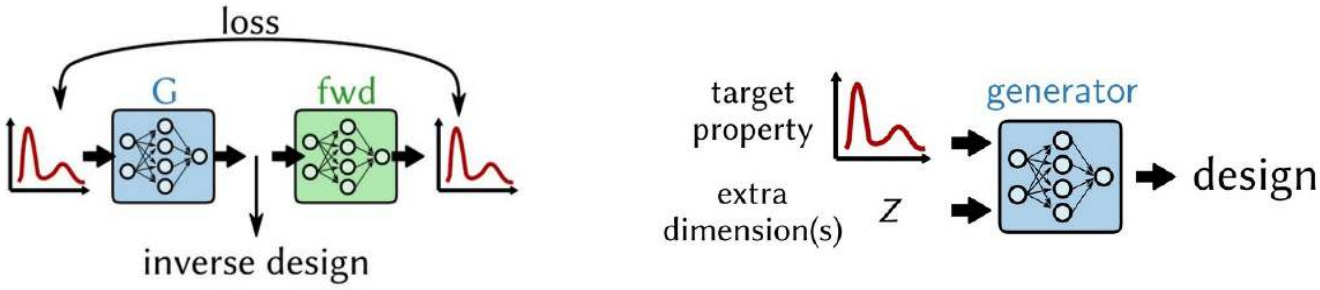

Fig.1 Left: Tandem inverse design network; right: latent space based inverse network concept

Artificial intelligence and in particular deep learning (DL) has proven in recent years to provide powerful numerical methods for various fields of research. DL is particularly interesting for inverse design tasks which mostly cannot be solved with analytical or direct approaches [1]. Often, very cost-intensive, iterative solvers are used. For nano-photonics inverse design, various deep learning methods have been proposed and benchmarked in the recent past [2]. Frequently used methods are the so-called tandem network (Fig 1, left), or latent space method (Fig 1 right), such as conditional variational autoencoders (cVAE) and conditional generative adversarial networks (cGANs). However all of those methods do not perform an optimization of the design to a given task, but rather match the physical property approximately with the design target. As a result, the inverse designed systems often roughly match the desired functionality, while it would be physically possible to achieve better performance.

The recently proposed neural adjoint (NA) method [4,5] is a deep learning based approach which actually optimizes the target functionality by using a forward network as fast differentiable surrogate, to optimize many random geometries concurrently via gradient descent (Fig 2). It has been shown, that at the cost of an increased computational budget, the NA is in fact delivering superior designs compared to one-shot methods like the tandem [2].

A major subtlety in NA is to constrain the geometry with an additional design loss, since feed-forward neural networks are weak in extrapolation tasks. While this is straightforward in multilayer

perceptron (MLP) networks [4,5], it is a significant challenge for convolutional neural networks, taking free-form geometries as input. The problem can be circumvented by an additional, pre-trained, generator network that maps the free-form design to a latent space, the latter being optimized by the NA. By constraining the latent-space during optimization using an additional KL loss, we obtain robust and stable inverse design results. Furthermore, the design-generator can implicitly incorporate further constraints such as fabrication accuracy

I will give an overview over the most important inverse design techniques techniques, will discuss respective drawbacks and advantages, while discussing also potential dangers and risks, that come with data-driven techniques in a general picture.

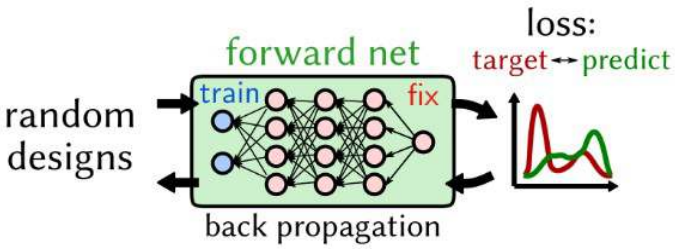

Fig.2 The neural adjoint (NA) method uses a pre-trained forward neural network as ultra-fast, differentiable surrogate for gradient-based, stochastic optimization.

Digital Twins for Generic Radio Environments Parametrized by Reconfigurable Intelligent Surfaces: Physics-Based vs. Physics-Agnostic Surrogate Models

Hugo Prod'homme[†] and Philipp del Hougne[*]

Univ Rennes, CNRS, IETR—UMR 6164, F-35000 Rennes, France

[†]presenting author
[*]corresponding author: philipp.del-hougne@univ-rennes1.fr

Abstract: Optimizing the configuration of reconfigurable intelligent surfaces (RISs) in generic (potentially complex-scattering) radio environments for a desired communications or sensing functionality is challenging because of the non-linear manner in which the RIS impacts the wireless channel. The availability of a learned surrogate forward model of the mapping from RIS configuration to wireless channel can substantially facilitate the optimization problem. Here, we explore different approaches (physics-based vs. physics-agnostic) to learning such digital twins.

The ability to control the wireless radio environment via programmable metasurfaces (often referred to as RIS) constitutes a paradigm shift because the system engineer can now not only control the input signals but also the wireless channel itself. However, while the wireless channel is a linear input-output relation, its dependence on the RIS configuration is in general non-linear [1], [2]. This "structural non-linearity", largely overlooked by the signal-processing community to date, originates from proximity-induced mutual coupling between close-by RIS elements and reverberation-induced long-range correlations among all RIS elements. The non-linear dependence of the wireless channel on the RIS configuration constitutes a substantial challenge for optimizing the RIS configuration.

In this presentation, we will explore the feasibility of learning digital twins of the physical system that act as surrogate forward model, i.e., that map the RIS configuration to the experimentally observed wireless channel. We will explore a variety of surrogate models, ranging from a blind (completely physics-agnostic) model, via various hybrid intermediate steps, to a fully physics-based model. We compare the fidelity with which these models can approximate the experimental reality, and we explain what physical parameters of the experimental setting determine the difficulty with which surrogate models can be learned. We validate our techniques both based on the physics-compliant channel model PhysFad [1] as well as various experimental data sets.

Exploring Multiple Network Architectures to Solve Selected Challenges in Computational Nanophotonics

Abstract: We present our most recent contributions to explore the use of different architectures for artificial neural networks to simulate the interaction of light with nanostructured materials. Among others, we exploit graph neural networks to substitute a finite-difference time-domain scheme and Fourier neural operators as surrogate solvers for electromagnetic scattering problems. For the latter, we highlight the opportunity to solve tasks in the context of the inverse design of free-form scatterers with an optical response on demand.

Methods and techniques from the field of computer science, and especially from the field of machine learning, currently penetrate optics and photonics and are explored for selected purposes. While multiple networks were studied for designing specific nanophotonic devices [1, 2], we explore from a slightly different perspective the use of particular architectures of artificial neural networks for the more general task of solving Maxwell's equations or replacing traditional techniques to simulate the interaction of light with nanostructured photonic materials.

One example of the latter would be the finite-difference time-domain (FDTD) method, where simulations are made by discretizing Maxwell's equations in space and time on a grid and evolving an initial field through a given spatial domain using a leap-frog-scheme. In our work, we have been using graph neural networks (GNN) for the same purpose. By representing the electromagnetic field distribution as a graph, we successfully train a GNN to propagate the field for a fixed time step. Despite relatively small domain sizes in training, our GNN can extrapolate to arbitrarily large domains while preserving high prediction accuracy. Additionally, our approach works on square grids, the backbone of any FDTD, but also on arbitrary unstructured meshes. Hence, this GNN architecture opens novel opportunities to bypass a notorious shortcoming of the traditional FDTD approach.

On the other hand, we introduce a Fourier neural operator network as a surrogate solver for Maxwell's equations. The FNO is not a general-purpose Maxwell solver but requires a set of structures and their scattering response as training data. The model is trained on a diverse set of free-form electromagnetic scatterers, and we compare its performance to a state-of-the-art convolutional architecture (UNet). We show that FNO requires significantly fewer data to reach the same accuracy as UNet. Further, we show the inverse design of free-form three-dimensional optical elements using our pre-trained model. We obtain feasible devices while achieving a significant speedup over conventional means for inverse design. The model is geared to predict structures feasible for fabrication with additive manufacturing technologies. The FNO makes it possible to design structures with disparate objective functions and is, in that sense, a general-purpose tool.

Abstract: We have proposed a deep learning (DL) approach for reconstructing images taken through meta-lenses. We trained a deep neural network (DNN) that can recover the chromatic aberration of meta-lens imaging. The invented DNN can be used to restore images taken from different focusing distances. The designed DNN model achieved high fidelity computationally and great meta-lens imaging performance.

1. Introduction

Metasurfaces are capable of controlling wavefronts with compact size and flat shape, which have great potential to replace conventional refractive optical components [1-4]. For example, metasurfaces can work as meta-lens in visible light with a hyperbolical phase design. However due to inherent dispersive behavior of metasurfaces, meta-lens imaging can experience strong chromatic dispersion. Various approaches [1-4] have been proposed in recent years to solve this problem.

In this paper, we proposed a novel Deep Learning (DL) method to solve the chromatic dispersion of meta-lens imaging. We used a modified U-Net [5] structure DL network to correct the image color and reconstruct the image to its original quality. With this fully trained network, we could process a single image in less than 1 second with high fidelity.

2. Meta-Lens Imaging Reconstruction

To restore the image color, we designed our model based on the U-Net model [5,6]. In addition to the original U-Net model, we add more skip connections between different convolutional blocks to capture more color features and avoid model degradation. The detailed network architecture is shown in Fig. 1. The encoder and decoder blocks consist of several convolutional and upsampling layers. The dashed lines between blocks represent exemplar skip connections we added to our DL model's encoder and decoder blocks.

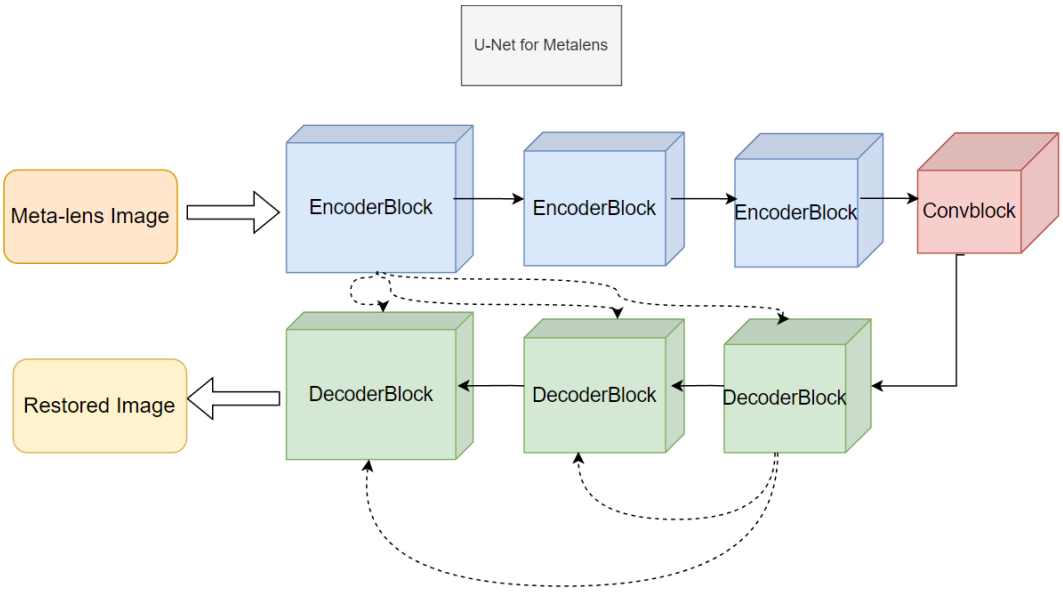

Fig. 1. General architecture of the proposed network.

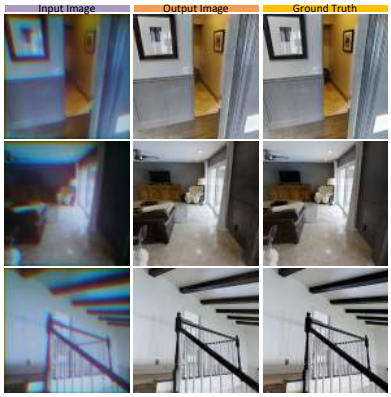

Fig. 2. Examples of image reconstruction using the proposed network.

After hundreds of epochs of training, our DL model can eliminate chromatic dispersion from meta-lens imaging with losing texture details. A few examples are shown in Fig. 2. It is found that, with this model, we can efficiently process any meta-lens imaging in a short time with promising quality.

3. Meta-lens Design and Imaging Setup

The proposed meta-lens is fabricated on silicon-on-Sapphire (SOS) wafers. Meta-atoms are formed by silicon cylindrical pillars with various diameters to achieve different phase responses. The total phase coverage exceeded 360° across the operating wavelength range.

The targeted wavelength of the meta-lens is 560nm, so that at such wavelength, all the meta-atoms achieved at least 80% transmission efficiency. Photos of the fabricated meta-lens are shown in Fig. 3. This meta-lens has a diameter of 1mm, and the focal length is set to be 5mm.

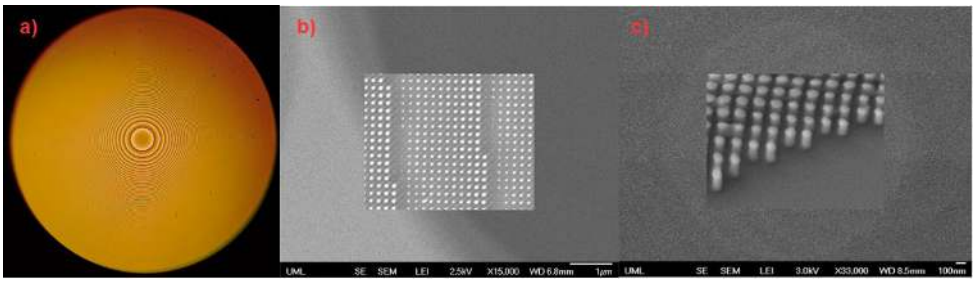

Fig. 3. a) The photo of whole fabricated meta-lens. b) SEM photo of the fabricated meta-lens (top view). c) SEM photo of the fabricated meta-lens (tilted view at the edge).

Abstract: Training data are very expensive for metasurface designs using deep-learning based methods. To achieve data efficiency, we introduced normalization flows to inversely design metasurfaces through learning the probabilistic distribution of the data. To explore the distribution efficiently, we proposed a prior shaping method to re-weight the data based on their fitness to the design target. Through implementing the algorithm, we obtained an emitter with in-band emittance efficiency close to 99%. Our results present a new route for designing metasurfaces inversely.

Deep learning techniques have triggered new perspectives not only for our daily life, but also for science exploration and engineering designs. To achieve functional metasurface with better performance, various machine learning algorithms have been investigated, such as generative adversarial networks (GANs), variational auto-encoders (VAEs), adversarial auto-encoders (AAEs), and the neural adjoint (NA). [1-4] To better explore the data and model the probability of data distribution with respect to the design target, we propose conditional probabilistic learning – specifically a normalizing flow (NF) method – for inverse design. In recent literature, the normalizing flow architecture has also been termed invertible neural networks (INNs) [5], which can be trained with exact log-likelihood, which leads to better convergence and performance. We also proposed a novel prior reshaping (PR) method to explore the feasible design parameter space more efficiently, which can be adjusted freely with a hyperparameter τ without re-generating new data. Using the NF-based inverse design, we successfully designed an Nb-based emitter working for GaSb with nearly 100% in-band efficiency. We also experimentally show that the normalizing flow model trained on a large-scale dataset can be transferred by only using a few new data. Using only 5% of the original data, we inversely designed an emitter working for InGaAsSb with in-band efficiency up to 99.7%. And the correlation between the design variables and the latent parameters provides excellent interpretation for the underline physics. Our results indicate that this method can be used to generate feasible design variables and enables sampling from different prior data distribution efficiently without re-simulation. Our proposed method is not limited to the demonstrated metasurface emitters, and may also be applied to other design problems in photonics, plasmonics, materials, and mechanics.

Adaptive physics-driven neural networks for electromagnetic inverse problems and design of ultracompact diffractive devices

L. Dal Negro[1,2,3*], Y. Zhu[2], and R. Riganti[3]

[1]Department of Electrical & Computer Engineering and Photonics Center, Boston University, USA
[2]Division of Materials Science & Engineering, Boston University, USA
[3]Department of Physics, Boston University, USA
[*]corresponding author: dalnegro@bu.edu

Abstract: We present a robust computational framework that combines artificial neural network architectures with scattering and wave transport physics for the inverse design of ultracompact diffractive devices and for the inverse solution of high-dimensional integro-differential problems of relevance to optoelectronic and metamaterial technologies. Specifically, we develop and test different adaptive learning strategies that provide enhanced accuracy and scalability for the design and discovery of novel nanophotonic and metamaterial devices.

There is a growing interest in developing deep learning (DL) and artificial intelligence (AI) algorithms for electromagnetic wave engineering and metamaterials design. These rapidly emerging approaches include training artificial neural networks (ANNs) to solve inverse problems and parameter estimation in complex photonic environments [1,2]. Although successfully demonstrated at solving several inverse design problems, traditional DL methods are essentially data-driven techniques requiring time-consuming training steps that use massive datasets. Moreover, in order to improve on purely data-driven methods, it is also important to constrain and regularize them leveraging on the underlying physics of the investigated problems. Here we discuss our approaches to build a robust framework that efficiently integrates powerful ANN architectures and the physical laws that fundamentally constrain the wave scattering and parameter retrieval inverse-problems for metamaterials and nano-optical devices. In particular, we introduce and discuss adaptive learning methods based on diffractive optical networks (a-DONs) for the inverse-design of ultracompact spectroscopic imaging devices [3,4] as well as physics-informed neural networks (a-PINNs) for complex electromagnetic inverse scattering and radiative transfer problems [5,6,10]. The flexible a-DONs approach builds on diffractive optical networks that naturally combine optical diffraction physics and deep learning capabilities [7-9]. In our work, we demonstrate the inverse design of two-layer focusing devices that selectively focus incident radiation over well-separated spectral bands at desired distances, achieving focusing efficiencies beyond the limit of single-layer diffractive optical elements (DOEs). Moreover, we engineer the angular dispersion and steering behavior of broadband incident radiation across predefined focal trajectories achieving nanometer spectral resolution in diffractive devices with $L = 100\ \mu$m side length and $f = 300\ \mu$m focal length across the visible spectrum. We also address the fabrication and characterization of the designed devices using multi-level lithography and doublet metasurface technology, potentially enabling single-shot focusing spectrometers with customized focal trajectories for applications to ultracompact spectroscopic imaging and lensless microscopy. Finally, we discuss our recent work on the development and testing of adaptive PINNs methods for the accurate solution of complex forward and inverse problems in electromagnetic scattering and radiative transfer theory. We introduce a-PINNs architectures for the inverse solution of high-dimensional integro-differential transport problems of relevance to optoelectronic devices and metamaterials technologies. In particular, we demonstrate efficient parameter estimation in coupled

conductive-radiative systems and discuss applications to the inverse design of heat transfer in nano-devices with engineered thermal properties [10]. Our work shows that a-PINNs possess the flexibility, accuracy, and noise robustness required to become a powerful design approach for inverse scattering and the non-local homogenization of multi-scale optoelectronic devices and metamaterials.

Importance of Metric Learning and Manifold Learning in Knowledge Discovery and Inverse Design of Nanophotonic Structures

Mohammadreza Zandehshahvar, Muliang Zhu, Mohammad Hadigheh Javani, and Ali Adibi*

School of Electrical and Computer Engineering
Georgia Institute of Technology
Atlanta, GA 30332-0250

Abstract: We discuss the importance of manifold-learning algorithms in reducing the dimensionality of the nanophotonic design problems while enabling the better visualization of their input-output relation. This can be helpful in forming least complex structures for a given response while also uncovering subtle details about the physics of light-matter interaction. We also show the importance of metric learning in the efficacy of the manifold-learning algorithms and empowering them to distinguish different classes of responses while preserving important response features.

Nanophotonics structures have a wide range of applications in different disciplines from virtual reality and lens design to computing thanks to their unique features and capabilities in manipulating light spatially, temporally, and spectrally. The recent advances in fabrication technologies have enabled the design of structures with more degrees of freedom compared to the past. This makes the inverse design of such structures more challenging and yet more important than ever.

The gradient-based inverse-design techniques such as topology optimization and adjoint optimization have been on the forefront of the inverse design in nanophotonics and shown promising performance on the design of different classes of structures over the past few years. However, since these methods rely on an electromagnetic (EM) solver at each iteration, they can become computationally extensive in the cases that the forward problem and its gradient cannot be calculated efficiently, and the inverse design needs to be solved repeatedly for different solutions. These methods also cannot provide insight about the hidden patterns in the data and are not easy to interpret.

More recently, machine-learning (ML) approaches have been extensively employed for the inverse design in nanophotonics thanks to their unique features in processing high-dimensional data. These methods mainly use a set of training data that is generated using EM solvers to learn the mapping between the input (i.e., the design space) and the output (i.e., the response space) and use the surrogate model to solve the inverse design with far less computation. These approaches have been applied to different classes of structures including binary structures, thin films, multi-layered structures, metasurfaces, etc.

In addition to the utilization of ML methods for inverse design, they have been used for knowledge discovery and uncovering hidden patterns of the high-dimensional data in these structures. Reducing the dimensionality and visualization of the data in the lower-dimensional space can facilitate the interpretation of the results and understanding the role of design parameters.

In this work, we present a manifold-learning approach for efficient inverse design and knowledge discovery in nanophotonics. We use this approach for understanding the range of responses in a class of nanostructures with different geometric complexities and study the role of design parameters. We also present a new approach for metric learning to define new metrics (i.e., similarity measure) that are well-suited for nanophotonics applications. We show how this approach can result in a better representation of the data in the embedding space (i.e., low-dimensional space or latent space).

Multipolar Resonance Engineering Using Machine Learning

Wenhao Li,[1] Hooman Barati Sedeh,[1] Willie J. Padilla,[1] Jordan Malof,[2] and Natalia M. Litchinitser[1]

[1]Duke University, USA
[2]University of Montana, USA
[*]corresponding author: natalia.litchinitser@duke.edu

Abstract: We developed machine learning models to predict the multipolar resonances and electric field distributions of all-dielectric meta-atoms. Machine learning method is also used for inverse designing meta-atoms based on the desired multipolar resonances.

Machine learning methods have been widely used in subwavelength photonic structure designs since they are capable of solving the non-intuitive and nonlinear relationship between subwavelength structures and their optical responses and are significantly faster than the traditional numerical simulation methods. However, in the inverse design problems, machine learning models usually serve as black boxes which take the desired spectrum as an input to predict the shape of meta-atoms without elucidating the physics behind it. This makes the machine learning method difficult to apply when designing structures aimed at performing complicated functions. At the same time, the multipole expansion of the scattering cross sections, i.e. multipolar resonances, has been instrumental in analyzing and designing meta-atoms. In this work, we developed forward prediction models to discover hidden relationships between scattering behavior and the shapes/optical properties of meta-atoms, and an inverse design model to reconstruct the meta-atoms having desired properties under the guidance of multipole expansion theory. We discuss several linear and nonlinear optics examples of applications that are likely to be enabled by the developed multipolar resonances guided machine learning approach.

Meta-Atom Design for a Highly-Sensitive Liquid Sensor

Kazunori Serita, Luwei Zheng, Kazuki Hara, and Masayoshi Tonouchi

Institute of Laser Engineering, Osaka University, Suita, Osaka, 5650871 JAPAN
*corresponding author: tonouchi.masayoshi.ile@osaka-u.ac.jp

Abstract: We propose new type of a highly-sensitive liquid sensor. Terahertz (THz) point source was combined with a few arrays of meta-atoms, and reflection type THz-TDS was developed. The design of the meta-atoms and configuration of the array were studied to enhance the sensitivity.

The femtosecond laser pulses are focused in a GaAs wafer from the backside and, by adjusting the focus near the surface, a point THz source is formed. Combining with a few arrays of meta-atoms, the highly-sensitive sensor for liquid biopsy can be developed in a reflection mode (Fig.1). However, a variety of meta-atom design should be considered. In the present work, we examine the some types of meta-materials design, and evaluated their performance experimentally with the point source as indicated in Fig.2.

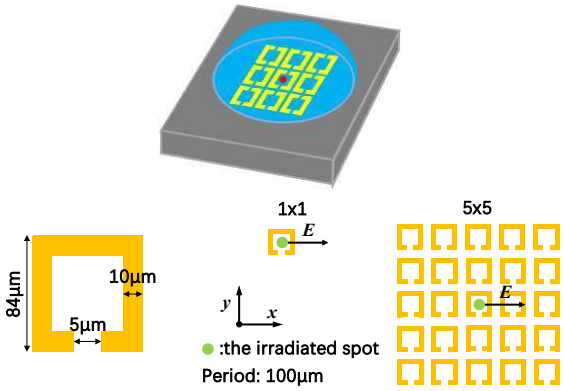

Fig. 1 Schematic of solution sensing using the arrays of meta-atoms and the configurations of meta-atoms.

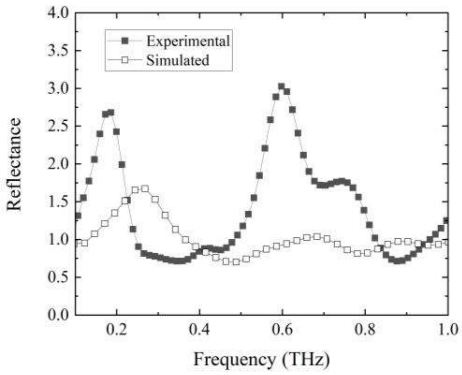

Fig.2 THz reflectance of arrayed meta-atoms.

In the presentation, we will report the optimization of the design of the meta-atom and its array configuration for highly-sensitive liquid biopsy.

Broadband invisibility cloaking design of concentric multilayered cylindrical metamaterials based on genetic algorithm

Tomoya Momose, Mana Toma, and Kotaro Kajikawa*

Tokyo Institute of Technology, Japan
*corresponding author: kajikawa@ee.e.titech.ac.jp

Abstract: A computational approach to design a cloaking medium is presented on the basis of the genetic algorithm (GA). The cloaking target is a dielectric cylinder with a diameter of 1 μm, and the cloaking medium is multilayered cylindrical layers with a thickness of 0.5 μm. The cloaking performance designed by the GA is much better than that designed on the basis of the transformation optics and the effective medium approximation.

Introduction

Invisibility cloaking is a technique to make a cloaking target invisible. A cloaking design is based on the transformation optics proposed by Pendry *et al* [1]. In this method, the cloaking medium is designed so that light detours the target. But this method is impractical in the optical frequency range because it requires the cloaking medium with anisotropy and magnetic response. Cai *et al*. proposed the cloaking medium with no magnetic response [2] by modifying the expression of the transformation optics. Huang *et al*. replaced this medium with a concentric multilayered cylindrical metamaterial, using the effective medium approximation, alternating the layers with high and low dielectric constants to generate effective-medium layers [3]. However, the cloaking performance is not sufficient. Our approach delivers the optimal cloaking structure by performing the GA calculations by assuming a stacked structure with high and low dielectric constant layers.

Methods

The designed structure is shown in Figure 1. This structure consists of a cylinder (dielectric constant ε_0 : 9, radius r_0 : 500 nm) covered with 26 layers of cloaking medium (thickness of one layer: about 19.23 nm, total thickness: 500 nm). TE polarized light (perpendicular to the long axis of the cylindrical medium) was incident to the medium. The dielectric constant of each layer was determined so that the scattering cross section (C_{sca}) is small in the wavelength range of 400 - 700 nm. The dielectric constant was investigated in the range of 0 - 1 for odd layers and 1 - 30 for even layers, counting from the center. The parameters were set as follows: the size of tournament selection as 3, the probability of two-point crossover as 50%, the probability of calling the mutation subroutine as 20%, the probability of each gene mutating when the mutation subroutine was called as 5%, the number of individuals as 500, and the number of generations as 320. Then, 60 trials were performed with different random number seeds to find the solution with the smallest scattering cross-section.

Results

To compare the cloaking performance, the following evaluation function was introduced.

$$\text{Evaluation value} = \frac{\sum_{\lambda=400}^{700} C_{\mathrm{sca(cloaked)}}}{\sum_{\lambda=400}^{700} C_{\mathrm{sca(target\ only)}}} \tag{1}$$

Figure 2 shows that the cloaking performance of the medium designed by our approach is better than that obtained

by the previous approach [3]. It also shows that the 26-layer cloaking medium exhibits the most broadband invisibility among those designed by the GA. The scattering cross-section with the 26-layer cloaking medium was reduced to about 4.8% on average in the optical wavelength range (400-700 nm) compared to the case without the cloaking medium. Figure 3 shows the magnetic field for the target-only case obtained by FDTD simulation at a wavelength of 540 nm. Figure 4 shows it for the case of the target covered with 26 layers of cloaking medium. It shows that invisibility cloaking was achieved using our GA approach.

Enabling the inverse design of metasurfaces at the unit cell and the supercell level using neural network approaches for industrial applications

Konstantinos Dovelos[1], Evangelos Galaris[1], Vasiliki Vardakastani[1], Panagiotis Kosmas[1*], and Dimitrios C. Tzarouchis[1*]

[1] Meta Metamaterials Europe, Ap. Pavlou 10, 15123, Marousi, Athens, Greece

Abstract: In this work, we report a general methodology for the inverse design of metasurfaces at the unit cell and supercell level, using a combination of commercial software (FDFD) and a neural network approach, all controlled by a properly designed software wrapper in Python. This automated scheme can be used to develop metasurfaces with on-demand performance and functionalities for industrial applications.

Metasurfaces or intelligent surfaces are ubiquitous applications of applied electromagnetics and metamaterials that carry the momentum of transforming modern antenna systems from energy harvesting and telecommunications to biomedical devices and optics[1]. Many intuitive analytical/semi-analytical approaches have been used to design metasurfaces, delivering many exciting designs[1]. However, the design process for on-demand metasurfaces is a challenging task. It requires excellent knowledge of available libraries and procedures, often not easily adaptable from the available literature (reproducibility) and for different frequency ranges (scalability). Moreover, metasurfaces for industrial applications require robustness, high efficiency, specific frequency bands, and other quite strict modalities. In other words, real-world engineering metasurfaces entail a much more cumbersome process than the one usually found in academic research. To this end, inverse design is an excellent tool that explores a much larger design set, i.e., the set of non-intuitive geometries and designs[1-6] adding extra degrees of complexity and manufacturing constraints.

Here we describe a general methodological approach to develop a robust metasurface design pipeline for various functionalities, requirements, and constraints. To this end, the talk will present a broad methodological approach that utilizes standard commercial e/m simulation software, e.g., CST Microwave Studio (Dassault Systemes), combined with an appropriate tailored custom-made wrapper software code (Python). The automated process enables the usage of (any) commercially available software and, therefore, expands their optimization/inverse-design modalities.

By means of example, we start by assuming a given design goal, such as designing a metasurface absorber with three different absorption bands, and specific manufacturing constraints, such as realizing it with a flexible transparent material operating at the microwave regime. We then program the wrapper to reproduce thousands of randomized results with these specifications. These results are fed as the training set to a specifically designed neural network. While the procedural pipeline can be considered trivial, the process is redesigned to accommodate metrics such as high efficiency, accuracy, and manufacturing processes, dictated by industrial-level applications. The integrability of such a tool with the overall design manufacturing process via the Python interface makes it an ideal candidate for block design schemes and other custom design options.

Metasurfaces for light control emission

Universal light encoders: artificial intelligent hardware for nanoscale light control

A. Fratalocchi[1]

[1]Primalight, Faculty of Electrical and Computer Engineering, KAUST, Thuwal, Saudi Arabia
*corresponding author: andrea.fratalocchi@kaust.edu.sa

Abstract: Universal light encoders represent a new generation of metasurface that implements hardware machine learning for controlling light propagation. In this talk, I will review the fundamentals and application of this technology in various areas, ranging from the inverse design of ultra-flat optical components to Hyplex™ , an innovative camera for acquiring and processing high-resolution hyperspectral videos in real-time at 30 frames per second.

In this invited talk, I will summarize recent research results in the field of universal light encoders. These components represent a particular class of metasurfaces implementing optical hardware feedforward neural networks that can universally approximate any user-defined input-output function. In the first series of applications, I will discuss the exploitation of this technology to implement ultra-flat (60 nm thick) optical components for vectorial light control with near-unity experimental efficiencies in the visible. In the second part, I will discuss a new area of research that focuses on the implementation in the hardware of software machine learning concepts for various applications in machine vision. I will summarize the fundamentals of Hyplex™, a new hyperspectral technology platform that allows the acquisition and processing of high-resolution videos in real-time for a broad spectrum of applications, including remote sensing, medical diagnosis, precision agriculture, and security.

Abstract: All-dielectric metasurfaces have been proposed to enhance the emission of electric and magnetic quantum emitters via engineering of high-quality factor optical modes. The excitation of quasi-bound states in the continuum can offer high *Q*-factors in symmetry-broken metasurfaces. However, in most designs, the emission wavelengths are fixed by the geometric parameters of the metasurface. Here, we propose to use phase-change materials to tune the emission of light-emitting metasurfaces supporting quasi-bounds states in the continuum in the telecom spectral range. This work may find applications for tunable spectral shaping, dynamic wavefront shaping, tunable filters, or sensors.

The development of efficient quantum emitters is key in photonic quantum technologies. All-dielectric metasurfaces have been vastly investigated in the last years with the aim of improving the efficiency of quantum emitters. On the one hand, the directionality properties of the dielectric nanoparticles can redirect the emitted radiation towards the detector used in the experiment, improving the radiation collection [1]. On the other hand, the electromagnetic energy confinement inside the nanoresonators that conform the metasurface can increase the emission of electric or magnetic quantum emitters located in the hot-spots [2]. In order to boost the *Q*-factor of the structure, the possibility of exciting quasi-bound states in the continuum (quasi-BIC) has been proposed [3].

BIC are dark modes, which cannot couple to the incident radiation or, equivalently, emit radiation, showing an infinite *Q*-factor. However, BIC resonances are just a mathematical concept, which cannot be attained experimentally. In fact, in experimental demonstrations, the BIC is converted in a leaky mode known as quasi-BIC. This mode is characterized by a narrow asymmetric Fano resonance (high *Q*-factor) [4]. Different kinds of BICs can be distinguished depending on the origin of radiation suppression. In metasurfaces, symmetry-protected BIC can be achieved due to the spatial symmetry of the mode not being compatible with the symmetry of the radiating waves. By breaking the symmetry of the metasurface, it is possible to open a radiation channel through which the radiation of the mode can be coupled to the incident radiation, giving rise to the quasi-BIC resonance [3].

In spite of the high *Q*-factor that can be achieved in all-dielectric metasurfaces, for certain applications, their utility is limited due to the band emission being fixed by the geometry of the design. To avoid this constraint, phase-change materials or liquid crystals can be used [5].

In this work, we analyze different phase change materials ($Ge_2Sb_2Te_5$ and Sb_2Se_3) to tune the emission of a quasi-BIC mode excited in the telecom band. In particular, we analyze a silicon metasurface composed of two

asymmetric nanobars. A thin layer of the considered phase-change material is placed on top of each resonator. Fig. 1a shows a scheme of the unit cell of the metasurface.

In the amorphous state, a quasi-BIC for both $Ge_2Sb_2Te_5$ and Sb_2Se_3 is observed. However, for the crystalline state, the quasi-BIC is only attained for Sb_2Se_3. This is due to the high losses of $Ge_2Sb_2Te_5$ in the crystalline state. Fig. 1b depicts a comparison of the transmission spectra of the Si metasurface combined with Sb_2Se_3 for the amorphous and crystalline states. A 58-nm spectral shift is attained. In addition, two important features are observed: for the crystalline state the amplitude and *Q*-factor of the quasi-BIC resonance decrease due to the absorption rise. However, it is still possible to observe moderately high *Q*-factors for the quasi-BIC resonance in the crystalline phase.

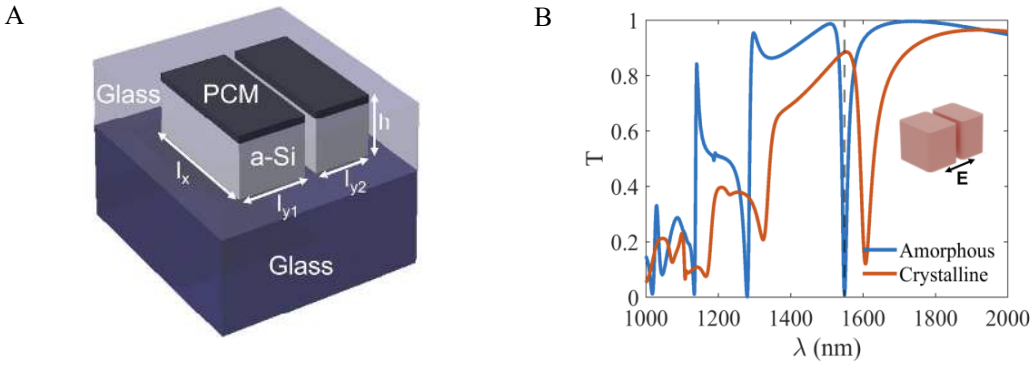

Figure 1. (A) Scheme of the unit cell of the asymmetric metasurface. (B) Trasmission spectra for the silicon metasurfaces combined with Sb_2Se_3. The inset indicates the polarization direction of the incident radiation with respect to the unit cell of the metasurface.

Electroluminescent Metasurface Light Emitting Diodes (Invited)

Jon A. Schuller

Electrical and Computer Engineering Department, UC Santa Barbara, USA
corresponding author: jonschuller@ucsb.edu

Abstract: Recent demonstrations of metasurface mediated photoluminescence[1-10] highlight their potential for future device implementation. However, phased array electroluminescent metasurface devices have not previously been realized. Here, we demonstrate GaN-based quantum well LEDs where light is generated within an integrated metasurface architecture. In addition to demonstrating directional and focused electroluminescence, we describe how previous photoluminescent metasurfaces must be modified to incorporate device functionality, and show that metasurface LEDs can add new functionality without negatively impacting device brightness or efficiency.

Amplifying nanophotonic lattices

A. Femius Koenderink

Department of Physics of Information in Matter & Center for Nanophotonics, AMOLF, Science Park 104, 1098XG The Netherlands

f.koenderink@amolf.nl

Abstract: Recent theory for scattering lattices with spatially distributed loss and gain point at the potential for topological and pseudochiral bandstructure physics. At the same time, these systems are quite different from true tight-binding systems, owing to long-range dipole dipole coupling, and diffraction channels. We study plasmonic realisations in a femtosecond pump probe set up that provides single-shot imaging, k-space mapping and photonic band structure mapping I will present experiments on diffractive and significantly sub-diffractive amplifying and lasing nanophotonic lattices.

Theory in context of PT-symmetry for plasmonic realizations of honeycomb, and Kagomé nanophotonic lattices with loss and gain that are spatially distributed point at the potential for topological and pseudochiral bandstructure physics in this system. At the same time, these systems are quite different from true tight-binding systems, such as coupled-waveguide realizations of topological bandstructires in photonics. This difference owes to long-range dipole dipole coupling, retardation effects, and the presence of radiation loss via diffraction channels. Motivated by these prospects, our group commissioned a set up for femto-second pump-probe studies on amplifying metasufaces, using white-light supercontinuum probe pulses in a high-NA microscope suited for simultaneously imaging real-space and k-space fluorescence, plasmon array lasing, as well as nonlinear reflectivity for samples that are, e.g., pumped into gain. Thereby we aim to reveal changes in metasurface bandstructure as function of optically pumped gain. While we ultimately aim to study lattices with spatially distributed loss and gain – for instance introduced by shaping the pump beam with a spatial light modulator –I will present results on homogeneously pumped lattices, which present diffractive plasmon array lasing behavior.

Plasmon antenna lattices enjoy a long history in the domain of fluorescence control, SERS, sensing and plasmon lasers, due to the combination of high Q and strong field enhancement that occur by virtue of diffractive resonances. While diffractive plasmon array lasers of various symmetries have been widely studied before, I will show that single-shot real-space and Fourier-space imaging gives a detailed view in hitherto unstudied physics in these systems, such as spontaneous symmetry breaking, and the singular polarization nature of lasing in K-point modes. To reach the regime of predicted topological and pseudochiral bandstructure physics it is necessary to move away from diffractive lattices, instead accessing subdiffractive periodicities, where strong near-field interactions between meta-atoms push the array bandstructure well beyond the light line. We will present an approach to access this band structure in optical experiments on basis of auxiliary periodicities in a supercell geometry to perturbatively cause band structure folding. This approach provides far-field access to guided modes, and we demonstrate lasing also in subdiffractive lattices. As an outlook we will discuss work from our group on how fluorescence and lasing in these systems could be harnessed for solid-state lighting, considering some of the challenges that integration of light emitting metasurfaces with practical devices present.

Abstract: In the last few years, polaritonic metasurfaces were established as a viable alternative to vertical cavities for realization of strong light-matter interaction regimes that in turn enable unique nonlinear and quantum phenomena. We explore topological exciton polaritons which are formed in a suitably engineered all-dielectric topological photonic metasurface coupled to transition metal dichalcogenide monolayers. We experimentally observe the transition of topological charge from photonic to polaritonic bands with the onset of strong coupling regime and demonstrate one-way spin-polarized edge topological polaritons.

One of the recently emerged research directions in the already mature field of topological photonics is aimed at expanding the developed concepts towards systems with strong light-matter interaction. This opens the possibilities for creation and control of exotic quasiparticles – topological polaritons. The first topolaritonic system characterized by a 2D topological invariant was demonstrated in GaAs quantum well lattices [1] for the case of broken time-reversal symmetry induced by magnetic field. Here, we realize topological polaritonic spin-Hall phase that does not require magnetic field in a topological metasurface based on planar Si photonic structure strongly coupled to excitons in transition metal dichalcogenides (TMD) monolayers. We experimentally demonstrate the transfer of topological charge from photonic to polaritonic mode, one-way propagation of the edge topological polaritons and conservation of valley polarization of the emission.

Our structure represents a Si photonic metasurface with a honeycomb shrink-expand lattice design [2,3] (Fig. 1a). We adjust it to support leaky topological edge modes near the exciton frequencies in $MoSe_2$ or WSe_2 (1.65 eV and 1.74 eV at 7K, respectively). To realize the transition to topological polariton regime, we transfer TMD monolayer on top of the metasurface together with thin hBN layers. We then measure the angle-resolved differential reflectivity spectra to reveal that the onset of strong coupling regime leads to the topological charge transfer from bulk photonic band to the newly formed upper polaritonic band (Fig. 1b). The change of the dispersion of the edge modes in strong coupling regime confirms their polaritonic nature.

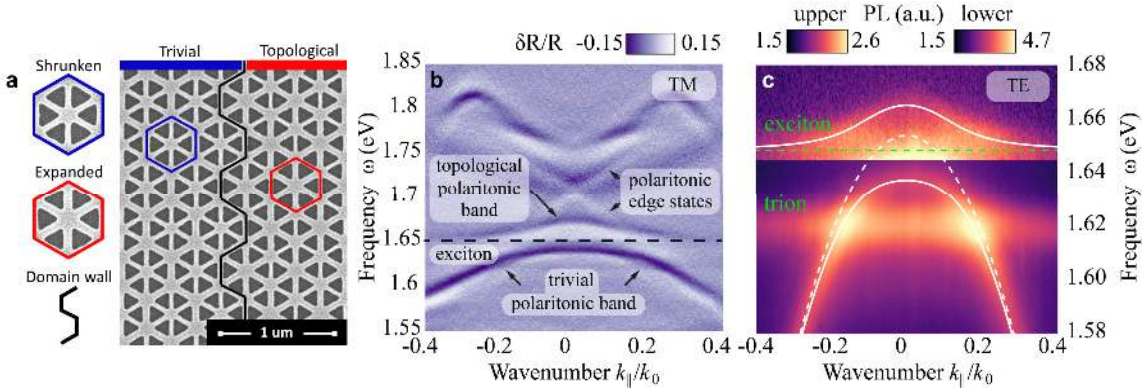

Fig. 1 (a) SEM image of the domain wall of the silicon topological metasurface based on the shrink-expand design. (b) Angle-resolved differential reflectivity measured from the domain wall of a metasurface coupled with a MoSe2 monolayer. (c) Angle-resolved PL spectra for TE polarization fitted with a coupled oscillator model.

We further extract the parameters of strong coupling regime from the angle-resolved photoluminescence spectra (Fig. 1c) and demonstrate one-way propagation of polaritonic topological edge modes for resonant excitation. Finally, we explore the possibilities of valley polarization transport with edge states for the sample coupled to a WSe_2 monolayer.

Abstract: We show ultrafast and coherent write and read states for valleytronic operations in an atomically thin semiconductor. We assign the write state to the generation of a valley imbalance by coherent optical Stark shift induced by off-resonance below gap excitation. The read state is enabled by the sensitivity of second harmonic generation to changes in the material symmetry, triggered by the valley imbalance.

Light is the ideal candidate to realize devices operating with high speed and low consumption thanks to all-optical operations [1]. A promising approach in this direction is based on valleytronics using two-dimensional transition metal dichalcogenides (TMDs): TMD monolayers are direct gap semiconductors with two energetically degenerate but non-equivalent valleys in the K and K' points of the Brillouin zone. The valleys can be selectively excited (write) in an all-optical fashion, because light of opposite helicity couples to opposite valleys, while their detection (read) was so far mostly based on polarization-resolved photoluminescence (PL). However, this approach has two main drawbacks: (1) it detects an averaged light emission over a time-scale that is much longer compared to the valley and spin lifetimes; (2) it is intrinsically a destructive method, which measures the valley polarization (VP) only after light emission. Nonlinear optics [2], and in particular second harmonic generation (SHG), overcomes these disadvantages and provides an ultrafast and non-destructive method for the detection of the VP in TMDs. The presence of a VP breaks time-reversal symmetry and leads to new terms in the nonlinear optical susceptibility. In this seminar, I will discuss our recent results, where we simultaneously pump (write) and probe (read) the VP in WSe_2 with one single elliptically polarized ultra-short pulse. We probe the VP using polarization dependent SHG measurements at different values of the fundamental wavelength and find that resonant SHG at the *1s* exciton state is the most sensitive probe of the VP. In addition, we show that, in the case of below gap excitation, the VP is generated by ultrafast coherent optical Stark-shift, which is valley selective in TMDs [3]. Thus, this work provides direct evidence of ultrafast and all-optical coherent generation and detection of valleys in atomically thin semiconductors.

Abstract: Strongly absorbing materials are needed for nanoscale optoelectronics and strong light-matter coupling applications. The absorption limit of ultrathin films is 50%. The strong excitonic resonance in monolayer WS_2 provides 16% absorptance. Here we demonstrate that monolayer WS_2 superlattices provide higher absorption while preserving the exciton emission. We show that an artificial superlattice structure increases absorptance to 37%. Our results put forward superlattices as a platform for developing novel two-dimensional semiconductor devices.

Strong light absorption in ultrathin materials plays a vital role in variety of applications including light detection, waveguiding, and modulation. One relatively new class of strongly absorbing materials is that of atomically thin materials. Transition metal dichalcogenides (TMDs), such as tungsten disulfide (WS_2) and molybdenum diselenide ($MoSe_2$) possess unique optical properties. Bulk TMDs consist of weakly bound atomically thin layers and stable monolayers can be easily prepared through exfoliation. Compared to other growth methods such as chemical vapor deposition (CVD), exfoliation provides the highest exciton quality for the strongest absorption and narrowest linewidth.

Monolayer TMDs, despite being less than one nanometer thick, show an exceptionally strong absorption of light: absorption of sunlight up to 5-10% has been observed in TMDs monolayer, an order of magnitude larger than GaAs or Si of comparable thickness[1]. The strong interaction of light with TMDs monolayers has potential advantages in atomically thin devices. The combination of strong absorption and the ability to tune the excitonic resonances through doping enables their use in nanoscale optical elements such as atomically thin photodetectors[2], modulators[3], and lenses[4]. TMD monolayers can also be used to create atomically thin mirrors that are promising for a range of uses, including spatial light modulators, active metasurfaces, and active cavity control[5]. In addition, the high oscillator strengths and sharp resonances of excitons in these materials can enable reaching the regime of strong light-matter coupling and the manipulation of light via surface exciton-polaritons[6,7].

Here, we create WS_2 monolayer-based structures to approach the fundamental thin-film absorption limit of 50%. We demonstrate three simple methods to obtain stronger absorption than that of monolayer WS_2. Different superlattice structures of WS_2 monolayers result in an increased light absorption, while also preserving the exciton emission and quality. We characterize these structures using transmission and photoluminescence spectroscopy. Additionally, we employ hyperspectral imaging to gain insight into the spatial variations of exciton properties.

We start with simple structures containing two monolayers separated by a spacer to retain the optical properties of the individual monolayers. However, such structures prove to have coupling between layers that is difficult to control reliably and results in absorption reduction. Instead, we demonstrate the use of a molecular spacer to construct stable stacked bilayers. Finally, we fabricate higher-order superlattices with an increased number of layers using Al_2O_3 as a thin dielectric spacer to approach the thin-film absorption limit in a more scalable process.

Our work puts forward the potential of monolayer superlattices as a flexible platform for developing novel two-dimensional nanophotonic devices. As the superlattice fabrication process relies on simple methods, such superabsorbing materials are posed to have an impact on a variety of fields.

Abstract: We present an exact multipolar expansion of f_{CD}, which can be used to deduce the integrated near-field CD enhancements of chiral molecules in the presence of scatterers under general illumination conditions. Our analytical findings reveal that the near-field f_{CD} factor is related to magnitudes that can be computed in the far-field, such as the scattering cross-section and the helicity expectation value. We demonstrate that in the case of lossless cylindrically symmetric samples, the near-field f_{CD} factor can be experimentally inferred from only two far-field measurements.

Molecular Circular dichroism (CD) spectroscopy faces significant limitations due to the inherent weakness of chiroptical light-matter interactions [1]. In this view, resonant optical antennas constitute a promising solution to this problem since they can be tuned to increase the CD enhancement factor, f_{CD}, a magnitude describing the electromagnetic near-field enhancement of scatterers [2] associated with a given helicity [3, 4] (Fig. 1).

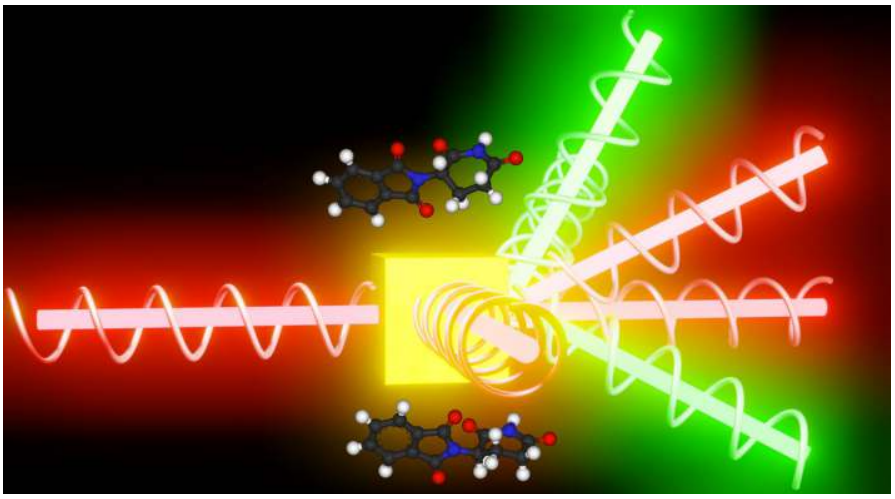

Fig. 1: Scattering process in which an incident field with well-defined helicity (red beam with σ = +1) impinges on an achiral antenna, represented by a glossy cube. Both R-and-S Thalidomide enantiomers are also depicted close to the achiral antenna.

However and in the context of CD enhancements, researchers rely exclusively on numerical methods to design enhanced chiral sensing devices as capturing the vector character of the near-field contribution can be challenging. In this work, we derive an exact multipolar expansion of f_{CD}, which is valid to deduce the integrated near-field CD enhancements of chiral molecules in the presence of scatterers of any size and shape under general illumination conditions [6]. From our analytical results, we show that f_{CD} is proportional to the scattering cross-section and the helicity expectation value, which are experimentally measurable magnitudes in the far-field. In addition to this, we also show that for lossless and cylindrically symmetric scatterers, it is possible to infer the f_{CD} factor only with two far-field measurements: the scattering cross-section and the helicity density at specific scattering angles. Our results pave the way for experimental verification and characterization of building blocks for CD enhancement from far-field measurements, and thus, may give rise to novel developments in the field of chiral light-matter interaction

Abstract: Trivalent lanthanides naturally offer strong magnetic dipole (MD) transition due to the selection rule forbidden electric dipole (ED) transition. This inspires the investigation of different nanophotonic platforms for efficiently modifying the magnetic nature of light. Here, we introduce high-index all-dielectric nanostructures including Mie-resonant silicon (Si) nanocylinder metasurfaces, broken symmetry titanium dioxide (TiO_2) metasurfaces supporting high Q-factor resonances, and an efficient fabrication process for deterministic coupling of the fluorophores to the hotspot of the Si dimers.

MD transitions in a quantum system are typically negligible at the optical frequency range since their transition rates are usually up to 5 orders of magnitude weaker than allowed ED transition rates. However, lanthanide ions, such as Eu^{3+}, exhibit MD transition with a comparable strength to ED transitions, which makes them a proper candidate for magnetic light-matter interaction studies. Eu^{3+} ions possess a strong MD transition at 590 nm ($^5D_0 \rightarrow {}^7F_1$) and several ED transitions including the most dominant one at 610 nm ($^5D_0 \rightarrow {}^7F_2$) [1].
High index all-dielectric nanostructures supporting multipolar electric and magnetic Mie-resonances are versatile platforms for both spectral and spatial tailoring of spontaneous emission from coupled emitters as they provide low absorption loss, high radiation efficiency, and substantial radiative decay rate enhancement [2]. A particularly interesting case are metasurfaces with a slightly broken in-plane symmetry that exhibit quasi-bound state in continuum (BIC) modes characterized by sharp, high quality (Q) factor resonances. Such a system can thus offer a strong fluorescence enhancement and emission directionality of the coupled emitters [3]. Efficiently enhancement of the emission from nanoscale emitters integrated with the photonic nanostructures requires a precise coupling of the emitters to the electromagnetic near-field hotspots of the nanostructure. Therefore, developing optimal methods of fabrication of fluorophore-embedded nanostructures that allow for the deterministic placement and immobilization of the emitters is particularly important. Here, we summarize our studies on three different platforms based on high index all-dielectric nanostructures for tailoring the MD transition of Eu^{3+} at 590 nm. In the first work [4], spontaneous emission enhancement of Eu^{3+} ions using Mie-resonant Si nanocylinder metasurfaces was experimentally demonstrated. Metasurfaces were fabricated featuring different nanocylinder radii, so that their strong quadrupolar Mie-resonances swept over the spectral range of Eu^{3+} electric and magnetic dipole transition bands. Then, they were covered by a thin layer of a $Eu(TTA)_3L18$ containing polymer and excited at λ = 325 nm. The emission was collected using a 0.4NA objective. Figure 1a shows the scanning electron micrograph (SEM) of the focused ion beam (FIB) cross section of the coated metasurface and Figure 1b demonstrates the systematic change of the enhancement ratio of emission via MD and ED transition channels as G_{590}/G_{610}, reaching the maximum of 1.12. This verifies that Mie-resonant all-dielectric metasurfaces allow for selective enhancement of the MD over ED emission for a proper choice of the metasurface

geometry. The next work was dedicated to design, fabrication, and characterization of Mie-resonant metasurfaces composed of broken symmetry TiO_2 nanoparticles, that support high Q-factor resonances at 590 nm, corresponding to the MD transition of Eu^{3+}. A top-view SEM image of the fabricated sample is shown in Figure 1c. The sample was spin-coated with a resist film (PMMA) containing $Eu(TTA)_3$. The fluorescence properties and emission directionality of the coated sample were characterized by fluorescence spectroscopy and back focal plane (BFP) imaging, respectively. Using a 0.1NA collective objective in fluorescence spectroscopy, as illustrated in Figure 1d, a brightness enhancement of up to 15.5 for the MD transition and an enhancement ratio of $G_{590}/G_{610} = 8.7$ were achieved. Also, Figure 1e show the measured BFP images using a 0.6NA objective. The results illustrate that the designed broken symmetry metasurface allows for the strong fluorescence enhancement for near-zero polar angles as well as selective routing of the MD transition of the coupled Eu^{3+} ions. In the last work, deterministic fabrication of Eu^{3+} embedded nanostructures with the minimal number of steps, for localizing the MD emitters in the hotspot of a Si dimer was represented. The sample was spin-coated with the mixture of an electron beam resist (ma-N2401) with $Eu(TTA)_3$ with a final thickness of ~80 nm. Then, the film was exposed using electron beam lithography (EBL) and developed. The SEM image of the fabricated hybrid system is shown in Figure 1f. This fabrication process allows for the precise control over the shape and size of the resulting fluorescent structures with a resolution of ~100 nm. Figure 1g shows that the fluorescence from Eu^{3+} embedded in resist is robust for the exposure doses up to 500 $\mu C.cm^{-2}$. In conclusion, our results offer novel possibilities toward spectrally and spatially tailoring the MD-dominated spontaneous emission, thus allowing to exploit magnetic component of light which is essential for applications such as chiral sensing [5].

Abstract: Although metasurfaces are intrinsically planar objects, geometrical variations in the third – out-of-plane – direction are becoming instrumental to engineer exotic optical responses. Unfortunately, such complex three-dimensional meta-atoms are extremely difficult to fabricate at the nanoscale. Here, we demonstrate that similar optical responses are amenable to simple geometries that include different materials, thus paving the way for a new class of hybrid metasurfaces.

Metasurfaces have appeared very naturally as the field of metamaterials strived to evolve toward the visible part of the spectrum and technology challenges emerged. Whilst it is possible to fabricate intricate three-dimensional (3D) meta-atoms that operate at microwave frequencies,[1] this becomes extremely difficult at optical frequencies, where their dimensions should be in the order of 100s of nanometers. The reason being that 3D nanofabrication is still in its infancy and it is very hard to control nanostructures' shapes in all three directions, especially throughout the depth of a material.[2] Fortunately, planar technologies are very well developed, and it is possible to manufacture a broad variety of nanostructures with different lateral shapes and materials on a two-dimensional (2D) substrate, to fabricate a metasurface.[3]

Although metasurfaces are in principle flat and 2D, it is emerging now that variations outside of their 2D plane can enable specific phenomena at optical wavelengths. This is the case for example to achieve arbitrary beam-steering with maximum efficiency,[4] to enable the excitation of multipolar resonances to better control scattering properties,[5] or even to produce exotic effects such as asymmetric responses in the linear or nonlinear regimes.[6] This novel development toward 3D meta-atoms is quite challenging from a technological point of view, especially when geometrical variations are required in the out-of-plane direction, as illustrated in Fig. 1(a).

In this presentation, we will demonstrate that a similar optical response can be achieved from heterogeneous nanostructures with a more regular shape, but composed of different materials, Fig. 1(b).

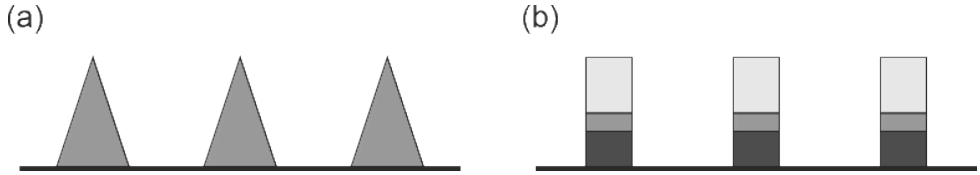

Figure 1: (a) 3D homogeneous meta-atoms made from a single material with geometrical variations in the out-of-plane direction can be replaced with (b) simpler geometries that incorporate different materials and are much easier to fabricate at the nanoscale.

A similar response between these two very different meta-atoms can be obtained by controlling the various multipolar contributions that arise in both systems. For example, among the two materials families used in nanophotonics, the fundamental mode for metal nanostructures is electric, while that for dielectric nanostructures

is magnetic and heterogeneous meta-atoms that mix both materials have a very rich electromagnetic response.[7] Two such metasurfaces built from heterogeneous meta-atoms are illustrated in Fig. 2: a combination of dielectric and plasmonic materials produces extremely narrow spectral features that can be used for sensing, Fig. 2(a).[8] A combination of two different plasmonic metals exhibits an asymmetric nonlinear response that depends on the illumination direction, akin to an optical diode.[6] These exotic optical responses originate from the spatial dispersion in the out-of-plane direction of the metasurfaces, which – in this case – does not occur through complicated geometrical variations as in Fig. 1(a), but through a mere combination of different materials.

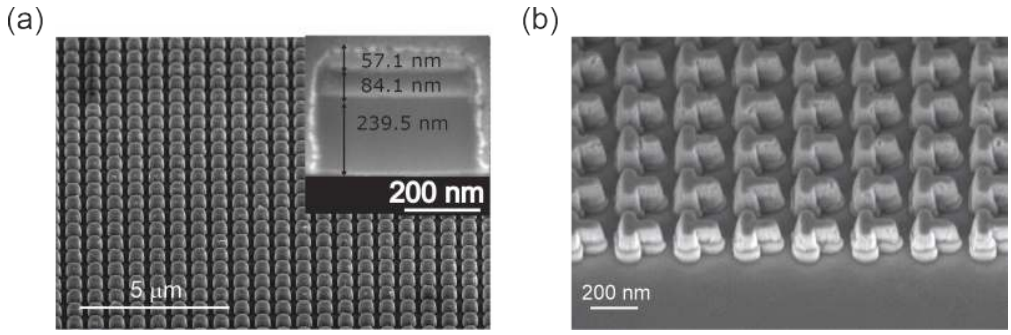

Figure 2: Two examples of metasurfaces built with heterogeneous meta-atoms that achieve similar functionalities as homogeneous nanostructures with a more complicated geometry: (a) cylindrical meta-atoms built from Si, SiO_2 and Al; (b) T-shaped meta-atoms built from Al, SiO_2 and Ag.

Abstract: Artificial photosynthesis of carbon dioxide, using water as the reducing agent and sunlight to drive the reaction, has the potential to provide renewable fuels at scale. Key challenges in the field are realizing product selectivity and enhancing yields. Our work aims to exploit the strong, confined near fields and hot carriers generated at specific energies by suitably designed plasmonic nanostructures to control chemical reaction pathways. We focus on understanding underlying mechanisms and developing scalable plasmonic substrates with suitable resonances.

Photocatalytic processes mediated by strong, tunable, plasmonic resonances have the potential to provide optical control of chemical reactions. It is well known that plasmonic resonances can be induced and sensitively controlled by modifying the geometry of sub-wavelength metal nanostructures, as well as their composition and the optical properties of their surroundings. Molecules can couple with these resonant optical modes, through either electron or photon transfer (fig 1a), driving reactions and activating bonds to initiate particular reaction pathways.

The mechanism of plasmonically-mediated reactions has been the subject of lively debate in the field. Our work employs a practical approach to exploring the underlying mechanisms of plasmonic control of reactions, and distinguishing between thermal and optical driven chemistry[1]. We focus on a model system comprised of methylene blue (MB) adsorbed on random arrays of gold nanoparticles. Methylene-blue can undergo a transformation to thionine which can be monitored *in-situ* using surface enhanced Raman spectroscopy (SERS) (fig 1b). By varying the average size of the nanoparticles in the disordered arrays, the wavelength of the excitation of plasmonic resonances, and the incident power, we are able to explore the dependence of the reaction yield on the excited plasmonic resonances. We couple these experiments with rigorous theoretical analysis of the photothermal induced temperature increase, the induced near-fields, and the generation of hot-electrons in the plasmonic array. In doing so, we can infer that the reaction is primarily driven by enhanced optical near-fields and transfer of hot-carriers. This is an important result, as it suggests that such reactions can be optically controlled.

Practical application of artificial photosynthesis will require scalable, stable photocatalysts in continuous flow reactors[2]. To progress towards this goal, we demonstrate plasmonic photocatalysts based on complex 3D metallic nanostructures electrodeposited over centimeter scales on commercial electrode materials[3]. The resulting substrates are coated in dense arrays of hierarchical, gold dendrites. Using cathodoluminescence (CL) measurements, we map the plasmonic 'hot-spots' excited on these substrates, revealing the spatial and spectral distribution of the plasmonic resonances excited on such structures (fig 1c). We are able to qualitatively reproduce the variety of CL spectra observed experimentally by simulating simplified conical and triangular geometries using boundary element method (BEM) (implemented in the freely available MNPBEM toolbox). By doing so we were able to conclude that 1) the optical properties of the hot-spots are determined by the local

geometry, rather than the overall interconnected sample morphology; and 2) there is a clear correlation between the tip shape and the spectral and spatial distribution of the plasmonic resonances and corresponding hot-spots. These insights offer the potential to design scalable plasmonic substrates, engineered to selectively drive chemical reactions.

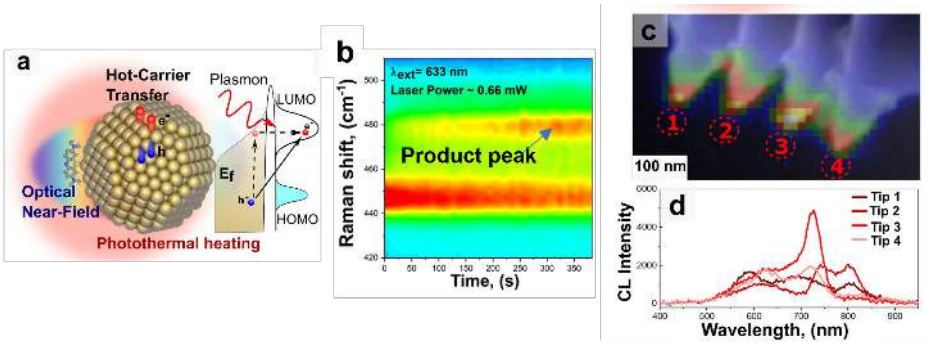

Figure 1. a) Illustration of possible mechanisms for transferring energy from plasmonic resonances to adsorbates. b) Time evolution of SERS spectra. c) Cathodoluminescence mapping of plasmonic resonances on gold dendritic structures

The insights from the studies discussed above are combined to progress towards practical plasmonic catalytic substrates for selective, solar-driven, renewable fuel production. The conversion of carbon dioxide to valuable hydrocarbons is a complex, multistep process requiring multiple electron and proton transfers which can proceed through several different radical intermediates[4]. The existence of multiple, branching, and co-existing reaction pathways can lead to a variety of different produce – some much more valuable than others. Selectively producing desired products is an ongoing challenge. Our ongoing work focuses on harnessing the strong, confined, optical near fields and energetic hot carriers generated by the dendritic structures to drive gas-phase CO_2 photoreduction. Preliminary results have demonstrated 57% selectivity for desirable double-carbon bond (C_2) hydrocarbons under 1-sun illumination.

Abstract: A wide range of optical and optoelectronic applications requires surfaces with specific properties, such as optical and electrical tunability, self-cleaning and cooling, antimicrobial properties, etc. In this talk, we will review recent efforts from our group in developing optical surfaces with unique properties based on ultrathin materials and nano-structuring. In particular, we will describe the use of ultrathin metals films (UTMF), dewetted nano-particles (DNPs), scalable nano-patterning for transparent electrodes, transparent antimicrobial glass for display applications, optical windows and infrared sensing.

UTMFs are emerging as game-changing optoelectronic materials for many applications in transparent electronics and plasmonic meta-surfaces. For practical use of UTMFs, transparent dielectric substrates and large-scale fabrication are desirable which require physical vapor deposition (PVD) techniques. However, if no measures are taken, metal PVD onto dielectric substrates typically results in an island like structure at the initial stage, and only show long-range connectivity (percolation) at mass equivalent thicknesses ≥5 nm. We show that by using a fully transparent seed layer of copper oxide (CuO) for subsequent Ag and Au UTMF growth, percolation is achieved at thicknesses close to 1nm. We will then explore possible optoelectronic applications, such as infra-red reflector or plasmonic resonant structures. In these, the UTMF's properties are continuously tuned and reconfigured by surface electrolyte electrical gating, which is only possible due to their small thickness. The results demonstrate the potential applications of UTMFs in reconfigurable and tunable devices such as smart-windows and plasmonic bio-sensing.

Scalable DNPs (i.e. large area fabrication of randomly distributed nano-particles on a surface) are of great interest for industrial applications. As example, metal DNPs can be used as a mask to pattern glass surfaces (SiO_2) via reactive ion etching (RIE), allowing the fabrication of large area nanopillars and nanoholes, which has shown unpreceded optical properties such as anti-reflection and increased transparency, as well as self-cleaning properties. Moreover, when large nanopillars are fabricated, surface phonon polaritons (SPhP) on glass can be excited i.e. increase the optical emissivity in the infrared (IR) , allowing the use of these surfaces for passive radiative cooling (PRC). We also exploit the antimicrobial properties of surfaces starting from copper (Cu) UTMFs by demonstrating their effectiveness to kill viruses and bacteria.

Enhanced light-matter interaction in a hollow nanocuboid metasurface supporting delocalised quasi-BIC modes

Abstract: The two main problems of dielectric metasurfaces for sensing based on enhanced light-matter interaction are that resonances are mainly localised inside the resonator volume and experimental Q-factors are very limited. We investigate a dielectric metasurface supporting delocalised modes based on quasi-bound states in the continuum (qBICs) to address these issues. The metasurface comprises a periodic array of silicon hollow nanocuboids patterned on a glass substrate. The resonance stems from the excitation of a symmetry-protected qBIC mode, accessed by perturbing the arrangement of the nanocuboid holes. Thanks to the variation of the unit cell with a cluster of 4 hollow nanocuboids, delocalised modes with ultra-high Q-factor are produced.

Bound States in the Continuum (BICs) are a unique class of optical modes localised within a photonic structure and immune to radiative losses [1]. Metasurfaces, which are two-dimensional arrays of subwavelength scatterers, have emerged as a promising platform for engineering BICs. In these structures, symmetry-protected BICs are eigenmodes situated above the light cone, possessing different symmetries than the incoming wave, rendering them unexcitable within the continuum of radiation modes. By introducing some kind of perturbation, pure BICs transform into quasi-BICs with a finite lifetime, narrow linewidth and arbitrarily high radiative Q-factor. Indeed, quasi-BICs have been intensely investigated in dielectric metasurfaces with symmetry breaking, such as by introducing geometrical asymmetry or using anisotropic materials [2]. Although in most cases the resonant near fields are mainly confined to the interior of the high-index subwavelength scatterers, thus providing limited light-matter interaction with the surrounding material, it is still feasible to achieve interaction at the interface, allowing for biosensing and integration with 2D materials [3], as well as in slotted regions [4]. Furthermore, it has been recently reported that asymmetric dielectric particles arranged in clusters can be used to achieve greater flexibility in obtaining the desired near-field configuration [5] and enhancing the sensing capabilities for refractometry [6]. The operation principle in the latter case is based on plasmon-like surface waves, which are delocalised over a wide area to provide a large interaction volume with the matter but are excited in an all-dielectric structure.

In this work, we investigate a dielectric metasurface supporting delocalised quasi-BIC modes. The metasurface comprises a periodic array of hollow nanocuboids patterned on a glass substrate and designed to produce ultra-high Q-factor delocalised resonances. The authors previously demonstrated this structure for toroidal responses [7-9], but now, the cluster arrangement has advanced features. The device in Figure 1 consists of a periodic array of silicon hollow nanocuboids patterned on glass (silica). As observed, the electrical field is mainly located outside the resonator volume at the telecommunication wavelength of 1.55 μm.

(a) (b) (c)

Figure 1. qBIC mode electrical profile for two different hole asymmetries (a) 20% and (b) 80% (it has to be taken into account that the hole is 20% of the total cuboid width). (c) Q factor as a function of the hole asymmetry.

The proposed hole symmetry-breaking mechanism has several advantages: normal coupling, polarisation independency, ultra-high radiative Q-factor (minimum 10^4) and delocalised field confinement. Furthermore, this kind of metasurface paves the way for different applications in which light-matter interaction is critical, e.g. refractometric sensing and spectroscopy.

Abstract: Colloidal quantum dots (QDs) have been extensively used for their size dependent optoelectronic properties resulting in broadband detection of electromagnetic radiation. Conventionally photoluminescence (PL) enhancement requires plasmonic structures or high refractive index dielectric metamaterials. We report on a 1600% structure dependent PL enhancement with the aid of low refractive index ZnO coated laser-printable 3D infrared (IR) metamaterials. The metamaterial structure is used to enhance interaction between light and PbS QDs. Our findings shed light on conformal QD coating over complex surfaces of 3D structures, and open new avenues in the use of QDs for optoelectronic and nanophotonic applications.

I. INTRODUCTION

Quantum dots (QDs) find extensive applications in optoelectronic devices. Detection of electromagnetic radiation for example, particularly in near-infrared (NIR) and shortwave-IR, has relevant potential, for example thanks to the biological window between 700-1400nm, where tissues show reduced absorption offering the opportunity for noninvasive monitoring [1]. For the realization of such wearable and miniaturized devices, there are several limitations currently. First, QDs-based devices mainly concern coating of flat surfaces however, curved and bendable substrates for such applications is a critical need. Further, small fingerprint optoelectronic devices are ideal for not invasive and cost-effective applications, and processing issue point to the reduction of layers' thicknesses. Reducing the overall size of such architectures leads to reduced light interaction with the 'active' medium of the device, minimizing the detected signals.

In this work, we show how conformal QDs coating of 3D structures is possible overcoming geometrical restrictions and how miniaturizing the active-photonic area leads to higher photoluminescence (PL) signal compared to normal QDs films due to optical resonances of laser-printable structures. Our recent results open up new directions for designing optoelectronic devices beyond 2D geometries as well as a broader range for materials selection necessary for applications ranging from energy harvesting and light emission to photocatalysis and biosensing [2-3].

II. STRUCTURE FABRICATION, ZNO COATING AND QDS DEPOSITION

For the fabrication of 3D metamaterials, we use direct laser writing (DLW) and specifically multi-photon polymerization allowing fabrication of features with resolution as high as 100nm. Here we use a conventional nanoprinter (Nanoscribe Photonic Professional GT) with Ti:Sapphire femtosecond laser at a center wavelength of780 nm, 25 kW peak power, 100 fs

pulse duration, and 80 MHz repetition rate. For achieving high-resolution features, we use a 63x (1.4NA) oil-immersion objective and IP-Dip photoresist (Nanoscribe) in dip-in laser lithography mode on standard Si wafer (Fig. 1a). For achieving optical resonances at wavelength of interest, we use a standard woodpile-like geometry with periodicities of 1.0, 1.1 and 1.2μm and overall size of 70x70μm^2. The structures periodicity chosen carefully to provide an optical resonance within the excitonic peak of the QDs.

Polymeric structures have relative low refractive index (~1.4), thus challenging to facilitate optical resonances. To increase the refractive index, 80nm of ZnO (~1.7) is deposited in a custom-built atomic layer deposition (ALD) system using diethyl zinc (DEZ) precursor and water (H_2O) co-reactant. The optimal deposition temperature for the ZnO created by DEZ/H_2O is still ambiguous compared to other precursor recipes. The temperature chosen was 50°C for the reactor walls and the sample, and room temperature for the reservoir. Such lowering of the temperature is possible thanks to the high reactivity of DEZ. Moreover, the deposition parameters were 0.1s for precursor pulse, 1s for exposure and 90s for the purge in both cases (DEZ and H_2O). The precursor pulse and the purge were executed with 15sccm and 100sccm argon flows, respectively. Using transmission electronic microscope (TEM), we determine the thickness of the ZnO layer (80nm) and calculate the growth per cycle (GPC) of about 0.12 Å/cycle allowing coating with extreme sub-nm resolution (Fig. 1b).

PbS QDs have been synthesised following the method from Hines et al. [4] with slight modification, obtaining a final dispersion of 5nm particles absorbing at 1380nm, capped with oleic acid ligands in octane at a concentration of 40mg/mL. QDs are carried to a nitrogen glovebox and deposited as synthesised via spin coating at 2000rpm for 30s, and annealed at 75°C for 30s, obtaining a conformal layer of 70nm onto 3D ZnO structures (Fig. 1c). After deposition, the excitonic peak of QDs is red-shifted to 1435nm.

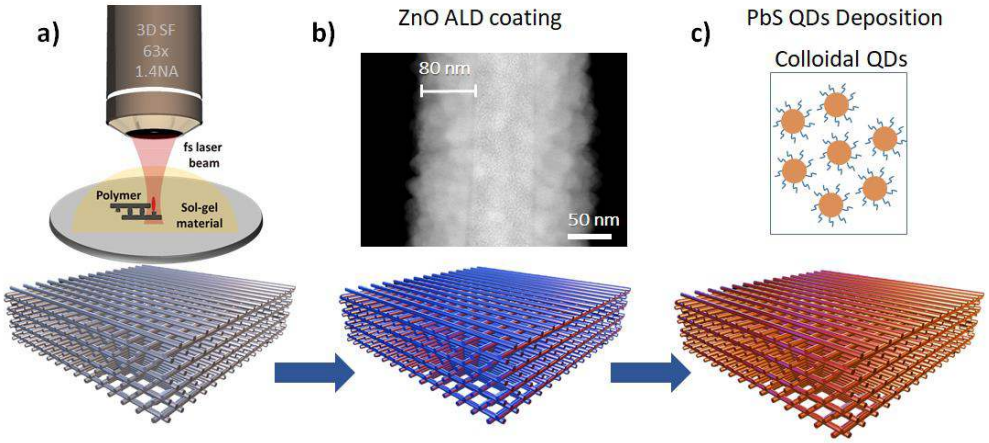

Fig. 1. 3D laser-processed metamaterials. a) Nanoscale 3D fabrication of woodpile structures via multi-photon polymerization. b) Atomic-layer deposition (ALD) conformal coating with 80nm of ZnO. c) Deposition of PbS quantum dots (QDs) with an excitonic peak at wavelength of 1435 nm.

III. Nanoscale Photoluminescence Measurements

To evaluate performance of the 3D laser-printed structures, we perform PL nanoscale measurements. First, we obtain PL maps centered at the excitonic peak of PbS QDs (1435nm) with pump laser centered at a wavelength of 640 nm (Fig. 2b). Woodpile structures show extreme PL enhancement compared to QDs film on Si. The PL enhancement is even high enough to identify the exact position of the woodpile structures (see Fig. 2a-b). PL signals is increasing with periodicity, as expected, due to the optical resonance of the 1.2μm structure that is 'closer' to excitonic peak of the QDs. To understand this better, we perform wavelength resolved measurements for the QDs film and woodpiles) with pump laser centered at a wavelength of 785 nm. While PL of QDs film is relative low, it increases with periodicity dramatically resulting in almost 1600% higher PbS PL signal (Fig. 2c). Inset shows PL *vs* periodicity for clarity.

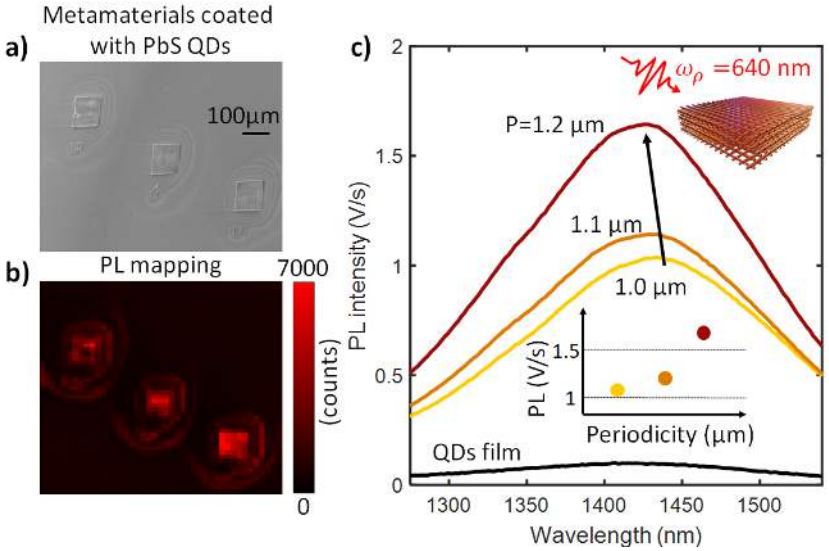

Fig. 2. Low refractive index 3D metamaterials for structure dependent QDs PL enhancement. a) Scanning electron microscope image of the QDs coated metamaterials. b) PL mapping (ω_P=785nm) shows extreme signal boosting on the dielectric IR photonic structures compared to the QDs film on Si. c) Wavelength-resolved PL for different metamaterial periodicities. Insets show the laser pump wavelength of 640nm and periodicity dependent PL enhancement.

IV. Conclusion

Here we show how QDs conformal coatings can be achieved over 3D structures overcoming current geometrical deposition restrictions. Furthermore, low refractive index dielectric laser-printable IR metamaterials boost PL of PbS QDs resulting in an increase of about 1600% compared to QDs film. This makes a wide materials collection beyond the standard plasmonic or high refractive index dielectrics available for nanoscale optoelectronic and photonic applications.

Nonlinear dielectric metasurfaces for infrared imaging and light sources

Dragomir Neshev

*corresponding author: Dragomir.Neshev@anu.edu.au

Abstract: We review the recent achievements of nonlinear frequency conversion in dielectric metasurfaces and show the different strategies for optimization of the nonlinearity enhancement. We further review the important applications of such nonlinear metasurfaces for infrared imaging and novel photon sources.

Nonlinear optical phenomena are central to a myriad of applications in light sources and microscopy. Nonlinear optical effects, such as harmonic generation, frequency mixing and spontaneous parametric down conversion (SPDC) are fundamentally enhanced in materials with a high refractive index, as well as by the presence of a resonant photonic environment. These conditions have triggered a quest for nonlinearity enhancement in nanoscale resonators of high refractive index, where resonant dielectric metasurfaces play a key role. However, the applicability of high-index single-crystal metasurfaces for enhanced nonlinear light matter interactions has remained limited. This is hindered by several factors, including low conversion efficiency, difficulties in the fabrication of nanostructures from high-index crystalline materials, as well as by the diffractive nature of the emitted nonlinear light.

Here we discuss the recent advances in the field of nonlinear metasurfaces for enhancement of nonlinear frequency conversion, including second harmonic generation, sum-frequency generation and third harmonic generation. We present how the resonant effects of bound states in the continuum together with free-form optimization techniques for optimization of the mode overlaps inside the metasurfaces can significantly enhance the nonlinear conversion. In particular, we explore different materials platforms, including III-V semiconductors, single-crystal transition-metal-dichalcogenide (TMDC) and lithium niobate metasurfaces. We further present possible applications of nonlinear metasurfaces for nonlinear infrared imaging and non-classical photon sources.

Light source engineering of directive photoluminescent metasurfaces with the local Kirchhoff's law

E. Bailly[1], **J.-P. Hugonin**[1], **B. Vest**[1], **J.-J. Greffet**[1*]

Abstract: Light-emitting metasurfaces are nanostructured surfaces covered with emitters. The interaction between emitters and the metasurface enables a precise control of the emission properties. In practice, devices can be designed exploiting a reciprocity picture given by the local Kirchhoff's law [1]. The emission features can be derived from the absorption features. In this presentation, we report on the whole process of quantitative design, fabrication and characterization of devices made on nanoplatelets deposited on a 2D metallic grating, providing highly directional photoluminescence.

Light-emitting metasurfaces are devices consisting of a nanostructured surface covered with dense ensemble of emitters. In the standard model, the emitters are considered as a collection of electric dipoles randomly oriented inside the structure, whose contribution can be added incoherently [2]. This approach however does not account for modifications of the spectrum influenced by temperature and pumping conditions and cannot predict the intensity of the emitted signal. Here, we present an alternative procedure to model emission by light-emitting metasurfaces, using a generalized Kirchhoff's law formalism [1], as the product of a local absorptivity rate by a Planckian exponential contribution depending on the temperature and the photon chemical potential. Thanks to this formalism, we were able to design a directive photoluminescent metasurface made of nanoplatelets on a 2D silver grating with absorption computations. The fabrication and characterization of this source are in great agreement with the theory. In particular, the photoluminescent emission can be retrieved numerically with a Brendel-Bormann model of permittivity for the nanoplatelets [3]. Figure 1 presents the experimental results of the photoluminescence signal obtained as a function of the energy and parallel wave vector (Fig. 1b), for a non-polarized light. The radiation pattern is given in Fig. 1c for the nanoplatelets on top of the silver grating (red line) at the wavelength corresponding to the maximum of emission (black dotted line in Fig 1b), compared to the emission of the nanoplatelets on top of an untextured silver substrate (blue line). The metasurface leads to a directive emission in a 30° cone at half maximum.

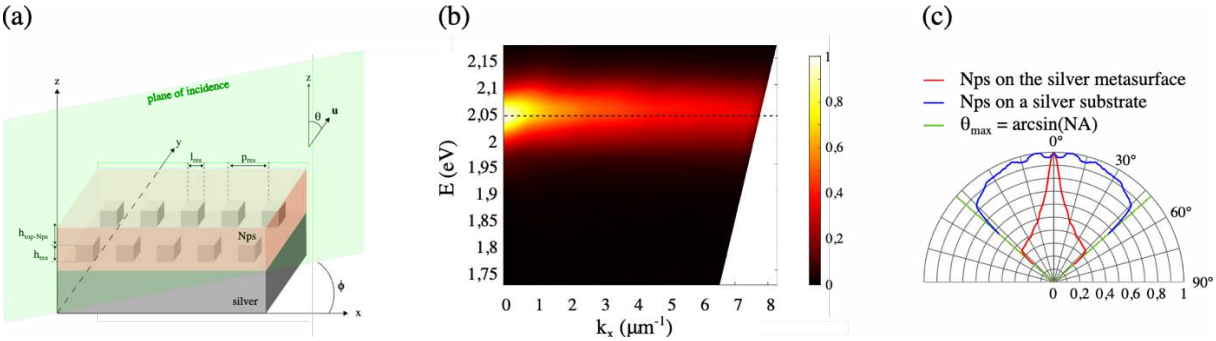

Fig. 1 : Directive photoluminescent metasurface. (a) Schematic diagram of the metasurface, made of nanoplatelets (Nps) located on top of a 2D silver grating. The parameters of the metasurface are h_{res} = 100 nm, l_{res} = 460 nm, p_{res} = 600 nm, $h_{top\text{-}Nps}$ = 6 nm. (b) Normalized photoluminescent emission as a function of the energy E and parallel wave vector $k_x = k_0 \sin(\theta)$, for ϕ=0°. (c) Radiation pattern of the photoluminescent emission at the maximum value of emission represented by the horizontal dotted line of figure b, in presence of the metasurface (red line) or without (blue line). The emission is limited by the numerical aperture of our objective, NA = 0.75 (green line).

Stick-and-play nanoantenna stickers to control photoluminescence

S. Murai*, T-Y. Lo, K. Tanaka

Department of Material Chemistry, Graduate School of Engineering, Kyoto University, Japan
*Corresponding author: murai@dipole7.kuic.kyoto-u.ac.jp

Abstract: Nanoantenna stickers, where the periodic array of nanoparticles is embedded in an elastomer film, can be easily attached to and detached from the surface of target materials and work as nanoantenna to control light. The stickers can be fabricated by nanoimprint lithography followed by a transfer process. We make stickers consisting of the nanoantenna made of aluminum, silver, silicon or titania embedded in polydimethylsiloxane, and demonstrate a photoluminescence outcoupling by placing a sticker on luminous layers.

Periodic arrays of metallic nanoparticles act as nanoantennas to control light at the interface. Although the combination of a variety of functional materials with nanoantennas should open a rich scientific research field, the application degree of freedom is limited severely by the fabrication process. We developed a "nanoantenna sticker" that can be stuck on any surface and gives control over in- and outcoupling of light. The stickers consist of the nanoantenna made of aluminum, silver, silicon or titania embedded in polydimethylsiloxane. We demonstrate a photoluminescence outcoupling by placing a sticker on the luminescent layers: the emission pattern is modulated both spatially and spectrally in a way defined by the nanoantenna sticker. The sticker is useful for enhancing optical response from many different surfaces including those that are incompatible with the nanofabrication processes and should help the integration of nanoantennas into functional devices.

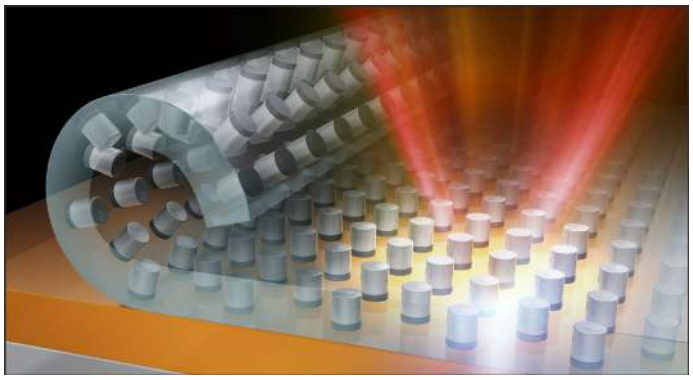

Fig. 1: Sketch of the nanoantenna sticker on a phosphor layer, radiating photoluminescence with a directionality. The nanoantenna sticker is flexible and can be attached to any clean surfaces.

Reciprocity Violation in Time-Modulated Structures for Enhanced Optical Heating

V. M. Levkovskaya[1], A. V. Kharitonov[1*], and S. S. Kharintsev[1]

[1]Insitute of Physics, Kazan Federal University, Russian Federation
[*]corresponding author: antonharitonov@gmail.com

Abstract: In recent years, resonant nanostructures have been demonstrated that are capable of absorbing >99% of incident light in the wide spectral range. However, the photo-heating efficiency observed in these structures is low, which is due to processes of heat diffusion and thermal radiation. These processes can be substantially suppressed by violating the reciprocity. For this purpose, we propose thermophotonic nanostructures, whose optical and thermal properties are simultaneously modulated in time.

Highly efficient local heating plays a crucial role in many applications, such as thermophotovoltaics, photothermal therapy etc. For this purpose, nanostructures are typically used, which absorb the incident light and then convert it into the heat. As a result, one can obtain a nanosized heat source. In recent years, resonant nanostructures have been demonstrated that a capable of absorbing more than 99% of the incident light. However, the photoheating temperature observed in such structures is typically low: on the order of tens of degrees. This is due to the heat dissipation through the two main mechanisms, such as heat diffusion and thermal radiation. In general, these processes are difficult to control since they obey the Lorentz reciprocity principle. In this article, we propose an approach that allows to break the reciprocity for heat diffusion and thermal radiation. The approach is based on the use of time-varying media [1,2].

Kirchhoff's law for thermal radiation states that the absorptivity of a body is equal to its emissivity. Therefore, if the nanostructure absorbs light with high efficiency, then it will also efficiently lose the absorbed energy upon heating. One of the ways to break the reciprocity is the use of magneto-optical materials [3]. However, this requires sufficiently strong magnetic fields on the order of 1 T, which hinders the practical applications.

The heat diffusion rate, according to the heat equation, can be decreased by reducing the thermal diffusivity. This can be done by using the appropriate material. The disadvantage of this approach is the limited set of existing materials. Breaking the reciprocity [4] may potentially lead to the situation, in which the heat does not flow in one or more directions, even in a material with high thermal conductivity.

This work is devoted to the development of an approach for reciprocity breaking in thermphotonic nanostructures. Our approach is based on the use of time-varying media, i.e., media whose parameters are modulated in the time domain. For the case of optical processes, the dielectric permittivity is modulated. For the case of heat diffusion, the thermal conductivity, density or heat capacity are the parameters that can be modulated to achieve a desired functionality. We carried out numerical simulations in order to investigate the propagation of electromagnetic waves (heat flow) in media, which is spatially uniform, but has a temporal inhomogeneity. For this purpose a finite element method was used. We investigated the effect of parameters of the temporal inhomogeneity (switching speed, depth and profile) on the asymmetry in light (heat) propagation. It is shown that in time-varying media the violation of the Kirchhoff's law takes place only in the presence of losses. For the case of heat diffusion, the reciprocity breaking requires simultaneous modulation of two parameters. This stems from to the continuity equation.

Thus, time-varying media provides new opportunities for boosting the light-to-heat conversion in nanostructures. The development of non-reciprocal devices is of great importance for many applications, including radiative heating/cooling, wireless power transfer, and ultrafast information processing.

This work has been supported by the Kazan Federal University Strategic Academic Leadership Program (PRIORITY-2030).

Abstract: We describe a heterogeneously integrated, on-chip, III-V on diamond platform designed for color centers in diamond that circumvents the need for etching the diamond substrate. Through evanescent coupling to defects near the surface of diamond, the platform will enable Purcell enhancement and efficient frequency conversion to the telecommunication C-band.

Color centers in diamond combine optical addressability with long spin coherence times, making them promising candidates for repeater-based quantum networks [1]. However, currently known platforms suffer from either degraded optical coherence when incorporated into nanophotonic devices [2, 3], or limited electron spin coherence times of milliseconds combined with the requirement to work at millikelvin temperatures [4]. The recently reported SiV0 center in diamond has the potential to overcome many of these challenges [5, 6]. The unique combination of stable optical transitions and long spin coherence times at liquid helium temperature makes the SiV0 center an attractive building block for nodes in quantum networks. One proposal for enhancing the entanglement generation rate in color-center-based quantum networks is to integrate color centers with nanophotonic devices. Optical cavities greatly enhance atom-photon interaction, which improves spin readout and spin-photon entanglement fidelity. Furthermore, nanophotonic devices can enable other functionality such as on-chip quantum frequency conversion (QFC), which is key to achieving long-distance quantum communication. Monolithic fabrication techniques of diamond nanophotonic cavities require milling or etching bulk single crystal diamond. A promising method to mitigate the constraints imposed by diamond nanofabrication is heterogeneous integration of diamond and a separate device layer material. The photonic device is fabricated in a high-index photonic layer on top of the diamond substrate such that photons can evanescently couple to color centers that are close to the diamond surface (Fig.1).

We present a platform for integrating III-V nanophotonic devices with SiV0 centers [7]. One-dimensional photonic crystal cavities enhance the optical emission from single SiV0 centers, and the emission can then be routed on-chip to a microresonator-based frequency converter using a four-wave mixing Bragg scattering (FWM-BS) scheme. In contrast to previous demonstrations, our design does not require etching into the diamond, avoiding deleterious effects on the color center. We report on recent experimental progress towards fabricating these photonic structures and integrating them with SiV0 defects in diamond.

Plug & play quantum light sources with fiber-integrated quantum emitters

W. B. Jeon and J.-H. Kim*

[1] Department of Physics, Ulsan National Institute of Science and Technology, Republic of Korea
*jehyungkim@unist.ac.kr

Abstract: We demonstrate a highly efficient fiber-interfacing photonic device that directly launches single photons from quantum dots into a standard FC/PC-connectorized single-mode fiber. An optimally designed hole-based circular Bragg grating produces an ultra-narrow vertical beam whose emission angle matches the small numerical aperture of a single-mode fiber. The heterogeneously integrated fiber–quantum dot system enables the compact plug-and-play operation of single photons from a source to a detector with high coupling efficiency and long-term stability.

The future quantum photonic system requires the integration of highly reliable quantum light sources with low-loss optical channels as well as highly efficient single-photon detectors. Interfacing quantum dots with fiber optics opens the door for quantum networks that transmit quantum information over long distances and create remote entanglements between separated quantum systems. The primary challenge when connecting quantum emitters to fiber channels is the large mismatch in spatial field profiles of the dipole emission and the fiber mode. Several different approaches have been proposed for achieving high coupling efficiency between a quantum dot and a single-mode fiber, including integration of micro-optics and adiabatic coupling. However, they lack practicality and long-term reliability.

Here, we present efficient and compact plug-and-play single-photon sources based on hole-based circular Bragg gratings (hole-CBGs). Compared to conventional ring-based circular Bragg gratings, a newly designed hole-CBGs produces an ultra-narrow vertical beam whose emission angle matches the small numerical aperture of a single-mode fiber (Fig.1 (a)). The advantages of hole-CBGs come from several factors. First, according to the effective medium theory, hole patterns lower the refractive index contrast between air and matter (InP) than ring-CBGs. A smooth refractive index gradient in hole-CBGs enlarges the spatial mode size, resulting in a narrow divergence in momentum space. Moreover, hole-CBGs optimize the optical mode in both the radial and axial directions, whereas ring-CBGs optimize the structure parameter only in the radial direction. This additional degree of freedom enables further optimization of constructive and destructive interferences, resulting in highly enhanced vertical emission and suppressed higher-order diffraction. In the numerical simulation, the integrated hole-CBGs on a single-mode fiber (SMF28) can couple single photons more than 60%.

To implement a fiber-integrated single-photon source, we fabricated hole-CBGs on a telecom-emitting InAs/InP quantum dot membrane. Using a pick-and-place technique, the fabricated hole-CBGs were precisely integrated into the core of a single-mode fiber (Fig,1 (d)). The integrated fiber–QD system successfully demonstrated the efficient and reliable transmission of single photons into an all-fiber coupled system from a source to a detector without any optical alignment. The results represent a major step toward the practical and reliable transmission of quantum light across a fiber network.

Spin and level structure of positioned sulfur vacancies in MoS_2 acting as quantum emitters

A.W. Holleitner[1*]

[1]Walter Schottky Institute, TU Munich, Germany
[*]holleitner@wsi.tum.de

Abstract: We report on the level structure of single vacancies in monolayer MoS_2 and WS_2 which are generated by the help of a helium ion microscope at a lateral accuracy of <10nm. The vacancies turn out to be quantum emitters in the near-infrared electromagnetic regime. Moreover, we demonstrate the absorption characteristics of the defect emitters measured by utilizing both a cavity enhanced detection scheme and a highly sensitive photocurrent tunneling spectroscopy.

Summary: In our endeavor to explore atomistic quantum emitters in 2D materials, we report on the deterministic generation of optically active defects in monolayer MoS_2 and WS_2, which can act as single photon emitters [1-3]. The defects are generated by the help of a helium ion microscope on a lateral scale <10nm, and they can be attributed to single sulfur vacancies [4,5]. Based on high-field magneto-photoluminescence experiments, we demonstrate how to lift the spin-degeneracy of the involved defect states [6]. The results highlight that defects in 2D semiconductors may be utilized as spin-photon interfaces in quantum technologies even at zero magnetic field. In the last part, we highlight our recent experiments on the absorption characteristics of the sulfur vacancies by utilizing both, a cavity enhanced photonic detection scheme [7] and a highly sensitive photocurrent tunneling spectroscopy down to a single defect.

We acknowledge the very fruitful collaboration with J. Finley, K. Müller, A. Stier, and C. Kastl and financial support by the Munich Quantum Valley, MCQST, and e-conversion.

Modeling exciton dynamics behind single-phonon emission by interacting solid-state defects

A. Piryatinski

Theoretical Division, Los Alamos National Laboratory, USA
*corresponding author: apiryat@lanl.gov

Abstract: We discuss an open quantum system approach to model exciton dynamics within coupled multi-level states facilitating the spontaneous emission of quantum photons. Our goal is to establish a connection between statistics of emitted photons quantified by the two-photon correlation functions $g^{(2)}$, typically measured via the Hanbury Brown and Twiss (HBT) interferometry, and associated dynamics of the excitons. We apply these techniques to interpret experimental studies of single-photon emission properties of DNA-functionalized single-wall carbon nanotubes and indented MoS_2-WSe_2 2D layered heterostructures.

Ideally, a single photon emitter can be described by an isolated two-level system subject to incoherent pumping and radiative decay resulting in the production of single photons. However, the electronic structure of solid-state defects deviates from the two-level system by a manifold of interacting exciton states that includes spectrally separated bright states, dark states, and the band exciton states. Furthermore, the defect environmental fluctuations result in a broad variety of relaxation timescales, i.e., the exciton transfer and nonradiative decay rates. In this complex situation interpretation of experimentally measured two-photon correlation functions $g^{(2)}$, relies on the modeling of the exciton dynamics within multi-level state manifolds.

We approach this problem by implementing an open quantum system approach. Specifically, we describe the exciton states interacting with each other and the environmental bath using the reduced density operator, ρ. Its time evolution is governed by the following Liouville-Lindblad equation

$$\partial_\tau \hat{\rho}(\tau) = \frac{i}{\hbar}\left[\widehat{H}, \hat{\rho}(\tau)\right] + \sum_{\hat{C}_\uparrow} \widehat{D}_{\hat{C}_\uparrow}[\hat{\rho}(\tau)] + \sum_{\hat{C}_\downarrow} \widehat{D}_{\hat{C}_\downarrow}[\hat{\rho}(\tau)]. \quad (1)$$

Here, the first term on the right-hand side describes the defect's coherent dynamics governed by the exciton Hamiltonian $\widehat{H}$. The second term is a sum of all pathways for the incoherent excitation (irreversible energy pump) each defined by a set of collapse operators $\hat{C}_\uparrow$. The last term describes the dissipation pathways defined by a set of collapse operators $\hat{C}_\downarrow$. In Eq. (1), the Lindblad superoperator is

$$\widehat{D}_{\hat{C}}[\hat{\rho}] = \hat{C}\hat{\rho}\hat{C}^\dagger - \frac{1}{2}(\hat{C}^\dagger\hat{C}\hat{\rho} + \hat{\rho}\hat{C}^\dagger\hat{C}). \quad (2)$$

Leveraged by the quantum computational package QuTiP,[1] we developed a computational code for solving Eqs. (1) and (2) for an arbitrary multi-level system with the excitation and relaxation rates encoded into the collapse operators. With the help of the quantum regression theorem,[2] obtained trajectories for the density operator are used to evaluate the two-time exciton correlation functions

$$G^{(2)}_{ij}(t,\tau) = Tr\{\hat{\rho}\,\hat{b}_i^\dagger(t)\hat{b}_j^\dagger(t+\tau)\hat{b}_j(t+\tau)\hat{b}_i(t)\}, \quad (3)$$

where $\hat{b}_i$ and $\hat{b}_j$ are the ladder operators for defects *i* and *j*. Armed with these correlation functions, we can model the two-photon correlation function $g^{(2)}$ in the continuous-wave (CW) and impulsive excitation regimes. For the coupled defect states emitting quantum photons, this methodology provides us with a complete set of two-photon auto-correlation, $g_{i,i}^{(2)}$, and cross-correlation, $g_{i,j}^{(2)}$ functions.

We have applied this methodology to gain insights into the features of the auto-correlation and cross-correlation functions measured, using both CW and impulsive HBT interferometry, from coupled quantum defects in the DNA-functionalized carbon nanotubes[3] and indented MoS_2-WSe_2 layered heterostructures.[4] In Figure 1A, we show schematics of quantum defects created via chemical bonding between DNA segments wrapped around a (6, 5) single-walled carbon nanotube. Adopting a two-defect model interacting via the exciton band, we explained features of the experimentally measured (dots) CW defect total correlation function (panel B), spectrally filtered auto-correlation function of each defect (panels C and D), and the cross-correlation function of the defects (panel E). Our model fit is shown by solid lines. Each defect emits photons through the spontaneous decay of optically active two levels. This explains the strong anti-bunching at zero delay times in panels B-D. The bunching observed in the same panels for non-zero delay times is a signature of the dark (shelving) states. Most interesting is the behavior of the cross-correlation function in panel D. As our modeling confirmed, a sharp dip at zero delay time is a signature of the interaction between the defects via the exciton band. In general, we demonstrated the importance of the cross-correlation functions to carry unique signatures of the defect interaction mechanisms. Our further analysis (not shown in Fig. 1) reveals connections between histograms obtained in the impulsive and CW HBT measurements. Finally, theoretical modeling of the impulsive $g^{(2)}$ in MoS_2-WSe_2 layered heterostructures showed good agreement with the experiment and pointed towards the existence of long-lived, ~1 μs, dark states coupled to the optically active quantum defects.

Efficient outcoupling of light from single-photon emitters in 2D materials

R. Bratschitsch[1*]

[1]Institute of Physics and Center for Nanotechnology, University of Münster, Germany
[*]corresponding author: Rudolf.Bratschitsch@uni-muenster.de

Abstract: We demonstrate how single photons originating from 2D materials can be efficiently collected and routed either on a photonic chip or beamed into the far field. For on-chip coupling, we deposit GaSe crystals with embedded single-photon emitters onto silicon nitride rib waveguides. For efficient far-field collection, we 3D-print elliptical polymer microlenses on an array of hBN nanocrystals hosting single-photon emitters.

Single-photon sources are crucial components for building quantum networks and communications. Recently, single-photon sources in 2D materials have emerged as robust solid-state quantum light emitters [1]. Promising materials include transition metal dichalcogenides, such as WSe_2 or $MoTe_2$, transition metal monochalcogenides (e.g. GaSe), and also hexagonal boron nitride (hBN). For collecting and making use of single photons emitted from these 2D materials, different strategies can be envisioned, whether the photons are needed on-chip or in free space.

Interestingly, nonclassical light is commonly coupled onto photonic chips from the outside, because presently only few integrated single-photon sources exist. In my talk, I will present waveguide-coupled single-photon emitters in the layered semiconductor gallium selenide (Fig. 1, left) as promising on-chip sources [2]. GaSe crystals with a thickness below 100 nm are placed on Si_3N_4 rib or slot waveguides, resulting in a modified mode structure efficient for light coupling. Using optical excitation from within the silicon nitride waveguide, we find nonclassicality of generated photons routed on the photonic chip. Thus, our work provides an easy-to implement and robust light source for integrated photonic quantum technology.

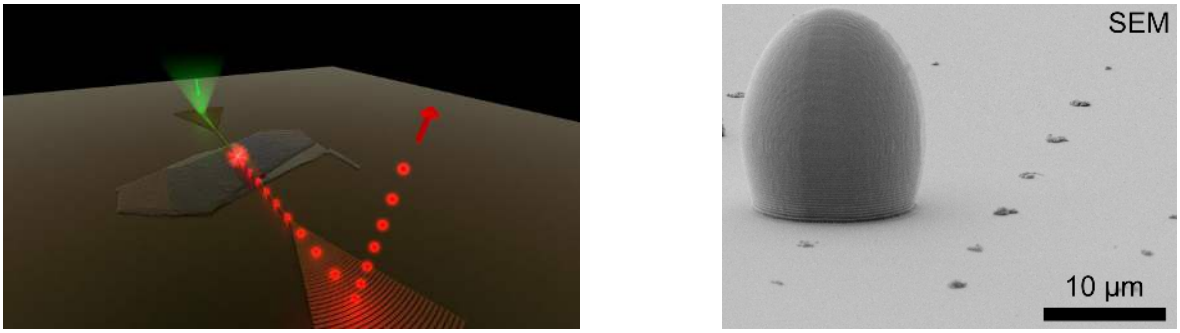

Figure 1. (left) Artistic impression of an on-chip single-photon source based on a GaSe crystal placed on a linear silicon nitride waveguide. To verify its operation, light used for excitation of the emitter is coupled into the waveguide with a grating coupler. Single photons are routed in the waveguide on-chip and are detected at the second grating coupler. (right) Scanning electron microscopy (SEM) image of an elliptical polymer microlens 3D-printed on a hBN nanocrystal.

Coupling light into the far-field calls for different methods. Ideally, the emitted light is collimated. In

contrast, expensive and bulky collection optics, such as objective lenses with a high numerical aperture are widely used today to collect the light emitted under high angles. We present polymer microlenses, which are 3D-printed directly on 2D single-photon emitters. We use commercially available hexagonal boron nitride (hBN) nanocrystals, which host the emitters. First, a regular array of hBN nanocrystals is created (Fig. 1, right) using capillary assembly [3]. Then, we 3D-print elliptical polymer microlenses with direct laser writing onto hBN nanocrystals, which host emitters. An ultra-low-fluorescence polymer ensures that negligible background luminescence is added to the single-photon stream. The light emission is efficiently collimated to angles below 5°, while the emission of the in-plane dipole in the 2D material without the microlens occurs mostly under high angles. The small angle of emission of the new single-photon source allows for using collection lenses with very low numerical apertures of NA > 0.06, including optical fibers.

In conclusion, we have demonstrated two efficient methods to efficiently harvest single photons from 2D materials, rendering these single-photon sources highly promising for quantum optics and photonic quantum technologies.

Nanometric axial localization of color centers in hexagonal boron nitride flakes

Pankaj K. Jha

Quantum Technology Laboratory ⟨Q | T | L⟩, Department of Electrical Engineering and Computer Science, Syracuse University, Syracuse, NY, USA
*Corresponding author: pkjha@syr.edu

Abstract: Novel materials are the backbone of next-generation quantum technologies. In this talk, color centers in hexagonal boron nitride, will be discussed as a promising candidate for single photon sources at room temperature. Nanometric axial localization of these color centers with 3D characterization of their dipole orientation will be highlighted.

Quantum emitters are the building blocks of photonic quantum technologies. Discovery of bright quantum light emission at room temperature from point defects in hexagonal boron nitride (*h*BN) has introduced a promising candidate for single photon emitter (SPEs) [1,2]. Owing to 2D nature of the host material, these SPEs offer easier integration with photonic structures and minimal loss due to refractive index mismatch. To date, emission characteristics of *h*BN quantum emitters in multi-layered flakes are superior to those in monolayer and few-layered flakes. However, the exact location of any quantum emitter within the thickness of a multi-layered flake remains unknown due to the random nature of defect formation. Determining the exact location and 3D orientation of their dipole moment is critical for quantum applications.

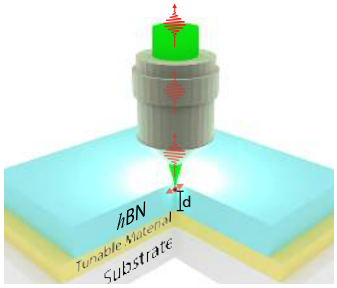

Fig 1: Extracting axial position *d* using a nanophotonic interface.

In this talk, I will discuss a tunable nanophotonic platform which can be employed to extract the axial position of quantum emitters in a multi-layered *h*BN with nanometer-scale accuracy while also determining their full dipolar orientation [3]. We leverage the sharp change in complex refractive index of vanadium dioxide (VO_2), a phase change material, at room temperature to tailor the optical environment and induce a highly sensitive, axial distance-dependent decay rate of a quantum emitter located in the vicinity of the *h*BN/VO_2 interface. Using our approach, we were able to locate several quantum emitters at a distance of ~ 20 nm from the surface of VO_2 with axial position uncertainty (full width) down to ~ 7 nm. Such accurate measurement of *h*BN quantum emitter's location and 3D orientation together with advances in precise transfer and stacking of 2D materials, interfacing with engineered interfaces (4-6) would offer unprecedented opportunities for both fundamental physics advances and quantum photonic technologies.

Carbon nanotubes and atomically thin materials integrated with silicon photonic crystal nanocavities

Y. K. Kato[1,2*]

[1]Nanoscale Quantum Photonics Laboratory, RIKEN Cluster for Pioneering Research, Saitama 351-0198, Japan
[2]Quantum Optoelectronics Research Team, RIKEN Center for Advanced Photonics, Saitama 351-0198, Japan
[*]corresponding author: yuichiro.kato@riken.jp

Abstract: Excitons in carbon nanotubes exhibit single photon emission at room temperature, and their telecommunication wavelength emission make them ideal for integration with silicon photonics. We have recently developed a transfer process utilizing anthracene crystals which allows for deterministic coupling of a nanotube emitter to a cavity. The same transfer process can be used to integrate atomically thin materials with the cavities, offering opportunities for manipulation of the photonic structures.

Electron-hole pairs form tightly-bound excitons in carbon nanotubes due to limited screening of the Coulomb interaction, and these stable excitonic states exhibit single photon emission at room temperature. Furthermore, they are ideal for integration with silicon photonics as their emission is in the telecommunication wavelength range [1,2]. In pristine air-suspended nanotubes, efficient exciton-exciton annihilation leads to antibunching [3], and cavity quantum electrodynamical effects can be utilized by coupling to silicon photonic crystal nanobeam cavities [4]. Functionalizing the nanotubes with organic molecules [5,6] should further enhance their performance. To overcome the low device yields with the probabilistic approach, we have developed a transfer process which allows for deterministic coupling of a nanotube emitter to a cavity [7]. Single-crystalline anthracene is used as a medium which readily sublimes by mild heating, leaving behind clean nanotubes and thus enabling bright photoluminescence. We are able to position nanotubes of a desired chirality with a sub-micron accuracy under in-situ optical monitoring. The anthracene assisted transfer process can also be used to integrate atomically thin materials with the nanobeam cavities to manipulate their properties [8]. With atomically precise thickness over a macroscopic area, few-layer flakes give rise to quantization of the mode shifts.

Abstract: We investigate 3-level quantum ladder systems in optically active quantum dots and use additional stimulation lasers to tailor the emitted photons properties. We are able to realize highly indistinguishable photons and the on-demand generation of frequency tuned single-photons with polarization control.

With the advent of the second quantum revolution, striving for real-world applications of photonic quantum technologies, enormous efforts have been made to develop and optimize the necessary building blocks, in particular quantum light source. In recent years, epitaxial semiconductor quantum dots have made substantial progress as suitable quantum emitters.

One big advantage of quantum dots is their biexciton-exciton cascade forming a 3-level quantum ladder system commonly used to generate entangled photon pairs. However, the cascaded emission typically hinders the generation of highly indistinguishable photons, due to the intrinsic time correlation of the cascade [1]. To overcome this challenge, we proposed to use tailored Purcell enhancement to change the life time ratio between the exciton and biexciton states. The realization of such nanostructured cavities is technologically very demanding but to experimentally proof the concept we artificially reduced the biexciton excited state life time using a depopulating control laser [2]. With this technique we were able to restore the degree of indistinguishability to the level of the strictly resonantly excited exciton case. The benefit of using the two-photon excitation of the cascade plus a depopulating control laser is that we not only restore the degree of indistinguishability but also maintain the lower multi-photon emission stemming from the two-photon excitation of the cascade. Thus our scheme combines the advantages of strictly resonant excitation of the exciton (high indistinguishability) and two-photon excitation of the cascade (low multi-photon emission).

Furthermore, we are able to detune the control laser to use a virtual state for the realization of a stimulated spontaneous down-conversion process [3]. This process, which can also be explained in the dressed state picture, enables the on-demand generation of frequency tuned single-photons with polarization control. Based on our theoretical framework, we expect that the efficiency and tuning range of the down-conversion process can be vastly improved by the employment of cavities with high Purcell-factor.

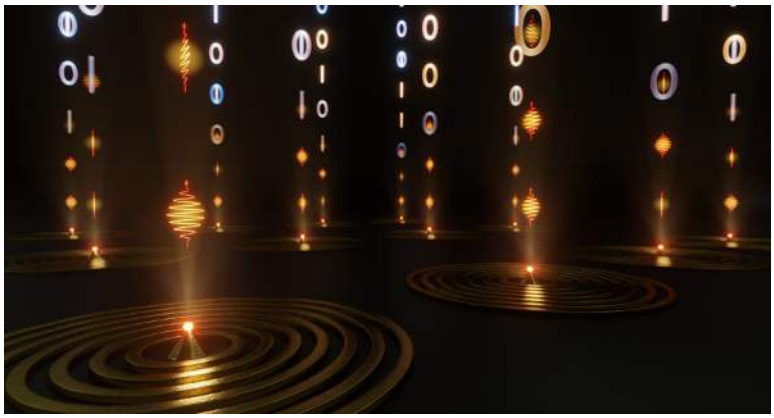
Room-temperature ultrabright single photon sources based on colloidal quantum dots on directional resonator-antennas: towards high dimensional encoding of photonic qudits



Ronen Rapaport[1, 2,*]

[1]*Racah Institute of Physics, The Hebrew University of Jerusalem, Jerusalem 9190401, Israel*

Abstract: we present a novel approach that overcomes the outstanding challenge of the rate-directionality tradeoff of monolithic single photon sources operating at room temperature, and demonstrate ultrabright, highly directional single photon sources based on colloidal quantum dots positioned on a hybrid nano-resonator – antenna device, that can be used for both free-space and fiber applications. We also demostrate methods for encoding high-dimensional qudits on the different spatial degrees of freedom of the photons emitted from these sources.

Deterministic GHz-rate single photon sources at room-temperature would be essential components for various quantum applications. However, both the slow intrinsic decay rate and the omnidirectional emission of typical quantum emitters are two obstacles towards achieving such a goal which are hard to overcome simultaneously. We solve this challenge by a novel hybrid approach, using a complex monolithic photonic resonator constructed of a gold nanocone responsible for the rate enhancement, enclosed by a circular Bragg antenna for emission directionality [1,2]. A repeatable process accurately binds giant colloidal quantum dots that show blinkingless emission which is stable over hours, to the tip of the antenna-embedded nanocone. As a result we achieve simultaneous >20-fold emission rate enhancement and record-high directionality leading to an increase in the observed brightness by a factor as large as 450 (80) into an NA = 0.22 (0.5). We project that these miniaturised on-chip devices can reach photon rates approaching 1.4×10^8 single photons/second thus enabling ultrafast light-matter interfaces for quantum technologies at ambient conditions.

We further demostrate a significant progress towards a practical plug-and-play single photon source with an antenna device which allows back optical pumping of the quantum dots and a front directional single photon emission with high single photon purity and an almost unity colllection efficiency [3-6], as well as a direct coupling to a fiber without any coupling optics.

Finally, we show two distinct methods for encoding high-dimentional quantum information on the spatial degrees of freedom of the emitted photons. The first method takes advantage of the radial polarization nature of the emitted photons from the resoator-antenna device to encode information on mutually unbiased hybrid polarization modes. The second method utilizes spatial light modulators to encode information on the spatial orbital angular momentum states of the unpolarized photons emitted from the quantum dot.

Biography

Ronen Rapaport is a Professor at the Racah Institute of Physics at the Hebrew University of Jerusalem, Israel (HUJI). Ronen has received his PhD in Physics from the Technion, Israel in 2001, where he studied the physics of exciton polaritons. Ronen then became a principle investigator (MTS) at the Optical Physics department, Bell Laboratories, where he conducted research in various fields related to quantum nano-structures of semiconductors until 2007. Ronen is heading the Nanophotonics of quantum structures Lab at HUJI, with research efforts ranging from many-body quantum physics of excitons and polaritons in low dimensional quantum structures, to light-matter coupling of quantum emitters and nano-optical devices.

Generating Quantum Emitters in 2D Semiconductors Using UV Light

Xuedan Ma
Argonne National Laboratory
xuedanma@anl.gov

The controlled creation of quantum photon sources in two-dimensional transition metal dichalcogenides (TMDs) has attracted considerable interest primarily due to the unique characteristics of TMDs. Studies have discovered that both local strain modification[1] and ion beam irradiation[2] are viable approaches for creating quantum defects that are capable of single photon emission.

In this work, we report an alternative approach for generating quantum photon sources in TMDs utilizing easily accessible UV light.[3] This method leverages two recent findings: the small formation energies (a few eV) of chalcogen vacancies in this group of materials,[4] and the association of such chalcogen vacancies with single photon emitters.[5] By irradiating MoS_2 monolayers in vacuum with UV light, we discover quantum defects capable of single photon emission can be created. The success of this approach relies critically on the irradiation environment: only defects that are generated in vacuum exhibit single photon emission characteristics, whereas those created in air do not support single photon emission. Combining the optical features of the UV-induced defects with density functional theory calculations, we attribute the quantum defects generated in vacuum to pristine sulfur vacancies, whereas those in air to oxygen-passivated defects. These findings suggest that energies provided by UV photons are sufficient for creating quantum emitters in TMDs.

Abstract: We performed 1-2 keV focused Au implants into Si, in which the depth was validated by atom-probe tomography. We show that identical results are achievable by either lowering the column voltage, or decelerating ions using bias – while maintaining nanoscale spatial resolution. Furthermore, our data reveal that standard implant modeling overestimates experimental depth by 4.7× and 3.8× at 1 and 2 keV respectively. Finally, we demonstrate how our results pave a way to eV-scale implantation energies, while maintaining high spatial resolution.

Technological scaling towards smaller devices and shallower junctions requires decreasing ion energy. In parallel, the integration of novel materials necessitates additional ion species. Lastly, integration of 2D materials requires ion implantation to deterministically target single atomic layers, at precise location[1]. Focused ion beams (FIB) have demonstrated the ability of targeting nanoscale features, and using liquid metal alloy ion sources, a variety of ion species is available with isotopic resolution, required for QIS applications due to precise control over implanted ion hyperfine coupling. Here, we address the gap of low energy and precise positioning of exotic ion species by combining a multi-species FIB with a biased sample holder to allow implantation at 1 keV enabling a path towards implantation at eV-scale energies. The results of implantation by low source energy are compared to those using the biased plate and show agreement in ion range and straggle.

We use a 35 kV Raith VELION to implant Au. The ion landing energy is determined by both the source voltage and the bias plate voltage Fig. 1(a). We implant at V_S = 1,2,5 kV with the biased plate held at V_P = 0,0,4 kV leading to ion landing energies of 1, 2, and 1 keV, respectively.

The implants are assessed by atom-probe tomography (APT), a highly depth sensitive technique, although sample requirements are stringent. Commercially available pre-sharpened Si tips were used as the substrate for Au ion implantation for the APT experiment. As-received tips were first be pre-dulled in the APT setup using voltage mode and stopping at 5 kV to increase the top surface area because as-received tips consist only of a few unit cells at the surface. A scanning electron microscope image of a pre-dulled tip is shown in Fig. 1(b) with the original tip shape denoted by the white lines. APT is ideal for this measurement because it is a three-dimensional projection microscope equipped with a time-of-flight mass spectrometer that is capable of Å depth resolution (z). The resulting implant depth reconstruction of a tip is shown in Fig. 1(c). The datapoints are the measured Au concentration with different implant condition. Blue points correspond to V_S = 1 kV, V_P = 0 V, E = 1 keV, magenta points are V_S = 2 kV, V_P = 0 V, E = 2 keV, and red points denote V_S = 5 kV, V_P = 4 kV, E = 1 keV. The dashed lines are Gaussian fits to the data. Additionally, the results from Stopping and Range of Ions in Matter (SRIM) simulation are shown as the cyan (green) curves for E = 1 (2) keV, respectively. Notably, SRIM overestimates the range of ions by 4.7×, and 3.8×, at 1 and 2 keV, respectively. This discrepancy is explained by SRIM not considering multiple collisions, which are a significant stopping mechanism at low energy[2].

Lastly, we assess the feasibility of focused low energy implantation, required for devices. For this, we simulate a simplified version of the FIB in SIMION, consisting of a collimated beam being focused by an Einzel lens. The

optimal focus solution obtained at V_S = 5 kV, V_P = 0 kV, E = 5 keV is found to be a spot with 60 nm diameter. Then, the same focusing solution is used but V_P is increased to 4 kV, such that E = 1 keV, similar to the experiment performed in Fig. 1(a). Since refocusing of the beam using the biased plate may not be feasible due to the low ion energy leading to low secondary electron yield and the biased plate attracting any secondary electrons, we believe this to be a reasonable estimate of the best achievable spot size using this technique. We find that the ion beam diverges to form a 500 nm beam spot on the sample. However, by refocusing the Einzel lens our SIMION simulations shows we can obtain an 80 nm spot by changing the Einzel lens voltage by only 0.74 %.

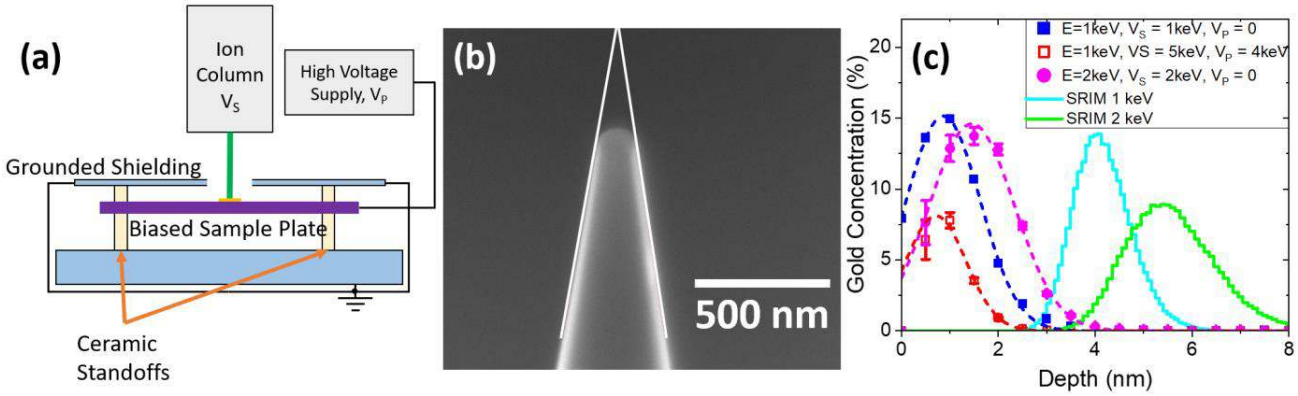

Figure 1(a) Schematic of the low energy focused ion implantation setup. The ion column produces ions at energy $q \times V_S$ where q is the ion charge state and V_S is the source voltage. The high voltage plate decelerates ions such that the ion landing energy $E = q \times (V_S - V_P)$. (b) Dulled APT tip used for measuring implant depth. The original tip shape is denoted by the white lines. (c) Measured implant depth using APT (points) and Gaussian fit (dashed lines). The corresponding ion landing energy SRIM simulations are shown as the solid lines.

In conclusion, we have implanted Au ions at landing energies of 1 and 2 keV and verified the implant depth using APT. Our results show the implant depth at 1 keV is 0.8 nm and at 2 keV it is 1.45 nm. SRIM simulations are found to be inadequate at these ions energies, overestimating the implant depth by 4.7× and 3.8× at 1 and 2 keV, respectively requiring more involved treatment of the modeling of low energy implantation. We also present a focusing solution of the decelerated ions using SIMION, showing a 60 nm beam spot can be achieved for 5 keV Au ions while a 1 keV ion may be focused to a 80 nm spot size.

Abstract: Elastic waves and phonons are an indispensable resource for radio frequency signal processing. Recently, elastic waves have been recognized as versatile transducers between dissimilar quantum systems for hybrid quantum technologies. Here show recent advances including piezo-optomechanical wave mixing by a single quantum dot, acoustically regulated single photon emission or dynamic routing of on-chip generated single photons. Finally, we highlight how the governing acousto-optic interactions can be deliberately enhanced in heterogeneously integrated devices and nanophononic devices.

Over the past decades, innovation for radically new devices was mostly driven by controlling electrons and photons: microelectronics (electrons) and photonics (photons) revolutionized our everyday life. Today, Surface Acoustic Waves (SAWs) and other types of elastic waves are one of the only very few phononic technologies of industrial relevance. Acoustic radio frequency filters, for instance, are integral parts of wireless devices and SAWs find applications in life sciences and microfluidics for sensing and mixing of tiny amounts of liquids (1). In fundamental and applied research, these “nanoquakes on a chip” provide an extremely useful and versatile tool for massively parallel addressing a broad variety of nanosystems at radio frequencies via strong acousto-mechanical and acousto-electric couplings.

In this presentation, we highlight our recent advances towards the realization of hybrid phononic quantum technologies. We synergistically couple single quantum emitters in the form of III-V compound semiconductor quantum dots (QDs), laser photons and phonons in the form of nanoscale sound waves and demonstrate several key functionalities required for hybrid quantum technologies. Specific examples include the deliberate coherent control of optically active quantum dots and their coupling to light by the SAW’s coherent acoustic field. The coherent optomechanical coupling gives rise to wave mixing between optical photons and GHz phonons by the optical dipole of the quantum dot (2). Moreover, QDs embedded in integrated photonic structures enable precisely triggered single photon generation by dynamic modulation of the Purcell-effect (3) or single photon routing at GHz frequencies in a SAW-modulated integrated Mach-Zehnder interferometer (4). Finally, we show

that these concepts can be transferred to a hybrid architecture comprising epitaxial QD membranes heterogeneously integrated onto $LiNbO_3$ (5,6). This novel class of devices combines the superior optical properties of semiconductor QDs and strong piezoelectricity of $LiNbO_3$ for efficient on-chip optomechanical quantum transduction, ultimately in the limit of single quanta.

Carbon nanotubes have emerged as solid-state sources of quantum light for advances in quantum photonic technologies [1]. In particular, luminescent quantum defects in carbon nanotubes with deep exciton-localizing potentials are known to exhibit highly non-classical correlations in photon emission statistics up to room temperature [2] with emission wavelengths that can be tailored to the telecom band [3]. Here, we report successful incorporation of luminescent quantum defects with room-temperature telecom-band single-photon emission into a fiber-based open microcavity [4] and report the characteristics of the coupled system in the regime of incoherent good cavity coupling [5].

ABSTRACT: 2D semiconductors such as transition metal dichalcogenides (TMDs) and defects in hBN are ideally suited for solid-state cavity quantum electrodynamics (cQED) investigations. The exciton binding energies in TMDs are very strongly bound and emission linewidths close to the homogeneous limit when monolayers, hetero- and homo-bilayers are suitably encapsulated by hexagonal boron nitride (hBN). In addition, 2D-heterostructures can be readily attached to a wide range of substrates, making them ideally suited for solid-state cQED experiments with heterogeneous integration.

In this contribution, we describe our recent investigations of the heterogeneous integration of 2D materials onto novel Si_3N_4 nanobeam optical cavities [1-5]. Such zip-tie nanobeam optical resonators host ultra-high $Q > 10^4 - 10^5$ cavity modes and allow us to explore novel light-matter and multimodal *vibronic – phonon – photon* couplings mediated by electronic excitations. For hBN-encapsulated MoS_2 monolayers, we observe a nonmonotonic temperature dependence of the cavity-trion interaction strength, consistent with the nonlocal light-matter interactions in which the extent of the centre-of-mass wave function is comparable to the cavity mode volume in space [1]. For $MoSe_2$ homo-bilayers [2], we study the twist-dependent moiré coupling. For small angles, we find a pronounced redshift of the K−K and Γ−K excitons, an effect that we trace to the underlying moiré pattern. Studies of thick hBN layers coupled to ziptie cavities reveal intriguing dynamics: For example, we identify the zero phonon line transition of charged boron vacancies (V_B^-) [3,4] and observe a novel tripartite coupling between the cavity photonic modes, lattice phonon and nanobeam vibrational modes. The fingerprint for this tripartite coupling is a pronounced asymmetry in the emission spectrum for cavities with Q-factor above a threshold of ~10^4. Similar asymmetries are not observed for cavities without V_B^- centers, or lower Q-cavities. To explain our findings, we model the system with phonon-induced light-matter coupling and compare it to the Jaynes-Cummings model for usual emitters. Our results reveal that the multipartite interplay arises during the light-matter coupling of V_B^- centers, illustrating that it is phonon-induced, rather than caused by the thermal population of phonon modes. Our results indicate how different photon (V_B^- emission, cavity photonic) and phonon (V_B^- phonon, cavity mechanical) modes provides a novel system to interface spin defects, photons and phonons in condensed matter systems.

Abstract: *: The stacking of 2D materials in Moiré heterobilayers provide a novel platform to study intra and interlayer excitons. Of interest for quantum science is the bilayers exhibit a natural and periodic trapping potential that enables a spatially periodic array of programmable quantum emitters. In this talk we discuss the $MoSe_2$-WSe_2 system. The atomically sharp interface between the two monolayers creates an effective type-2 heterojunction that allows ultrafast charge transfer and the existence of trapped interlayer excitons upon optical excitation. Our work investigates and elucidates the nature of the quantum emitter ensemble in these materials. We demonstrate the existence of valley coherence for trapped trions, excitons, and biexcitons. Our results contribute to an understanding of trapped excitonic species in these systems and how they may be utilized for quantum information storage.*

A. Observation of Valley Coherence

Moiré excitons represent a new paradigm in exciton photophysics and should inherit some photophysical properties from the constituent monolayer materials[1-5]. One characteristic, excitonic valley coherence, is well-studied in monolayer transition metal dichalcogenides [6-8]. In this work, we use low-temperature polarization resolved micro-photoluminescence (PL) spectroscopy to characterize interlayer exciton valley coherence in H-type $MoSe_2$/WSe_2 Moiré hetero-bilayers.

In Figure 1, an exemplary data set on valley coherence is presented. The valley coherence is measured as a function of the laser illumination wavelength. To access the valley coherence, linearly polarized laser excitation excites the sample excitons. PL with a polarization oriented parallel (perpendicular) to the excitation direction is measured. From the recorded spectrum, the degree of valley is calculated by taking the difference between the measured spectra over their sum. The left panel of Fig. 1 and middle panel of Fig. 1 presents the recorded parallel and perpendicular spectra for an excitation wavelength of 725 nm and 705 nm. In the right panel of Fig. 1 the spectral variation of the valley coherence is shown. Similar to the degree of valley polarization [9-11], the A-exciton resonances of both $MoSe_2$ and WSe_2 lead to larger amounts of observed valley coherence.

We note that on average the observed degree of valley coherence found in the sample (~10%) is less than that reported for monolayers. This can be attributed to the spatial nonuniformity in PL we have seen across the interlayer region. In certain sample locations we did observe valley coherence of ~ 50%, but it was not the average observed behavior.

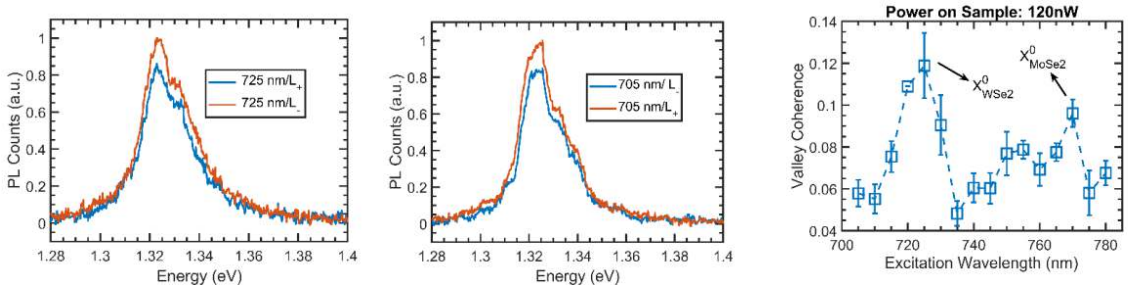

Figure 1 PL from interlayer excitons showing different intensities for parallel-polarized (L_+) and perpendicularly-polarized(L_-) emission. The left panel is for 725 nm excitation and the right panel is for 705 nm excitation. Both data sets exhibit valley coherence. Right panel is the variation observed in valley coherence as a function of excitation wavelength. For all data the excitation laser powers is kept at 120 nW.

Abstract: Colloidal quantum dots (cQDs) synthesized in simple laboratory flasks are finding real-world applications in demanding technologies from displays and lighting to photovoltaics and photodetectors. In the future, cQDs may be the basis for single-photon devices in quantum networks. Beyond quantum-size control, we pursue an expanded "structural toolbox" to synthetically engineer new quantum emitters with optimal photophysical properties.[1-8] Taking advantage of their solution-phase processibility, we demonstrate deterministic, direct-write placement of the quantum emitters into photonic and plasmonic platforms using scanning-probe techniques.[9,10]

New cQDs and other nanocrystalline semiconductor quantum emitters continue to be discovered. Here, I will describe our efforts using two strategies to identify and control quantum optical properties in new/optimized systems: (1) solution-phase chemistry to "nanoengineer" all aspects of the nanocrystal via a deep understanding of synthesis-nanostructure-property relationships (Figure. 1a-c) and (2) deterministic integration of quantum emitters with nanoplasmonic/photonic structures via a scanning-probe technique (Figure 1d).

Recently, we demonstrated through designed shell growth PbS/CdS core/shell cQDs that could deliver single photons in the telecom O and S bands at room-temperature, obtaining single-emitter spectra at this elevated temperature for the first time.[1] Two shell-growth methods—cation exchange and successive ionic layer adsorption and reaction (SILAR)—were employed to prepare cQD heterostructures with shells of 2–16 monolayers, allowing us to identify the shell properties responsible for enhanced stability. With collaborators we have since rectified the inherently slow photon-delivery rate characteristic of Pb-chalcogenide cQDs by integration with nanoplasmonic antenna—demonstrating >2000-fold rate enhancement with retention of non-blinking/non-photobleaching behavior.

Deterministic emitter-photonic/plasmonic integration has been aided by our development of a three-step reading-inking-writing approach using dip-pen nanolithography (DPN).[9,10] First, atomic force microscopy (AFM) images of a nanostructured surface are obtained that serve as a "topography map" to guide writing of liquid ink. The DPN "ink" comprises gQDs suspended in a solvent, e.g., *o*-dichlorobenzene. Systematic analyses of factors influencing deposition rate—dwell time, ink-substrate contact angle and ink volume—were assessed for flat substrates and pushed to small (sub-500 nm) feature sizes.[9] This knowledge was subsequently translated to the 3-step writing process to deposit cQDs onto photonic or plasmonic nanostructures, now down to the single-QD level.[10] Overall, the results lay the groundwork for expanded use of nanocrystal liquid inks and DPN for fabrication of multi-component nanostructures that are challenging to create using traditional lithographic techniques.

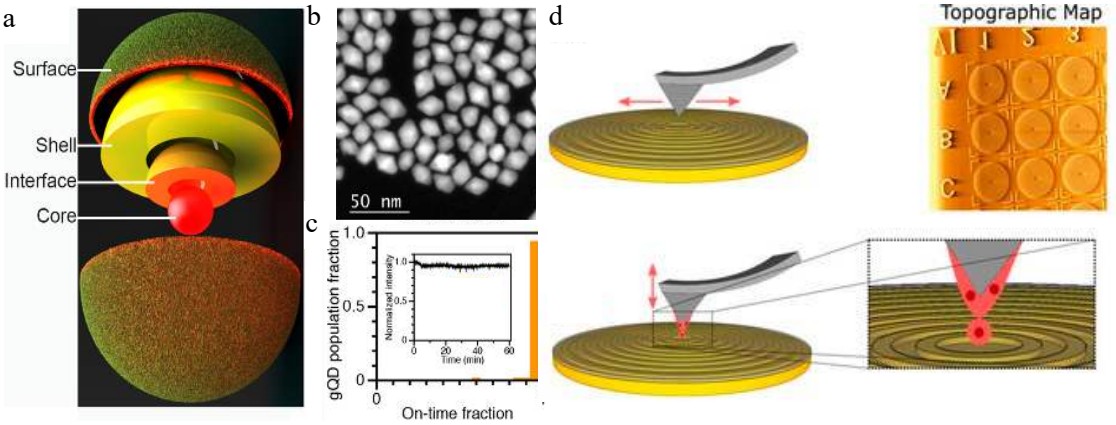

Figure 1. (a) Schematic illustration of the components of a core/shell QD from the inside out. Whether a spherical QD or some other shape, these components must be synthetically controlled to obtain ideal single-photon emission. **(b)** High-angle annular dark-field (HAADF-STEM) image of CdSe/CdS "giant" QDs (gQDs), the prototype gQD.[8] **(c)** On-time fraction as a function of CdSe/CdS gQD population fraction under high pump-fluence widefield excitation and collection conditions (1 W/mm^2, 405 nm continuous-wave excitation, room-temperature), demonstrating non-blinking behavior—*a key attribute for an on-demand quantum emitter that has now been extended from the blue-green to the full telecommunications window*.[1-7] Inset shows non-photobleaching over a long observation time (1 h). **(d)** Precision additive nanofabrication via dip-pen nanolithography (from Ref. 10): **(top)** An AFM scan of the area of interest is conducted; right panel shows an actual image of the scanning of an antenna array comprising hybrid metal–dielectric bullseye antennas. **(bottom)** AFM writing tip is wetted, and a droplet of dilute QD suspension is placed at the center of each bullseye structure (guided by the image created in the first step), leaving behind a single QD or a small cluster with ~25% success rate, far exceeding random distribution approaches.

Localized Dipolar Excitons in 2D Semiconductors for Quantum Sensing of Correlated Electrons

A. Srivastava[1*]

[1]Emory University, USA

[*]corresponding author: ajit.srivastava@emory.edu

Abstract: We report localized dipolar excitons as high-resolution quantum sensors of generalized Wigner crystals in $WSe_2/MoSe_2/WSe_2$ heterotrilayer.

Atomically thin materials, such as graphene and transitional metal dichalcogenides (TMDs), are at the forefront of research in materials physics. This is largely due to the ease with which they can be combined into artificially engineered heterostructures that exhibit emergent electronic and optical properties. Enhanced Coulomb interactions in the truly 2D limit, reduced kinetic energy of electrons in moiré heterostructures and the presence of nontrivial quantum geometry is a perfect recipe for strongly correlated and topological electronic phases. Moreover, strong light-matter coupling results in stable optically excited quasiparticles such as excitons and their neutral and charged complexes. Furthermore, moiré heterostructures present a unique opportunity to study the interplay of correlated electrons and excitons. While electronic phases have garnered a lot of attention, many-body correlated phases of interacting optical excitations remain poorly studied. These out-of-equilibrium quantum phases could also serve as sources of exotic light.

In this talk, I will begin by highlighting some unique properties of excitons in TMDs. Next, I will show how trapped dipolar excitons can serve as high-resolution quantum sensors of correlated electronic phenomena[1]. Finally, I will talk about our recent efforts to engineer the internal structure of excitons to tune the strength and sign of excitonic interactions[2] as a step towards realizing on-demand quantum matter in a driven-dissipative setting.

Abstract: We demonstrate the first site-controlled integration of an SiN/SiO2 single photon emitter (SPE) with a topology optimized coupler. Previously our group demonstrated the large scale fabrication of such emitters in nanopillars with high yield (67%). This work leverages this fabrication process to allow for the large-scale integration of such nanopillar SPEs with complex nanophotonic devices such as topology optimized couplers. This is a major step on the path towards wafer-scale fabrication of quantum-photonic circuitry with precisely integrated SPEs.

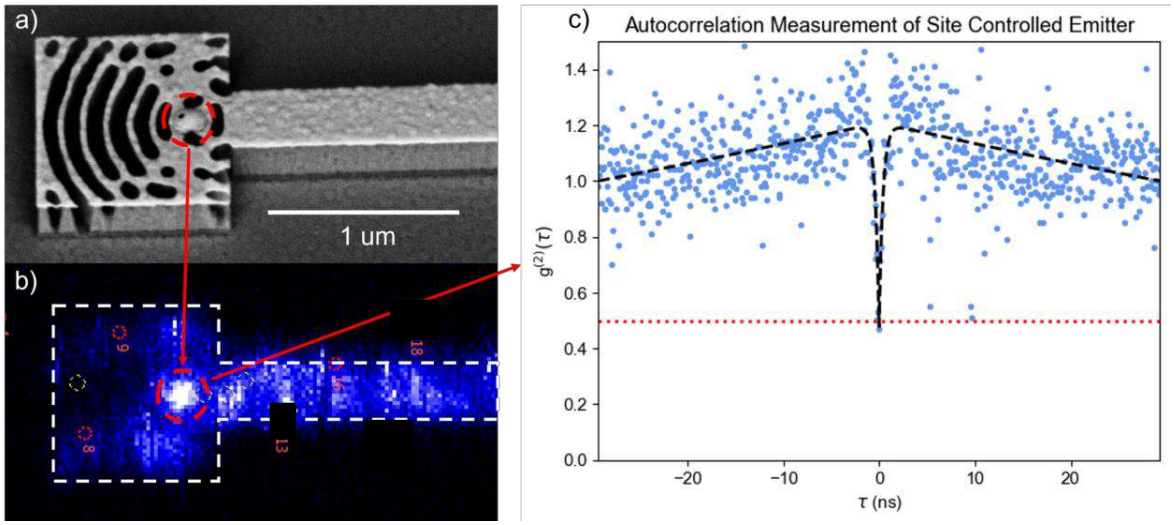

Figure 1 a) A scanning electron microscopy image of a fabricated TO coupler. The red circled bump is the location of the nanopillar hosting the SPE. **b)** A photoluminescence image of a similar structure, the red circled bright spot is the location of the embedded SPE, **c)** An autocorrelation measurement with the Hansbury-Brown-Twiss setup showing a dip at 0 of 0.47 indicating that the bright spot is hosting a SPE.

For photonic quantum information systems and technology (QIST), photons are the basic information-carrying units. One of the major approaches for generating single photons useful for QIST application is the application of solid-state single-photon sources – mechanically stable, bright, on-demand, and potentially ultra-compact sources of indistinguishable photons. However, integrating such emitters into nanophotonic structures is generally very challenging, both from a design and fabrication point of view [1–4]. One of the challenges is to efficiently channel the SPE light into nanophotonic circuitry with high efficiency [1–4].

We will briefly overview an adjoint topology optimization scheme used to design high-efficiency couplers [5]. This technique is computationally tested for coupling light emitted by an hBN SPE into a single-mode on-chip

silicon nitride (SiN) waveguide.

Recently, a new type of SPEs occurring at the interface between SiN/SiO_2 was discovered. They have proven to be bright, stable, and, most importantly, native to SiN [6], making its integration with SiN circuitry much more straightforward and monolithic. We demonstrated some initial integration of such emitters with on-chip waveguides and developed a novel technique for the site-controlled fabrication of SiN/SiO_2 emitters achieving 67% yield with an estimated lateral placement accuracy < ±85nm [7]. The approach includes fabricating SiN/SiO_2 nanopillars followed by thermal processing. Since the emitters are defined lithographically, multi-mask alignment techniques can create other structures aligned with the SPE-filled nanopillars. This is leveraged to align TO couplers and other nanophotonic elements with SPE-containing nanopillars. The scanning electron microscopy (SEM) image (figure 1a) shows the TO coupler etched around the emitter. The emitter is visible as the red circled bump where the emitter is encased in the SiN layer forming the TO coupler and waveguide. Figure 1b depicts an image of a similar structure using a custom-built scanning confocal photoluminescence setup at room temperature. As expected, the red-circled bright spot in the photoluminescence image is right at the SPE location. Finally, $g_2(0)$ measurement with a typical Hanbury-Brow-Twiss setup at room temperature confirms that the emission originates from an SPE with a $g_2(0)$ of 0.47.

In conclusion, we will briefly overview a technique for designing TO couplers. We also discuss the large-scale production of such couplers with precisely integrated SiN/SiO_2 SPEs leveraging a novel site-controlled fabrication technique. The method allows for high yield and precision alignment of such SPEs with complex nanophotonic elements such as TO couplers. As a proof of concept, we demonstrate the successful integration of such site-controlled emitters with TO couplers. Future work will involve further optimization and customization of the TO techniques to leverage and enhance this exciting industrially-scalable method of integrating SPEs with nanophotonic circuitry.

Abstract: We investigate two-photon interference of a quantum emitter generated in hexagonal boron nitride (hBN) using an electron beam. We measure the correlations of zero-phonon-line photons in a Hong-Ou-Mandel (HOM) interferometer under non-resonant excitation. We find that the emitted photons exhibit a partial indistinguishability of 0.56 ± 0.11 in a 3 ns time window, after accounting for imperfect emitter purity. With this result, we provide the first demonstration of photon indistinguishability from a 2D material quantum emitter.

In the context of photonic quantum information science, hexagonal boron nitride (hBN) has emerged as a very promising material. The two-dimensional character of hBN renders it attractive for the realisation of compact heterostructures and integrated photonic devices. Moreover, this wide-gap material has been shown to host single-photon emitters (SPEs) with appealing optical properties in the red and near infrared regions[1]. However, the deep defects initially observed in hBN suffer from the wide distribution of their emission wavelength and, in most cases, a random spatial location[2,3]. These limitations hinder the scalability of the system for applications.

Recently, a new family of quantum emitters has been observed in hBN – a class of blue-emitting colour centres that have appealing properties[4,5,6]. We demonstrate deterministic positioning of these SPEs with reproducible emission wavelengths, based on irradiation with an electron beam[5,7]. The SPEs are locally activated in exfoliated hBN flakes using a focused electron beam and subsequently characterised using microphotoluminescence (fig. 1,2). They exhibit narrow linewidths at low temperature and a drastically reduced ensemble distribution of their emission wavelength ($\Delta\lambda < 1$ nm) (fig. 3). Individual emitters display low $g^{(2)}(0)$ as well as high and stable count rates. Moreover, emission is observed up to room temperature.

Finally, we investigate two-photon interference between consecutively emitted photons based on the Hong-Ou-Mandel effect. We use coherent photons from the zero-phonon-line that are obtained under non-resonant excitation. This measurement leads to a sizeable degree of indistinguishability[8] of 0.56 ± 0.11 in a 3 ns time window, after accounting for imperfect emitter purity (fig. 4). The dependence of the HOM visibility on the width of the post-selection time window allows us to estimate the dephasing time of the emitter to be ~ 1.7 ns. This is the first observation of photon indistinguishability from a 2D material quantum emitter and opens the way to the use of these SPEs for quantum information applications.

Our results suggest new avenues towards top-down realisation of integrated quantum optical devices based on indistinguishable single photon sources in hBN.

Abstract: We created single-photon sources that are directly integrated into a monolithic hBN (hexagonal Boron Nitride) waveguide. The color centers are locally activated using an electron beam and emit photons at 436 nm that couple to the guided mode and can be collected after having crossed the waveguide. Such structure would be the starting point for designing a nanophotonic circuit.

Single-photon emitters in hexagonal boron nitride are promising candidates for applications in integrated quantum nanophotonics. One requirement for creating quantum photonic circuits is to find a way to couple a quantum emitter to the guided mode of a photonic waveguide. Several structures have already been developped, including hybrid integration of a quantum dot on a silicon waveguide [1], or etching of a monolithic waveguide around previously created color centers [2,3].

Here we propose a protocol that starts with the fabrication of the waveguide by performing electron beam lithography on an exfoliated hBN flake. Then we integrate a quantum emitter within the waveguide by electron irradiation. Indeed this technique enables position-controlled activation of defects that emit single photons at 436 nm [4,5,6]. Previous studies on these color centers have shown that they display high and stable count rates, good single-photon purity and coherence properties that allow indistinguishability between the emitted photons [7,8].

After irradiation the waveguides are studied with a confocal microscope at room temperature. The emitters are spotted along the waveguide and their photophysical properties are determined using usual photon-counting techniques. Then, the excitation path is decoupled from the collection path in two different manners. First, the excitation laser is sent at one end of the waveguide, couples to the guided mode and excites the emitters along the waveguide. We collect directly from one color center the photoluminescence that is emitted in the far-field. The other configuration consists in exciting a defect directly and collecting its single-photon emission at one end of the waveguide to evaluate the efficiency of the coupling to the guided mode. The second-order auto-correlation histograms reveal a good preservation of the source's antibunching whether the excitation or photoluminescence photons couple to the waveguide.

Extending and building from this prototype would enable to design integrated quantum photonic circuits in the

frame of applied quantum information science.

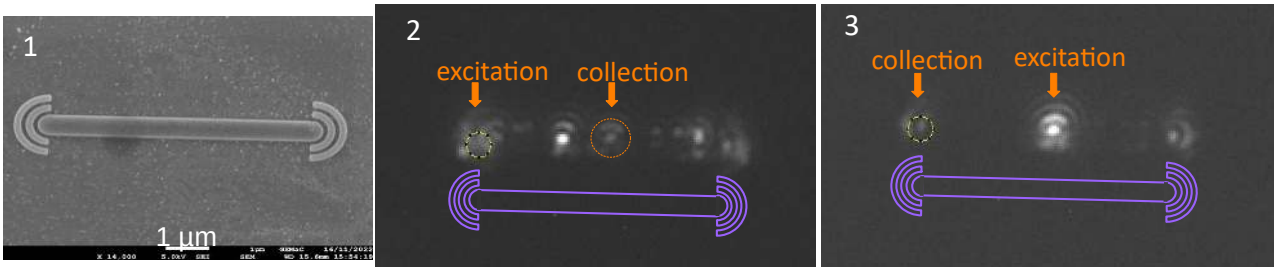

Figure 1 : SEM image of a hBN waveguide. **Figure 2 :** CCD image showing the emitters along the waveguide (white spots) when the are excited by a 405nm laser passing through the waveguide. The reflected light of the excitation is suppressed by a pass-band filter. A scheme of the waveguide in purple was added under the actual waveguide. **Figure 3 :** CCD image showing the photoluminescence of one single-photon emitter that is directly excited, after filtering to suppress the excitation light. The photons that coupled to the guided mode appear at both ends of the waveguide.

Dynamic control of emission from quantum emitters embedded in ultra thin ENZ media

*corresponding author: itsmearun18@iisertvm.ac.in

Abstract: Controlling light-matter interactions at the nanoscale has been the basis of most of the active plasmonic, photonic and optoelectronic systems. The ability to tailor emission from quantum emitters by tuning the optical parameters of an epsilon near zero (ENZ) material environment around is both of fundamental and applied interest. The understandings provide newer degrees of freedom in controlling and trapping fields within confined regions and in designing opto-mechanical systems, which may be exploited for quantum information processing.

Understanding the interactions between quantum emitters (QE) such as quantum dots or dye molecules, and resonant cavity has been a norm in cavity quantum electrodynamics (QED) with a commensurate body of work to comprehend its fundamental aspects. In parallel, immense technological advancement has leveraged associated phenomena in lasing, cavity opto-mechanics, dielectric micro-cavities, single-photon nonlinearities, photonic systems, etc. [1,2]. While light-matter interaction is weak in general, its is significantly more interesting with the ENZ materials [3]. In these materials the real part of dielectric permittivity goes to zero at the ENZ wavelength (λ_{ENZ}). Close to this λ_{ENZ} the non-trivial properties are evidenced such as enhanced nonlinear optical response in the otherwise linear media, slow light etc. [4,5] The materials of study in this work is Indium Tin Oxide (ITO), these are widely used transparent conducting oxide having the ENZ region in the near IR. In this work we study the far-field emission of a point dipole embedded within a thin-film of ITO backed with a metal substrate using finite element method (FEM). This simulations were carried out by using the wave optics module in COMSOL© Multiphysics. The geometry is as shown in figure 1a and the red gradient cone depicts the emission from the point dipole. A small area of ITO around the center of the embedded dipole is electrostatically gated using a very thin gate electrode. Electrostatic gating can dynamically modulate the carrier density locally, which in turn shifts the plasmonic frequency and λ_{ENZ}, thus changing the refractive index of ITO. [5] Here, we exploit the fact that, emission from a quantum emitter buried in 10 nm thick ENZ material is quenched if the emission wavelength matches the ENZ wavelength (λ_{ENZ}) of the material. This stems from the fundamental understanding that for a lossless ENZ material at the λ_{ENZ} its refractive index ($n + ik$) is zero, which only sustains non-radiative modes in the ENZ media. While finite solutions for the electric field exists in this media, its impedance and the associated wavelength diverges as $n \to 0$, quenching the magnetic field that kills radiation. Real systems are not loss less thus the radiative modes are only partially quenched.

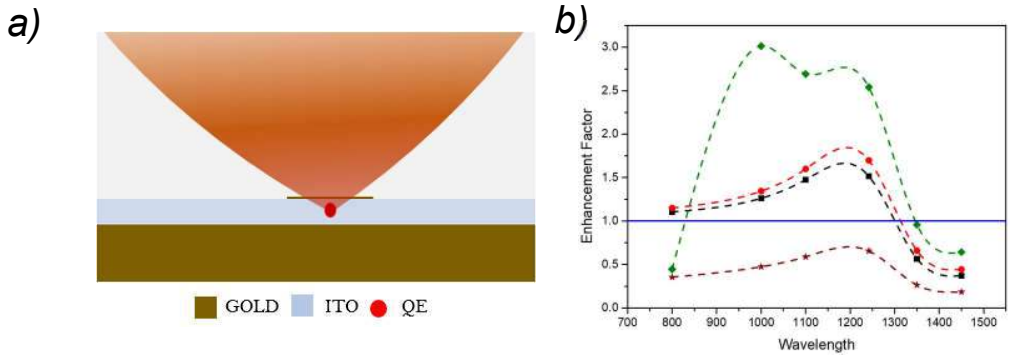

Figure 1: (a) Schematic of the dipole embedded in a thin-film of ITO. (b) Far field power enhancement factor increases as ITO becomes more dielectric.

Figure 1b plots the calculated far field emission intensity of a quantum dipole emitter embedded in the center of 20nm pattered ITO film. As such the ITO is specified to have ENZ wavelength of 1245 nm. Upon activation of the gate bias the far field radiation enhances in the local ITO is depleted of carriers i.e. the ENZ wavelength is shifted to the IR above 1500 nm. Conversely, the far field radiation quenches if the local ITO is rendered metallic by accumulation of charge carriers via positive gate bias.

Abstract: The crystal structure of vanadium dioxide is monoclinic at temperatures below 58°C and tetragonal at temperatures above 72°C. Both monoclinic and tetragonal crystals exist at temperatures in the range (58°C, 72°C). Monoclinic vanadium dioxide is a dissipative insulator. Tetragonal vanadium dioxide is a dissipative insulator only at free-space wavelengths less than 1100 nm; at longer free-space wavelengths it is a plasmonic metal. The monoclinic–tetragonal transition is reversible but hysteretic. Manifestations of this thermal hysteresis were found in theoretical studies of (i) scattering by vanadium dioxide spheres; (ii) constitutive parameters of columnar thin films made from vanadium dioxide; and (iii) surface-plasmon-polariton waves propagating at a silver-vanadium dioxide interface.

The prospect of thermally controlling the dielectric properties of materials, metamaterials, and metasurfaces is attractive for numerous applications involving reconfigurable and multifunctional devices [1]. In particular, vanadium dioxide (VO_2) looks promising in this context as it exhibits a thermally induced, hysteretic phase change over the temperature range (58°C, 72°C) [2]. While VO_2 is electromagnetically isotropic and characterized by its (complex-valued) relative permittivity ε_{VO2}, its crystal structure is monoclinic at temperatures below 58°C and tetragonal at temperatures above 72°C [3]. Both monoclinic and tetragonal crystals exist at temperatures in the range (58°C, 72°C). Tetragonal vanadium dioxide is a dissipative insulator only for $\lambda_0 < 1100$ nm, where λ_0 is the free-space wavelength; at longer free-space wavelengths, it is a plasmonic metal. At a fixed free-space wavelength, the value of ε_{VO2} for monoclinic VO_2 differs from its value for tetragonal VO_2. The transition from monoclinic VO_2 to tetragonal VO_2 can be achieved by heating, and the transition from tetragonal VO_2 to monoclinic VO_2 can be achieved by cooling. For temperatures in the range (58°C, 72°C), the value of ε_{VO2} depends on whether VO_2 was heated up or cooled down to reach that temperature [4].

Manifestations of thermal hysteresis in the monoclinic–tetragonal transition for VO_2 were investigated in the following three theoretical studies:

(i) The extinction, total scattering, absorption, radiation-pressure, back-scattering, and forward-scattering

efficiencies of a VO_2 sphere were calculated [5]. Manifestations of thermal hysteresis were found in (a) the forward-scattering, back-scattering, and absorption efficiencies for $\lambda_0 < 1100$ nm, and (b) the forward-scattering, back-scattering, total scattering, and absorption efficiencies for $\lambda_0 > 1100$ nm.

(ii) The Bruggeman homogenization formalism was used to numerically investigate the dielectric properties of a columnar thin film (CTF) made from VO_2 [6]. For visible and near-infrared wavelengths, the CTF is electromagnetically equivalent to a homogeneous orthorhombic material. The anisotropy revealed through the eigenvalues of the CTF's relative permittivity dyadic, and the anisotropy of the associated hysteresis, were investigated in relation to temperature for CTFs of different porosities and columnar cross sections. For $\lambda_0 = 800$ nm, the CTF is a dissipative dielectric material that exhibits temperature-dependent anisotropy and anisotropic hysteresis. In contrast, for $\lambda_0 = 1550$ nm, the CTF can be a dissipative dielectric material, a hyperbolic material or a metal-like material, depending on the temperature and the porosity of the CTF.

(iii) The propagation of surface-plasmon-polariton (SPP) waves at the planar interface of a metal and VO_2 impregnated with a combination of active dyes was numerically investigated [7]. Depending upon the volume fraction of VO_2, either attenuation or amplification of the SPP waves may be achieved, the degree of attenuation or amplification being strongly dependent on both the temperature and whether the temperature is increasing or decreasing.

Abstract: Temporally modulated optical media have amazing potential to amplify signals. Here we investigate the behaviour of temporal boundaries, and show that traditional approaches that assume constant dielectric properties, with loss incorporated as an imaginary part, necessarily lead to unphysical solutions. Furthermore, although physically reasonable predictions can be recovered with a narrowband approximation, we show that appropriate models should use materials with a temporal response and dispersive behaviour. We indicate recent experiential demonstrating temporal boundaries.

A very exciting new concept is time dependent media, where abrupt changes in permittivity can create a temporal boundary. Boundaries play a key role in many physical models; they provide initial and final states in dynamical systems, constrain analytic solutions in confined systems, and represent transitions between different modes of operation. We show [1] that modelling loss using a constant complex permittivity and permeability is physically incompatible with a temporal boundary. Such models can lead to unphysical post-boundary solutions that grow exponentially, despite being applied to passive and lossy materials; or fields may become complex-valued despite being real-valued before.

To see this consider the simple scenario with vacuum constitutive relations before the the time bounty and a constant complex permittivity $\varepsilon\in\boldsymbol{C}$. An initial propagating wave of the form

$$E_x(t,z)=E_0\exp(-\omega t+ikz)$$

where $c_0 k=\omega_a$. By imposing the the boundary conditions $[\boldsymbol{E}]=0$ and $[\boldsymbol{B}]=0$ we obtain the solution after the time boundary as

$$E_x(t,z)=g_1 e^{ik_c(-c_R t+z)}e^{kc_I t}+g_2 e^{ik(-c_R t-z)}e^{kc_I t}+g_3 e^{ik(c_R t-z)}e^{-kc_I t}+g_4 e^{ik(c_R t+z)}e^{-kc_I t}$$

where $c_R+i\,c_I=c_0(\varepsilon_c\mu_0)^{-1/2}$ and $\omega_c=k(\varepsilon_c\mu_0/c_0)^{1/2}$. Now we have $C_I\neq 0$, so *E* increases exponentially with time *despite* this being a lossy medium. Clearly this is physically invalid, so the constant complex CR model has *failed*. This has a crucial significance for

any technology relying on temporal boundaries.

We propose two methods to avoid this unphysical result. The first is to use a narrowband approximation, which requires two permativities. The second is to consider full dynamical models of permittivity.

To examine the predicted behaviour of electromagentic waves in time dependent media, we have constructed an time dependent metamaterial, from sub-wavelength active components. In the experiment an externally applied DC current to the material dynamically changes the permittivity. Preliminary results indicate that in some frequency regimes it behaves as expected, producing a time mirror, whereas at other frequency there are unexpected results.

Solution generation in electrodynamics

Robert T. Thompson[1*] and Martin W. McCall[2]
[1]*Rhea Space Activity, Washington DC, USA*
[2]*Department of Physics, Imperial College London, UK*
*rtthompson.phd@gmail.com

Abstract: The transformation approach can be understood as a method of solution generation. We discuss solution generation in electrodynamics and seek to develop a systematic approach to identifying mechanisms for generating non-trivial electromagnetic field solutions.

We take as our starting point the electromagnetic vector potential 1-form $\boldsymbol{A}$ and the field strength tensor $\boldsymbol{F} = d\boldsymbol{A}$. Maxwell's homogeneous equations $d\boldsymbol{F} = 0$ follow directly from the fact that $d^2\omega = 0$ for any scalar-valued differential form ω. The inhomogeneous equations $d \star \boldsymbol{F} = \boldsymbol{J}$ follow from a variation of the Yang-Mills action. Separating $\boldsymbol{J} = \boldsymbol{J}_{free} + \boldsymbol{J}_{bound}$, we can find a particular solution $\boldsymbol{P}$ that satisfies $d \star \boldsymbol{P} = \boldsymbol{J}_{bound}$. Absorbing a sign, we can write $d \star (\boldsymbol{F} + \boldsymbol{P}) = \boldsymbol{J}_{free}$. In macroscopically neutral media, polarizations arise in response to the free solution $\boldsymbol{F}$ (a combination of homogeneous and particular solutions to the free charge source), thus we expand $\boldsymbol{P}$ in terms of $\boldsymbol{F}$

$$\boldsymbol{P} = \boldsymbol{\xi}(\boldsymbol{F}) + \boldsymbol{\Xi}(\boldsymbol{d} \star \boldsymbol{F}) + \boldsymbol{\Lambda}(\boldsymbol{F} \wedge \boldsymbol{F}) + \cdots. \tag{1}$$

The precise form of $\boldsymbol{P}$ requires a physical model. Here we merely write down some possible terms that are in keeping with exterior calculus. Notice that there is no term dependent on $d\boldsymbol{F}$ since $d\boldsymbol{F} = 0$.

A. Solution generation in the vacuum

The general covariance of Maxwell's equations follows directly from the commutativity of the exterior derivative with diffeomorphisms. In other words, given a coordinate transformation ϕ, and its associated action on the tangent space $\psi = d\phi$, then, with an abuse of notation whereby we let ψ also denote the action of ϕ on products of the tangent space, e.g. $\psi(\boldsymbol{F}) = \psi_\alpha^\mu \psi_\beta^\nu F_{\mu\nu}$

$$\psi(d\boldsymbol{F}) = d\psi(\boldsymbol{F}) = 0, \quad \text{and} \quad \psi(d \star \boldsymbol{F}) = d\big(\psi \star \psi^{-1}\psi(\boldsymbol{F})\big) = \psi(\boldsymbol{J}) \tag{2}$$

preserves the form of Maxwell's equations in different coordinate systems. On the other hand, the game is slightly different if one is interested in generating new vacuum solutions from a given initial solution, rather than a coordinate transformation. Given the initial solution $\boldsymbol{F}$, we suppose that $\boldsymbol{F'} = \Lambda(\boldsymbol{F})$ is a new vacuum solution for some transformation Λ, and we wish to know what conditions Λ must satisfy such that $\boldsymbol{F'}$ is in fact a solution to Maxwell's equations. In other words, we must find conditions on Λ such that $d\boldsymbol{F'} = d\Lambda(\boldsymbol{F}) = 0$, and $d \star \boldsymbol{F} = d \star \Lambda(\boldsymbol{F}) = 0$ are true. From the first equation, we see that Λ must commute with the exterior derivative so that $\Lambda(d\boldsymbol{F}) = 0$, which will be satisfied since $d\boldsymbol{F} = 0$ for the seed solution $\boldsymbol{F}$. Similarly, we must be able to demonstrate that the second equation can put into the form $\Lambda(d \star \boldsymbol{F}) = 0$. Since we have already required that Λ and d commute, this requirement is equivalent to $\star\,\Lambda(\boldsymbol{F}) = \Lambda(\star\,\boldsymbol{F})$. By linearity, Λ must therefore preserve the Hodge $\star$ on 2-forms

$$\Lambda \star \Lambda^{-1} = \star \tag{3}$$

Which leads to the condition $\Lambda_\mu^\alpha \Lambda_\nu^\beta g^{\mu\nu} = \pm\sqrt{\det(\Lambda)}\, g^{\alpha\beta}$. Remarkably, we started by looking for constraints on the allowable transformations of the *field* and found a condition with respect to the space-time *metric*. At any space-time point $\boldsymbol{x}$ the metric may be put into the Minkowski form, so local Lorentz transformations with determinant ±1 are valid, as are conformal transformations of the form $\Lambda = \boldsymbol{\Omega I}$. This is a compact derivation of well-known results [1–3].

B. Generation of more arbitrary solutions

We are not constrained to generate just vacuum solutions. Linear transformation optics supposes we begin with the seed solution $\boldsymbol{F}$ within an initial linear dielectric $\boldsymbol{\chi}$, satisfying $d\boldsymbol{F} = 0$ and $d \star$

$\boldsymbol{\chi F} = 0$ with $\boldsymbol{F}$ and $\boldsymbol{\chi}$ complex. Let $\boldsymbol{F'} = \Lambda(\boldsymbol{F})$ where Λ is a (complex) transformation that commutes with the exterior derivative such that $d\boldsymbol{F'} = d\Lambda(\boldsymbol{F}) = \Lambda(d\boldsymbol{F}) = 0$ is satisfied. We demand that $\boldsymbol{F'}$is a valid solution to Maxwell's equations in some non-vacuum but again linear medium $\boldsymbol{\chi'}$. In this case the inhomogeneous equation for the primed field is $d \star \boldsymbol{\chi'}\boldsymbol{F'} = d \star \boldsymbol{\chi'}\Lambda(\boldsymbol{F}) = 0$, which, similarly to the vacuum case, will be true if $d \star \boldsymbol{\chi'}\Lambda(\boldsymbol{F}) = d\Lambda(\star\, \boldsymbol{\chi F}) = 0$. As before, we are not changing coordinates but rather generating new solutions. So the coordinates and space-time are unchanged, which means that $\star$ must again be preserved, but this time we have the freedom to modify $\boldsymbol{\chi'}$ to support the new field. Thus, it may be quickly determined that for any given Λ that commutes with the exterior derivative, $\Lambda(\boldsymbol{F})$ will be a solution as long as

$$\boldsymbol{\chi'} = - \star \Lambda \star \boldsymbol{\chi}\Lambda^{-1} \tag{4}$$

which we already knew from transformation optics, and which immediately recovers the vacuum condition Eq. (3) when $\boldsymbol{\chi'} = \boldsymbol{\chi} = \boldsymbol{\chi}_{vac}$.

However, the linearity of $\boldsymbol{\chi'}$ turns out to be a consequence of demanding that Λ be the pullback of a manifold diffeomorphism. By relaxing the assumptions on linearity, we may start with a slightly different point of view, one where we haven't imposed a model on the bound charges. Then it is possible to systematically consider the effect of more general solution generating transformations by studying (in the case of no free charges)

$$d \star (\boldsymbol{F'} + \boldsymbol{P'}) = d \star ((\Lambda(\boldsymbol{F}) + \boldsymbol{P'}(\Lambda(\boldsymbol{F}))) = 0. \tag{5}$$

C. Bundle map automorphisms

Given a point p on manifold M, the associated tangent space $T_p(M)$ is a vector space. The collection of all tangent spaces for all points on the manifold is the tangent (vector) bundle TM. The tangent bundle is itself a manifold, and a point on the tangent bundle is given by the pair $(p, \boldsymbol{v})$ with $p \in M, \boldsymbol{v} \in T_p(M)$. Given a diffeomorphism $f: M \to N$ between two manifolds M and N, one can find a map $f^*: T_p(M) \to T_{f(p)}N$ between tangent spaces. Hence the pair

$$(f, f^*): TM \to TN, \tag{6a}$$

$$(p, \boldsymbol{v}) \mapsto (f(p), f^*(\boldsymbol{v})) \tag{6b}$$

defines a map between bundles. However, there is no requirement that a bundle map be formulated this way, and the map $\Lambda: T_p(M) \to T_q(N)$ can be defined independently from the map identifying p and q, so the pushforward is a special case of bundle map. In particular, suppose we define an automorphism of the bundle by

$$(id, \Lambda): TM \to TM, \tag{7a}$$

$$(p, \boldsymbol{v}) \mapsto (p, \Lambda(\boldsymbol{v})). \tag{7b}$$

This bundle map is similar to a "frame transformation" of the tangent space; for example when one wants to formulate equations relative to a tetrad field. One can show that this bundle map will preserve Maxwell's equations *iff* $d\Lambda = 0$. Bundle maps are a class of transformations that has not been well-studied in transformations optics [4–6]. I will discuss the combination of these more general types of transformations with the approach of Eq. (5).

Abstract **– Corrugated waveguides can be modelled as a spatially dispersive media. By varying the structure we can make the electric field obey Mathieu's equation. This is utilised to tailor the dispersion relation to match phase and group velocity of the waves to the particle beam. These corrugated structures can be used as slow wave structures to either produce EM fields or accelerate charged particles.**

I. Introduction

One of the reasons to design artificial structures in electromagnetism is creating an electro-magnetic dispersion relation with certain useful properties. One of the desirable features, for either electromagnetic radiation generation or charged particle acceleration structures, is dispersion relation having a point where phase and group velocities are the same. Moreover, a range of frequencies at which phase and group velocities are very close is even more desirable. This, as we show below, can occur in a medium, plasma frequency of which is varied periodically; and is also achievable in a relatively simple corrugated waveguide.

To simplify analytical study system's dispersion relation it is convenient to consider periodic systems that can be described by Mathieu equation. This enables us to easily calculate the dispersion relation, for example as given by figure 2. The longitudinal component of the electric field $E_z(t,z)$ along the centre of waveguide can be modelled as a 1-dimensional medium with spatial dispersion, which is also spatially dependent.

II. Spatial dispersion and Mathieu's equation

We choose corrugation profile of the waveguide in the form $\mathcal{L}_x(z) = \left(L_0^{-2} + 2L_z^{-2}\, p_x^{-2}\, q\, \cos(2\,\pi\, L_z^{-1}\, z)\right)^{-1/2}$. The guide height $\mathcal{L}_x(z)$ oscillates non-sinusoidally around the central height L_0. For physical solutions $\mathcal{L}_x(z) > 0$, we require $2\,q < L_0^{-2}\, L_z^2$. The Mathieu parameter q effectively defines the corrugation depth. For small corrugation with $q\, L_0^2\, L_z^{-2} \ll 1$ the undulations take a simple sinusoidal form $\mathcal{L}_x(z) \approx L_0 - L_0^3\, L_z^{-2}\, q\, \cos(2\,\pi\, L_z^{-1}\, z)$

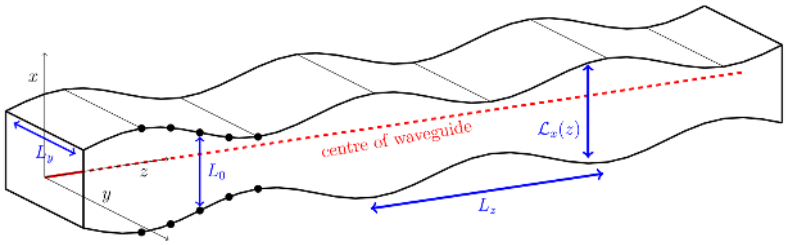

Fig. 1: Corrugated Wave Guide

This profile shape leads to longitudinal field of a transversal magnetic mode $\mathrm{TM}_{p_x p_y}$ (p_x and p_y are odd integers) to be in the form

$$E_z\left(\vec{r},\omega\right) = E_\perp(x,y)\left[\left(\frac{\pi p_x}{\mathcal{L}_x(z)}\right)^2 + \left(\frac{\pi p_y}{L_y}\right)^2\right]\phi\left(\frac{\pi z}{L_z}|a,q\right), \tag{1}$$

Here $\phi\left(\xi|a,q\right)$ is a solution of the Mathieu equation $\phi''\left(\xi\right) + \left(a - 2q\cos(2\xi)\right)\phi\left(\xi\right) = 0$, and $a = L_z^2\left(c^{-2}\pi^{-2}\omega^2 - p_x^2 L_0^{-2} - p_y^2 L_y^{-2}\right) = \hat{\omega}^2 - \hat{\omega}_c^2$.

For a given TM mode we can reduce the propagation of the electromagnetic waves to one dimensional problem of propagation through spatially variying the susceptibility $\chi(\omega, z)$of the effective medium by choosing an appropriate $\chi(\omega, z)$ in the polarisation equation

$$\frac{\partial^2 E_z(z,\omega)}{\partial z^2} - \frac{\omega^2}{c^2} E_z(z,\omega) = \frac{\omega^2}{\epsilon_0 c^2} P_z(z,\omega), \quad \Leftrightarrow \quad \frac{\partial^2 E_z(z,\omega)}{\partial z^2} = -\left(\frac{\omega^2}{c^2} + \frac{\omega^2}{c^2}\chi(\omega, z)\right) E_z(z,\omega) \quad (2)$$

Alternative formulation of material properties can be done using spatially varied plasma frequency ω_P of the material. Thin wire medium, studied in [1-4], is an example of such system with spatial variation of plasma frequency along z as: $\omega_P^2(z) = \omega_c^2 + 2\,\Lambda\,\cos\left(\frac{2\,z}{L_z}\right)$; longitudinal field in the medium E_z obeys an equation:

$$\beta^2\, c^2\, \frac{d^2 E_z}{dz^2} + \left(\omega^2 - \omega_p^2\right) E_z = 0 \quad (3)$$

Since the solutions to Mathieu's equation are known, we can use them to find parameters a, q, $\hat{\omega}$, and $\hat{k}$ such that the optimal wave-particle interaction can take place. For example in figure 2 where we see that the phase and group velocities are matched at an inflection point - leading to extended interaction range.

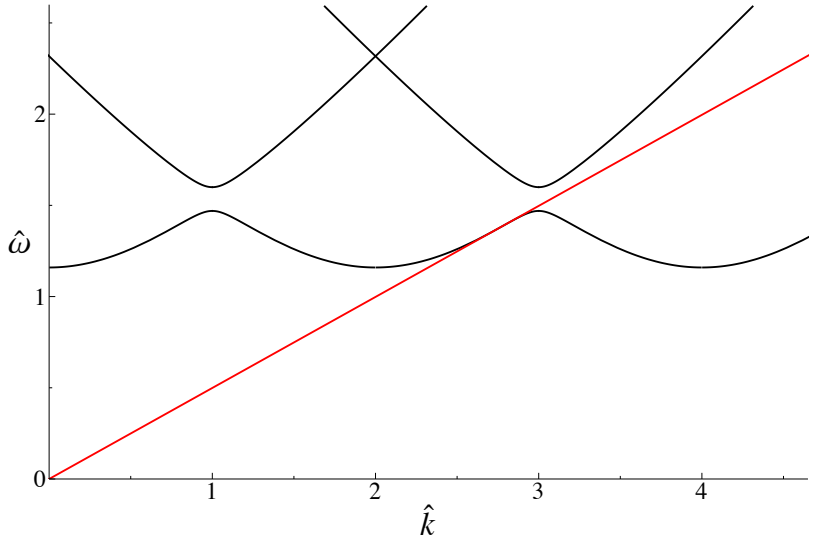

Fig. 2: Dispersion relation for scaled frequency $\hat{\omega}$ versus scaled wavevector $\hat{k}$, for Mathieu's parameters $q = 0.2$ $a = \hat{\omega}^2 - \hat{\omega}_c^2$ where $\hat{\omega}_c = 1.168$. For these values the phase and group velocities are approximately equal. Both correspond to a beam travelling at about 0.5c

III. Conclusion

We have shown how to use Mathieu's equation and a spatially dispersive model of the medium to predict the dispersion relation for a corrugated structure, and tailor them to a preferred wave-particle interaction.

We have compared corresponding modes can then be checked by running a full numerical simulation with the corrugated structure.

Twisting an optomechanical cavity

Daigo Oue[1,2,3*] **and Mamoru Matsuo**[1,4,5]

Abstract: In this presentation, we show introducing birefringence in an optomechanical cavity breaks the rotational symmetry and induces two nondegenerate modes: ordinary and extraordinary rays. Mechanically twisting the cavity mixes the two modes and modulates the electromagnetic energy. Consequently, we find that the two optical modes behave as an effective two-level system which is coupled with torsional mechanical oscillation. We can also find the torsional oscillation can be resonantly driven by optically pumping the cavity.

Light is far from mechanical rotation and vibration in the frequency domain; thus, the optical and mechanical systems cannot resonantly interact with each other. That was why transporting linear momenta between optical and mechanical degrees of freedom was inefficient as experimentally investigated by Nichols and Hull a long time ago [1].

Recently, it has been realized that light and quantized mechanical vibration are coupled with one another by confining both of them in the same 'optomechanical' cavity [2]. There are various types of optomechanical cavities, including a micro-disk resonator [3], a periodic photonic structure [4], a suspended membrane in an optical cavity [5], a levitated particle in a cavity [6]. All of these examples are about the coupling of light with linear mechanical oscillation, and, to the best of our knowledge, it has never been studied that with torsional oscillation in solid-state materials.

In this presentation, based on our recent paper [7], we show breaking rotational symmetry in an optomechanical cavity produces the interaction between optical fields and torsional mechanical oscillation. Our key to break the symmetry is filling the cavity with a birefringent medium which induces uniaxial anisotropy and thus two nondegenerate optical modes: ordinary and extraordinary rays. If the cavity is mechanically twisted, the two modes are mixed, and the electromagnetic energy is modulated. Following the standard quantization procedure of the electromagnetic energy as well as mechanical energy, we can find that the two optical modes can be regarded as an effective two-level system interacting with torsional mechanical oscillation. We can also find the torsional oscillation can be resonantly driven by optically pumping the cavity.

Our setup comprised two mirrors and a uniaxial filling medium, which support two orthogonal eigenmodes: ordinary and extraordinary rays. Mechanical twisting of the medium induces position-dependent anisotropy (Figure 1).

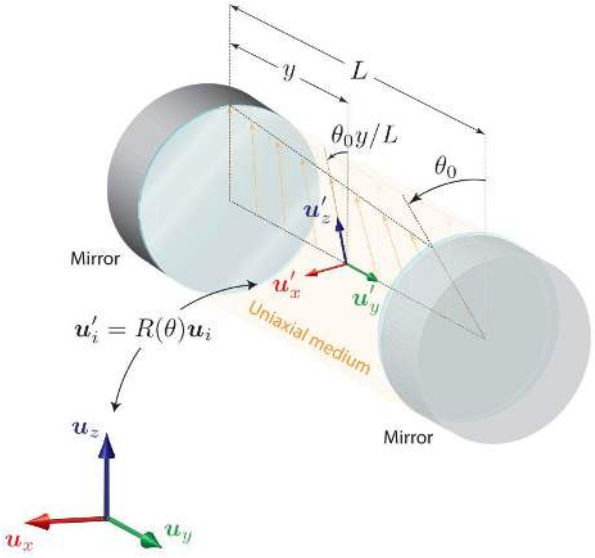

Figure 1.: uniaxial medium filling a cavity. The twisting induces position-dependent anisotropy.

Applying a coordinate transformation maps the inhomogeneous anisotropic medium to a homogeneous one and provides the interaction energy between the twisting and two optical modes in the cavity. Due to this rotational nature, the interaction becomes an angular-momentum-exchange type, through which we can optically pump mechanical torsional motion [7].

Time-varying fundamental acoustic equations

R. Picó[1*], J. Redondo[1], and V. J. Sánchez Morcillo[1]

Abstract: The basic equations of acoustics are developed for a purely time-varying medium. The linear non-invariant continuity equation is established by considering the time dependence of the mass density and the adiabatic bulk modulus. A parametric study is carried out to consider the influence of the terms in the equation. Numerical simulations using the Finite-Differences Time-Domain (FDTD) method show the peculiarities of these wave phenomena in different scenarios for time-varying parameters of the medium in specific acoustic systems.

Applications such as unidirectional amplification [1-2], frequency conversion [3] and non-reciprocal transmission [4] are supported by spatiotemporal modulated metamaterials in incredibly diverse ways. Metamaterials have been used to modulate material properties in time to increase the degrees of freedom in wave control. In particular, they have been used in acoustics for sound diffusers [5], diffraction gratings [6], metasurfaces [7] and spatiotemporal sonic crystals [8].

In the following, we derive the basic first-order linear equations of acoustics by assuming that the properties of the medium depend on time but not on space. Thus, we consider here a purely time-varying medium. If we assume that the non-linear terms are negligible, Euler's equation can be linearised as follows:

$$\rho_0(t)\frac{\partial \vec{u}(\vec{r},t)}{\partial t} + \nabla p(\vec{r},t) = 0, \tag{1}$$

where ρ_0 is the equilibrium density, $\vec{u}$ the particle velocity and p the acoustic pressure. This equation applies to small amplitude acoustic processes. The other linear equation is the exact continuity equation [9] is:

$$\frac{\partial \rho}{\partial t} + \nabla\left(\rho_0(t)\vec{u}(\vec{r},t)\right) = 0, \tag{2}$$

where $\rho = \rho_0(1+s)$ is the instantaneous density, ρ_0 is the equilibrium density and s is the condensation. If we develop the partial derivative of time we get:

$$\frac{\partial \rho_0(t)}{\partial t}(1+s(\vec{r},t)) + \rho_0(t)\frac{\partial s(\vec{r},t)}{\partial t} + \rho_0(t)\nabla\vec{u}(\vec{r},t) = 0. \tag{3}$$

If we assume small concentrations $|s| << 1$, that is $|\rho - \rho_0| << \rho_0$, and pressure-concentration linear relationship $p(\vec{r},t) = B(t)\cdot s(\vec{r},t)$, the continuity equation with time-varying parameters can be written as:

$$\frac{\partial \rho_0(t)}{\partial t} + \rho_0(t)\frac{\partial}{\partial t}\left(\frac{p(\vec{r},t)}{B(t)}\right) + \rho_0(t)\nabla\vec{u}(\vec{r},t) = 0. \tag{4}$$

To obtain the wave equation (second order equations), one performs the partial derivative of time of (4) and the gradient of (1) and gets:

$$\frac{\partial^2 \rho_0(t)}{\partial t^2} - \frac{\partial \rho_0(t)}{\partial t}\frac{p(\vec{r},t)}{B(t)} + \rho_0(t)\frac{\partial^2}{\partial t^2}\left(\frac{p(\vec{r},t)}{B(t)}\right) - \Delta p(\vec{r},t) = 0. \quad (5)$$

If ρ_0 and B are assumed to be invariant, the first and second terms of (5) vanish and we obtain the well-known wave equation:

$$\frac{\partial^2}{\partial t^2} p(\vec{r},t) - \frac{1}{c^2}\Delta p(\vec{r},t) = 0, \quad (6)$$

where $c = \sqrt{B/\rho_0}$ is the speed of waves.

By replacing the derivatives with central difference approximations in equations (1) and (4), these can be transformed into updating equations to obtain a FDTD leapfrog scheme. In this way, we can perform numerical simulations of one-dimensional media with time-varying parameters:

$$u\left(x+\Delta x, t+\frac{\Delta t}{2}\right) = u\left(x+\Delta x, t-\frac{\Delta t}{2}\right) - \frac{1}{\rho_0(t)}\left(p\left(x+\frac{\Delta x}{2}, t+\Delta t\right) - p\left(x-\frac{\Delta x}{2}, t+\Delta t\right)\right)\frac{\Delta t}{\Delta x}, \quad (7)$$

and

$$p\left(x+\frac{\Delta x}{2}, t+\Delta t\right) = p\left(x+\frac{\Delta x}{2}, t\right)\left(1+\Delta t\left(\frac{B(t+\Delta t)}{B(t)}-1\right)\right) - B(t)\left(u_x\left(x+\Delta x, t+\frac{\Delta t}{2}\right) - u_x\left(x, t+\frac{\Delta t}{2}\right)\right)\frac{\Delta t}{\Delta x} - B(t)\left(\frac{\rho(t+\Delta t)}{\rho(t)}-1\right) \quad (8)$$

Time-varying metasurfaces for parametric amplification of electromagnetic waves

F. V. Kovalev* **and I. V. Shadrivov**

ARC Centre of Excellence for Transformative Meta-Optical Systems (TMOS),
Research School of Physics, The Australian National University, Canberra ACT 2601, Australia
*corresponding author: fedor.kovalev@anu.edu.au

Abstract: We propose and study a time-varying metasurface for parametric amplification of electromagnetic waves. We found that our subwavelength thin metasurface can provide amplification of up to 10 dB and analysed its stability. The proposed amplification principle can be used for electromagnetic waves in the radio, microwave and subterahertz range and is limited by the properties of modern varactor diodes.

Time-varying metasurfaces give us access to many non-trivial physical effects. They can shift the frequency of the radiation, steer electromagnetic beams, control parametric waves in the scattered field and exhibit nonreciprocity, meaning that electromagnetic waves are transmitted through the metasurface differently depending on the direction of incidence [1]. The higher the modulation rate, the more interesting effects can be achieved. When it becomes comparable to the frequency of an electromagnetic wave, it is possible to have complete control over light both in space and time [2].

Recently, several research groups used different methods to amplify incident radiation with the help of metasurfaces. They utilised active substrates, used parametric rotation of the anisotropy of surface susceptibility, permittivity modulation, or integration of power amplifiers and transistors. Parametric amplification in left-handed transmission line media and metamaterial waveguides was studied almost two decades ago [3], but these methods have not yet been applied to amplification of free-space propagating electromagnetic waves. Parametric amplification techniques are used in electronic circuits and optics. In particular, they became the leading technology for ultralow-noise microwave measurements in quantum computing.

In this work, we propose a new approach to electromagnetic wave amplification using time-varying metasurfaces. Each meta-atom of the developed metasurface acts as a parametric amplifier based on a split-ring resonator (SRR) with variable capacitance. By applying the appropriately modulated voltage to the embedded varactors in each SRR we can change its capacitance with the pump frequency according to the following periodic law:

$$C(t) = C_0\left[1 + \beta\cos\left(\omega_p t + \varphi_p\right)\right] \quad (1)$$

where C_0 – the medium capacitance, $\beta = \Delta C/C$ – the parametric modulation coefficient, ΔC – the amplitude of the parametric modulation, $\omega_p \approx 2\omega_s$ – the parametric modulation frequency, ω_s – the incident electromagnetic wave frequency, φ_p – the phase of the parametric modulation.

We use numerical simulations to model the three-dimensional geometry along with a nonlinear circuit simulation of a real variable capacitance diode and an appropriate biasing network. We studied various regimes of operation of the system and found that we could achieve a significant gain of more than 10 dB. The gain can be controlled by the parameters of the modulation. We studied the instability threshold for this system and our model shows excellent agreement with the results of numerical simulations. The instability threshold corresponds to a change in the resonance frequency of the circuit equal to its bandwidth.

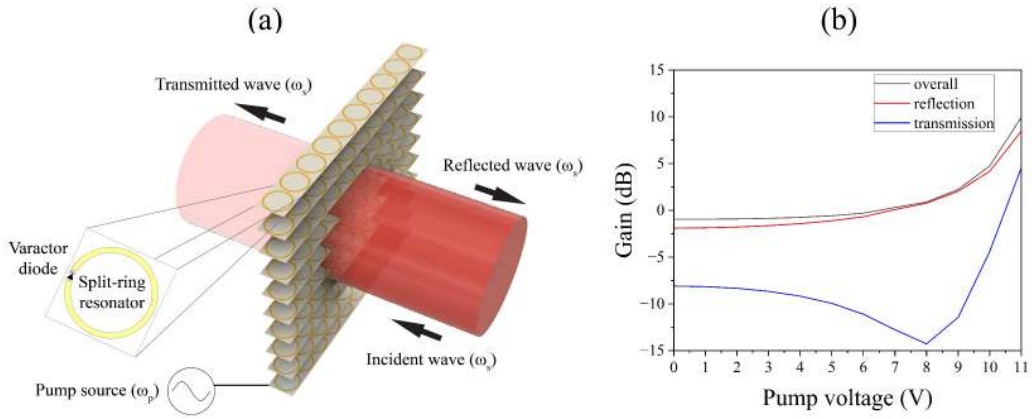

Figure 1. The proposed time-varying metasurface with the pump source connected electrically (a) and dependence of the gain on the pump amplitude (b).

We considered two different pump schemes: applying the parametric modulation electrically (Fig. 1a) and inducing the currents in SRRs at $\omega_p \approx 2\omega_s$ by the incident electromagnetic wave (Fig. 2a). The gain increases with increasing the parametric pump amplitude and ΔC in both cases, as shown in Fig. 1b and Fig. 2b.

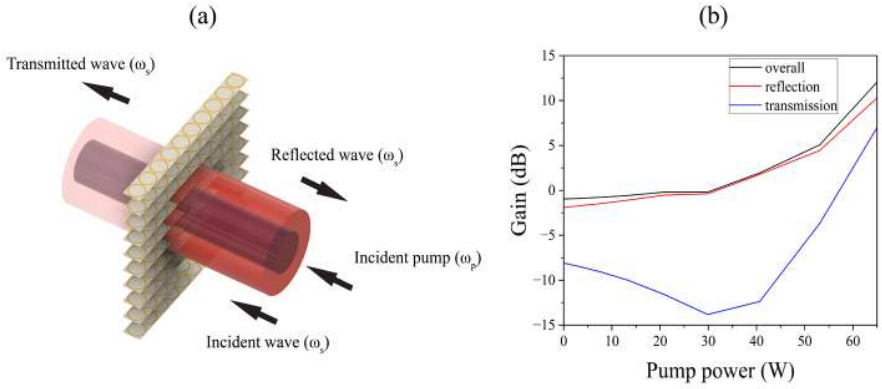

Figure 2. The proposed time-varying metasurface with the external pump source (a) and dependence of the gain on the incident pump power (b).

We anticipate that the proposed structure also be able to provide spatial control of amplified waves using spatially inhomogeneous amplification. Such integration of several functionalities can be useful in a range of applications; for example, in multifunctional and programmable antenna radomes or repeaters on the ground and in orbit that can reflect and amplify incident signals.

The operator theory of dispersive time varying media

S. A. R. Horsley[1*]

[1]School of Physics and Astronomy, University of Exeter, Stocker Road, Exeter, EX4 4QL UK
[*]corresponding author: s.horsley@exeter.ac.uk

Abstract: The theory of dispersive, time varying materials is challenging: the material response is both externally modulated, and depends on the history of the field. I will explain a new approach, where the optical 'constants' (refractive index etc.) become operators. I will show the resulting theory predicts spectrally tailored 'eigenpulses' of modulated materials and matches well with numerical simulations. Finally I will illustrate connections with the ABC problem of non-local media and also discuss some surprising connections with quantum mechanics.

Some fascinating wave physics has been discovered through considering materials with properties that vary in time. In the simplest case, an instantaneous change in the refractive index causes a wave to reflect without any spatial boundary, through making a transition to a negative frequency. However, in all experiments to date, the refractive index has neither been changed instantaneously, nor without depending on frequency (e.g. [1-3]). This presents a theoretical challenge: what is the best way of describing wave propagation in a dispersive time varying material?

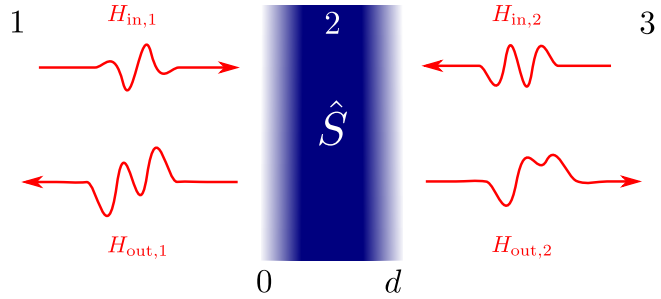

Figure 1: *Scattering from a time varying dispersive medium:* The scattering operator $\hat{S}$ acts on the incident spectra $H_{\mathrm{in},1/2}$ to give the output spectra. We compute $\hat{S}$ through describing the permittivity via Eq. (2), and find its eigenvectors, which represent the special pulses with a spectrum that is unchanged by the medium.

Here I shall discuss our attempt to solve this problem, where arbitrary dispersion and time variation are modeled through letting the common constants of electromagnetism (refractive index, wave-number, impedance etc.) become operators [4]. To see how this works, consider the displacement field in a dispersive time varying material

$$D(t)=\int_{-\infty}^{t}\epsilon(t,t-t')E(t')dt' \qquad (1)$$

If we attempt to write this in the frequency domain through inserting the Fourier representation of the electric field, we are prevented by the explicit time dependence of the permittivity. However, in the frequency domain the time variable is equivalent to a frequency derivative, allowing us to write (1) in the form

$$D(\omega)=\hat{\epsilon}(i\partial_\omega,\omega)E(\omega) \qquad (2)$$

We can numerically construct this operator through e.g. using a finite difference approximation to the frequency derivative and evaluating the permittivity as a function of a matrix argument. Following this line of argument, all quantities involving the permittivity (e.g. the wave number) become operators but otherwise we can treat the problem like an ordinary frequency domain one. Inside a time modulated material the field then takes the familiar form $E(x,\omega)=\exp(i\hat{K}x)A_{+(\omega)}+\exp(-i\hat{K}x)A_{-(\omega)}$.

Using this approach I shall show we can derive semi-analytic expressions for the scattering from a arbitrarily time varying slab. In addition to comparing this approach to existing numerical and analytical techniques, we find that the eigenfunctions of these operators represent pulses (eigenpulses) that do not change their spectra after interaction with the time-varying, dispersive material (see Fig. 2). Furthermore, the poles of these operators represent the non-time harmonic bound states of the system, the time varying medium analogue of surface plasmons. Finally I shall demonstrate the application of this theory to problems of quantum emission in time varying media, taking the particular example of a moving grating [5] where we can compare our method with fully analytic results.

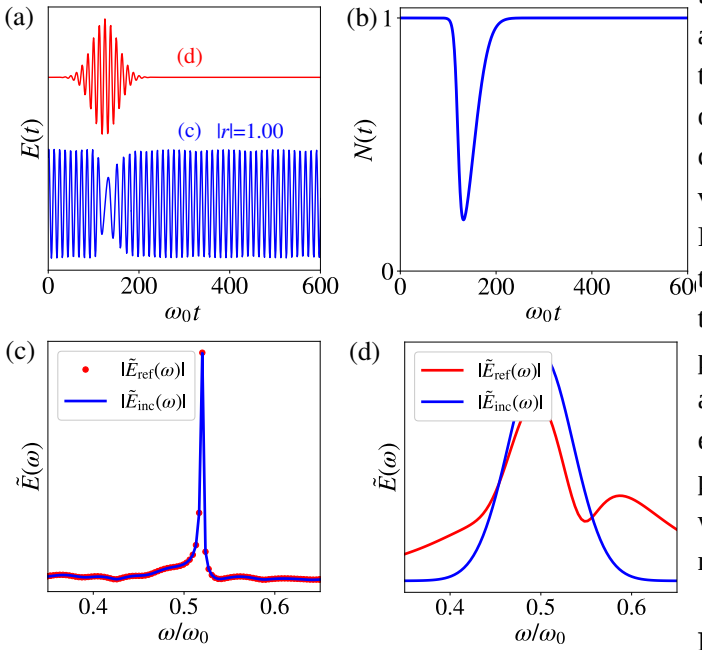

Figure 2: *Eigenpulses of a time varying dispersive medium:* (a) we compare the scattering of two pulses incident onto a metal with the time dependent carrier density shown in (b). (c) shows the incident and reflected spectrum of an eigenpulse, illustrating the medium acts as a mirror, while (d) shows the effect on a Gaussian pulse, which is reshaped.

Surface plasmon polaritons are not polaritons, and not plasmons either

Antoine Moreau[1]

[1]Université Clermont Auvergne, Clermont Auvergne INP, CNRS, Institut Pascal, F-63000 Clermont–Ferrand, France

[*]corresponding author: antoine.moreau@uca.fr

Abstract: Recent interest in the study of spatial dispersion has brought forward some difficulties in the way the community has named physical objects for decades, sometimes describing electromagnetic guided modes using a vocabulary coming from solid state physics and quantum mechanics. While changing our habits now may not be the best idea, it could be interesting to clarify a few points: the guided mode that we call now a surface plasmon polariton (SPP) has not always been called so, and its properties do not match with those of the polariton, nor on those the plasmon as defined by the solid state community. Understanding why not sheds light on the way spatial dispersion has an influence on "surface plasma oscillations" and why this may be important in the future.

Ten years ago, an experiment has renewed in the community of photonics, the interest for the study of spatial dispersion, also called non-locality[1]. In metals, the repulsion between electrons, which cannot be taken into account in the framework of the Drude model, makes the optical response of the jellium intrinsically non-local. Taking into account this phenomenon means taking into account another wave inside the jellium, considered as a plasma: the Langmuir wave, the corresponding quantum being the actual plasmon[2]. At the edges of a plasma, a surface wave, initially called "surface plasma oscillation" and that we call today an SPP can be excited. This solution of Maxwell's equations is completely transverse, while the plasmons correspond to a purely longitudinal solution. Ironically enough, we now have to call plasmons "bulk" to distinguish them from the surface plasmon. We underline that there is no conversion, inside the metal, from the transverse to the longitudinal wave and thus no coupling mechanism which would characterize a polariton. When light is able to couple to vibration degrees or to generate excitons, true surface polaritons can be supported by the interface. But the mechanism is very different from the SPP. The negativity of the permittivity is, in that case, linked to this coupling mechanism while in a jellium the negative permittivity is due to the Drude model in the framework of which no true plasmon can propagate. Or course, things are never simple, so that a more accurate description of a SPP taking into account spatial dispersion shows that there is a small longitudinal component accompanying the wave[2] – this small component being able to bring dramatic changes to the dispersion curbe of the mode[3]. We will try, in this talk, to sort things out – and to pinpoint when in history, shifts in the vocabulary of the community occurred[4].

We would finally like to underline that, while this discussion has been for decades focused on metals, highly doped semi-conductors are probably the materials for which such a discussion is the most illuminating – especially for epsilon-near-zero materials, for which spatial dispersion has to be undoubtedly taken into account.

Abstract: In recent years, there has been a growing interest in metamaterials that a capable of performing mathematical operations on the optical signals. However, this concept requires a complicated distribution of spatial inhomogeneities, which hinders its practical applications. Here, we propose an approach for analog optical computing using spatially uniform systems. For this purpose, we leverage novel regimes of light-matter interactions arising in time-varying media. The target operation is achieved by controlling the Fourier amplitudes through the effect of wave amplification/attenuation.

The ability to perform ultrafast and energy-efficient computing is of key importance for the development of cutting-edge technologies. However, widely used integrated electronic circuits are reaching their physical limitations [1] and, therefore, they cannot meet the growing demands for computing performance. New platforms and physical approaches are needed to outperform existing computers. Analog optical computers have recently attracted renewed interest as an alternative to digital electronic computers []. These devices, in their modern form, are artificial materials – metamaterials – that can perform mathematical operations and even solve integro-differential equations [2, 3]. Computational metamaterials provide opportunities for real-time processing of large amounts of data using on-chip architectures.

Computational metamaterials modulate the optical field so that the output signal is the result of performing a mathematical operation on the input signal. This functionality is achieved by suitably designing the metamaterial's building blocks. However, this concept requires a complicated distribution of spatial inhomogeneities, which hampers its practical applications. Here, we show that analog wave-based computing can be performed using spatially uniform systems. For this purpose, we exploit the properties of time-varying media. Time-varying media is a class of artificial materials that are spatially uniform, but has inhomogeneities in the time domain [4]. The latter means that one of the parameters of the medium, e.g., dielectric permittivity, is modulated in time. This can be implemented by means of external influence. Time-modulated structures have attracted a great fundamental and practical interest due to recent observations of fascinating wave phenomena [4].

The underlying principle of our computing system is that a linear mathematical operation on the spatial profile can be described as a kernel, which operates on the incident momentum spectrum [3]. The desired kernel is imprinted on the spatially uniform structure by suitably tailoring its temporal inhomogeneity. For this purpose, we exploit the effect of energy non-conservation in time-modulated systems. This effect allowed to control the Fourier components of the signal through wave amplification/attenuation. Using numerical simulations we investigated the process of light interaction with a time-modulated slab. Simulations were carried out by means of commercially available 3D electromagnetic solver (COMSOL Multiphysics). We calculated the transmission (T) and reflection (R) coefficients for various incident angles and various parameters of temporal inhomogeneity (switching time, modulation depth and switching profile of the refractive index). R and T coefficients reflect the efficiency of light conversion in time-modulated systems. The obtained results allowed us to optimize the

parameters of the temporal inhomogeneity in order to realize the desired mathematical operation. The resulting material represents a filter of spatial frequencies with suitably designed optical transfer function.

The computational metamaterials based on time-varying media open up novel opportunities for designing and practical implementation of analog optical computers with simple spatial configuration and extended functionalities.

Abstract: Plasmonic fiber tips have attracted considerable research interest from a broad range of perspectives. However, they have been hindered by the turbidity of the fiber combined with the resonant properties of the nanostructures. By applying wavefront shaping, we show that either a sub-region or entire plasmonic structure can be holographically activated. We have applied this method to a wide range of plasmonic structures including periodic nanostructures for EOT and sub-diffraction beam formation and nanoislands for Surface Enhanced Raman Spectroscopy (SERS).

The tip of a multimode optical fiber (MMF) has emerged as a natural candidate to host plasmonic structures as it is miniaturized and inherently light coupled. This has enabled a set of applications across a wide range of fields including enhanced sensing[1], integrated phase shift/beam steering[2] and second harmonic generation[3]. However, these technologies have been limited by the turbidity of the MMF that scrambles the structured input light over the entire core thus limiting the optical control of the plasmonic effects through the fiber.

Here, we propose to use a wavefront shaping technique to reveal links between input light and the mode coupling with the plasmonic resonances through the turbid MMF[4]. In particular we show that the optical transmission may be confined to a focal spot of few micrometers on the plasmonic fiber facet,limited only by the fiber numerical aperture. The wavefront shaping technique enables us to generate a re-configurable spot scanning the fiber facet or to activate an entire plasmonic structure.

We have investigated two intrinsically different classes of plasmonic structures: periodic nano-structures milled on the fiber facet by focused ion beam milling (top-down) and gold nanoislands grown on the fiber by a dewetting procedure (bottom-up). The periodic nanostructures exhibit well-defined transmission properties known as the extraordinary optical transmission (EOT) and are also well suited to generate beams with sub-diffraction features. The nanoislands, instead, exhibit broad resonances and are well suited to enhanced sensing via SERS. This opens up the possibility to host a variety of plasmonic structures on the tip of a MMF, potentially enabling multi-functional, and hyperspectral plasmonic fiber optic sensing.

The optical setup used to focus light through a plasmonic fiber optic is shown in 1a. Prior to transmission through the fiber, a spatial light modulator (SLM) was used to pre-shape the laser light (633 nm) to generate reconfigurable foci at the output. Both the surface of the output facet and its angular output were monitored on CCD2 and CCD3. Inelastically backscattered light collected by the fiber was sent to the spectrometer (SF).

To fabricate plasmonic structures, firstly a thin layer of gold (ranging from 5-100 nm) was evaporated onto the facet of an optical fiber, then the fiber was transferred to either the FIB for milling or furnace for dewetting.

Firstly nanohole arrays were milled on the facet of fiber. Panel 1c shows how each nanohole array may be holographically activated with the SLM, the foci were found to have diameter in the vicinity of the diffraction limit (approx. 3.5 um). On closer inspection with a higher NA objective collecting from the plasmonic facet we found clear evidence of sub-diffraction beam formation, leading us to conclude that the combination of periodic nanostructures and wavefront shaping show great potential for super resolution imaging through a MMF.

The final panel shows a focused spot on the nanoisland annealed surface. Benzenethiol molecules (BT) were functionalized to the facet and SERS spectra were collected through the fiber. The spectra are a convolution of both the silica background from the fiber and the BT molecule SERS signal, with prominent peaks as shown in panel 1d. Both components are of similar intensity, which marks a clear enhancement when compared with our Raman through blank fiber experiments.

Due to the diverse application of plasmonic fiber optics, the ability to confine light to a sub-region of the plasmonic facet could lead to a number of new applications. In particular, we envisage that the ability to perform sub diffraction beam formation, and enhanced sensing at the fiber tip in a reconfigurable manner will lead to a new generation of high sensitivity, multifunctional, plasmonic endoscopes potentially hosting a range of nano-photonic structures.

Inversely design a phase mask for an extended depth of focus through adjoint optimization

Huade Mao[1], Jiqiang Kang[1,2], and Kenneth K.Y. Wong[1,2*]

Abstract: We present an adjoint optimization method to inversely design a phase mask for an extended depth of focus. It reduces computation burden and has a promising application in optical imaging.

In optical imaging field, extended depth of focus (EDOF) demonstrates great importance in improving imaging depth and resolution [1]. In this regard, Bessel beam and Airy beam has been frequently adopted as a penetration beam due to their diffraction-free features [2]. However, such features come with high-energy side lobes, which will cause background noise and photobleaching [2]. Therefore, the community spends huge efforts in designing different optical devices, e.g. metasurface [3], phase mask [4], to achieve an EDOF with reduced side lobes. However, the forward process, e.g. phase mask designing, may pose high computation burden [2] but lead to a decreased focusing efficiency [3]. Recently, some inverse design methods have been applied in metasurface designing [5]. However, the research on inversely designing a phase mask for an EDOF is very limited.

Here, we present an adjoint optimization method to deliver a phase mask so as to achieve an EDOF. The phase mask could be easily accomplished through a spatial light modulator (SLM) or metasurface. The EDOF will empower optical imaging with a higher resolution and signal-to-noise ratio (SNR) compared to Bessel beam.

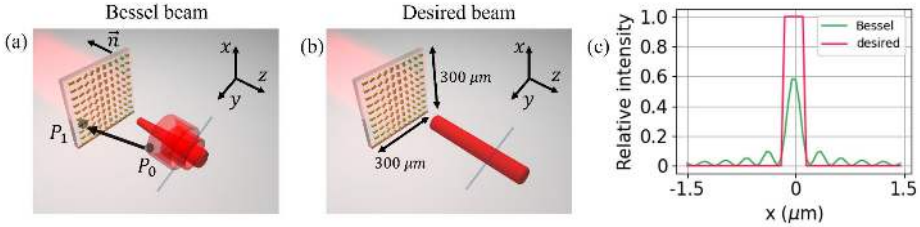

Figure 1. Schematic demonstration of the beam profile. (a) Bessel beam intensity distribution. (b) Desired beam intensity distribution without side lobes. (c) Intensity at a cross section.

Figure 1 presents our schematic setup. The size of the metasurface is 300×300 μm^2. The wavelength is 532 nm. Each pixel has a size of 250×250 nm^2. For a given phase mask $U(\vec{r})$, we can have its far-field radiation $U(P_0)$ through Fresnel-Kirchhoff formula $U(P_0)=\frac{1}{j\cdot 2\lambda}\int \frac{exp(jkr_{01})}{r_{01}}\cdot U(\vec{r})\cdot\cos(\vec{n},\overrightarrow{r_{01}})dS$, where $\overrightarrow{r_{01}}$ points from the field to the phase mask, λ is the wavelength and k is the wavenumber. It can be written in a nonlinear matrix form $g(v,p)=A_{nl}(p)v-b(p)=0$, where v is the field value, and p is the tunable phase modulation.

Here, we initialize the phase profile $p(x,y)$ for Bessel beam generation. Then, we use the adjoint optimization to update the phase pattern. We firstly propose a desired focus field I_0. The objective function we want to minimize is $f(v,p)=\sum_{x,z} abs(I_0-U)$, where U is the far-field intensity distribution during iteration.For each pixel on the phase mask, we apply a gradient descent updating rule, which is $p_{i+1}:=p_i-\frac{df}{dp_i}$. The gradient on each pixel can be obtained through only two adjoint simulation. The adjoint simulation is solving

the following equation of $\left(\frac{\partial g}{\partial v}\right)^T \cdot \lambda = -\left(\frac{\partial f}{\partial v}\right)^T$. The gradient can be readily calculated from this adjoint simulation as $\frac{df}{dp} = \frac{\partial f}{\partial p} + \lambda^T \cdot \frac{\partial g}{\partial p}$. In the end, we output the phase mask when the objective function is lower than threshold.

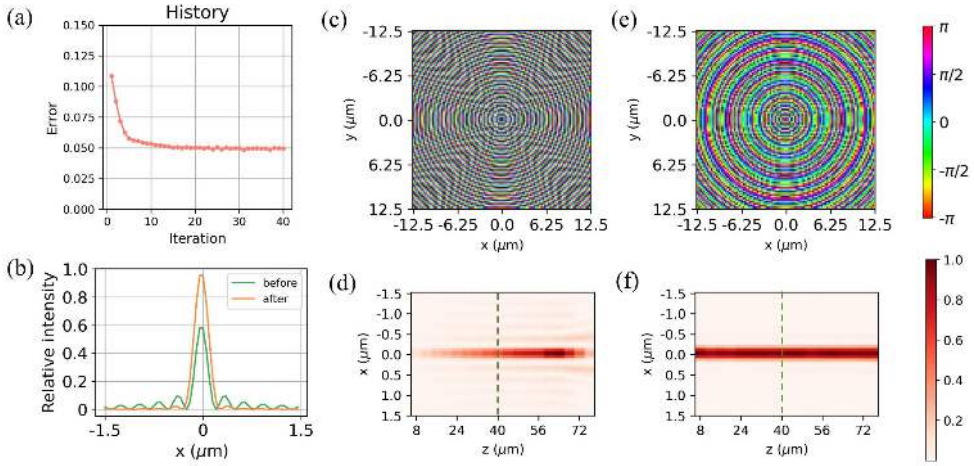

Figure 2. (a) Optimization history. (b) Intensity distribution at z-axis distance of 40 μm displayed in (d) and (f) before and after optimization. (c) Initial phase mask. (d) Initial intensity distribution. (e) Optimized phase mask. (f) Optimized intensity distribution.

The optimization result is shown in Figure 2. After optimization, the far-field focus has been greatly improved with a reduced side lobe in Figure 2(f). In Figure 2(a), the error is defined as the deviation from the desired intensity averaged across pixels. During the iteration, the error has been lowered from 10.84% to 4.90%. Once optimized, the phase mask can be uploaded to SLM or fabricated into a metasurface. It shows a great potential in an enhanced biomedical tissue imaging.

Plasmonic infrared sensor aided with artificial intelligence and immunoassay for structural protein biomarker-based neurodegenerative disease detection

D. Kavungal[1], P. Magalhães [2], S.T. Kumar [2], R. Kolla [2], H.A. Lashuel[2*] and H. Altug[1*]

[1]Institute of Bioengineering, EPFL, Switzerland

[2]Brain Mind Institute, EPFL, Switzerland

Abstract: We introduce an infrared metasurface sensor based on plasmonic surface-enhanced infrared absorption spectroscopy combined with immunoassay, which detects alpha-synuclein, an early structural biomarker protein for Parkinson's disease with clinical specificity and identifies its different structural species using their unique spectroscopic signals. Unprecedentedly, we augmented the sensor with Deep Neural Network, enabling quantitative differentiation of aSyn aggregates. Capable of multiplexing and retrieving aggregate absorbance from complex biomatrix, our sensor shows promise for PD diagnosis, disease progression monitoring, and drug efficacy assessment.

Parkinson's disease (PD) is the fastest-growing neurodegenerative disorder with devastating consequences on patients' health and quality of life. Yet, there is neither a cure that can thwart the progression of the disease nor any diagnostic method for early detection and disease progression monitoring. The structural misfolding of protein biomarker: alpha-synuclein (aSyn) from its physiologically disordered or alpha-helix form into beta-sheet enriched fibrillar aggregates *via* intermediary oligomers is an early event in PD progression (Fig. 1A) [1]. For the first time, we will present a plasmonic surface enhanced infrared absorption (SEIRA) spectroscopy-based sensor combined with immunoassay and custom-made microfluidics (ImmunoSEIRA), which detects aSyn with clinically relevant specificity in real-time and distinguishes its different structural species using their unique infrared absorption spectra. This structural biomarker-based detection scheme involves a plasmonic chip combined with PDMS-based microfluidic channels in a backside measurement configuration (Fig. 1B). Sensor is immobilized with antibodies for specific capture of aSyn species (Fig. 1C). The plasmonic nanorod array design on the chip is tuned to resonate around the infrared amide absorption bands of proteins (1500-1700 cm^{-1}), thereby collecting enhanced absorption spectra of the captured aSyn (Fig.1D). Among this, the Amide I band (1600-1700 cm^{-1}) can provide quantitative information on the different secondary structure motifs that are present differently in each structural species of aSyn (Fig.1E). Thus, this method helps to identify and classify aSyn monomers from the pathological species of oligomers and fibrils based on their unique spectral response, which forms the basis of our structural biomarker-based detection [2] (Fig.1F).

Unprecedently, by combining ImmunoSEIRA with Deep Neural Network (DNN), we show the ability to quantitatively predict the individual presence of aggregates, i.e., oligomers and fibrils from mixed aSyn aggregate samples [2] (Fig.2). This is not achievable by any other existing methods and assays. The DNN-aided ImmunoSEIRA analysis is substantial for obtaining the quantitative presence of different aggregate species of the same protein biomarker in patient body fluids for accurate and timely diagnosis and to differentiate PD from other synucleopathies. We will also present other results showing the multiplexing aspect of the sensor to monitor different protein biomarkers at the same time, along with its capability to retrieve the protein signature in the presence of human cerebrospinal fluid. These results bring our sensor one step closer to clinical standards for PD diagnosis with future applications, including disease progression assessment, patient stratification, and aSyn-targeted drug engagement studies.

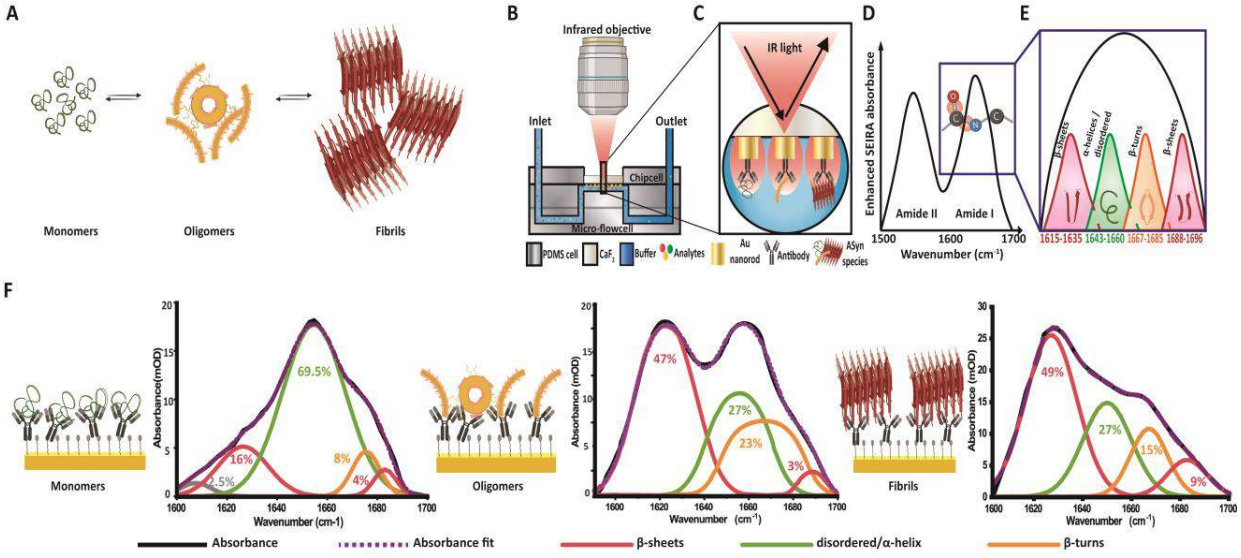

Figure 1. (A) Scheme showing aggregation of unstructured aSyn monomers into beta-sheet enriched fibrillary aggregates through intermediary oligomeric species (B) Structural biomarker-based detection scheme involving a plasmonic chip combined with PDMS-based microfluidic channels in a backside measurement SEIRA configuration (C) Immunoassay combined SEIRA (ImmunoSEIRA) for specific capture of aSyn protein species (D) Collection of enhanced SEIRA signal from aSyn protein amide absorption bands (E) Presence of different secondary structure motifs present in the protein extracted from the Amide I band based on distinct sub-bands (F) SEIRA enhanced absorbances of aSyn monomers, oligomers, and fibrils with their corresponding retrieved percentage presence of secondary structures.

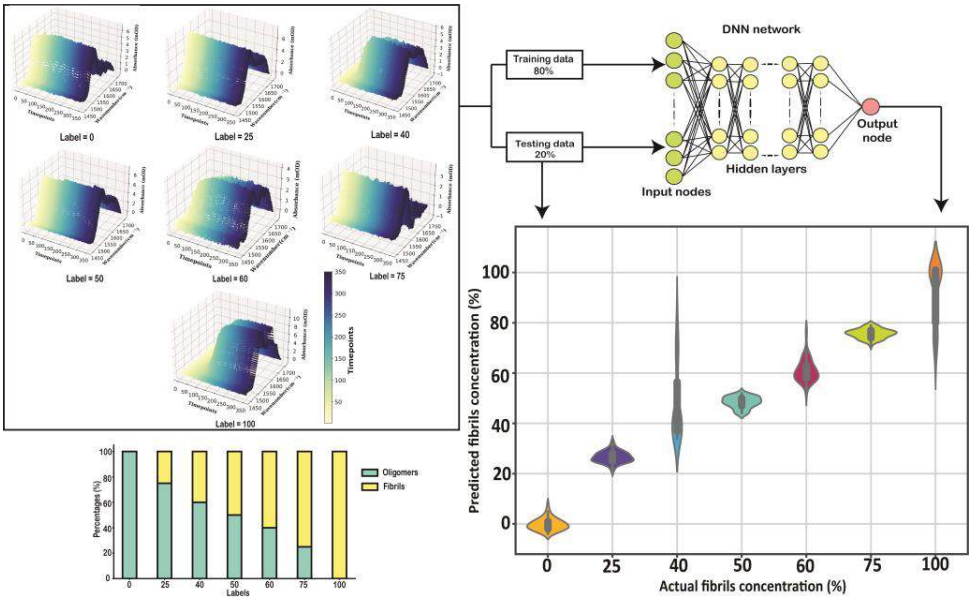

Fig. 2: 3D absorbance profile of different aggregate mixture samples, as mentioned in the stacked bar plot collected using the ImmunoSEIRA setup with labels corresponding to the percentage presence of fibrils, forms the entire dataset. This is split into training (80%) and testing (20%) datasets. The output produced by the trained DNN network shown in the violin plot compared with the actual output shows excellent accuracy of the network in predicting the individual presence of oligomers and fibrils in a mixture.

Abstract: Sensors based on Localized Surface Plasmon Resonance (LSPR) reach impressive detection limits, however their fabrication in most cases is time-consuming and costly. In this work, we immobilized LSPR sensor with antiadhesive layer that allows detection of analyte through shift of the resonance and it subsequent recovery to initial LSPR peak position. Immobilization on 4 sensors from the same pattern family (Achiral Octupolar) with different pitch is performed to investigate what role nanostructure dimensions play in sensor's response.

Ideal LSPR sensor for biomedical application should be rapid, reusable (or inexpensive) and specific (low cross-sensitivity to typical contaminants). Developing such a device is a long and complicated process. Moreover, biomolecules such as DNA have size comparable to sensing volume of nanostructure which can't be neglected.

In our recently published paper [1], we have reported protocol for creating DNA antiadhesive layer for LSPR sensors fabricated with Electron Beam Lithography. Its reusability was shown by performing 13 measurements of analyte at various concentration, each one followed by washing (recovery protocol) – measurement protocol in Figure 1. Calibration curve was constructed and limit od detection (LOD) of 105 ng/ml was calculated. Standard deviation of LSPR peak after recovery was equal to 711 ± 2 nm, proving that recovery outcome is repeatable, therefore antiadhesive layer remains intact.

Subsequently, to find optimal nanostructure, immobilization is done on 4 sensors – each of Achiral Octupolar pattern but with a pitch of 25 nm, 50 nm, 100 nm and 263 nm. As analyte A we use 1 μg/ml sodium salt salmon dsDNA in deionized water (~2000 bp, salt/DNA 5% mass concentration) and as analyte B (B1, B2, B3) we use 1 μg/ml dsDNA of specific molecular weight (546 bp, 1064 bp and 1614 bp) in 100 mM Tris buffer and 10 mM $MgCl_2$. All analytes contain molecule of interest but of various size and with other solutes present.

Achiral Octupolar 25 yielded LSPR shift of 16 ± 4 nm and 46 ± 2 nm for analyte A and analyte B (average of B1, B2, B3), respectively. As we increase pitch of Achiral Octupolar structure to 263 nm the difference becomes negligible – down to shifts of 25 ± 5 nm and 32 ± 4 nm for analyte A and B, respectively. For all Achiral Octupolar structures solutions B1-B3 yield similar shifts. Therefore variations in molecular weight within 546 bp-1614 bp do not change sensor's response. Shift of LSPR resonance peak is linear with refractive index change, which was also verified for Achiral Octupolar family [2]. Ratio of shifts between solution A and B yields 2,88 and 1,28 for pitch of 25 nm and 263 nm, respectively. Those results indicate clearly a pitch effect response beyond each structure's inherent sensitivity to refractive index change.

Simultaneously, difference between LSPR shifts of analyte B and A decreases as pitch increases – 30 nm, 17 nm, 12 nm and 7 nm for dimensions of 25 nm, 50 nm, 100 nm and 263 nm, respectively. Ionic strength of solution affects DNA persistence length [3]. We hypothesize that sensor with 25 nm pitch gives much larger

response to analyte B as Mg^{2+} changes DNA persistence length, allowing it to penetrate more efficiently into sensing volume. For pitch of 263 nm, analyte A and B can both reach sensing volume with a comparable efficiency, regardless of Mg^{2+} presence.

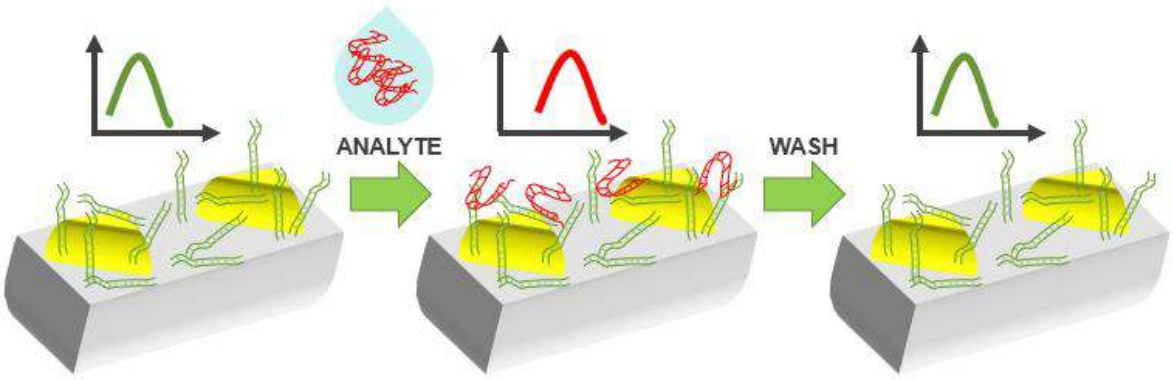

Figure 1. Scheme of measurement protocol: immobilized sensor with given LSPR peak position (left), analyte deposition and LSPR peak shift observation (centre) and recovery back to initial LSPR (right).

Using DNA solutions with relatively small concentration of other solutes allows successful sensor recovery. In order to manipulate well DNA persistence length, high concentration of buffers and salts is required. Unfortunately, they also reduce reusability of the protective layer. Currently, we are working on developing recovery protocol that could tackle that problem. In perspective, we hope to take advantage of the pitch-analyte interplay to develop multiplex sensor calibrated for typical solutes present in DNA samples. Such sensor could offer a full lab-on-chip functionality.

This work was funded by PNR 2015−2020 (POC01_00109), PULSE-COM (Grant agreement No 863227) and Erasmus+.

Abstract: Ultrafast (<~130 fs) chirality all-optical modulators and various chirality logic gates with chirality nonlinear optics in monolayer semiconductors are demonstrated.

Chiral light, referring to left-handed (σ^-) and right-handed (σ^+) circularly polarized light, has been extensively studied both in linear optics [1] and nonlinear optics [2]. Recently, intrinsic chiral coupling effect in nanostructures (e.g., nanofiber and photonic waveguide) due to the spin-momentum locking in evanescent waves has been revealed for nanophotonics and quantum optics applications [3,4]. Here we demonstrate an ultrafast (<~130 fs) chirality all-optical gate and logic gates with chiral THG in monolayer semiconductors.

Figure 1. **Chirality nonlinear optics in monolayer MoS_2. (a)** Schematic illustration of chirality THG process in monolayer MoS_2. **(b)** Illustration of an ultrafast optical gate enable by chiral THG when the two opposite circularly polarized pump beams are employed. **(c)** The truth table of the chirality XOR logic gate based on the chiral THG.

Figure 1(a) shows the chiral third harmonic generation (THG) in monolayer MoS_2. The chiral THG effect is defined as the presence or absence of THG signal when the two fundamental waves possess opposite or identical circular polarization, which is since THG cannot be generated by a circularly polarized pump beam [5]. By controlling the time delay between the two oppositely polarized pump beams (~1560 nm), an ultrafast gate is demonstrated as shown in Fig. 1 (b) [6]. The operation speed (~130 fs) of the ultrafast gate is only limited by the pulse duration of the pump beam (~81 fs). Note that this ultrafast gate also provides an easy solution for

characterizing the pulse width of the fundamental wave due to the lift of strict symmetry breaking requirement as that in the $\chi_{(2)}$ nonlinear process. Figure 1(c) shows the truth table of the chirality XOR logic gate based on the chiral THG, where the two incident beams with different chirality, i.e., σ^- or σ^+ circular polarization, are synchronized in the time domain (i.e., $\Delta\tau$=0) and defined as input logic 0 or 1, the presence and absence of output THG signal is defined as logic output 1/0. By changing the chirality of the incident beams with waveplates, other chirality logic gates, such as XNOR, NOR, AND, OR, and NAND, can also be constructed as previous demonstrated with nonlinear optics [7]. With the electrically tunable THG in graphene [8], it is feasible to realize the electrical reconfigurable chirality logic gates, which is promising for next-generation mixed and hybrid computing technology.

In conclusion, we have demonstrated two prominent all-optical functions based on chiral THG in monolayer MoS_2. The relaxed phase matching limitation in nonlinear effect of monolayer materials implies broad working bandwidth, ultrafast, and on-chip devices possiblities. These demonstrated devices provide a promising all-optical approach for emerging nano-photonics applications based on chiral nonlinear effects.

Abstract: Understanding the optical properties of 2D magnetic materials in relation to the number of layers is crucial for their application in photonics research. In this study, we investigate the modulation of the optical properties of CrI_3 across different thicknesses ranging from single layer to hundreds of layers. Our findings reveal a crossover in the modulation of optical properties at the mesoscale, which aligns with the thickness range at which the low-temperature magnetic properties of CrI_3 changes from antiferromagnetic to ferromagnetic.

Magnetic 2D materials have garnered substantial interest from both fundamental groundbreaking studies[1] and their potential applications[2]. The posiblity to create ultra-thin magnetic devices allows new chances to overcome the limitations of magnetic-enabled microelectronics and integrated photonics. An essential step[3] towards integrating these materials into photonic devices is to understand their optical properties as a function of the number of layers, from bulk down to the monolayer limit, which is still missing. In this study, we employed a hyperspectral imaging technique to acquire visible transmittance spectra of numerous CrI_3 flakes. These flakes whose thicknesses ranges from monolayer to more than 100 layers, were obtained by mechanically exfoliating bulk crystals onto standard microscopy glass slides. To prevent degradation, the samples were encapsulated with a coverslip that was sealed using a thermoplastic material. The hyperspectral imaging was performed employing a modified transmittance microscope. Here, the illuminating light comes from a bespoke monochromator which allowed to select the excitation wavelength. By sweeping the wavelength from 430 nm (2.9 eV) to 720 nm (1.7 eV) in increments of 1 nm, transmission images of several regions of interest in the samples were acquired at room temperature. For this purpose, the optical microscope was equipped with a monochrome CMOS camera, which was specifically chosen for its high linear range and low noise, enabling accurate quantitative analysis of even thin layers in the visible range. This wide-field method enhances the reliability of data under the same experimental conditions by acquiring images containing different samples and background. Regarding the data analysis, multiple spectra of different thickness flakes have been fitted simultaneously[4] to a transmittance model for increasing the accuracy of the results. We consider our experimental system as a basic Fabry-Pérot cavity formed by a stack of three layers and two interfaces. Here, the dielectric function of CrI_3 is assumed to follow a Lorentzian-based model composed by two oscillators whose parameters include a dependency with the sample thickness. Among other examined alternatives, the measuring method based on transmittance, the minimum multilayer system composed of air-CrI_3-glass and the simultaneous fitting process have been chosen to obtain robust and accurate results. Figure 1a presents the spectral changes of the minimum dip positions of the transmittance spectra, and Figure 1b displays the imaginary part of the dielectric function extracted from the

simultaneous fitting process. Rather than observing two thickness regimes (corresponding to few-layer and bulk thickness), an intermediate multi-layer regime shows a distinct behavior. Specifically, a crossover in the modulation of optical properties can be observed at the mesoscale. This peculiarity coincides with the thickness range in which the low-temperature magnetic properties of CrI3 changes from antiferromagnetic to ferromagnetic[2].

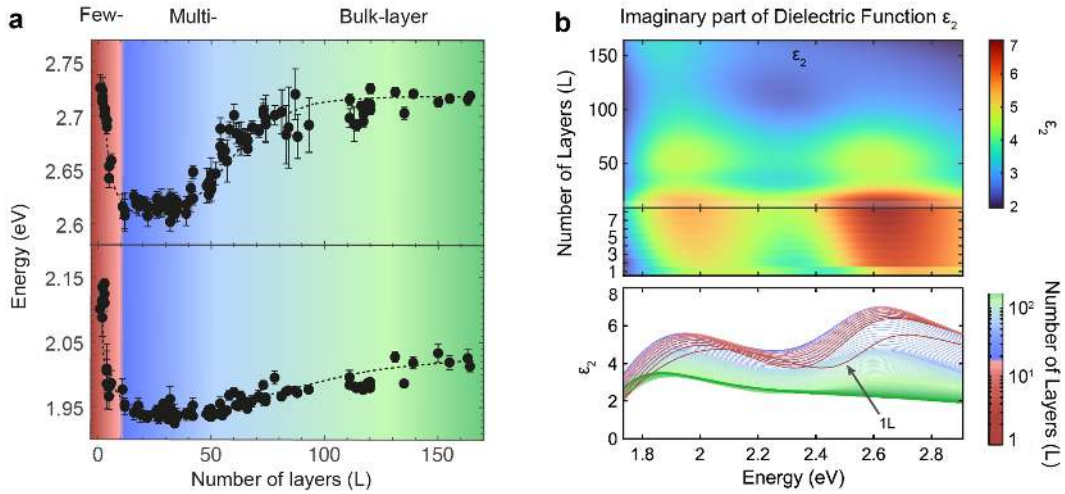

Figure 1. (a) Few-layer, multilayer and bulk thickness regimes are depicted according to the low (bottom panel) and high (top panel) energy transmittance minima experimentally measured. Markers display experimental data while the dotted lines are guides to the eye. (b) Evolution of the imaginary part of the dielectric functions (ε_2) in CrI_3 as a function of the number of layers. ε_2 is represented by way of colourmaps (top panel) and line plots (bottom panel).

Abstract: Exciton-exciton annihilation (EEA) processes are a fundamental limit for the efficiency of two-dimensional (2D) semiconductors. Here, we demonstrate suppressed EEA by enhancing light-matter interaction in hybrid 2D-dielectric nanophotonic platforms, by coupling excitons in a transition metal dichalcogenide (TMDC) WS_2 monolayer with optical Mie resonances in gallium phosphide (GaP) dielectric nanoantennas. From their ultrafast dynamics, we show reduced EEA processes, even under high exciton density, demonstrating the potential of all-dielectric nanoantennas for low-power integrated nanophotonic devices based on 2D semiconductors.

2D semiconductors, such as TMDCs, exhibit exceptional optical properties governed by strongly bound excitons, opening novel opportunities for engineering light-matter interaction at the nanoscale. However, their in-plane confinement leads to large rates of Auger-type non-radiative EEA processes, even at relatively low exciton densities, which sets a fundamental limit for their applications [1]. Here, we demonstrate EEA processes can be suppressed via enhancement of light-matter interaction in hybrid 2D-dielectric nanophotonic platforms [2,3]. We achieve this by coupling excitons in a TMDC monolayer of WS_2 with optical Mie resonances in GaP dielectric nanoantennas. We observe intermediate light-matter coupling regime between excitons and nanoantennas, as well as photoluminescence enhancement factors above 10^2. Probing the ultrafast dynamic via pump-probe spectroscopy reveals suppressed EEA processes for coupled excitons (Figure 1a). Owing to the increased radiative recombination rate, we observe reduced EEA processes, even under a high exciton density > 10^{13} cm^{-2}, as evidenced by the absence of the onset of a bimolecular recombination process ascribed to EEA [4]. For uncoupled monolayers, we observe the expected onset under fluences above 10 $\mu J/cm^{-2}$ (Figure 1b). We extracted EEA coefficients in the order of 10^{-3}, compared to 10^{-2} for uncoupled monolayers, as well as absorption enhancement of 5.6 and Purcell factor of 4.5. Our results highlight all-dielectric nanoantennas as a promising plaform for hybrid nanophotonics with 2D materials, paving the way to the realization of higher quantum efficiencies and larger exciton densities, towards low-power integrated nanophotonic devices based on atomically thin semiconductors

Abstract: Monolayer MoS_2 films can be used as a high-index core to support guided modes and create slab waveguides. These waveguides can guide light waves for millimeter-scale propagation lengths across a broad range of wavelengths, including the visible and near-infrared regions. The guided wave exhibits significantly reduced light momentum in the out-of-plane direction compared to its momentum along the waveguiding plane, indicating the guiding of 2D light waves.

We have developed an atomically thin waveguide that can guide visible and near-infrared light waves over millimeter lengths [1]. The waveguide is constructed by growing a monolayer MoS_2 film on fused silica substrate using metal organic chemical vapor deposition [2], and then embedding it in an index-matched liquid environment. This results in a slab waveguide with an atomically thin core layer embedded in semi-infinite symmetric claddings. The waveguide is excited using a free-space laser beam in an edge-on configuration where the beam is incident on the edge of the waveguide with a beam trajectory nearly parallel to the waveguiding plane. Wide-field microscopy is used to investigate the light-field intensity on the film, which exhibits a field profile that starts from the edge of the MoS_2 film and gradually decays as it propagates.

Our study confirms that the atomically thin MoS_2 waveguide supports an optical mode that starts at the edge of the film and gradually decays as it travels along the film. We found that for near-infrared light with photon energies lower than the bandgap energy of MoS_2, the propagation loss of observed modes is less than 1 dB/mm, which corresponds to millimeter-scale propagation length as predicted by theoretical investigation [3]. The waveguide is capable of taking light only with near-zero out-of-plane momenta as confirmed by the angle-resolved in-coupling efficiency measurement that couples the free-space laser beam into the guided mode by adjusting the relative angle between the incident beam and the waveguide. This result indicates that the atomically thin waveguide wave may generate light waves that have 2D dispersion with greatly suppressed out-of-plane momentum broadening. We believe this waveguide has the potential to enable the development of novel photonic devices and systems for taking advantage of the 2D light waves.

S Vacancies-Triggered High SERS Activity of MoS_2 for Ultrasensitive Detection of Trace Diclofenac

Y. N. Quan [1*], X. J. Huang[1], and W. Q. Liu[1]

[1] University of Science and Technology of China Hefei 230031, P. R. China

Abstract: Recently, non-metallic surface-enhanced Raman scattering (SERS) substrates such as MoS_2 have developed rapidly due to the photo-induced charge transfer characteristics. However, the low SERS activity of intrinsic MoS_2 has hindered its application in SERS. Here, a high SERS active MoS_2 substrate based on sulfur vacancy (V_S) excitation is proposed, which aims to enhance SERS effect by regulating the structure of V_S. The research results show that V_S-MoS_2 can accurately perceive the nanomolar concentration of diclofenac in the actual water environment.

The preparation process of V_S-MoS_2 substrate is shown in Figure 1. First, the micro-nano MoS_2 flowers with abundant folds were synthesized by hydrothermal method, and then the MoS_2 with different degrees of defects was obtained by controlled annealing in a high temperature furnace (temperature controlled at 400-1000 ℃). V_S-MoS_2 presents a large number of adsorption and active sites that facilitate its effective binding to probe molecules (such as diclofenac). Therefore, based on the exploration and analysis of corresponding Raman signals, combined with other structural characterizations, the optimal conditions for regulating the S-vacancy in MoS_2 can be screened out, so as to obtain the optimal V_S-MoS_2 substrate for the SERS detection of diclofenac.

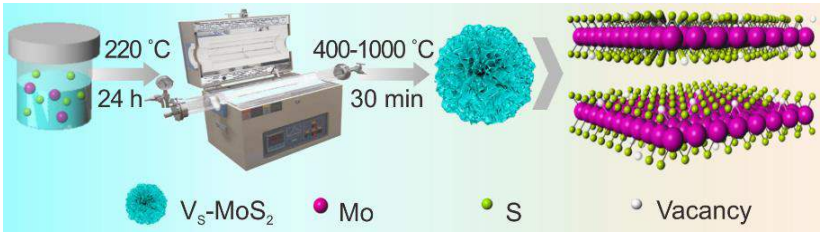

Figure 1. Schematic illustration of the synthesis of V_S-MoS_2.

The V_S-MoS_2 substrate was characterized by LABRAM HR800 Raman system equipped with 532 nm excitation wavelength. As shown in Figure 2a, the unannealed MoS_2 exhibits two first-order Raman modes, E^1_{2g} and A_{1g}, at 375.7 and 402.9 cm^{-1}, respectively. Studies have shown that the position of E^1_{2g} mode varies with the change of strain or interlayer van der Waals forces, while the peak position of A_{1g} is related to electron-phonon interaction [1]. It can be seen from the figure that the E^1_{2g} and A_{1g} peaks of MoS_2 annealed at 400 and 600℃ are roughly in the same position, which is caused by their insensitivity to electron density, strain and interlayer van der Waals forces. However, when the annealing temperature rises to 800 ℃, the positions of these two peaks appear obvious redshift, which is due to the high temperature calcination destroying the local S-Mo-S bond in MoS_2, resulting in a large number of S vacancies. As the temperature continues to rise (1000 ℃), the peak shift of the two decreases, which is because a large number of S vacancies lead to the change of the restoring force constant of the system or the chemical adsorption of foreign molecules. In addition, studies have shown that the full width at half maximum (FWHM) of Raman peaks is determined by crystallinity and charge density, and will broaden with the increase of vacancy density [2]. Both E^1_{2g} and A_{1g} peaks broaden first and then narrow with the increase of annealing temperature, which again shows that MoS_2 calcined at 800 ℃ has the most abundant

vacancies. After annealing at 1000 ℃, the reason for the decrease of the FWHM of the Raman peak may be that the adsorbed foreign molecules occupy some vacancies. Generally speaking, the specific surface area of the substrate materials was one of the important factors affecting SERS response. The larger the specific surface area is, the more adsorption/active sites are, the more significant the enrichment effect is, which is more conducive to the adsorption of the molecules to be tested. Figure 2b shows the N_2 adsorption and desorption isotherms of MoS_2 and V_S-MoS_2-800. The specific surface area of V_S-MoS_2-800 (29.83 $m^2 \cdot g^{-1}$) is significantly larger than that of MoS_2 (5.85 $m^2 \cdot g^{-1}$). Lattice fracture and dislocation are caused by the generation of S vacancy and the fracture of local Mo-S bond. The stress generated by this phenomenon makes the surface of the sample rougher, the specific surface area increases, and the enrichment effect is enhanced, which is conducive to the enrichment of probe molecules.

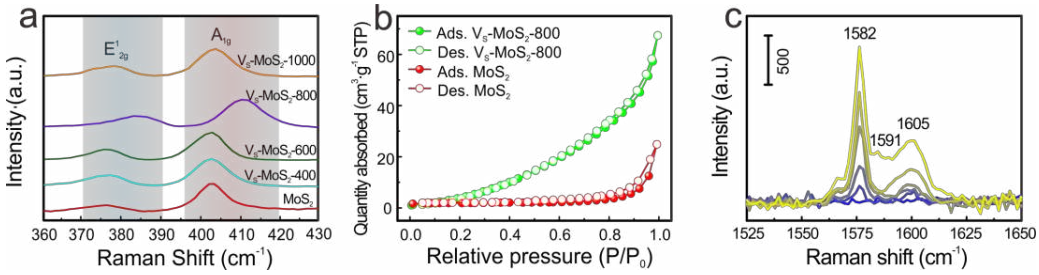

Figure 2. a) Raman spectra of MoS_2, MoS_2-400, MoS_2-600, MoS_2-800 and MoS_2-1000, respectively. b) N_2 adsorption-desorption isotherms of MoS_2 and MoS_2-800. c) SERS response of diclofenac in the concentration range from 10^{-4} M to 10^{-9} M in the real water samples.

Further, this work used V_S-MoS_2-800 sample with excellent enrichment ability as SERS substrate to detect diclofenac, an antibiotic environmental pollutant. Practicality is one of the difficulties that need to be overcome for the highly sensitive SERS substrate in recent years. We took the real water sample from Dongpu Reservoir (Hefei, China) to simulate the actual detection environment, and explored the actual detection ability and anti-interference ability of the V_S-MoS_2-800 substrate. Figure 2c shows the SERS spectra of diclofenac at different concentrations (10^{-4}-10^{-9} M) in real water samples collected using V_S-MoS_2-800 as the substrate. Three characteristic peaks in the range of 1525-1650 cm^{-1} were analyzed. Among them, the characteristic peak at 1582 cm^{-1} corresponds to the asymmetric stretching vibration of $O_1C_8O_2$, the peak at 1591 cm^{-1} corresponds to the stretching vibration of dichlorobenzene ring, and the peak at 1605 cm^{-1} is caused by the stretching vibration of phenylacetic acid ring. It was found that characteristic peaks at 1582 and 1605 cm^{-1} could still be identified when the concentration of diclofenac was as low as 10^{-8} M. The results of this experiment (33.8 ng/L) were far lower than the environmental quality standard for diclofenac in inland waters listed (100 ng/L) in the Water Framework Directive (2013/39/EU) [3]. This work has realized the SERS analysis of diclofenac residues in real water samples, and is expected to play a huge potential in practical applications such as water pollution control and detection.

Mesoporous g-C_3N_4/TiO_2 photonic film with a chiral nematic structure: slow photonic effect inducing improved H_2 generation

M. Johar[1], C. Wang[1], and M. N. Ghazzal[1*]

[1]Institut de Chimie Physique, UMR 8000 CNRS, Université Paris-Saclay, 91405 Orsay, France

[*]corresponding author: mohamed-nawfal.ghazzal@universite-paris-saclay.fr

Abstract: Photocatalysis is one of the ideal approaches to address the energy crisis. Graphitic carbon nitride (g-C_3N_4) is a promising photocatalyst that attracts attention due to its unique properties. However, its photocatalytic activity remains low due to high photogenerated charges recombination and low absorption factor. Therefore, massive efforts have been undertaken to solve these problems. This presentation proposes a fabrication of a bioinspired photonic crystal SiO_2/g-C_3N_4/TiO_2 film with a chiral-nematic structure to enhance the photocatalytic activity of g-C_3N_4.

Summary: Energy crises have flashed in the last few decades. Different materials and technologies were developed to convert solar light into usable energy, such as photovoltaic solar cells, H_2 generation, and CO_2 reduction. However, these technologies suffer from poor energy-conversion efficiency due to low optical-absorption coefficients and quantum-conversion yield of the currently developed materials. Photocatalysis is one of the promising sustainable processes to convert solar energy into chemical fuel under a mild reaction. Different semiconductors were used as photocatalysts, such as TiO_2, Fe_2O_3, WO_3 etc. However, most semiconductors share common problems, which are high recombination of charge carriers and low absorption factor directly affecting their photocatalytic efficiencies.

Among the reported photocatalysts, g-C_3N_4 shows interesting properties and promising photocatalytic activity. It is a metal-free semiconductor formed by the stacking of g-C_3N_4 layers consisting of tri-s-triazine units linked by amino groups. This photocatalyst has a moderate band gap of 2.7 eV, corresponding to the visible range, with potential band edge of the conduction band (CB) and valence band (VB) at -1.4 eV and 1.3 eV, respectively, favorable to performing water splitting. g-C_3N_4 is known for its high chemical stability, low cost, nontoxicity, appropriate band structure, and facile synthesis. However, g-C_3N_4 exhibits high photogenerated charge recombination and low absorption factor.[1] Different strategies have been developed to improve the photocatalytic activities of g-C_3N_4, including chemical modification, exfoliation into nanosheets, and fabrication of heterojunctions[2–4]. Even if these strategies enabled the enhancement of the photocatalytic of g-C_3N_4, the efficiency for photon conversion and the spatial separation for photogenerated charges carries of g-C_3N_4 is still limited. In this work, we designed a bioinspired photocatalyst with a photonic structure using cellulose nanocrystals as biotemplate seems to be a promising strategy.[5–7] The films showed iridescent color and Bragg peak reflection, which were tuned by controlling the sol formulation, see Figure 1. The films were characterized using UV-vis spectroscopy, scanning electron microscopy (SEM), Scanning transmission electron microscopy (STEM), X-ray photoelectron spectroscopy (XPS), and then the photocatalytic activity was evaluated for H_2 generation under Xenon lamp illumination. The results demonstrate that the structure can be controlled by the adjusting the formulation of the sol and thus the optical properties and the position of the Bragg peak reflection. We found that adjusting the Bragg position affect directly the photocatalytic performance of the photocatalyst for H_2 generation.

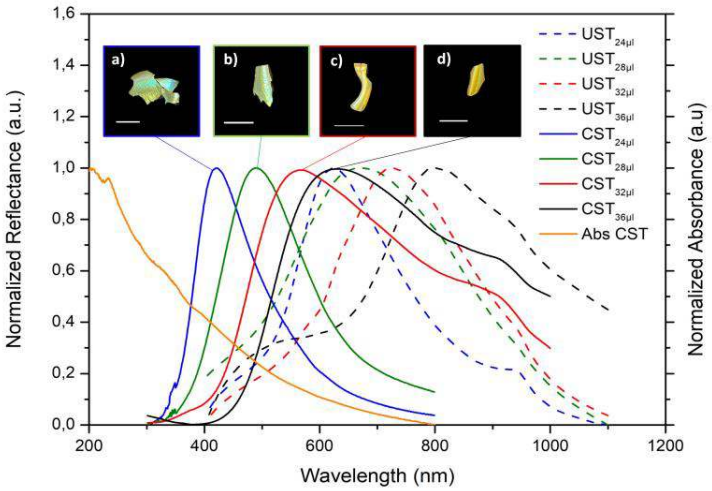

Figure 1. UV-vis reflectance spectra for calcined and hybrid films showing variable Bragg peaks as well as the absorption spectra for Mesoporous photonic g-C_3N_4/TiO_2. Photographic images of chiral nematic C_3N_4/SiO_2/ TiO_2 films a) CST-$_{24µl}$ b) CST-$_{28µl}$ c) CST-$_{32µl}$ d) CST-$_{36µl}$. UST is an abbreviation for the precursors used: Urea/TMOS/TAA (before calcination) and CST corresponds to g-$C_3N_4/SiO_2/TiO_2$ (after calcination).

Abstract: Atomic-scale material optical properties are universally described within the electric dipole approximation—bulk optical frequency light-matter interactions are assumed to arise solely from electric dipoles interacting with electric fields. This inability of matter to interact with optical frequency magnetic fields led to the advent of metamaterials. Atomic-scale optical magnetism represent an unrealized frontier in optical materials. Here, we demonstrate in 2D Hybrid Organic/Inorganic Perovskites the only known example of an atomic scale non-unity optical frequency magnetic permeability.

At optical frequencies and atomic length scales quantum mechanical light-matter interactions are inherently non-magnetic. Linear and nonlinear processes are treated in the electric dipole (ED) approximation and assumed to be driven purely by the *electric* field component of light. The lack of intrinsic optical magnetism—i.e., deriving from atomic-scale magnetic dipoles (MD)—led to the advent of metamaterials[1] wherein artificial optical magnetism is engineered at the mesoscale (~ λ/5). Metamaterials phenomena such as negative refractive index[2,3], "perfect" lensing[4,5], and electromagnetic cloaking[6,7] have captivated the imagination of scientists and laypeople alike. Here, I describe our recent discovery of atomic-scale optical magnetism in 2D Layered Hybrid Organic/Inorganic Perovskites (2D HOIPs). First, I briefly detail our use of momentum-resolved optical spectroscopy to demonstrate magnetic dipole (MD) light emission originating from self-trapped excitons[8,9]. Subsequently, I describe a series of optical experiments that demonstrate a non-unity optical frequency magnetic permeability in a 2D HOIP[10]—the only known material with bulk atomic-scale optical magnetism (Fig. 1).

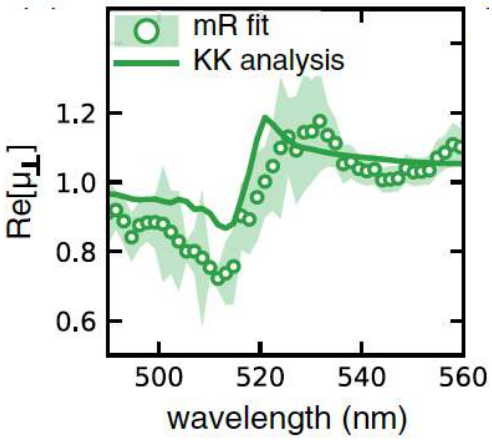

Figure 1. Real part of the magnetic permeability from a 2D HOIP. Solid markers represent experimental values determined from unconstrained momentum-resolved reflectometry measurements. The filled color region represents the standard deviationa cross all measurements. The solid line is determined from a Kramers-Kronig transformation of the measured imaginary part of the magnetic permeability.

All optical measurement, analysis, theory, and instrument design were supported by the National Science Foundation (DMR-2004093). Sample growth was supported by the U.S. Department of Energy, Office of Science, Basic Energy Sciences, under Award No. DESC-0012541.

Abstract: Recently, flexible electronic and optoelectronic devices have gotten excessive attention because of their role in wearable technology. This work successfully fabricates Pd/ZnO-SWCNT/Pd flexible interdigitated photodetector. Hydrothermal growth of ZnO thin films was used. A device's I-V characteristics were evaluated in both dark and UV light environments over a voltage range of -5 to 5 V. The barrier heights for the fabricated devices were 0.765 eV, while the ideality factors were 1.84. The responsivity was found to be 14.8 A/W, the device exhibited gain.

Introduction: Flexible electronics is a new type of electronic device that has mechanical capabilities. To make such electrical devices, the components and materials must be pliable in multiple directions, stretchable, and shrinkable [1]. Photodetectors (PDs) have found use in a wide range of industrial and military applications due to their ability to convert incident light into charge carriers via the photoelectric effect. The elasticity of flexible photodetectors versus PDs on rigid substrates has inspired a variety of new applications, including wearable electronics, e-skin, smart fabrics, and electronic eye cameras, among others [2-4]. The UV photodetectors cut off wavelength at 400 nm. Wide band gap (WBG) semiconductors have attracted substantial attention for the detection of UV wavelengths, afforded by the correlation of their band gap energies [4]. Zinc oxide (ZnO) stands out inorganic material among wideband potential candidates for UV photodetectors fabrication. ZnO has gotten a lot of attention as a semiconductor material with a direct bandgap of 3.20-3.37 eV and a significant exciton binding energy of 60 meV at 25℃. The seed layer affect the ZnO nanostructured growth. Here we use the single-walled carbon nanotubes (SWCNTs) as a seed layer to enhance the orientation and crystallinity of the ZnO nanorods. SWCNTs can be thought of as a perfect sheet of graphene rolled up into a cylinder, with the hexagonal rings touching and fitting together perfectly [3]. In this work, Pd/ZnO-SWCNT/Pd flexible interdigitated MSM UV photodetector has been fabricated, characterized and studied.

Result and Discussion: The I-V characteristics of the ZnO-SWCNT-based MSM PDs in the dark as shown in Fig. 1 (a), governed by the thermionic emission. It is possible to calculate the saturation current I_S from I-V characteristics by extrapolating the dark current and setting the voltage to zero. The extracted saturation currents for devices were found to be 3.62×10^{-7} A. The computed barrier height from thermionic theory is 0.765 eV. The value of the ideality factor of Pd/ZnO-SWCNT/Pd is found to be 1.84). ZnO-SWCNT thin film-based devices were constructed, tested, and evaluated under UV irradiation (254 nm) at varying optical power levels (from 163.2 to 171.8 µW). Equation (1) [5] describes the photodiode's responsivity that connects the photocurrent (I_{ph}) to the optical power (P_{opt}) Fig.1 (b) illustrate the dark and illumination current under different UV level. The maximum responsivity for the fabricated devices at optical power 163.2 µW is 14.8 A/W as shown in Fig. 1 (c). Using the external quantum efficiency Equation (2) to calculate the O/E conversion efficiency [4]. As shown in Fig.2 .(d), the MSM highest EQE is 7160 (gain) at 163 µW. Equation (3) may be used to get the voltage-dependent detectivity value. From Fig. 2 (e), the detectivity begins to

increase at 163.2 μW and reaches maximum values at 164.6 μW, are $4.82\times10^{11} cmHz^{1/2}W^{-1}$ after which it decreases to $1.77\times10^{11}\ cmHz^{1/2}\,W^{-1}$ at 165 μW.

$$R = \frac{I_{Ph}}{P_{opt}} \qquad (1)$$

$$n_{ext} = \frac{I_{Ph}}{P_{pot}} \times \frac{h\nu}{q} \qquad (2)$$

$$D = \frac{\lambda n_{ext} q}{hc}\sqrt{\frac{RA}{4KT}} \qquad (3)$$

Figure 1. (a) I-V characteristics, (b)I-V under dark and illumination conditions, (c) Responsivity, (d) Gain, and (e) Detectivity

Conclusions: In conclusion, simply fabricated flexible interdigitated MSM PD ZnO-SWCNT on a PET/ITO substrate. Based on the findings of dark I-V measurements, it is evident PD performs like a conventional MSM. The actual barriers heights are lower than their theoretical values. The existence of elevated surface charges or a nonhomogeneous barrier may cause the estimated and ideal barrier height values to diverge. The performance characteristics responsivity of 14.8 A/W A/W , detectivity of $4.82\times10^{11} cmH^{1/2}W^{-1}$, with a high gain of 7160.

Abstract: We present a comprehensive study of vanadium dioxide, a phase-changing material relevant for active plasmonics and optical metasurfaces, using analytical scanning transmission electron microscopy combined with in-situ heating. A combination of imaging, diffraction, and spectroscopy with nanometer spatial resolution allowed us to locally correlate the optical properties with applied temperature and local variations in stoichiometry. We observed a reduction of the oxide for sample thickness below 30 nm and the formation of nanoparticles at elevated temperatures.

Vanadium dioxide is a phase-changing material with a low transition temperature (around 67 °C) with a dielectric low-temperature and metallic high-temperature phase. Due to the proximity of its transition temperature to the room temperature, VO_2 is a promising candidate for applications in photonics including fast optical switching or tunable optical metasurfaces [1]. Moreover, it was shown that VO_2 is biocompatible [2], which open a way to design a temperature-driven plasmonic biosensor. However, the nature of the metal-insulator transition in VO_2 is not yet fully understood, with the Mott transition and Peierls transition being the most considered scenarios.In this contribution, we present a comprehensive study of vanadium dioxide using analytical scanning transmission electron microscopy (STEM) combined with in-situ heating. A combination of imaging, diffraction, and spectroscopy with nanometer spatial resolution allowed us to locally correlate the optical properties of VO_2 with applied temperature and local variations in stoichiometry.

First, we fabricated a thin layer of VO_2 by evaporation and verified the presence of metal-insulator transition by ellipsometry. Next, we fabricated lamellas by focused ion beam milling. Energy-dispersive X-ray spectroscopy revealed a rather homogeneous composition with only discernible contamination by Ga ions implanted during the milling. High-angle annular dark field (HAADF) STEM imaging revealed pronounced structural inhomogeneity – a porous and polycrystalline character of the examined lamella. A thinned part of the lamella has been examined by core-loss and low-loss electron energy loss spectroscopy (EELS) at temperatures well below and above the transition, and the experimental loss spectra were interpreted by ab-initio simulations and by comparison with literature [3,4]. We observed that the thin part of the lamella is dominated by reduced vanadium oxides (VO, V_2O_3) and exhibit no switching. This fact presents an important limit for the fabrication of VO2 nanostructures. The thicker parts of the lamella are dominated by VO_2 and exhibit signatures of thermal-induced switching (Fig. 1). Second, we fabricated thin layers of VO_2 by atomic layer deposition. One of them was further recrystalized into nanoparticles. Investigation of such nanoparticles revealed signatures of thermal-induced switching in the low-loss EELS (Fig. 2).

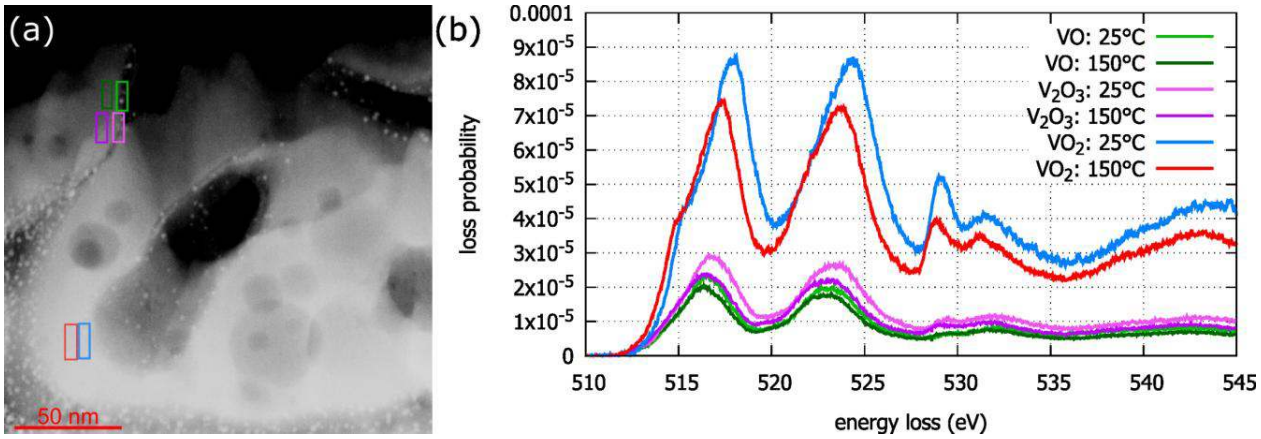

Figure 1: (a) STEM-HAADF micrograph of VO_X lamella reveals its porous character. (b) Core-loss EELS obtained from marked positions. The spectra from the thin part of the lamella are attributed to VO (green) and V_2O_3 (magenta) and do not change with the temperature. The spectra from the thicker part are attributed to VO_2 (blue and red) and exhibit possible changes with the temperature.

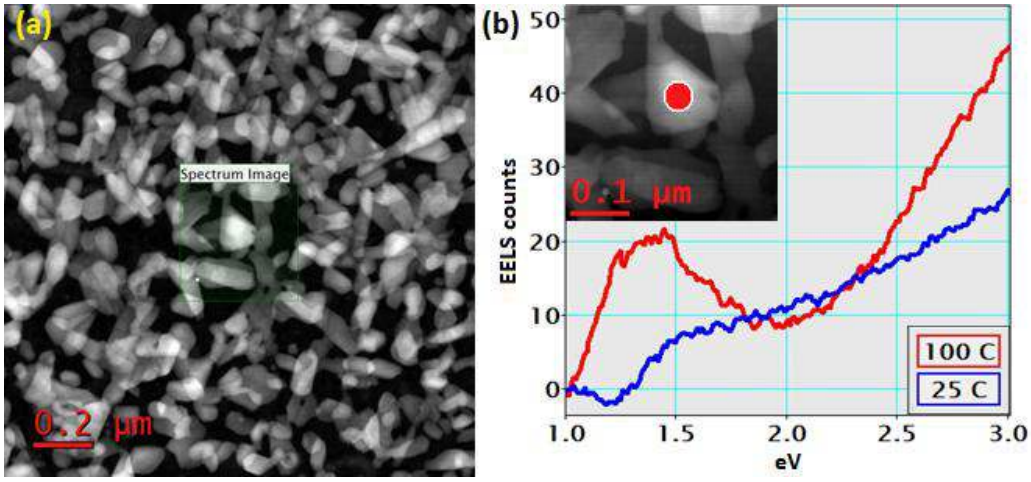

Figure 2: (a) STEM-HAADF micrograph of VO_2 nanoparticles, (b) Low-loss EELS of one nanoparticle at room temperature (dielectric phase) and at 100°C (metallic phase).

Abstract: High refractive index dielectric nanoparticles have gained considerable attention as an alternative to plasmonic nanoparticles. In this study, we developed a new method for producing Mie resonant silicon nanoparticles using laser annealing, and were able to control the Mie resonance wavelength across the entire visible region by adjusting the laser annealing conditions. The Mie resonant Si nanoparticles were then utilized to enhance the fluorescence of analytes in their vicinity.

Dielectric nanoparticles with a high refractive index and low energy losses have attracted much attention as a new visible light resonance medium to replace plasmonic nanoparticles. The electric and magnetic multipoles excited in dielectric nanoparticles enable the manipulation of light at the nanoscale and exhibit high electromagnetic field enhancement effects. In this study, we developed a practical method to fabricate silicon (Si) nanoparticles with Mie resonances in the visible region over a large area on a substrate by laser annealing, as schematically shown in Fig. 1a.

Laser annealing was performed by focusing a CW laser with a wavelength of 532 nm on a Si thin film deposited on a glass substrate. Figure 1b shows a dark-field optical image of the laser-annealed Si substrate, exhibiting strong green scattering color over the entire irradiated area. SEM observations and dark-field scattering spectrum measurements revealed that Si nanoparticles with a diameter of about 150 nm were produced by the annealing effect in the laser irradiation area (as shown in inset of Fig. 1b) and had a Mie resonance mode near 530 nm. The size of the Si nanoparticles was controlled by the laser annealing conditions (irradiation time and power density), enabling us to tune the Mie resonance wavelength in the entire visible region. Finally, the Si nanoparticles were utilized to enhance fluorescence of dye molecules with an excitation wavelength close to the Mie resonance wavelength, resulting in two-order-of-magnitude fluorescence enhancement in the vicinity of the Si nanoparticles (Fig. 1c).

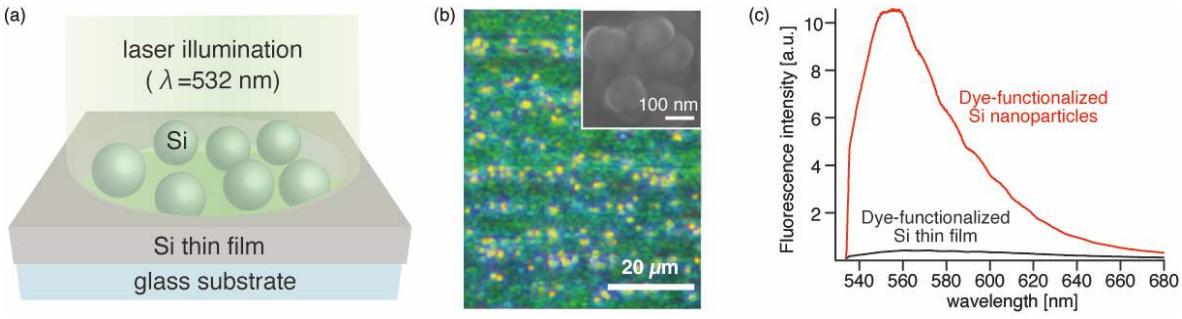

Figure 1 (a) Schematic of fabricating Si nanoparticles by laser annealing of a Si thin film. (b) Dark-field optical image of the laser-annealed Si substrate. The inset shows an SEM image of the annealed substrate, indicating formation of spherical nanoparticles. (c) Fluorescence spectra of dye-functionalized Si nanoparticles and Si thin film.

Graphene-based plasmonic nanostructures for efficient SERS detection of odor molecules

S. Ozeki[1], R. Kato[1, 2], T. Tanaka[1, 2], and T. Yano[1, 2*]

[1]Institute of Post-LED Photonics, Tokushima University, Tokushima, Japan
[2]Innovative Photon Manipulation Research Team & Metamaterials Laboratory, RIKEN, Saitama, Japan
[*]corresponding author: yano.takaaki@tokushima-u.ac.jp

Abstract: Graphene-based plasmonic nanostructures were investigated for highly sensitive Raman detection of odor molecules. Odor molecules with aromatic benzene rings were preferentially adsorbed on graphene through π-π stacking in the proximity of metallic nanostructures. Raman enhancement factor varied significantly depending on the number of graphene layer, and the highest enhancement was obtained for the monolayer graphene substrate due to the strongest field confinement in the vicinity of metallic nanostructures.

Optical detection of odor molecules is of great importance for healthcare monitoring. Among various analytical tools, surface-enhanced Raman scattering (SERS), in which strong electromagnetic field is generated in the vicinity of the metallic nanostructures and enhances Raman scattering of molecules near metallic nanostructures, is a promising technique for detecting odor molecules with high sensitivity, down to the single-molecule level. However, it is challenging to capture the SERS signal of odor molecules because they do not directly adsorb onto metallic surfaces. Here, we propose to utilize graphene-based metallic nanostructures as a SERS substrate where odor molecules are selectively adsorbed on graphene through π-π stacking in the proximity of metallic nanostructures, as schematically shown in Fig. 1(a).

Graphene-based metallic nanostructures were fabricated by depositing 8 nm-thick silver (Ag) layer on mechanically-exfoliated monolayer (1L) graphene using thermal evaporation. Figure 1(b) shows an atomic force microscope (AFM) image of the Ag-deposited graphene substrate, exhibiting Ag nanograins with nanometric separation distance. More interestingly, the size and the separation distance of the nanograins varied significantly depending on the number of graphene layers. To investigate the layer-number-dependence of plasmonic Raman enhancement, 4-aminothiophenol (4-ATP) molecules were adsorbed on the Ag nanograins deposited on 1L, 2L, and 3L graphene, respectively. Figure 1(c) shows SERS spectra of 4-ATP measured on the substrates with different number of graphene layers. The SERS intensity was significantly dependent on the layer number, and the highest Raman enhancement was obtained for the 1L graphene. This is because the separation gap distance of Ag nanograins decreased as the layer number decreases, resulting in the highest field-confinement of -enhancement at the small gap for the 1L graphene substrate. Finally, SERS measurement of odor molecules were demonstrated using the 1L-graphene-based substrate.

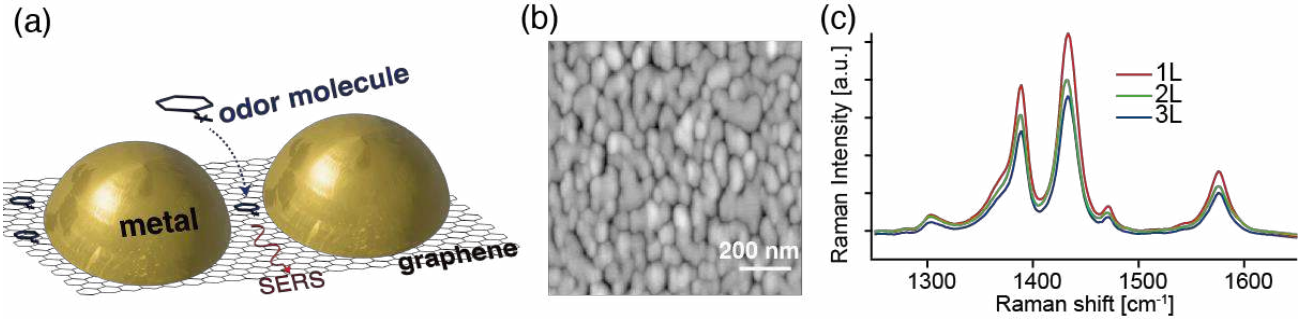

Figure 1 (a) schematic of graphene-based SERS substrate, (b) AFM image of silver nanograins formed on 1L graphene, (c) layer-number-dependent SERS spectra of 4-ATP monolayer.

Abstract: We introduce a class of nanoresonators that incorporate a new degree of freedom: twist tuning. To achieve this result, we place a pristine slab of the van der Waals α-MoO_3 crystal on an array of metallic ribbons. This sample design based on electromagnetic engineering, allows the definition of α-MoO_3 nanoresonators with low losses (Q up to 200) and enables a broad spectral tuning of the polaritonic resonances (up to 32 cm^{-1}) by an in-plane rotation (from 0 to 45º).

Thin uniaxial and biaxial vdW crystal slabs have recently emerged as an extremely attractive playground for manipulating light on deeply subwavelength scale[1-4]. Here, we design an array of in-plane anisotropic resonators by placing a continuous (pristine) thin biaxial vdW crystal slab α-MoO_3 on top of a grating (Figure 1) formed by metal ribbons. In the areas above the ribbons, the refractive index of the PhPs supported by the slab changes, so that PhPs can bounce back and forth between the boundaries of these areas, forming resonant modes. We characterize our refractive index engineered PhP resonators by both the far-field Fourier-Transform IR spectroscopy (FTIR) and near-field scattering type scanning near-field optical microscopy (s-SNOM), disentangling the resonant PhP modes from the experimental data with the help of the theoretical analysis. By rotating the α-MoO_3 slab above the grating, we demonstrate tuneability of the PhP resonances, and reconstruct the isofrequency curves of the PhP modes.

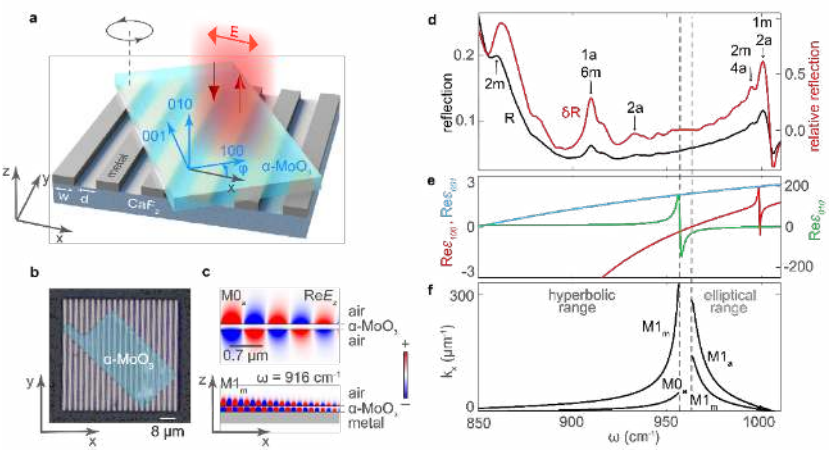

Figure 1 | PhPs nanoresonators in α-MoO_3 defined by placing a pristine α-MoO_3 slab on metallic ribbons. **a**, Schematics of the studied structure that allows defining the nanoresonators by "electromagnetic engineering" and controlling them by a twist angle, φ. Abstract: We show that monolayer semiconductors, a rising material family in photonics and electronics, can exhibit noise-like, localized fluctuations in their fluorescence. Inspired by a superresolution technique, we use imaging to show that the fluctuation strength depends on the monolayer's nanoscopic environment. Fluctuation imaging, a fast and simple method, can thus be used for quality control throughout a manufacturing process flow to quantify and map disorder. Our results are relevant for the integration of monolayer semiconductors into nanophotonic devices and metasurfaces.

Two-dimensional semiconductors are promising materials for the fields of electronics, optoelectronics, and photonics. Monolayer transition-metal dichalcogenides (TMDs) are particularly interesting because they host excitons that dominate the optical properties even at room temperature. The exciton electric field extends outside the monolayer rendering it sensitive to the surroundings. Together with other effects like charge transfer, interaction with the local environment makes excitonic fluorescence potentially unstable over time[1,2]. The fluctuations in the fluorescence depend thus on disorder in the monolayer, which is generally detrimental for devices[3].

Here, we adapt a fluctuation-based super-resolution technique to image the localized exciton fluctuation strength in monolayer TMDs[4]. Fluctuation imaging shows fluctuating spots on a stable monolayer. We correlate the presence of localized fluctuations with features in atomic force microscopy (AFM) height scans. We compare different TMDs and substrates to test the role of different material combinations in these fluctuations. To gain more insight into the disorder behind these fluctuations, we employ hyperspectral mapping. Furthermore, we evaluate a thermal annealing process as a method to clean the monolayers and evaluate their fluctuations before and after cleaning.

To conclude, fluctuation imaging is a simple technique that can be used in any camera-based fluorescence microscope. Our results show that fluctuation imaging reports features that would take a longer time to characterize using more complex equipment such as AFM or hyperspectral imaging. It is, therefore, a promising method for fast evaluation of the quality of monolayer semiconductors and their interfaces with other materials, including nanostructures such as metasurfaces or nanophotonic devices.

Towards Graphene-comprising Waveguide Resonators for Kerr Comb Generation in the Non-Perturbative Electrodynamic Nonlinearity Regime

Alexandros Pitilakis[1*] and Emmanouil. E. Kriezis[1]

[1] School of Electrical and Computer Engineering, Aristotle University of Thessaloniki, 54124 Thessaloniki, Greece

Abstract: We present a study of Kerr microcombs generated by CW pumping of graphene-comprising silicon nitride waveguide ring resonators in the NIR. Our resonator is designed to access the dissipative cavity soliton regime under the combined effect of defocusing nonlinearity from graphene and normal group velocity dispersion (GVD) from a slot waveguide, properly accounting for the wideband dispersion of all waveguide parameters. We then proceed to study the effect of non-perturbative graphene nonlinearity on comb formation and efficiency.

Optical frequency combs can be efficiently generated in small travelling wave resonators made of dispersive materials with third order (Kerr-like) nonlinearity [1]. The most frequently used resonators are bulk whispering-galleries (e.g., magnesium fluoride micropillars) designed for very high Q-factors and critically coupled to optical fibers. As practical applications shift towards integrated optics, waveguide ring resonator (WRR) Kerr combs have also appeared, underpinned by the same principles but also requiring for redesign to exploit the stronger light-matter interaction in integrated nanophotonics. To that end, graphene is a novel optical material that can enrich integrated WRR Kerr combs with its electro-optic tunability of its dispersion [2] and nonlinearity [3], controlled by tuning its chemical potential μ_c. Recent studies have shown that when graphene interacts with high electric field intensities, like the ones that can develop in high-Q photonic resonators, its nonlinearity transcends from a perturbative third order to a non-perturbative photoconductivity regime [3]; the latter is characterized by both self-focusing or defocusing refraction, depending on μ_c, and a deep saturation of its absorption as intensity increases. In this work, we investigate these features, i.e., the intensity- and μ_c-dependent electrodynamic nonlinearity, and exploit them for Kerr comb formation, while rigorously accounting for the frequency dispersion of all properties.

To model the Kerr comb formation, we use the Lugiato-Lefever equation (LLE) framework, in the two-timescale arrangement, that monitors the total electric field inside the cavity. The LLE can be considered as a driven, damped, and detuned variant of the nonlinear Schrödinger equation (NLSE) typically used to model pulse propagation along nonlinear waveguides [3]. The LLE, following the variable notation of [1], is:

$$t_R \frac{\partial E(t,\tau)}{\partial t} = L\left[-\frac{\alpha}{2} + i\sum_{n\geq 2}\frac{\beta_n}{n!}\left(i\frac{\partial}{\partial \tau}\right)^n + i\gamma|E|^2\right]E(t,\tau) + \left(-\frac{\theta}{2} - i\delta_0\right)E(t,\tau) + \sqrt{\theta}E_{in}, \quad (1)$$

where $E(t,\tau)$ is the E-field amplitude inside the resonator (fast-time: τ) as the slow-time (t) progresses. The dispersion of the two Q-factors (α and θ), the nonlinear parameter (γ), and β, are incorporated in the LLE.

For the WRR, we consider a graphene monolayer-clad air-slot design, formed by two rails of silicon nitride on insulator (SNOI), transparent down to the visible range; the slot design was chosen for its normal GVD, a prerequisite for soliton formation under the defocusing nonlinearity of graphene in the μ_c range considered. The waveguide cross-section, inset of Fig. 1(a) [800 nm $\times$ 500 nm SNOI rails separated by a 50 nm slot], was tuned for operation in $\lambda_0 = [1.1,2.3]$ μm, i.e., in an octave span around 1.55 μm. The frequency and μ_c dispersion of the waveguide parameters is depicted in Fig. 1(a)-(c); for this preliminary study, we used standard linear and third-order surface conductivity formulas for graphene, at room temperature and assuming regular quality samples

(τ_{intra} = 20 fs). We tune graphene at μ_c = 0.5 eV, as an optimal compromise between attenuation and nonlinearity, and set the WRR round-trip at L = 100 μm for a pump power $|E_{in}|^2$ = 10 W. Using the LLE, we slowly detune the pump frequency through the 1.55 μm resonance, from −10 to +50 GHz, acquiring a 50 THz (quarter octave) comb, Fig. 1(d). Due to the non-negligible high-order dispersion of the waveguide, the produced soliton is stable but highly dispersive in the fast time frame. Nevertheless, all the Kerr comb regimes are traversed, Fig. 1(d)-(e): modulation instability (MI), chaos, unstable/breather solitons, and stable phase-locked cavity solitons.

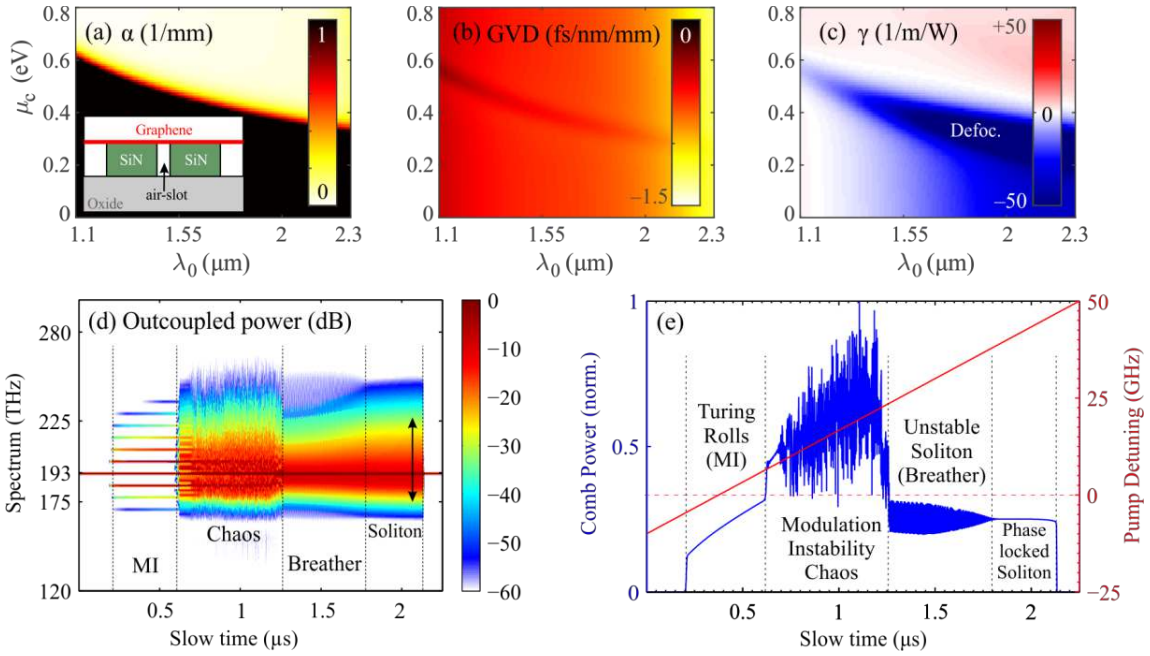

Figure 1. Frequency and μ_c dispersion of the waveguide (a) attenuation, (b) GVD, and (c) nonlinear parameter. The FSR=1.48 THz Kerr comb's (d) outcoupled spectrum and (e) total power, as the pump frequency is detuned.

These results provide encouraging evidence that graphene-comprising WRRs can indeed produce adequately wide Kerr combs in the NIR whereas graphene's tunability can be used not only to control the dispersion [2] but also the nonlinearity and intrinsic Q-factor in a non-trivial way. Our next endeavor will be to study Kerr comb formation under graphene's non-perturbative electrodynamic nonlinearity [3], that could potentially offer improved efficiency owing to the combination of saturable absorption and high nonlinear refraction.

Non-linear Optical Properties Investigation on the Colloidal WS_2 nanosheets

Y. Zhao[1], M. Fröhlich[1], O. Strolka[1], T. Parker[1], J. Lauth[1], A. J. Meixner[1] and D. Zhang[1*]

Abstract: The relationship between the local structure and optical properties of colloidal WS_2 nanosheets is studied by nonlinear confocal microscopy. Experimental results show that individual WS_2 nanosheets have higher second harmonic signal intensity and shorter fluorescence lifetimes compared to those of clusters, which could be attributed to the different optical properties of monolayers and multilayers.

In the relationship between the optical properties of two-dimensional transition metal dichalcogenides (2D-TMDCs) materials and their local structural properties, especially syntheses process and layer numbers are important since the features could exhibit optoelectronic properties that are significantly different from bulk materials[1, 2]. With the help of Fluorescence Lifetime Imaging (FLIM) technique, the photoluminescence distribution and intensity from 2D-TMDCs can be clearly characterized due to its deeper analysis of the emission properties of nanoscale sample, as it reveals both intensities and photoluminescence lifetimes in space. The optical Second Harmonic Generation (SHG) process is a promising tool since it performs strong sensitivity to the local structural properties of nonlinear optical materials, which usually characterizes the irregularities in the layers of 2D-TMDCs materials[3, 4]. For colloidal 2D-TMDCs which are prepared by wet-chemical syntheses, are becoming rapidly popular, and representing promising prospects in the application of scalable and nanoscale devices. Therefore, further investigation on the optical properties of colloidal 2D-TMDCs should be carried out since previous studies sparsely provide reports on the layer-dependent characterization.

Here, colloidal WS_2 nanosheets prepared by wet-chemical syntheses are applied for local optical properties measurement. Detailed synthesis information can be found in the previous work[5]. Fluorescence lifetime imaging is supported by FLIM microscopy system with pulsed laser excited at 750 nm and oil-immersed objective (numerical aperture = 1.4).

The preliminary working progress is shown in Figure. 1. The nanosheets show significant SHG signal compared to the large cluster which has much weaker resonance intensity in Figure. 1a. In Figure. 1b, the two-photon photoluminescence image also displays similar features on the intensity distribution, for the nanosheets they show higher intensity which contributes to find valuable regions for further investigation on SHG detection with femtosecond pulsed laser. The FLIM images Figure 1c and 1d, which are collected from different regions, represent notable short lifetime from nanosheets. The distribution difference agrees to the description in literature very well[6], that the monolayers of WS_2 nanosheets have shorter fluorescence lifetime than that of the multilayers.

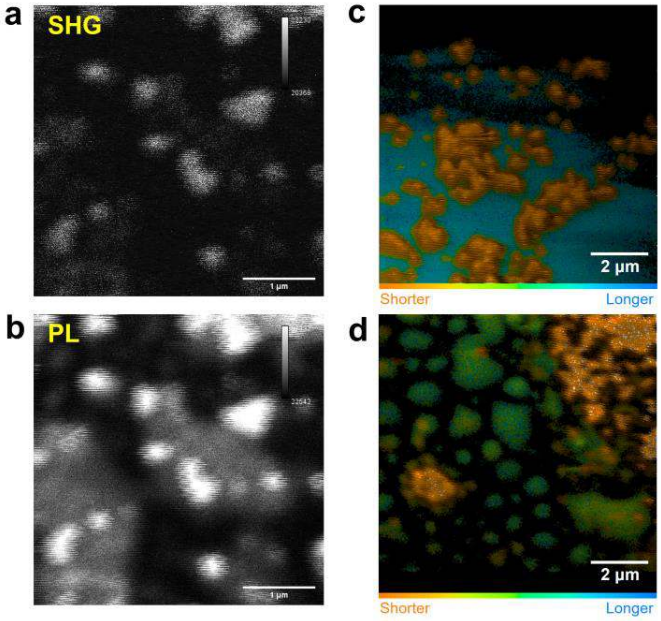

Figure 1. Second harmonic, photoluminescence and fluorescence lifetime signals collected from FLIM microscopy system. a) Second harmonic signal distribution of WS_2 nanosheets collected with 750 nm pulsed laser; b) Photoluminescence signal distribution of WS_2 nanosheets collected with 750 nm pulsed laser; c) and d) Emission FLIM of the WS_2 nanosheets between the detection range 509 and 594 nm.

Enhanced As(III) detection under near-neutral conditions: Synergistic effect of boosted adsorption by oxygen vacancies and valence cycle over activated Au NPs loaded on $FeCoO_x$ nanosheets

Cong-Cong Huang[1*], Xing-Jiu Huang[1], and Meng Yang[2]

Abstract:

As(III) has always been detected in acidic environments while the unstable modified nanomaterials under this case may lead to unreliable results. Herein, $FeCoO_x$ nanosheets with oxygen vacancies were employed to stabilize even activate Au NPs for enhancing As(III) detection under mild conditions. The sensitivity of 1.45 μA ppb^{-1} with a detection limit of 0.27 ppb were obtained. This study reveals synergistic effect of the defects and valence cycles on catalytic performance, also gives guidelines for constructing electrochemical sensing interface.

Summary:

Electrochemical method is one of the most traditional technologies for detecting the highly toxic pollutant of As(III) since the efficient redox reaction under acidic conditions[1]. However, the decomposition and agglomeration of metal nanoparticles in the strong acid solution leads to poor reproducibility as well as low precision of the results, which seriously limited the practical applications[2]. Hence, improving the stability for sensitive electrocatalysis of As(III) under mild conditions is still an intractable and indispensable problem. In this work, functionalized nanosheets with rich oxygen vacancies named Au NPs/ $FeCoO_x$ were synthesized to minimize the aggregation of Au NPs and provide abundant sites for As(III) adsorption due to the huge surface area. The square wave anodic stripping voltammetry (SWASV) technique was adopted to detect As(III) under optimal conditions while getting rid of the dependence on the strong acidic substrate and the sensitivity of 1.45 μA ppb^{-1} was obtained. A detection limit (3σ method) of 0.27 ppb in this work meets the maximum concentration in drinking water set by the World Health Organization. In addition, the tests of reproducibility, stability, anti-interference detection of Cu(II), and concrete analysis of real water samples were also conducted, all of which achieved satisfactory results, indicating the potential application of the proposed method. The possible mechanism of Au NPs/$FeCoO_x$ nanosheets enhanced detection of As(III) was proposed in Fig. 1. It was found that the large specific surface area of the nanosheets and the introduced oxygen vacancies provided abundant active sites for As(III) adsorption, as well as stabilized Au NPs to ensure the ideal electrocatalytic activity of uniformly dispersed Au NPs. Besides, the process of electron transfer from Fe sites to Au sites activated Au NPs to promote the reduction of As(III). What's more, the valence cycle of Fe(II)/(III) and Co(II)/(III) synergistically improved the electrochemical performance towards As(III). This work not only parsing the excellent electrochemical performance for synergistic effect of the defects and valence cycles, but also provide new insights into the design

of nanomaterials with excellent adsorption capacity and electrocatalytic activity to achieve effective detection of heavy metal pollutants.

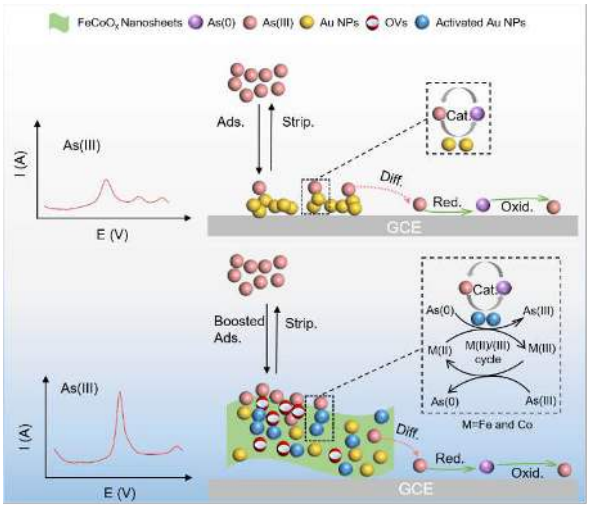

Fig. 1. Schematic of electrochemical detection of As(III) by SWASV method on Au NPs/FeCoOx nanosheets: boosted adsorption of As(III) and activated Au NPs by valence cycle for enhanced electrochemical performance, compared to that of Au NPs.

Improved Control over Multipole Excitations in Multi-Shelled Particles Leads to Higher Directivity Scattering

S. Min[1*] and J. Shin[1]

[1]Department of Materials Science and Engineering, Korea Advanced Institute of Science and Technology, Republic of Korea

[*]corresponding author: seokhwan.min@kaist.ac.kr

Abstract: Directional scattering has been studied for decades since the discovery of the Kerker conditions. Numerous studies on superdirective scattering have found that the collective interference of a large number of modes is a crucial factor. In this study, we show that multiple shells are required for the independent control of such an extended number of multipole modes. Furthermore, we use a topology nucleation method tailored to layered systems to design particles with high scattering directivities in the visible wavelengths.

Multi-shell particles and cylinders have a special importance in photonics due to its increased geometric complexity compared to homogeneous particles. When designing traditional homogeneous or core-shell particles, one only has access to at most four degrees of freedom: two layer thicknesses and two refractive indices. On the other hand, there are many more multipole modes in the particle, especially in the Mie scattering regime ($x \approx 1$), with significant excitation strength whose amplitudes and phases can be freely designed. Thus, it is evident that more shells, and therefore, more design parameters, are needed for better control over the large number of multipole modes. The collective interference of a large number of multipoles with specific amplitudes and phases can lead to many interesting optical phenomena such as superdirective scattering [1–2], superscattering [3–4], and super-absorption [5–6].

Despite the benefits of increasing the number of shells, it also significantly raises the design complexity of the particle. This complexity is exacerbated by the fact that there are three different types of parameters for a typical multi-shell particle: (1) layer thickness, which is continuous, (2) materials, which is discrete, and (3) the number of layers, which is related to particle topology. Optimization methods that can handle all three variable types simultaneously are conspicuously absent in the literature, particularly since most studies opt to fix the particle topology throughout the optimization process [7–10]. In our study, we use a topology nucleation approach to design multi-shell, lossless directional scatterers with high directivity values in the visible wavelengths (Fig. 1). Notably, to ensure that the designed particles are experimentally realizable, we restrict the material permittivities to those of existing dielectrics; namely, SiO_2 and TiO_2.

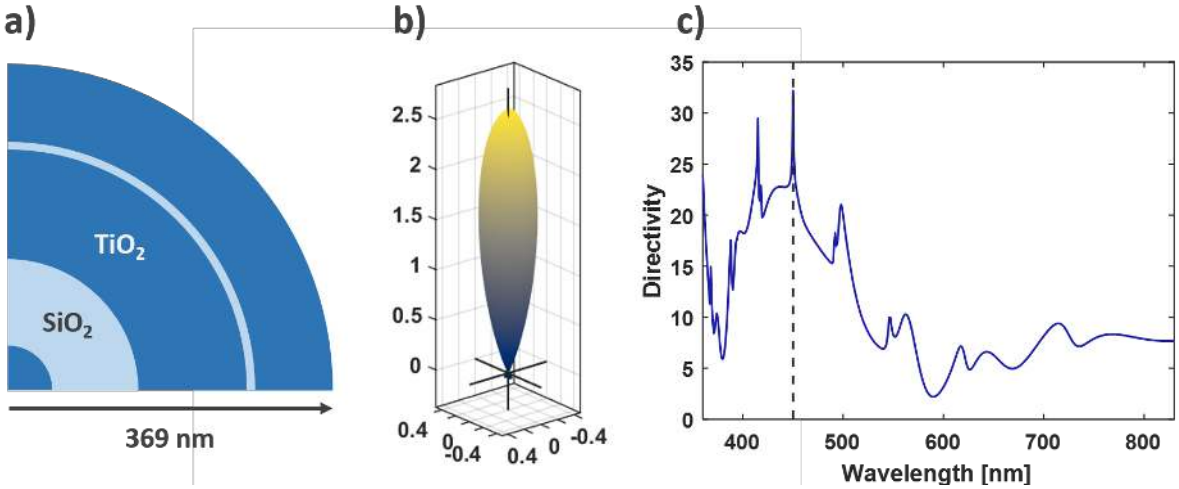

Figure 1. Example optimization result for directional scattering at 450 nm. **a)** Optimized particle geometry. **b)** Three-dimensional plot of the scattering phase function. Light is incident from the *–z* direction. **c)** Forward directivity as a function of wavelength. A sharp peak can be seen at the target wavelength.

Abstract: We present here a new structure allowing for independent addressing of sub-micrometric area. Plasmonic chains are deposited above a waveguide array. The coupling between the chains and the waveguides is numerically analyzed. This structure could have applications in various domains, from holography with reconfigurable metasurfaces to biotechnology with lab-on-chip structure.

Pixel pitch is critical for achieving high-resolution holograms with a large viewing angle. Today, spatial light modulators (SLM) based on Liquid-Crystal on Silicon (LCOS) technology are used to make dynamic holograms. However, it does not enable downsizing the pixel pitch under 1µm [1,2]. On the other hand, metasurface based on optical resonators can reach such a pixel pitch. Nevertheless, the remaining challenge of metasurface is reconfigurability. Phase change materials seem to be a promising way to achieve reconfiguration. It was shown that it was possible to enable reconfigurability over the entire metasurface by controlling the temperature [3]. Solutions to reconfigure each meta-atom independently have been realized in the IR range using a free-space system [4]. Here, our structure is integrated and could help to achieve reconfigurability in the visible range.

We have focused on a new all-optical addressing principle based on silicon-guided optics coupled to plasmonic nanoparticles (NPs). The target structure is composed of a matrix of single-mode rectangular silicon waveguides (height h=220 nm and width l=500 nm). This matrix is encapsulated in HSQ resist and is relying on a SiO2 box. Each intersection of sub-micrometric size is functionalized by chains of elliptical gold NPs where each pair of perpendicular chains forms the base of a pixel. TE modes propagated in silicon waveguides can efficiently couple to plasmonic chains [5] and generate sub-wavelength hot spots on some NPs [5]. The wavelength range studied here is near-infrared (1200-1650nm).

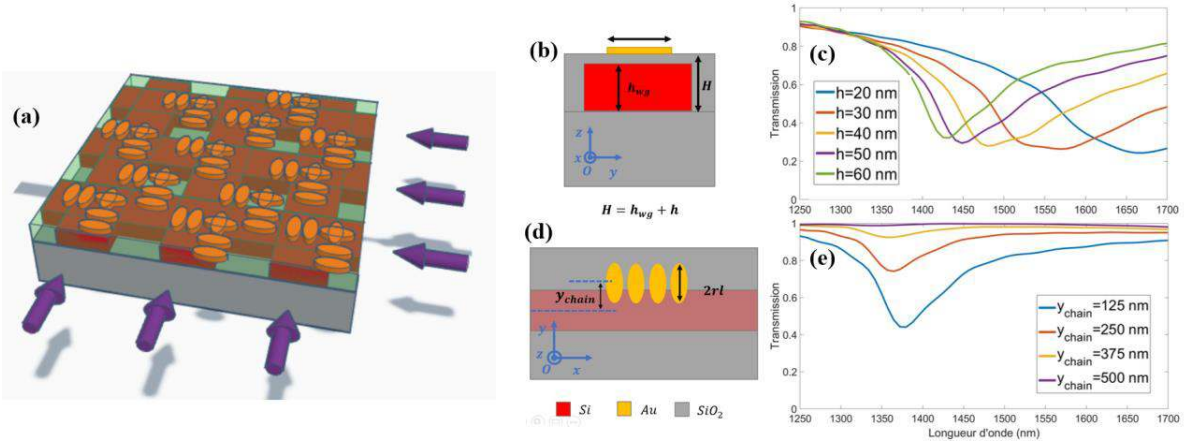

Figure 1. (a) Schematized global structure. (b, d) Simulated structure. TE mode transmission for different height of SiO_2 (c) and for different lateral alignment (e).

We use FDTD simulation to analyze the chain's plasmonic excitation in different configurations. In Fig.2, we analyze the effect of encapsulation height, showing a decrease in the coupling strength with a height beyond 50 nm. Simulations were also used to define lateral alignment tolerance allowed by the encapsulation.

The independent addressing principle is based on the geometry dependence of the plasmonic resonance wavelength. Each chain will have NPs with different size or shape on one waveguide, allowing it to have a specific wavelength resonance. Then, to select the chain to excite, one needs to inject the wavelength corresponding to its resonance in the waveguide.

To this end, we numerically determine the minimum nanoparticle's radius difference between two chains to ensure that two spectrally separated resonance is at least 30 nm. Then, we simulate two potential pixels at the intersection of two silicon guides where two couples of identical perpendicular chains are placed so that the last nanoparticles of each chain form a cross at the intersection (Fig.2b-d). The pixel pitch is 600nm. The NPs size of each couple of chains is different, leading to different resonance wavelengths. Thus, the pixel to be addressed can be selected by propagating the relevant, exciting wavelength in both perpendicular waveguides simultaneously.

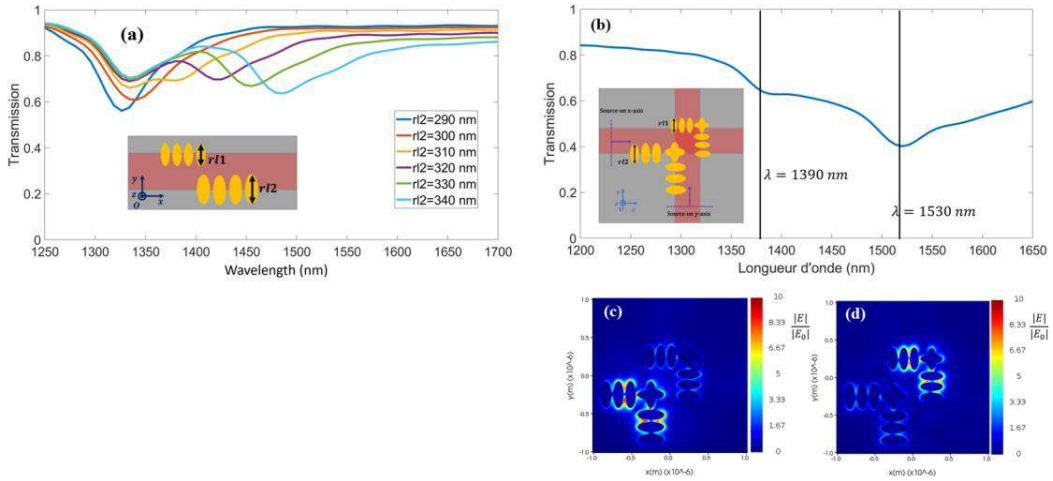

Figure 2. (a) TE mode transmission for different NP ellipse major axis rl2 of one chain whereas the NP size of the other is constant. (b) X-axis TE mode transmission. (c) Electric field module at λ=1390 nm, and (d) at λ=1530 nm

This design could also be used for other applications such as optical trap for lab-on-chip structure. We will show that the flexibility of chains positions allows different arrangements of nanoparticles to be created without being limited by the width of the guide, leading to a greater variety of optical traps or pixels on a dense waveguide array.

Room-temperature waveguide-coupled plasmonic crystal lasers on GaAs substrate

Y. T. Tsai, Y. H. Wu, C. C. Wu, and S. D. Lin*

Institute of Electronics, National Yang Ming Chiao Tung University, Taiwan.
*corresponding author: sdlin@nycu.edu.tw

Abstract: Semiconductor-based 2-D plasmonic crystal lasers (PCLs) has been studied in this work. The waveguide mode coupling with the surface plasmonic mode plays an essential role in these GaAs-based PCLs. The cooperation of the dielectric layers and the metallic nano-pillar array gives the needed resonant mode of high-quality factor. The polarization-dependent two-wavelength lasing in the PCLs with a rectangular lattice has been demonstrated at room temperature.

Due to their easy fabrication, small divergence angle and wide tuning range of lasing wavelength, semiconductor-based plasmonic crystal lasers (PCLs) have received increasing attentions [1-2]. Recently, the PCLs lasing at and above room temperature have been achieved and a very wide tuning range in lasing wavelengths has been reported [3-4]. Although these results were exciting and could lead to realizing plasmonic laser diodes, the underlying reason for enabling successful lasing remains unclear.

The sample structure illustrated in Fig. 1 was grown by molecular beam epitaxy. The photoluminescence from the four InGaAs/GaAs quantum wells (QWs) had the peak around 985 nm. The full-structure, 3-D FDTD simulations on the unit cell shown in Fig. 2 have been performed. For a square lattice with a period of 260 nm, the simulated transmission spectra in Fig. 3 indicates a high-Q mode ~897 nm. The electric field distribution in Fig. 4 tells that the resonant mode is formed by the coupling between the surface plasmonic mode and the waveguide mode and the strong electric field at the InGaAs QWs gives a high confinement factor needed for lasing. Experimental L-L curves in Fig. 5 and lasing spectra in Fig. 6 for the square-lattice devices with the period of 260-280 nm evidence the successful lasing at room temperature. The inset in Fig. 6 indicate a divergence angle of ~ 2.4^{o}. For PCLs with rectangular lattice, the simulation results in Fig. 7 predict a polarization-dependent behavior, which has been confirmed with our measurements shown in Fig. 8. The two-wavelength lasing due to the different periods in two directions has been observed.

In conclusion, the room-temperature 2-D PCLs have been investigated by simulation and experiment. The waveguide mode effect on PCL operation is the key for room temperature lasing. The rectangular lattice devices exhibited a two-wavelength polarization-dependent lasing, which is consistent with our simulation results.

Abstract: We use the tunneling junction between a nanoantenna and a gold film to electrically excite propagating surface plasmons. The nanoantenna consists of a gold nanocube that is separated from a thin Au film by an insulating molecular layer. A novel method for completing the electrical circuit between the nanoantenna and gold film using an atomic force microscope is developed. Thanks to numerical modeling, the nanoantenna modes exciting the SPPs are identified as gap modes or hybridized gap and antenna modes.

Using a nanoantenna to control the emission properties of light (such as the intensity, direction and spectrum) is an active field[1]. The use of a tunneling junction as a nanoscale electrical source of photons[2-4] and surface plasmon polaritons (SPPs)[5-6] is also extremely promising. In this work, we combine a nanoantenna and a tunneling junction in order to locally and electrically excite propagating surface plasmons and light.

The sample consists of chemically synthesized gold nanocubes (~50-nm side length) separated from a thin (50-nm) Au film by a molecular layer (~1 nm) as shown schematically in Fig. 1a. When a conducting AFM tip is used to apply a potential difference between the nanoantenna and gold film, a tunneling current flows between the cube and substrate. The inelastic component of this current excites the available optical modes of the system. In particular, these include gap modes in the tunneling junction which locally increase the electromagnetic density of states, and an antenna mode which may be engineered to efficiently couple to the propagating SPP modes on the film. The light emitted from the excited SPPs is then detected through the transparent substrate in a leakage radiation microscopy configuration.

Figure 1b depicts the resulting spectrum in such an experiment. Two distinct peaks may be seen which, thanks to numerical modeling [7], may be identified as arising from specific gap modes or hybridized gap and antenna modes (see insets to Fig. 1b). The ability to interrogate individual nano-antennas and the theoretical comprehension of the nano-antenna junction system lead to system optimization, an enhanced excitation efficiency and the ability to control the SPP spectrum. These results will also lead to the development of new electrical nanosources of surface plasmon polaritons and light.

Abstract: We fabricated a visible range active metasurface device with Mo/AlO/ITO/AZO/Ag/AZO/AlO/Mo layers and explained its working principle as interacting coupled gap plasmons modes. The metasurface device showed peculiar reflectivity modulation characteristics as a function of incoming electric polarizations, Mo antenna's pitch/space, and applied electric voltage polarity.

For the metaverse era, a realistic and embedding three-dimensional display is a necessary item for online communication. Among competing three-dimensional displays, many researchers believe that the ultimate winner will be a holographic display if high quality and ultrawide visual angle are guaranteed. Metasurface device is an ideal candidate for the holographic display because it can control both amplitude and phase of the light and narrow down the pixel pitch of the display under visible wavelength.

Recently, amplitude, phase, and polarization modulations are fancy research items and many researchers suggested innovative ideas theoretically and experimentally [1]. But the fabricated metasurface devices usually resides in infrared wavelength due to the limitation of small refractive index change in the visible wavelength.

In the paper, we designed the coupled gap plasmon active metasurface device with Mo/AlO/ITO/AZO/Ag/AZO/AlO/Mo layers and fabricated using e-beam lithography as shown in figure 1. During the metasurface device manufacturing, the AZO (aluminum doped zinc oxide) layer is so important to stabilize the silver layer. The FDTD simulation shows the enhanced electric field on the ITO layer due to the gap plasmon generation. Figure 2 shows the modulation characteristics according to the variation of Mo antenna's pitch/space. As the pitch was increased, the resonant dip showed redshift, but the space showed the blue shift. Figure 3 shows the reflectivity variation as a function of the applied voltage. Even though its change is small, it showed different reflectivity modulation with the different voltage polarity. We checked the hologram generation with the fabricated device.

Abstract: We explore the potential for the realization of fast, energy-efficient photonic memory and computing devices arising from the combination of the energy-efficient silicon nitride platform, the sub-wavelength light-squeezing and field-enhancing capability of plasmonic resonant structures, and the intrinsic tuneability brought by chalcogenide phase-change materials. We concentrate on designs that should be readily manufactured, comprising plasmonic dimer-bar nanoantenna deposited on top of a phase-change cell, itself deposited on top of an integrated photonic waveguide.

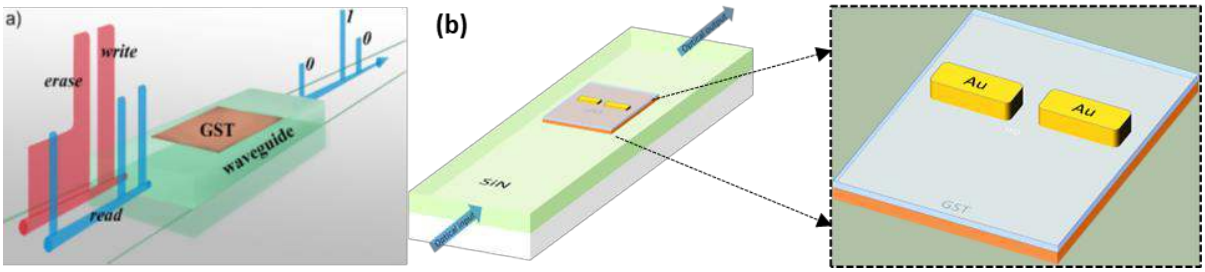

Fig. 1. Integrated phase-change photonic memory, configuration and operation schematic. (a) The conventional configuration with a GST cell on top the waveguide. (b) The proposed plasmonically-enhanced configuration.

Integrated phase-change photonic memory devices offer a novel route to non-volatile storage and computing. Such devices generally consist of integrated waveguide structures onto which are fabricated small phase-change memory cells (e.g., $Ge_2Sb_2Te_5$, or GST), as shown in Fig. 1(a). In the drive to reduce switching energies and increase switching speeds, plasmonic enhancement of the interaction of the propagating mode with the phase-change cell has been proposed [1,2]. Here we explore further this concept of plasmonic enhancement, concentrating on device designs with relatively simple architectures that lend themselves to easy manufacture.

As shown in Fig. 1(b), our proposed plasmonic device consists of a SiN ridge waveguide (1200 nm x 334 nm) fabricated on top of a SiO_2 substrate. A gold plasmonic nanoantenna is deposited on top of a 500 x 500 nm GST patch of 10 nm thickness. The nanoantenna employs a dimer-bar configuration, each bar here being 40 nm wide and 30 nm thick. The gap between each bar is either 40 nm or (for easier fabrication) 80 nm, and each vertical corner of the bar is rounded (curvature radius of 10 nm) to reflect fabrication realities. Since gold tends to diffuse easily with chalcogenides, resulting in adverse changes in the latter's optical and electrical properties, a 5 nm ITO layer is deposited on top of the GST patch as a barrier layer to eliminate the diffusion. The basic operating concept of the device, shown in Fig. 1(b), employs of the nanoantenna's capability to maintain a localized plasmonic resonance by coupling with the optical mode propagating in the waveguide. This plasmonic resonance results in a very strong enhancement of the electric field in the gap region, as compared to the conventional integrated phase-change photonic cell [1]. Such enhancement increases the interaction between the

phase-change cell and propagating light significantly, so improving switching energies and speeds. We here analyse the proposed concept via finite element modelling (FEM) method in the COMSOL package and fabricate test devices using e-beam lithography.

Exemplar simulation results of the device optical performance are shown in Fig. 2, for a range of dimer bar lengths and excitation wavelengths. The transmission contrast of the devices confirms that both GST amorphous and crystalline states exhibit distinguishable resonance features, with a peak contrast of around 22% for bar lengths of 165 nm at 1550 nm wavelength. This contrast is around double that of the conventional device of Fig. 1(a). This is a direct result of the substantial electric field enhancement in the nanogap resulting from the plasmonic resonance. The insertion loss, see Fig. 2(b), of our plasmonically-enhanced design was also found to be acceptable, with a value of approximatively -0.3 dB at the 165 nm bar length.

(a) (b) (c)

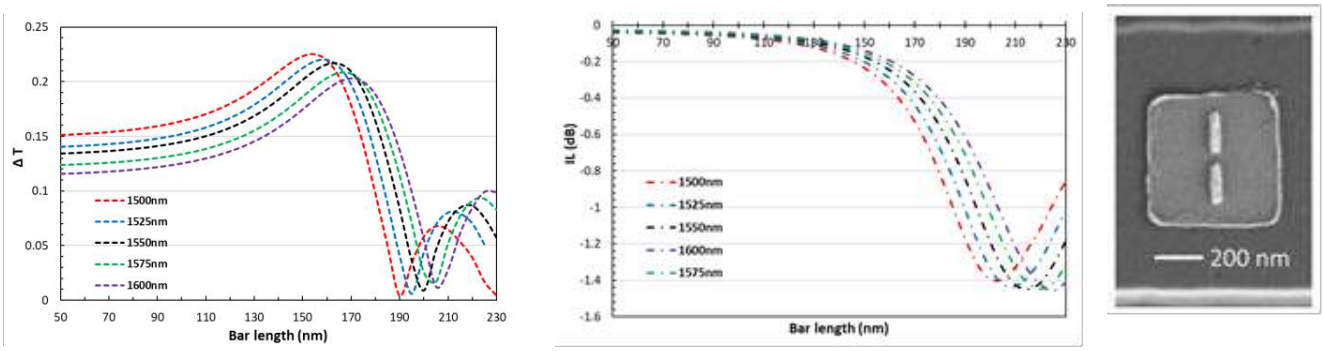

Fig. 2. (a) Simulated optical contrast as a function of dimer bar length for the plasmonic cell architecture shown in Fig. 1(b). (b) Simulated insertion loss as a function of bar length. (c) Experimentally fabricated plasmonically enhanced device.

The fabrication of our proposed plasmonically-enhanced phase-change photonic device designs has also been achieved, with a typical as-fabricated device shown in Fig. 2(c). Experimental characterization results will be compared to simulation predictions and devices further optimized.

Abstract: Light-driven soft actuators have been gaining attention in soft robots, although the challenges of accurately and reversibly modulating in various directions remains. Here we present a strategy for wavelength-selective photoactuation based on Au nanorod/reduced graphene oxide nanocomposites. The plasmonic characteristic of Au nanorods can induce strong photothermal conversion at different wavelengths depending on the aspect ratio of that. The reduced graphene oxides have high thermal conductivity and negative coefficients of thermal expansion, leading to significant bending in bilayer configurations.

Stimuli-responsive actuator, which can convert energy into mechanical motion, have been intensively attracted for leading-edge applications such as micro-electromechanical systems, microrobotics, and sensors [1-3]. Many researchers have performed for developing artificial smart actuators enabled by heat, humidity, electric, magnetism, and light. Of the various environmental stimuli, light is a clean and safe energy with the unique properties of omnipresence, high spatial and temporal resolution, and degrees of control freedom including wavelength, polarization, and intensity [4]. Photothermal effect is a primary mechanism of light-driven actuators, and induces the thermal expansion, leading to deformation in a multi-layer configuration with different a coefficient of thermal expansions (CTEs).

In this study, we propose a strategy of making a wavelength-selective photoactuation system capable of carrying out multi-directional movement, which is based on selective photothermal heating in multi-layer structured actuator consisting of flexible substrates and Au nanorod (NR)/reduced graphene oxide (rGO) nanocomposites. The surface plasmon resonance characteristic of Au NRs can bring about intense photothermal conversion at different wavelengths in visible and near-infrared range depending on the aspect ratio of that. The rGO have high thermal conductivity (~1500 $Wm^{-1}K^{-1}$) and negative CTEs (~0.77×10^{-6} K^{-1}), leading to significant bending due to the mismatch between the deformations between flexible substrates and rGO layers.

Figure 1 shows the strategy for wavelength-selective photoactuation based on Au nanorod/reduced graphene oxide nanocomposites. Figure 1(a) shows the schematic of the absorption spectra depending on the aspect ratio of Au NRs. Au NRs have the plasmonic resonance in visible and near-infrared region, and the plasmonic resonance can be modulated by control of aspect ratio of Au NRs. The soft actuators with multi-layer configurations are fabricated by inkjet printing process using Au nanorod/reduced graphene oxide nanocomposite inks as shown in Figure 1(b).

Au NRs in aqueous suspension are obtained by seed-mediated synthesis according to previous report [5]. Figure 2 shows the morphological and the optical characteristics of the Au NRs with the aspect ratio of 1. The average diameter and plasmonic resonance of the Au NRs with the aspect ratio of 1 are 34.7±3.6 nm and ~528 nm, respectively.

In a follow-up study, we examine the plasmonic property of Au NRs/rGO nanocomposite inks, and

investigate the effect of light illumination intensity and wavelength selectivity on photoactuation response.

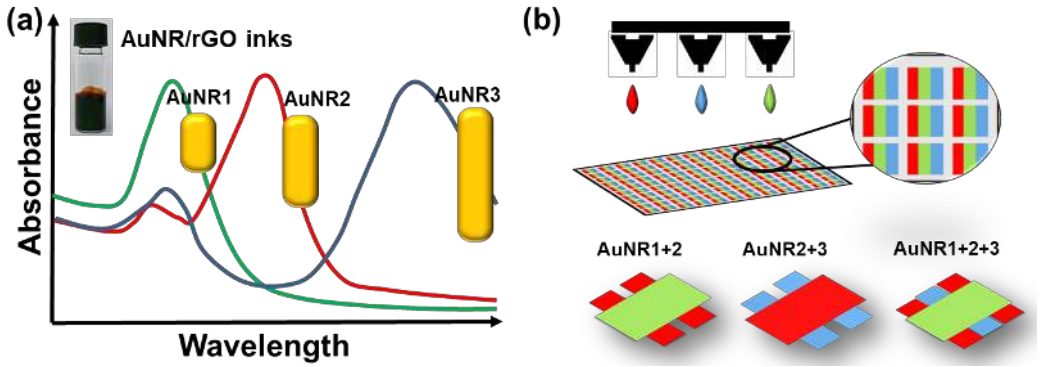

Figure 1. Strategy for wavelength-selective photoactuation based on Au nanorod/reduced graphene oxide nanocomposites. (a) Schematic of the absorption spectra depending on the aspect ratio of Au NRs. (b) Schematic of the multi-layered soft actuators fabricated by inkjet printing process.

Abstract: Successful control of Förster resonance energy transfer (FRET) through the engineering of the local density of states (LDOS) will allow us to develop novel strategies to fully exploit this phenomenon in key enabling technologies. Here we present an experimental and theoretical study on the effect of LDOS on the FRET rate and efficeny in plasmonic nanopatch antennas. Our results reveal that FRET rate is linearly dependent on LDOS and LDOS plays an important part in controlling FRET efficiency and range.

Förster resonance energy transfer (FRET) is a fundamental phenomenon in photosynthesis and is of increasing importance for the development and enhancement of a wide range of optoelectronic devices, including color-tuning LEDs and lasers, light harvesting, sensing systems, and quantum computing. Successful control of FRET will allow us to develop novel strategies to fully exploit this phenomenon in these key enabling technologies.

In this work, we present an experimental and theoretical study on the effect of the local density of optical states (LDOS) on the FRET rate and efficiency using plasmonic nanopatch antennas formed between a plasmonic nanoparticle and an extended metallic film. Our results reveal that LDOS plays an important part in controlling both FRET rate and efficiency. By tuning the nanoparticle size and material, we show that the FRET rate is directly dependent on the LDOS of the nanopatch antennas. We also found that plasmonic nanopatch antennas can be utilised to extend the FRET range over 200 nm while keeping the FRET efficiency over 0.38, with efficiency enhancement factor of ~10^3 with respect to homogeneous environment. Our findings contribute to the ongoing debate about the relation between the FRET process and the LDOS, as well as directly impacting the development of novel FRET based light harvesting and sensing devices.

Abstract: In this talk, we propose and demonstrate single subwavelength hybrid dielectric-plasmonic optical nanoantennas coupled to localized quantum dot emitters that constitute efficient and bright unidirectional photon sources under optical pumping. To achieve this, we devised a silicon nanoring sitting on a gold mirror with a 10 nm gap in-between, where an assembly of colloidal quantum dots is embedded, and obtain experimentally total fluorescence enhancement up to 600-fold, due to high radiative efficiency.

Hybrid dielectric-plasmonic optical nanoantennas have been recently put forward to mitigate the losses encountered in all-plasmonic nanostructures [1]. Here, we report on one of the first few experimental demonstrations of a subwavelength single hybrid dielectric-plasmonic optical nanoantenna coupled to localised quantum dot emitters, that constitutes an efficient and bright unidirectional photon source under optical pumping. To achieve this, we use a subwavelength silicon nanoring sitting on a metallic (gold) mirror with a 10 nm gap in-between, where an assembly of quantum dots is embedded. Such a structure presents the advantage of supporting two classes of modes, "gap" plasmon modes [2] and "antenna" (radiative) modes [3], to which the quantum dots can efficiently couple for the dual purpose of enhancing the absorption of the optical pump, and for out-coupling the light into the far-field with high directionality, respectively. Moreover, an almost independent control of the resonance spectral positions is achieved by a simple tuning of geometrical parameters such as the ring outer and inner diameters, which is not possible with other, simpler, nanoparticle-on-mirror antennas [4]. We obtain total enhancement factors of the fluorescence of the assembly of emitters up to 600-fold, simultaneously with a directional emission of the photoluminescence into a cone of $\pm 17°$ in the upward direction [5].

Abstract: In this study, we proposed a lasing mode selection scheme based on distributed feedback, achieved via the external nano-manipulation of single zinc oxide nanowires onto an aluminum grating. By orienting the nano-cavity perpendicular to the ridge direction, we identified an additional peak in the emission spectrum on the low-energy side of the gain envelope. As a consequence of the fulfillment of the Bragg condition, such a peak was attributed to a novel hybrid mode dominating the mode competition.

Tailoring the emission of plasmonic nanowire-based lasers represents one of the major challenges in the field of nanoplasmonics, given the envisaged integration of such devices into on-chip all-optical circuits[1]. In this work, we made use of a mechanical nano-manipulation approach, to study the effects of a metal grating[2,3], characterized by geometrical parameters tailored to the lasing emission wavelength, on the lasing properties of semiconductor nanowire-based plasmonic lasers. Namely, the same nanowire could be manipulated and "switched" among different configurations: from placed on dielectric/metal substrates (planar plasmonic configuration) to overlaid on metal gratings (nanowire-metal grating configuration) at different orientations with respect to the ridges. The optical characterization of single nanowires in a given configuration was measured by focusing the emission from an ns-pulsed, low-repetition-rate, frequency-tripled Nd:YAG laser onto the sample mounted into a liquid He flow cryostat. To explain the emergence of the additional peak in the low-energy side of the PL spectrum (visible in Figure 1a) for the $\vartheta \approx 90°$ on-grating configuration, we performed active lasing simulations using the software Lumerical. To this end, the geometrical parameters, extracted from the SEM cross-section of the "fenced" grating (shown in Fig. 1c), were used. The simulation results show that the excitation of surface plasmon polaritons at the fences enhances the mode confinement[3]: this, in turn, leads to a large modal mismatch between the "fence-coupled mode" supported by the parts of the nanowire in contact with the metal, and the "fence-uncoupled mode" supported by the free-standing parts. This results in a resonator feedback of about 50% (excluding the end-facet reflectance) even for a small number of periods (N = 40), as shown in Figure 1(d). Thus, for an orientation of the nanowire perpendicular to the grating ridges, the experimental and theoretical results showed that the lasing action is dominated by a hybrid mode, which is supported by its effective coupling with the localized plasmon polaritons at the fence edges.

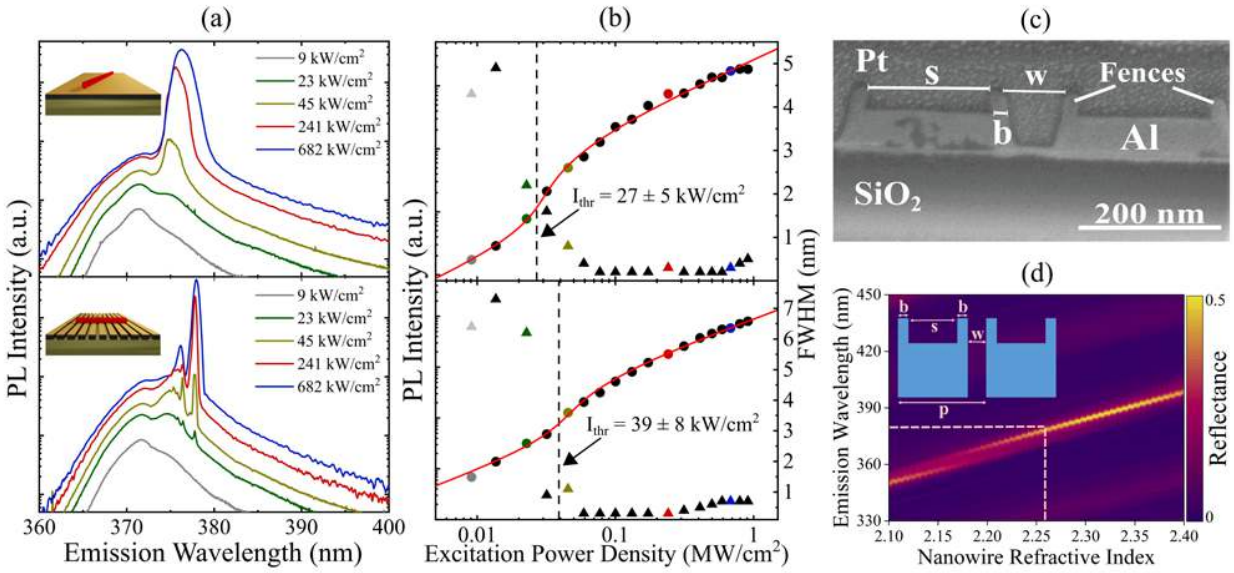

FIGURE 1: (a) PL spectra of the planar (top panel) and nanowire-grating (bottom panel) configurations acquired for different pump power densities at 150 K; the NW was oriented perpendicular to the ridge direction $\vartheta \approx 90^\circ$. (b) Corresponding light-in-light-out curves (circles) of the emission intensity and spectral width trends (triangles) of the emission for the planar (top panel) and nanowire-grating (bottom panel) configurations, as a function of the excitation power density. The dashed lines indicate the respective lasing thresholds estimated by fitting the experimental data points with an adapted multimode lasing model. (c) SEM cross-section of an Al grating with a nominal pitch p = 300 nm and fill factor FF = 0.3. (d) Simulated reflectance of the "fenced" Al grating (sketched in the inset) for the lasing mode as a function of the wavelength and nanowire index. The intersection point of the dashed white lines indicates the reflectance at λ = 378 nm for the corresponding material index value (n_{ZnO} = 2.26).

Abstract: We show that SERS from monolayer 4-Aminothiophenol (4-ATP) bonded to a plasmonic gap waveguide is directed into a single mode with >99% efficiency. Although sacrificing a confinement dimension, we find a 10^3x SERS enhancement across a broad spectral range, enabled by the plasmonic waveguide's larger sensing volume and non-resonant waveguide mode. Waveguide-SERS (W-SERS) is bright enough to image Raman transport across the waveguides. This exposes the roles of nanofocusing, the Purcell effect and the spontaneous Raman scattering factor, or Raman β-factor.

To enhance the Raman scattering efficiency of light by molecules, various enhancement techniques relying on either stimulated or surface enhanced Raman scattering (SERS) have been developed [1-9]. Since the first SERS signal observed from pyridine adsorbed on a roughened silver electrode in 1973, various types of nanostructures for SERS have been designed, for instance, rough metallic surfaces, nanoparticles, and metallic tips. Remarkable enhancement of Raman scattering efficiency has been achieved by using those SERS techniques, but they are either limited by the poor control of the scattered light, narrow bandwidth of the resonance frequency, or restricted area of field enhancement.

In this talk, we present a unique plasmonic waveguide approach to Raman scattering enhancement with precise control of both the incident light intensity and the scattered Raman light [1]. Raman scattering is enhanced in a plasmonic waveguide via two mechanisms. Firstly, the local intensity of the pump light is increase by efficient nano-focussing into a plasmonic slot waveguide with approximately 30% coupling efficiency. Secondly, within the optically confined slot waveguide environment, molecules experience increased local vacuum fluctuations. Since the waveguide presents both nano-focussing and confinement over a broad spectral range, it provides a broadband Raman enhancement.

In particular, we report directional broadband Raman scattering of light by 4-Aminothiophenol (4-ATP) molecules which are chemically bound as a single molecular layer onto well designed plasmonic slot waveguide. The waveguides are decorated with optical antennas that allow light to couple in and out of the slot waveguide with 30% efficiency, evaluated experimentally. Since we observe strong Raman signals from these waveguide, we have been able to spatially resolve the coupling in of the excitation laser and coupling out of Raman scattering. This enables us to precisely investigate how the scattered Raman photons of molecules couple into the waveguide, propagate and couple out via the antennas. In this way, we have experimentally determined the spontaneous Raman beta factor in a plasmonic waveguide for the first time. We have demonstrated that 99% of the Raman photons are coupled into the waveguide and coupled out through the antenna pairs of the waveguide.

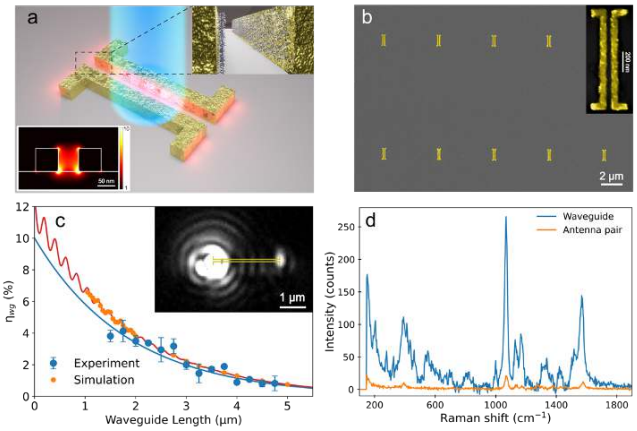

Figure 1. a) Schematic of the plasmonic waveguide bonded with 4-Aminothiophenol (4-ATP) molecules. b) Scanning electron microscopic image of the waveguide. c) The waveguide coupling efficiency was measured by focused excitation on the waveguide's antennas and compared with theory. d) Comparison of Raman spectra from an antenna coupled waveguide and a single antenna. Both spectra were recorded at 400 µW power, and 10 s integration. The waveguide SERS sample shows a 10-fold enhancement relative to the antenna alone.

The high Raman beta-factor is due to the largely enhanced spontaneous Raman scattering rate into the waveguide mode. The enhancement mechanism can be understood analogously to fluorescence emission enhanced by the Purcell effect, which is due to increased vacuum fluctuations and increased density of states. While Raman scattering in highly localised metallic hotspots offer high enhancement factors for a few molecules, here, a plasmonic waveguide offers predictable broadband enhancement for many molecules with a greatly improved interaction volume compared to other SERS approaches.

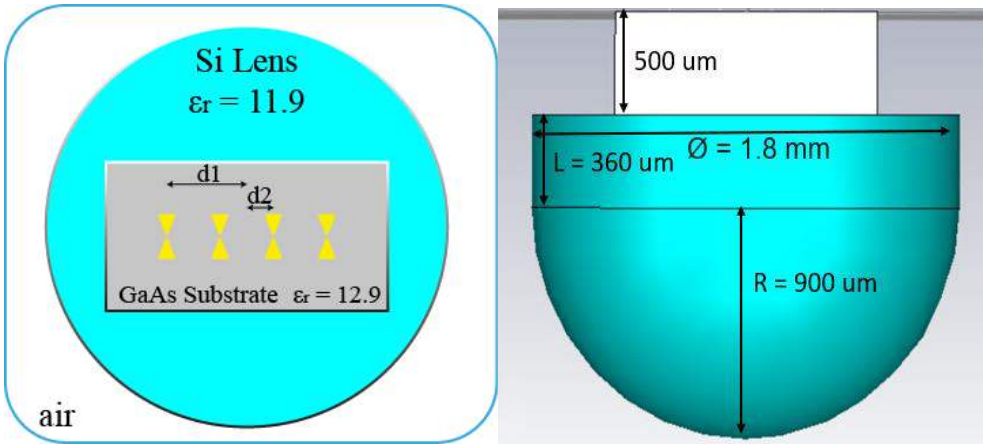
A Terahertz Lens Antenna Array Design for Beam Steering in Time-Domain

A.C. Songur[1], A.O. Sakin[1], H.A. Gunes[1], B. Akcay[1] and, M. Unlu[1*]

[1] Dept. of Electrical and Electronics Engineering, TOBB University of Economics and Technology, 06510 Ankara, Turkey

[*]corresponding author: munlu@etu.edu.tr



Abstract: In this paper, a terahertz switched antenna array allowing beam steering between ±30° in the time-domain for 0.8-2 THz band has been designed. A silicon lens is utilized, which also allows a time-domain steering range between ±30° and is custom-developed as an extended-hemispherical lens, and the elements of the antenna array consist of broadband bowtie antennas. The far-field terahertz radiation has been successfully obtained in terms of time-domain performance criteria.

Terahertz waves exhibit several unique attributes that other bands cannot, since electromagnetic waves in the terahertz frequency band have some characteristics of both RF frequencies and optical frequency waves. To efficiently use terahertz waves in next-generation communication systems, it is imperative to develop efficient terahertz sources and detectors. However, the development of terahertz sources and detectors showing high performance is currently one of the most challenging topics of terahertz research since in these photoconductive antenna (PCA) systems, the optical-to-electrical conversion is inefficient [1]. As a remedy to the power loss problem in PCAs, it is critical to design high-gain antennas and antenna arrays. In addition to the antenna array design, high-performance terahertz lens designs are required to augment the terahertz power radiated by the PCA array. The beam-steering capability of terahertz PCA arrays, on the other hand, is critical for the deployment of terahertz sources in next-generation communication systems. Thus, the terahertz lens antenna array to be designed is crucial not only for enhancing terahertz radiation effectively but also for beam steering [2].

Furthermore, short-pulsed signals with high bandwidth are used in terahertz PCA excitation. Hence, the characterization of antennas and lenses in the classical frequency domain loses its functionality. Purely time-domain characterization of antenna arrays and lenses is substantially more efficient than the former. To the authors' best knowledge, a lens photoconductive antenna array capable of beam steering at terahertz frequencies in the time-domain has not been presented in the literature.

In this study, a terahertz-switched lens antenna array capable of beam steering between ±30° in the time-domain has been developed for 0.8-2 THz band. The silicon lens, capable of effective time-domain steering between ±30°, has been custom designed as an extended-hemispherical lens, and the elements of the antenna array consist of broadband bowtie antennas. Successful far-field time-domain terahertz radiation was obtained, similar to what the authors demonstrated in a previous single terahertz time-domain antenna study [3]. In Figure 1, the proposed time-domain terahertz switch lens array and its dimensions are given. In Figure 2, the time-domain far-field radiation result indicating successful 30° steering is given.

Extended-hemispherical lens design for beam-steering mostly follows the thin lens approximation which associates the focal length of a thin lens to the scan angle of the lens. The extension height, denoted by "L" in Figure 1.b, can be interpreted as the effective focal length of a thin lens [4]. The steering angle depends on the geometrical parameters of the lens (“L” and “R” in Figure 1.b) as well as the positioning of array elements with respect to the lens center (“d1” and “d2” in Figure 1.a).

A Terahertz Time-Domain Antenna Array based on a Parametric Study

A.C. Songur[1], A.O. Sakin[1], B. Akcay[1], H. A. Gunes[1] and, M. Unlu[1*]

[1] Dept. of Electrical and Electronics Engineering, TOBB University of Economics and Technology, 06510 Ankara, Turkey

[*]corresponding author: munlu@etu.edu.tr

Abstract: In this paper, the design parameters are examined in detail for the terahertz photoconductive antenna arrays operating in the terahertz frequency region, which is one of the most important band candidates for future communication systems, and a 1x4 wide-band time-domain bowtie antenna array providing 30° steering is designed for 0.8-2 THz band. This study is entirely realized in the time-domain to process the broadband terahertz pulsed signals more efficiently.

The terahertz band is classified as the frequency range between 0.3 THz and 10 THz in the electromagnetic spectrum, corresponding between the microwave and infrared parts of the spectrum. Effective THz sources and detectors must be developed for terahertz applications. Terahertz photoconductive antennas (PCA) combined with photonic integrated circuits (PICs), particularly those based on metamaterial topological structures can be critical for advanced communication systems [1-2]. In this context, it is critical to construct broadband antennas that can be compatible with ultra-wide bandwidths of THz pulsed signals. THz antenna arrays, which are to be developed for beam steering applications that are compatible with next-generation communication systems, also gain importance within this frame of reference [3]. On the other hand, because THz pulsed signals are inherently broadband, it is essential to design these antenna arrays in the time-domain, and thus THz ultrawide-band pulses include multiple frequency components, antenna characterization in the frequency domain loses its effectiveness. Instead, conducting direct time-domain characterization is substantial for processing these signals more efficiently. The concept of time-domain analysis of THz antennas has previously been presented in our study where the 3D time-domain solver has been validated using the time-domain analytical approach [4]. The time-domain analytical approach was previously presented at lower frequencies for short-dipole antennas [5]. The preceding single-element work is adapted to the time-domain antenna array in this study.

We first propose a parametric-comprehensive study in this paper which we expect will be pertinent for future time-domain THz antenna array designs. We investigate the effect of spacing, element length, steering angle, and observation angle on the time-domain maximum electric-field radiation emitted by the antenna array within this framework. We also offer a study of a time-domain THz PCA array system capable of beam steering and present a THz time-domain wideband 1x4 bowtie antenna array, whose performance is enhanced with a custom design. Further, it is aimed to provide a 30° steering for the purpose of communication applications. Such an antenna array can be used in both high-power transmission and steering applications using effective compatible optical lasers and substrates in a photoconductive antenna system. Therefore, it is also critical to employ a suitable laser (e.g., 1550 nm ultra-short-pulsed laser) and a substrate with a properly grown active layer (e.g., InGaAs) to obtain the maximum efficiency from the THz PCA array system.

In Figure 1, a summary of the parametric study is given. The 1x4 bowtie antenna array, designed in the light of the parametric study, is also given in the right-bottom inset, and the resulting time-domain radiated field, maximum towards 150° meaning 30° steering, from the array is given the left-bottom inset in Figure 1.

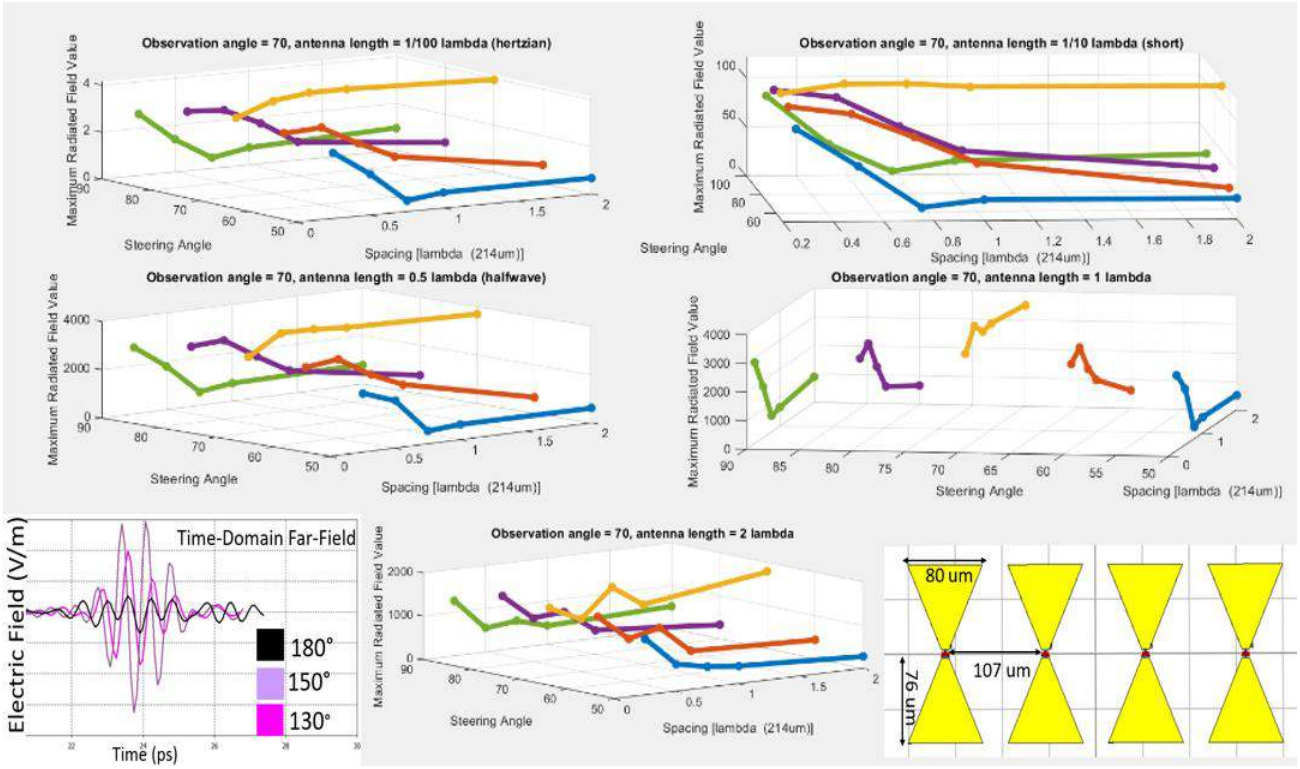

Figure 1. The effect of antenna length variation (0.01 λ to 2 λ) and spacing (0.25 λ to 2 λ) variation on the time-domain maximum radiated field (V/m) under 70° steering (insets: the designed 1x4 bowtie antenna array and the resulting radiated electric-field in the time-domain)

Abstract: A low-profile metamaterial structure is designed to achieve an analogue of electromagnetically-induced transparency (EIT) in the mid-infrared regime. By breaking the symmetry of the gold resonator, a transmission window occurs around 8.5 μm, instead of a reflectance peak as in the symmetric configuration. The EIT behavior was investigated using near-field distribution analytics and confirmed by microfabrication and FTIR spectroscopy. Based on the EIT effect, the realization of strong dispersion and high Q-factor resonance metamaterials is the first step to the development of sensing devices or optical modulators that we are focusing.

1. Introduction

"Metamaterial" (MM) was introduced in the 2000s and has gained popularity in recent years. Simply put, it is a branch of artificial structure in which properties can be predesigned by quasi-atoms and their arrangement in a subwavelength quasi-lattice and described by effective medium theory [1]. In this study, we proposed a simple structure, in which the symmetry-breaking approach allowed us to achieve the so-called electromagnetically-induced transparency (EIT) effect in the mid-infrared region (see Figure 1). This effect was first observed in the field of quantum mechanics, where two highly coherent optical sources (e.g., lasers) are used simultaneously (as pump and probe fields) to interact with multiple-quantum-state materials [2]. Interestingly, it can be mimicked in metamaterials using multi-resonant metamaterials with individual resonances tuned as bright and dark states (see Figure 1c). The effective medium theory was also used to compute the group index and group delay of a propagating wave. After confirming the effect, we fabricated the sample and characterized its optical spectrum to demonstrate its dependability. The reflectance spectra obtained from Fourier-transform Infrared spectroscopy (FTIR) spectroscopy match well with the simulations.

2. Methodology

Firstly, we optimized the MM structure through simulations of its optical spectra using CST Suite Studio with the finite element method. Then MMs were fabricated using electron beam lithography (EBL) to pattern the MM design, followed by molecular beam epitaxy (MBE) to deposit 5 nm platinum and 50 nm gold, before finishing with a lift-off procedure. FTIR spectroscopy (Vertex 80V) was used to measure the reflectance of the sample before and after the plasma treatment process for characterization.

3. Results

We investigated the reflectivity of EIT-MM in symmetric and asymmetric configurations under different polarization mid-IR sources (TE and TM modes) in both simulation and experiment (Figure 2). The reflection dip in TE mode seen at 8.8 μm for the asymmetric configuration corresponds to the EIT transmission window. Because the symmetry of the TM mode is protected along the electric field direction, the reflectivity in both symmetric and asymmetric structures is nearly unchanged. The slight difference in resonant frequencies between

simulation and experiment could be caused by fabrication tolerance and measurement conditions.

4. Conclusion and outlook

In this study, we have proposed and demonstrated a simple approach to achieve an analogue of the intriguing EIT phenomenon. Following the realization in this study, we can now dig deeper into the nature of EIT effect, by using more profound characterization, such as ultrafast laser stimulation and time-resolved studies on short time scales. Then, the time delay due to the dispersion or near-field enhancement caused by high Q-factor resonance can be best understood and utilized. In sensing applications, the former characteristic will enhance the interaction of light with molecular vibrations, especially in the mid-infrared regime, and can be used in surface-enhanced IR absorption (SEIRA) spectroscopy [3] and surface-enhanced Raman spectroscopy (SERS) substrates [4].

Abstract: We report on actively controllable metasurfaces by in-situ electrostatic doping of graphene. A resonance tuning of 0.40 um is demonstrated around 7.06 um, allowing for more efficient optoelectronic devices operating under ambient conditions.

Metasurfaces are artificial two-dimensional materials with a periodic pattern of subwavelength-scaled structures, the meta-atoms. Metasurfaces can control the properties (amplitude, phase, polarization and momentum [1]) of the light with which they interact. However, conventional metasurfaces currently made are "passive'', i.e. fixed by the geometric design, and cannot be "actively'' controlled by an external stimulus of thermal, electrical, mechanical, or optical origin [2,3]. In modern photonics, it is highly desirable to develop real-time actively controllable metasurfaces for advanced applications. It has been proved that graphene can be integrated to the nanogaps of metallic plasmonic antennas and leads to the broad tuning of the antenna optical resonance [4]. So far, graphene tunable metasurfaces have been studied without in-situ monitoring of the graphene doping level [5], which is difficult to control in ambient conditions [6]. Here, we experimentally demonstrate electro-optic tuning of a mid-infrared plasmonic resonance using a graphene field effect transistor. The charge carrier concentration of graphene is controlled by a back gate voltage and the electronic transport characteristics are measured with the four-terminal circuit. At the same time, the optical tunability is measured by Fourier-transform infrared spectroscopy (FTIR).

The devices shown in Figure 1a and b consist of a monolayer graphene sheet which was grown by chemical vapor deposition and transferred onto a SiO_2/p^{++} doped Si layer [7]. Reactive ion etching was used to remove unnecessary graphene and the resulting pattern is a rectangular graphene sheet. A plasmonic antenna array was fabricated on the graphene sheet by electron beam lithography (EBL), followed by molecular beam epitaxy (MBE) of 10 nm platinum and 30 nm gold, and lift-off. Also source, drain and four other contacts (10 nm titanium and 200 nm gold) were deposited on top of the graphene sheet by EBL and MBE. For the as-fabricated graphene field effect transistor (GFET), the charge neutral point (CNP) is at -5 V (Figure 1c). The insets show graphene's dispersion relation, where the shaded areas represent the level filling. The reflectance of the hybrid metasurfaces is calculated by the FDTD simulations (Lumerical Solutions, Inc.).

We used in-situ current-voltage (I-V) measurements in the FTIR setup to study the reflectivity of the device for different gate voltages, ranging from -100 V to 100 V. The conductance of graphene is measured in-situ. As shown in Figure 2a (simulation) and b (measurement), the resonance wavelength of the zero-bias system at 7.06 μm could be blue shifted to 6.64 μm by an -100 V applied gate voltage. This shift is due to an increased graphene charge carrier concentration, resulting in a decrease of the real part of graphene permittivity. Figure 2c shows the resonance wavelength as a function of the back gate voltage in both simulations and measurements. A maximum reflectance modulation of ~ 8% is achieved when the device is in resonance, corresponding to the reduced ratio of

the dip reflectance from 60 V to -100 V (Figure 2d). The results are promising for novel on-chip biosensors in the mid-infrared range, as well as for on-chip optical modulators.

We have demonstrated a broad tuning of the resonance of electro-optic metasurfaces based on a GFET configuration. Our four-terminal measurement circuit offers in-situ monitoring of the graphene Fermi level, while obtaining the optical spectrum with FTIR. We anticipate that the combination of a high switching speed and a high Q resonance will not only make graphene metasurfaces suitable for biosensing application, but also provide a perfect platform for efficient optical modulation.

Abstract: This paper presents a novel design of a polymer-based 3D FZP near-field probe with sub-wavelength resolution and significant optical field enhancement with the possibility of implementation of such a device onto the optical fiber

Herein we aimed to optically characterize and compare the near-field emission of a 2D and 3D fresnel zone plate (FZP) structures using both numerical simulation and experimental setup of conventional near-field scanning optical microscope using metal-coated fiber-based pulled probe. The overall conceptualization is based on the fresnel zone plate (FZP) design, where each individual zone influences the phase of the transmitted wave so that they interfere constructively at a given distance of the focal plane [1-2]. The main input parameters characterizing a FZP are its diameter, the focal length, the refractive index of the structure and the incident wavelength. These parameters directly influence the radius of each zone according to equation

$$r_k = \sqrt{\frac{k\lambda_0 f}{n} + \frac{k^2\lambda_0^2}{4n^2}},$$

where k is the integer number, λ_0 is the incident wavelength in vacuum, f is the focal length of the FZP, and n is the index of refraction. The overall design is shown in Fig.1.

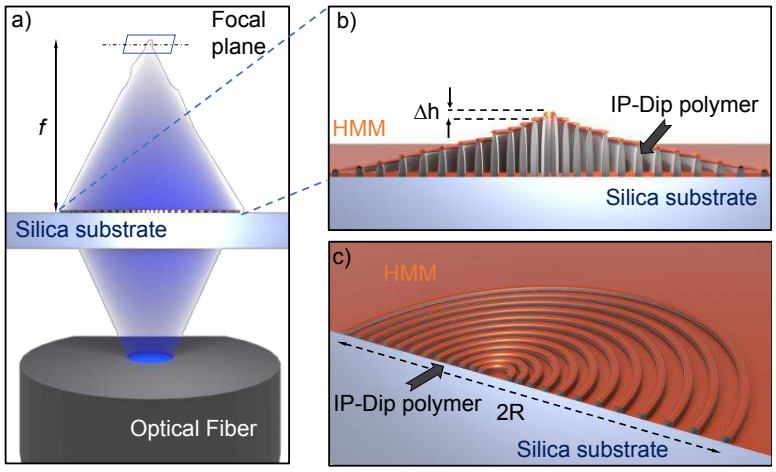

Figure 1: Schematics of the 2D fresnel zone plate design with its a) working principle, b) a simulation of the Poyinting vector distribution at the x-z plane of the 2D fresnel zone plane antenna, c) schematic of the structure physical parameters, with 2R depicting the diameter of the FZP antenna.

The implying structure was designed for λ_0= 420nm, focal length of 300 nm and refractive index of the IP-Dip polymer n= 1,53. The total number of the FZP zones was chosen to be 11, in order to address the previous

documented results of the efficiency gain of FZPs with higher number of zones. The diameter of the whole structure is 12.15 μm, indicated in Fig. 1 c) as the distance 2R, while the height of each individual zone is 760 nm with the HMM included. It is also worth to mention, that we chose to design the structure without the innermost first zone to avoid the effect of undesirable polymerization of the IP-Dip forming a 3D defect documented in our previous study [3]. Fig. 2 documents the topography of both designs as well as the result of the near-field characterization by NSOM.

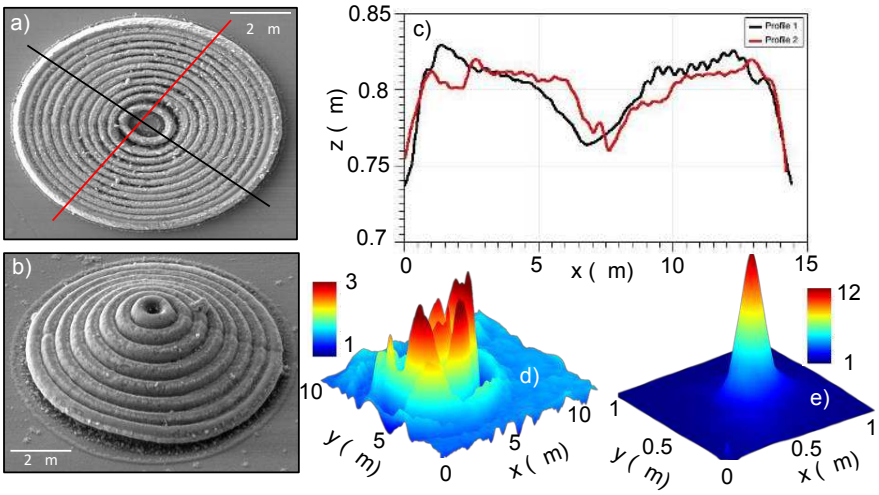

Figure 2: Experimental results of the a) AFM topography measurement of the 2D FZP, b) SEM of the 3D FZP, c) Surface profile lines depicted from a), d) NSOM measurement of the 2D FZP taken above the surface, e) NSOM map of the 3D FZP measured at the apex of the aperture. The color-scale depicts the intensity of the electric field enhancement with respect to the source

The SEM images show clear distinguishable features of the FZPs, however the spacers between the zones are partially filled out after the HMM deposition. It is worth to mention that for the 3D design, the deposition resulted in the formation of subwavelength aperture with diameter of 300 nm, resulting in the suppression of the side-lobes and enhancement of the central peak with FWHM of 0.6λ making a great candidate for a fiber-integration and further optical characterization. Such a probe would prove to be an excellent near-field characterization tool implemented on an optical fiber tip, tuning fork or a cantilever for SNOM.

Enhancement of a single molecule triplet depopulation rate by a dielectric nanoantenna

R. Trojanowicz[1], S. Vassant[1*], F. Charra[1]
[1]Université Paris-Saclay, CEA, CNRS, SPEC, 91191, Gif-sur-Yvette, France
[*]corresponding author: simon.vassant@cea.fr

Abstract: In this work, we investigate the effect of a dielectric nanoantenna on a single Terrylene molecule's photon statistics. Nanoantenna increases the excitation intensity and local density of optical states (LDOS), affecting the rates at play in the fluorescence process. Compared to its plasmonic analog, a dielectric antenna introduces low background and no quenching. Experiments show that the nanoantenna increases the efficiency of pumping the lowest-energy triplet state into higher-level triplets by excitation field concentration.

Terrylene in p-terphenyl is a perfect host-guest system for single molecule and nano-antenna studies. Using simple spin-coating one can produce thin films down to sub-30 nm with fluorophores of well-defined orientation that are photostable for hours [1]. Previous studies proved that Terrylene in p-terphenyl has a power-dependent effective triplet lifetime due to additional decay channel such as pumping triplets to higher levels and reversed intersystem crossing (rISC) [2,3]. The influence of a dielectric nanoantenna on the singlet rate was previously reported [4], but to our knowledge, its influence on the intersystem crossing rate and on the triplet depopulation rate are not reported yet.

As dielectric nanoantenna, we use pulled glass fiber with sub-100 nm radius of curvature in Scanning Probe Microscopy configuration (Figure 1. left). We use an inverted microscope coupled to a Hanbury-Brown-Twiss detection scheme with Time-Correlated Single Photon Counting to extract all the rates at play in the photon emission process of single Terrylene molecule, and observe in particular how the presence of the nanoantenna affects the triplet depopulation rate. We perform 3 experiments on each molecule: Terrylene alone (pre-approached), Terrylene with nanoatenna (approached) and again Terrylene alone (post-approached) as nanoantenna effect should be reversible in nature – Figure 1, right.

Terrylene is modeled as 3 level system to extract molecular rates. Via a linear fit of the triplet depopulation power-dependence $k_{31}(P)$ intercept and slope can be extracted – power-independent component corresponds to T1-S0 transition and power-dependent component corresponds to pumping higher triplet states and subsequent rISC.

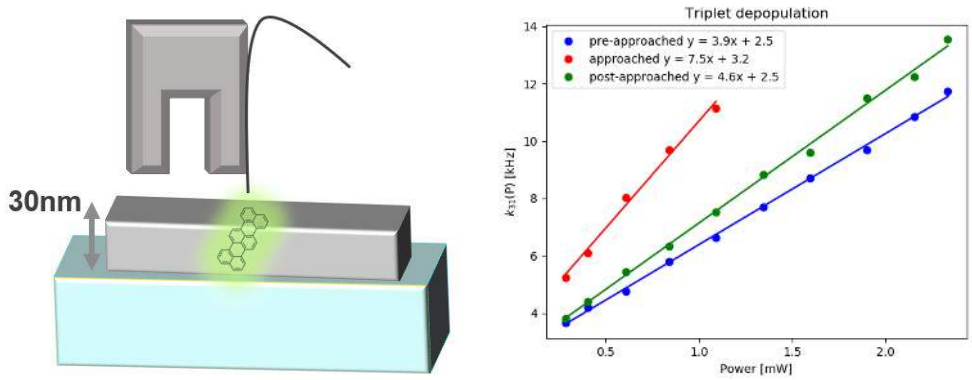

Figure 1. Scheme of set-up: tuning fork with a nanoantenna (glued pulled optical fiber) working in shear-force mode above sub-30 nm thin film of p-terphenyl doped with Terrylene molecules (left). Power-dependence of triplet depopulation rate (k_{31}) for the same molecule with nanoantenna pre-, post- and approached (right).

Across population, we observe around 2-fold reduction in lifetime due to change in LDOS. Power-dependent component in k_{31} and excitation rate k_{12} have similar enhancements of around 2. This indicates an excitation field concentration by the nanoantenna. Small differences between enhancements of these two rates may imply slight misalignment of singlet and triplet transition dipole moments in space. Effect on power-independent component in k_{31} and k_{23} are very small with dispersion across molecules. In some cases, measurements have a slight pre-/post-approach hysteresis that indicates a small modification in those rates (Figure 1, right). This highlights the importance of our measurement protocol as changes in rates can originate from modification of molecule environment by the scanning probe, rather than from nanoantenna effect itself.

This work in funded by the ''Controlled influence of a Plasmonic nano-antenna on a single molecule Instersystem Crossing Rate'' (PlasmonISC; ANR-19-CE09-0009) project.

Abstract: Resonant nano-optical tweezers based on dielectric, plasmonic and metamaterial nanostructures have been recently proposed to overcome the diffraction limit imposed by conventional optical tweezers. As a result of this innovative approach, it was possible to reduce the confinement volume of the trap (nanometer scale), increase the intensity of the gradient force, and decrease the power of the incident light. However, local and multiresonant isotropic confinement of nanoparticles (NPs), the size limit of the captured NP in the sense of Rayleigh scattering theory, and the modeling of realistic PNOs with the mentioned characteristics still remain major challenges. In this paper, using electromagnetic modeling (FDTD simulations) and dipole approximation, we proposed a multiresonant nano-optical tweezer based on coaxial plasmonic nanoapertures with the ability to trap small nanoparticles smaller than 5 nm.

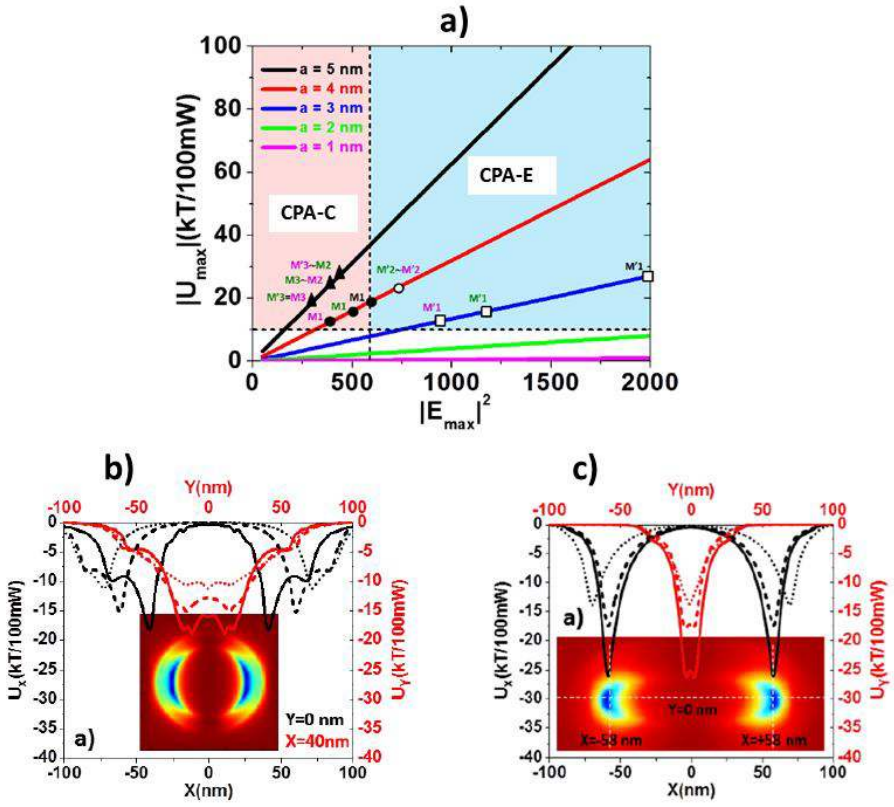

Figure 1

The first theoretical design of an optical tweezer using localized surface plasmons was independently reported by Novotny [1] and Martin [2]. After this proposal of nanoplasmonic optical trapping, many other theoretical and experimental works were developed replacing metallic nanostructures with more complex structures [3-5]. In this sense, a local and stable trapping (via surface plasmons) of Rayleigh particles with diameters up to 10 nm was possible. However, plasmonic optical tweezers for nanoparticles with diameters smaller than 3 nm still face many technical challenges [3,6,7].

Figure 1(a) shows the linear relationship between the absolute value of the minimum optical potential, $|U_{min}|$, and the maximum electric field enhancement factor, $|\mathbf{E}_{max}|^2$, for spherical proteins with radii of 1, 2, 3, 4 and 5 nm. The propagating modes M1 (dipole resonance), M2 (quadrupole resonance) and M3 (sextupolar resonance) belong to a coaxial plasmonic aperture with cylindrical symmetry (CPA-C), whereas the modes M'1, M'2 and M'3 belong to a coaxial plasmonic aperture with elliptical symmetry (CPA-E). Note that Figure 1(a) has been divided into two regions separated by the factor $|E|^2 = 600$ which corresponds to the upper limit of near-field enhancement generated by a CPA-C. Above 600, with an upper limit of 2000, corresponds to a CPA-E.

Figure 1(a) shows the transverse optical potentials U_X and U_Y along the X-axis (for Y = 0) and the Y-axis (for X = ±X0 nm), respectively, for three CAPs-C. The optical potentials were calculated for proteins of 4 nm radius using the M1s modes: CAPs-C1 with $|E|^2 = 600$ and $\lambda_1 = 755$ nm; CAPs-C2 with $|E|^2 = 500$ $\lambda_1 = 900$ nm and CAPs-C3 with $|E|^2 = 340$ and $\lambda_1 = 1027$ nm. These tweezers with two potential wells have an optical potential depth between -17kT/100mW and -11kT/100mW enough to trap proteins of 4 nm radius when the particle approaches the regions of high near-field enhancement.

Finally, in order to show the efficiency of CPAs-E as optical tweezers, Figure 1(c) shows the results of optical trapping of a 3 nm radius protein using the M'1s resonant plasmonic modes of three CPAs-E with eccentricity of 0.9: CAPs-E1 with $|E|^2 = 2000$ and $\lambda_1 = 809$ nm; CAPs-E2 with $|E|^2 = 1200$ and $\lambda_1 = 935$ nm and CAPs-E3 with $|E|^2 = 900$ and $\lambda_1 = 1030$ nm. As can be seen, the X component of the double optical potential, U_X, corresponds to the greater near-field intensification (~2000) and presents a greater depth $U_X = -27$kT/100 mW with a full-width at half-maximum of 10 nm, which indicates a high stability and a high confinement of the protein at the ends of the elliptical nanoaperture.

Abstract: The lack of color diversity is the fundamental problem inherent in the radiative cooling system, which raises practical issues of eye safety, light pollution, and aesthetics. In this work, we show a breakthrough for colored radiative cooling by experimentally demonstrating that sub-ambient cooling under direct sunlight is possible for all colors, including black. The key principle is thermal non-equilibrium between color and cooling parts, which can potentially serve as a new avenue for radiative cooling applications requiring diverse color expression.

In recent years, radiative cooling has emerged as a promising approach to alleviate power consumption driven by cooling demand, with no carbon emission. Despite intensifying interest in the carbon-free cooling system, the lack of color diversity is a critical obstacle for outdoor applications of radiative cooling to commercial buildings and residential houses; because the ultra-bright appearance (mostly in white [1], or silvery colors [2]) of current radiative cooling materials raises questions of eye safety, light pollution, and aesthetics. Based on similar concerns, several countries have already banned the use of highly reflecting materials in buildings [3], which makes current radiative cooling materials and schemes inapplicable.

Here, we propose a novel radiative cooling system, recently published in Ref. 4, that can express arbitrary colors while being cooled below the ambient temperature during all daytime. Experimentally, we present that radiative cooling systems with dark colors (black and red) absorbing solar power over 640 Wm^{-2} (which far exceeds the fundamental cutoff of ~110 Wm^{-2}) reach sub-ambient temperatures with the average cooling over 3.5 K in the daytime. We emphasize that the thermal effect of atmospheric non-radiation, which normally serves as heating, is flipped in our case to improve sub-ambient cooling performance.

This counter-intuitive result is possible by separating the color and cooling parts and inducing non-equilibrium between them (Fig. 1). In our system, the thermal emitter releases radiative heat toward the outer space while being decoupled from the sunlight by the color part. The middle part is composed of high thermal resistive material, which allows a steep temperature gradient. Due to this non-equilibrium configuration, the thermal emitter can maintain a sub-ambient temperature even under the perfect solar absorption condition of the color part, unlike the previous isothermal emitter.

Building upon theoretical study for non-equilibrium systems, we built colored radiative cooling systems for black and red (Fig. 2). The color part is optimally designed as a multi-layer stacking composed of germanium and zinc sulfide on a germanium substrate. The cooling part is designed with PDMS and Al foil, which works as a broadband emitter. These two parts are separated by a thermal-resistive wall that is mostly filled with air. The outdoor measurement results show that, as expected, the emitters with black and red exteriors cool by an average of 3.7 K and 3.5 K compared to daytime ambient temperature.

Further examination of the same principle [4] also confirms the feasibility of other colors (e.g., blue, green,

cyan, magenta, and yellow) and the reliability of the experimental results over a longer period (~ 3 days). Based on reproducible and consistent cooling results with diverse exterior colors, we envision that our work would be a complete and general solution to practical applications that require both carbon-free cooling and aesthetics.

Surface absorbers for thermomechanical bolometers

B. Bertoni[1]*, L. Vicarelli[2], S. Zanotto[2]*,
S. Roddaro[1,2], A. Tredicucci, and A. Pitanti[2]

[1]Dipartimento di Fisica, Università di Pisa, Largo B. Pontecorvo 3, Pisa, Italy
[2]NEST Lab., CNR Istituto Nanoscienze, piazza San Silvestro 12, Pisa, Italy
* b.bertoni@studenti.unipi.it , simone.zanotto@nano.cnr.it

Thermomechanical bolometers based on high-quality mechanical resonators are a promising technology for broadband light detection. Further functionalities can be added by controlling the absorption spectrum of the devices. To this end, we embedded (almost-) 2D layers, minimally impacting the mechanical quality while, at the same time, offering strong absorbance. Further layer patterning could grant resonant absorption, for hyperspectral imaging or polarization sensitive detection.

Thermomechanical bolometers (TB) detect radiation by measuring the thermal shift in the resonant frequency of a microresonator when heated up trough light absorption [1]. The main shift contributions come from thermal expansion and tensile stress reduction of the materials constituting the suspended mechanical resonator, granting for room-temperature operation of the devices. Here, as a further progress, we will introduce smart absorbers, capable of enhancing thermomechanical detection without impacting on the mechanical quality of the resonator. Weightless and stiff 2D materials, which can also be patterned for complex light control, are the perfect candidates to this end.

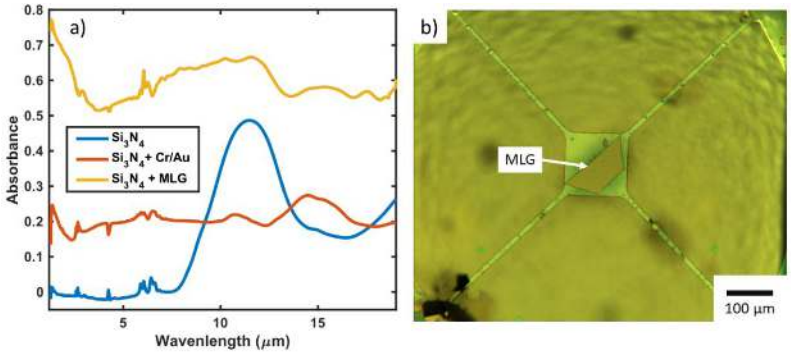

Figure 1: a) Absorbance of bare, Cr/Au and MLG coated Si_3N_4 membranes. b) Microscope image of a graphene flake on a Si_3N_4 trampoline

We considered multi-layer graphene (MLG) obtained from graphite mechanical exfoliation with the 'Scotch tape method' [2] as a first candidate. We prepared a set of homogeneous, 300 nm thick, silicon nitride membranes covering some of them with a 3/15 nm Cr/Au film. Furthermore, we successfully transferred MLG onto some of them, using a PMMA/PVA vector, as detailed in [3]. The membrane absorbance in the mid-infrared range was measured via FTIR spectroscopy and reported in Fig.1a. While the bare Si_3N_4 material gives a sharp absorption peak around 11 μm wavelength (with negligible absorption elsewhere), the metal film shows a flat absorbance

of about 20% in the investigated spectral region. Conversely, MLG exhibits large and broad absorbance, up to 60% in the whole frequency range. Promising, the MLG can also be transferred on patterned membranes, which constitute the core device for thermomechanical bolometers. The microscope image of Fig. 1b shows, as an example, a roughly 100 μm x 50 μm MLG flake deposited on the central plate of a trampoline resonator. While the main limit of exfoliation lies in the non-deterministic nature of available thickness and size of the flakes, other techniques based on pyrolyzed polymers [4] can overcome this issue and grant for reliable and large-scale fabrication.

An intriguing possibility of further optimization considers a complex patterning of the smart absorbers. By defining an artificial surface with the introduction of subwavelength and periodic scattering centers (metasurface), it is possible to implement selective absorption, creating hyperspectral detectors. More complex geometries can give rise to new functionalities. Chiral scatterers couple preferentially with selected polarization state of light and can be employed for polarimetry based on selective absorption [5]. As described in the sketch of Fig. 2, an interesting scenario would see the use of polarization sensitive TBs, which could respond to circular right polarization while being insensitive to illumination with circular left one.

With the technological possibility of electrical read-out, large scale fabrication and video rate operation, arrays based on TBs with smart absorbers could realize a promising technology for field applications requiring detection of mid- and far-infrared light, with use in security, healthcare and quality control.

Designing tunable, broadband absorber/emitter using epsilon near zero media

Sraboni Dey* **and J. Mitra**

School of Physics, Indian Institute of Science Education and Research, Thiruvananthapuram, India-695551
*corresponding author: srabonidey20@iisertvm.ac.in

Abstract: Customizing the optical response of surfaces, using subwavelength thick coatings is an area of topical interest. The advent of novel materials like ENZ materials along with the capability of nanostructuring has enabled realization of new design strategies to control absorption/emission properties over broad spectral ranges. We present a straightforward design using a multilayer ITO/SiO_2/Au coating which shows wide-angle absorption over tunable broadband regimes.

Introduction

Recently, perfect broadband absorption and emission have drawn significant attention in optical devices. Engineered metal-insulator-metal (MIM) structures, gratings, meta-materials [1], etc. have been shown to be crucial in tailoring different aspects of emission including directionality and spectral efficiency with applications in various fields, from solar energy harvesting to photo-thermal cooling [2]. Further, the advent of nanofabrication tools has provided novel pathways to engineer coatings with periodic subwavelength structures and thickness that result in highly isotropic optical responses, over broad spectral ranges. Evidently, the choice of materials plays an integral role in effecting such control and epsilon-near-zero (ENZ) materials has been at the forefront of research in the area. ENZ materials undergo optical dielectric to metal transition at a particular wavelength known as the ENZ wavelength (λ_{ENZ}) at which the real part of permittivity goes to zero [4,5]. Phenomena like perfect absorption, strong electric field enhancements and giant optical nonlinearities are realized in this regime [3], which can be harnessed to enable selective light absorption and emission.

In this work, we have discussed a straightforward approach to simulate a broadband absorber/emitter employing a 200 nm bi-layer coating of dielectric (SiO_2) on metal (Au) on a transparent glass (NBK7) substrate, decorated with a grating of an ENZ material (ITO). The results show that the system has above 90% absorption in the wavelength window 1310 - 2125 nm and very low absorptance of ~ 10% elsewhere. The coating design is shown to be elemental in achieving the desired absorption/emission spectral response that is independent of the angle from 0° - 60°. Further, the absorption window can be tuned to higher wavelengths leveraging the tunable λ_{ENZ} of ITO.

Results and Discussions

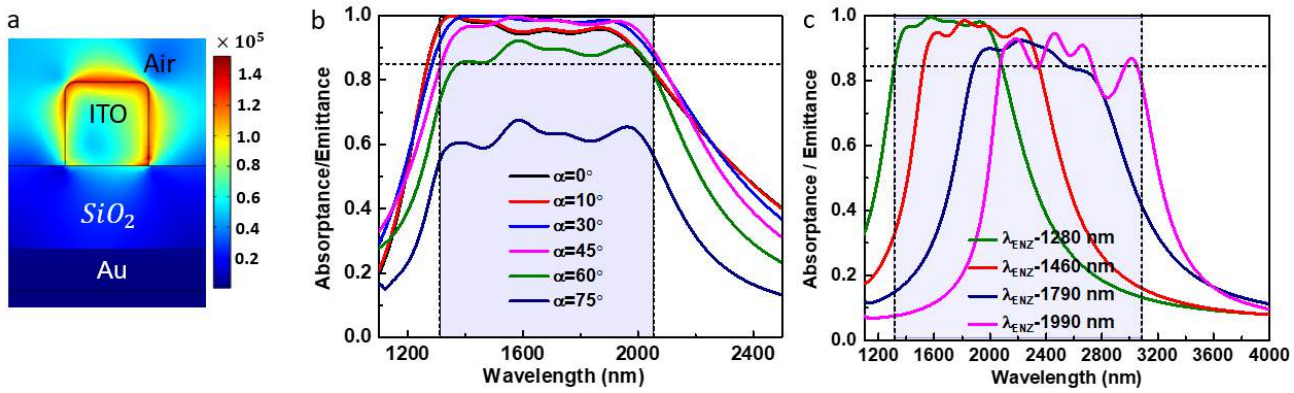

Figure 1: (a) Simulated electric field at λ=1450 nm, (b) Simulated absorptance spectra for different angles of incidence (0º, 10º, 30°, 45°, 60º, 75°), b. Simulated absorptance spectra for the broadband absorber system for different λ_{ENZ} (1280 nm, 1460 nm, 1790 nm, 1990 nm) of ITO at 45° oblique angle of incidence.

The multilayer structure optimization and the simulations were conducted using a finite element method solver in COMSOL® Multiphysics 5.3a. The structure consists of a periodic array of ITO nano-ridges on the top and gold as the back reflector separated by a SiO_2 layer as shown in Fig 1a. The optical properties of ITO can be modeled using the Drude model that connects the λ_{ENZ} with the electron density in ITO, which can be reversibly controlled by various means [4]. Figure 1b shows the simulated spectral response for the multilayer structure for ITO with λ_{ENZ} = 1280 nm, that is very weakly dependent on the angle of incidence or emission, between 0 - 60º. The strong absorption, selectively in the 1310 - 2125 nm wavelength range is understood to be brought about by the plasmonic response of the ITO nano-ridge array in its metallic regime, facilitated by the refractive index contrast provided by the underlying SiO_2/Au layers. To obtain a comprehensive picture of the phenomena, the λ_{ENZ} of ITO was changed to 1460nm, 1790 nm, and 1990 nm, the response for which is shown in figure 1c. Evidently, the multilayer supports a high absorption/emission spectral window (~ 800 nm) that is readily tunable in the near IR regime and is potentially elemental in various photo-thermal applications.

Pd nanoparticles as Visible and near-IR plasmonic catalysts

Y. Yokota*, A. Fujita and M. Abe

Sophia Univ., Japan
*corresponding author: y_yokota@sophia.ac.jp

Abstract: Pd nanoparticles are used as catalysts for organic chemical reactions and exhibit higher catalytic activity than commercial Pd catalysts. In this study, we have prepared Pd nanoparticles by liquid-phase synthesis and and investigated their optical properties. The optical properties of Pd nanoparticles depending on shape and size, and the reaction kinetics of model reactions were compared.

Transition metal Pd nanoparticles exhibit high catalytic activity in coupling reactions to their large surface area and can store hydrogen on their surface[1), 2)]. Noble metal nanoparticles interact with light to induce localized surface plasmon resonance (LSPR), which is affected by the type of metal. The effect on LSPR is related to the dielectric in the bulk metal, with the real part of the dielectric being less negative than in gold or silver. Although Pd nanoparticles have weaker LSPR electric field enhancement, the new plasmon-enhanced fields, which are characteristic of Pd, have potential applications in photocatalysis and energy storage and conversion. In this study, Pd nanocubes (PdNCs) were synthesized in the liquid phase and their plasmon optical properties were investigated. The kinetics of the p-nitrophenol reduction reaction was also compared as a model reaction.

PdNCs were synthesized seed-mediated method. The morphology of PdNCs was observed by Scanning electron microscopy (SEM). The synthesized PdNCs were dispersed in aqueous solution, and the absorption spectra were measured with an ultraviolet-visible spectrophotometer. The synthesized PdNCs were used as a catalyst for the reduction of *p*-nitrophenol in aqueous solution with an excess of $NaBH_4$. The reaction was carried out in the dark and under Xe lamp irradiation (wavelength: 440 nm-740 nm).

Fig. 1(a) and 1(b) show SEM images of the synthesized PdNCs with CTAB and PVP, respectively. When CTAB was used as a protector of nanocubes, the average side length was 61 nm. In addition to the cubes, about 16% of the Pd nanorods were also formed. The average side length of PdNCs with PVP was 55 nm and a larger percentage of rounded cubes were formed than PdNCs with CTAB. The absorbance of PdNCs in aqueous solution is shown in Fig. 1(c). PdNCs with PVP have a single peak at 380 nm. Multiple plasmon resonance peaks were observed for PdNCs with CTAB; the peak around 400 nm is from the cube and the peak at 520 nm is from the long axis of the nanorods.

Fig. 2 shows the time-dependent absorption spectra of p-nitrophenol reduction catalyzed by PdNC synthesized in the dark. p-Nitrophenol becomes *p*-nitrophenoxide ion due to the addition of $NaBH_4$ and stirring, and the reaction time is 0 s. Because the solution is an aqueous solution with pH above 10, p-nitrophenol becomes p-nitrophenoxide ion and has an absorption peak at a wavelength of 400 nm with an absorption peak at 400 nm. The peak decreased with reaction time when PdNS of either surfactant was used as a catalyst. In the case of CTAB, the peak at 300 nm increased, while in the case of PVP, an absorption peak at 310 nm appeared at 240 s reaction time, and its intensity decreased with time with a blue shift, until a peak at 300 nm appeared at the end of the reaction. The peak of 310 nm is derived from the reaction intermediate, *p*-hydroxylaminophenol. The *p*-nitrophenol reduction reaction can be regarded as a pseudo-

first-order reaction, and the rate constants were determined from the slope of the approximate straight line. The reaction rate constants of PdNS with PVP were little changed by dark and light irradiation. In the case of CTAB, the value of the reaction rate constant was about three times larger under light irradiation than in the dark. The results of reduction reactions at different reaction temperatures will also be presented on the same day.

Abstract: Metallic nanostructures supporting plasmonic resonances offer potential for efficient spectroscopy and photocatalysis. Here, we fabricate hierarchical Au dendrites and map their plasmonic properties using cathodoluminescence spectroscopy. We demonstrate a controllable hot-spot density and show a correlation between the spatial and spectral distribution of resonances and their morphology. Their performance as both SERS substrates and as photocatalysts is investigated, revealing large SERS enhancements with high hot-spot density and high photocatalytic yields with low hot-spot density. These findings provide insights for the rational design of plasmonic architectures for various applications.

The field of plasmonics has emerged as a promising platform for enhancing light-matter interactions, offering the potential to manipulate light at the nanoscale with unprecedented precision. In particular, metallic nanostructures with complex three-dimensional geometries, have attracted significant attention due to their large surface areas, broadband absorption and multiple resonances, making them attractive candidates for a variety of applications, including photocatalysis and spectroscopy[1].

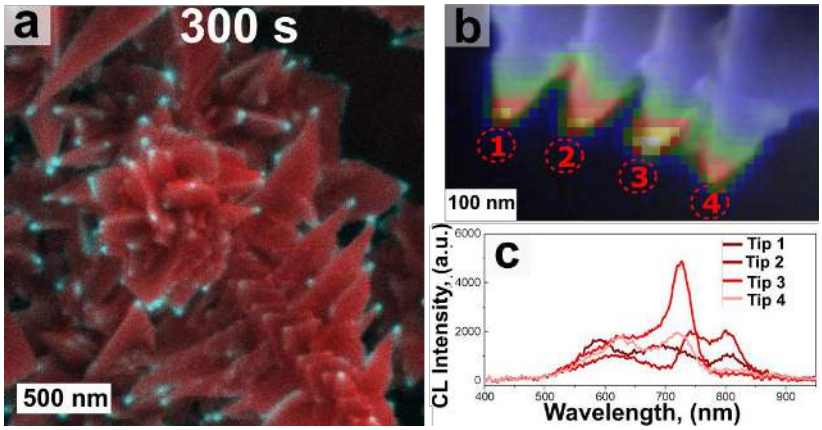

Figure 1. a) CL emission superimposed on the image of a 3D Au dendritic structure. b-c) Panchromatic CL map and spectral distribution of CL emission of a Au dendritic structure, respectively.

In this study, we mapped the spatial and spectral distribution of plasmon hot-spots in 3D complex Au structures with nanometric resolution, using cathodoluminescence (CL) spectroscopy[2]. Hierarchical Au dendrites were deposited over centimeter-scale conductive substrates by a single-step electrodeposition technique, which allows statistical control of the morphology by modifying the electrodeposition time. The resulting structures had self-similar properties, high curvature regions, and multibranched architectures that result in broadband visible and near-infrared absorption. These structures support a multitude of plasmon resonances in the wavelength range of 400–900 nm, which strongly correlate with the local morphology of the network. We demonstrate that

the hot-spot density correlates with morphology, increasing by more than threefold as the deposition time increased from 100 to 400 s. Boundary element method simulations on simplified geometries supported the experimental results and showed that the plasmon modes supported by the complex morphologies are determined by the details of the local geometry of sharp features.

We studied the performance of these dendrites as surface-enhanced Raman scattering (SERS) substrates for the detection of parts-per-million concentration of methylene blue (MB) and as photocatalysts, by monitoring the N-demethylation reaction of MB. Architectures with higher hot-spot density resulted in better SERS detection, while a lower hot-spot density led to improved reaction yields, indicating that the hot-spot density alone is not sufficient to optimize the photocatalytic performance of plasmonic substrates. This highlights the importance of considering the spectral distribution of plasmon resonances in the design of plasmonic architectures for photocatalysis, which can modify the hot electron generation efficiency.

Building on the insights gained from our investigation of hierarchical Au dendrites in promoting the N-demethylation reaction, we are exploring the possibility of these structures for achieving selective CO_2 photoreduction. In summary, supported by experimental results and theoretical analysis, this work provide insights for the rational design and realization of efficient and selective plasmon-mediated photocatalysis.

Synergistic Photonic and Morphology Design of Solar Powered Redox Cells

Jiaming Ma[1], Kiseok Oh[1], Giulia Tagliabue[1]*

[1] Laboratory of Nanoscience for Energy Technologies (LNET), STI, École Polytechnique Fédérale de Lausanne, 1015 Lausanne, Switzerland

Abstract

Solar powered redox cells (SPRC) offer compelling opportunities for large-scale and long-term storage of solar-energy and have thus attracted increasing attention[1-3]. Yet, to date, photoelectrodes suffer from poor light absorption and limited charge transport [4,5]. While efforts have primarily focused on heterostructure engineering, the potential of synergistic morphology and photonic design has not been carefully investigated. In our work, we study the wavelength-dependent effects of light-absorption and charge transfer characteristics on the performance of gold decorated TiO2-based SPRC photoanodes operating with RFB-compatible redox couples[6]. On one hand, engineering nm-scale TiO_2 semiconductor can increase the light absorption because of its good light scattering property and maximize charge carrier collection as the semiconductor size is comparable to the charge carrier mean free path. On the other hand, metallic nanostructure supporting plasmon resonances can help overcome light-absorption limitations and suppress charge recombination due to it acting as intermedia between semiconductors and hot charge carries. Using an in-depth optical and photoelectrochemical characterization of Au/TiO2 based SPRCs, including IPCE and IQE measurements, we are able to disentangle the roles of charge generation, charge transport and charge collection in these photoanodes. Ultimately, we demonstrate that the synergistic effect of nm-scale semiconductor and plasmonic design can greatly improve optical and photoelectrochemical performance.

More specifically, we report an in-situ directly growing TiO_2 nanotubes on FTO substrate with plasmonic Au nanoparticles coating. The nanotubes have an ultrathin thickness (10 nm) with length range from 1.2 -1.5 um, which possess more electrode/electrolyte interface and higher electrochemical active surface area, as well as creating more sites for plasmonic structure. Benefiting from its morphology, the charge transfer distance in those nanotubes is comparable to the mean free path of electrons, which can enhance the photo-generated carrier separation. Meanwhile, the plasmonic Au nanoparticles not only provide extra light absorption in visible range but also enhance the catalytic activity across the whole spectrum, thus improving incident photon to current efficiency. In particular, we achieve a high photocurrent at 0.098 mA/cm^2 with an interior stability during long time photo-charging process in an H-cell under no bias. The incident photon to current efficiency (IPCE) is also superior to non-modified TiO_2 showing a high value of 54.7%, indicating the role of plasmonic nanoparticles in SPRC. This design is expected to be a potential candidate for the rechargeable solar-energy technologies such as solar redox flow batteries.

Abstract: In this study, we demonstrate a high-quality transfer method for a multi-periodic array of plasmonic nanodiscs onto a graphene monolayer by carefully adjusting the surface tension of a water-ethanol mixture. Our analysis using optical microscopy, scanning electron microscopy, and optical spectrum measurements revealed little difference compared to those formed by direct patterning. We observed multispectral selective enhancement of photo-absorption at resonant wavelengths corresponding to each period of the plasmonic absorber array.

The lithographic fabrication of plasmonic nanostructures on graphene hindered by the lack of interfacial chemical bonding, and may even cause surface damage and contamination, leading to the deterioration of their functionality. Layer transfer technique offers a great alternative to this issue. However, the hydrophobic nature of graphene surface requires careful consideration of interfacial wetting properties to prevent bursting or defect formation during the drying process, and to obtain uniformly transferred plasmonic nanostructures over a large area. We used a water-ethanol mixture as a transfer liquid in the convention PMMA support wet transfer method to improve the wettability on the graphene layer by reducing the surface tension of the liquid. We found that the optimum condition was achieved with approximately 0.3 moles of ethanol, and any additional amount of ethanol would cause the PMMA film to sink. Figure 1 compares photographs of layer-transferred plasmonic nanodiscs arrays on hydrophobic Si substrates using deionized water (a) and a 0.3 mole ethanol-water mixture. Optical microscopy images before PMMA support layer removal are shown in (b) and (f), while (c) and (g) display the images after removal.

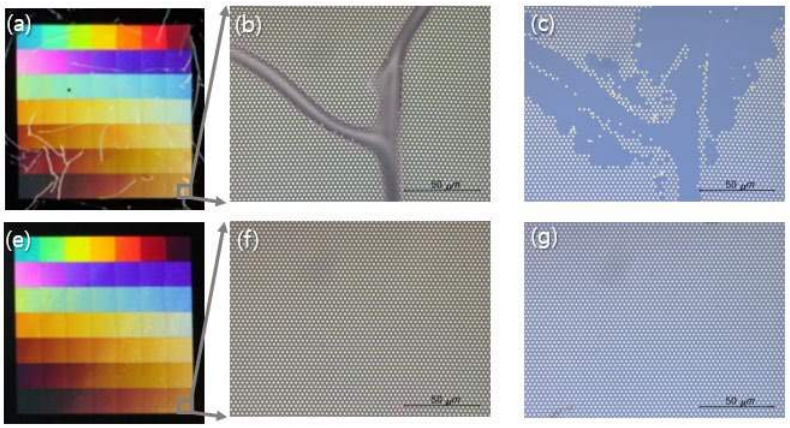

Fig. 1. Photographic images of multispectral plasmonic nanodiscs absorbers layer-transferred onto Si substrates using deionized water (a) and a 0.3 mole ethanol-water mixture (e), along with optical microscope images before (b, f) and after (c, g) PMMA support layer removal.

Using the optimum condition, a multi-periodic array of plasmonic nanodiscs was transferred onto a Si substrate coated with a graphene monolayer, and the optical absorption spectra were compared between samples with and without graphene layer inserted between the nanodiscs and Si substrate. Figure 2 shows the relative optical absorption ratio profiles depending on the period of the nanodiscs array, which confirms a significant enhancement of light-graphene interaction facilitated by the plasmonic selective absorbers at each resonant wavelength. These results are expected to contribute to the development of spectral-selective optoelectronic detectors and devices based on graphene.

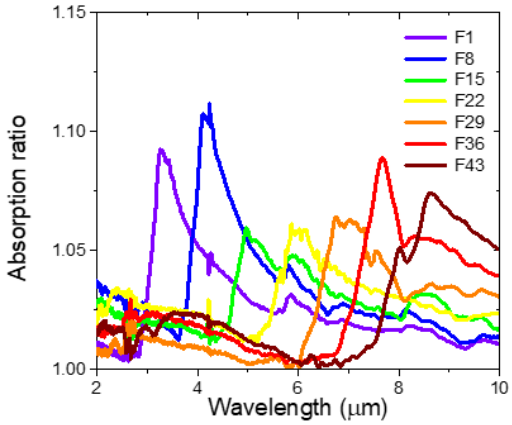

Fig. 2. The measured optical absorption ratio profiles of graphene with multispectral plasmonic selective absorbers layer transferred onto it.

Abstract: This study implements an ultrasensitive platform technology that integrates a wet-chemistry scalable sensor with optical artificial intelligence hardware attached to a conventional monochrome camera. The system extracts sensing features in the optical hardware, enabling accurate quantification of glucose concentration with a detection limit as low as 10^{-20} mol/L. The results improve the current state-of-the-art by six orders of magnitude. The system does not require an electrochemical workstation and works in real-time.

Refractive index (RI) sensing attracts considerable interest in the analysis of blood components [1], DNA [2], proteins [3], cancerous cells [4], virus and bacteria [5]. Traditionally, RI sensors measure refractive index variation via localized spectral features, such as frequency shift or width changes in resonances [6]. This approach, while straightforward to implement, suffers from the effects of noise and does not allow to reach detection limits comparable to chemical techniques [7]. For example, in the detection of glucose, which is essential in detecting heart failure, diabetes, and other metabolic syndromes [8], the best RI-based results reach the detection limit of 10^{-6} mol/L [9]. Conversely, enzymatic can detect glucose at levels as low as 1×10^{-13} mol/L with a GOx/ZnONPs-[EMIM][Otf]/ESM sensing platform [10] and 4.2×10^{-14} mol/L with a CuONPs/Ni-foam sensing platform [11], respectively.

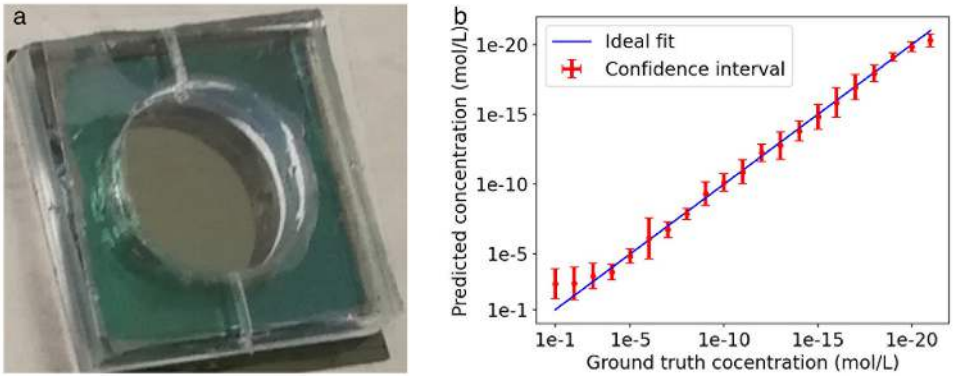

Figure 1: (a) A fabricated optical RI sensor. (b) Prediction results on a test dataset, including 20 different glucose concentrations varying from 10^{-1} mol/L to 10^{-20} mol/L. The presented confidence interval is magnified by 30 times for better visualization.

This work implements an ultrasensitive detection framework by integrating RI sensors with artificial intelligence (AI) optical hardware into a monochrome camera. The hardware comprises inversely designed metasurface encoders [12], which extract sparse spectral features that train a regression model. We fabricate the

sensor via wet chemistry, expandable up to 4 inches. Figure 1a shows a picture of a manufactured device. The sensor includes a structured silicon substrate covered by golf film and a top cover glass that confines the incident light on the substrate. The semi-enclosed container used in our system automatically removes invisible residue after each measurement, making it possible to reuse the container and collect large-scale datasets for subsequent training of the AI models. Figure 1b depicts the sensitivity of this system in determining glucose concentration, achieving detection resolutions as low as 10^{-20} mol/L, the lowest reported for this analyte to date. Our regression network shows high measuring accuracy with an R^2 value of 0.9648.

Effect of Mirror Quality on the Optical Properties of Nanoparticle-on-Mirror Plasmonic Nanocavities

Z. X. Wang[1*], A. V. Krasavin[2] and P. Wang[1]

[1]State Key Laboratory of Modern Optical Instrumentation, College of Optical Science and Engineering, Zhejiang University, Hangzhou 310027, China

Abstract: As an important part of nanoparticle-on-mirror (NPoM) plasmonic nanocavities, metal mirrors play an important role in determining the optical properties of the nanocavities and their application performance. Here, we experimentally study the effect of mirror quality (e.g., surface morphology, crystalline quality) on optical properties of NPoM nanocavities including nanosphere-on-mirror (NSoM) and nanocube-on-mirror (NCoM) designs, which improve the understanding of optical properties of the nanocavity and provide guidelines for the design of nanocavity-based devices with optimized performance for practical applications.

Plasmonic nanocavities based on metal nanoparticle-on-mirror (NPoM) nanostructures, have attracted extensive research interest due to their ability of extreme optical field localization and enhancement. They provide an intriguing platfrom for the study of light-matter interactions at the nanoscale and have enabled a series of breakthroughs in nanophotonic research and applications[1,2]. They are usually fabricated using deposited polycrystalline metal films with a rough surface or template-stripped polycrystalline metal films with a very smooth surface as the mirrors[1,2]. Recently, we have employed chemically grown single-crystalline gold microflakes (GMFs) as the metal mirror[3], providing NPoM nanocavities with significantly reduced loss. Because of the strong confinement of optical fields in the nanoscale gap, the optical property of NPoM nanocavities is very sensitive to the nanoscale morphology of the gap as well as the crystalline quality of the bottom metal mirror. A small change in the gap morphology induced by a rough mirror surface may result in a significant variation of the spectral position of the plasmonic resonances. Meanwhile, the scattering of electrons by surface roughness and numerous grain boundaries can cause a significant optical loss and resonance broadening. Therefore, it is highly required to investigate how the mirror quality affects the optical response of NPoM nanocavities. Here we systematically investigate the effect of mirror quality on the optical properties of plasmonic NPoM nanocavities including nanosphere-on-mirror (NSoM) and nanocube-on-mirror (NCoM) nanocavities[4].

Polycrystalline sputtered gold films (SGFs), template-stripped gold films (TSGFs) and single-crystalline gold microflakes (GMFs) were employed as the mirrors. Firstly, the structural and dielectric properties of the three kinds of gold films were investigated. Their surface quality and crystal structure were characterized. Besides, their dielectric functions were measured and compared for subsequent simulation verification. Then, the scattering intensities, quality factors, peak wavelengths of the plasmonic modes of NSoM and NCoM nanocavities formed on these mirrors were compared and analyzed. Due to the greatly improved surface roughness that can minimize the fluctuation in the gap morphology, the scattering spectra of NSoM and NCoM nanocavities formed on smooth TSGFs and GMFs have a better cavity-to-cavity homogeneity than those formed on rough SGFs. Furthermore, there is an obvious difference in the average peak wavelengths of resonance modes

of NSoM and NCoM nanocavities formed on different gold films, which can be attributed to the difference in their dielectric functions and surface qualities. And this is well reproduced by theoretical calculations based on the measured dielectric functions of the gold films. Moreover, due to the improvement in the surface smoothness and crystalline quality from SGF to TSGF and GMF, there is an increase in the quality factors and scattering intensities of the resonance modes for nanocavities formed on the corresponding films due to the reduced loss. This research deepens the understanding of the nanocavity properties and provides a guideline for the realization of high-performance nanocavities for practical applications.

In conclusion, we have demonstrated both experimentally and theoretically that the mirror quality has a significant effect on the optical property of NPoM nanocavities. Surface roughness of the metal mirrors can introduce significant change in the gap morphology, resulting in a poor cavity-to-cavity homogeneity of the optical response as well as a shift in the peak wavelength of resonance mode compared with nanocavities formed on smooth mirror. Overall, single-crystalline GMFs provide a fascinating platform for the construction of high-quality (low-loss and high cavity-to-cavity homogeneity) NPoM nanocavities, especially when the mirror thickness is further decreased, compared with deteriorated film quality for SGFs and TSGFs. However, for the construction of large-scale nanocavity arrays, TSGFs are recommended due to the limited lateral size (several hundred micrometers) of GMFs.

Abstract: The development of actively tunable plasmonic nanostructures enables real-time and on-demand enhancement of optical signals. This is an essential requirement for a wide range of applications such as sensing and nanophotonic devices. Here we show that by modifying the transition energies of a material via the application of an electric field, the Stark effect offers practical approach to realise nano-scattering sources with high integration potential and a direct method to probe the excitonic properties of semiconducting materials on the nanoscale.

In this work, we report on the use of the Stark effect to control the scattering response of a plasmonic nanogap formed between a silver nanoparticle and an extended silver film separated by a 20 nm thin layer of the organic semiconductor PQT-12. The constructed plasmonic device can be utilised as an electrically tuned multiband nano-scattering source. Both observed plasmonic modes are red-shifted with electric field according to a quadratic Stark shift, providing a promising way for achieving electrically tuned plasmonic devices for active nanopixels and real-time sensing applications. In addition, our approach allows one to experimentally determine the polarizability of the semiconductor material embedded in the nanogap region, offering a new approach to interrogate the excitonic properties of semiconductor materials at the nanoscale.

Microscopic Theory of Tip-Enhanced Nonlinear Raman Scattering with Self-Consistent Nonlocal Response

H. Ikagawa[1*], M. Tamura[1,2], T. Yokoyama[1] and H. Ishihara[1]

[1]Department of Materials Engineering Science, Osaka University, Japan
[2]Research Institute for Light-induced Acceleration System, Osaka Metropolitan University, Japan

Abstract: We constructed a microscopic theory of tip-enhanced coherent anti-Stokes Raman scattering (TE-CARS) which utilizes a metallic probe tip to enhance the CARS. To describe the optical response in a mesoscopic system including a metal and sample, we self-consistently solved the Maxwell's equations and a nonlocal constitutive equation for the polarization of sample. Based on this theory, we discuss the enhancement effect and spatial resolution in the TE-CARS.

Tip-enhanced Raman Spectroscopy (TERS), a technique combined Raman spectroscopy and scanning near-field optical microscope (SNOM), has been attracting much attention due to nanoscale vibrational nanoimaging[1]. The TERS utilizes a sharp metallic probe tip to enhance and confine a near-field at the tip apex by a localized surface plasmon (LSP) on the tip. These effects allow the TERS to achieve optical sensing with high spatial resolution beyond the diffraction limit of light.

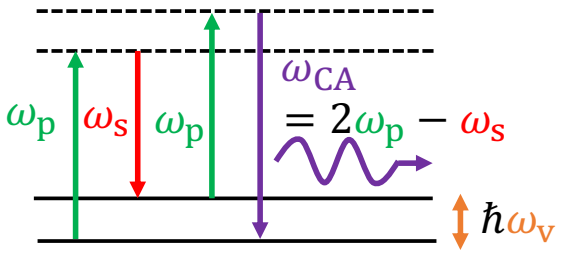

Fig. 1. Energy diagram of CARS process.

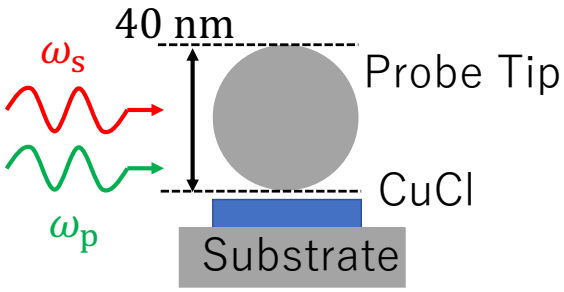

Fig. 2. Calculation model.

Furthermore, the TERS based on the nonlinear Raman scattering has been studied. Ichimura, et al., realized the tip-enhanced microscopy with the coherent anti-Stokes Raman scattering (CARS), namely, tip-enhanced CARS (TE-CARS)[2]. The CARS is a third-order nonlinear Raman scattering caused by the two incident light sources, a pump light with the frequency ω_1 and Stokes light with the frequency ω_2 $(\omega_1 > \omega_2)$, which emits the anti-Stokes light with the frequency ω_{CA} (Fig. 1). There has been an expectation that the CARS nonlinearity could contribute to improving the spatial resolution and intensity of the signal in TE-CARS. However, the detailed discussion about the nonlinear interaction in the TE-CARS has been insufficient. Therefore, we have constructed a theoretical framework to evaluate the TE-CARS, and studied the contribution of nonlinearity for the spatial resolution and intensity of the signal.

In a mesoscopic system such as the TE-CARS, the optical response reflects spatial distribution of wave functions of elementary excitations in the sample. In other words, in a sample, the polarization $\boldsymbol{P}(\boldsymbol{r},\omega)$ at a position $\boldsymbol{r}$ can be induced by the electric field $\boldsymbol{E}(\boldsymbol{r}',\omega)$ at a different position $\boldsymbol{r}' \neq \boldsymbol{r}$ nonlocally. Thus, the linear and third-order nonlinear polarizations are described as,

$$\boldsymbol{P}^{(1)}(\boldsymbol{r},\omega) = \int d\boldsymbol{r}' \boldsymbol{\chi}^{(1)}(\boldsymbol{r},\boldsymbol{r}',\omega)\boldsymbol{E}(\boldsymbol{r}',\omega), \quad (1)$$

and

$$\boldsymbol{P}^{(3)}(\boldsymbol{r},\omega) = \iiint d\boldsymbol{r}'d\boldsymbol{r}''d\boldsymbol{r}'''\boldsymbol{\chi}^{(3)}(\boldsymbol{r},\boldsymbol{r}',\boldsymbol{r}'',\boldsymbol{r}''',\omega',\omega'',\omega''')\boldsymbol{E}(\boldsymbol{r}',\omega')\boldsymbol{E}(\boldsymbol{r}'',\omega'')\boldsymbol{E}(\boldsymbol{r}''',\omega''') \quad (2)$$

respectively. $\boldsymbol{\chi}^{(1)}(\boldsymbol{r},\boldsymbol{r}',\omega)$ and $\boldsymbol{\chi}^{(3)}(\boldsymbol{r},\boldsymbol{r}',\boldsymbol{r}'',\boldsymbol{r}''',\omega',\omega'',\omega''')$ are linear and third-order nonlinear susceptibility, respectively. These susceptibilities include the information of the wave function as the nonlocality. To derive these polarization and susceptibility, we assumed the following Hamiltonian,

$$\hat{H} = \hat{H}_{\mathrm{v}} + \hat{H}_{\mathrm{ex}} + \hat{H}_{\mathrm{ex-r}} + \hat{H}_{\mathrm{ex-v}}, \quad (3)$$

$$\hat{H}_{\mathrm{v}} = \hbar\omega_{\mathrm{v}}\hat{a}^{\dagger}\hat{a},\ \ \hat{H}_{\mathrm{ex}} = \hbar\omega_{\mathrm{ex}}\hat{b}^{\dagger}\hat{b},\ \ \hat{H}_{\mathrm{ex-r}} = -\int d\boldsymbol{r}\hat{\boldsymbol{P}}(\boldsymbol{r})\cdot\boldsymbol{E}(\boldsymbol{r}),\ \ \hat{H}_{\mathrm{ex-v}} = F\hat{b}^{\dagger}\hat{b} + \mathrm{H.C.}, \quad (4)$$

where $\hat{H}_{\mathrm{v}}, \hat{H}_{\mathrm{ex}}, \hat{H}_{\mathrm{ex-r}}, \hat{H}_{\mathrm{ex-v}}$ are the Hamiltonian of the system of excitons, the system of phonons, polarization-electric field interaction, and exciton-phonon interaction, respectively. The operator $\hat{a}\ (\hat{a}^{\dagger})$ and $\hat{b}\ (\hat{b}^{\dagger})$ are the annihilation (creation) operator of phonons and excitons, respectively. The expression of polarization can be derived as an expectation value of the excitonic polarization operator $\hat{\boldsymbol{P}}(\boldsymbol{r})$ with the quantum master equation.

On the other hand, the electric field can be described as,

$$\boldsymbol{E}(\boldsymbol{r},\omega_j) = \boldsymbol{E}_{\mathrm{inc}}(\boldsymbol{r},\omega_j) + \int d\boldsymbol{r}'\boldsymbol{G}(\boldsymbol{r},\boldsymbol{r}',\omega_j)\{\boldsymbol{P}^{(1)}(\boldsymbol{r}',\omega_j) + \boldsymbol{P}_{\mathrm{bg}}(\boldsymbol{r}',\omega_j) + \boldsymbol{P}_{\mathrm{metal}}(\boldsymbol{r}',\omega_j)\}, \quad (5)$$

where $\omega_j = \omega_1, \omega_2, \omega_{\mathrm{CA}}$, $\boldsymbol{E}_{\mathrm{inc}}(\boldsymbol{r},\omega_j)$ is incident field, $\boldsymbol{G}(\boldsymbol{r},\boldsymbol{r}',\omega_j)$ is a Green's function of Maxwell's equation, $\boldsymbol{P}_{\mathrm{bg}}(\boldsymbol{r},\omega_j)$ is a background polarization of the sample, and $\boldsymbol{P}_{\mathrm{metal}}(\boldsymbol{r},\omega_j)$ is a polarization of the metal. We self-consistently solved the induced polarization and electric field at each frequency, while the equations at CARS frequency are solved with regarding the scattering field from the nonlinear polarization as the incident field, $\boldsymbol{E}_{\mathrm{inc}}(\boldsymbol{r},\omega_{\mathrm{CA}}) = \int d\boldsymbol{r}'\boldsymbol{G}(\boldsymbol{r},\boldsymbol{r}',\omega_{\mathrm{CA}})\boldsymbol{P}^{(3)}(\boldsymbol{r}',\omega_{\mathrm{CA}})$.

To evaluate the CARS spectra, we assumed the calculation model shown in Fig. 2, where the sample was located between the metal substrate and probe tip, and they were irradiated by the two light sources with the frequency of ω_1 and ω_2. We assumed that the sample was a CuCl rectangular nanoparticle and the material of metal structure was aluminum. For the elementary excitations in the CuCl, we assumed the presence of LO phonons and Z_3 excitons with the eigenenergy 3.2022 eV and 23.1 meV, respectively. Fig. 3 shows the calculated CARS power as TE-CARS signal. There was a peak of LO phonon near 190 cm^{-1}. In addition, the probe tip enhances the CARS power with an enhancement factor (EF) of nearly 10^5. Such a high EF results from the nonlinearity of the optical response. Furthermore, the scanned signal of the nanostructure can be obtained by displacing the probe tip, where the spatial resolution of TE-CARS was estimated about 4 nm also attributed to the nonlinearity. The obtained results show the advantage of TE-CARS by the nonlinearity.

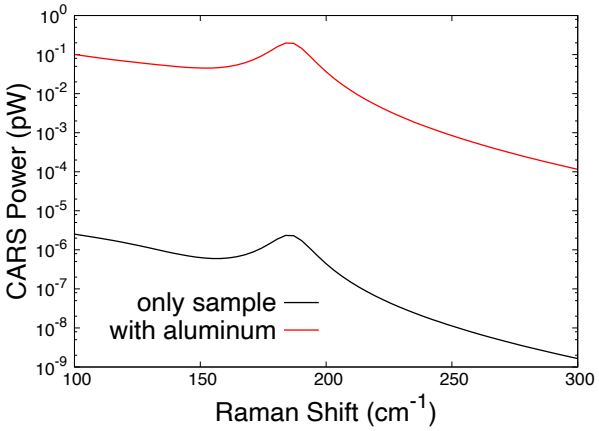

Fig. 3. CARS spectra. Black and red lines are spectrum from the CuCl nanoparticle without and with aluminum, respectively. The value of Raman shift $\omega_1 - \omega_2$ is converted into the wavenumber.

In this work we report a novel approach to resonant surface enhanced infrared absorption (SEIRA) sensing employing Cd(Zn)O nanoparticles. We provide experimental demonstration of the coupling between the localized surface plasmons supported by the nanoparticles and the narrowband absorption of PMMA resist. Our system becomes an excellent alternative to the lossy metals commonly used in the mid infrared (mid-IR) and prevents the need for complex lithographic processes for SEIRA sensing.

Resonant SEIRA allows the resonant coupling of a broadband plasmonic mode supported by a metallic micro or nanostructure and the narrowband absorption minimum of the analyte to detect. With this method, enhancements up to a factor 7 in the signal of the analyte have been reported [1]. However, most reports rely on noble metals that suffer from high losses in the mid-IR range [2], and complex lithography is required to place the plasmonic resonances at the desired wavelengths. In this study, we report a novel approach for resonant SEIRA sensing, completely free of lithography. We employ self-assembled nanoparticles (NPs) made of $Cd_{1-x}Zn_xO$ –a material characterized by its low losses in the mid-IR [3]— deposited on GaAs. The deposition on a high-refractive index substrate allows plasmonic resonances at frequencies well below the plasma frequency of the $Cd_{1-x}Zn_xO$ [3].

Resonant coupling between the localized surface plasmons (LSPs) supported by the NPs and the sharp absorption minimum presented by PMMA resist at 1730 cm^{-1} is demonstrated. This minimum corresponds to the vibrational mode of the double C=O bond of the PMMA molecule. This is a good example of one of the bonds that absorb in the so-called functional group region of the mid-IR [4], where most of the carbon-based molecules from organic chemistry have their resonances. By controlling the plasma frequency of the $Cd_{1-x}Zn_xO$ via doping or Zn alloying, we expect to target other frequencies within this region.

The samples were grown by metal organic chemical vapor deposition (MOCVD) at 300 ºC on a semi-insulating GaAs substrate. The nominal Zn percentage was set to 10% following Tamayo-Arriola *et al.* [5]. Figure 1 shows a SEM view of the surface, where a homogeneous distribution of multiple-sized, isolated NPs is shown. The plasmonic response of the samples was characterized by its transmission spectrum, obtained by Fourier transform infrared (FTIR) spectroscopy at an angle of incidence of 45º.

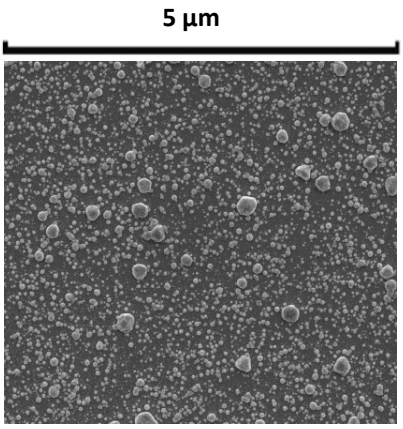

Figure 1. SEM micrography of the $Cd_{0.9}Zn_{0.1}O$ NPs on a semi-insulating GaAs substrate.

Due to the high refractive index of the substrate (n=3.3), a broad LSP resonance is found at around 1750 cm^{-1}, well below the plasma frequency of $Cd_{0.9}Zn_{0.1}O$ (~ 4000 cm^{-1}). This energy matches that of the C=O absorption in the PMMA. Figure 2 presents the transmission spectrum of a $Cd_{0.9}Zn_{0.1}O$/GaAs sample before and after the deposition of a thin layer of highly diluted PMMA. Here, the PMMA absorption band appears as a sharp, well-defined maximum in the middle of the broadband LSP. This paradoxical behavior where an absorptive mode appears as a non-symmetrical maximum is typical of this type of resonant coupling, as first described by Fano and shown in most successful SEIRA experiments [5]. Other absorptive modes of PMMA can be observed at energies below 1730 cm^{-1}, and are weakly coupled to the LSP.

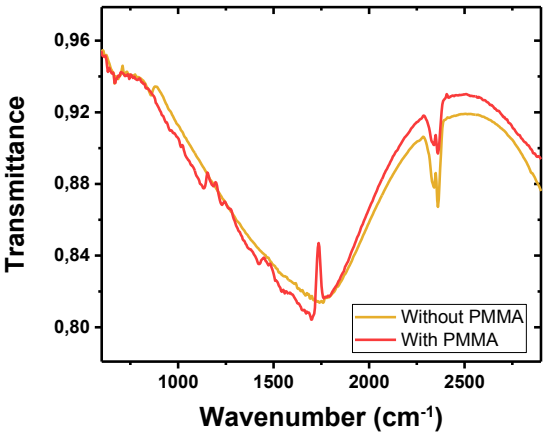

Figure 2. Transmittance spectra of the $Cd_{0.9}Zn_{0.1}O$ NPs on GaAs, with and without a layer of PMMA on top.

With these results, we have proven the resonant coupling between the LSP supported by self-assembled, lithography-free $Cd_{0.9}Zn_{0.1}O$ NPs grown on GaAs and the narrow band absorption mode presented by PMMA resist at 1730 cm^{-1}. Further optimization of NP density and size are necessary to maximize the resonant signal shown here. This approach is not restricted to Cd(Zn)O as we expect other transparent conductive oxides grown in a similar pattern to produce similar results. Different approaches to tune the SEIRA frequency across the mid-IR using Cd(Zn)O will also be addressed.

Synergetic hot carrier generation due to coherent couplings of plasmon-carrier excitations and plasmon hybridization in a metallic nano-chain array

S. Inoue [1*], T. Yokoyama [1] and H. Ishihara [1,2]

[1] Graduate School of Engineering Science, Osaka Univ., Japan

Abstract: Hot carrier generation is one of the most significant issues in plasmonics and energy conversion of light. In this study, we discuss a novel mechanism of coherent energy transfer between the plasmon and carrier excitations mediated by radiative and cavity fields. In the case of metallic nano array, such coherent effects can be enhanced. We elucidated that plasmon-carrier excitations' coherence and plasmon hybridization in the array cause a synergetic effect and it could enhance the energy conversion efficiency.

Localized surface plasmon resonance (LSPR) is a key ingredient for a light-induced phenomena on nanoscale metals. A hot carrier generation is one of the most attractive phenomena by the LSPR. The hot carrier is a nonequilibrium electron distribution, where the electrons have exceeded energy more than that of thermal distribution. Then, the hot carrier can be injected to an attached semiconductor and several applications have been proposed, e.g., photovoltaics [1] and photosynthesis [2]. The LSPR induces a strong electric field near the surface of metallic nanostructures. In the array of such metallic nanostructures, the enhanced electric field causes an interaction between the plasmon excitation on the nanoscale metals and results in a hybridization of the plasmons [3]. This plasmon hybridization could enhance the hot carrier generation efficiency. Recently, X. Shi, et al., have studied an enhancement of the hot carrier generation by the design of spatial structure of electromagnetic field based on cavity structures [4].

A mechanism of the hot carrier generation has been discussed based on several relaxation and damping process theoretically [5], where the photon energy of incident light is transferred unidirectionally to the hot carrier via the LSPR. In our previous study, we have considered the radiative field induced by the plasmon excitation in a single nanostructure and discussed a coherent coupling between a collective (plasmon) excitation and individual (electron-hole pair) excitations owing to the radiative field [6], where bidirectional energy transfers could be obtained by the coherent couplings.

In this work, by imitating [4], we consider light-plasmon interactions, plasmon-plasmon interactions and novel coherent interactions between plasmon and carrier excitations like Fig. 1. We applied this minimal model to a metallic nano-chain array and investigate the relation between plasmon-carrier excitations' coherence and hot carrier generation. As a result, if we consider coherent couplings between plasmon and electron-hole pairs, a sharp behavior happens in absorption spectra at the electron-hole pair's excitation energy position (Fig. 2). In addition, looking at hot carrier generation efficiency spectra toward absorbed photon number, if plasmon-carrier excitations' coherence is absent, no features appear in spectral shapes due to only thinking incoherent carrier generation process (Fig. 3). However, thinking the coherence, we indicate that resonant peak appears and this peak increases as plasmon-plasmon interactions become bigger (Fig. 4). It indicates that plasmon-carrier excitations' coherence induces a resonant energy transfer from plasmon to electron-hole pairs, that lead to enhance the efficiency of photoelectric conversion. Moreover, hybridization of plasmon excitations as with [3] interplay with this novel

coherent coupling and it is expected that an Fano resonant-type energy transfer will occurs as the synergetic effect. This result shows the possibility to realize more efficient carrier devices only by controlling the arrangements of nano-metal structures.

Abstract: we investigate the optical properties of single self-assembled hybrid gold-CdSe/CdS/CdZnS colloidal nanocrystal supraparticles. First, spectrally time resolved photoluminescence experiments show that they exhibit Förster resonance energy transfer (FRET) that is inhibited by the gold nanoshell, in agreement with the results of numerical simulations. Next, the analysis of the intensity autocorrelation function $g^{(2)}(\tau)$ reveals that FRET combined to non radiative Auger recombination can result in photon antibunching. Bunching at short time scale related to coherent collective emission is finally reported.

Despite continuous improvements, colloidal semiconductor nanocrystals (NCs) still exhibit limitations such as residual blinking or photobleaching. The progress in chemical synthesis offers new possibilities like the realization of close-packed self assemblies of nanoemitters as well as hybrid structures consisting in colloidal fluorophores encapsulated in plasmonic resonators. Beyond the standard increase of the decay rate by Purcell effect, this new class of emitters exhibit specific optical properties due to collective emission or related to the mesoscopic number of emitters.

In this presentation, we first report the synthesis of supraparticles (SPs) consisting in compact ensembles of CdSe/CdS/CdZnS colloidal nanocrystal (NCs) with a mean diameter about 8 nm and emitting at 645 nm (FWHM = 30 nm) [1]. Briefly, the NCs are aggregated by a micro-emulsion/evaporation method before encapsulation into a silica shell (thickness = 15 nm). After its functionalization by reaction with aminosilane precursors, a gold shell (thickness = 19 nm) is then synthesized following [2]. The overall diameter of the resulting golden supraparticles (GSPs) ranges between 100 nm and 500 nm.

The optical properties of the GSPs are studied at the single particle level by spin coating few tens of µL of the solution on a glass coverslip. The optical measurements are performed between 4 K and 300 K with a confocal microscope under optical pulsed excitation. The emission is detected with a standard Hanbury Brown and Twiss setup based on two avalanche photodiodes (APDs), a standard spectrometer or an interferometer associated with an APD. The latter enables to carry out spectrally and time resolved experiments to establish a fluorescence map as a function of the wavelength and photon time emission.

As a first step, the Purcell effect as a function of the GSP diameter is measured by fitting the PL decay of several single GSPs. The variations of the decay rate with the GSP diameter (the PL decay rate is twice higher for the smallest GSPs with respect to the biggest ones) is well fitted by a multilayer spherical model based on Mie theory [3].

Interestingly, we next show that the Purcell enhancement results in the decrease of the non-radiative FRET which is commonly observed in NC aggregates (when optically excited, the smallest diameter NCs tend to

transfer non-radiatively and incoherently their energy to bigger diameter NCs) [3]. Whereas, due to FRET, the PL decay rate is highly dependent on the detection wavelength for SPs without a gold nanoshell, the difference is much less significant for the GSPs. For the smallest ones, we measured a reduction by a factor 3 of the FRET efficiency. Simultaneously, we show a reduction of the broadening of the overall emission spectrum induced by FRET [4].

The number of emitters involved in the GSP emission could also be deduced from a detailed analysis of the specific shape of the emission spectra [5]. By using a simple analytical model and numerical simulations, we demonstrate that the autocorrelation function of the emission provides simultaneously the number of bright emitters and their mean linewidth. This general method when applied specifically to single GSPs also provides the fraction of photobleached emitters by comparison with the geometric parameters of the structure.

The last part of the presentation is devoted to the opportunities opened by the inhibition of incoherent FRET processes in terms of collective emission of the NCs. By using the function $g^{(2)}(\tau)$ and its analysis with a method first used in [6], we first show that despite the mesoscopic number of emitters, antibunching, which is well modelled by a Monte Carlo simulation taking into account residual FRET and Auger processes, can be evidenced. More interestingly, we finally show that bunching at sub-ns time scale is observed for several GSPs. It corresponds to a coherent emission involving a large ensemble of NCs [7].

In conclusion, GSPs are very promising hybrid gold-NC supraparticles. Beyond their brightness and photostability, these mesoscopic systems exhibit specific emission regimes and enable to explore collective emission with colloidal structures.

Investigation of Terahertz SSPP Waveguides Using TRL Calibration

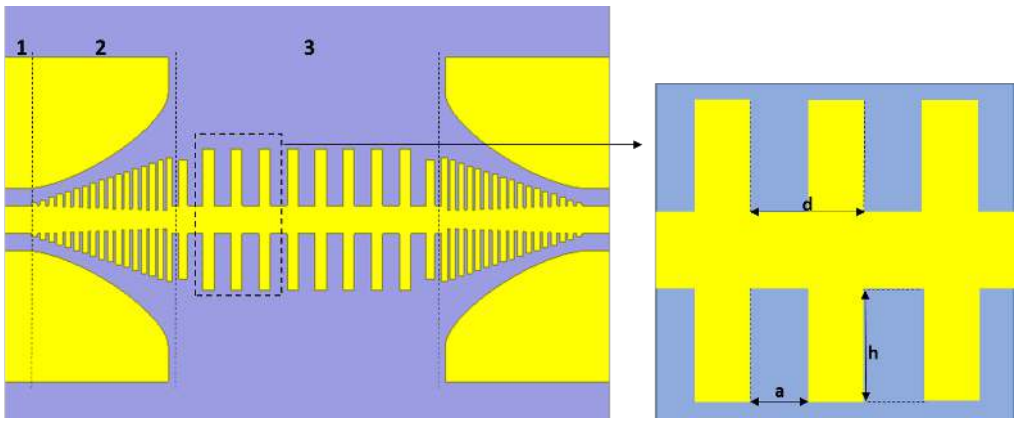
Y. Colak[1], M. Demircioglu[1], and M. Unlu[1]

[1]TOBB University of Economics and Technology, Turkey

Abstract: Spoof surface plasmon polaritons waveguides (SSPP WGs) have shown record-breaking performances at the terahertz frequencies to enable CMOS technologies. In this paper, we present the TRL calibration of the SSPP WGs between the 0.22 THz and 0.3 THz. We utilize the TRL calibration to extract the real loss behavior of the SSPP WGs. By designing two different length lines, we prove that the TRL calibration of SSPP WGs is internally consistent.

Surface Plasmon Polaritons (SPP), which is a commonly used concept in optical frequencies, does not exist in Microwave and Terahertz bands due to metals behave like perfect conductors instead of negatively permittivity plasmas [1]. As a solution to this, the spoof surface plasmon polariton waveguides (SSPP WGs) are presented, which is corrugated structures, and planned to be used in many areas such as near future CMOS technologies [2]. On the other hand, the real loss behavior of the SSPP WGs is not characterized due to the need of the CPW-to-SSPP WG transition circuit [3]. Moreover, TRL calibration, which takes its name from the initials of the Through-Reflect-Line standards, is a type of calibration that supports two-port connections [4]. In this paper, we present the TRL calibration of the terahertz Spoof Surface Plasmon Polariton Waveguides (THz-SSPP WGs) that operate at 0.22 THz to 0.3 THz frequencies. In order to remove systematic errors, especially the errors of the transition circuit, the TRL calibration technique is used to setup the reference plane at the device under test (DUT).

The SSPP WG structure, which consists of two-sided corrugated structures, is given in Figure 1. The entire structure consists of Coplanar Waveguide, Transition and SSPP Structure. The transition circuit is necessary for the mode conversion between the CPW and SSPP WGs. The transition circuit proposed in *Unutmaz et.al*. [5] which is named as Transition-6 is utilized in all the designs in this paper, namely thru, reflect, line calibration kits and DUTs.



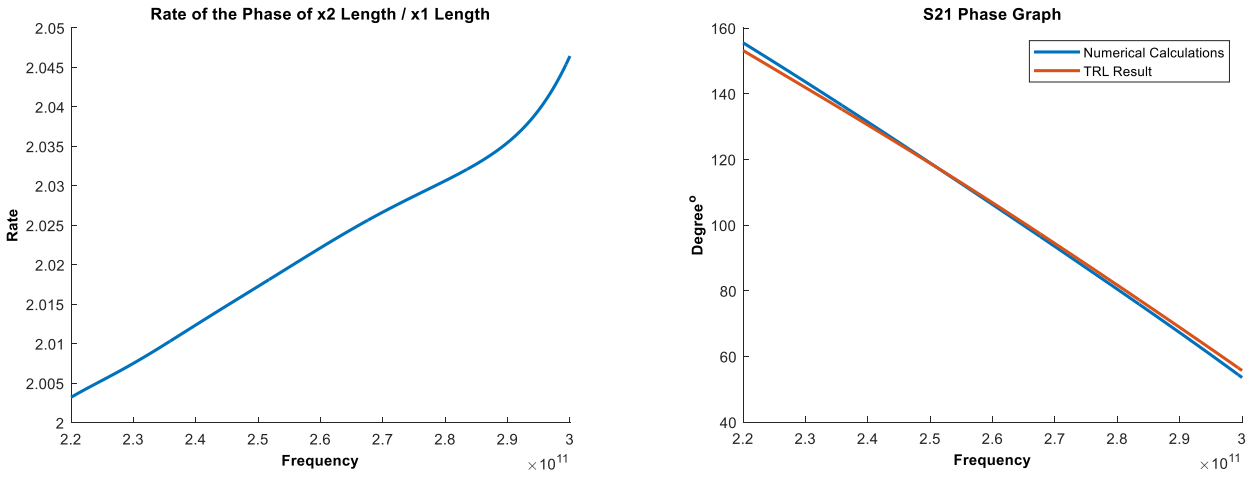


Figure 1. The schematics of SSPP WGs from top side (1) Coplanar waveguide section (2) Transition section (3) SSPP section

The ANSYS HFSS program is used for all the simulations. In simulations, Si substrate is used with ε_r=11.62

and ρ_{Si}=10 kΩ-cm and the Au metal is taken as σ_{Au}=28 MS/m. Two different DUT designs are designed with the same parameter values, the aperture (a) of 15 µm, the periodicity (d) of 25 µm, and the corrugation depth (h) of 50 µm, but in different periods. Applying the TRL calibration for the SSPP WGs, the real loss behavior of the DUTs is acquired. The phase difference between the 8 period and 16 period DUTs is presented in figure 2 (a), two times phase difference, which is theoretically expected, is obtained between both DUTs. Furthermore, by extracting the back-to-back transition from the whole SSPP WGs, numerical insertion phase is calculated and given in figure.2 (a). The insertion phase values of the TRL results and numerical calculations prove that the TRL calibration of the SSPP WGs is successful.

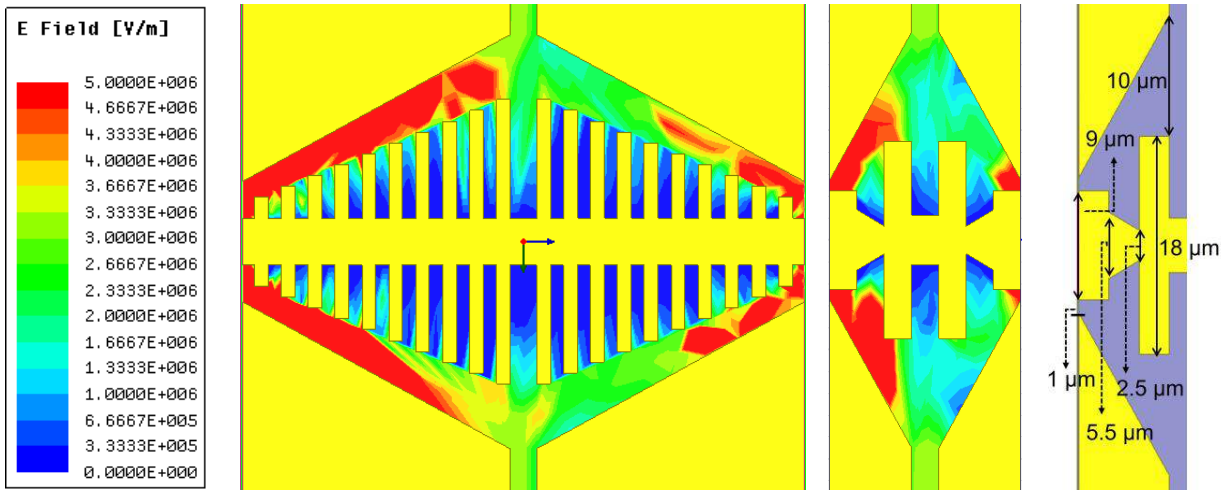
Abstract: In this paper, we present the design and simulation results of the Terahertz Subwavelength Confinement Waveguides (TSCW) operating at 1 THz. The design of the TSCWs includes CPW-to-TSCW transition circuits and the Spoof Surface Plasmon Polariton (SSPP)-based waveguides. The best-case simulation results exhibit return loss and insertion loss of -13.86 dB and -1.72 dB for the back-to-back (b-to-b) transition circuit and -26.5 dB and -4.66 dB for the TSCW with a total length of 267 µm at 1 THz, respectively.

The terahertz frequency range, which is between the microwave and infrared frequency bands, has unique abilities for applications such as imaging, sensing and communication [1]. Compact, on-chip and high-performance terahertz components are required in order to utilize the terahertz frequencies efficiently, one of the required terahertz components is the terahertz waveguides [2]. The Terahertz Subwavelength Confinement Waveguides (TSCW) are among the leading design methods to attain compact and high-performance waveguides [3]. Nevertheless, they are generally investigated at the sub-terahertz frequencies [3]-[5]. In this paper, we present the design steps of the CPW-to-TSCW transition and TSCW with optimum performance at 1 THz.

All the designed structures are simulated in ANSYS HFSS program. The metal is considered as Au with a conductivity of 28 MS/m and the Si substrate is taken with bulk resistivity of 10 kΩ/cm and relative permittivity of ε_r=11.62.



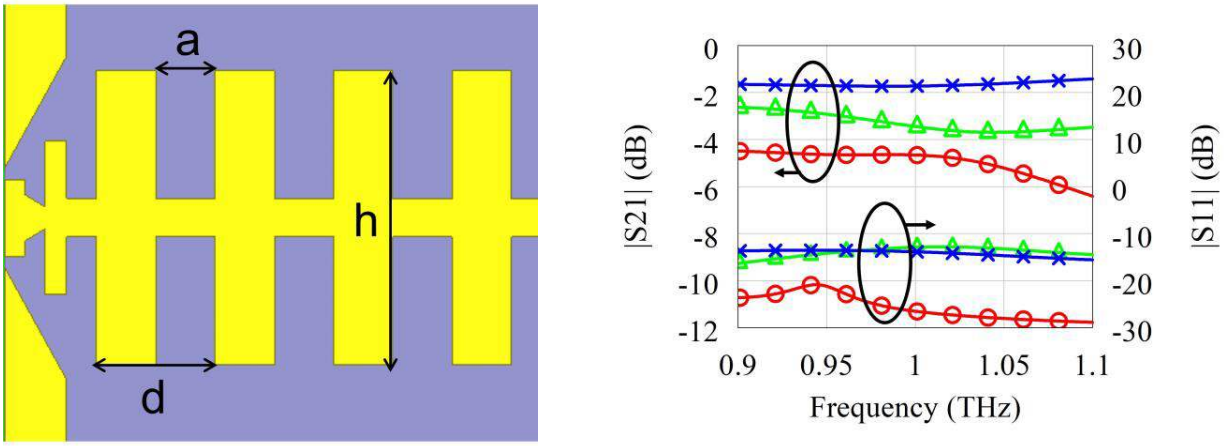


Figure 1. The electrical field distribution scale (a), electrical field distribution of TC-1 (b), electrical field distribution of TC-2 (c) and the physical lengths of TC-2 (d)

The first transition circuit (TC-1) is designed with adapting the transition circuits given in *Unutmaz. et.al.* to 1 THz [5]. The second transition circuit (TC-2) is designed from the TC-1 as analyzing the electrical field distribution and S-parameters of the simulation results. The electrical field distribution scale, electrical field

distribution of the CPW-to-TSCW transition circuits and the physical dimensions of the TC-2 are given in Figure 1. In addition to the electrical field distributions, the S-parameter results of the TC-1 and TC-2 is presented in Figure 2 and insertion losses of -3.44 dB and -1.72 dB at 1 THz, respectively. These results exhibit the advantage of TC-2 over TC-1.

(a) (b)

Figure 2. The schematic of the TSCW (a) and the S-parameter results (b) of the TC-1 (Δ), TC-2 (x) and TSCW (○)

With the TC-2, 267 µm length TSCW having a periodicity (d) of 14 µm, aperture width (a) of 7 µm and corrugation depth (h) of 15 µm is simulated. The simulation results of the TSCW are presented in Figure 2, the results show the return losses are lower than -20 dB between 0.9 THz and 1.1 THz and the insertion loss is -4.66 dB at 1 THz.

Abstract: Understanding electrocatalytic processes is crucial to realize the transition toward a sustainable zero-carbon future. Surface-enhanced infrared absorption spectroscopy (SEIRAS) is a suitable method to monitor the mechanisms of these processes with chemical specificity. However, it remains difficult to detect many relevant aspects of electrochemical reactions such as short-lived intermediates. Here, we demonstrate an integrated nanophotonic-electrochemical SEIRAS platform for the *in-situ* investigation of molecular signal traces emerging during electrochemical experiments.

Working in an attenuated total internal reflection (ATR) geometry (Figure 1a), we detect *in-situ* the CO vibrational mode at 2033 cm^{-1} emerging during the electrochemical conversion of CO into CO_2 using a platinum nano-slot metasurface on a CaF_2 substrate (Figure 1b) by coupling its resonance to the molecular vibrational mode and analysing the perturbation of the intensity in reflection[1]. Pt is a catalytic material for many reactions, making this platform very useful not only for the CO oxidation reaction but also for other reactions. Nano-slots can be tuned to enhance the electric and magnetic near-fields (Figure 1c) due to the excitation of a magnetic dipole aligned parallel to the long axis of the slot.[2] We confirm the detection of adsorbed CO (Figure 1d-f) *via* the observation of the typical Stark shift and resolve a so far scarcely studied[3] effect due to the decrease of the CO coverage on the surface of platinum during the electrochemical oxidation (Figure 1e-f). Furthermore, the presence of a second peak at 2086 cm^{-1} on the spectral location of the linear vibrational mode could be attributed to the effect of the crystal orientation.

Compared to conventional unstructured platinum films, our nanophotonic-electrochemical platform delivers a 27-fold improvement of the experimentally detected characteristic absorption signals, enabling the detection of new species with weak signals, fast conversions, or low surface concentrations. By providing a deeper understanding of catalytic reactions, we anticipate our nanophotonic-electrochemical platform to open exciting perspectives for electrochemical SEIRAS, surface-enhanced Raman spectroscopy, and other fields of chemistry.

We thank Thomas Weber for his help with the temporal-coupled mode theory algorithms and Simon Stork for the platinum and titanium electron beam evaporation. Abstract: The desire to control the interaction between surface plasmons and quantum systems as cells, molecules, polymeric macromolecules has boosted the progress in theoretical and experimental techniques for the effective manipulation of such objects. The work here presented is somehow at the frontier between quantum chemistry and nanophotonics, providing, within the TD-DFT framework, a deeply understanding of the coupling mechanisms between the azobenzene photoswitch and a prototype plasmonic nanocluster, showing the effects of the localized plasmon on strong-coupling and charge-transfer phenomena.

Fabrication and characterization techniques are nowadays able to finely control light-matter interaction at sub-nanometer scales where classical electrodynamics fails. New theoretical frameworks able to overcome the limits of the classical vision and to fully take into account quantum mechanical effects (i.e. nonlocality, electron spill-out, charge transfer) are, thus, required. By means of a fully atomistic TDDFT approach, in this work we show how the potential energy surfaces for a photochemical system of practical interest as azobenzene, can be importantly modified by both classical electromagnetic and charge transfer effects in the presence of a metal nanostructure. Inspired by the pioneering work in 2012 by Ebbesen's group [1], polaritonic chemistry, i.e., the field caring of manipulating chemical structure and reactions through the formation of polaritons, hybrid half-light half-matter states, has become the attraction of several experimental and theoretical researches in the last few years. From a theoretical point of view, the problem of the perturbations induced on the potential energy surfaces of a molecule by photonic modes has been largely faced in the framework of Quantum Electrodynamics (QED) [2].
In this work a fully-QM scheme, based on an atomistic description in the linear response framework of the TD-DFT of both the matter and light components, is proposed to analyze a chosen isomerization pathway for an azobenzene molecule interacting with a plasmonic nanocluster put in its proximities (Fig. 1). Azobenzene represents one of the simplest photochromes able to interconvert between trans- and cis- forms. Despite its isomerization process has not yet been fully understood, numerous applications have been developed: in biomedicine, in bioimaging, in photopharmacology, etc. The metallic counterpart is a tetrahedral cluster of Ag_{20}. This choice is due to the fact that this cluster has a simple spectrum dominated by only one narrow excitation in the same spectra range of Azobenzene which can be associated to a localized plasmon [3]. Recent works have shown that the strong coupling between surface plasmon-polariton mode and excitons could lead to the formation of hybrid states, namely polaritons or plexcitons [4]. Here we show the onset of these new states for particular conditions and how these can modify the potential energy landscape of the molecule. Moreover we introduce a

new figure of merit defined *Polaritonic Index* (PI) which allow us to identify all the hybrid excitations and among them to distinguish polaritonic (Fig. 1) from charge-transfer states (Fig. 2).

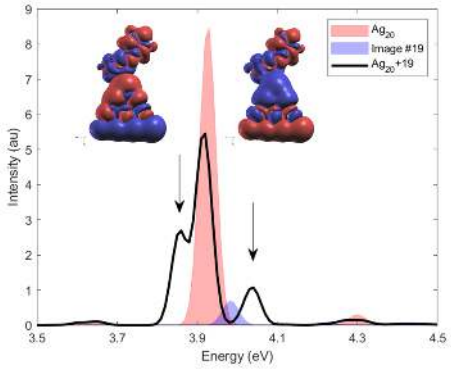

Fig. 1 Comparison between the TD-DFT absorption spectra of the isolated Ag, isomer #19 and the hybrid systems composed of Ag_{20} + isomer #19 (Gaussian broadening of 0.02 eV). Inset: transition densities of the lower and upper polaritonic states.

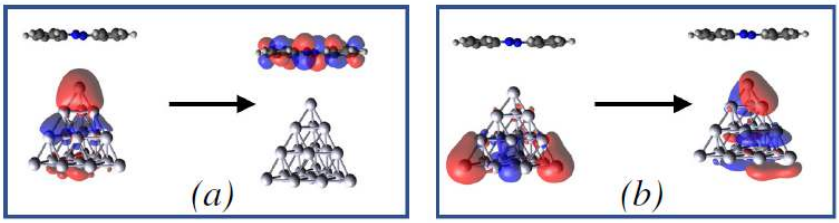

Fig. 2 First two Natural Transition Orbitals pairs for the lowest energy CT state appearing under S2.

While polaritonic states appear only in the barrier region, charge transfer excitations seem to be present along the selected isomerization pathway from trans- to cis- conformation in between S_1 and S_2, this possibly providing additional channels whose relevance is likely dependent on the relative molecule-metal distance and orientation [4]. The work has a double mission. From one side it shows how a theoretical scheme beyond classical EM descriptions is required to properly explain the physics underlying the interaction between metallic and molecular excitations. From the other one, it presents a possible scenario of plasmon-induced perturbations in the photoisomerization of a switch of practical interest, as azobenzene, opening the way to polariton chemistry applications.

Abstract: Plasmon is a collective excitation by the longitudinal electron-electron interaction. The plasmon excitation radiates the transverse field. In this study, we formulate a microscopic self-consistent theory for the nonlocal electronic response and the Maxwell fields. The collective (plasmon) and individual (electron-hole pair) excitations are coupled coherently with each other by the longitudinal and transverse fields in nanostructures. This coherence means a bidirectional energy transfer between their excitations, which would provide an efficient hot carrier generation.

A light-matter interaction is one of the central subjects in physics. Plasmon is a collective excitation of electrons and provides rich applications, e.g., sensor, photovoltaics, photosynthesis, etc. The plasmon excitation is owing to the electron-electron interaction which is a part of longitudinal field. Hence electromagnetic field response due to the plasmon excitation has been discussed based on the Drude model in many studies. However, if material size is nanometer-scale, the nonlocal response due to a quantum coherence of electron wavefunctions should be significant and the phenomenological treatment must be extended. Then, the hydrodynamic Drude model has been developed [1,2], where the spatial gradient of current is incorporated into the Drude conductivity. On the other hand, for the atomic scale cluster, a microscopic description based on the first principle calculation has been developed [3], where the longitudinal component is treated with high accuracy. However, in the electromagnetic field response by the plasmons, the transverse field is induced and can cause the collective (plasmon) and individual (electron-hole pair) excitations. Therefore, for several tens to hundreds nanometer scale, a microscopic description with a self-consistent treatment of electronic response and Maxwell's equation including both the longitudinal and transverse component should be discussed [4,5].

In this study, for nanostructures, we develop the microscopic description with the self-consistent treatment of the nonlocal response and the Maxwell field [5]. In the formulation, the electronic response is described in terms of charge and current densities. The longitudinal and transverse fields are expressed by scalar and vector potentials, respectively. By this formulation, we can develop an understanding for th e collective and individual excitations based on both the longitudinal and transverse components. Our formulation reveals that the transverse field provides a coherent coupling between the

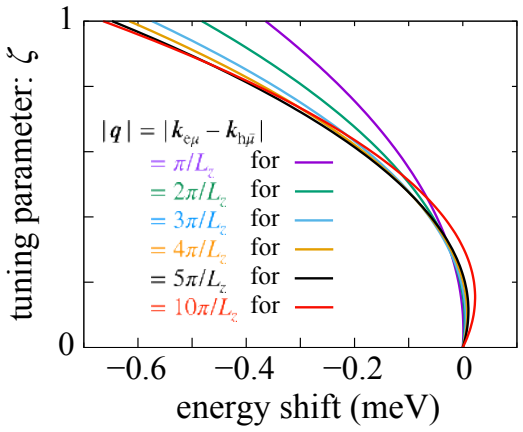

Fig. 1: Energy shift of collective excitation modulated by a tuning parameter ζ.

collective and individual excitations, which means bidirectional energy transfer between them.

Figure 1 shows energy shifts of the collective excitations by the transverse fields with small "wavenumbers" $|\boldsymbol{q}| = |\boldsymbol{k}_e - \boldsymbol{k}_h|$ of excitations in a rectangular nanoscale rod with L_z being the length of rod. Our parameter ζ tunes the contribution of transverse field, and $\zeta = 1$ ($\zeta = 0$) corresponds to full (no) contribution. We obtain finite shifts by the transverse field. As ζ approaches full contribution, the transverse field operates to lower the collective excitation energy. The shifts can be enlarged by a design of nanostructure and electromagnetic fields. Then, this result gives possibility of an enhancement of hot carrier generation due to the plasmon excitation.

Reconfigurable Non-Volatile Silicon Photonics Using Ultralow-Loss Phase-Change Chalcogenide Sb_2Se_3

Sophie Blundell[1,2*], Daniel Lawson[1,2], David J. Thomson[1], Ioannis Zeimpekis[1], and Otto L. Muskens[2]

Abstract: Antimony Selenide (Sb_2Se_3) is explored as an alternative to popular phase-change materials (PCMs), such as Ge-Sb-Te (GST), for modulation of light through silicon photonic devices. Previous investigations of Sb_2Se_3 have been limited by using thin surface films, where only the evanescent field is modulated. By creating waveguide structures where light travels directly through the PCM, greater modulation depths are achieved, resulting in a higher change in effective refractive index. Applications of this work include light routing, photomodulation and photonic computing.

We demonstrate an increased phase shift incurred for light travelling through thicker layers of Sb_2Se_3 using a novel method for increasing the modulation depth of devices. Recently, Sb_2Se_3 has gathered interest because it demonstrates very low losses at 1550nm, and due to its large refractive index contrast ($\Delta n \sim 0.77$ [1]). So far, this has only been explored for thin layers of Sb_2Se_3, which does not take advantage of the excellent matching of refractive indices between silicon and Sb_2Se_3, allowing low losses to be achieved even for large thicknesses. This is vital for creating high enough modulation to enable compact devices. By argon-ion etching into the SOI chip before then depositing the layer of Sb_2Se_3, light is modulated as it travels directly through the PCM, rather than evanescently coupling. A schematic of this method of fabrication is shown in Figure 1.

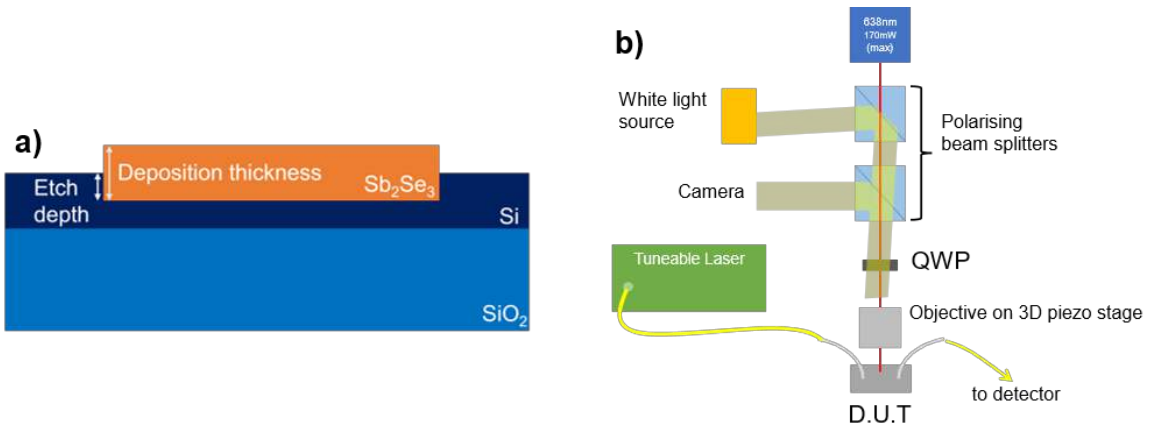

Figure 1: Demonstrating the variation in etch depth and deposition thickness of the different chips, b) diagram of switching set-up used to take data in Figure 2.

A chip was fabricated with 60nm etched out of the original sample and 80nm Sb_2Se_3 deposited into this gap. Measuring the devices on this chip with the PCM in both amorphous and crystalline (hot plate annealed) states showed a change in insertion loss.

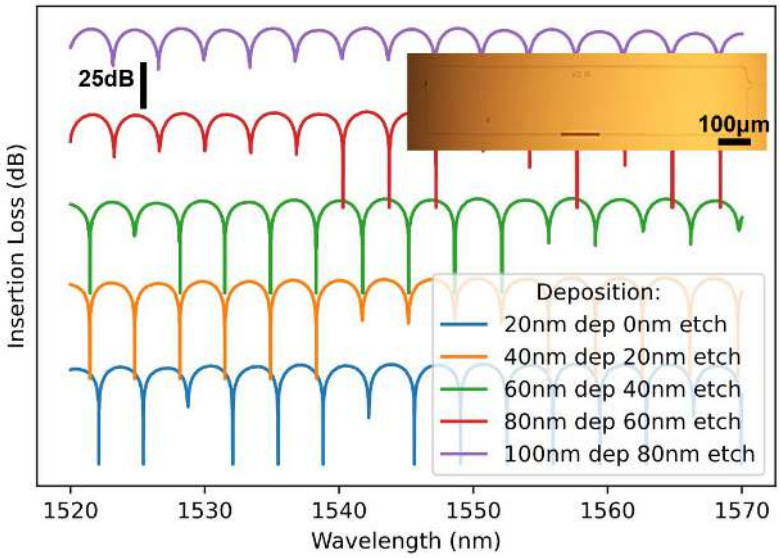

Figure 2: Spectral response of MZIs with 125µm length of Sb_2Se_3 on lower arm, vertically spaced to ease comparison between chips with differing depositions. Scale bar in y-direction of 25dB.

Further chips were fabricated with a range of etch depths and deposition thicknesses. Figure 2 shows the difference in Mach-Zehnder Interferometer (MZI) spectra found by increasing the depth of etch and subsequent deposition, demonstrating that the infiltration of Sb_2Se_3 into the device does not degrade it in the amorphous state.

This work shows the possible benefit of increasing the thickness and depth of Sb_2Se_3 used for photomodulation in SOI chips with multiple different devices. This has applications within neuromorphic computing, as a method for weighting photonic neurons. PCMs are sought after for such uses because they are capable of existing in multiple solid states that have different refractive indices, which can be switched between, thermally, electrically, or optically [2-4]. Integrating PCMs onto waveguide devices enables light travelling through the device to be directionally controlled and as such is a method for storing memories, or weighting neurons [5].

This work is funded by an EPSRC PhD studentship.

High resolution plasmonic-based impedance microspectroscopy

Sidahmed A. Abayzeed

Optics and Photonics Research Group, Faculty of Engineering, University of Nottingham, University Park, Nottingham, NG7 2RD

This talk presents a novel optical imaging technique that is capable of mapping electrical impedance with submicrometric diffraction-limited resolution. The method presented is based on the widely used surface plasmon resonance imaging; an optical microscopy technology with an emerging application in label-free and non-scanning imaging of voltage. High resolution probing of electrical impedance is extremely important. For instance, it provides a way of studying electrical properties of living cells that use electrical signaling to communicate and regulate a range of physiological processes.

Measurements of electrical current and impedance is performed using plasmonic sensors that can be viewed as two-dimensional electrodes with optical readout. They are highly sensitive to external voltage. The principle of the technique is based on surface plasmon resonance that occurs due to optical excitation of electron density waves at the metal dielectric interface. Externally applied voltage alters the density of free electrons in metal surface and therefore changes the resonance position of the sensor. Gold thin film is commonly used to construct the sensing structure where sample under study is deposited or cultured in case of living cells. This metallic thin film is also used as a working electrode in combination with a proximal reference electrode. To perform impedance spectroscopy, a small alternating voltage is applied to the gold surface, against a reference electrode, resulting in a current flow across the electrolyte solution and the sample under the test. The real-time change in resonance position of the sensor is monitored that is directly proportional to the charge modulation. Voltage-modulated surface charge density varies spatially depending on the impedance of the object.

One of the major challenges of impedance imaging is that measurements are distorted by the crosstalk from the optical properties of the sample resulting in an inaccurate impedance mapping. In this talk, a correction method is presented that provides an effective way of separating the effect of optical properties and therefore produces quantitative measurements of dynamic electrical signals. The method is illustrated by mapping the impedance of Bovine Albumin Serum (BSA) patterns deposited on the gold film. BSA patterns were fabricated on the gold surface using micro-contact printing. Impedance microspectroscopy was performed by sweeping voltage between 1 and 100 Hz while computing impedance and current maps for each frequency. Local spectroscopic information was analysed using least square fitting to produce the equivalent electrical network of the sample. Within this frequency range, the surface capacitance has a dominant effect. Contrast in capacitance between the BSA and the gold background is observed. This is expected since the protein deposits have a lower static permittivity compared to the water molecules that constitute the dielectric properties of the double layer capacitor of the gold electrolyte interface. The technique shows a remarkable sensitivity being able to detect current as low as 0.1pA on a 0.5 micrometre scale. These findings demonstrate that this new impedance imaging technique is capable of revealing microscopic electrical properties with promising applications in studying cells and biomolecules.

Abstract: Chirality discrimination plays a critical role in various scientific disciplines such as biology, chemistry, and pharmaceuticals. We propose a novel theoretical concept of collective CD resonances (CRs), which exhibit much stronger optical chiral hotspots over a broad region compared to conventional methods. As a result, we have successfully demonstrated the in situ determination of molecular chirality at the picomole level, with ultra-high sensitivity.

Determining the chirality of molecules is deemed a crucial challenge in several fields, including chemistry, biology, and pharmacology. The conventional method for analyzing molecular chirality, circular dichroism (CD), relies on measuring the difference in absorbance between two circularly polarized lights rotating in opposite directions. However, this method has the drawback of requiring a high-concentration sample and a long measurement time due to the mismatch in size between the molecules (a few Å) and light (a few 100 nm) being measured.

Since 2010, the concept of optical superchirality suggests that exposing molecules to a strong chiral optical environment leads to an enhancement of optical chiral response, and it has been established through both theoretical and experimental methods that the circular dichroism (CD) signals of chiral molecules can be significantly amplified in a chiro-optical environment[1]. Despite this, challenges in sensing at low concentrations have persisted due to the confined nature of conventional chiro-optical systems in local regions. To address this issue, we propose an extension of the traditional sensing theory, referred to as the extended chiral-sensing theory. Additionally, we seek to maximize the interaction between plane wave light and chiral molecules by incorporating the collective vibrations (CR) that occur in two-dimensional helicoid lattices, thereby enhancing the molecular CD signals[2].

Figures: Numerical simulation result of 2D helicoid crystal **a**. Spatial distribution of the $\boldsymbol{h}_{\mathbf{sca}}$ at CR mode under 60° oblique incidence of LCP (left) and RCP (right) light. The $\boldsymbol{h}_{\mathbf{sca}}$ values exhibit the same sign over the entire surface **b**. CD spectra ($\equiv T_{RCP} - T_{LCP}$) for media with $\kappa = 0$ (racemic), $\kappa < 0$ (D-molecules), and $\kappa > 0$ (L-molecules). The asymmetric shift in transmission spectra results in pronounced peak changes in CD spectra.

Abstract: Recently, integrated photonic chips, particularly those with the aid of transformation optics, have simulated various aspects of curved spacetime. However, thus far, studying the influence of curved space on quantum entanglement on this type of platform has not yet occurred. Here, we propose and experimentally realize quantum walks of entangled photons near an emulated event horizon, resulting in a counterintuitive phenomenon of optical escape. Our study paves a tabletop platform for studying quantum entanglement in curved space.

Quantum walks (QWs), the quantum mechanics analog of classical random walks [1], are a powerful tool used in quantum computing and simulation. In contrast to classical random walks, QWs have the distinct advantages of coherent superposition and quantum interference, making them a compelling platform for simulating topological physical phenomena, constructing novel quantum algorithms, and realizing universal quantum computing. Recently, there has been an increasing interest in quantum effects in curved space [2-4] arising from quantum gravity, which is a great challenge field for unifying quantum mechanics and general relativity in modern physics. The salient example is the Hawking-Unruh effect, which has been well-emulated using a variety of quantum architectures. Nevertheless, methods to leverage the advances of QWs on photonic chips to study the quantum aspects of general relativity have rarely been investigated.

At the same time, recent years have witnessed remarkable progress in the highly efficient manipulation of electromagnetic waves on the subwavelength scale using metamaterials, as well as the production of various functional photonic architectures with unprecedented performance in integrated photonic chips. In particular, the emerging concept of transformation optics [5-6], a design method for controlling photons at a researcher's discretion, opens up unique possibilities for advancing the integration of complex functionalities in photonic circuits. Additionally, optical simulations of large-scale astrophysical phenomena using small-scale photonic chips [7]. Nevertheless, in all these experiments, simulations were carried out using either classical Gaussian or a single-photon wave packet, both of which could be explained classically. Based on this background, we propose the use of the QWs of entangled photons [8] to study quantum interference in a noninertial frame with a Rindler metric that is emulated by a nonuniform photonic lattice with the aid of transformation optics. Thus far, however, no experiments have been carried out for quantum interference of entangled photons in the emulated curved space using transformation optics.

Here, we present the first experimental observation of the QWs of entangled photons near an emulated event horizon. We exploit silicon-on-insulator (SOI) technology to fabricate a nonuniform silicon waveguide lattice with site-dependent coupling coefficients inspired by transformation optics (Fig. 1(a)). This technology can map the space around the event horizon of a Schwarzschild black hole. We find that QWs of single photons and two

indistinguishable photons exhibit optical trapping near the emulated event horizons, which is a well-known classical physical process due to the strong gravitational force of a black hole (Fig. 1(b), Fig. 1(c)). Intriguingly, for a certain type of path-entangled photon, there is a counterintuitive phenomenon of optical escape arising from quantum interference (Fig. 1(d)).

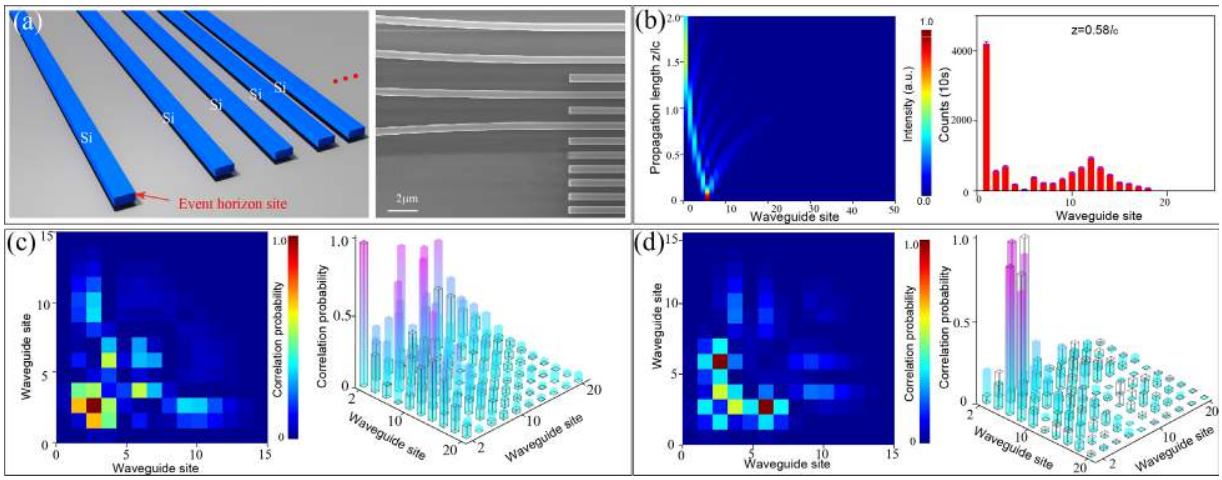

Fig.1 (a) Schematic of the nonuniform silicon lattice. (b), (c), (d) are respectively quantum walks of single photons, two indistinguishable photons and path-entangled photon.

In conclusion, we have experimentally realized the quantum walks of single photons, two indistinguishable photons, and entangled photons in the emulated event horizon using silicon photonics. To our knowledge, our work is the first to exploit silicon photonics to conduct QWs for simulating quantum effects in curved space. These types of nonuniform silicon photonic lattices inspired by transformation optics may provide a promising platform to study more challenging works about quantum mechanics and general relativity, such as the Anti-de Sitter/Conformal Field conjecture and loop quantum gravity.

Abstract: I will discuss TeraHertz (THz) cavities exploiting the resonance of THz surface plasmons which achieve extreme plasmonic confinement of the EM-field together with a large tunability as compared to more conventional THz cavity architectures based on noble metals. Deep inside the plasmonic regime, the THz cavities exhibit strong signatures of electromagnetic nonlocality. Our work introduces a new platform for exploring nonlocal aspects in plasmonics at an unprecedentedly large, i.e. micrometer, scale and may open the door to many THz applications.

In optics, surface plasmons can provide an efficient confinement of light at visible/infrared frequencies, i.e. in the range of the plasma frequency of noble metals. On the other hand, the use of noble metals in most of the THz cavity architectures realized to date [1-5] does not harness the potential of THz surface plasmons for photon confinement. In this study, by relying on a THz plasmonic material, we manufacture THz cavities which exploit the resonance of localized THz surface plasmon modes [6].

Based on this, we demonstrate plasmonic confinement of free space THz radiation in cavities of mode volumes V_{cav} as small as $V_{cav}/\lambda_0^3 \sim 10^{-8}$ ($\lambda_0 =$ free space wavelength). We also demonstrate large temperature-tunability of the cavity resonances as compared to more conventional architectures. Finally, as the length scales of the smallest cavities manufactured become comparable to that of the microscopic degrees of freedom of the plasma, we find strong evidence supporting the onset of nonlocal EM interactions.

Our experimental results may open the door to a wide range of THz applications and will allow to explore surface plasmonic phenomena in a brand new regime of parameters and tunability that are not accessible at optical frequencies.

Surface material dependance in tip enhanced Raman spectroscopy

Tim Parker*, Felix Schneider, Yang Zhao, Alfred J. Meixner, and Dai Zhang

Eberhard-Karls Universität Tübingen, Institute of Physical and Theoretical Chemistry, Germany
*corresponding author: tim-maikel.parker@uni-tuebingen.de

Abstract: Raman spectra may strongly be enhanced through the use of a sharp gold tip in close proximity to the samples surface. A great difference in the enhancement factor for the Raman spectra can be observed for various substrates and their surface properties.

Tip enhanced Raman spectroscopy (TERS) is a great technique to acquire optical and topological information from a large variety of samples [1,2].
In TERS a great deal of attention is paid to the tip, both to its material and geometry. The use of noble metal tips, either made of solid metal or a coating, such as gold or silver is common. The plasmonic properties of the tip must be in accordance with the incident lasers wavelength. The geometry of the tip plays a role in the enhancement of the electric field [3]. A smaller tip apex generally leads to a stronger amplification of the signal. For the probe scanning aspect of TERS, the geometry has an influence on the quality of the recorded topography.
For surface enhanced Raman spectroscopy, the surface of the sample is often reported to have a significant impact on the recorded spectra and is often varied accordingly [4-6].
The substrate on which TERS measurements are performed is often dictated by the sample of interest. In this work a dependence similar to surface enhanced measurements is investigated. The enhancement of Raman spectra is observed when the samples surface is varied.

Measurements were performed on a home built parabolic mirror scanning confocal microscope. The tip used was etched from gold wire. Tip sample distance was controlled using shear force feedback. Two different substrates were used: a glass surface and a smooth gold film.

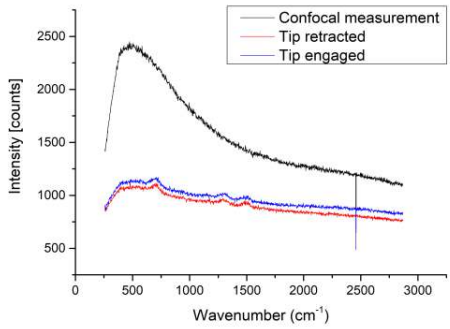

Figure 1: Comparison of confocal and TERS measurements on glass

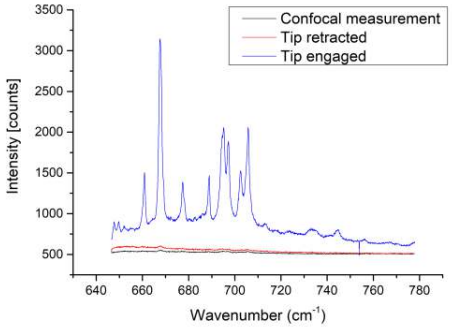

Figure 2: Comparison of confocal and TERS measurements on smooth gold

In both figures presented a clear trend can be observed. For Figure 1 which was recorded on glass very little difference can be seen with either engaged or retracted tip. A comparably low Raman enhancement can be concluded. The confocal measurement shows luminescence which is absent in the TERS spectra. For the smooth gold surface, shown in Figure 2, a very strong Raman enhancement can be seen. Additionally, the clarity of the spectrum is greatly improved, with many peaks which cannot be seen in confocal measurements becoming visible. The TERS measurement with tip retracted shows a slight increase in intensity compared to the confocal measurement. For the smooth gold film an enhancement factor of $4 \cdot 10^3$ can be calculated.

It can be concluded that for varying surfaces the TERS enhancement can be strongly different. For glass surfaces a slight enhancement of the Raman signal can be observed. For the smooth gold film, a significant increase in the Raman signal can be found.

Abstract: The VO_2 attracts wide interest for its insulator-to-metal transition when heated-up above the relatively low critical temperature of 68˚C. Plasmonic nanoantennas are known to concentrate light at the nanoscale around their surface when resonantly illuminated in the Vis-NIR. Here we show how this nanoantennas plasmonic feature can be used to steer and control a fast and nanoscaled insulator-to-metal transition in a VO_2 film. We investigated the effect of a single nanoantenna, which is the smallest unit-block.

Introduction

Gold single nanoantennas are well-known for addressing plasmon excitations when illuminated at a specific wavelength [1], giving rise to, e.g., enhanced light extinction and electromagnetic field concentration close to the antenna surface [2]. Due to these properties, plasmonic antennas are often combined with active materials, namely materials whose properties change under the application of an external stimulus, to obtain metasurfaces with enhanced optical properties [3–5]. Among phase transition materials, VO_2 is one of the most studied because its insulator-to-metal transition, induced by heating, occurs at relatively low critical temperature (68˚C).

In a previous study we showed that it is possible to originate a picosecond phase transition in a VO_2 film by using plasmonic nanoantenna lattices [5]. In this combined experiential-theoretical investigation, we show how a single plasmon nanoantenna can be used to induce and actively control the reversible phase transition in a VO_2 film down to the nanoscale [6]. The determination of the properties of the single antenna coupled to VO_2, which can be used as a building-block in nanodevices, is fundamental for the design and miniaturization of nanoscaled nonlinear optical devices and switches.

Results and Discussion

A gold single nanoantenna with size 312 nm x 105 nm x 50 nm (length x width x height) was fabricated by e-beam lithography on top of a 50 nm thick VO_2 film, which was deposited on a glass substrate. The spatial modulation microscopy (SMM) technique was used for single-antenna spectroscopy, namely to obtain the normalized spatial modulation transmission of the single antenna $(-\Delta DT/T)_{SMM}$, where ΔT is connected to the difference between the transmission of the system with and without the antenna. A pump laser (λ_{laser} = 1060 nm) illuminates the antenna-VO_2 hybrid for 10 ps with a polarization either parallel or perpendicular to the antenna length, and after 40 ps from the pump switching off, the spatial modulation transmission of the system is recorded by a probe laser characterized by a polarization parallel to the antenna length. Figure 1A shows the $(-\Delta DT/T)_{SMM}$ obtained under no pump (black curve) and a 0.6 nJ pump with polarization parallel (blue curve) and perpendicular (red curve) to the antenna length. The peak in the spectra is ascribable to the plasmon excitation in the antenna. For both polarizations the pump produces a red-shift of the peak and a decrease of the

optical response, with respect to the unpumped system, with the perpendicular pump providing more effect on the antenna response.

Numerical hybrid optical-thermal multiphysics simulations via the Finite-Element-Method were performed to obtain the theoretical normalized differential transmission with and without the antenna $(-\Delta DT/T)_{th}$. The simulated electromagnetic-illumination and heat diffusion reveal the presence, at the probing time, of hot-spots in the VO_2 around the nanoantennas where the temperature is higher than the initial one of 45˚C (yellow-to-white regions in the colormaps of Figure 1C and 1D). To obtain the $(-\Delta DT/T)_{th}$, to be compared with $(-\Delta DT/T)_{SMM}$, we changed the permittivity of the VO_2 around the nanoantenna according to the obtained temperature maps and then we calculated the optical response. For accurate results, a bi-dependent temperature-wavelength modelling of the complex permittivity of the VO_2 was developed. The theoretical results, displayed in Figure 1B, are qualitatively in agreement with the experiments, confirming that our modelling is well-suited. The red-shift of the plasmon peak for the pumped systems is due to the creation of VO_2 regions around the antenna where the permittivity decreases, even if a metallization is not reached. Even if this higher temperature is not enough to obtain a complete metallization (observed for T>90˚C), the reached value leads to a permittivity close to zero, making the system of interest for applications based on epsilon-near-zero materials. The dependence of the size, shape and position of the hot-spots on the pump polarization explains the difference observed between the blue and red curves of Figure 1A and 1B.

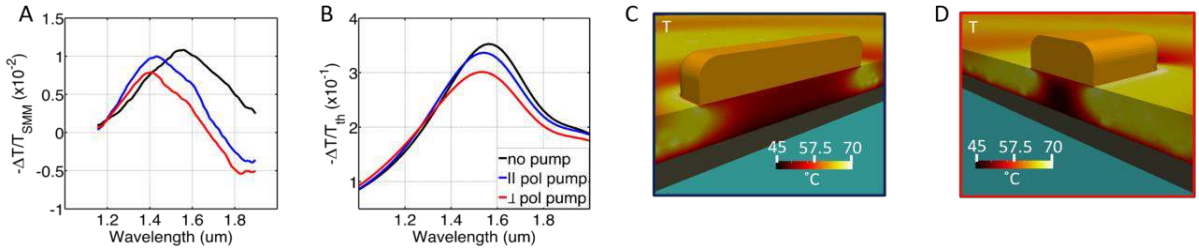

Fig. 1. (A) Measured $(-\Delta DT/T)_{SMM}$ and (B) simulated $(-\Delta DT/T)_{th}$ of the system as a function of the probe wavelength. (C, D) Colormap of the temperature in the system under pumping (C) parallel and (D) perpendicular to the antenna length.

Orbit–Orbit Interaction of Light: Harnessing Vortex–Trajectory Interplay for Light Manipulation

Raghvendra P. Chaudhary[1], **Avraham Reiner**[1], **Nir Shitrit**[1*]

[1]School of Electrical and Computer Engineering, Ben-Gurion University of the Negev, Beer Sheva 8410501, Israel
[*]Corresponding author: nshitrit@bgu.ac.il

Abstract: The orbit–orbit interaction of light is the interaction between the intrinsic and extrinsic orbital angular momenta associated with optical vortex beams and varying beam trajectories, respectively. We report the orbit–orbit interaction of light in a plasmonic ellipse cavity, whose unique geometry facilitates vortex–trajectory interplay when a vortex is considered in one of the foci of the ellipse. This interaction, manifested by vortex-dependent shifts, opens a new paradigm for light manipulation by leveraging the manifold vortex states.

Light can carry three types of angular momenta: a spin angular momentum, an intrinsic orbital angular momentum (OAM), and an extrinsic OAM (1). These momenta are associated with the handedness of the circular polarization, optical vortex beams with helical phase fronts, and varying beam trajectories, respectively (1). The interplay between these momenta yields the spin–orbit interaction (SOI) of light (2), in which the spin (circular polarization) controls the spatial (orbital) degrees of freedom of light: either the extrinsic OAM (trajectory) or the intrinsic OAM (vortex). By providing a toolbox for spin-controlled light manipulations, the SOI plays a crucial role in the new reality of nano-optics. However, while the SOI of light has been studied extensively (2,3), the interaction between the intrinsic OAM and the extrinsic OAM—the orbit–orbit interaction (OOI) of light—has remained elusive. In this nontrivial interplay, the helical phase fronts of optical vortices control the spatial trajectory of light, which gives rise to vortex-dependent shifts of optical beams. Strikingly, the OOI of light significantly enhances the toolbox available for controlling light by leveraging the *manifold* OAM states for vortex-controlled light manipulation, in contrast to SOI-based light manipulation (2,3), which exploits the *binary* polarization helicity.

Here, we report the OOI of light in a plasmonic ellipse cavity, whose unique geometry facilitates the OOI when a vortex is considered in one of the foci of the ellipse. In this configuration, the OOI between the intrinsic OAM and the extrinsic OAM is achieved by the interplay between the vortex of the source and the ellipse-induced transverse shift of the source beam, positioned at one of the focal points. The OOI of light in the plasmonic ellipse cavity induces transverse vortex-dependent shifts, i.e., shifts that depend on both the vortex helicity and strength, at the second focal point (Fig. 1).

To demonstrate the OOI of light, we investigated a plasmonic cavity, defined by an ellipse Bragg grating, in which a source of intrinsic OAM is considered in one of the foci of the ellipse (Fig. 2B). The ellipse cavity was chosen due to its unique geometric property, i.e., a curve on a plane surrounding two focal points, such that for every point on the curve, the sum of the distances to the two focal points is constant. Therefore, if we place a source without an intrinsic OAM (a Gaussian beam) at one of the foci of the ellipse cavity, then, according to Fermat's principle, we expect the source to be perfectly "imaged" to the second focal point (Fig. 2B). Conversely, if the source carries an intrinsic OAM, we expect to reveal transverse vortex-dependent shifts at the

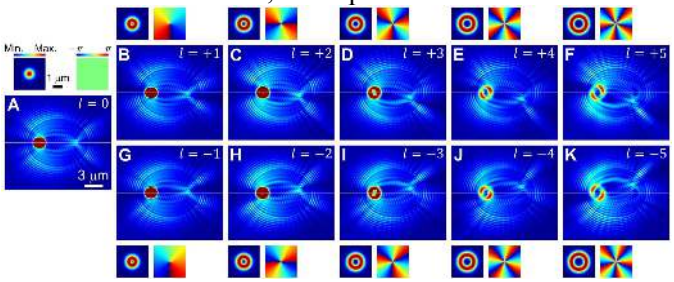

Fig. 1. Intensity and phase profiles of the Laguerre–Gaussian source beam with a topological charge l are shown in the left and right insets, respectively. (**A**) Simulated near-field intensity map of the plasmonic ellipse cavity for $l = 0$, where a transverse shift from the right focal point is not observed. (**B**–**F**) Simulated near-field intensity maps for $l = +1$ to $+5$, respectively. (**G**–**K**) Simulated near-field intensity maps for $l = -1$ to -5, respectively. The horizontal symmetry lines reveal the vortex-dependent shifts.

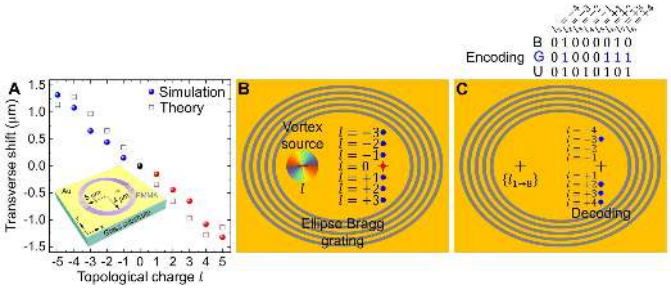

Fig. 2. (**A**) Dependence of the transverse shift on the topological charge l of the source beam. The inset shows the simulated structure. (**B**) Vortex-dependent shifts induced by the OOI of light in the plasmonic ellipse cavity. (**C**) On-chip information processing based on the OOI by encoding information (e.g., using ASCII binary strings) via the different vortex states $\{l_{1\to 8}\}$ in the superposed source beam, and decoding the information via the spatially separated vortex-dependent shifts.

second focal point (Fig. 2B). This anticipated observation is the manifestation of the OOI of light, where the helical phase fronts of optical vortices control the spatial trajectory of light. Uniquely, the geometric property of the ellipse makes it an excellent candidate to study the OOI via the interplay between the vortex of the source and the ellipse-induced transverse shift of the source beam, positioned at one of the focal points.

We performed numerical simulations to observe the vortex-dependent shifts in the plasmonic ellipse cavity by using a finite-difference time-domain algorithm to calculate the electromagnetic near fields. We considered an ellipse with semi-major and semi-minor axes of 5 μm and 4 μm, respectively (Fig. 2A, inset). To define the plasmonic ellipse cavity, we introduced an air–PMMA–gold structure to realize the ellipse Bragg grating, that defines the plasmonic ellipse cavity by encircling it and provides high reflectivity for the SPPs by satisfying the Bragg condition. For the source, we realized Laguerre–Gaussian beams carrying an intrinsic OAM determined by the topological charge of the vortex $l = 0, \pm 1, \pm 2,\ldots$—an integer representing the phase increment around the singular vortex core. We considered normally incident beams at the wavelength of 810 nm and a varying topological charge l (Fig. 1, insets). This vortex source was positioned at the left focal point of the ellipse and the incident polarization was set to be linear (zero spin angular momentum).

Figure 1 shows the simulated near-field intensity distributions of the plasmonic ellipse cavity for different topological charges l of the source. The test case of a source without a vortex, i.e., a Gaussian beam with $l = 0$, shows the expected result—the source is "imaged" to the right focal point due to the unique geometry of the ellipse (Fig. 1A). Conversely, once the vortex is introduced by the source beam, vortex-dependent shifts from the right focal point are clearly observed (Figs. 1B–1K). This observation stems from the OOI in the plasmonic ellipse cavity, which enables the interplay between the vortex of the source beam and its transverse shift, induced by the ellipse, once the source is positioned at one of the focal points. Figure 2A shows the dependence of the shift, extracted from the intensity patterns, on the topological charge of the source beam. In this effect, the shift depends on both the vortex helicity and strength, such that higher values of intrinsic OAM result in larger shifts. Moreover, we derived a theoretical wave interference model by which we calculated the vortex-dependent shifts that exhibit good agreement with the simulated results (Fig. 2A).

Owing to the inherent orthogonality of OAM beams and the linear nature of the OOI, this interplay can be harnessed to enable both the multiplexing and demultiplexing of OAM beams—which is desired for high-capacity optical communications (4). Figures 2B and 2C show a proof-of-concept demonstration for information processing via on-chip OAM demultiplexing based on the OOI by encoding information via different vortex states and decoding it via the spatially separated vortex-dependent shifts.

In summary, we report the OOI of light in a plasmonic ellipse cavity, whose unique geometry facilitates the vortex–trajectory interplay when a vortex is considered in one of the foci of the ellipse. By utilizing the multiple OAM states as a new degree of freedom in light manipulation, the OOI offers great potential for OAM-supported applications, including high-bandwidth optical communication and quantum information processing, enhanced resolution in imaging and microscopy, control of matter by optical trapping and tweezing, and many more.

Abstract: To address the growing need of energy efficient (~100's of fJ/bit) and high-speed (100's of GHz) optical components, we design, fabricate, and optically characterize an all-oxide ENZ plasmon-assisted modulator based on sputtered ITO and a planar Si slot waveguide. For an 8-um long device, simulations predict a low insertion loss (< 0.2 dB), a modulation depth of 9 dB, an RC-limited speed of 333 GHz, and a switching energy consumption of 480 fJ.

Telecommunications applications and technologies have rapidly evolved over recent decades, evolving from slow (kbps) point-to-point communications from between home and offices to universally connected devices. This tremendous growth has been supported by a deeper penetration of optical technologies such as fiber to home (FTTH), short distance fiber communication (within data centers), and massive parallelism. However, as 5G and millimeter-wave technologies become more ubiquitous, a growing need exists for optical components that are more energy-efficient and provide a bandwidth closer to that of the carrier wave. Indeed, current devices are limited in optical bandwidth to speeds about a thousand times slower than what can be theoretically accommodated by the carrier signal.

State-of-the-art optical modulators leverage active dielectric optical materials such as Si, Si_3N_4 or $LiNbO_3$. The relatively weak tunability of typical electro-optic materials nonlinearities, lead to devices requiring light-matter interaction lengths that limit the frequency of operation, such as long waveguide interferometers with large capacitive footprints (f ~ 1/RC) or high-quality-factor ring resonators with long ring-down times (f ~ 1/Q) [1,2]. On the other hand, plasmonic devices offer great potential for addressing some of the limitations of silicon photonics. Recent literature has demonstrated plasmonic modulators realizing speeds > 600 GHz in compact footprints (<20 μm^2) [3]. However, high insertion loss and on-state transmission efficiencies of ~10% have restricted the practicality of these devices.

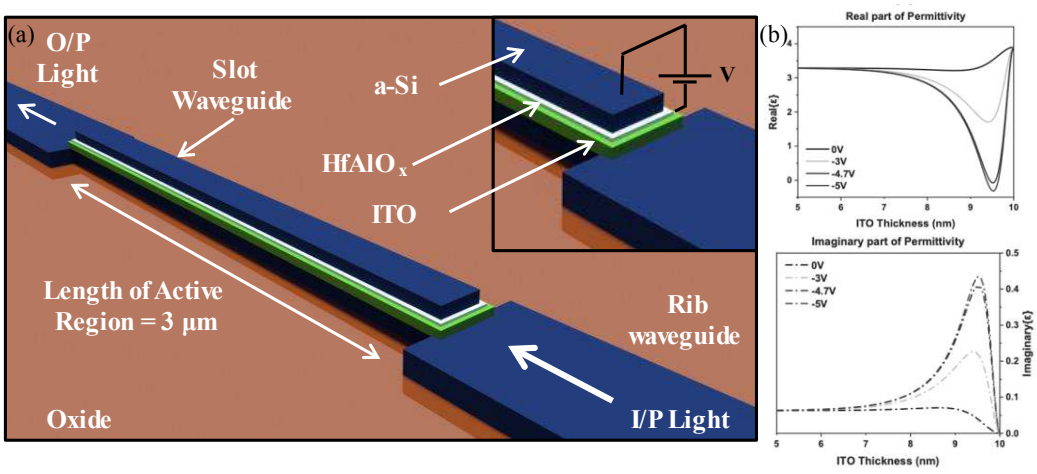

Figure 1: Proposed vertical alternative to the horizontal slot design, (b) Real and imaginary part of permittivity within ITO as a function of gate voltage and position within the ITO layer (COMSOL simulations)

To overcome the speed, transmission, and insertion-loss limitations of both dielectric and plasmonic electro-optic modulators to date, we realize a Si waveguide modulator incorporating an active layer of indium tin oxide ITO in a slot configuration, which combines the high-speed benefits of metal-based plasmonic devices with the low-loss advantages of dielectric-based photonic devices by allowing selective engagement or disengagement of a lossy plasmonic state (Fig. 1(a)). In this device, operating at a standard telecommunications wavelength of 1550 nm, electrically induced modification of the electromagnetic permittivity of the ITO in the slot enables switching of the optical mode profile in the slot between a dielectric state with high transmission ("off state") and a plasmonic state with low transmission ("on-state").

More specifically, optical switching is achieved by formation of an electron accumulation layer in the ITO under bias by a Si/Al_2O_3 gate, which takes the local electromagnetic permittivity, via change in free carrier dispersion, from an unperturbed positive "dielectric" value to a value close to zero in its real part, known as an epsilon-near-zero (ENZ) condition (Fig. 1(b)). This change leads to a radical reconfiguration of the optical mode profile due to continuity of the electric displacement vector normal to the accumulation layer, squeezing it into a quasi 2D plasmonic state and fully absorbing the propagating mode over only a few microns (Fig. 2).

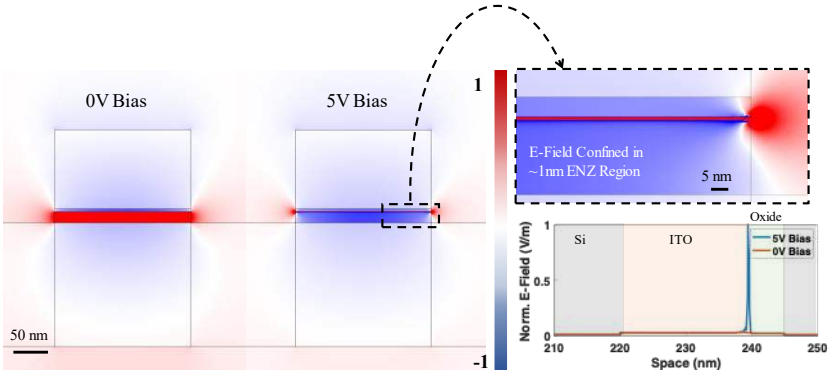

Figure 2: Simulated E-field profiles of the active region (COMSOL). At a bias of 0V, an incoming optical mode, polarized with electric field normal to the plane of the layers, occupies the full volume of a low-index slot region (consisting of ITO and Al_2O_3 gate-insulator layers), experiencing an all-dielectric environment and hence low-loss propagation. Upon application of a 5V bias, a ~1-nm thick region at the ITO/insulator interface acquires a permittivity close to 0, leading to drastic mode confinement into this narrow region (right inset), along with drastic enhancement of its electric field, increased mode losses due to increased electron-electron scattering, and drastic propagation attenuation as a result.

We will present the design, construction, and optical characterization of an ENZ plasmon-assisted modulator based on sputtered ITO and a fabrication-friendly, planar Si slot waveguide configuration, enabling well-controlled field profiles and high field enhancement without the use of lossy metal. For an 8-um long device, simulations predict a low insertion loss (< 0.2 dB), a modulation depth of 9 dB, an RC-limited speed of 333 GHz, and a switching energy consumption of 480 fJ/bit.

Synopsys Workshop at META 2023

Automated Inverse Design Solution for Metalenses

July 18 and 19

5:00-6:00 pm

Location: Salle des Conseils

To help researchers design metalenses easily and quickly, Synopsys has developed MetaOptic Designer, a fully automated design tool for metalenses. Based on a few inputs from designers, such as a pre-built meta-atom library and basic lens configuration, MetaOptic Designer generates an optimized design to meet all design targets.

Synopsys will introduce and demonstrate MetaOptic Designer in two workshop sessions at META 2023. On July 18, we will provide a general overview of the MetaOptic Designer optimization algorithm, followed by quick demonstrations of the tool's capability. On July 19, we will demonstrate advanced metalens applications with tips and tricks; applications will include:

- Achromatic metalens
- Wide-angle metalens
- Chiral hologram
- Reflective metalens
- Hybrid optical system with both metasurfaces and traditional refractive lenses

The workshop is free and open to all META conference attendees.

META 2023, PARIS - FRANCE, JULY 18 – 21, 2023

Photonic Band Structure Calculations of 3D Finite Nanostructured Supercrystals

N. Large[1*], J. L. Montaño-Priede[1]

[1]Department of Physics and Astronomy, University of Texas at San Antonio, United States
[*]corresponding author: Nicolas.Large@utsa.edu

Abstract: Computational modelling of plasmonic periodic structures are challenging due to their multiscale nature. Here, we developed a computational approach, based on the finite-difference time-domain method to accurately calculate the photonic band structures of finite supercrystals, accounting for both nanoscale features an overall habit of the supercrystal. We applied this new approach to 3D periodic microstructures of Au nanoparticles with cubic, spherical, and rhombic dodecahedral habits and discuss how their photonic band structures differ from those of infinite structures.

Well-structured, periodic plasmonic supercrystals possess the unique ability to retain the intrinsic properties of their building blocks but also display unique collective properties originating from interparticle coupling effects [1-4]. With the countless superlattices now synthetically realizable [4], computational methods and theoretical models play a crucial role in identifying the supercrystals that exhibit the most exciting properties. When the supercrystal lattice parameter is much smaller than the wavelength, the medium usually behaves like a uniform, continuous material, characterized by an effective dielectric permittivity and magnetic permeability, which are modelled using effective medium models. However, when the lattice parameter is comparable to the optical wavelength, the photonic band structure plays a key role. In such assemblies, the interparticle distance becomes the critical parameter that governs the collective optical properties. When the distance is larger than the wavelength of optical excitation the NPs are uncoupled and the collective optical response is the incoherent summation of individual responses of each NP constituting the assemblies. Additional photonic behaviors arise when the interparticle distance satisfies Bragg's law (*e.g.*, Rayleigh anomalies) or when multipolar interactions are involved. Finally, geometrical aspects such as the dimensionality and the habit of the supercrystal, the lattice parameter in each spatial direction, and the morphology of the NPs composing the supercrystal play a key role in defining their optical properties including (an)isotropy/birefringence [5], the emergence of Fabry-Pérot resonances and whispering gallery modes (WGM) [6], and decrease of the photonic mode lifetime.

Here, we theoretically investigate the photonic properties of 3D periodic microscale arrangements of plasmonic nanoparticles that form supercrystals, also known as plasmonic supercrystals, 3D superlattices, or plasmonic photonic crystals. To that end, we proposed a theoretical and computational approach for calculating the photonic band structures of finite supercrystals (**Fig. 1**), and investigating the effect of the habit (*i.e.*, crystal shape) and size on its photonic properties [7]. Our approach allows for accurately calculating the photonic band structures from finite-size 3D superlattices of various habits (cubic, spherical, rhombic dodecahedral) and building blocks (spheres and rods). We showed that they differ from the band structures computed for infinite structure and encompass phenomena such as the Fabry-Pérot interferences, whispering gallery modes, the decrease in photonic mode lifetime, and the formation of polaritonic bandgaps.

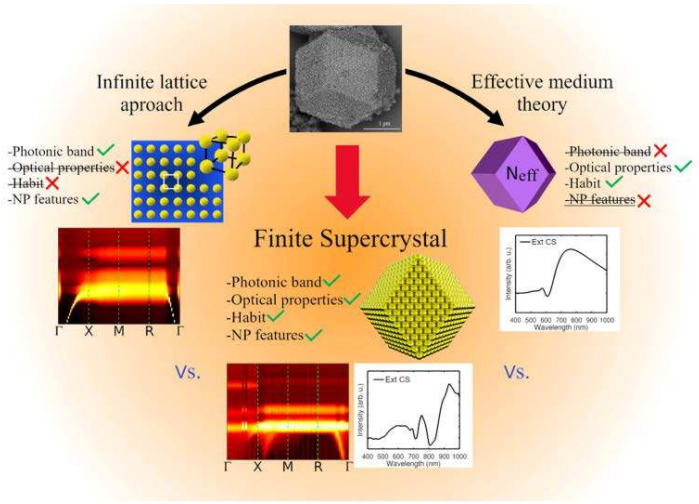

Fig. 1. Approaches to calculate the properties of photonic crystals, i.e., infinite lattice for band structure calculations, effective medium theory for optical properties like reflectance, and proposed FDTD simulation for finite supercrystals.

It is important to notice that, although this approach was applied to 3D supercrystals, it is far more general and versatile. Not only it applies to various morphology, composition, and size of the building blocks (*e.g.*, cubes, prisms …), but also to different unit cell symmetries (*e.g.*, fcc, bcc …), supercrystal habits (*e.g.*, ellipsoidal, pyramidal …), and dimensionalities of the periodic structures (*e.g.*, 1D chains, 2D arrays).

Directional scattering by composite SiO2/Au nanoparticles

T.P.S. Kotte[1*], A.J.L. Adam[1], and H.P. Urbach[1]

[1]Delft University of Technology, the Netherlands
[*]corresponding author: t.p.s.kotte@tudelft.nl

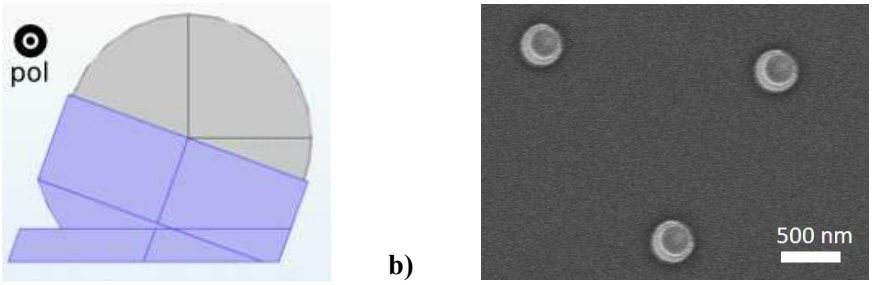
Abstract: We show that composite nanoparticles can be designed to scatter light into a desired direction. By choosing the materials of the nanoparticle carefully, the phase of the scattered light by the different components can be controlled. This leads to constructive interference is certain directions and destructive interference in others, resulting in directional scattering obtainable for a large bandwidth. FEM simulations were used to validate the theory. Furthermore, SiO2/Au nanoparticles were fabricated and measured confirming the directional scattering.

Introduction

Most studies towards scattering by nanoparticles have focused on particles made up of a single material, where the scattering is determined by multipole resonances[1]. Combining particles of different materials allows for more degrees of freedom, which has been demonstrated for dimer and trimer structures[2,3]. However, the directional scattering by these configurations is determined by interference between their different components, acting as spatially separated point sources. Therefore, the direction of the scattered field is highly dependent on the wavelength of the light and the distance between the point sources. Thus, broadband light scattering where the scatter pattern remains constant is hard to attain. Composite nanoparticles (CNPs) could be a solution for this, as the materials are not separated.

Approach

Let us consider a linearly polarized plane wave traveling in the x-direction incident on a CNP, which is inside a homogeneous medium with permittivity ε_{med}. For now we will assume that the contrast of the particle is very low compared to the medium. In this case, we can use the Born approximation in the Lipmann-Schwinger equation to calculate the scattered field. Using a spherical coordinate system, with polar angle θ (from the z-axis) and azimuthal angle φ (from the x-axis) and some algebraic steps we get the following expression for the field scattered in the forward direction:

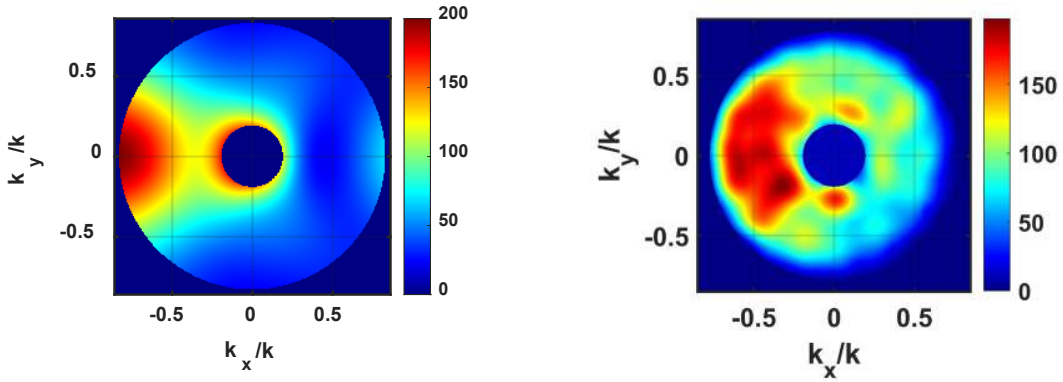


$$\bar{E}^{sc}(r,0,\pi/2) = \bar{E}_0 \frac{k^2 e^{ikr}}{4\pi r}\left[\left(\varepsilon_{\Omega_1} - \varepsilon_{med}\right)\int_{\Omega_1} d^3 r_0 + \left(\varepsilon_{\Omega_2} - \varepsilon_{med}\right)\int_{\Omega_2} d^3 r_0\right]. \quad (1)$$

Here, k is the wavenumber in the medium, ε the permittivity, E the electric field and Ω_1 and Ω_2 the volumes occupied by the different materials. From Equation 1, we see that the scattered field is determined by the volume of the materials and their permittivity. By choosing different sizes and materials, the magnitude of the scattered field can be controlled.

To investigate whether this relation holds beyond the Born approximation, a SiO2/Au CNP in air was simulated using the FEM software COMSOL. To make fabrication possible, a geometry was chosen of a spherical SiO_2 particle (with a diameter of 300 nm) with Au attached to its side (Figure 1a). The calculated scattered light intensity for incident light with a wavelength of 633 nm is shown in Figure 2a.

Samples of SiO2/Au CNPs of the same geometry were fabricated. A solution of colloid SiO2 nanospheres were deposited onto a glass wafer. Next, the sample was sputtercoated with a layer of 40 nm Au. Finally, most of



the gold was removed by ion beam etching at an angle of 20 degrees, so that only the Au in the shadow of the nanoparticle remained. The samples were inspected using a SEM, the result can be seen in Figure 1b.

a) **b)**

Figure 1: a) Geometry of the SiO2/Au CNP in the simulation. The blue part is made of Au and the grey part is made out of SiO2. The polarization of the incident light used for simulations and measurements is also indicated; **b)** SEM micrograph of three fabricated SiO2/Au CNPs

The scattering of the manufactured CNPs was measured using a transmission Fourier microscope setup using a HeNe laser as a light source with a *y*-polarization. Figure 2 shows the simulated and the measured scattering intensity produced by a single CNP in the Fourier plane. It can be seen that most of the light is scattered to the left of the particle and that the measurement corresponds to what is expected from the simulation.

a) **b)**

Figure 2. Scattered light intensity in the Fourier plane by a SiO2/Au CNP on a glass substrate with incident y-polarized light: **a)** simulated using a FEM software; **b)** experimentally measured. (arbitrary units)

Conclusion

We have shown that directional scattering can be achieved by CNPs with the right material combinations for their components. Theory and FEM simulations show that the phase differences of the scattered field caused by the material properties of the CNP are the source of the directional scattering. Subsequent experimental measurements confirm the directional scattering found by the FEM software.

Abstract: We present the displacement trajectory of a gold nanoparticle under photonic nano-jet and photonic hook fields generated with an ultrashort pulsed beam. We compared the optical forces exerted on the nanoparticle under pulsed and CW illumination and calculated its displacement. We observed peculiar nanoparticle trajectories when placed in different initial positions, under pulsed light. To understand the effect, we analyzed the gradient and scattering forces. Our work stimulates the development of experimental methods for opto-mechanical manipulation.

The trapping and manipulation of particles by optical tools have been widely used in biological research and implemented in medicine [1], yet nanoscale objects cannot be manipulated by such tools due to the diffraction limit of light [2]. Therefore, achieving manipulation on the nanoscale requires auxiliary structures that generate a tightly confined electric field. Photonic nano-jets are high intensity, narrow light beams generated by dielectric structures that are subjected to illumination by a plane wave [3]. When the symmetry is broken, the generated structured light becomes curved, which is known as a photonic hook effect [4]. In this research, we report the displacement trajectory of gold nanoparticles under photonic nano-jet and hook fields generated with an ultrashort pulsed beam. The studied system is composed of a micro-cylinder and metallic mask that partially blocks the incident light and creates an asymmetric illumination [5]. We simulated the electric fields and calculated the optical forces exerted on the nanoparticle. We compared between continuous wave and pulsed illumination, and found that the forces exerted on the gold nanoparticle generated via pulsed illumination are five orders of magnitude higher and are significant enough to move the nanoparticle. We observed peculiar nanoparticle trajectories when placed in different initial positions, and found that the trajectory is not affected by input intensity. To better understand our results, we analyzed the gradient and scattering forces exerted on the nanoparticle by the photonic nano-jet and hook. Our results stimulate the development of experimental methods for the opto-mechanical manipulation of nanoparticles. Opto-mechanical manipulation opens a venue for future fundamental investigations and a range of practical applications, where accurate control over the mechanical motion of small objects is required.

The research reported in the manuscript was funded by Israel Science Foundation (ISF no. 2598/20).

Abstract: Ion traps are a promising platform for the realization of high-fidelity quantum information processors. Integrated photonic components are important for scaling ion trap systems to large numbers of qubits. Polarization control is essential for state preparation, electron-shelving and quantum logic operations. Here, we present our work on ion traps with integrated grating couplers combined with metasurfaces as a two-layer system for the conversion of linear polarization to circular polarization.

Ion traps are one of the most promising platforms for quantum computers to solve classically intractable problems efficiently [1,2,3]. To enable scalability of these systems, integrated photonic components for guiding, manipulating and shaping laser light are essential. Polarization control is useful for state preparation, electron-shelving, and quantum logic operations.

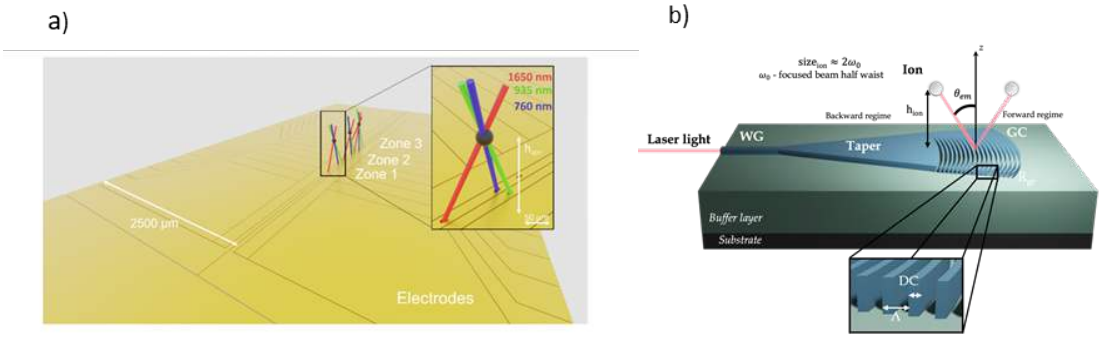

Figure 1: a) Surface ion trap with integrated photonics to control the outcoupled beams for addressing the ions (black spheres) in different trap zones; b) Waveguide – Grating coupler design scheme with forward and backward light focusing regimes.

Figure 1 a) show a photonically integrated ion trap. To guide the laser light on the chip, different passive optical elements are utilized. The light is guided to the ion via waveguides, taper and focusing grating outcouplers as shown in Figure 1 b).

Standard grating couplers only provide linear polarized light. During the past years, metasurfaces have been demonstrated to realize polarization control on chip [4, 5, 6]. In Figure 2 we present a two-layer system for

converting the linear polarization into circular polarization. The light is guided and outcoupled as indicated in Figure 1b) and a metasurface as a second layer above the grating layer is added to control the polarization.

We perform simulations of this system using LUMERICAL®. In our simulations, we take a wavelength of 760 nm as an example and select Si_3N_4 as waveguide and grating material, SiO_2 as the cladding material, while the metasurface material is selected to be Si, which provides a large refractive index contrast. The grating coupler is designed to emit the light vertically. The metasurface is composed of asymmetrically arranged rectangle elements, which generate a phase difference for the two electric field components of the light coming from the grating couplers. For a metasurface with a thickness of 500 nm, pixel size of 433 nm x 744 nm, element size of 333 nm x 100 nm, we get a circular polarized beam (phase difference is 90°).

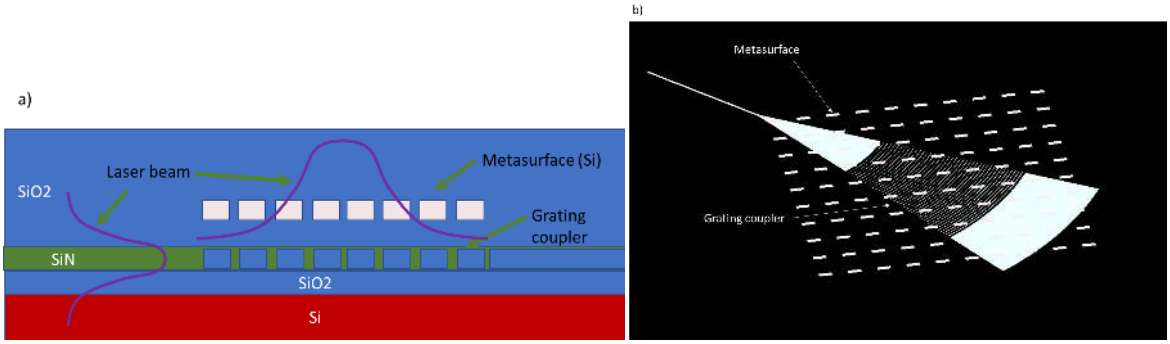

Figure 2: a) two-layer system using grating coupler combined with a metasurface to couple light out of the surface and change its polarization from linear to circular; b) 3D view of the two-layer system.

Vertical Injection and Wideband Grating Coupler Based on Asymmetric Grating Trenches for Higher Coupling Efficiency

Md Asaduzzaman*
School of IT and Engineering, Melbourne Institute of Technology, Melbourne, Victoria 3000, Australia
*Corresponding author: masad@mit.edu.au

Abstract: A Silicon-on-insulator (SOI) perfectly vertical fibre-to-chip grating coupler is proposed and designed based on engineered subwavelength structures. The high directionality of the coupler is achieved by implementing step gratings to realize asymmetric diffraction and by applying effective index variation with auxiliary ultra-subwavelength gratings. The proposed structure is numerically analysed by using two-dimensional Finite Difference Time Domain (2D FDTD) method and achieves 96% (-0.2 dB) coupling efficiency and 39 nm 1-dB bandwidth. This highly efficient GC is necessary to applications where coupling efficiency is critical such as photonics quantum computing.

Grating couplers (GC) are most preferred choice for light coupling between optical fibre and nanophotonic waveguides [1]. However low coupling efficiency (CE) of vertical GC [2-3] has been an active issue specially where near unity CE is highly desirable, for instance, in quantum photonics experiments. In this work, we propose a new GC structure for perfectly vertical coupling by creating asymmetric grating trenches with a combination of step and engineered subwavelength gratings that manipulate the effective refractive index to achieve higher coupling efficiency along wider wavelength range. Our proposed structure can be fabricated on standard SOI wafer using Focused Ion Beam (FIB) or few steps of etching with Electron Beam Lithography (EBL) process. Although the fabrication complexity of the structure might be relatively higher, it promises of higher CE (96%) and provides solutions to various applications, e.g. for the experiments of photonics quantum computing.

The proposed GC with secondary gratings including step gratings is simulated by 2D FDTD. The electromagnetic field distribution and CE obtained are shown in Fig.1. The light that coupled with substrate through BOX is reduced in the redesigned structure as can be seen in Fig.1 (a). The directionality of the power propagation in subwavelength grating coupler is improved significantly. With such engineered sub-wavelength grating structure, the CE of ~72% is achieved as shown in Fig.1 (b) that peak coupling efficiency occurred at 1550 nm with 1-dB bandwidth of ~ 44 nm.

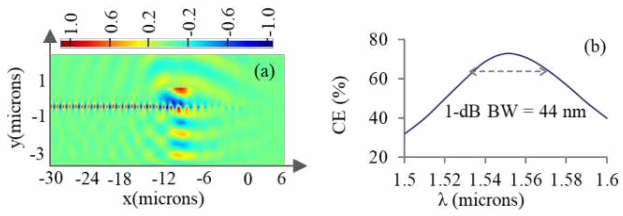

Fig. 1. (a) Electromagnetic field distribution along the grating structure and (b) coupling efficiency at wavelength range from 1500 nm to 1600 nm with centre at 1550 nm for grating coupler with secondary ultra-subwavelength grating.

Finally, the estimated coupling efficiency over the wavelength range of 1500-1600 nm for grating coupler with optimized secondary grating parameters as of in Table 1 is shown in Fig.2. The CE and BW increases with

Table 1: Optimized secondary grating parameters.

Λ_s (nm)	DC_s	w_s (nm)	w_{gs} (nm)	d_s (nm)	w_{ss} (nm)	t_s (nm)
154	0.4	62	92	15	38.6	15

the number of step gratings in the primary groove up to 4 steps and nearly saturates with higher numbers as shown in Fig. 2. Significant increment of CE can be observed from step number 1 to 4 but are similar CE for steps 4 and 5. The peak coupling efficiency of ~ 96% is achieved at wavelength of 1550 nm with 1-dB coupling bandwidth of ~39 nm for 4 step gratings in the primary groove. Although the efficiency is improved with optimized structure, the bandwidth is little lower than that of obtained in Fig.1 (b). This is due to fact that the modified effective refractive index causes lower coupling efficiency for longer wavelengths. This once again proves that there always exists compromise between coupling efficiency and coupling bandwidth in a grating coupler.

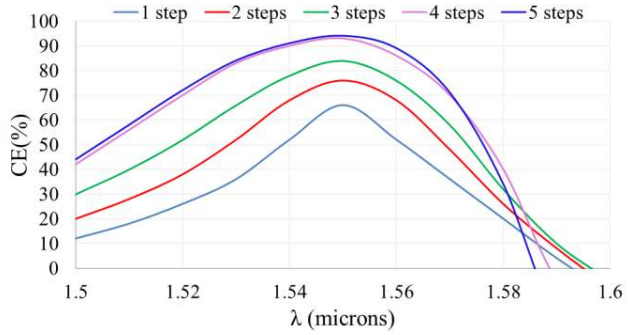

Fig. 2. Coupling efficiency vs. wavelength for optimized grating coupler with various numbers of step gratings in the primary groove.

In summary, a perfectly vertical grating coupler is proposed for light coupling between SOI waveguides and optical fibres in this work. The symmetrical propagation nature of the diffracted waves from grating is broken by incorporating asymmetric grating trenches with step gratings. The coupling efficiency of the coupler is also boosted by implementing effective index variation of the primary grating achieved by combination of auxiliary ultra-subwavelength gratings and step gratings. In this design the coupling efficiency is estimated as high as 96% (-0.2 dB) and 1-dB coupling bandwidth of 39 nm. Our proposed structure provides solutions where coupling efficiency between optical fibre and nanophotonics waveguide is critically important, for instance, experiments of the quantum photonics integrated circuits. Such efficient and broadband perfectly vertical grating couplers are also significantly advantageous in high dense photonic packaging.

Abstract

With the increasing need for scaling down devices to the nanoscale, the quest for an ideal photon pair source having a high degree of brightness and purity with an ability to operate under ambient temperature has never been more relevant than it is now. Within this context, here we demonstrate a framework to evaluate photon pair generation efficiency via spontaneous parametric down conversion (SPDC) from nonlinear crystal coupled to plasmonic nanoantennas (hereby called hybrid nanostructures) and we report on the experimental advances made towards this purpose.

SPDC being a quantum process, traditional approaches to numerically evaluate it have been (i) to neglect the quantum effects by using quantum classical correspondence with the reverse process of SPDC which is sum frequency generation, (ii) to perform a Hamiltonian treatment given the known optical mode of fields at excitation and emission.

In this work, by correlating quantum fluctuations associated to signal and idler photons at emission and detector using classical Green's function we evaluate photon pair emission rate from a hybrid nanostructure under pulsed field excitation. The numerical modelling of the currents generated in the nanostructure is based on solving Maxwell's equation using finite element methods. The framework we develop here is adapted to realistic experimental setups by taking into account analytically the propagation of the generated fields through a glass substrate and collection by a microscope objective.

Additionally, we investigate the effect of plasmonic field enhancement of aluminum and gold nanoantennas on KTP crystal which is well studied from the point of view of second harmonic generation as well as the effect of absorption inherent in metals. Finally, we also explore the feasibility of experimental photon pair generation from a novel nonlinear material such as gallium phosphide and field enhancement resulting from different geometry of the plasmonic nanoantennas.

Abstract: Due to their unique plasmonic and mechanical properties, plasmomechanical systems have become thoroughly investigated for strain sensing applications. The realization of strain sensors with high performance requires plasmonic resonances with high quality Factor (Q) such as Fano resonances (FR). In this respect, we have carried out an optomechanical study of a plasmomechanical system supporting FR, consisting of two gold nanoparticles (GNs), a disk and a rod, deposited on a polydimethylsiloxane (PDMS) substrate.

1. Introduction

The capability of metallic nanoparticles to generate localized surface plasmon resonances (LSPR), resulting from the interaction between the conduction electrons and the incident light, have made them choice candidates in many applications, from biosensing to solar energies.[1] In nanostructure assemblies consisting of two nanoparticles or more, the LSPR depends strongly on the interparticle spacing due to the coupling via their near-fields.[2] The possibility of exploiting this property in the realization of strain nanosensors has led to the birth of a new field in nanophotonics called plasmomechanics.[3] Rod-shaped nanoparticles are known to support plasmonic narrow dark modes which can be used, in combination with bright modes supported by other particles such as disks, to generate FR whose shape can be modified by deformation of a PDMS substrate.

2. Structure and simulation method description

The investigated structure as schematically shown in Figure 1 consists of a Au disk (R=90nm) and a rod (w=50nm and l_r=320nm) with a fixed thickness h=30nm. Displacements (ε), ranging from 0% to 20%, have been applied in opposite directions on the substrate. The structure has been illuminated by a p-polarized monochromatic planewave, propagating normally from the (-z) direction. Refractive index of PDMS is 1.4 and that of gold is taken from Johnson and Christy database.[4] Simulations have been performed using *Comsol Multiphysics* software, based on finite element method. An hyperelastic model have been used to model the PDMS based on a nearly incompressible neo-Hookean material model, and an elastic model for GNs.

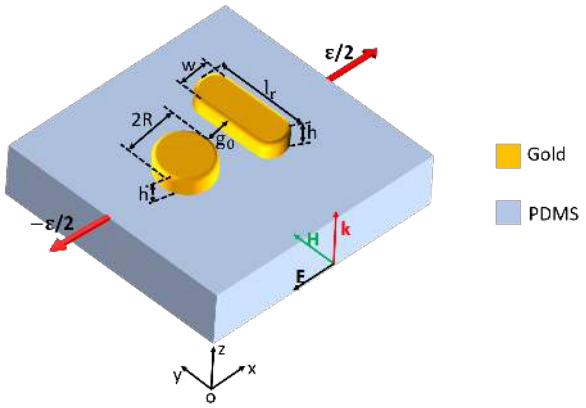

Figure 1. Schematic illustration of the investigated structure under stretching.

3. Results

When the GNs in this system are close enough (few ten nanometers) to each other, the first excited dark mode of the rod can hybridize with the bright dipole mode of the disk, leading to the formation of a bonding and an antibonding modes whose interference is at the origin of a Fano resonance profile. Figure 2 represents the evolution of the resonance maxima as a function of the applied displacements, the inset showing the FR for ε=0%. When the displacement percentage passes from 0% to 20%, the bonding mode (long wavelength maximum) exhibits a strong blue shift of 32nm while the antibonding mode shows a smaller shift in the opposite direction, of 10nm. Indeed, when the PDMS is under stretching, GNs move away from each other and the gap undergoes a dramatic amplification with a percentage higher than that of the applied strain, which causes a decoupling and a transition to weak interaction between the two modes, as it can be seen on the electric field maps, (d) and (e), where a strong amplitude decrease is observed in the gap region.

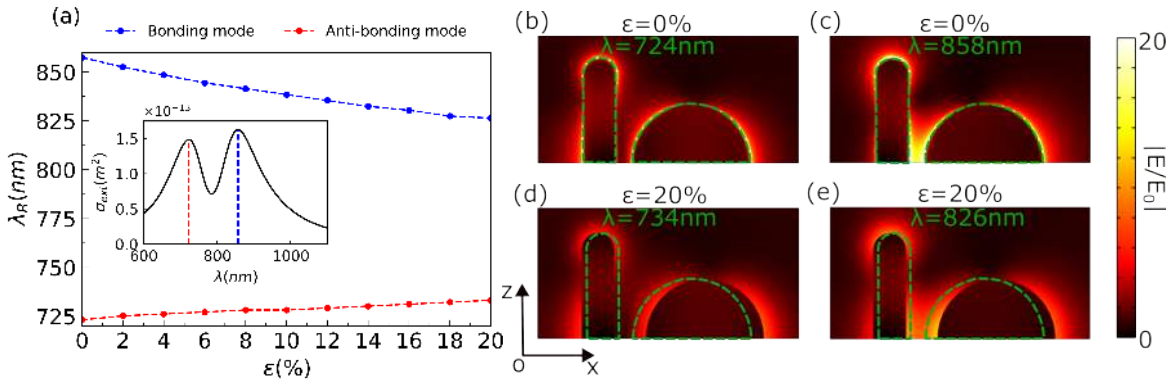

Figure 2. Calculated trend of the resonance wavelength as a function of the applied displacement ranging from 0% to 20% (a), Electric field distribution of the structure at rest and under 20% of displacement: for the antibonding mode [(b) and (d)], and for the bonding mode [(c) and (e)].

4. Conclusion

Resonance wavelength of FR shows a strong sensibility to the applied displacements due to the dramatic gap amplification. In fact, when ε=0% of strain is applied, the gap passes from g_0=25nm to g=48.6nm which corresponds to a relative gap variation of $\Delta g/g_0$=0.94 higher than the elastic variation $\Delta g/g_0$=0.2. As consequence, the proposed plasmomechanical system can be used in strain sensing applications.

Abstract: Recent advances have led to the realization of plasmonic nanocavities that have gaps of just 1-2 nm, and have allowed for light-matter strong coupling at room temperature. Previous studies have focused on the energy coupled to the far-field, however the energy carried out by propagating surface plasmon polaritons (SPPs) is often neglected in literature. Here we quantify the fraction of energy coupled in to SPPs and that coupled into plane waves (PWs), which carry the energy into the far-field.

Metallic nanostructures are able to confine light through localized surface plasmons. At extreme nanogaps of just 1-2 nm extraordinary light confinement occurs due to tight coupling between two plasmonic structures [1]. A geometry that has attracted considerable attention over the past few years is the nanoparticle-on-mirror (NPoM) configuration (Fig 1.a) with which light-matter strong coupling of a single molecule at ambient conditions was realized [2]. This nanocavity is made of a usually spherical nanoparticle, separated from a gold substrate by a molecular monolayer. Such optical resonators play a key role in various areas in nanophotonics, including quantum information processing, lasers, nonlinear optics and ultrasensitive biosensing [2,3].

Most studies have been focusing on the scattering and absorption properties of such nanocavities, while a few recent ones have explored the system's photonic quasinormal modes (QNMs) (see Fig 1.b) and how they couple energy to the far-field (Fig 1.c) [1]. However, the same QNMs have a propagating SPP component, bound and propagating on the metal substrate. Here, we develop different methods that allow us to quantify how each QNM couples energy into a propagating SPP, and to the far-field in the form of a plane wave (PW). Although the propagating SPP component of the QNMs has been largely ignored by the community, we find that it is in fact dominant for almost all plasmonic modes for nanocavity configurations.

We use three different approaches to analyze and quantify the propagating SPP and PW component of each plasmonic mode. We first consider the radiative decay rate (γ_{rad}) of the system, where a dipole source is placed in the centre of the nanocavity, and we identify how much energy is coupled in the SPP and PW components. However, this method is dependent on the position of the dipole source. To avoid this problem, we perform QNM numerical solutions [3], and find that the propagating SPP is launched along the same direction as the near-field enhancement (see Fig 1.d). We then consider the QNM expansion coefficients proposed in [3], which demonstrate how much an incident PW or propagating SPP couples into a specific QNM, which we integrate over all possible incident angles for both propagating SPPs and PWs:

$$A_m(\omega) = \iint \left(\frac{\tilde{\omega}_m}{\tilde{\omega}_m - \omega} \left\langle \tilde{\boldsymbol{E}}_m^* \middle| \varepsilon(\tilde{\omega}_m) - \varepsilon_b \middle| \boldsymbol{E}_{inc}(\omega, \theta, \varphi) \right\rangle_{V_{res}} + \left\langle \tilde{\boldsymbol{E}}_m^* \middle| \varepsilon_b - \varepsilon_\infty \middle| \boldsymbol{E}_{inc}(\omega, \theta, \varphi) \right\rangle_{V_{res}} \right) d\varphi \, d\theta, \quad (1)$$

where $\boldsymbol{E}_{inc}$ is the incident field, $\tilde{\boldsymbol{E}}_m$ the QNM field and V_{res} is the resonator domain, and ε_b, $\varepsilon(\tilde{\omega}_m)$ and ε_∞ are respectively the permittivity of the background medium, the resonator's permittivity at a given QNM frequency and the asymptotic permittivity of gold.

Finally, we calculate new coefficients from the QNM expansion that do not require us to consider an incident field, so are independent of the source fields. Using all three methods, we show that the propagating SPP component of the plasmonic modes in nanocavities is dominant for most modes. This means that most of the energy does not reach the far-field, but instead is launched on the metal surface as a propagating SPP.

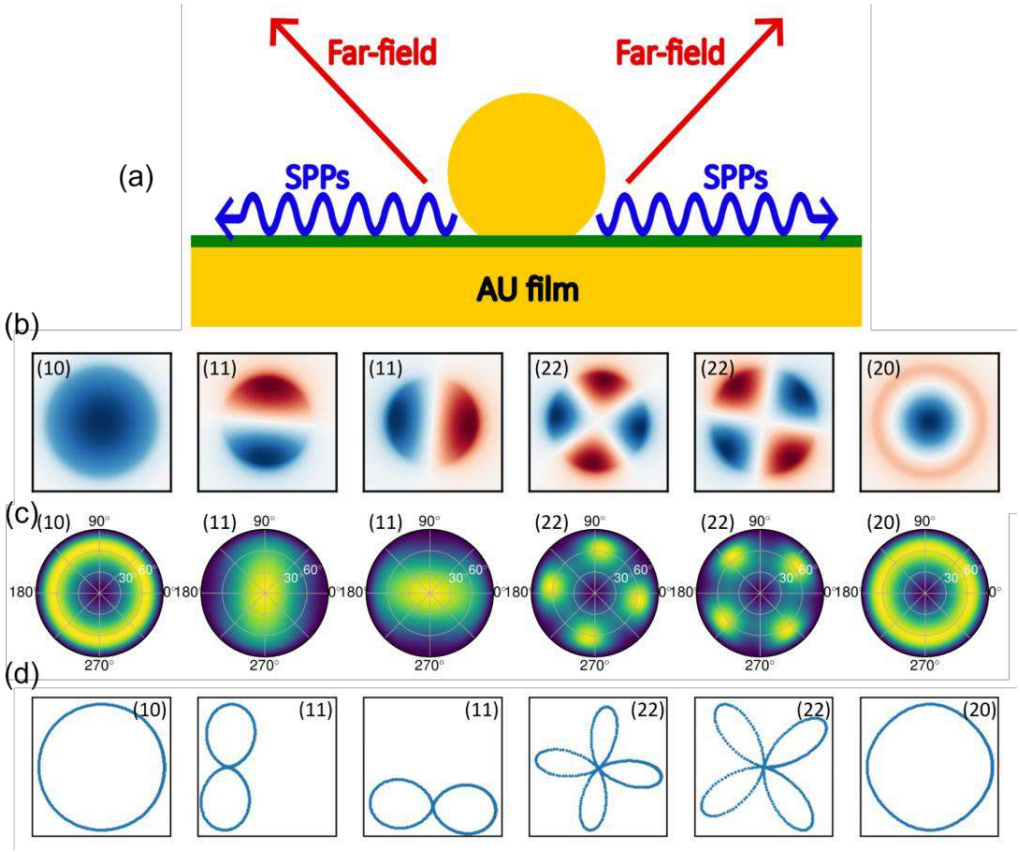

Figure 1: (a) NPoM geometry considered. (b) Normalized QNM electric fields E_z, (c) Normalized Poynting fluxes and (d) SPP radiation patterns of the first 6 QNMs.

In conclusion, we show using various methods that plasmonic nanocavities have two distinct components, a plane wave component that carries energy to the far-field and a propagating SPP component that is bound on the metal surface and dominates the nanocavity behavior.

Abstract: The frequency response of a resonator is governed by the locations of its quasi-normal modes (QNMs) in the complex frequency plane. The real part of the QNM determines the resonance frequency and the imaginary part determines the width of the resonance. For applications such as energy harvesting and sensing, the ability to manipulate the frequency, linewidth and multipolar nature of resonances is key. Here, we present a simple analytical tool to control the location and polarity of radially symmetric resonators.

Many photonic devices are composed of dielectric or plasmonic resonators. The spectral properties of a resonator are governed by its geometry and the material it is made from. In many applications, such as sensing, it is desirable to have a particular character of resonance occur at a particular frequency. Currently, however, the design of resonators to have specific spectral properties involves the exploration of large parameter spaces manually [1,2]. Here we build upon the results of [3] to develop a framework that can be used to design isotropic or graded radially symmetric resonators that exhibit specific multipolar resonances at specific frequencies.

Quasi-normal modes are the complex frequency bound states of a system, corresponding to poles of the scattering matrix. Motivated by the direct connection between the location of the quasi-normal modes in the complex frequency plane and scattering properties of a resonator, we derive a method to design resonators that support quasi-normal modes at specific complex frequencies. This allows us to control the resonance frequency and linewidth of modes simultaneously, as well as the multipolar characteristic of the mode. Our method is based on the insight of Chen et al. [4], who proposed that one could approach quasi-normal mode expansions by keeping k real, but extending the permittivity ε into the complex plane. We instead treat ε as a free parameter that can be chosen in order to place a resonance at a particular location. To do this, we begin from the 2D Helmholtz equation

$$\left(\frac{\partial^2}{\partial r^2}+\frac{1}{4\,r^2}-\frac{m^2}{r^2}+k^2\varepsilon(r)\right)\psi(r)=0,$$

where we have assumed a solution of the form $\phi(r,\theta)=\psi(r)e^{i\,m\,\theta}/\sqrt{r}$ to eliminate the first derivative. Splitting the permittivity into a spatially varying part and a background $\varepsilon(r)\rightarrow\varepsilon(r)+\varepsilon_b$, we can then formulate an eigenvalue problem for the background as

$$-\frac{1}{k^2}\left(\frac{\partial^2}{\partial r^2}+\frac{1}{4\,r^2}-\frac{m^2}{r^2}+k^2\varepsilon(r)\right)\psi(r)=\varepsilon_b\,\psi(r).$$

This allows one to choose a complex k value at which one would like a mode with polarity m to occur, then find a background permittivity that can be added to the initial structure so that it supports the desired mode.

It is important to note for this to be applicable to quasi-normal modes the boundary condition on the second derivative operator must be set to correspond to an outgoing wave at the edge of the resonator. This means that at $r = a$, where a is the radius of the resonator, $\phi \propto H_m^{(1)}(kr)$, which has the asymptotic form of a plane wave.

As an example of applying this framework, we consider a 2D circular resonator of initial permittivity of $\varepsilon = 4$ and radius a = 550 nm. This supports a dipolar (m = 1) quasi-normal mode at 97 - i 21 THz. For isotropic cylinders, one can find the locations of the quasi-normal modes using many methods: analytically using Mie theory, numerically by formulating the Helmholtz equation as a matrix with the appropriate boundary conditions, or using finite element solvers such as COMSOL. Each of these methods is shown in Figure 1a). To now *move* the dipole mode to 100 – i 1 THz, our framework can be applied to find that a background shift of $\varepsilon_b = -0.046 + i\,0.483$ will facilitate this. These results are shown in Figure 1.

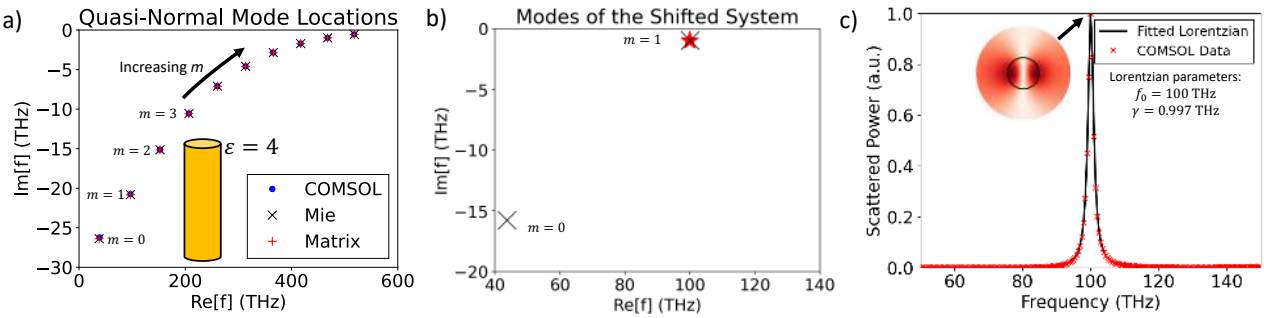

Figure 1 An example of using our framework to move the dipole resonance of a dielectric cylinder. a) the initial locations of all of the quasi-normal modes of a cylinder of permittivity $\varepsilon = 4$. The dipole (m=1) mode is at f = 96.8 – i 20.8 THz . Applying a background shift to the permittivity of the cylinder, calculated using our proposed framework, the new location of the m=1 mode is shown in b). The target frequency of 100 - i THz is shown as a red star. To verify that shifting the mode modifies the scattering behaviour of the resonator, we use COMSOL to calculate the scattered power under plane wave incidence as a function of frequency, shown in c). A clear peak is seen at the desired frequency, and with the correct width. The scattered field at 100 THz, shown in c) inset, verify that the scattering peak is indeed due to the re-located dipole mode.

Abstract: We reported the 6 nm spatial resolution for invisible-near IR (415nm-980nm) ultra-broadband near-field scanning optical microscope (NSOM). The NSOM provides two different channels to see the absorption and scattering spectroscopy at the same time. Using this super tool, we revealed a colorful nano-world on the sub-10nm scale. This is the first time that humans can "see" the carbon nanotube, which is well-known as one of the blackest materials, and find them colorful on the nanoscale.

Light is one of the most powerful and popular tools to interact with matters[1], such interactions are critical in quantum information processing, nano-lasing, spectroscopies, optical cavities, sensing, etc[2]. Light is also one of the most important mediums for humans to interact with the world. Light can be treated as a "ruler" to measure or see the world. However, light, especially in the visible region, has a wavelength ranging from 400 nm to 800 nm and it is too "long" to see the nanoscale world, and that is the diffraction limit[3]. One of the major tasks of the modern microscopy technique is increasing the spatial resolution by either enhancing the light-matter interaction strength or shrinking the dimension of the light source into sub-wavelength. Tip-enhanced probing techniques tried to enhance the near-field energy of light and shrink the hot spot to enhance the light-matter interaction, and the representatives include Tip-enhanced Raman Spectroscopy (TERS) and scattering-Scanning Near-field Optical Microscope (s-SNOM)[4]. Because of the requirement to filter out the large background noise, typically, interferometry is needed and thus the higher order or harmonic signal can give pure near-field signals. However, the direct signals (zero-order or first-order) signals provide much higher information and the s-SNOM cannot provide[5]. Alternatively, creating a nano-light source can intrinsically enhance the sensitivity and resolution of a microscope technique and achieve the zero-order signal. Principally, the color of light, which is determined by the frequency (*f*), is one of the intrinsic properties of photons and will not be changed in a linear process. Thus, the nano-focusing can compress the light but maintain its color. Here, we use the nano-focusing technique to compress the light volume into deep-sub-wavelength ($< \lambda/100$) and achieved the 1 nm resolution of Raman spectroscopy and 6 nm white light Near-field Scanning Optical Microscope (NSOM) absorption and scattering images[6]. To highlight that by using this super tool, we, for the first time, took a colorful picture of the single-walled carbon nanotubes (SW-CNTs), which are recognized as the darkest materials in the world. In addition, thanks to the super-resolution of both spectral and spatial, the chirality of CNTs can be distinguished from the CNT near-field color and the stress force stored in CNT can be mapped.

Figure 1 shows the details of the nano-focusing technique. Inspired by Otto's coupling configuration, which can provide up to 100% coupling efficiency to couple the light from free space into surface plasmon polariton (SPP) mode using a prism, we use the tapered single-mode optical fiber to replace the prism and couple the guided light into silver nanowire (AgNW)[7]. The light can be compressed by an adiabatic process into deep-sub-wavelength and be scattered from the sharp tip of the AgNW (Figure 1 b and c). By using this configuration, the nano-focusing efficiency was revolutionary and increased from 1%- 9% to 70%. By using this super tool, we achieved a 1 nm spatial resolution of TERS imaging in our previous work (see ref.). The configuration of the nano-focusing support ultra-broad band coupling as well. We used the normal LED, which just cost 1 dollar, to do the nano-focusing and achieved the ~5 nm focused white light source. Thanks to the ultra-confined white light source, the direct signal of bright field and dark field images are achieved with ~ 6 nm spatial resolution. To highlight that the spectral resolution is high as well, and thus it can be used to distinguish the chirality of CNTs (Figure 2b and c). This is the first time a human can direct see so small features with their intrinsic colors.

In summary, we used the nano-focusing technique to achieve colorful NSOM images with the highest-ever spatial resolution (6 nm). With this super tool, we took the first color pictures of the CNT.

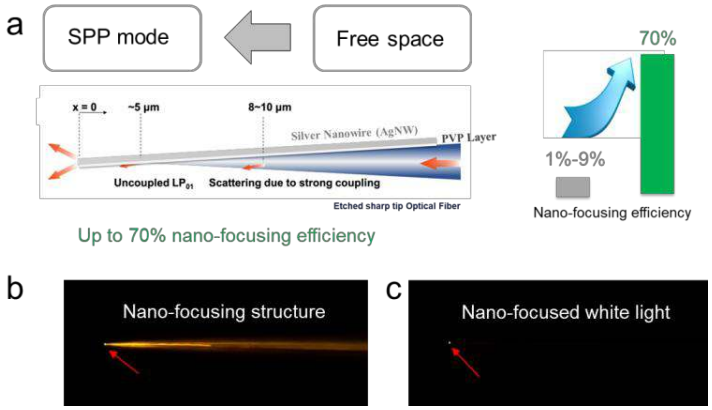

Figure 1. The details of nano-focusing. a) White light couple from a tapered single mode optical fiber into a sharp tip silver nanowire (AgNW) by Otto's coupling configuration. The nano-focusing efficiency was enhanced from 1%-9% to 70%. b) and c) show the nano white light source is scattered from the tip.

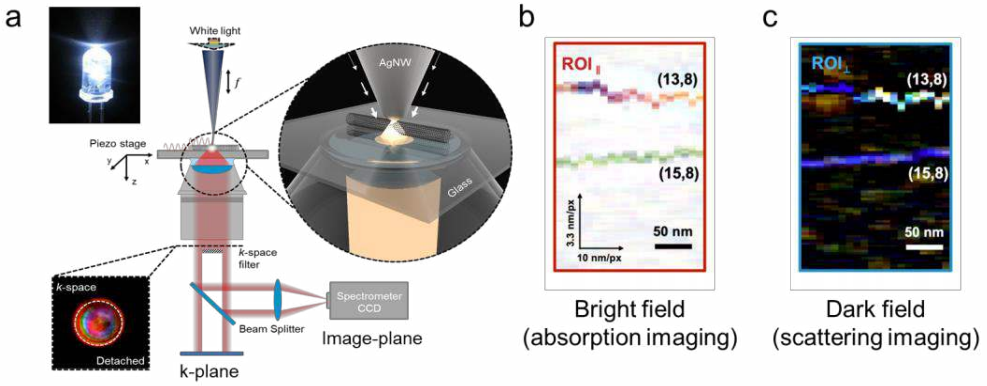

Figure 2. a) The configuration of the white-light NSOM setup. White light generated from the LED was compressed into a sub-wavelength hot spot and can interact with matters. By using a *k*-space blocker to filter out the undesired low-*k* light, the high-*k* signal with high resolution can be detected by the spectrometer in the image plane. b) and c) show the bright field and dark field of the near-field imaging to present the absorption signal and scattering signal, respectively. By using the reconstruction process, the colorful images of CNTs can be achieved.

Supersymmetric Reshaping and Higher-Dimensional Rearrangement of Photonic Lattices

Tom A. W. Wolterink*, Matthias Heinrich, and Alexander Szameit

Institute for Physics, University of Rostock, Albert-Einstein-Straße 23, 18059 Rostock, Germany

Abstract: Self-imaging J_x photonic lattices enable perfect imaging and coherent transfer of quantum and classical states, yet their large-scale implementation remains challenging. We harness supersymmetry to engineer compacted two-dimensional systems that exhibit imaging and state transfer characteristics equivalent to one-dimensional J_x lattices and experimentally investigate their dynamics.

Evolution dynamics of wave-mechanical systems are governed by the full set of their modes and their respective eigenvalues. The key task of transferring arbitrary excitation patterns between two specific planes can therefore be accomplished by an appropriate structure of the eigenvalue spectrum. Along these lines, self-imaging is particularly effective if the spectrum is equidistantly spaced, similar to that of the harmonic oscillator. In finite-size discrete systems, the so-called J_x lattice fulfils this condition and has been employed for the perfect coherent transfer of quantum and classical states [1–3]. Yet, implementing large-scale J_x arrays remains experimentally challenging, as this class of systems relies on a precise realization of a large number of different yet finely tuned nearest-neighbor interaction strengths spanning a substantial dynamic range. To overcome these limitations, we leverage the concept of supersymmetric (SUSY) photonics [4,5] and present a method to design families of compact two-dimensional equivalent systems that inherit the spectral and key dynamic features of one-dimensional J_x arrays while requiring dramatically fewer distinct coupling values [6].

Our approach iteratively applies discrete SUSY transformations to decompose the original Hamiltonian of a J_x array, resulting in a sequence of higher-order superpartners and isolated sites. This is followed by reattachment of these sites in a series of inverse SUSY transformation steps in the orthogonal direction, thereby constructing two-dimensional arrays. The two-dimensional structure and its original one-dimensional counterpart share all their eigenvalues and will therefore exhibit similar characteristics.

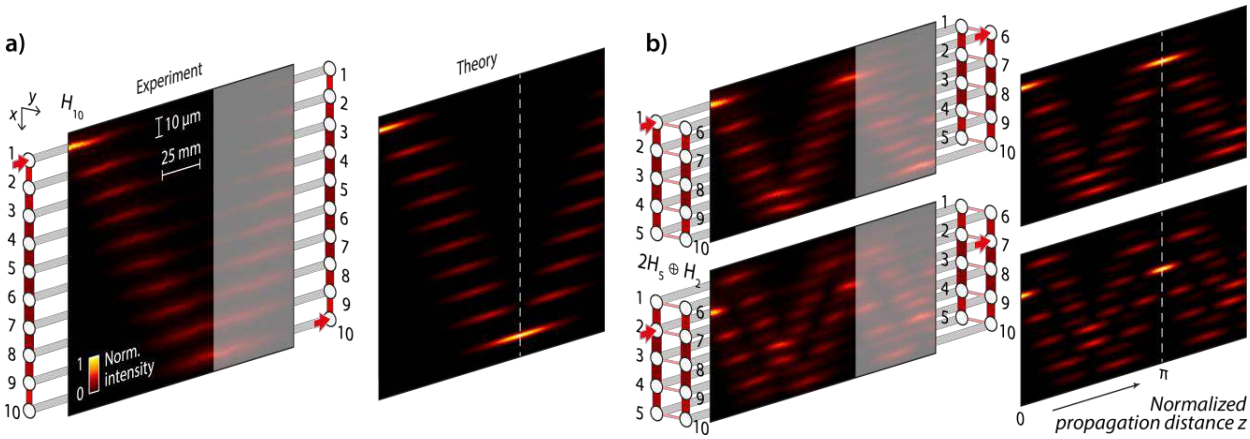

Figure 1. Measured (left) and calculated (right) evolution dynamics of light in a) a ten-waveguide J_x array and b) its two-dimensional superpartner. The initially excited and imaging target waveguides are marked by arrows. The imaging distance $z = \pi$ is indicated by semitransparent overlay (experiments) and dashed lines (simulations).

We experimentally realize these systems in arrays of evanescently coupled waveguides fabricated by femtosecond-laser direct writing and investigate their imaging properties by recording the intensity dynamics of guided light through fluorescence microscopy. We implement a conventional ten-waveguide J_x array and its two-dimensional superpartner of 5×2 sites. Figure 1 shows the observed light evolution for distinct input waveguides in each of these systems. We find that, while exhibiting systematically different dynamics in these two systems, light coalesces to the single target waveguide at the same imaging distance, demonstrating the desired perfect state transfer enabled by their identical spectra. In conclusion, our method readily allows for the design of compact self-imaging architectures with a minimum of structural parameters. By enabling increased robustness to perturbations and fabrication inaccuracies, it provides an avenue for high-fidelity coherence-maintaining state transfer in larger-scale photonic circuits.

Abstract: Quasi-dark states in optical metasurfaces has a significant impact on the control of electromagnetic fields at subwavelength scales. These exceptional states, resembling bound states, have resulted in unparalleled light enhancement and a dramatic increase in the quality factor under the resonance condition. This phenomenon has been recently employed for refractometric sensing and near-field imaging. In this study, we demonstrate a hybrid metasurface without inversion symmetry, revealing a quasi-bound state in the continuum with a remarkable field enhancement at subwavelength scales.

Metasurfaces have emerged as a promising synthetic material with a finite extended constituent [1]. In fact, this subwavelength depth characteristic has proven to be a viable option in several aspects, including reducing the usage of high-consumption materials and streamlining overall manufacturing procedures, as they do not require a deep anisotropic profile akin to photonic crystals and metamaterials. Recently, these planar structures have exhibited their ability to shape the wavefronts as one can tune the structure, which leads to the emergence of a diverse range of lenses with different focus [2]. Moreover, with the optimized structure, a light-matter enhancement through the emergence of a quasi-bound state in the continuum is observed, thereby providing a novel perspective on amplifying electromagnetic intensity at a subwavelength scale. Recently, the concept of bound states in the continuum has stimulated the interest of the quantum mechanics community, as it demonstrates the mathematical possibility of high-energy electrons in a quantum wall can exhibit a localized state, commonly known as a dark state [3]. The Schrödinger equation's all-encompassing nature has bestowed upon phenomenon with versatility and ease of implementation across various disciplines, including optics, acoustics, and mechanics. Non-radiative sources, in particular, have attracted great interest due to their capacity for confining light to a nanoscale dimension. This property holds immense potential for various applications, including light enhancement at nanoscale in dielectric material with near-zero energy dissipation, in contrary to their plasmonic counterparts. Thus, the strong light confinement based on the quasi-dark state generated on the metasurface has bolstered for enhanced near field imaging, and increase of the refractometric sensitivity of optical devices [4]. Here, in this work, we have proposed a hybrid metasurface that integrates a non-centrosymmetric dimer made of Indium Tin Oxide (ITO) deposited on a Silicon Dioxide (SiO2) substrate. The unit cell has a spatial period of $\boldsymbol{a}$ and a total thickness $\boldsymbol{T}$ defined as the sum of $\boldsymbol{h1}$ and $\boldsymbol{h2}$. A detailed geometric parameters can be found in Figure 1. We have obtained the transmission and reflection amplitude at the lower and uppermost parts of the structure. These results were prompted by the impingement of y-polarized light upon its uppermost region, indicates a manifestation of significant light-matter interplay with a quality

factor of 2.6×10^7. In Figure 2, the illustrations of the calculation of the electric field norm in both the far field and near field are presented, demonstrating a strong confinement of energy associated with the emergence of quasi-bound states in the continuum under the resonance condition.

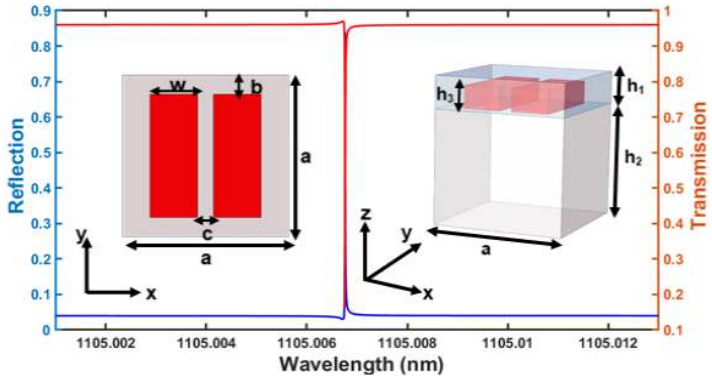

Figure 1: Schematic figure of the unit cell of our metasurface in 2D and 3D, with a variety of geometrical parameters, including: a = 750 nm, b = 95 nm, c = 70 nm, w = 210 nm, h1 = 200 nm, h2 = 700 nm and h3 = 140 nm. The transmission spectra (red curve) and reflection spectra (blue curve) of the quasi-bound state at the resonance.

Abstract: In this work an inverted plasmonic honeycomb lattice is studied by using state-of-the-art fabrication techniques, optical and electron spectroscopy, and simulations. The plasmonic lattice exhibits several bright and dark modes in the visible and near-infrared energy regime. Moreover, dark modes with anti-ferroelectric charge distributions that extent out of the unit cell of the honeycomb lattice have been experimentally found.

Plasmonic lattice nanostructures are of technological interest because of their capacity to manipulate light below the diffraction limit. Here, we present a detailed study of dark and bright modes in the visible and near-infrared energy regime of an inverted plasmonic honeycomb lattice by a combination of state-of-the-art Au+ focused ion beam lithography, optical and electron spectroscopy, and finite-difference time-domain simulations. The lattice consists of slits carved in an Au thin film, exhibiting a plethora of resonances in the visible and near-infrared ranges.

A detailed description of the charge distribution and near-field enhancement has been given by virtue of the good agreement between the electron energy loss spectroscopy (EELS) measurements, the optical measurements, and simulations. The most remarkable result is the finding of dark modes that may be caused by antiferroelectric arrangements of the slit polarizations, giving rise to charge arrangements with a unit cell four times larger than that of the original honeycomb lattice (see Figure 1b and 1e). Additionally, bright plasmonic modes exhibiting hotspots far from the metal slits are also found. The studied plasmonic resonances take place within 0.5 and 2 eV energy range, indicating that they could be suitable for a synergistic coupling with excitons in 2D transition metal dichalcogenides materials or for designing nanoscale sensing platforms based on near-field enhancement over a metallic surface. For example, the exciton energies for 2D WSe2 and MoS2 on an Au substrate, 1.75 and 1.9 eV, respectively [1], could be targeted by easily tuning manufacturing parameters such as the pitch of the lattice, thus changing the spectral position of the plasmonic resonances.

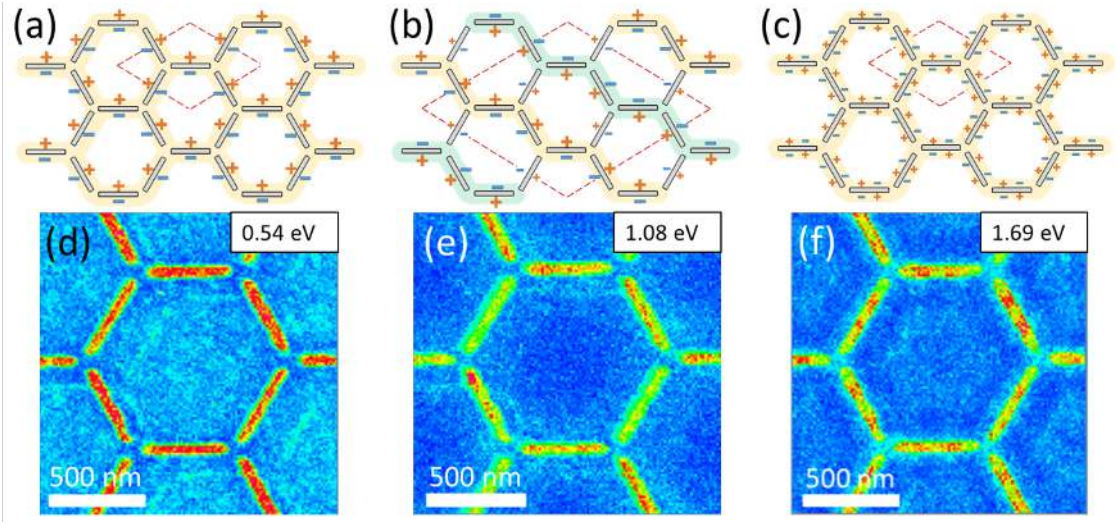

Figure 1. Plasmonic modes measured in the lattice at three different energies. (a), (b) and (c) show schematic representations of the charge distributions associated with one bright and two dark modes, respectively. Panels (d), (e) and (f) present the EELS mapping for the each of the modes depicted in the upper panels.

A Planar, NEMS-Based Terahertz Phase Shifter Using Subwavelength Confinement Waveguides

M. Demircioglu[1], M. A. Unutmaz[2], and M. Unlu[1*]

[1]TOBB University of Economics and Technology, Turkey

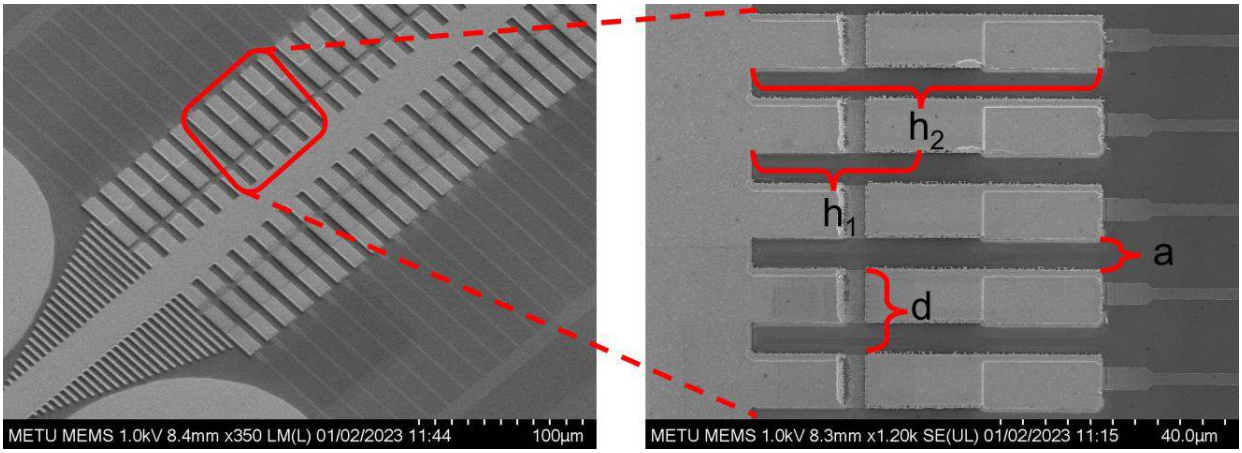
Abstract: In this paper, we present the Nano-Electro-Mechanical Systems (NEMS)-Based phase shifter using the Terahertz Subwavelength Confinement Waveguides (TSCW). The 90° phase difference is obtained from the OFF- and ON-states of the NEMS-based phase shifter at 0.29 THz. The measurement results of the 90° phase shifter show -4.79 dB worst-case insertion loss for the TSCW with 630 µm total length, which indicates the performances of 7.60 dB/mm and 18.8 °/dB.

The terahertz spectrum is an interesting frequency range for researchers due to the capabilities that are not achievable by the other spectrums, specifically the ultra-high data transfer rate supporting high-speed wireless communication [1]. There is an absolute necessity for compact, high-performance terahertz active and passive devices to enable high-speed communication [2]. Terahertz phase shifters are among the most required circuit elements for high-speed communication and currently have been worked on by many research groups [3]. TSCW have shown record-breaking degree per dB (°/dB) performance among all the planar terahertz phase shifters [4]. Nevertheless, they only presented theoretical records and did not present a real-time controllable phase shifters [5]. In this paper, we present the design, fabrication and the measurement of the Nano-Electro-Mechanical Systems (NEMS)-based 90° phase shifter using the Terahertz Subwavelength Confinement Waveguides (TSCW) operating at 0.29 THz. Combining the capabilities of NEMS and TSCW, a real-time controllable, miniature size and low-loss phase shifter is designed.

The NEMS switches have a perfect isolation during the OFF-state and good contact during the ON-state. The states can be controlled real-time by applying a DC voltage of 120 V. With the abilities of the TSCW, which is the effect of corrugation depth (h) on insertion phase, it provides a phase difference of 90° between the OFF- and ON-states.



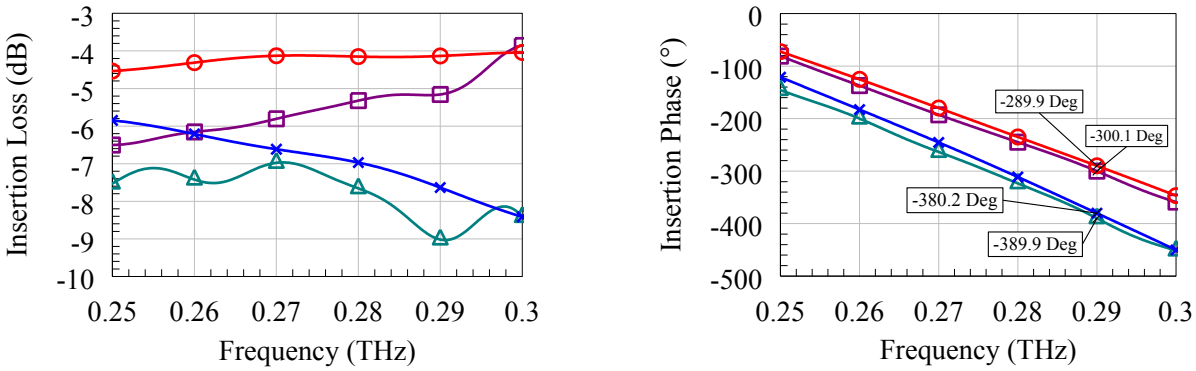


Figure 1. The SEM images of the fabricated NEMS-based phase shifters using TSCW.

Figure 1 shows the SEM images of the fabricated NEMS-based phase shifters. Corrugation depths (h_1), (h_2) show the corrugation depths of OFF- and ON-states and have 30 µm and 60 µm lengths, respectively. Additionally, the periodicity (d) and aperture width (a) are 15 µm and 5 µm, respectively.

(a) (b)

Figure 2. The insertion loss (a) and insertion phase (b) graphs for the comparison of the simulation and measurement results of OFF- (○), (□) and ON-states (x), (Δ) of the NEMS-based phase shifters, respectively.

In Figure 2, the comparison of simulated and measured S-parameter results of OFF- and ON-states are given. The simulation and measurement results exhibit a good match. The insertion losses of the OFF and ON-state are -5.16 dB and -9.02 dB at 0.29 THz. Extracting the back-to-back insertion loss of -4.23 dB, the worst-case insertion loss of -4.79 is obtained. For both simulation and measurement results 90° phase difference is obtained. The measurement results exhibit the performances of 7.60 dB/mm and 18.8 °/dB at 0.29 THz.

Abstract: We present active 3D-FDTD calculations of the field distribution and polarization of zinc oxide (ZnO) nanowires in the lasing regime coupled to dielectric cylinders. Significant coupling between nanowire and cylinder can be achieved, showing mode-specific resonance signatures when the cylinder diameter and refractive index are varied. By this modification of the nanowire lasing environment, we numerically demonstrate control of the polarization state of the lasing mode.

The lasing mode structure is calculated via the commercial FDTD software Lumerical, utilizing its built-in 4-level-2-electron system as an active lasing model. The gain profile is assumed to be spatially homogenous, which is a valid approximation when the nanowire is optically pumped in a quasi-static temporal regime. The nanowire is excited via a mode source placed perpendicular to the nanowire axis, which permits solving for different transverse field distributions. In prior work, this approach has proven useful for the study of the coupling between nanowire lasers and planar metallic substrates [1] as well as metallic gratings [2]. Here, a dielectric cylinder with a refractive index of n = 2.7 is placed close to the nanowire. Figure 1 shows a sketch of the investigated geometry. On a dielectric substrate (n = 1.4), two fundamental modes of perpendicular polarization, called the HE_{11x} and HE_{11y} modes, are excited separately and the average intensity in the cylinder is recorded and plotted in Fig. 2. Resonant coupling to whispering-gallery modes inside the cylinder is observed, independently of the nanowire size and refractive index.

In an active simulation, this knowledge is utilized by placing a nanowire on top of an aluminum substrate, separated from the nanowire by a small spacer. The nanowire is brought into contact with a cylinder tuned into resonance with the HE_{11x} mode, which would be the lasing mode if there were no cylinder. The HE_{11x} and HE_{11y} modes are excited simultaneously and the HE_{11y} mode is found to be lasing, contrary to the case where there is no cylinder. With this, it is proven possible to control the polarization of the lasing mode by placing a dielectric cylinder close to it. Since the resonance diameter of the cylinder is independent of the nanowire size, this approach paves the way towards deterministic, low-threshold excitation of Surface-Plasmon-Polaritons, which on perfect metals are surface modes mostly polarized perpendicular to the metal plane.

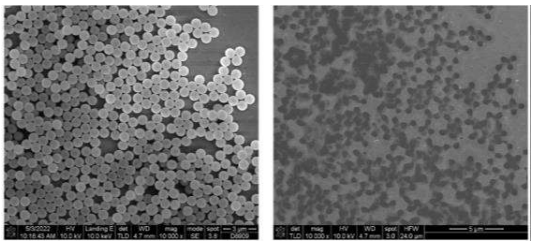
Abstract: This paper presents the initial tests regarding the development of the technology process necessary to obtain large sensitive areas based on plasmonic metasurface for low-cost fluorescent biosensors. The nanostructured surfaces are attained using polystyrene nanospheres lithography and lift-off, processes that do not require high manufacturing time or cost. The test showed that the presence of the metallic nanostructures increases the fluorescence of Rhodamine 6G dispersed in a 170 nm thick PMMA film.



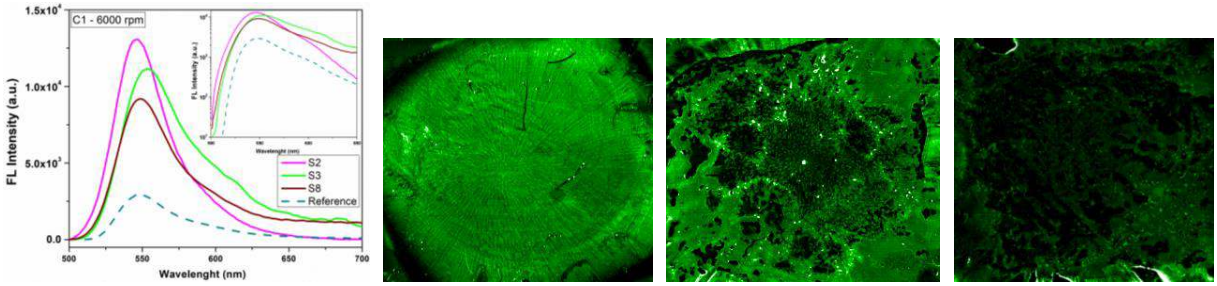
There is a constant need in the medical domain for reliable, fast and inexpensive methods for diagnostics and imaging [1]. Florescence biosensors based on metasurface structures are one of the best solutions [2]. Our aim is to develop a low-cost process suitable for large-scale fabrication of plasmonic nanostructures used to improve fluorescent emission. The process we propose allows the fabrication of metasurface platforms based on silver nanostructures on silicon obtain using polystyrene lithography and lift-off. We employed different deposition methods (spinning/droplet/immersion) and diameters for the polystyrene nanospheres (PSn) (Tabel 1) to determine the best uniformity which offers an optimal distribution of the metallic nanostructures, and consequently a significant fluorescence improvement. The silicon substrate was immersed in an aqueous based priming agent (SurPass 4000) for 2 minutes to maximize the adhesion properties, and PSn (water solution 2.5 wt%) were functionalized in a methanolic solution of Triton-X (1:400).

Table 1. Technological parameters employed in the substrate preparation and PSn deposition

No.	Substrate Functionalization	PSn deposition	PSn	No.	Substrate Functionalization	PSn deposition	PSn
S1	SurPass 4000	Spinning	880 nm	**S5**	SurPass 4000	Spinning	700 nm
S2	SurPass 4000	Spinning	940 nm	**S6**	SurPass 4000	Droplet	700 nm
S3	SurPass 4000	Spinning	700 nm	**S7**	SurPass 4000	Immersion	700 nm
S4	SurPass 4000	Spinning	850 nm	**S8**	-	Droplet	450 nm

*SurPass 4000 is an advance aqueous based priming agent which provides maximum adhesion to a wide range of substrate materials [3].

Figure 1 presents the SEM micrographs of structure S3 after silver deposition (Figure 1a) and after lift-off (Figure 1b). To investigate the improvement of R6G fluorescent intensity due to the presence of the metallic nanostructures, we deposited on top of the metasurface a 170 nm thick Rhodamine 6G (R6G) dispersed in polymethylmethacrylate (PMMA) film with a concentration of 50 µM. A fluorescence spectrometer FLS920 (Edin. Inst. Ltd, UK) was employed to perform steady-state photoluminescence emission. The excitation of $\lambda = 480$ nm was used to measure the emission/fluorescence intensity of the samples. Figure 2a shows the FL intensity spectra consisting of an emission band around 550 nm specific to the R6G thin films.



a) b)

Figure 1. SEM micrographs of S2 structure obtained: a) before lift-off; b) after lift-off

The results show a promising intensity improvement with a fluorescence enhancement factors (FLEN) between 3.1 (S8) and 4.5 (S2) (Figure 2a), depending on the distribution of the polystyrene spheres on the surface.

Also, samples' fluorescence was detected using a laser scanning confocal fluorescence system (GeneTAC UC4 Microarray Scanner, Genomic Solutions), by scanning the dices with Cy3 (532 nm) excitation laser. Figure 2 presents the images of the best samples (Figure 2b - S2 and Figure 2c - S3) and the faintest one (Figure 2d - S8).

a) b) c) d)

Figure 2. Fluorescence intensity: a) enhancement for different metasurfaces obtained on **Si** substrate; and images obtained with a laser scanning confocal fluorescence system: b) S2; c) S3; d) S8.

The results demonstrate that we can achieve a promising FLEN for R6G fluorophore up to 4.5 folds, depending on the distribution of PSn and the deposition method, and that these types of metasurfaces are useful in various biosensing applications. Our next steps are to optimize both the functionalization parameters and the deposition parameters of the polystyrene nanoparticles by employing different ratios of polystyrene solution and surfactant for the functionalization of the PSn, and deposition by progressive spinning with several steps, and also to investigate the FLEN for fluorophores with quantum efficiencies lower/equal to 0.5, (e. g.: Rose Bengal, Coumarin 153, Nile Blue, Oxazine Perchlorate 1, Crystal Violet, IR-140).

Single-shot mapping of the second harmonic 3D radiation pattern by harmonic holography

S. Goldmann[1*], S. Grésillon[1], I. Izeddin[1], G. Tessier[2] and Y. De Wilde[1]

[1] Institut Langevin, ESPCI Paris, Université PSL, CNRS, 75005 Paris, France

Abstract: Digital holography is an imaging technique which measures both the amplitude and phase, from which the 3-dimensional electromagnetic field scattered objects can be reconstructed by digital propagation. Since Second Harmonic Generation (SHG) is a coherent process, SHG light can be used to generate interferences and holograms. We apply SHG holography to nonlinear nanostructured samples made of dielectrics or metals to obtain single-shot measurements of their second harmonic 3D radiation pattern and to map intensity and phase variations near the sample.

Digital holography is an interferometric imaging technique which can measure both the optical amplitude and phase. A digital back-propagation of this field therefore allows a 3-dimensional reconstruction of the electromagnetic field scattered by an object. We demonstrated its use in linear mode in off-axis digital holographic microscopy for the full 3-D mapping of the field scattered by single nanostructures such as nano-antennas [1] and near-field probes [2]. Since holography is an interference-based method, it can be performed at the laser illumination wavelength, but also with second harmonic generation (SHG), since the latter is a coherent process [3,4].

Here, we describe the development of a harmonic holographic microscope to map the second harmonic 3D radiation pattern in the vicinity of samples with non-zero second harmonic susceptibilities in one single-shot acquisition.
The knowledge of the scattered field (amplitude and phase) in a given plane (that of the camera) allows its reconstruction in any other plane using e.g. the angular spectrum representation of optical fields [5], and assuming propagation in homogeneous media, a process called 3D numerical back-propagation [6].

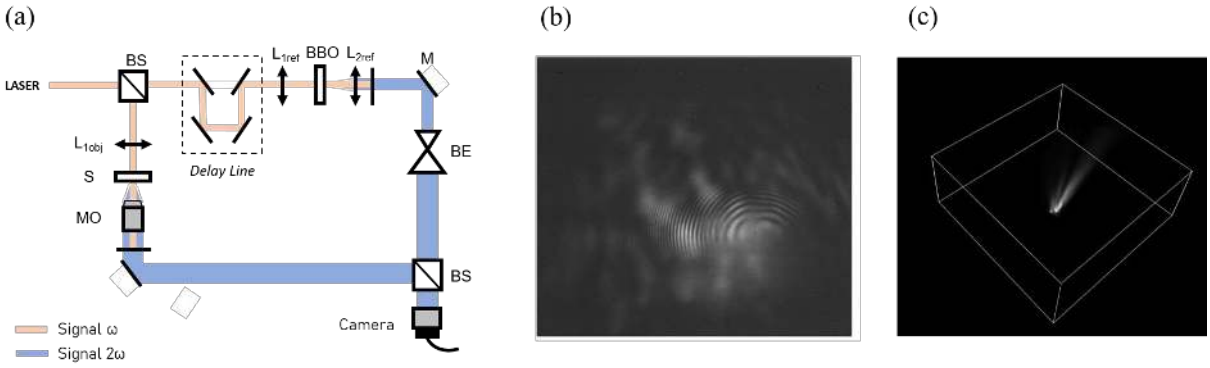

Fig 1.(a) Experimental setup schematics : BS, beam splitter ; L, lens ; MO, microscope objective ; BE, beam expander ; M, mirror ; BBO, beta-barium borate crystal ; S, sample (b) Hologram (c) 3D Reconstruction of the SH generated by a small (a few μm) BBO crystal.

In addition to providing 3D reconstruction, thus enhancing the imaging capabilities beyond those of back focal-plane imaging, the harmonic holography microscope also benefits from an amplification effect [7] since the signal from the sample is multiplied by an intense reference in the interference term, making the method particularly well suited to measure the weak SHG signals produced by metallic nanostructures [8]. The technique also benefits from the laser's short coherence length, which is 10 micrometers only with the 100 fs- source we use. The resulting coherence sectioning enables to proceed to a tomographic mapping of the sample.

After a first validation on dielectric samples made of nonlinear micro-crystals and cornea collagen, we are currently implementing it to unravel the SHG field radiated by plasmonic nano-antennas.

The authors are very grateful to Marie-Claire Shanne-Klein for stimulating discussions regarding SHG microscopy. This research is supported by the French National Research Agency (ANR-20-CE24-0021), and LABEX WIFI under references ANR-10-LABX-24 and ANR-10-IDEX-0001-02 PSL*.

Spectral Control of Plasmonic response and Spontaneous Emission Reinforcement from Quantum Dot near Nanoplasmonic Structures

R. Choudhary[1], and S. K. Srivastava[1,2*]

[1]Departmrnt of Physics, Indian Institute of Technology Roorkee, Roorkee-247667,India
[2] *Center for Photonics and Quantum Communication Technology*, *Indian Institute of Technology Roorkee,* Roorkee, *India*

Abstract: We show that the tuning of geometrical parameters of nanoplasmonic structures changes not only the electric field enhancement and plasmonic response but also the spontaneous emission. Spontaneous emission increases due to interaction between the quantum dot (QD) and the localized electric field in its vicinity. The spontaneous emission rate enhancement of the quantum dot follows plasmonic response of the nanoplasmonic structures. Thus, modified emission rate leads these nanostructures to have potential applications in sensing, integrated photonics, and solar energy conversion.

The coupled hybrid systems consisting of quantum dot and plasmonic nanostructures have been of interest for decades [1]. The plasmonic nanostructures confine the light below the diffraction limit [2]. Coupling between the quantum dots and localized plasmonic resonances in the nanoplasmonic structures leads to an increase in the emission rates of the quantum dots [3]. The electromagnetic near-field confinement due to localized plasmon resonance (LSPR) can lead to enhancement of the Purcell factor and thus plasmon enhanced Fluorescence (PEF) [4]. The Purcell factor is defined as the ratio between the modified (Γ_g) and free-space emission rates (Γ_0) of the quantum dot, given by [5]

$$F_P = \frac{\Gamma_g}{\Gamma_0} = \frac{3\,Q\left(\frac{\lambda}{n}\right)^3}{4\pi^2 V_0} \quad with\ V_0 = \frac{\int \varepsilon |E|^2\, dr}{\max\left(\varepsilon |E|^2\right)} \tag{1}$$

Where n is refractive index of the host medium, λ is the wavelength, Q is the quality factor of the cavity mode and V_0 is its volume.

In this work, we employed a commonly used method to calculate the Purcell factor of quantum dot put exactly at the center of the nanoparticle (NP) dimer cavities. We show that due to the localized field in the vicinity of plasmonic dimer cavities, the peak of extinction cross-section changes with the shape (sphere, cube, nanorod) and size of the plasmonic cavities leads to change the spontaneous emission rate of the quantum dot.

The schematics of plasmonic NP dimer cavities of different shapes (sphere diameter =60 nm, cube side =60 nm, nanorod length =60 nm) has been shown in Fig.1(a-c) with interparticle gap d taking surrounding medium as air. In Fig.1(d), the normalized extinction cross-section has been plotted as a function of the incident energy for each shape of the nanoparticle dimer. The resonance wavelength of plasmonic dimer cavities sphere, cube and nanorod were 532, 585, 577 nm respectively. We have optimized the spherical NP dimer for PEF based sensing application at excitation wavelength of 532 nm. The Purcell factor of the quantum dot placed at the center of the optimized plasmonic cavity (diameter=60 nm and d=6 nm) has been calculated using equation (1). A scattering resonance with Q=7.04 occurs near λ =542 nm, with 1350 times $|E|^2$ enhancement polarized along the dimer axis for the spherical NP dimer. Purcell analysis predicts a Purcell factor F_p~874. In Fig.1(e, f), the electric field profiles for spherical nanoparticle dimer have been shown at the excitation wavelength 532 nm both in absence and presence of a quantum dot (point dipole). As can be seen from Fig.1(e), the hotspot is generated between the

nanoparticles. This leads to an increase in the spontaneous emission rate of the point dipole.

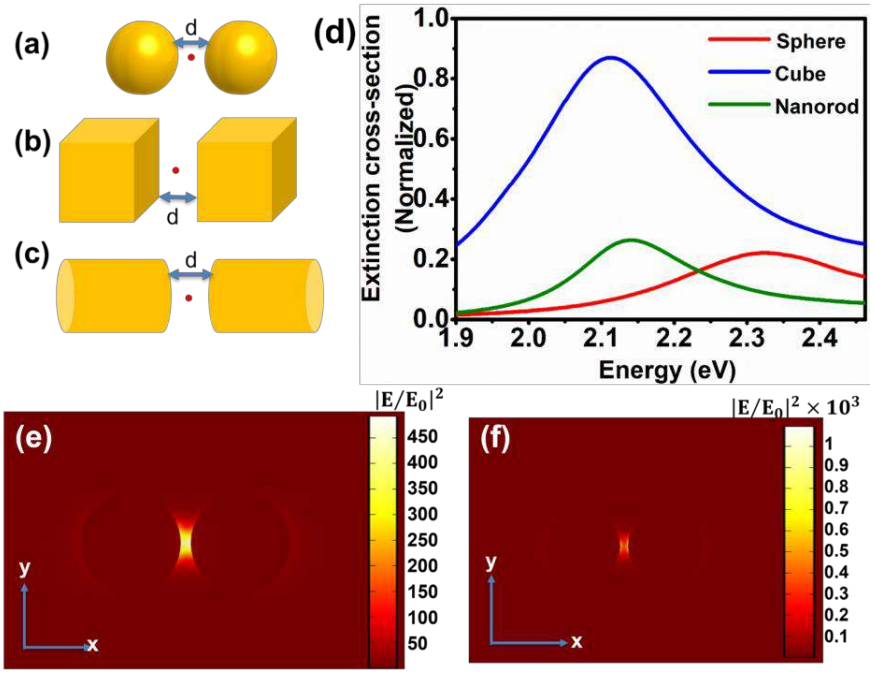

Fig.1.The schematics of the plasmonic dimers with quantum emitter (a) sphere, (b) cube, (c) nanorod respectively (d) Normalized extinction cross-section. The Electric field profiles at wavelength 532 nm in the (e) absence and (b) presence of quantum emitter (point dipole) for spherical dimer of diameter =60 nm, gap d=6 nm.

In conclusion, we have simulated plasmonic dimer cavities of different shapes (sphere, cube and nanorod) with quantum dot placed at the center. The resonance wavelength corresponding to peak extinction cross-section changes from 532 nm to 585 nm. We have optimized the spherical NP dimer cavity at the excitation wavelength of 532 nm for PEF based sensing applications. The Purcell factor F_p~874 was calculated for optimal parameters (diameter =60 nm, gap d=6 nm) for spherical NP dimer cavity.

Abstract: Thin and tiny metasurface-based flat optics based on exciton resonances can be used as the replacement for bulky optical elements to develop tuned nanophotonic structures. We present that the optical response of this type of metasurface can be enhanced by improving the photoluminescence properties of their semiconducting building blocks made of a MoS_2 monolayer by their treatment using an atomic hydrogen beam source.

1. Introduction

Metasurfaces are two-dimensional (2D) versions of metamaterials with impressive abilities to control their electromagnetic response by a properly designed flat structure consisting of specific sub-wavelength resonant scatterers. Metasurfaces with tailored wavefronts find applications at frequencies ranging from microwaves to UV, namely metasurface lenses, antennas, and optical devices (e.g., lidars, non-linear modulators) and sensors [1]. Localized surface plasmon resonances (LSPR) are caused by collective oscillations of electrons in metallic nanostructures – sub-wavelength elements, e.g., Au, Ag antennas [2], [3]and thus, naturally, their performance is hindered by strong dissipative losses (heating) in these elements. These detrimental effects are not present in Mie-type resonances [1], [4], but with LSPR–based metasurfaces, those utilizing Mie resonances show up limitations in the electrical tunability of their functionalities. With this respect, the utilization of exciton resonances represents a promising method for overcoming this problem [4]. Unlikely to bulk materials, excitons (i.e., coupled electron-hole pairs) in some 2D semiconductor materials dominate in the optical properties even at room temperature. However, a light-matter interaction with atomically thin materials such as transitional metal dichalcogenides (TMDCs) is generally weak. On top of that, even though 2D TMDCs should show more powerful photoluminescence (PL) ability in contrast to bulk counterparts, in reality, they exhibit poor luminescence quantum yield (QY) due to the defect-mediated nonradiative recombination and biexcitonic recombination at higher excitation powers. However, 2D TMDCs are generally known to be amenable to defect surface passivation by a chemical treatment using (bis(trifluoromethane) sulfonimide (TFSI)) [5] or, as we propose, by their treatment via a home-built atomic hydrogen beam source (expected QY ≥ 60% - more than 100-fold increase). Naturally, it would open ways for novel applications of metasurfaces not achievable so far. In this presentation, we report on an improvement of PL properties of a TMDCs material, namely MoS_2. Consequently, we will present the results on patterning of nanoflakes by electron beam lithography and dry etching (plasma treatment) to get an assembly of sub-wavelength building blocks of a metasurface flat optics for the dynamic wavefront control of optical beams.

2. Nanofabrication

We have prepared MoS_2 monolayered flakes by mechanical exfoliation from a bulk crystal, and they were

transfered on a fused quartz substrate. After that, we have treated the samples by a home-built atomic hydrogen beam source to verify this method for enhancement of PL properties (QY) of these flakes. Consequently, the patterning of flakes to fabricate a metasurface-based flat optics using electron beam lithography (EBL), reactive ion etching (RIE), and flake protection by a resist film (e.g., polymethyl methacrylate, PMMA) was done (Figure 1).

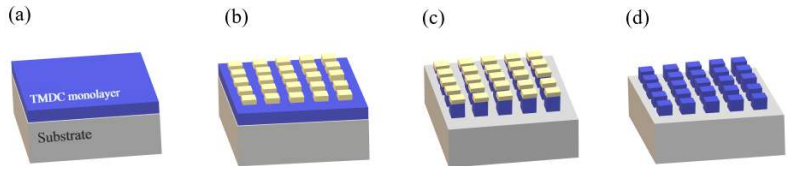

Figure 1. Nanofabrication process (patterning). (a) TMDC monolayer on a substrate (not-to-scale drawing), (b) PMMA (yellow) patterned using EBL on top of the TMDC (c) TMDC etched by RIE, (d) patterned TMDC after removing PMMA in acetone.

3. Results and discussion

The results of the MoS_2 treatment are shown in Figure 2. One can see the PL enhancement was 2-fold. This value can certainly be increased by optimization of process parameters (e.g., better aiming of the beam, proper flux density, and exposure time). Generally, the optical quality of commercially available MoS_2 flakes prepared by a CVD method is notably poorer compared to the exfoliated ones. Hence, one can anticipate a more significant improvement of in PL after the application of hydrogen atoms to them.

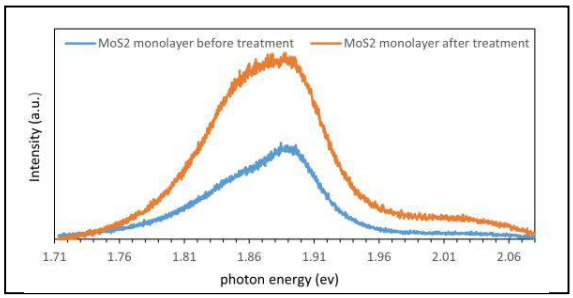

Figure 2. PL spectrum for MoS_2 monolayer before and after atomic hydrogen source treatment

4. Conclusions

We have proved that the proposed method based on the application of the atomic hydrogen beam source is capable of improving the PL of MoS_2 monolayers. In the next step, larger, commercially available MoS_2 flakes prepared by a CVD method will be tested for this method and, consequently, patterned by EBL, this would open the way to a design of more efficient metasurface devices based on atomically thin 2D layers.

Abstract: Nanosphere lithography (NSL) is a straightforward, cost-efficient technique for creating plasmonic nanostructures with high precision. This work reviews the challenge of the NSL mask preparation by spin coating. The process parameters to achieve large, well-ordered monolayer areas covered by polystyrene (PS) nanoparticles with a diameter of 400 nm over a glass substrate are discussed. The results reveal that the surface coverage increases with decreasing spin velocity and acceleration in a certain range.

Nanosphere lithography (NSL) has been used in various applications like bio/chemical sensors and light trapping in solar cells or spectroscopy [1]. Within the range of methods used for NSL, spin coating stands out for its effectivity, fastness, and flexibility in controlling the process [2]. However, the uniformity and compactness of the nanospheres depend on several interdependent parameters, and finding an optimal recipe is still a challenge [3]. This work aims at revealing the influence of spin acceleration and velocity on the mask prepared by NSL.

For this purpose, a solution of 4% weight of polystyrene (PS) nanospheres (purchased from Thermo Fisher Scientific) is deposited onto 2.5 x 2.5 cm^2 glass substrates via spin coating (WS-650Sz-23NPP Lite Single Wafer Spin coater). The substrates are pre-treated with a series of ultrasonication baths (in acetone, ethanol, and de-ionised water for 15 minutes each) followed by rinsing in ethanol to increase the wettability of the surface. The substrates are then dried with nitrogen flow. After the substrate cleaning, drops of 100 µl of the dispersed suspension are pipetted over the surface of the substrate and accelerated to specific spin velocities for 2 min. The samples are covered with gold by thermal evaporation and are analyzed by scanning electron microscopy (FEI Nove NanoSEM 200). In the first series of experiments, the spin velocity is varied while the spin acceleration is fixed at 200 rpm/s. In the second series of experiments, the spin acceleration is varied at a fixed spin velocity of 6000 rpm.

The optimal velocity is found at the lowest value (4000 rpm), at which nanospheres assemble and form large domains of well-ordered and compacted nanosphere arrays (figs. 1a,d). At a higher velocity (6000 rpm), the self-assembling of the nanospheres is weakened, leading to distorted and non-compacted areas as well as a sharp decrease in the total surface coverage (figs. 1b,e). Increasing the velocity further (8000, 10000 rpm) leaves a high percentage of the sample uncovered. At these high values, the nanospheres are mainly agglomerated at some impurities, forming small islands, in which we find some compact and uniform hexagonal nanosphere arrays (figs. 1c,f).

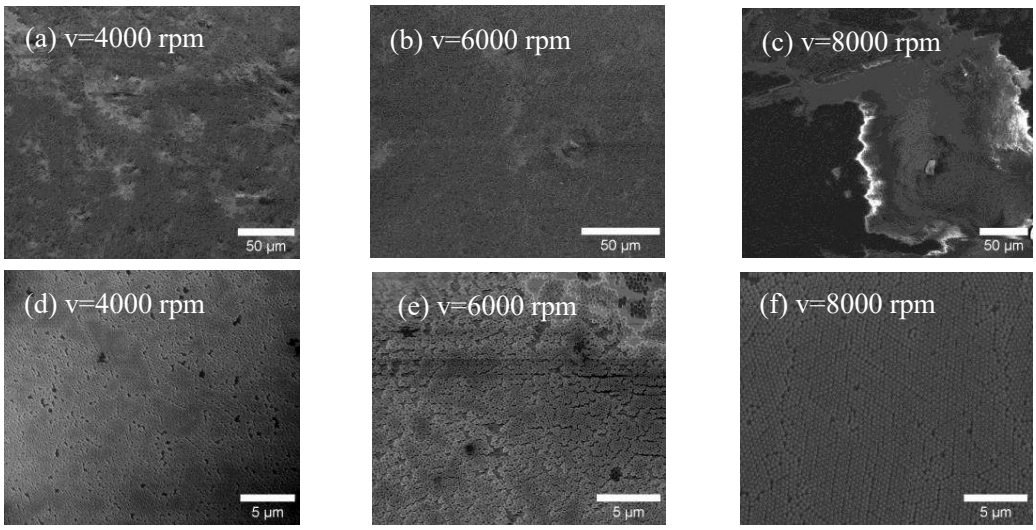

Fig. 1: SEM images of nanostructures obtained at different spin velocities: (a-c) at low magnification (d-f) at high magnification.

Considering the spin acceleration the highest total surface coverage is achieved at the lowest acceleration of 200 rpm/s while lower surface coverage is observed with increasing acceleration value (600 rpm/s, 1000 rpm/s) (figs. 2a,b).

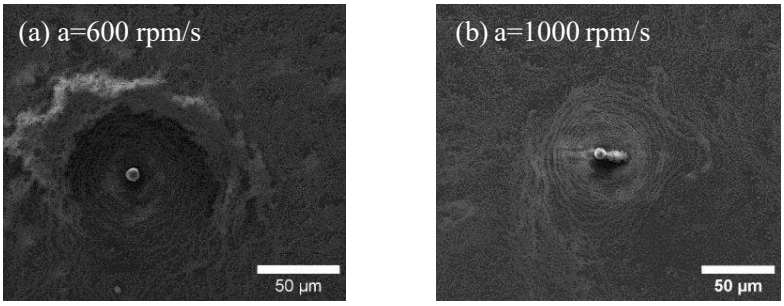

Fig. 2: SEM images of nanostructures obtained at different spin accelerations with low magnification.

In summary, spin coating at low spin velocities and accelerations is preferred to form a large hexagonal compacted nanosphere arrays. However, there is a need for fine-tuning the spin parameters for NSL.

Size-dependent Localized Surface Plasmon Resonance of Structures Prepared by Nanosphere Lithography

Milad Karami[1,2*], Lu He[1,2], Teresa I. Madeira[1,2], and Dietrich R. T. Zahn[1,2]

[1]Semiconductor Physics, Chemnitz University of Technology, D-09107 Chemnitz, Germany

Abstract: Nanosphere lithography (NSL), which is used to generate ordered two-dimensional periodic arrays of plasmonic nanostructures, is an inexpensive, versatile, intrinsically parallel, and high-throughput nanofabrication technique [1]. Localized surface plasmon resonances (LSPRs) produced by MNPs offer essential application opportunities in photonics, electronics, and nanotechnology [2]. The LSPR can be tuned by different methods, where changing the geometry of metal nanoparticles (MNP) provides a very diverse approach. We systematically studied the geometry dependence on LSPR produced by polystyrene beads of various sizes.

For the preparation of nanosphere monolayers a colloidal solution is first created by mixing ethanol and polystyrene nanospheres in a 1:1 volume ratio and then ultrasonicated for 10 minutes. A glass slide is then washed using acetone, ethanol, and water, followed by drying with N_2 gas to create a hydrophilic surface. Subsequently, a petri dish is filled with distilled water to facilitate the deposition of 10 µL of colloid dispersion onto the glass slide. As a result of the interfacial tension between the liquid and air, the colloid particles self-assemble into a monolayer at the water-air interface, as illustrated in Figure 1. Finally, the glass substrate is gently lifted to retrieve the monolayer of polystyrene nanospheres.

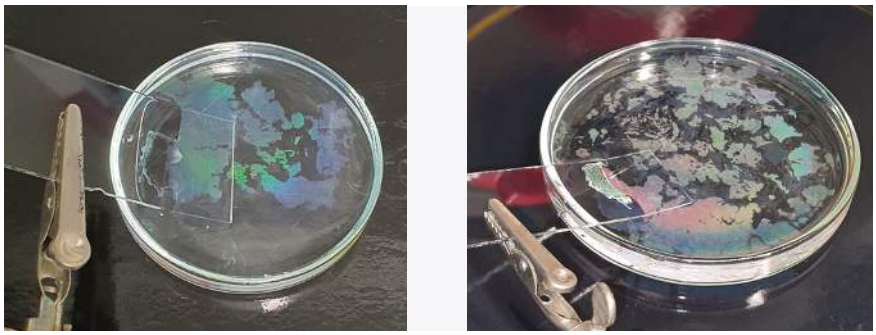

FIG. 1. Images of colloidal film at the water-air interface.

Scanning electron microscopy is used to analyze the geometry of the structures after deposition of approximately 50 nm gold layer [3]. Figure 2 displays the typical formation of monolayer of self-assembled nanospheres with a diameter of 200 nm (left) and 400 nm (right). The 200 nm nanosphere size (left) leads to well-ordered hexagonal close-packed (hcp) structures of nanospheres with some impurities. For 400 nm nanosphere size (right), the nanospheres are arranged in well-ordered hcp structures with some stacking faults.

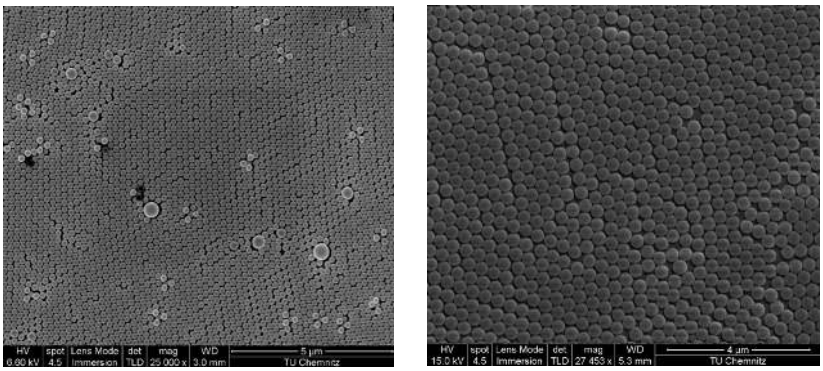

FIG. 2. SEM images of gold covered 200 nm (left) and 400 nm (right) polystyrene spheres on glass.

Theoretically, the size of the Au nanotriangles, a, which are obtained on the substrate after removing the nanospheres is directly related to the size of the polystyrene nanospheres (D) by the following expression [1,4]:

$$a = (3/2)\,(\sqrt{3} - 1 - 1/\sqrt{3})D = 0.233D \quad (1)$$

In Figure 3, the transmittance spectra for gold nanotriangle arrays fabricated using the polystyrene nanospheres are presented. The reference transmittance spectrum corresponds to the glass substrate. Examination of the spectra demonstrates that the localized surface plasmon resonance (LSPR) for a 400 nm nanosphere size occurs at 1.65 eV, while for a 200 nm size, it is observed at 1.85 eV. This finding provides evidence for the correlation between the size of the Au nanostructure and the LSPR energy, where smaller structures lead to higher LSPR energy.

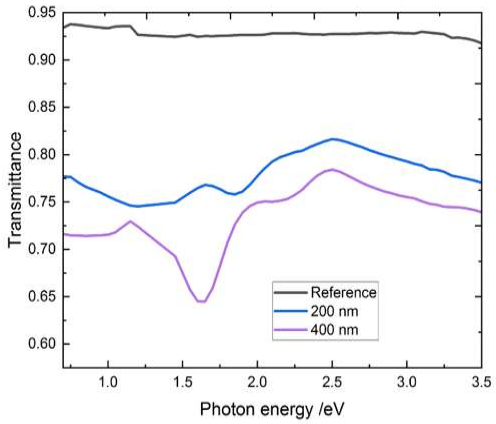

FIG. 3. Transmittance spectra of gold (Au) nanotriangles on glass as a function of polystyrene nanosphere size.

Our findings demonstrate that the localized surface plasmon resonance (LSPR) of the plasmonic nanostructures can be changed through the utilization of polystyrene nanospheres of varying sizes. This outcome holds significant potential for applications that necessitate a tunable resonance wavelength, as it enables tailored optimization of the LSPR properties to suit the specific requirements of the given application.

Abstract: We report asymmetric tuning of nanogap resonance between gold nanoparticles (Au NPs), deposited on anisotropically stretchable polydimethylsiloxane (PDMS) for directional strain sensing. The alternate high and low Young's modulus PDMS line patterns induce anisotropic Poisson's effect (0.45 to 0.61), resulting in direction-dependent plasmon resonance between the Au NPs. For the light polarized perpendicular to the stretching direction, the maximum absorbance peak shift of ~90.85 nm and ~39.13 nm is achieved for $\theta = 0°$ and $\theta = 90°$ direction, respectively.

Localized and coupled plasmon resonance based on metallic nanoparticles has been investigated thoroughly for promising applications in color filtering and sensing [1]. The coupled plasmonic resonance resulting in distinctive colors depends on several parameters, such as materials, their arrangement, interparticle distance, and the nanostructure's geometry [2]. Among these parameters, the mechanical substrate can reversely tune the interparticle distance [3]. However, multidirectional and broadband resonance tuning is hard to achieve based on conventional isotropic mechanical substrates. We propose a highly directional and polarization-sensitive coupled plasmon resonance between the Au NPs deposited on an anisotropic line pattered PDMS substrate with alternate high and low Young's modulus (Fig. 1a(i)). The deposited Au NPs (diameter of ~20nm) on anisotropic PDMS exhibit localized resonance initially. Meanwhile, its size was grown hydrothermally up to the diameter of ~36 nm to reduce distance between the NPs until the coupled resonance was achieved, as shown by the SEM image (inset of Fig. 1a(i)). The alternate high and low modulus line patterns of PDMS induce anisotropic Poisson's effect (width change $W_{\perp}$ perpendicular to stretching direction), which is verified using COMSOL simulations (Fig. 1a(ii)). These results show a considerable change in $W_{\perp}$ when stretched parallel to patterns ($\theta = 0°$) compared to the stretching perpendicular to the patterns ($\theta = 90°$).

When the external force is applied in $\theta = 0°$, it sharply decreases the interparticle distance between the Au NPs (Fig. 1b) along the perpendicular direction to the stretching due to high Poisson's effect. Consequently, it enhances the coupled resonance, and the maximum absorbance peak shifts from 539 nm to 629 nm as the force intensity increases from 0 N to 1.3 N for linearly polarized light perpendicular to the stretching direction. In contrast, when force is applied in $\theta = 90°$ direction, the interparticle distance is not significantly reduced perpendicular to the stretching direction since the high modulus PDMS patterns hinder the width W change$_{\perp}$ (low Poisson's ratio). This results in a comparably minor peak shift of ~39.13 nm in a range of 539 nm to 578 nm for the light polarized perpendicular to the stretching direction. Our proposed plasmomechanical structure shows a visible color shift to distinguish the deformation direction as well as the intensity of applied force which can have a significant impact in the field of wearable and stretchable sensors.

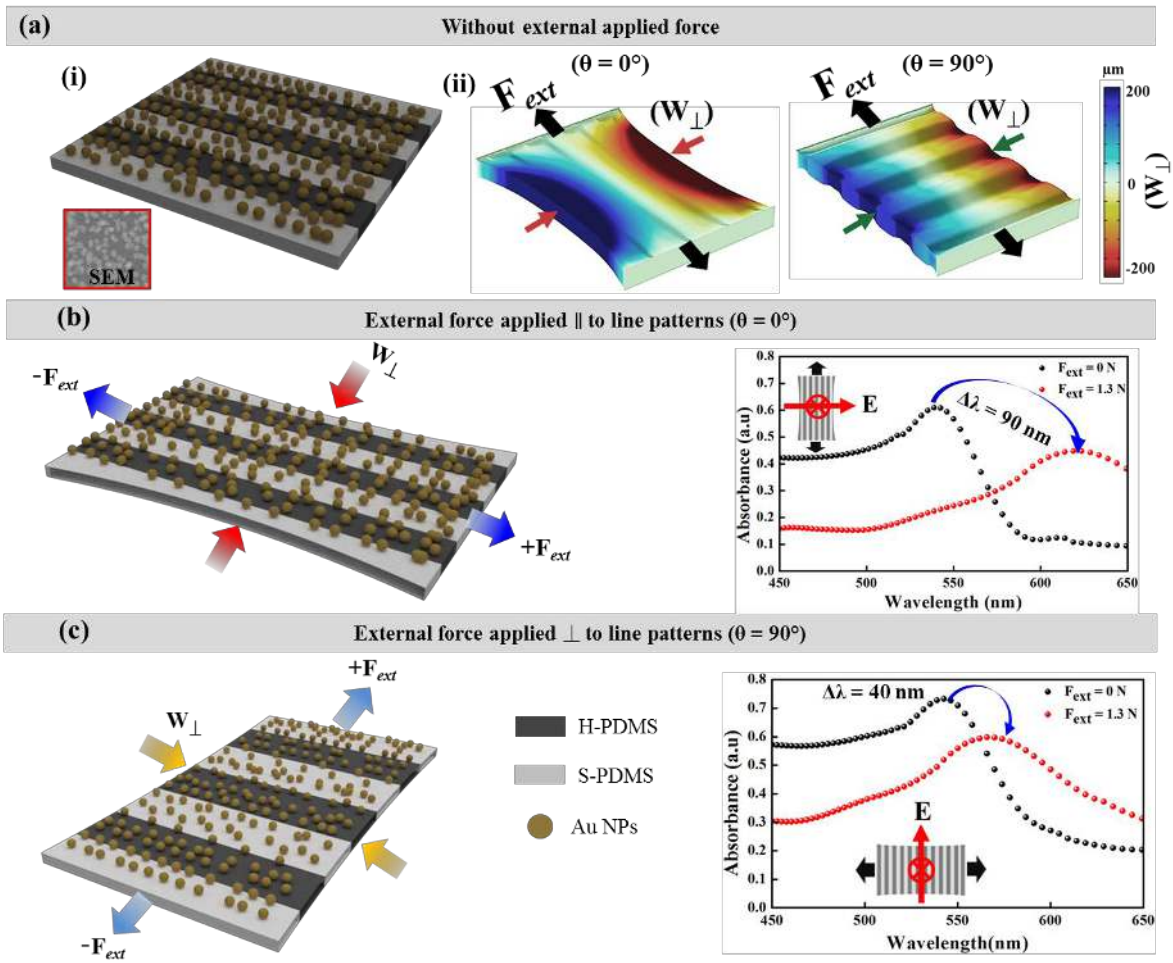

Figure1. Schematic and experimental illustrations of directional plasmomechanic strain sensor, (a) (i) shows the proposed device in its unstretched condition, inset shows scanning electron microscopy (SEM) image of Au NPs on PDMS substrate, (ii) simulated results of anisotropic Poisson's effect of the substrate for θ = 0° and θ= 90° directions, (b, c) the device structure and measured wavelength-dependent absorbance under the external force applied along θ = 0°, and θ = 90°, respectively.

Development of a novel optical label-free voltage sensing technique

O.G.Barajas, J. Sollini , M. G. Somekh and S.A. Abayzeed

[1]Optic and Photonics Research Group, Faculty of Engineering, University of Nottingham, United Kingdom

Abstract: This work presents an innovative impedance microscopy approach that promises the capability of measuring the bioelectrical properties of single cells. This optical label-free method exploits the sensitivity of metal's dielectric constant to voltage-induced changes in electron density in thin metallic films [1,2]. This can be monitored by tracking the change in intensity of optical transmission or reflection of metal [3]. This technique is a novel form of performing impedance microscopy using a simple optical configuration, which can allow exploring wide applications in studying living organisms and material characterisation.

Living organisms generate and conduct electrical signals that are critical for living functions. Retrieval of information at sub-cellular levels is critical to understanding cell bioelectrical function. However, this capability is not currently available due to the lack of appropriate imaging technology. Here, we present preliminary results towards a novel method for performing impedance microscopy using a simple optical sensing setup. To test this concept, a simple optical system was configured where the sample is illuminated using a collimated light beam, and the light transmitted through the sample is focused onto the photodiode to measure changes in light intensity. To test voltage-induced changes in light transmission, a sinusoidal voltage form with different frequencies was applied to the metal surface against a reference immersed in sodium chloride (NaCl) solution. When a voltage is applied to the metal film, a nanoscale capacitor at the metal-electrolyte interface is charged, leading to changes in electron density. The results show that we can detect voltage of 200mVpp with a modulation depth lower than $1x10^{-5}$ with a bandwidth of 10 kHz.

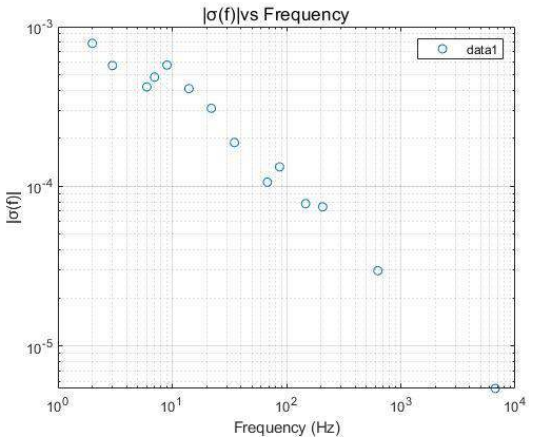

Fig.1. Change in transmitted light intensity at different frequencies in the range of 1Hz to 10 kHz in response to 200mVpp voltage signal.

Abstract: Downscaling of conventional Yagi-Uda antennas to nanometer size provides a powerful tool to influence the behavior of visible light for optical applications. For this, the plasmonic properties of gold nanorods are combined with the geometry of the well-established Yagi-Uda antenna. The impact of the linear polarization direction on their excitation and emission behaviors is investigated in optical spectra and the k-space. Here, we demonstrate strong discrepancies between on- and off-resonance excitation.

At larger scale, antennas are commonly used all over the world to send and receive electromagnetic waves with varying wavelengths. They are engineered to be resonant for specific wavelength and frequency regions. Yagi-Uda antennas are directional antennas and are mostly used for TV signals in the MHz range. They are composed of one feed, which is the resonantly engineered heart of the antenna, with an adjacent reflector on one side and multiple directors on its other side [1] (Fig. 1). This special design allows for a precisely directed emission of radiation due to interaction of plasmonic nanostructures [2], including destructive interference on the reflector side and constructive interference on the side of the directors, resulting in strongly preferred angular emission towards the directors [3]. In this work, this principle at nanoscale size is investigated with nonlinear optics combined with k-space imaging.

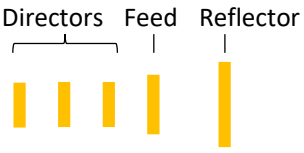

Figure 1: Geometry of a Yagi-Uda antenna

Figure 2: SEM-image of the fabricated nanoantenna

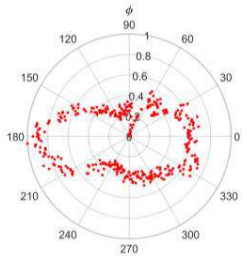

Figure 3: Emission pattern x-y-directionality on resonance

The probed Yagi-Uda antennas were manufactured as an array of gold nanorods with defined sizes and distances using microlithography techniques (Fig. 2). For the feed, the nanorod was designed to have a long axis plasmonic resonance matching the laser excitation wavelength. The Yagi-Uda antennas did not include any additional emitter, thus the observed signal is originating in the antenna itself [4]. A pulsed laser with λ = 779 nm and 40 MHz repetition frequency was focused onto the sample by a parabolic mirror with NA = 0.9986 to induce two-photon excitation processes. Second harmonic generation (SHG) and the combined signal of SHG and two-photon luminescence (2PPL) were investigated using a laser beam linearly polarized by a Glan-Taylor prism. The orientation of the linear polarization could be modified by a $\lambda/2$-waveplate to match the long axis of the antennas feed nanorod. Depending on the linear polarization direction, a strong difference in emission intensity is observed accompanied by changes to the observed emission patterns in the k-space (Fig. 3).

When the polarization direction of the laser matches the long axis of the feed nanorod (here: 90°), a strong enhancement of the SHG and 2PPL intensity is observed (Fig. 4). A gradual change of the intensity depending on the rotation of the linear polarization direction shows a good agreement with the theoretical expectations for on- and off-resonance measurements in proximity to plasmonic gold nanostructures [5]. The integrated intensity of the 2PPL is much larger than that of the SHG, which means the combined back focal plane image of SHG and 2PPL is dominated by the 2PPL signal. Preliminary experiments indicate a directionality of the nonlinear signal, which predicts that the nanoscale Yagi-Uda antenna is working properly and is suitable for use in further optical applications.

High resolution impedance imaging with plasmonic nanostructures

F. Nelson[1], R.Fuentes-Dominguez[1], F. Hei[1], R. Smith[1], M. Clark[1], G. Gordon[1], S. Abayzeed[1*]

[1]Optics and Photonics Research Group, Faculty of Engineering, University of Nottingham, United Kingdom

Abstract: We present a high resolution impedance microscopy technique for imaging the local electrical properties of cells in an effort to obtain an in-depth understanding of their bioelectrical functions. This information is critical to understanding aspects of cell activity such as metabolism, disease state, and cell stress. Our approach involves the investigation and utilisation of the tuneable local surface plasmon resonances (LSPR) of highly ordered nanoparticle arrays to make impedance imaging possible with spatial resolutions not achievable using pre-existing methods.

A cell can be described as an electrical system that generates and conducts electrical signals vital for living processes, but due to a lack of suitable measurement techniques there is limited knowledge as to how the electrical properties of such cells vary in space and in time. Single electrode techniques offer no spatial resolution while multi-electrode arrays find that their resolution limits arise from difficulties surrounding the density with which the increased number of electrodes can be arranged. As electrodes have grown smaller, new challenges surrounding signal-to-noise ratio, and in the case of scanning microelectrode techniques the propensity to damage samples, have driven to search for a new approach to electrophysiology at the single cell level [1].

In order to measure local impedance with the sub-micrometre resolution necessary to fully characterise the electrophysiology of individual cells, this work describes an optical approach to impedance imaging based on the local surface plasmon resonance (LSPR) of highly ordered nanoparticle arrays. Fabricated using electron beam lithography, these allow minute fluctuations in sub-microscopic charge density to be used as an indirect measurement of local impedance. Confining surface plasmons to nanoscale volumes offers the spatial resolution that conventional surface plasmon resonance sensing lacks [2], and in addition to its unrivalled spatial resolution, LSPR impedance microscopy is non-invasive, non-destructive, and has no external influence on cell behaviour nor the quantities it measures.

Here, we discuss the design, fabrication, and testing of homogeneous nanoparticle arrays for LSPR impedance imaging using several geometries including rods, discs, triangles and prisms. Based on thorough simulation of the opto-electronic properties of plasmonic nanoparticles and several analytical expressions including the scattering theories of Mie and Gans, particle dimensions have been carefully selected so as to tailor the location of LSPR according to the frequency of incident light. These simulations allow us to determine the relationship between particle geometry and the sensitivity of particle resonances to charge density variations. Validated by experiment, this information allows us to quantify sensor performance and ultimately obtain the highly localised electrical properties necessary for single-cell impedance imaging.

The plasmonic properties and local electric field enhancements associated with different particle types have been investigated and exploited in an effort to maximise sensitivity and signal quality. It is expected that this approach to impedance imaging will pave the way towards imaging the electrical properties of single cells at a length-scale not yet seen using existing techniques. With thanks to Richard Cousins and the nanoscale and microscale research centre (nmRC) for their assistance in sensor fabrication and imaging throughout this work.

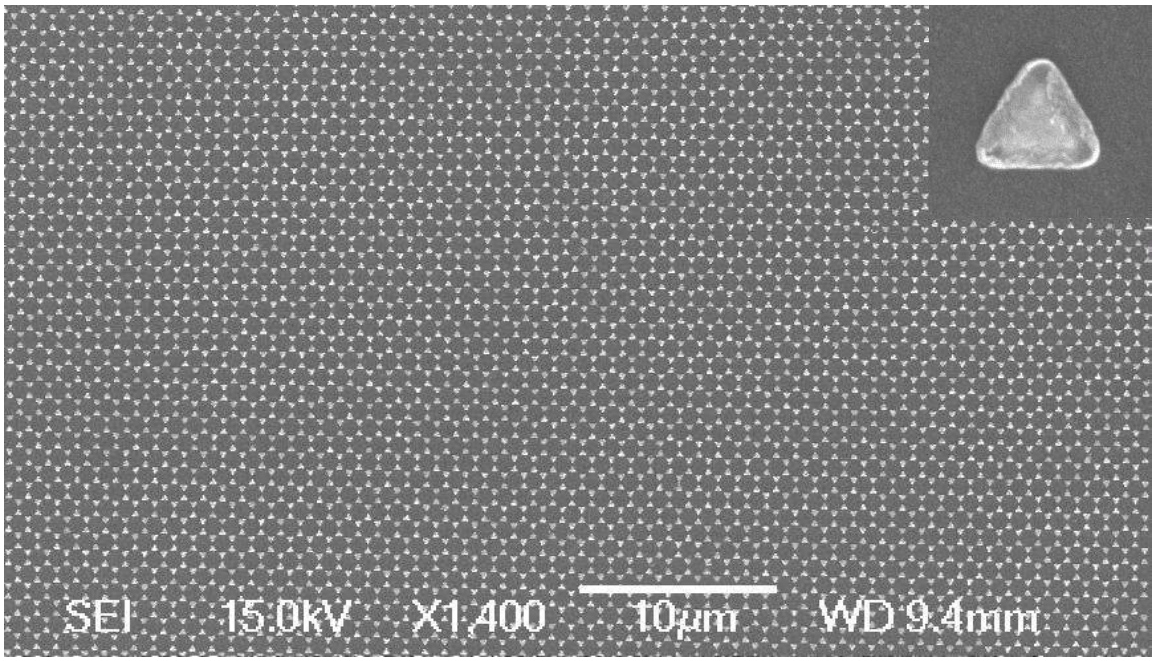

Figure 1. A representative scanning electron microscopy image of a 1cm^2 nanotriangle array prepared using electron beam lithography. Arrays comprising rods, discs, and prisms have also been fabricated with similar uniformity to investigate the geometric-dependence of LSPR and its bearing on impedance sensing. The inset shows a single nanotriangle magnified to 60,000x whose sides measure ~352nm

Quasi minimum-scattering-superabsorbed nanowires

Jeng Yi Lee[1*]

[1] 1Department of Opto-Electronic Engineering, National Dong Hwa University, Hualien 974301, Taiwan.

[*]corresponding author: jengyilee@gms.ndhu.edu.tw

Abstract: With consideration of an energy function involving scattering and power cross sections for a nanowire under a normal incidence for one polarization (either TE or TM), by using variational calculus, we propose a power diagram where can indicate all scattering properties. Without lock of scattering resonant modes with same phases and amplitudes, we design a nanowire with scattering performances having minimum-scattering superabsorption by exciting higher modes.

Understanding limitation of light-matter interaction has important applications in biological non-invasive cell-tracking, solar energy harvesting, optical sensors, enhanced single photon emission, enhanced Raman spectroscopy to name a few. Inspired by metamaterials, compact scatterers composed by multilayers with plasmonic and high indexing dielectric embedded can boost overlapping resonant modes for specific designs, such as superabsorption, superdirective nanowires, and superscattering [1, 2, 3].

In this work, by introducing an energy function with absorption and scattering cross sections as well as employing the calculus of variation, we can provide a normalized power diagram for any passive nanowire systems, beyond any specific system configurations, materials, and operating frequency, as shown in Fig. 1 (a). Here the exciting electric field is along z-axis direction (**s**- polarization) and normal incident to our nanowire systems. We find that there exists a physical boundary for scattering and absorption powers for any N-dominant resonant modes [4]. In the boundary (blue for ED (electric dipole), purple for ED and MD (magnetic dipole), green for ED, MD, and MQ (magnetic quadrupole)), the scattering systems can exhibit superscattering, superabsorption or minimum scattering superabsorption. However, we further find that when exciting more modes, its scattering boundary can wrap up that of the lower ones. This result indicates the degeneracy of power in light scattering and absorption, that two scatterers with different N dominant modes can display the same scattering and absorption cross sections.

To demonstrate this degeneracy property, in Fig. 1 (b), we design two nanowire systems, where one is made by silicon and another is made by gold (core) and silicon (shell). In the right panel of (b), by tuning outer radius a, we display its dominant scattering modes, where we can see only ED is primary scattering in silicon nanowire. However, in the gold-silicon nanowire, at a=74nm and radius ratio of 0.2, we can see the dominant modes are ED, MD, and MQ, belonging to higher excited levels. These two systems can have same absorption and scattering powers at the black stars. Next, our interest is to design a quasi-minimum-scattering superabsorbed nanowire where its scattering and absorption powers are same as the case of minimum-scattering superabsorbed nanowire [4], while its phases and amplitudes are not identical. In Fig. 1 (c), we design the nanowire by empolying gold in core with radius of 55.85nm and silicon in shell with outer radius of 132.98nm. Interestingly, we can see although the overall light scattering and absorption spectra are at the boundary, its scattering coefficients for the dominant modes are ED, MD, and MQ.

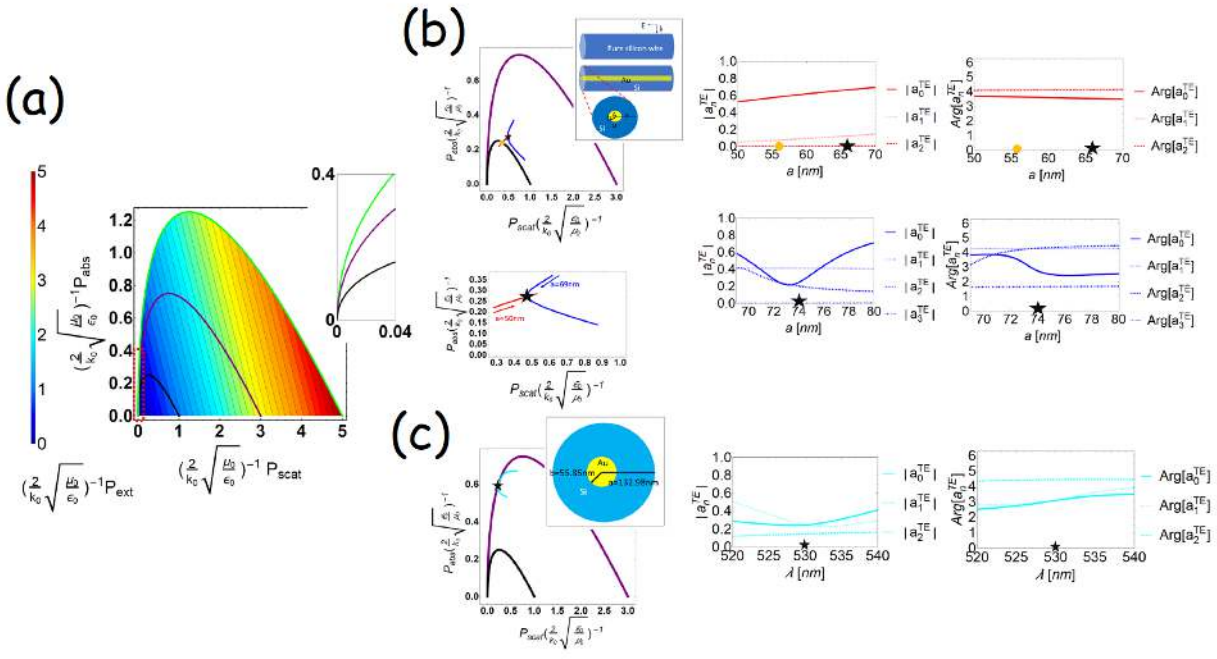

Figure 1. (a) Power diagram of absorption and scattering for any passive systems. The scattering boundary are depicted by blue line (ED), purple line (ED and MD), and green line (ED, MD, and MQ). (b) The red line in the power diagram denotes the silicon nanowire by tuning radius from 50nm to 70nm. Here the dominant mode is only ED. The blue line is, from the nanowire made of gold in core and silicon in shell, with a thickness ratio of 0.42, with respect to outer radius from 70nm to 80nm. Here the dominant modes are ED, MD, and MQ. (c) Quasi minimum-scattering-superabsorption result is achieved by the nanowire by gold in core and silicon in shell at operating wavelength of 530nm [4].

In this work, by using the concept of calculus of variation for introducing an energy function with absorption and scattering powers, we provide a power diagram to indicate all possible scattering results, beyond specific system configurations, materials, and operating wavelengths. We find the scattering and absorptions by any scatterers can exhibit degeneracy, that passive scattering systems excited by different N-level modes can have the same light scattering and absorption powers. Consequently, we design the quasi-minimum-scattering superabsorbed nanowire.

[*]corresponding author: rinahb@usp.br

Abstract: We have fabricated three hexagonal arrays of gold nanoparticles (Au-NPs) using template-assisted electrodeposition. The main geometric parameter that characterizes each of the hexagonal arrangements of NPs is the distance neighboring NPs. Our transmission measurements show redshifts of the plasmonic resonance as the distance between Au-NPS decreases (or increasing the diameter of the NPs). Using FDTD simulations it can be shown that the redshifts can be explained by a dipolar interference model of localized surface plasmons (or plasmonic surface lattice resonances). Our computational simulations based on the experimentally extracted parameters show an increase in near-field enhancement (27-fold in water) compared to a typical single-NP localized surface plasmon.

Figures 1(a), 1(b) and 1(c) show SEM images of ordered hexagonal arrays of Au-NPs with average diameters of 60, 75 and 85 nm, respectively. These NPs were fabricated by AC electrodeposition using porous anodic alumina as templates (1 µm thickness). The self-organizing alumina nanostructures (with average pore diameters of 90 nm and fixed interparticle distance of 110 nm) were obtained by two-step anodization using a simple electrochemical cell with two electrodes in 0.5 M $H_2C_2O_4$ at 25°C and 45 V. To increase the diameter of the nanopores we performed a 40 min etch on the anodized samples using 1 M H_3PO_4. The Au-NPs was conducted in an electrolyte containing 1 g/L $HAuCl_4{:}3H_2O$ + 30 g/L H_3BO_3, with a pH of 1.5, AC voltage of 10 V (RMS), and a frequency of 200 Hz [1].

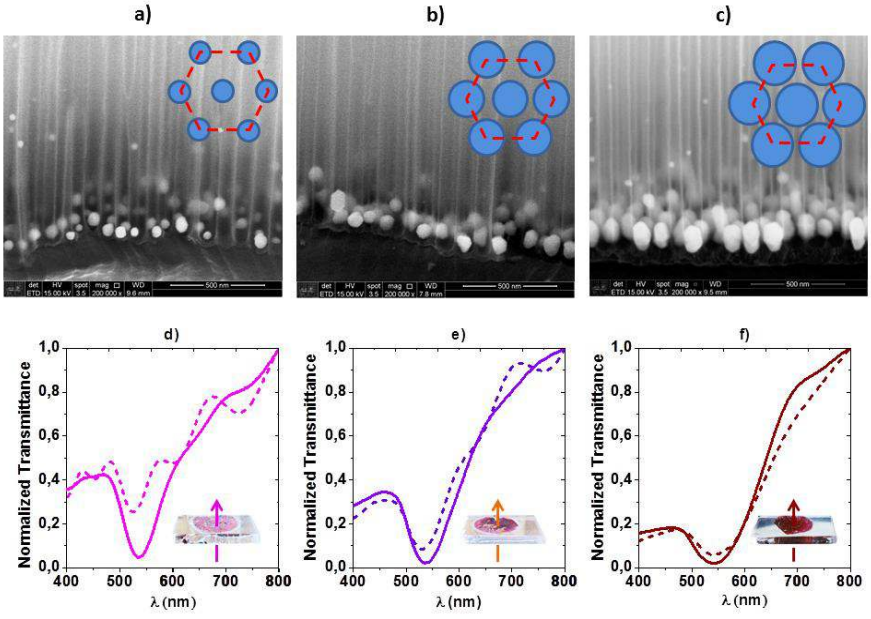

Figure 1

Figures 1(d), 1(e) and 1(f) show normalized transmission measurements (UV-Vis spectrophotometer) for the different hexagonal arrays of Au-NPs (60, 75 and 85 nm in diameter) in host media air (line dotted) and water (solid line). The insets of these figures show the Au-NPs/Al2O3 composite films on quartz sheets and the incidence of unpolarized light. In the transmission spectra we can clearly see drops in transmission (absorption peaks) due to surface plasmons in the Au-NPs. Note that the positions in the transmission drops shift to the near-infrared as the size of the Au-NPs increases (or the distance between neighboring NPs decreases). This displacement of the surface plasmon is closely related to the interaction between neighboring NPs or in other words it is an interference effect of plasmons [2].

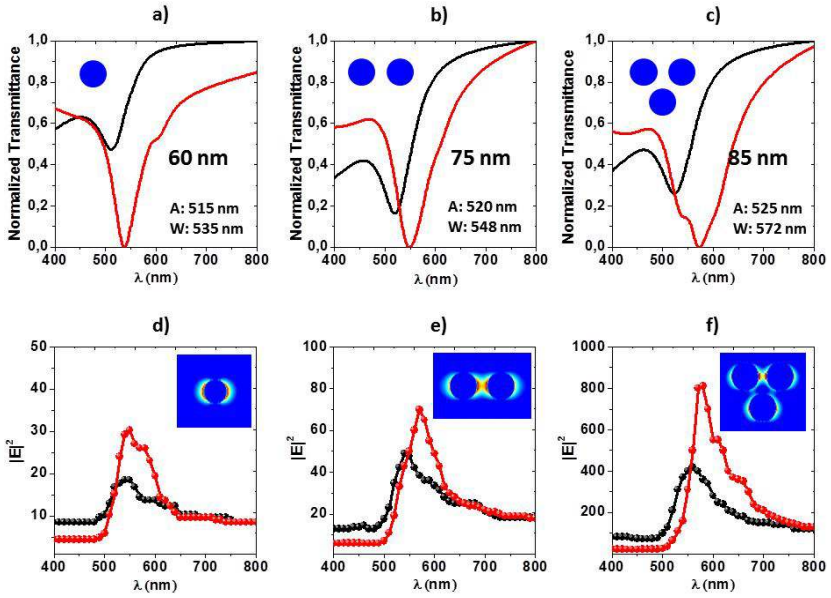

Figure 2

Figures 2(a), 2(b) and 2(c) show FDTD numerical simulations (FDTD Solutions 8.5, Lumerical Inc., Canada) of the transmission spectra for the fabricated Au-NPs arrays. In the simulations, experimental parameters such as NP diameter, distance between NPs, refractive index of the effective medium (Au-NPs/Al_2O_3 composite). To understand the effect of the displacement of the collective plasmon relative to the localized surface plasmon (LSP), we performed numerical simulations for 1, 2 and 3 NPs in mutual interaction [insets of Figures 2(a)-(c)]. The numerical results shown in Figures 2(a)-(c) are in good agreement with the experimental results for single spherical NPs (60 nm diameter), NP dimers (75 nm diameters) and NP trimers (85 nm). The effect of this plasmon coupling (LPSs interference) can be clearly noted in the electric near-field intensification that reaches a value of 800 (water host medium) for the trimers (interparticle distance of 25 nm). Higher values for near-field enhancement can be reached when the distance between NPs is less than 20 nm.

Using the lattice modes to intensify the near-field could improve the sensitivity of biosensors, increase the efficiency in plasmonic optical traps and increase the optical chirality in optical enantioseparation devices [3].

Metal-insulator-metal metamaterial as optoplasmonic biosensor for refractive index sensing

Z. Ayareh[1,2], D. Sutherland[2*], and M. Moradi[1]

[*]Duncan@inano.au.dk

Abstract: The optoplasmonic biosensor is a label-free sensor which has significant potential to detect biomolecules. We proposed it based on metal–insulator–metal (MIM) metamaterials utilizing the gap between two metals as a space to detect biomolecules. We fabricated Au/SiO_2/Au heterostructures using the hole-mask colloidal lithography method. In this work, the localized surface plasmon resonance was demonstrated by modifying the MIM heterostructure by etching back the insulator (SiO_2) to provide a sensing cavity. A bulk sensitivity of 285 nm/RIU was measured.

The metal-insulator-metal (MIM) metamaterials are high potential elements for the development of various novel materials, such as optoplasmonic heterostructures or highly efficient biosensors [1]. Their exceptional properties and performance rely on localized surface plasmon resonances (LSPR), i.e., spatially confined charge-density oscillations that are readily excited at optical frequencies in noble-metal structures [2]. In MIM metamaterial, LSPR waves demonstrate strong optical absorption in two plasmon peaks at a broad range of incident angles and polarizations of the incidence light [3]. After coupling of light and a MIM metamaterial, the excited LSPR modes are strongly confined in the gap between the two metals which has the potential to high optical fields enhancement and importantly, small volumes of detection which can allow high sensitivity for the detection of biomolecules. The advantage of LSPRs in MIM metamaterial is that it makes them suitable for fabricating biosensors. Herein, we present a very simple but effective approach to fabricate an improved biosensor via etching of SiO_2 to have a cavity between the two Au disks. The SiO_2 layer is introduced into the double stacked Au disk, forming Au disk/SiO_2 bridge/Au disk heterostructure. Then, part of the SiO_2 between the Au disks is removed by chemical etching, producing the nanogap between Au disks. The nanogap size can be easily and precisely tuned to nanometer scale by adjusting the thickness of SiO_2 disk and etching time. The spectroscopy results show that Au disk/SiO_2 bridge/Au disk heterostructure has a good refractive index sensitivity. This heterostructure shows good potential for MIM metamaterial fabrication and biosensor application. Hole Mask Colloidal Lithography method [4] was used to prepare MIM heterostructures. As a brief, the PMMA solution was added to the glass substrate by spin coating and baked. The three polyelectrolyte layers were then sequentially deposited. (2 wt% PEI, 2 wt% PSS, and 0.2 wt% PDDA). Finally, 0.2 wt% of polystyrene nanoparticles (200 nm diameter) were added to the samples. After removing PS nanoparticles, the mask was finalized by an O_2 plasma etching step to make holes through the PMMA layer. The TiO2 (4nm) /Ti (2nm) Au/Ti(1nm)/SiO_2/Ti(1nm)/Au disks on the glass substrate were deposited with a thickness of 20 nm for each disk (Fig1). We used TiO_2 to protect the etching of the glass substrate and Ti as an adhesion layer. To have a SiO_2 bridge we used 20% KOH solution as chemical etching and the sample has immersed in 120 s at 30℃. Optical spectra were taken of the final structures and peak shifts with refractive index made using glucose solutions (Fig 2).

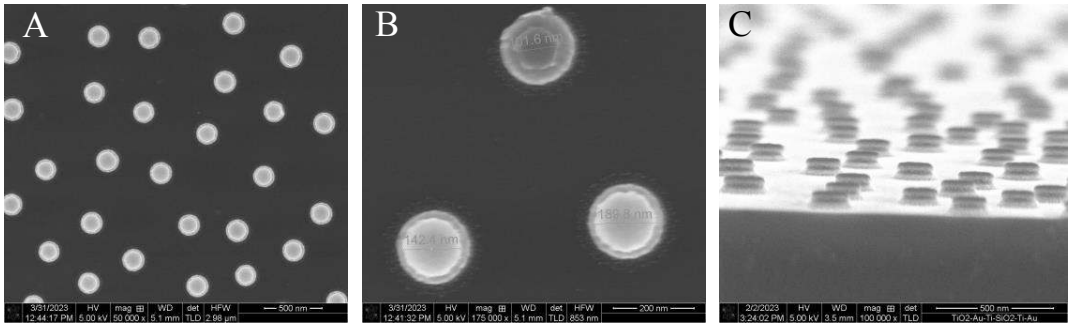

Figure 1: SEM images of Au/SiO2/Au heterostructure after etching. (A) The top of MIM (B) after removing the second Au disk to see the SiO2 bridge (C) The cross-section image of MIM heterostructure.

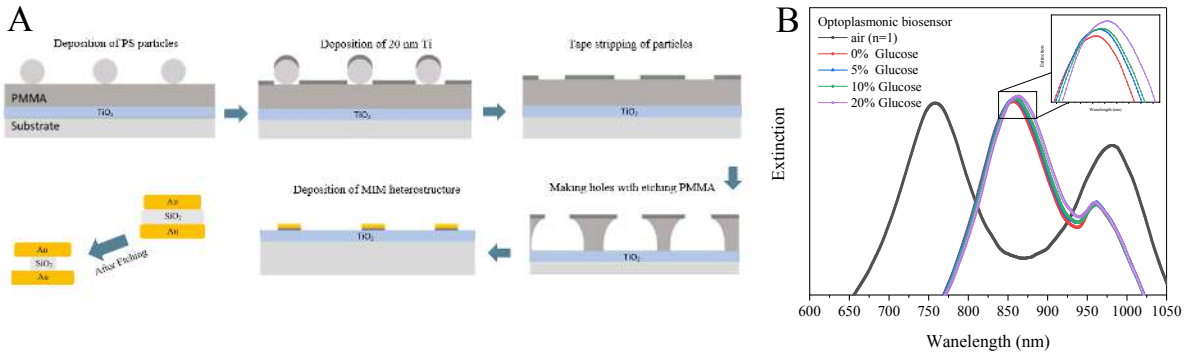

Figure 2: (A) Schematic of fabrication of MIM heterostructure on the glass substrate. (B) Extinction measurement of the optoplasmonic biosensor with different concentrations of Glucose solution using a flow cell.

In summary, we have successfully presented a simple high throughput approach to fabricate Au disk/SiO_2 bridge/Au disk heterostructure for biosensor application with two plasmon peaks at 758 nm and 980 nm. The nanogap size can be easily and precisely controlled to nanometer scale by adjusting the thickness of the SiO_2 disk and etching time. The chemical etching process could expose the strong electromagnetic field area to analytes allowing specific functionalization of the silica bridge to localize molecular recognition events in the gap. The MIM heterostructure with 20 nm height and 40 nm width gap size shows the best bulk sensitivity (285 nm/RIU).

META conference 2023 committee,

I am writing in a recommendation and my strong support of Zohreh Ayareh, as a promising candidate to obtain your support. As her record show, she is a motivated and first-best Ph.D. student in the nanoscience and nanotechnology department at Kashan University, Iran. Zohreh has vastly worked on plasmonic material and plasmonic sensor fields. I evaluate Zohreh as a unique, dedicated, hard-working, and creative problem-solver person who actively seeks new opportunities and experiences. I am completely sure this conference can be extremely effective for her creativity. She has received a grant from her home university to spend 6 months at Aarhus university as a gest Ph.D. student, unfortunately, this budget is not enough to cover the whole cost of living in Denmark and participating in the META conference. In this case, after receiving support from the META conference, the grant can cover any remaining cost. Undoubtedly, the META's contribution would be highly appreciated. In receiving this travel grant, Zohreh will obtain an opportunity that would otherwise not be possible. If you need more information, please do not hesitate to contact me.

Sincerely

Dr. Mehrdad Moradi

LSPR enhanced In-situ Ellipsometry as a Label-free Optical Sensing Platform

Natasha Mandal[1*], Rakesh Singh Moirangthem[2]

[1] Nanophotonics Lab, Dept. of Physics, Indian Institute of Technology (Indian School of Mines) Dhanbad, India
[2]Dept. of Physics, Manipur University, Manipur-795003, India
[*]corresponding author: natashamndl@gmail.com

Abstract: We present an efficient, highly surface-sensitive, non-invasive, label-free optical sensing platform by integrating Localized Surface Plasmon Resonance (LSPR) and Ellipsometry. We adopted a facile route of solid-state thermal dewetting for preparing a LSPR sensor chip by the formation of highly stable, partially embedded bimetallic alloy nanoparticles with an average size of 27±8 nm. The experiment was performed in in-situ mode (90°)) using our custom-built 3D printed cell setup. We obtained sensitivity of around 1870±273 °/RIU for the prepared LSPR chip.

Over the past 30 years, integrating optical techniques with other analytical methods has become progressively popular for higher sensitivity, accuracy, precise analysis, and device miniaturization. SPR, LSPR, and Ellipsometry are well-recognized optical sensing techniques due to their real-time, label-free, non-invasive, rapid detection features. The basic theory of Ellipsometry is based on the change in the polarisation state of the p- and s- polarized light after reflection from the sample's surface. It determines the film thickness, optical properties, complex refractive index, dielectric function, surface roughness, elemental composition, etc. Ellipsometry signal is measured in terms of Psi (Ψ, 0°< Ψ <90°) and Delta (Δ, -180°<Δ<+180° or 0°<Δ<360°) parameters, representing the amplitude ratio and phase difference of reflected p- and s- polarized light, respectively, and defined by the following expressions [1].

$$tan\,\Psi = \frac{|R_p|}{|R_s|} \; and \quad \Delta = \delta_p - \delta_s$$

One of the limitations encountered in in-situ Ellipsometry measurement is that incident and reflected light from the sensor surface must pass directly through the sensing medium. The detection of low molecular weight analytes is challenging in SPR/LSPR techniques. Thus, we could overcome these limitations using Ellipsometry in SPR conditions [2–4] and utilize both advantages. The LSPR-enhanced in situ-Ellipsometry method, also known as Total internal Reflection Ellipsometry (TIRE), has the potential to be a reliable, rapid, non-destructive, label-free optical sensing platform with enhanced sensitivity and lower detection limit [5]. We have prepared the highly stable LSPR sensor chip using a facile, economical, and single-step solid-state thermal dewetting method by annealing Ag_5nm/Au _5nm bimetallic film deposited on a piranha cleaned glass substrate (3cm×2cm) at 550°C (glass transition temperature brings the embeddedness of nanoparticles) for 5 hrs in air ambient. The FESEM, EDX and UV-VIS absorbance spectra at 522 nm confirmed that the shape of the nanoparticles are spherical with an average size of 27±8 nm, mostly within the size of 20-30 nm, and the content of Au and Ag elements. The performance of the LSPR chip was investigated by the bulk refractive index sensitivity measurements. The experiment was performed using our custom-built 3D printed module incorporated with the commercial Ellipsometer by exposing the LSPR chip with the 0-50% concentrations of glycerol-water solutions with refractive indices in the 1.333-1.3981 (flow rate 1ml/h, 15 mins each solution). The real-time response of Ψ at the wavelength of 586 nm and Δ at 540 nm, which correspond to the maximum sensitivity, are depicted in fig.1(d,e), and the bulk sensitivity was obtained around 1870±273 °/RIU and 274±20 °/RIU for Ψ and Δ respectively from the sensitivity plots (fig. f,g). The Δ signal is more pronounced than Ψ, a

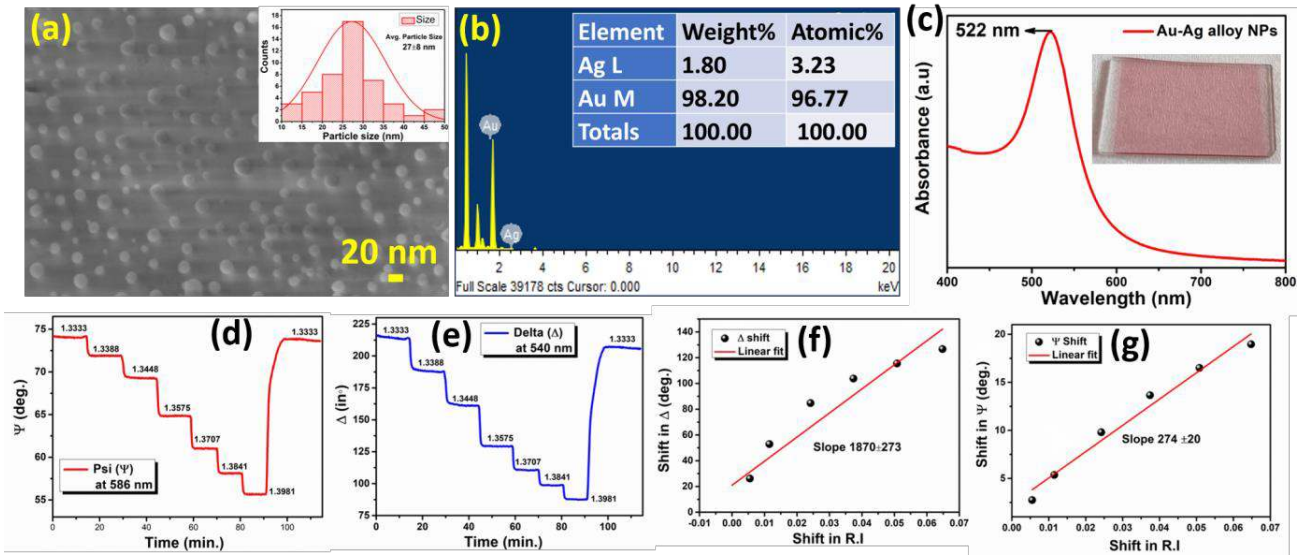

Figure 1. (a) FESEM image and inset shows the histogram plot, (b) corresponding EDX spectra, and (c) UV-VIS absorbance spectra for the prepared sensor chip. Real-time Ellipsometry response in terms of (d) Ψ, (e) Δ , and (f,g) corresponding sensitivity plots for 0-50% glycerol-water solutions.

small change in sensing media leads to a significant shift in Δ response. This integrated platform is not limited to transparent liquid analyte media. It could be explored in non-transparent or opaque gaseous media, and the sensitivity can be enhanced by several modifications (e.g., using 2D materials) of the LSPR chip. Our approach for preparing LSPR chips could be produced on a large scale at a low cost with good reproducibility, and the proposed integrated technique could be used in industrial applications.

We acknowledge the funding from the SERB-DST, India (EEQ/2017/000370).

Exploring Propagation Characteristics of Ga:ZnO Thin Films in the Epsilon-near-zero Region

Ranjeet Dwivedi[1*] and Dorota A. Pawlak[1]

[1]ENSEMBLE3 Centre of Excellence, Wolczynska 133, 01-919 Warsaw, Poland
[*]corresponding author: ranjeet.dwivedi@ensemble3.eu

Abstract: We examined the propagation characteristics of Ga:ZnO (GZO) thin films in the epsilon-near-zero (ENZ) region, revealing a novel non-radiating TM mode with strong field enhancement. We also explored a multilayer structure of GZO layers in a ZnWO4 matrix, which exhibits strong polarization selectivity and resonant absorption. The spectral location and bandwidth of absorption could be adjusted by carefully selecting the GZO layer thickness and geometrical parameters. Our results offer promising possibilities for developing ENZ-based devices with enhanced functionality and tunability.

Strong light-matter interaction in narrow region of space have many potential uses in photonic circuitry, including ultrafast switching, high harmonic generation, sensing, etc. To achieve these functionalities, transparent conducting oxides such as ITO, AZO, and GZO are often employed in photonic devices. These materials exhibit extreme field enhancement in the near-infrared region, which occurs when their permittivity approaches zero. Such materials, also called epsilon-near-zero (ENZ) materials, can be incorporated into various platforms such as meta-materials and surfaces [1], waveguides [2], and thin films [3] to create devices with a wide range of electromagnetic functionalities.

Propagation of light in ENZ thin films is characterized mainly by two modes: the radiating Berreman mode and the non-radiating ENZ mode [4–6]. The modal analysis of ENZ thin films presented in previous studies [4–6] is based on the calculation of complex frequency for a given real-valued propagation constant, which is relevant to Local Density of Optical States (LDOS) and pulsed excitation experiments. However, this analysis does not provide a complete description of modal field propagation characteristics, such as propagation length and confinement. To obtain a more comprehensive description of modal field propagation characteristics, one would need the complex propagation constant calculated at the real frequencies.

In this work, we analyze the propagation characteristics of ENZ films by solving the Helmholtz wave equation at real frequencies and calculating the complex propagation constants for ENZ layer thickness ranging between 2 - 100 nm (~ 1/600 - 1/12 of ENZ wavelength). The schematic of the considered structure is shown in Fig. 1(a), which consists of a Ga:ZnO (GZO) layer of thickness *d* surrounded by semi-infinite $ZnWO_4$ layers. We found that such a structure supports a novel non-radiating mode in the ENZ region of GZO. Such a mode has its dispersion curve lying to the left of the light line in the surrounding region (real part of effective index lower than the $ZnWO_4$ refractive index), as depicted in Fig. 1(b) and 1(c). However, the calculated electromagnetic fields display non-radiating (evanescent in the surrounding region) nature contrary to the Berreman mode. Subsequently, we studied the propagation characteristics of a multilayer structure constituting periodic array of GZO layer in $ZnWO_4$ matrix considering the modal field's excitation using the end fire coupling. Such a multilayer structure shows strong polarization selective and geometricaly tunable resonant absorption/emission. Moreover, incorporating antireflection coating at the facets of the structure empowers it to perfectly absorb the TM-polarized incident light. The spectral range of high absorption can be tuned by varying

the thickness of the GZO/ $ZnWO_4$ layer. We believe that our study will be helpful in the designing of photonic components such as modulators, sensors and other optoelectronic devices based on light absorption/emission.

Photonic nanojet enhanced Raman scattering: A new platform for Raman nanoscopy

Gour Mohan Das[1*], Piotr Paszke[1], Katarzyna Sadecka[1], and Dorota A. Pawlak[1,2,3]

Abstract: This study proposes a novel technique for enhancing Raman scattering signal using a combination of a single dielectric microsphere attached to a stem and confocal Raman microscopy. The technique involves directing laser through the glass microsphere to generate a photonic nanojet, a narrow-focused, non-evanescent, and highly intense electromagnetic beam with subwavelength lateral sizes, and obtaining Raman spectra. The method was tested on Bi_2O_3-Ag substrate, and an enhancement factor of ~90 was observed for the γ phase of Bi_2O_3.

Raman spectroscopy is a nondestructive analytical technique that is widely used in science and engineering applications for molecular identification, structural and quantitative analysis, and imaging often referred as molecular '*fingerprint*' [1]. In crystal engineering, Raman spectrum provides valuable information on the vibrational modes of the crystal lattice, which in turn provide insights into the crystal structure and composition, as well as defects, impurities, and lattice dynamics. However, there are certain limitations associated with the use of Raman spectroscopy for crystal phase determination. These include weak Raman signals, particularly for low-symmetry crystal structures or small crystals, and overlapping peaks from different crystal phases, especially for complex crystal structures or crystals with multiple phases present [2].

Herein we report a novel technique for enhancing Raman scattering signal with the combination of single dielectric optical microsphere attached with a stem and confocal Raman microscopy. In the conventional Raman scattering method, a microscopic objective lens directs laser light onto the top of the sample, and signal is collected in a back-scattering geometry. In photonic nanojet enhanced Raman scattering technique, the laser light coming from the microscopic objective lens is incident on the silica microsphere, and laser light can easily penetrate through the transparent glass microsphere and form the photonic nanojet at the shadow surface of the microsphere (the schematic is shown in figure 1a). Photonic nanojet is a narrow-focused, non-evanescent, and highly intense electromagnetic beam with subwavelength lateral sizes that emerged from the shadow side of dielectric microparticles (The generation of photonic nanojet from an optical microsphere is shown in figure 1b).

The microsphere was placed on top of Bi_2O_3-Ag substrate (an eutectic plasmon active multiphase material synthesized by micro pulling down method) using a customized manipulation system attached with the Raman spectroscopy. Raman spectra was collected with and without microsphere at the same location using similar experimental parameters (shown in figure 1c). The 826 cm^{-1} peak represents the γ phase of Bi_2O_3 while the other Raman peaks correspond to the α phase of Bi_2O_3 [3]. The enhancement is observed due to the presence of nano precipitates of γ phase of Bi_2O_3 close to Ag nanoparticles, and the further near-field enhancement of Ag nanoparticles by photonic nanojet, with an estimated enhancement factor of ~90 for the 826 cm^{-1} peak. We are confident that our developed technique will not only advance Raman nanoscopy in terms of chemical and phase

mapping but also pave a new path in vibrational spectroscopy-based optical nano-characterization.

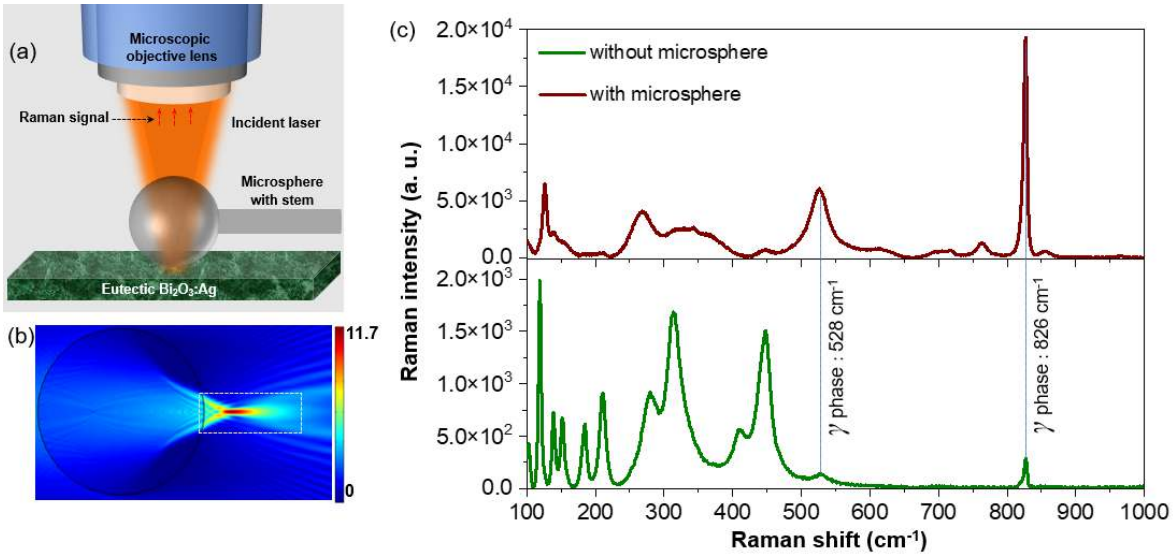

Figure: (a) Schematic of the photonic nanojet enhanced Raman scattering, (b) Numerical simulation of photonic nanojet from glass microsphere, and (c) the comparison between Raman scattering signal collected from an area of Bi_2O_3-Ag eutectic metamaterials without and with the presence of silica microsphere (enhancement factor ~ 90, excitation laser: 532 nm).

Optical control of topological and correlated electronic states

M. Hafezi[1]

[1]Joint Quantum Institute, and Quantum Technology Center, University of Maryland USA

[*]corresponding author: hafezi@umd.edu

Abstract: We discuss how quantum optical control techniques could pave a radically new way to prepare, detect and manipulate non-local and correlated electronic states. Specially, we discuss topological interplay between photons and electron and strongly correlated driven-dissipative system.

Given tremendous progress in controlling individual photons and other excitations such as spin, excitonic, phononic in solid-state systems, it is intriguing to explore whether these quantum optical control techniques could pave a radically new way to prepare, detect and manipulate non-local and correlated electronic states. After discussing several broad theoretical schemes, as the first experimental example, we report on optical and electrical tunable Bose-Fermi mixtures in hetero-bilayer systems and the observation of an excitonic Mott insulator [1]. This enables us to form strongly interacting excitons that are manifested in a large energy gap in the photoluminescence spectrum. The incompressibility of excitons is further corroborated by measuring exciton diffusion, which remains constant upon increasing pumping intensity, as opposed to the expected behavior of a weakly interacting gas of bosons, suggesting the formation of a bosonic Mott insulator. Our system provides a controllable approach to the
exploration of quantum many-body effects in the generalized Bose-Fermi-Hubbard model.

As the second experimental example, we report on the optical manipulation of quantum Hall states in graphene using twisted light. Specifically, we present a novel mechanism for such an orbital angular momentum transfer from optical vortex beams to electronic quantum Hall states [2-6]. Specifically, we identify a robust contribution to the radial photocurrent, in an annular graphene sample within the quantum Hall regime, that depends on the vorticity of light. This phenomenon can be interpreted as an optical pumping scheme, where the angular momentum of photons is transferred to electrons, generating a radial current with a polarity that is solely sensitive to the light's vorticity. Our findings offer fundamental insights into the optical probing and manipulation of quantum coherence, with wide-ranging implications for advancing quantum coherent optoelectronics.

Luminescence of molecular polaritons in a microcavity: non-Markovian Fano resonances, motional narrowing, and nonlinearity associated with vibronic coupling

B. D. Fainberg[1,2], **and V. Al. Osipov**[1]
[1]Faculty of Sciences, Holon Institute of Technology, Holon 58102, Israel
[2]School of Chemistry, Tel Aviv University, Tel Aviv 69978, Israel

Abstract: We develop a non-Markovian theory of polariton luminescence taking molecular vibrations into account. In the single-mode microcavity, our theory predicts the Fano resonances in the polariton luminescence, motional narrowing and explains experimental observations of the molecular Stokes shift in polariton fluorescence spectra in systems with strong light-matter coupling. Using the multiconfiguration Hartree approach we also derive nonlinear equations of motion for the polariton wavefunction, where vibration degrees of freedom interact with the polariton quantum field through the mean-field Hartree term.

In the last time Frenkel exciton polaritons (EPs) in organic materials and biological structures attracted considerable interest in relation to their Bose-Einstein condensation, low threshold polariton lasing, and polariton chemistry in microcavity. The concept of EPs suggests strong light-matter interaction that is supported by a considerably larger oscillator strength of organic systems compared to inorganic semiconductors. Theoretical description of EP luminescence in molecular systems is a challenge since in this case both the interaction with radiation field and electron-vibrational interaction are strong. In this work using a realistic non-Markovian theory for the description of the polariton-molecular vibrations interaction we calculate polariton luminescence in the polariton basis. To obtain the dispersion equation for the polaritons that coincides with the equation for the transverse eigenmodes of the medium, we average the Hopfield coefficients with respect to the optically active vibrations, and the polariton operators obey the Heisenberg equations [1]. We show that the frequency shift and broadening of polariton luminescence spectra strongly depend on the exciton contribution to the exciton polariton that is a function of frequency. Further we considered a single-mode microcavity (Fig.1a). It is usually believed that polariton states are formed when splitting of the upper and lower polariton branches is much larger than broadening of molecular resonances. In contrast, our non-Markovian theory [1] demonstrates the main characteristic features of the Fano resonance in the polariton luminescence (Fig.1b) associated with the characteristic "zero" frequency, at which luminescence intensity is equal to zero, and a peculiar asymmetric and ultra-sharp line shape for splitting of the upper and lower polariton branches of the same order of magnitude as inhomogeneous broadening of the molecular spectra. In addition, we predict motional narrowing of the EP luminescence spectrum in the microcavity. Our theory also enables us to consider a non-equilibrium (hot) EP luminescence.

It is worthy to note that the theory catches the effect of the Stokes shift in the polariton luminescence spectra. It can serve as a basis for the heuristic model formulated in experimental work [2] qualitatively explaining why the Stokes shift in resonant cavities filled with R6G:PMMA is larger than that in the same dye-doped films deposited on glass. Moreover, our theory explains also the luminescence spectrum

narrowing of the R6G:PMMA film in the cavity with respect to the luminescence spectrum of the same film deposited on glass [2].

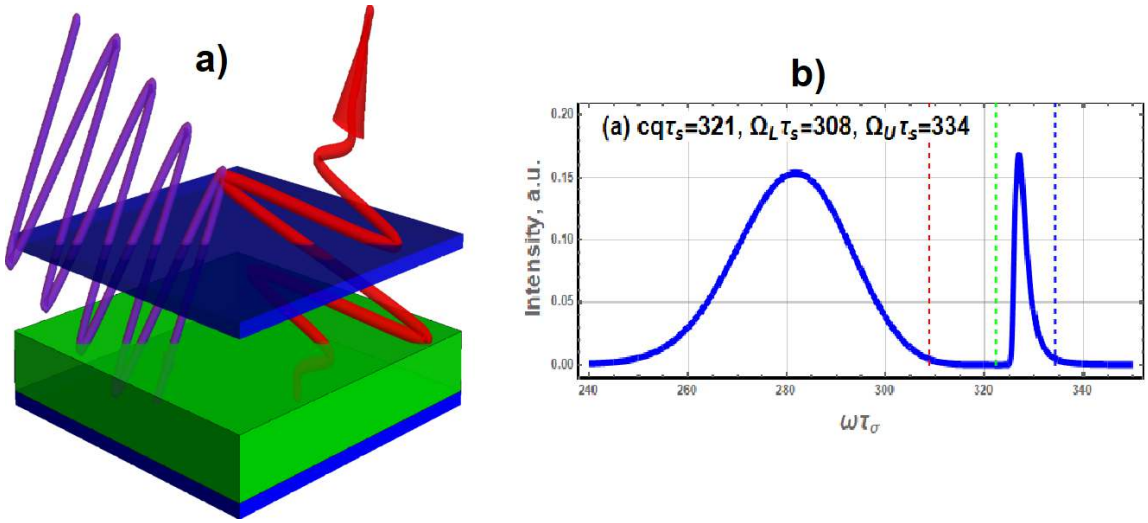

Fig.1. a) The molecular substance (green) is located between the cavity mirrors (blue) of a single-mode microcavity; the wavy arrows represent pumping (purple) and luminescence (red). b) Luminescence spectra of molecules in a single-mode cavity; the dashed lines correspond to the frequencies of the lower polariton branch (red) and the upper polariton branch (blue) and to the "zero" frequency (green).

Using the multiconfiguration Hartree approach we also derive nonlinear equations of motion for the polariton wavefunction, where vibration degrees of freedom interact with the polariton quantum field through the mean-field Hartree term [3]. We expect that the theory will lead us to new, associated with the nonlinearity, manifestations of the collective behaviour in polaritonic and similar systems, for example, mutual synchronization of interacting oscillators, oscillation death etc. [4].

Order-Invariant Quantum Correlations in non-Hermitian Interferometers

Tom A. W. Wolterink*, Matthias Heinrich, Stefan Scheel, and Alexander Szameit

Institute for Physics, University of Rostock, Albert-Einstein-Straße 23, 18059 Rostock, Germany
*corresponding author: tom.wolterink@uni-rostock.de

Abstract: We identify types of sequences of concatenated two-mode systems that perform distinct linear optical transformations, whereas their two-photon behavior is invariant under reversal of the order. We experimentally verify this systematic behavior in parity-time-symmetric complex interferometer arrangements of varying composition, and demonstrate that non-Hermitian quantum correlations may be preserved in counterintuitive ways even in small-scale networks.

Quantum correlations in linear optical networks are a crucial resource for quantum information processing. Correlations between multiple photons are described by the permanent of the transmission matrix of the optical network [1]. Yet, despite their central role, very few properties of permanents are known to exist and the calculation of matrix permanents remains a computationally hard problem. At large scale, this has sparked the field of boson sampling through the connection to linear optical quantum computing. However, the lack of tangible properties also affects small-scale networks, as it hinders intuitive prediction of the behavior of composite systems from their components. This especially holds for non-Hermitian systems that incorporate losses, which are known to drastically alter quantum correlations even in the simplest networks of just two modes, such as a lossy beam splitter [2,3]. Here, we systematically identify sequences of two-mode systems that perform distinct linear optical transformations, whereas their permanents remain invariant under reversal of the entire sequence's order. We experimentally verify this property by probing the two-photon correlations in parity-time (PT)-symmetric interferometers of wildly different composition.

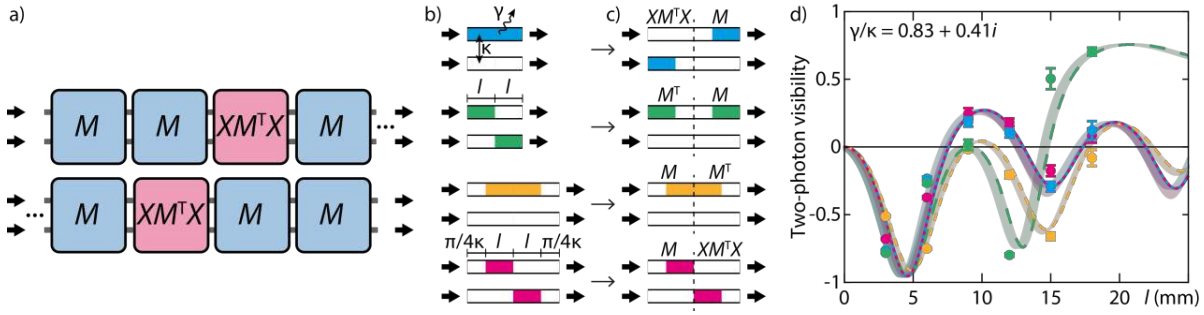

Figure 1. a) Sequences of two-mode transformations M and $XM^{\mathrm{T}}X$, concatenated in either forward or backward order, exhibit identical two-photon coincidences. b) Schematic drawing of concatenated PT-symmetric directional couplers and 50:50 directional couplers and c) their equivalent descriptions in terms of the transformation M. Color of the lossy section distinguishes the geometry. d) Measured (dots) and calculated (curves) two-photon visibility versus length.

Let us consider an arbitrary two-mode linear optical system described by its 2×2 transmission matrix M and its row-and-column-reversed transpose $XM^{\mathrm{T}}X$. When interpreting M as the transformation resulting from evolution of a time-dependent Hamiltonian $H(t)$, $XM^{\mathrm{T}}X$ corresponds to evolving $H(t)$ in reverse order while also swapping parity. Note that this is distinct from a simple time reversal, as it involves no complex conjugation. Concatenating these two systems results in different transformations $X(M^{\mathrm{T}}XM)$ or $M(XM^{\mathrm{T}}X)$, depending on the specific order. Surprisingly, their permanents turn out to be the same. Therefore, while these two sequences

show distinct behavior when probed with classical light or single photons, their two-photon behavior is identical. This peculiar effect does not arise from a trivial property of permanents and extends to longer sequences (Fig. 1(a)). As it holds for any complex matrix M, it provides a symmetry to link two-photon behavior in non-Hermitian systems.

To experimentally verify these invariant correlations, we study the two-photon behavior of interferometers consisting of multiple passive PT-symmetric directional couplers [4]. A passive PT coupler consists of two coupled waveguides of length l with coupling constant κ, one of which experiences loss at a rate γ. For $\gamma/\kappa < 2$, PT symmetry is unbroken and the Hamiltonian has real eigenvalues when viewed in the co-damped reference frame. We investigate interferometers of two concatenated passive PT couplers, either aligned with the lossy waveguide or opposite, as well as sandwiched between lossless 50:50 directional couplers on each end, as shown in Fig. 1(b). These four systems wildly differ in geometry, yet can all be described in terms of a transformation M, consisting of a 50:50 directional coupler followed by a PT coupler (Fig. 1(c)). We implement these non-Hermitian systems using evanescently coupled waveguides fabricated by femtosecond-laser direct writing and probe their two-photon behavior [5]. Figure 1(d) shows the measured visibility of the two-photon quantum interference as a function of the length of a single PT coupler. As a function of length we observe that the visibility oscillates between negative (Hong-Ou-Mandel bunching of photons) and positive (antibunching-like). Such antibunching behavior is precluded in a lossless system and can only be achieved in a non-Hermitian context. While differing in composition, the $X(M^{\mathrm{T}}XM)$ configuration indeed displays behavior identical to $M(XM^{\mathrm{T}}X)$, confirming the expectation that the permanent is preserved via their symmetry.

In summary, we have identified types of sequences of two-mode systems whose permanents remain invariant when reversing the order of the sequence, and experimentally verified these findings in PT-symmetric interferometers of varying composition by demonstrating that two-photon correlations are indeed invariant on the order. Our results emphasize that even in small two-mode systems quantum correlations may be related in ways that are a priori not obvious, which may inspire design of linear optical networks that harness non-Hermiticity for quantum information processing and sensing.

Space-time Quantum Metasurfaces

W. J. M. Kort-Kamp[1*], A. K. Azad[1], and D. A. R. Dalvit[1]

[1]Los Alamos National Laboratory, Los Alamos, NM 87545, United States
[*]kortkamp@lanl.gov

Abstract: We introduce the concept of space-time quantum metasurfaces for arbitrary control of the spectral, spatial, and spin properties of nonclassical light using a compact photonic platform. We show that spacetime quantum metasurfaces allow on-demand tailoring of entanglement among all degrees of freedom of a single photon and that spatiotemporal modulation induces asymmetry at the fundamental level of quantum fluctuations, resulting in the generation of steered and vortex photon pairs out of the vacuum.

Demonstrations of metasurfaces in quantum photonics are based on meta-atoms whose optical properties are determined by their material composition and geometrical design, and the lack of spatiotemporal control severely limits the functionalities that state-of-the-art quantum metasurfaces can attain. At the classical level, space-time metasurfaces have been shown to provide that higher degree of control, both by reconfigurable and fully dynamic tailoring of the optical response of meta-atoms using analog and digital modulation schemes. Transitioning spatiotemporal modulation through the classical quantum divide could be critical to enable novel opportunities for flat quantum photonics. We put forward the concept of space-time quantum metasurfaces (STQMs) for spatiotemporal control of quantum light [1]. In the STQM paradigm, meta-atoms are modulated in space and time enabling manipulation of quantum light interacting with the dynamical metasurface. STQMs come in different flavors, including quantum systems such as monolayer atom arrays driven by laser pulses, quantum-classical systems such as quantum emitters embedded in modulated nanostructures, and meta-atoms made of classical or quantum materials with a driven electro-optical response. Here, we discuss examples for the last two flavors.

We first study the entanglement dynamics of a single photon as it transits through a dielectric metasurface whose permittivity is spatiotemporally modulated to create a synthetic phase for photons. The identical meta-atoms are anisotropic and are suitably rotated with respect to each other (Fig. 1, top), imprinting a Pancharatnam-Berry geometric phase in the quantum light field. When the geometric phase is a linear function of the meta-atoms' positions, it generates spin-path correlations, while a linear synthetic phase creates path-color correlations. The two correlations are intertwined through the path and the photon evolves into a state that is hyperentangled in spin, path, and color. Considering an incident linearly polarized single-photon pulse impinges on the metasurface, the probability amplitude to find the output in a state with frequency $\omega_p = \omega_0 + p\Omega$, momentum $\boldsymbol{k}_{p,q} = \boldsymbol{k}_0 + p\boldsymbol{\beta}_s + q\boldsymbol{\beta}_g$, with left/right circular polarization is

$$|c_{p,q}^{L/R}(t)|^2 = \cos^2\left(\frac{\omega_0 t\Delta\alpha}{2V_{uc}}\right) J_p^2\left(\frac{\omega_0 t\Delta\alpha}{2V_{uc}}\right)/2,$$

where V_{uc} is the volume of the unit cell and $\Delta\alpha$ the meta-atom polarizability modulation amplitude. The probability that the output photon is in a given harmonic as a function of the modulation depth is

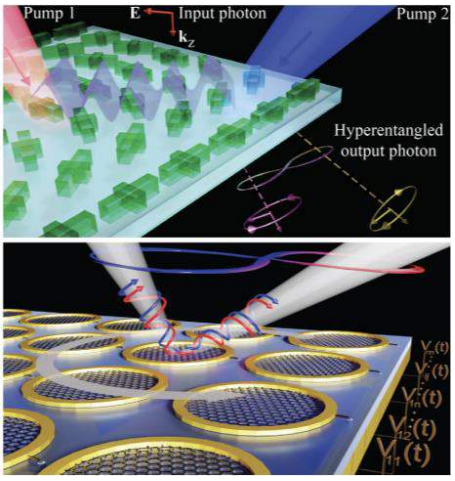

Fig. 1: *(Top) A dielectric STQM induces color-spin-path entanglement on a single photon. (Bottom) A graphene-based STQM generates entangled vortex photon pairs out of the quantum vacuum.*

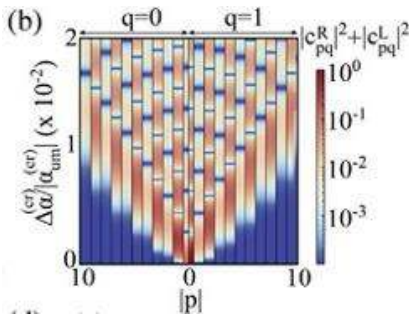

Fig. 2: *Conversion probability of an input photon into an output photon in frequency harmonic and momentum diffraction order versus polarizability modulation depth.*

shown in Fig. 2. At zero modulation, the output has the same frequency as the input and is an equal superposition of right- and left-polarized geometric-phase-kicked states. As the modulation increases, transitions to only the first few frequency and momentum harmonics occur and a larger amount of the Hilbert space is explored at large modulation depths.

We now study STQMs comprising modulated quantum materials and manipulating quantum vacuum fluctuations. We consider a graphene-disk STQM whose Fermi energy E_F is spatiotemporally modulated. The geometric phase is zero and the highly localized plasmons supported by the graphene disks [2] result in resonant enhancements of the light-matter interaction conducive to the efficient coupling of the STQM with the quantum vacuum. The STQM couples to the quantum electromagnetic field via a photon-number-nonconserving Hamiltonian that describes an analog of the dynamical Casimir effect (DCE) in which an oscillating boundary excites virtual into real photons. The STQM synthetic phase allows for a novel degree of control over the quantum vacuum, beyond previously demonstrated DCE setups: in STQMs steered and twisted DCE photons can be produced, reflecting that Lorentz reciprocity is broken at the level of quantum vacuum fluctuations. We design the metasurface to operate in the low-THz regime, and consider modulation frequencies also in the same range, which can be achieved using dynamical optical gratings and graphene's Kerr nonlinearity. We compute the rates of photon production out of the quantum vacuum using time-dependent perturbation theory. Energy conservation dictates that the photon pairs satisfy $\omega + \omega' = \Omega$. Figure 3 shows the emission rate for the linear synthetic phase as a function of momentum kick and Fermi energy. Giant photon-pair production rates on the order of 10^{12} photons/(cm^2 s) are obtained at low-THz driving frequencies and modest modulation depths.

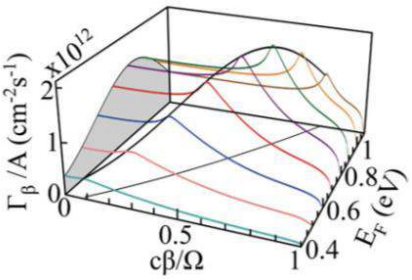

Fig. 3: *Two-photon emission rate of a graphene-based STQM versus dopintg level and linear synthetic phase gradient amplitude.*

In conclusion, we uncovered a key property of STQMs relevant for applications: On-demand reconfiguration of the synthetic phase allows dynamically tunable quantum correlations, enabling one to tailor the nature of entanglement depending on the symmetry properties of both geometric and synthetic phases. We also illustrated a second key property of STQMs with fundamental relevance: Lorentz nonreciprocity at the deepest level of vacuum fluctuations is attained through joint space and time modulations of optical properties and can be interpreted as an asymmetric quantum vacuum. Novel photonic devices potentially enabled by the proposed STQM concept include quantum emitters with reconfigurable spatial modes, quantum nonreciprocal routers and isolators for free-space photon transport in distributed quantum networks, and active quantum sensors with photon steering capabilities.

Abstract: A topological array composed of coupled microring resonators was simulated using passive lumped-element components. The topological bandgap is observable in the simulated spectrum, and no topological bandgap is present for a simulated trivial array which has no synthetic magnetic field phase accumulation. The material platform is oxide clad tantalum pentoxide which has low-loss performance at telecom wavelengths. The simulated transmission spectra have similar features to measured experimental arrays. This work demonstrates the capability of using rudimentary photonic circuit elements of waveguides and waveguide couplers to simulate and analyze complex topological array performance.

Topological photonic devices have similarities to bulk insulation and edge conduction of electrons in topological insulators [1-3]. These photonic devices are studied for robust light transmission even in the presence of defects. Silicon waveguide devices from photonic foundries have demonstrated topological behavior based on the integer quantum Hall Effect (QHE) [4]. Demonstrated applications are optical delay lines [3], and photon pair generation [5]. Recently the anomalous QHE has also been shown [6]. Frequency combs utilizing lower loss waveguides like SiN [7] have been proposed, and integer QHE devices have been demonstrated in tantalum pentoxide [8]. Tantalum pentoxide has a similar loss to SiN but a 3-times higher non-linearity [9].

The standard solution for simulating QHE topological arrays is using tight-binding modeling. This single-mode approximation is useful for modeling the energy transfer across the array based on coupling rates and accumulated phase shifts. It is valuable for viewing the energy distribution for a topological mode, and including disorder in site-resonators. However tight-binding simulations do not represent waveguide dispersion, group index, free spectral range, or include anti-resonant link-resonators.

Our alternate method for simulating topological array behavior was done with a commercially available photonic integrated circuit (PIC) simulation package [10] to graphically perform the transfer-matrix method (TMM). A ring resonator is represented by segmented waveguide regions and coupling regions, and an array can be constructed by coupling rings with link resonators. Waveguides were simulated using a finite-difference eigenmode (FDE) solver and waveguide coupling power transfer was simulated with finite-difference time-domain (FDTD). A synthetic magnetic field was imparted by modifying specific waveguide lengths for appropriate phase shifting. Once each component is defined by frequency dependent scatting matrix parameters, the components are assembled into an array and the transmission matrix for an entire array can be calculated. Backscatter, disorder, and array mode profiles are currently not included in these simulations. Figure 1 illustrates the transmission spectra for 10×10 arrays, a topological array with an applied phase shift and a trivial array with no phase accumulation. A flat bandgap is seen in the topological array that is not present in the trivial spectrum. Comparing with experimental results for the same modeled geometry shows the same features from the simulation, however there is more loss present in the experimental data. We believe that this work is the first use of photonic circuit modeling applied to simulate topological array behavior.

Abstract: GaN-based visible range topological PhCs consisting of a honeycomb lattice of C6 symmetry triangular nanoholes were successfully fabricated by a combination of hydrogen environment anisotropic thermal etching (HEATE) and wet etching of AlInN sacrificial layer. Experimentally obtained photonic band diagram showed manifestation of topological properties such as, intensity inversion of upper- and lower-band-edge at G-point, and interfacial topological edge states. These topological properties were verified by FDTD simulation with precisely reproduced three-dimensional models.

In topological photonic crystals (PhC) [1], which introduce the concept of topology into photonic crystals (PhC), topological edge states formed at the interface of PhCs with different topologies exhibit unique propagation phenomena such as strong robustness against bending and unidirectional propagation, and are expected to be applied to various novel functional devices. Experimental verification of topological PhC is progressing rapidly in the near-infrared (NIR) wavelength region, where fabrication techniques are mature. In this study, we report the first fabrication of topological PhC using GaN, a well-known visible light emitting device material, and the successful observation of its topological properties in the visible wavelength.

The issues in GaN based visible region PhCs are the fact that the dimension of PhC is miniaturized to less than half of it in NIR and difficult processability. We fabricated GaN PhC membrane using combination process of low-damage precise GaN etching technique of hydrogen environment anisotropic thermal etching (HEATE) [2], and wet etching of AlInN sacrificial layer[3]. A model of a typical topological PhC with triangular nanoholes arranged in a deformed honeycomb lattice having C_6v symmetry and a design of a GaN-based PhC are shown in Fig.1. A 15 nm-thick SiO_2 film was deposited on the GaN (200nm)/AlInN (300nm)/GaN (4.8μm)/(0001)Al_2O_3 wafer, then hexagonal clusters consisting six triangular nanoholes with a period a_0 (=500-400 nm) were formed to expose GaN surface via conventional electron beam lithography and CF_4 dry-etching process. The cluster region where the distance R between the center of gravity of the triangular nanohole and the hexagonal cluster center is $R<a_0/3$ is a trivial PhC and that with $R>a_0/3$ is a topological PhC, and a topological edge state is formed at the boundary between two PhCs. The PhC pattern was transferred to the upper GaN layer using HEATE, and then the AlInN sacrificial layer was selectively removed by hot nitric acid wet etching to fabricate a membrane topological PhC. Fourier images of the fabricated PhC in the visible wavelength (400-730 nm) were obtained by a spectral microscope system every 1.0 or 0.4 nm, and three-dimensional (3D) photonic band diagram was constructed by stacking these images and two-dimensional band diagrams were drawn from the cross section. The observed photonic band diagrams were compared with the 3D-finite-difference time-domain calculations (3D-FDTD) simulation based on actual PhC structure to verify the occurrence of topological properties.

Fig. 2(a), (c) show the photonic band diagrams observed in the trivial and topological PhC with a_0=450 nm,

and the surface SEM images of each PhC are shown in the inset. The formation of fine triangular nanoholes with a side length of 174 nm and a radius of curvature of 15 nm at the apex was confirmed. The membrane thickness was 170 nm. The photonic band gap was confirmed at around 620 nm in both PhCs. At the Γ-point, intensity of lower-band edge is stronger for trivial PhC but that of upper-band edge is stronger for topological PhC. This intensity inversion reflects the topological property related to the inversion of the P and d modes of the out-of-plane magnetic field component at the band edge. The band structures are in good agreement with the 3D-FDTD simulation results shown in Figs. 2(b) and 2(d). Figs. 3(a), (c), and (e) show the photonic bands obtained by irradiating the boundary region between the trivial and topological PhC with linearly polarized light, right-handed polarized light, and left-handed polarized light, respectively. Fig.3(b), (d), and (f) are corresponding simulation of edge modes calculated by 3D-FDTD using a supercell. The clear edge modes depend on the polarized light were observed at the band gap wavelength and the experimental results are well reproduced by simulation.

We have successful observed topological photonic phenomena in the visible region using GaN-based materials for the first time, and the results show potential of topological PhC devices in the visible region.

Abstract: We study the relation between the degree of circular polarization of eigenmodes and far-field optical properties in dielectric metasurfaces supporting Bound States in a Continuum (BICs) or with symmetry breaking leading to Circularly Polarized States (CPSs). The Stokes parameter S_3 is extracted from finite-difference time-domain (FDTD) and rigorous coupled-wave analysis (RCWA) simulations. In addition to the symmetries imposed by the lattice, the S_3 parameter has a nontrivial dependence on the wavevector, with different regimes that are manifest in the optical properties.

Photonic crystal (PhC) slabs, or periodic dielectric metasurfaces, support BICs that are not coupled to the radiation field. Such BICs lead to vortex singularities in momentum space with an integer winding number or topological charge [1]. Symmetry-protected BICs can split into CPSs with a semi-integer topological charge upon symmetry reduction [2,3]. Such polarization singularities are of current interest in the field of topological photonics and could in principle be used to tailor the polarization properties in the far field [4].

In this work, we consider a PhC with square lattice and different kinds of bases, leading to BICs and CPSs. Our goal is to explore the relation between the Stokes parameter S_3 of the eigenmodes (which measures the degree of circular polarization) and the optical properties in the far field. An example of polarization singularities is shown in Fig. 1: we consider the lowest resonance in the photonic band structure below the diffraction limit, which in the case of a circular hole displays a symmetry-protected BIC at k=0. The Stokes parameter S_3 is generally nonvanishing except along directions that correspond to symmetry planes, where the eigenmodes are linearly polarized. A nonvanishing S_3 is associated to the breaking of time-reversal symmetry in the formation of quasi-normal modes with complex eigenfrequencies. In the case of a triangular hole, the BIC splits in two CPS with $S_3=\pm1$ that appear along the [10] direction in the S_3 map.

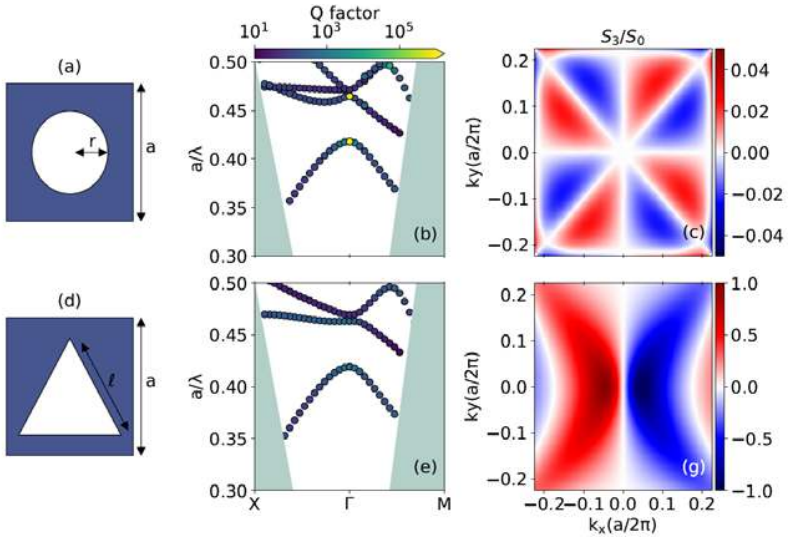

Figure 1: (a), (d) Sketch of a unit cell of a PhC slab with a square lattice of circular or triangular air holes. (b), (e) TE-like photonic band structure together with the quality factor (Q) of each resonance. (c), (g) k-space map of the normalized Stokes parameter S_3 of the lowest resonance. Parameters: photonic crystal slab of thickness d=0.3a, refractive index n=3.48, circle radius r=0.3a (b,c) or triangle side l=0.8081a (e,g) yielding the same air fill fraction in both cases.

In Fig. 2 we show an example of the relation between the far-field optical response and the properties of the eigenmodes. Reflection spectra for circularly polarized light show that around the incidence angles $\theta=\pm5°$ (which correspond to the CPSs in Fig. 1g), the incident field couples to the eigenmode only for right circular polarization (RCP) for positive θ, only for left circular polarization (LCP) for negative θ. The circular dichroism in reflectivity, $CD_R=(R_{lcp}-R_{rcp})/(R_{lcp}+R_{rcp})$, reaches ±1 at the same angles. Its dependence of the incidence angle θ corresponds very well to the behavior of the Stokes parameter S_3 extracted from FDTD and RCWA simulations.

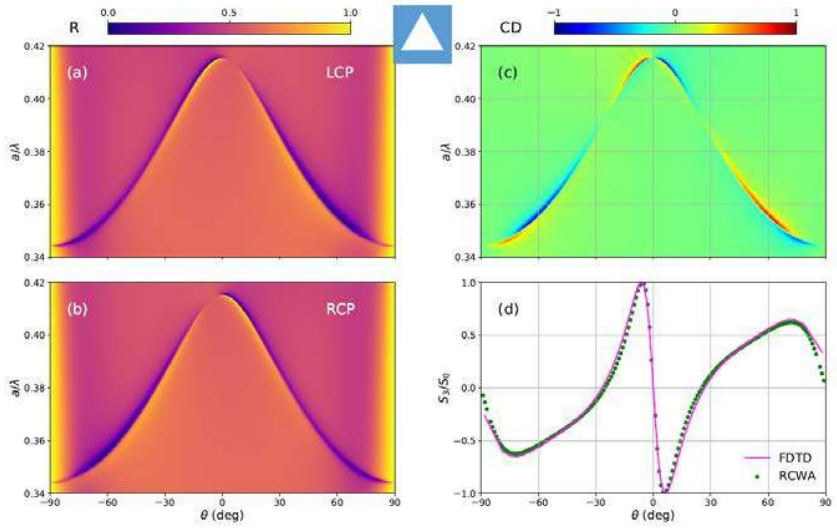

Figure 2: (a), (b) Reflectivity for left- and right-circular polarizations, (c) reflectivity CD, (d) normalized Stokes parameter S_3 of the lowest eigenmode extracted from the simulations. The results are for the square lattice PhC slab with triangular holes of Fig.1, lower panels, orientation along the [10] direction.

We further explore the relation between polarization singularities and the optical properties by considering various shapes for the holes, which continuously interpolate between a circular hole (leading to the C_{4v} point group in the square lattice) and a triangular hole (breaking the C_2 symmetry and leading to the C_{1v} point group). In general, the degree of circular polarization has a complex dependence on wavevector with sign inversions, and it is maximized close to CPS. The optical properties are found to be determined by a complex interplay between the effect of topological singularities and the direct scattering term, as follows from temporal coupled-mode theory [5]. The results may be exploited to design structures with given polarization properties.

Abstract: Abstract: The direct measurement of a single emitter decay rate and the simultaneous knowledge of its position is a powerful tool for the study of light-matter interaction at the nanometer scale. We use single-molecule fluorescence lifetime imaging microscopy (smFLIM) to map at the nanometer scale the decay rate enhancement of single emitters coupled to new nanomaterials platforms that significantly modified the electromagnetic environment.

Exploiting the quantum behavior of light for new or advancing existing technologies will rely on better understanding and manipulating light in the quantum regime. A necessary part of that developments must include understanding on how to control the spontaneous emission of light, process that determines how likely, how quickly and where an excited emitter will release a photon. In this work, we study how new dielectric and plasmonic structures and metamaterials platforms can manipulate the response of nearby quantum emitters, by using far-field super resolution microscopy we observe this light-matter interaction at the nanometer scale.

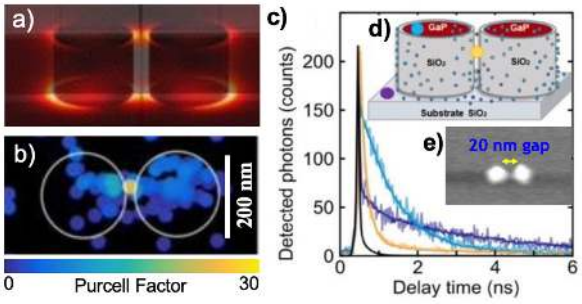

Figure 1. a) Electromagnetic field modification by a GaP nanodimer when illuminated by a 650 nm plane wave. b) Super resolved map of measured spontaneous emission lifetime of quantum emitters coupled to gap nanoantenna. c) Measured decay rate curves for single-emitter on glass substrate (purple), on top of antenna (blue) and in the 20nm gap of the dimer (yellow) as shown in d). e) Scanning Electron Microscopy of fabricated dielectric nanoantenna. The emission of the quantum emitter is divided into two detections paths; 1. The single-photon emission lifetime is measured by a single-photon avalanche diode connected to time correlating single photon counter (TCSPC) and 2. correlated with single molecule localization microscopy SMLM to image below the diffraction limit.

The principle of our research is shown in Fig. 1; when light illuminates a nanostructure, the electromagnetic field is concentrated extremely close to the particle by resonant optical modes. Quantum emitter's spontaneous emission will dramatically depend on its position near these modes. This makes the single-photon emission (SPE) rate a precise measure of location, far more accurate than the optical resolution from the same photon. In order to study at the super-resolution level, the modification of SPE with the proposed nanodevices that present unique photonics properties, we combine the Nobel prize winner single molecule super localization microscopy (SMLM) technique (used mainly for bioimaging) with Nanophotonics to unveil light-matter interaction at the nanoscale. Allowing the detection of the single-emitter position and emission rate modification with far-field microscopy without perturbing the local environment with metallic probes as previous works applying near-field scanning techniques. We show single-emitter super-resolved imaging of radiative decay rate enhancement a 20 nm gap dielectric nanoantenna, reporting the use of gallium phosphite (GaP) nanodimers for radiative decay rate enhancement (above 30 Purcell factor) at room temperature and detected at the single-emitter resolution.

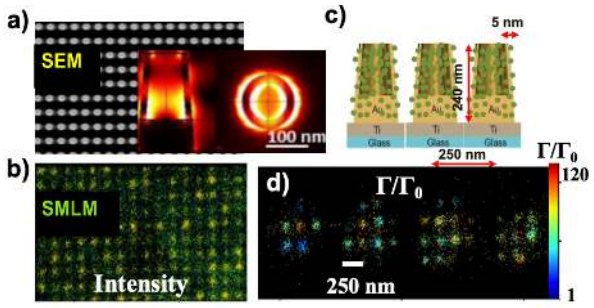

Figure 2. a) SEM images of 3D fabricated HCNPs and calculation of electromagnetic near-field modification with 3D distribution b) Measured Super-resolved image of emitters emission coupled to plasmonic modes in lattice of HCNPs. c) Representation of nanostructure dimensions with quantum emitters deposited all along separated 4 nm from Au surface. d) Measured Super-Resolved single-emitter decay rate enhancement map at room temperature.

In the contrary when placed single emitters on a square lattice hollow nanoconical pillars HCNP that presents high enhancement and 3D modification of electric field; SPE rate is modified significantly all along the material (Fig. 2). We show super resolved maps of total and radiative decay rate enhancement of quantum emitters coupled to the HCNP metamaterial at the super resolution level, with enhancement above 100. We study as well single emitters couple to hyperbolic metamaterials observed at the single-emitter resolution. We will discuss experimentally and numerically the important nanophotonics effects responsible of the modification of the quantum emitter properties in each studied material platform and how to optimize the emission depending on the wavelength and desired application. An interesting consequence of this work stems from the rate of emission being extremely position specific and enhanced at room temperature; this could have significant implications on the development of light sources capable of emitting single photons on demand at room temperature, for quantum sensing with atoms of local electric and magnetic fields, super-resolution microscopy and highly sensitive spectroscopic measurements.

Quantum remote control of vortex beams using a metasurface

Hong Liang[1], Hammad Ahmed[2], Wing Yim Tam[1], Xianzhong Chen[2*], and Jensen Li[1*]

[1]Department of Physics, The Hong Kong University of Science and Technology, Clear Water Bay, Hong Kong, China

Abstract: We propose and experimentally demonstrate a scheme to remotely and continuously control the vortex beam structure using polarization-entangled photon pairs together with a metasurface. With a heralding technique adopted, the spin-orbit coupling provided by the metasurface translates to a tailor-made entanglement of the orbital angular momentum and the polarization of the signal photon. Then, the polarization of the heralding photon is used to remotely control the vortex structure of the signal photon, directly manifested as a continuous orbital rotation.

Metasurfaces, with distinct capability to modulate light, have led to unprecedented applications such as beam steering [1]. One particular interest is to hybridize the polarization and orbital angular momentum (OAM) of light to generate vortex beams through spin-orbit interactions (SOI) [2]. The generated beams, carrying different OAMs, have a great potential to enhance the channel capacity in optical communication, leading to applications like OAM-encoded holograms [3]. At the same time, recent interests arise in adopting metasurfaces in quantum optics, including high-dimensional quantum sources, quantum entangled states manipulation and reconstruction [4-6]. Our work focuses on generating remotely controlled vortex beams with a geometric-phase metasurface and polarization-entangled photon pairs (heralding and signal photons). Specifically, the SOI from the metasurface entangles the OAM and polarization of the signal photons. As a result, we can select different heralding polarizations to control the vortex state of the signal photons remotely and continuously. Our demonstration using a metasurface can also be extended to more sophisticated vortex structures of the signal photon and opens a new avenue for quantum communication with increased information capacity.

Fig. 1(a) shows the proposed scheme for quantum remote control of vortex beams with a geometric-phase metasurface and a polarization-entangled photon pair (signal and heralding photons). The signal photon is sent to interact with the metasurface with SOI, while the heralding photon is sent to a polarization analyzer. The metasurface is designed to induce different OAM changes depending on the spin of the input light and hence entangles the polarization and the OAM of the signal photon. Together with the polarization entanglement between the heralding and the signal photon, the polarization of the heralding photon and the vortex structure of the signal photon are entangled as a result. Thus, the heralding detection with a rotating linear polarization will result in a rotating vortex structure of the signal photons. This control scheme can be visualized in Fig. 1(b) using the mapping between two Poincaré spheres for the heralding polarization and signal vortex state. As shown in Fig. 1(b), points with the same color on the two spheres show matching pairs of the controlling polarization and the corresponding vortex state. Specific cases located on the equator are examined and verified with experimental results.

Figs. 1(c-f) show the experimental and theoretical results for selected linear heralding polarizations, from the horizontal (H), diagonal (D), vertical (V), to antidiagonal (A) polarizations. For example, Fig. 1(c) shows the signal vortex state heralded by the photons with horizontal polarization. In this case, the signal vortex state collapses to the state $|+1\rangle - |-1\rangle$, with the normalization factor omitted, resulting in an intensity profile of two bright lobes with a horizontal dark line in between. On the other hand, using vertical photons to herald, the signal states collapse to $|+1\rangle + |-1\rangle$, with two lobes and a vertical dark line in between, as shown in Fig. 1(e). Similarly, the results with diagonal and antidiagonal heralding photons are shown in Figs. 1(d,f) with vortex states $|+1\rangle \pm i|-1\rangle$, where the "+" ("-") sign is for the D (A) polarization. Furthermore, the heralded results all have higher signal-to-noise ratios than the classical results, showing greater robustness to noise than single-photon imaging.

In conclusion, based on a geometric-phase metasurface, we experimentally demonstrate a heralding scheme, with great robustness to noise, to control vortex structures of OAM interference remotely and continuously using polarization-entangled photon pairs. Through this work, multifunctional metasurfaces further extend their applications in the quantum optical regime, providing a platform to implement quantum information processing with tailor-made vortex structures. Importantly, such a continuous heralding control of rotating orbitals provides additional dimensions in the quantum state manipulation that could benefit future quantum communication protocols.

With more complex metasurfaces, further extensions to higher OAM values, structured beams, and other degrees of freedom of light will be possible to enhance the associated information capacity in quantum communication.

Quantum dynamics and dissipation-driven formation of entangled dark states in strongly coupled many-qubit systems in solid-state nanocavities

M. Tokman[1], A. Behne[2], B. Torres[2], M. Erukhimova, Y. Wang[2], and A. Belyanin[2*]

Abstract: We study quantum dynamics of many-qubit systems strongly coupled to a quantized electromagnetic field of a nanocavity in the presence of decoherence and dissipation for both fermions and cavity photons, and taking into account the nonuniform nanocavity field and the spread of qubit transition frequencies. We show that the dissipation in a cavity may drive the system into many-qubit entangled dark states that live much longer than the cavity decay time and can be used for quantum information applications.

Solid-state nanocavity QED attracted much interest as a promising platform for quantum information and quantum sensing systems; A typical scenario involves an ensemble of quantum dots, defects in crystals, or molecules, strongly coupled to a quantized electromagnetic field in a plasmonic nanocavity. The cavity field is strongly nonuniform, which makes the qubit-cavity coupling strength strongly variable from qubit to qubit. Moreover, for many popular quantum emitters, such as quantum dots, optically active point defects, excitons in semiconductor nanostructures etc., the spread of transition frequencies exceeds homogeneous linewidth, making inhomogeneous broadening the dominant source of dephasing. Any of these factors break permutation symmetry and increase the complexity of the problem. We are able to drastically simplify the analysis and obtain analytic or semi-analytic solutions for quantum dynamics of strongly coupled dissimilar qubits or multilevel fermionic systems in the presence of decoherence and dissipation for both fermions and cavity photons. This progress is made possible by applying a modified version of the stochastic Schroedinger equation at the level of Lindblad approximation. Here we will concentrate on dissipation-driven formation of highly entangled dark states that are decoupled from the cavity field and therefore live much longer than the decay time of cavity photons, even though each qubit remains strongly coupled to the cavity field. The ability to generate and control such states is an important problem for plasmonic nanocavities where the dissipation of a cavity mode is much faster than the relaxation in quantum emitters. We determine the conditions in which the formation of dark states is possible even in systems with strong inhomogeneous broadening and with energy bands.

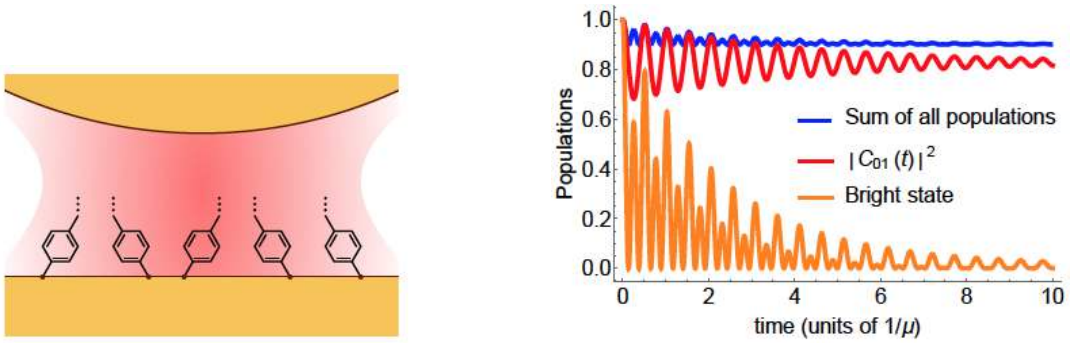

Figure 1. Left: A sketch of an ensemble of quantum emitters (e.g. quantum dots or molecules) in a strongly nonuniform field of a plasmonic nanocavity. Right: Time evolution of the populations for an ensemble of 21 qubits

in the nanocavity formed by the metallic sphere of radius 10 nm with its center located at 12 nm above the substrate. The molecules are assumed to be distributed randomly within a circle of radius 10 nm on the substrate, with the center of the circle at the cavity axis. The cavity decay time is $1/\mu$ = 20 fs. Top blue curve: The sum of the occupation probabilities of all qubits when only the qubit in the center of the cavity is excited, i.e., $C_{01}(0) = 1$; middle red curve: the occupation of the initially excited qubit; bottom orange curve: the sum of all occupation probabilities when the qubits were initially prepared in the bright state.

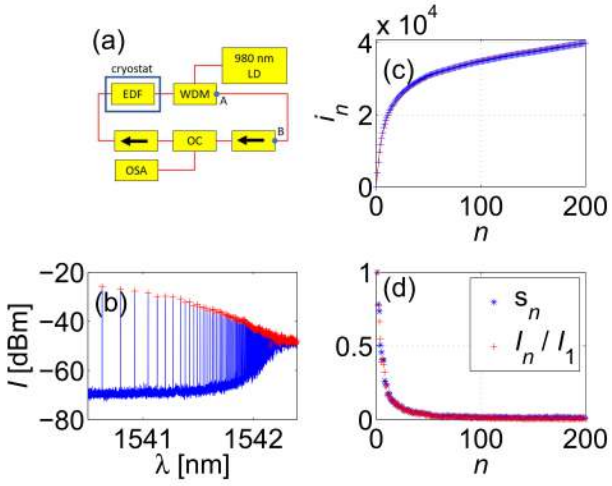
Abstract: We experimentally study a fiber loop laser with an integrated Erbium doped fiber (EDF). The output optical spectrum is measured as a function of the EDF temperature. We find that below a critical temperature of about 10K the measured optical spectrum exhibits a sequence of narrow and unequally-spaced peaks. Externally injected light and filtering are employed for tuning the peaks' wavelengths. Operation of the device as an optical memory having storage time of about 20 ms is demonstrated. The multimode lasing tunability can be exploited for novel applications in the fields of sensing, communication, and quantum data storage. © 2023 The Author(s)

1. Introduction

Erbium doped fibers (EDF) are widely employed in a variety of applications. Key properties of EDF can be controlled by varying the temperature. Multimode lasing has a variety of applications in the fields of sensing, spectroscopy, signal processing and communication. Multimode lasing in the telecom band has been demonstrated by integrating an EDF cooled by liquid nitrogen into a fiber ring laser [1–3]. It has been recently proposed that EDF operating at low temperatures can be used for storing quantum information [4].

In this work we study a fiber loop laser with an integrated EDF. We measure the emitted optical spectrum as a function of the EDF temperature. Below a critical temperature of about 10 K the measured optical spectrum exhibits an unequally-spaced optical comb (USOC) made of a sequence of narrow peaks. The observed USOC and multimode lasing are attributed to intermode coupling [5]. We find that the wavelengths at which the multimode lasing occurs can be controlled by light that is externally injected into the fiber loop. The possibility of using the device under study as an optical memory is explored, and a storage time of about 20 ms is demonstrated. The USOC controllability, together with its high stability, can be exploited for facilitating novel applications in the fields of sensing, communication, and quantum data storage.



2. Experimental setup

The experimental setup is schematically depicted in Fig. 1(a). EDF having length of 20 m, absorption of 30 dB m^{-1} at 1530 nm, and mode field diameter of 6.5μm at 1550 nm, is cooled down using a cryogen free cryostat. The EDF is thermally coupled to a calibrated silicon diode serving as a thermometer, and it is pumped using a 980 nm laser diode (LD) biased with current denoted by I_{D}. The cold EDF is integrated with a room temperature fiber loop using a wavelength-division multiplexing (WDM) device. Two isolators [labeled by arrows in the sketch shown in Fig. 1(a)] and a 10:90 output coupler (OC) are integrated in the fiber loop. The loop frequency f_{L} (inverse loop period time), which is measured using a radio frequency spectrum analyzer and a photodetector, is given by $f_{\mathrm{L}} = c/(n_{\mathrm{F}} l_{\mathrm{L}}) = 4.963\,\mathrm{MHz}$, where c is the speed of light in vacuum, $n_{\mathrm{F}} = 1.45$ is the fiber refractive index, and $l_{\mathrm{L}} = 41.7\,\mathrm{m}$ is the fiber loop total length. An optical spectrum analyzer (OSA) is connected to the 10:90 OC.

3. USOC

Near wavelength of 1540 nm and below a critical temperature of about 10 K the measured optical spectrum exhibits narrow peaks at a sequence of wavelengths denoted by $\{\lambda_n\}$, where $n = 0, 1, 2, \cdots$ [see Fig. 1(b)]. For the data presented in Fig. 1 $\lambda_0 = 1540.629\,\mathrm{nm}$ and $\lambda_1 - \lambda_0 = 0.1661\,\mathrm{nm}$. The frequency f_n associated with wavelength λ_n is given by $f_n = c/\lambda_n$. The intensity of the USOC peak occurring at wavelength λ_n is denoted by I_n.

The normalized frequency sequence $i_n \equiv (f_0 - f_n)/f_{\mathrm{L}}$, and the normalized intensity sequence $s_n \equiv I_n/I_1$ are

.

Fig. 1. USOC (a) The experimental setup. (b) The measured optical spectrum with diode current $I_{\mathrm{D}} = 120\,\mathrm{mA}$. (c) Comparison between the measured normalized frequencies $i_n = (f_0 - f_n)/f_{\mathrm{L}}$ and the calculated values of $\nu \log p_n$ [see Eq. 1]. The dimensionless pre-factor ν is found by fitting to be given by $\nu = 5610$. (d) Comparison between the normalized intensities I_n/I_1 and the normalized wavelength gaps $(\lambda_{n+1} - \lambda_n)/(\lambda_1 - \lambda_0)$ [see Eq. 2].

well describe by the following empirical laws

$$i_n = \nu \log p_n \,, \tag{1}$$

$$s_n = \frac{\lambda_{n+1} - \lambda_n}{\lambda_1 - \lambda_0} \,, \tag{2}$$

where ν is a positive constant, and p_n is the n'th prime number. The comparison between the measured values of $i_n = (f_0 - f_n)/f_{\mathrm{L}}$ and the calculated values of $\nu \log p_n$ [see Eq. (1)] yields a good agreement [see Fig. 1(c)]. The level of agreement is quantified by the parameter $\varepsilon = n_{\mathrm{m}}^{-1} \sum_{n=1}^{n_{\mathrm{m}}} |(i_n - \nu \log p_n)/i_{n_{\mathrm{m}}}|$, where n_{m} is the number of peaks that can be reliably resolved. For the data shown in Fig. (1) $n_{\mathrm{m}} = 200$ and $\varepsilon = 0.0043$. The comparison between I_n/I_1 and $(\lambda_{n+1} - \lambda_n)/(\lambda_1 - \lambda_0)$ [see Eq. (2)] is shown in Fig. 1(d). The underlying mechanism responsible for USOC formation has remained mainly unknown. The connection between the normalized frequency sequence $i_n = (f_0 - f_n)/f_{\mathrm{L}}$ and the sequence of prime numbers [see Eq. (1)] is discussed in [5].

4. USOC tuning and optical memory

A detailed description of USOC tuning measurements will be given in a forthcoming publication. These measurements demonstrate several methods that allow tuning of the wavelengths at which multimode lasing occurs. The forthcoming publication also reports on measurements of USOC memory time. Future study will focus on systematically characterizing spectral hole burning in the system under study, in order to explore its performance for quantum memory applications.

Abstract: Tip-enhanced photoluminescence (TEPL) can provide the spectroscopic image of photoluminescence with sub-nm resolution and probe the individual state of a single molecule. To discuss the microscopic optical response in the TEPL, we develop a theoretical framework based on nonlocal response theory and input-output theory. We can successfully obtain the photoluminescence intensity map reflecting the spatial distribution of transition dipole with distinguishing the different modes.

Tip-enhanced photoluminescence (TEPL) based on scanning probe microscopy enables to excite a sample locally and obtain an optical image with high resolution. The experiment demonstrated that TEPL could provide sub-nm resolution and the spectroscopic image of a single zinc phthalocyanine based on peak energy and line width of photoluminescence [1]. Imada et al. reported the capability to probe and control the individual state of a single molecule owing to the high space and energy resolution resulting from measuring the photoluminescence spectrum of a single phthalocyanine using a scanning tunneling microscope and tunable laser [2].

In this study, we propose the theoretical framework of TEPL based on the nonlocal response theory and input-output theory [3]. We self-consistently solve the molecular polarization and the electric field enhanced by the probe tip. The molecule is expressed with the nonlocal susceptibility based on the transition dipole of molecule. The electric field is expressed by the Green's function, where the presence of metallic structure is renormalized into the Green's function with the discrete dipole approximation [4]. Compared with the previous study on the theory of TEPL [5], we treat the Green's function with a dependency of frequency, and hence, we can correctly calculate photoluminescence even in the situation where the resonance level of the molecule shifts or splits due to the strong coupling between the gap plasmons sustained at the metal probe tip and the molecule.

Figure 1 shows the schematic model of TEPL calculation. The phthalocyanine molecule was located between the silver probe tip and the silver substrate. We considered the hemisphere with the minute protrusion as the silver probe. The Drude and critical points model was employed as the dielectric function of metal [6]. The transition

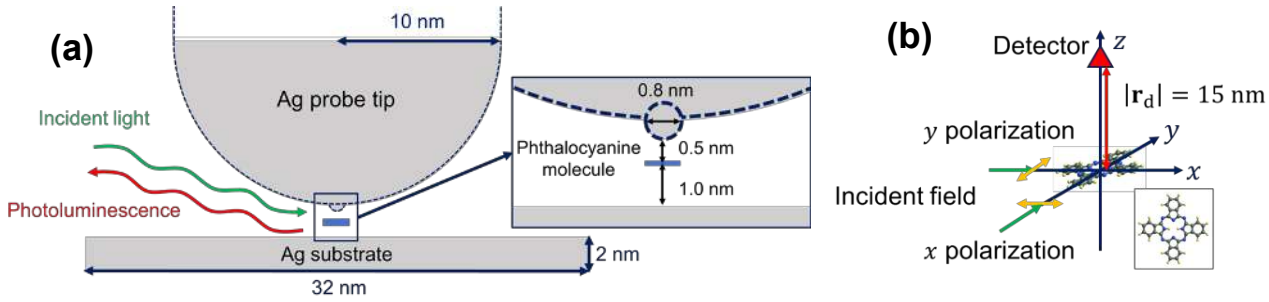

Figure 1 (a) Schematic model of TEPL. The inset shows the area in the vicinity of the protrusion. (b) The geometry of the incident field, the phthalocyanine molecule, and the detector. The inset shows the atomic structure of phthalocyanine.

dipole of the target molecule was obtained from the molecular orbit calculated by GEMASS [7]. We assumed the propagation and polarization direction of incident light for x and y as shown in Figure 1(b). As an elementary calculation at this time, we located the detector with the distance 15 nm from the sample above the tip and detected photoluminescence of the same energy as the incident light. Figure 2 shows a photoluminescence intensity map as a function of the probe tip position for optically allowed transition. Depending on the energy and polarization direction of the incident light, we can obtain the spatial distribution of the transition dipole of the selectively excited molecule. The effect of the nonlocality emerges especially in the case of optically forbidden transition with several nodes inside the molecule.

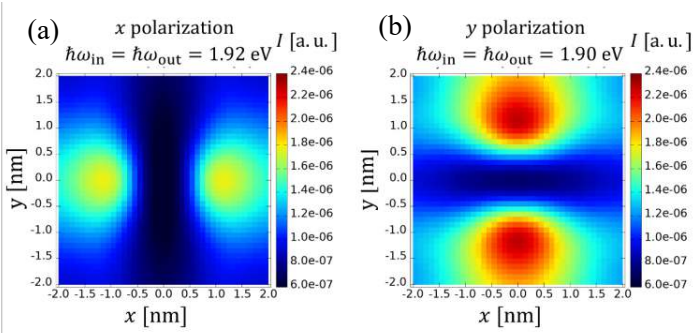

Figure 2 Photoluminescence intensity map in the case of the single molecule selectively excited by the incident field with (a) x and (b) y polarization.

In conclusion, based on the nonlocal response theory, we have constructed the theoretical framework of TEPL, which solved the electric field and the induced polarization of molecule self-consistently. By sweeping the probe tip location, we can successfully obtain the photoluminescence map of the phthalocyanine molecule. The obtained map indicated the selective excitation of molecule depending on the polarization of incident light. The theoretical framework will enable to explorer the physical properties inside of single molecules and contribute to the development of advanced technology of optical microscopy.

Terahertz virtual superlens via evanescent amplification in the radiating near-field

Alessandro Tuniz[1] **and Boris T. Kuhlmey**[1]

[1] The University of Sydney, School of Physics and Institute of Photonics and Optical Science, Camperdown, Australia

*corresponding author: alessandro.tuniz@sydney.edu.au

Abstract: We present a universal method for amplifying evanescent waves in the radiating near field, reconstructing sub-wavelength images akin to a virtual superlens. We quantify the trade-off between noise and measurement distance, and demonstrate complex image reconstruction down to λ/7 with amplitude signal-to-noise ratios below 25 dB between 0.18-1.5 THz. Our procedure applies to any near field probe, greatly relaxes experimental requirements for subwavelength imaging at sub-optical frequencies, and opens the door to non-perturbing near-field scanning.

Although imaging objects with sub-wavelength resolution is now common in the visible spectrum, it is experimentally challenging to do so at lower frequencies (GHz, THz), where it is most needed due to the large wavelengths used [1], and where a tip or antenna are typically brought into very close vicinity to the object in order to measure evanescent waves with high spatial frequencies. This can often be problematic, because the probe can perturb the near-field distribution itself. We show that the information encoded in evanescent waves can be probed much further than previously thought, as minute modulations in the signal, so that a near-field image can be obtained through suitable amplification of evanescent waves - akin to a virtual "superlens" [2]. Figure 1 shows a schematic of our approach: we image a planar source object with subwavelength field E_{obj}. Propagating waves (Fig. 1, dashed) carry information via $E \propto e(i\mathbf{k}\cdot\mathbf{r})$, where $k_z = (k_0^2 - k_x^2 - k_y^2)^{1/2}$ emerging from spatial frequencies satisfying $k_x^2 + k_y^2 < k_0^2$, imposing a lower limit on the features *d* which can be resolved in the far field. Evanescent waves carry spatial frequencies satisfying $k_x^2 + k_y^2 > k_0^2$ but exponentially decay in free space. We reverse this process via the transformation (x, y, z) → (-x, -y, -z) over a subsequent length *L*, numerically reversing the phase accumulated by the propagating waves and amplifying the evanescent waves. Figure 1(b) shows a photograph of the experiment, and Figure 1(c) shows a microscope image of the terahertz probe used. A moveable, fiber-coupled near-field (NF) detector [3] module enables the measurement of the electric field at the output of the laser-machined samples that spell the letters "THZ". The near-field is spatio-temporally resolved at every point via a raster scan, and is frequency resolved through Fourier transform.

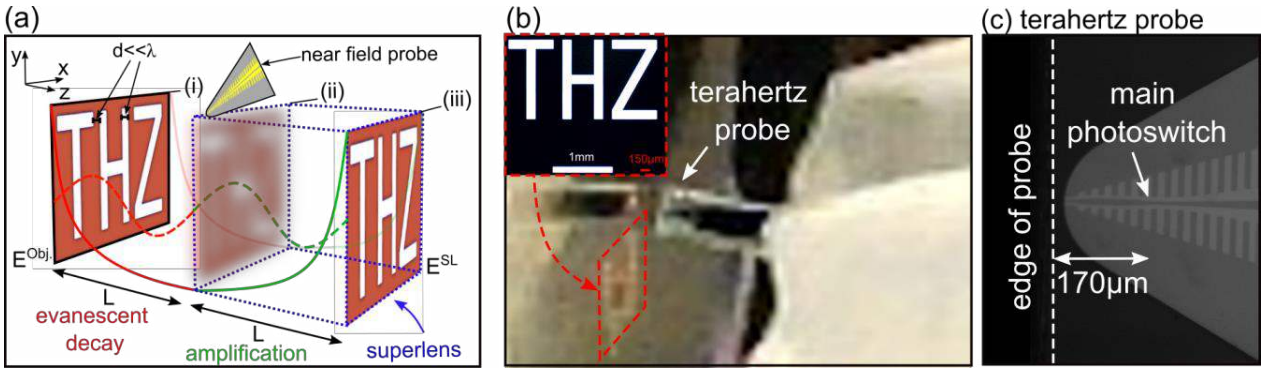

Figure 1. (a) Concept schematic of virtual superlens. (i) Sub-wavelength features are carried by evanescent waves which exponentially decay over L (red). (ii) The lower-resolution image is detected by a near field probe. The evanescent fields are then numerically amplified over L (green), leading to (iii) the original image, analogously to a superlens (blue). (b) Photograph of the near-field terahertz probe as it scans the surface of the sample. (e) Microscope image of the near-field terahertz probe, showing the location of its main photoswitch, which is at a nominal distance of 170 μm from the edge of the probe.

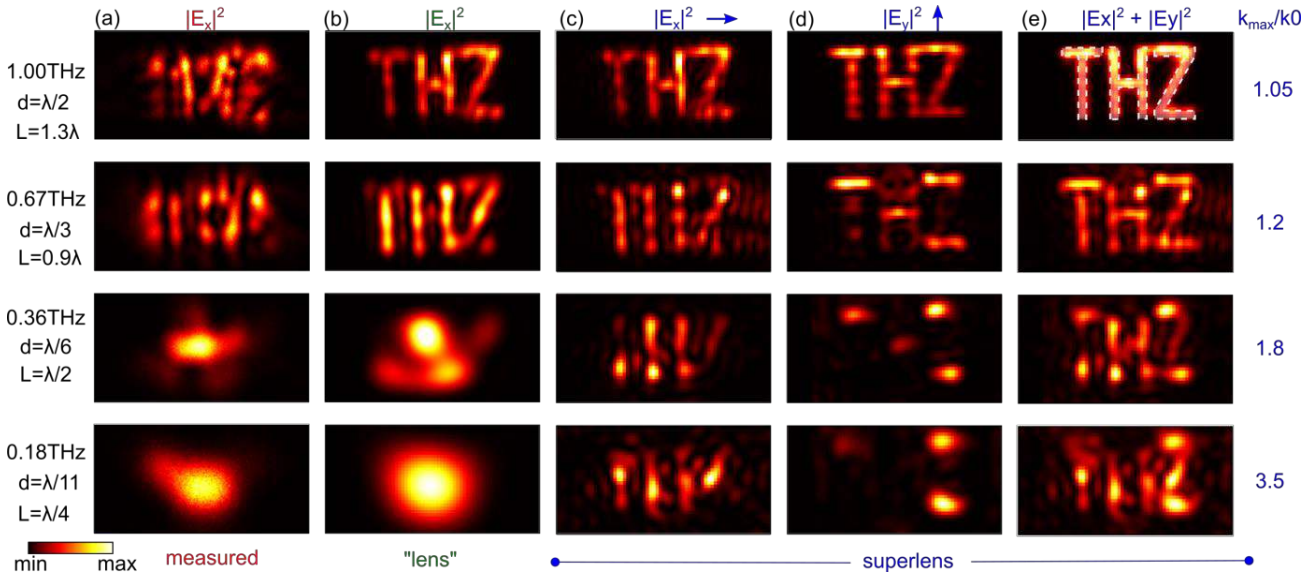

Figure 2. Superlens experiment, imaging the letters "THZ" (feature size: 150μm; detector distance: L = 440μm). (a) Raw measured $|E_x|^2$ at different frequencies labelled, with associated *d* and *L* in terms of λ. (b) Corresponding field after the superlens with maximum $k_{max} = k_0$ and (c) when $k_{max} > k_0$. (d) Reconstructed images using measured x- and y- polarized fields in (c),(d). k_{max}/k_0 for each row is shown on the right. Window area: 4mm × 2mm.

The gain applied to evanescent waves increases with spatial frequency, and is eventually dominated by noise. By equating the signal-to-noise ratio SNR with the amplification factor $\exp(k_z L)$ for a signal measured at a distance L, we obtain the maximum useful spatial frequency $k_{max}=k_0(1+\lambda/L\ \log 10/20\pi\ SNR)$ [4], which we use as a low-pass cut-off. We implement our procedure on a complex, large-area image formed by a laser-written metal sheet containing the letters "THZ" (minimum feature size: d=150μm; L = 440μm; SNR=15-25 dB, and k_{max}/k = 1-3.5) between 0.2-1 THz. Figure 2(a) shows the measured $|E_x|^2$ at different frequencies as labelled. Figure 2(b) shows the field after reversing the phase at different frequencies with $k_{max}=k_0$, i.e., conventional lens imaging. At 1.0THz (the diffraction limit) the letters can be discerned; at 0.67 THz, only the vertical features are resolved; lower frequencies do not provide a sufficiently sharp image to discern the finer features of the original image, with only a single large spot occurring at 0.18 THz. Figure 2(c) shows the corresponding retrieved intensity at different frequencies with k_{max}/k_0 as labelled in blue: vertical features are significantly sharpened. Note that horizontal features do not let E_x through. We repeat the above procedure for a polarization oriented in *y*, and plot the corresponding $|E_y|^2$ in Fig. 2(d) to resolve the horizontal features of each letter. The full image is obtained by summing the two contributions $|E_x|^2 + |E_y|^2$, shown in Fig. 2(e), revealing the letters "THZ" at all frequencies, down to λ/7. Our approach can be adapted to suit any near field experiment which measures amplitude and phase, immediately providing a pathway for increasing the imaging resolution of near field setups at any frequency.

Acoustic and seismic metamaterials

Sound insulation performance of ventilated labyrinthine metamaterial described by enriched homogenized continuum

Renan Liupekevicius, Hans van Dommelen, Marc Geers, and Varvara Kouznetsova
Eindhoven University of Technology, Netherlands
R.liupekevicius.carnielli@tue.nl, J.A.W.v.Dommelen@tue.nl, M.G.D.Geers@tue.nl, V.G.Kouznetsova@tue.nl

Abstract: Labyrinthine structures that increase the wave-path length can be used as an acoustic liner to attenuate sound in ducts while allowing net air flow. In this study, the performance of ventilated labyrinthine metamaterials is assessed utilizing a homogenized equivalent fluid continuum. The effective domain is a more computationally efficient way to compute the pressure field compared to direct numerical simulation thanks to a coarser mesh.

By coiling up the space, labyrinthine metamaterials are capable of interacting with large wavelengths compared to their unit cell size, in the so-called subwavelength regime. This attribute permits reducing the devices' dimensions, which is beneficial from a practical point of view considering they usually have to be integrated into larger engineering components. Ventilated sound silencers are one potential application of these metamaterials as demonstrated in [1], both attenuating sound and allowing airflow.

As the 3D printing resolution improves, fine-structured metamaterials can be created in non-trivial geometries and for large structures to explore designs with optimal sound attenuation. However, such engineered metamaterials pose computational problems because they tend to explode in the number of degrees of freedom that are needed to resolve the fine microstructure. Moreover, the processes at the microstructural level, such as coiling-up space and resonances, lead to a large-scale acoustic wave dispersion, giving rise to a multiscale phenomenon.

In this contribution, we develop a transient computational homogenization framework that gives rise to an enriched equivalent fluid continuum with additional field variables to capture the underlying localized resonances. Extending the approach proposed in [2] to quiescent fluid domains, the coupling between the scales is given by a variationally consistent averaging of the governing equations expressed in their weak form, i.e. a generalization of the Hill-Mandel condition. Numerical examples demonstrate the efficiency and suitability of the proposed two-scale approach paving the way to more affordable time-domain simulations of acoustic liners.

Abstract: We numerically and experimentally study anomalous reflection of underwater ultrasound by phase-gradient acoustic metasurfaces. We conduct finite-element calculations to design the metasurfaces for desired phase gradient and simulate the reflected wave fields. The results exhibit anomalous reflection. We fabricate the metasurfaces with sub-mm meta-atoms and conduct pulsed ultrasound experiments to measure the azimuth distributions of the reflected waves. The experimental results agree well with the numerical results, confirming that anomalous reflection of underwater ultrasound can be achieved by the metasurfaces.

In the past decade, a family of two-dimensional artificial materials called acoustic metasurfaces has been quickly emerging. The acoustic metasurfaces enables manipulating acoustic waves in nonconventional ways by introducing the generalized Snell's law. Capability of tailoring efficient and diverse interfacial acoustic-structure interactions makes acoustic metasurfaces especially suitable to manipulate sound wave in air and water [1]. In this paper, we show underwater acoustic metasurfaces operating in the high frequency regime. Slit structures are utilized as the meta-atoms. We reveal the wave-steering features of ultrasound by the acoustic metasurfaces. We focus our study on the underwater reflection behaviors of the gradient-type metasurfaces. To validate the underwater acoustic metasurfaces working at 0.5 MHz, pulsed ultrasound experiments are conducted. However, well control of the phase change along the metasurface requires a dense array of fine meta-atoms. Therefore, we employed wire electrical-discharged cutting to fabricated the slit meta-atoms in the sub-mm scale.

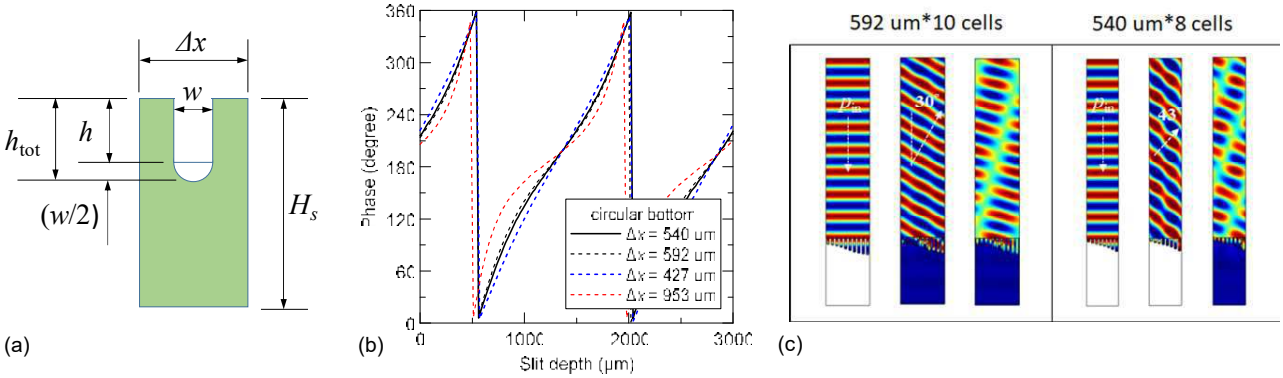

Figure 1 (a) Meta-atom. (b) Phase variation as a function of slit depth. (c) Simulated fields of designs I and II.

The meta-atom is made of stainless steel and has a circular-bottom slit of width w and depth h (Fig. 1(a)). Finite-element (FE) method is applied to design the acoustic metasurfaces and to simulate the propagation of the ultrasound in the system. We implement the numerical calculations using the commercial FE solver package COMSOL Multiphysics. Figure 1(b) shows the calculated reflected phase variation as a function of the slit depth, where the slit width w = 360 μm. To consider the influence of phase gradient, we build two different supercells (designs I and II) using the meta-atoms of a = 592 and 540 μm by following the strategy of engineering the phase profile to produce anomalous reflection with reflected angles of 30° and 43°, respectively. The calculated

normally incident, reflected, and total fields are shown in Fig. 1(c).

Figure 2 shows the full-wave results of plane-wave beam incident on the underwater metasurface. The used sound pressure beam width is 25 mm, which is about 8.4 times of the wavelength, covering about 42 and 46 unit cells of the design structures (corresponding to about 4.2 and 5.75 supercells). It can be observed from the results that reflected sound pressure beams with reflection angles of 30° and 43°are successfully generated, respectively. In addition to the sound pressure reflected back into the water, part of the sound wave energy penetrates into the material of the metasurface. Since the incident sound pressure is in the normal direction, it can be seen that the elastic wave penetrating into the solid mainly enters the steel solid in the form of bulk waves. Formation of the interface-coupled evanescent wave propagating to the left and right sides of the interface is not obvious.

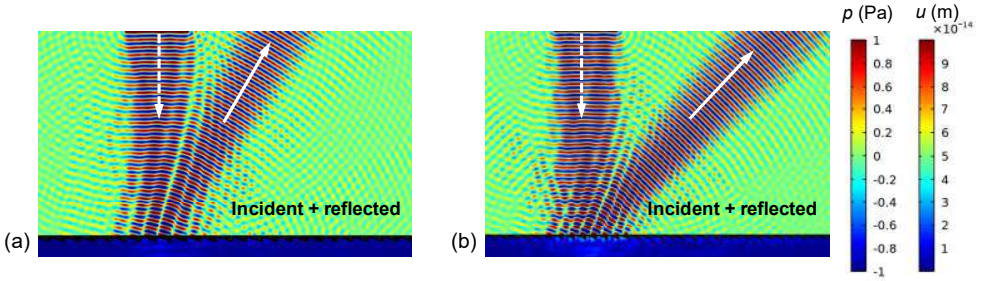

Figure 2 Full-wave results of plane waves incident on the underwater metasurface for designs I (a) and II (b).

In the experiments, we send ultrasound pulses and detect the ultrasound signals reflected by the underwater gradient metasurface in a water tank. Two identical immersion ultrasonic transducers of center frequency 0.5 MHz are properly positioned and oriented to emit and receive the ultrasound signals. A pulser-receiver is used to generates a high electric voltage pulse to be sent to the emitting transducer to excite the ultrasound pulse. The ultrasound pulse impinges on the underwater metasurface, and the reflected signal is detected by the receiving transducer and recorded by a digital oscilloscope. Figure 3 compares the calculation and measurement results of the azimuth distributions of the underwater ultrasonic reflection wave intensity. Briefly, the results of simulation and experiment show good agreement, which demonstrate that the designed and fabricated acoustic metasurface successfully produces the anomalous reflection of underwater ultrasonic waves.

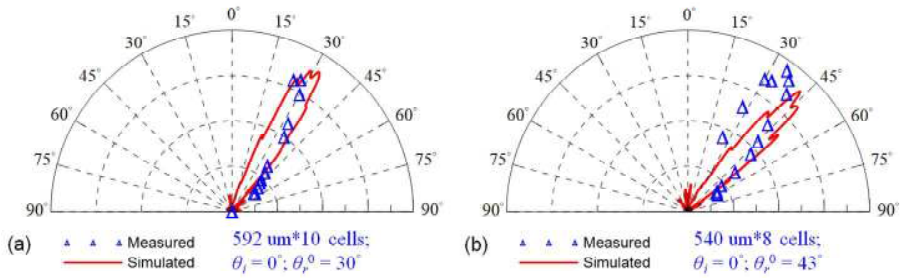

Figure 3 The azimuth distributions of the underwater ultrasonic wave intensity reflected by the metasurfaces.

Abstract: The absorption of underwater acoustic waves and vibrations is of great importance for underwater applications. In this work, we propose a well-performance acoustic anechoic coating by adopting the perforated honeycomb-corrugation hybrid (PHCH) sandwich panels consisting of aluminum and rubber. The composite structure possesses a high absorption coefficient of the low-frequency acoustic wave under an oblique incidence range. With well pressure resistance ability, the structure has been used in the design and experiment of our underwater detection system.

With the constant consumption of resources, the exploration and utilization of marine resources have become one the important development directions, and various exploration vessels and underwater detectors have been widely used. However, the acoustic environment is also more complex due to the low-frequency mechanical noise or propeller noise from these growing ships. Therefore, it is necessary to explore the acoustic anechoic coating that is more suitable for the current working conditions. Since the invention of the PHCH structure[1], it has attracted attention from numerous fields. However, there has been a relative lack of research on underwater PHCH structures for oblique incidence conditions. Here, based on our previous study of PHCH structure[2], we demonstrate a novel composite PHCH structure for underwater low-frequency acoustic anechoic coatings and show its application in our underwater detector design and experiment.

As shown in Figure 1a, It consists of two perforated panels sandwiching a honeycomb-corrugation rectangular core. The top panel is perforated with micro-holes as MPPs, while the bottom panel is a sealed backing panel for sound reflection. The micro-holes are cylindrical and distributed above every cavity in the center, so the water from above the MPPs can fill in the cavities through the micro-holes. And details of the 2-D modal are shown in Figure 1b, the composite structure consists of two different materials, the green parts and the orange parts are set as rubber, while the partition boards are aluminum. This composite design preserves the sound absorption ability of the rubber for low-frequency sound, while the introduction of aluminum increases the pressure resistance of the overall structure.

We use COMSOL Multiphysics 5.6 to operate the finite element method(FEM) and run the numerical simulation. The result is shown in figure 1c, the main absorption peak frequency is about 500Hz with an absorption band of about 775Hz. The Vibration of perforated rubber plates contributes significantly to low-frequency sound absorption, thus greatly reducing the mismatch of acoustic impedance. under oblique incidence, the sound absorption coefficient of composite structures increases with the increase of angle in frequency range <200Hz but decreases slightly in frequency range >300Hz. The spectrum proves that the composite structure is a proper omnidirectional underwater sound absorber. Rubber is known as a non-resistant material to pressure, while, on the contrary, aluminum is considered a more rigid material. The aluminum partition boards support the whole structure from the lateral side and restrict deformation. As a result, while inheriting the pressure resistance of the PHCH structure, the composite structure ensures that the rubber parts are only slightly deformed, improving the ability of sound absorption[3].

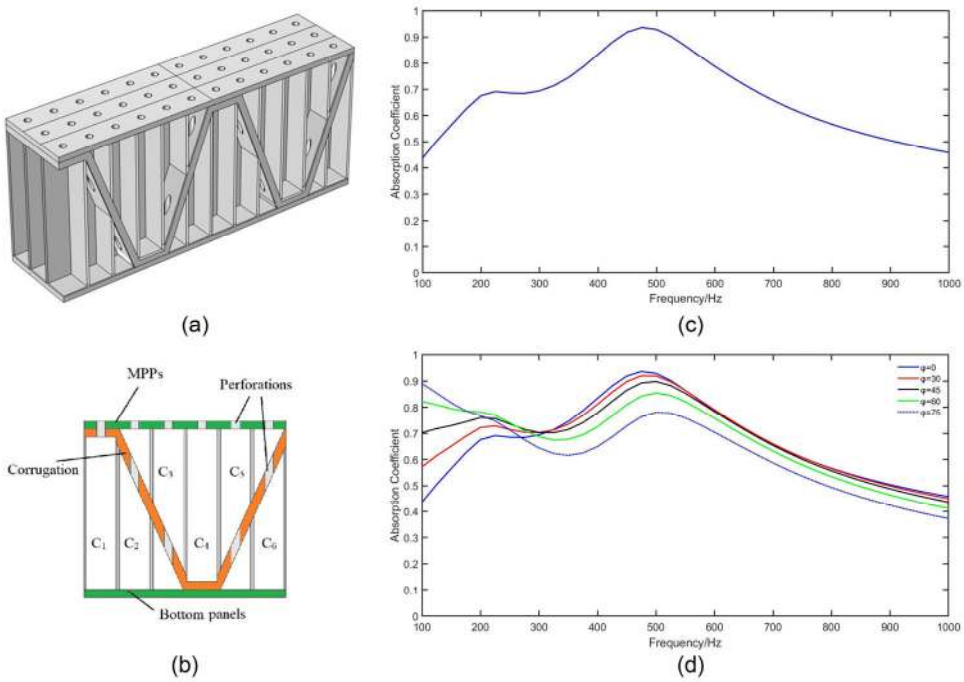

Figure 1: a) The geometry of the underwater PHCH structure. b) Details of the 2-D modal. c) Sound absorption coefficient of the composite structure underwater. d) Sound absorption coefficient under oblique incidence.

Based on the above characteristics, this composite structure has been used in the design and experiment of the underwater detection system. As the acoustic anechoic coating of the detector, it shows good resistance to compression, transverse deformation, and the generally good ability of sound absorption at different angles of incidence. Meanwhile, as the inner wall coating of the experimental water tank, the structure makes it possible to provide a relatively pure acoustic environment in the detector test. Therefore, it is more convenient to evaluate and contrast the performance of the detection system under different operating conditions. In addition, due to its deep subwavelength geometric design, this composite structure is expected to be more widely used as a lightweight and small-scale practical sound-absorbing material in other fields.

Abstract: A miniaturized, broadband (800 Hz - 5000 Hz) absorber with > 95% absorption is proposed and realized. The absorber is designed using quarter-wavelength resonator tubes coiled as a rectangular "meta-atom". The study describes the basic theoretical aspects of the absorber and compares it with the numerical simulations, fabrication, and experimental validation. The meta-atom, simple in design and made with fabrication-friendly materials, can provide greater spatial coverage through tiling over large surfaces.

Acoustic absorbers are essential for industrial and commercial applications that need to avoid noise pollution. In this work, we present an innovative structure based on a quarter wavelength resonator. Several air-filled quarter-wave resonators are arranged in parallel to achieve high absorption for a wide range of low-frequency sound. Numerous works have been reported on the resonator [1-5]. However, the unique structure and compact size with high absorption properties make it more applicable and cost-efficient. These resonator tubes show very high absorption at their resonance frequency. Since the absorption at resonance frequency is very sharp, a parallel arrangement of these tubes gives perfect absorption for a wide frequency range. The absorption coefficient is calculated using the formula given in Eq. (1)

$$\alpha = 1 - \left|\frac{Z_c/\phi - Z_0}{Z_c/\phi - Z_0}\right|^2 \quad (1)$$

Where Z_{eq} is the equivalent specific acoustic impedance can be obtained by using Eq. (2)

$$Z_{eq} = 1/\sum_{i=1}^{n} \frac{1}{Z_i} \quad (2)$$

(a) (b)

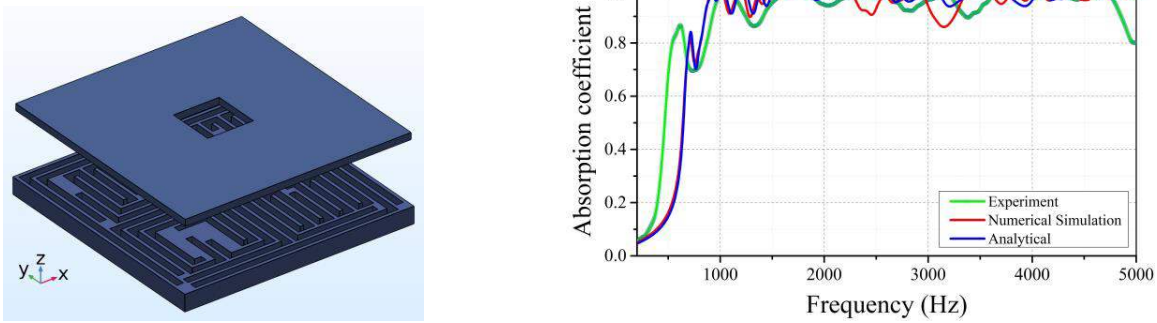

Figure 1: (a) Design of the unit cell of an acoustic metamaterial consisting of 20 resonant channels. (b) Absorption vs. frequency plot. The experimental results compare with the analytical and numerical results.

Highlights

- A unique and compact size sub-wavelength structure is proposed.
- The unit structure has a dimension of 70× 70× 8 mm^3.
- The lowest cutoff frequency (resonance frequency) is obtained at around 700Hz, decided by the longest tube in the structure.
- This 10 mm thick (including front and back penal) structure gives a very high absorption (more than 95%) spectrum for a wide range of frequencies (800 to 5000Hz).
- The experiment result is compared with theoretical and numerical outcomes. The agreement between experimental, numerical, and theoretical outcomes matches well.

Abstract: This work studies the propagation of valley Hall modes through turns of different angles in a discrete model. The main goal of our study is the quantitative analysis of the transmission and reflection coefficients through different turns, and to relate our results with the topological argument of valley conservation which predicts high transmission for specific angles. Using the transfer matrix method, we solve the problem semi-analytically and reveal that some angles allow for a rich variety of scattering possibilities.

Two-dimensional topological insulators allow for the possibility to guide waves in a media without backreaction. Prime examples include the quantum Hall effect, where the perfect transmission is assured by the breaking of time-reversal symmetry, and the quantum spin Hall effect where the properties of the spin guarantee the modes' immunity to backscattering. The development of metamaterials opened the doors for the realization of two-dimensional topological insulators in a broad class of systems from mechanical to optical to acoustics system. However, for classical waves in such platforms, the protection of topological modes to backscattering relies on weaker mechanisms which implies that in most scattering scenarios some reflection will be present. While topological arguments might explain the quantitative behavior of the reflection, they are insufficient to quantitatively characterize the scattering in these cases, which remains an open question [1].

In this work, we focus on the quantitative analysis of the scattering of a type of topological modes in a metamaterial, namely valley Hall states realized in a graphene ribbon with zigzag edges. Our ribbon is composed of two regions of graphene with opposite on-site potential which opens a gap in the band structure. At the interface of these two regions, and in the bulk gap, a pair of topological modes exists. The modes propagate in opposite directions and carry with them a conserved valley index [2]. The graphene bulk structure on one side of the interface and the associated Brillouin zone are depicted in Fig.1a) and b) respectively. Fig.1c) shows the Berry curvature whose sign, different in each valley K and K', defines the valley index.

a) Graphene bulk structure b) Brillouin zone c) Berry curvature

Figure 1: Graphene structure and valleys. Panel a) shows the bulk graphene structure. Panel b) shows the Brillouin zone and the inequivalent Dirac point K and K'. Panel c) shows the Berry curvature, taking different signs in the two valleys.

Conservation of valley index suggests that scattering in certain direction are to be privileged. A scattering through an angle of $\pi/3$ changes the valley index while an angle of $2\pi/3$ conserves it, while backscattering also changes the valley index, see Fig. 1b). The topological argument therefore suggests that scattering through an angle of $2\pi/3$ will lead to high transmission but cannot illuminate the situation in the case of a $\pi/3$ angle.

Using the transfer matrix formalism [3], we solve semi-analytically the problem of the scattering of a valley mode through a $\pi/3$ and compute numerically the reflection and transmission coefficients. We show that this situation allows for a broad range of scattering possibilities and that an incoming interface mode can be transmitted with little backscattering, completely reflected or transmission to edge modes, depending on the energy range considered. Those three cases are represented in Fig.2 b), c) and d) respectively. We show that the qualitative behavior can be understood solely from the properties of the dispersion relation. A quantitative analysis is performed, and we compare the backscattering in this situation and with the case of an angle of $2\pi/3$.

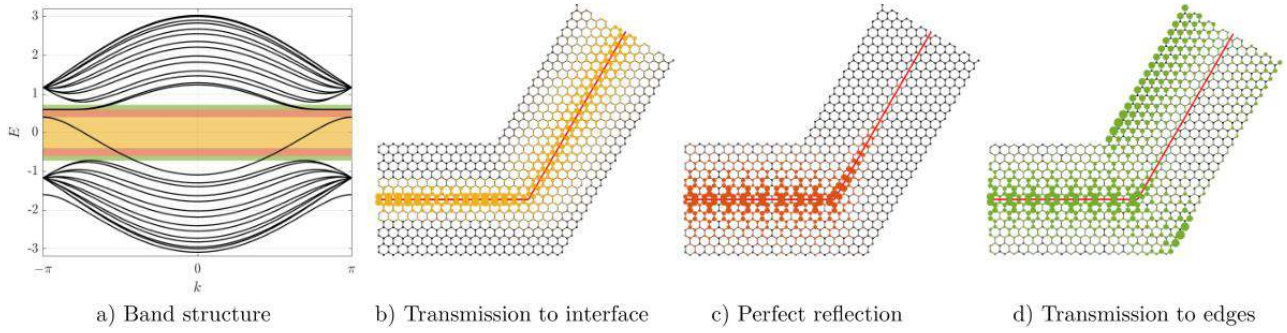

Figure 2: Band structure of graphene ribbon with bridge interface and scattering scenarios. Panel a) shows the band structure, revealing the topological band in the bulk gap. Panel b), c) and d) show the conversion through an angle of $\pi/3$ of a valley Hall mode coming from the left to another interface mode, evanescent modes and edge modes respectively.

Our results indicate that high transmission can be obtained even in cases where the scatterer changes the valley index. Our calculations are performed in a discrete model which while being simple remains general and can be applied to a variety of continuous systems. For example, our model can be seen as a tight-binding approximation or as a particular limit of an acoustic network [4]. We therefore believe that information about more general systems can be learned from our study, and we hope to trigger generalization of our results in continuous systems.

Superradiant Scattering from Nonlinear Wave-Mode Coupling

T. Pedergnana[1*] and N. Noiray[1*]

[1] CAPS Laboratory, Department of Mechanical and Process Engineering, ETH Zürich, 8092 Zürich, Switzerland
[*]corresponding authors: ptiemo@ethz.ch and noirayn@ethz.ch

Abstract: When waves are scattered at a resonant cavity, due to dissipation, the outgoing waves' energy is decreased compared to the incident waves. This limitation can be overcome if waves are instead scattered at a linearly unstable mode undergoing a limit cycle. Near the mode's eigenfrequency, synchronized self-oscillations feed energy to the outgoing waves, leading to superradiance, or amplification of incident harmonic waves. We derive a multiphysical theory of nonlinear wave-mode coupling and experimentally validate it on a superradiant aeroacoustic scatterer.

In this work, we show that waves scattered at a self-oscillating mode can exhibit superradiance. This exotic behavior, which arises from nonlinear coupling of the mode to the incident waves, is manifested by an amplification of an incident harmonic wave. On the theoretical side, we propose a generic, multiphysical theory of nonlinear mode-coupling, which is derived in analogy to the temporal coupled-mode theory of Fan et al.[1] Using the Moore-Penrose pseudoinverse, the scattering matrix can be explicitly expressed in terms of the incident and outgoing waves as

$$S = \frac{|s_{out}\rangle\langle s_{in}|}{\langle s_{in}|s_{in}\rangle}. \qquad (1)$$

The equations governing the nonlinear wave-mode coupling are shown in Fig. 1. Through the nonlinear term in the modal equation, the scattering matrix becomes dependent on the incident wave amplitude s_{in}. Theoretical predictions of the scattering matrix are shown in Fig. 2.

On the experimental side, a well-reproducible aeroacoustic realization of a superradiant scatterer was used to test the theory's predictions. The self-oscillating mode was achieved by subjecting a side cavity to a low-Mach mean flow, leading to a whistling phenomenon involving a purely acoustic longitudinal mode of the cavity.[2] Acoustic waves are sent from compression drivers located upstream and downstream of the cavity to obtain the scattering matrix. Repeated experiments on this carefully designed and characterized set-up demonstrate outstanding qualitative agreement between theory and experiment (see Fig. 3).

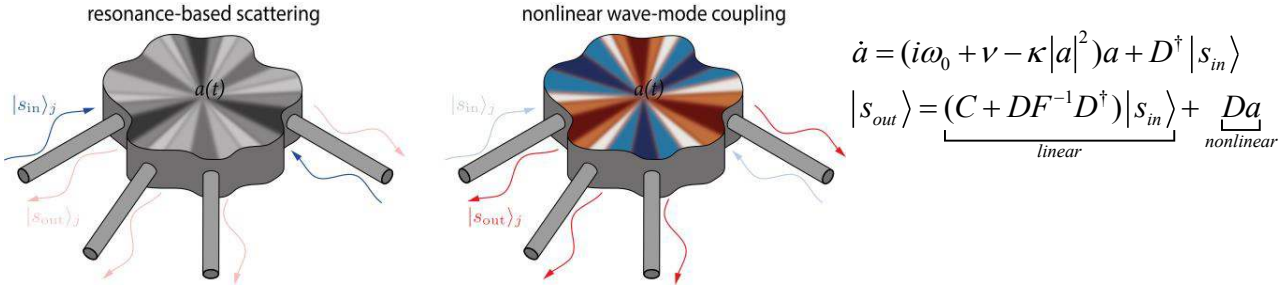

Figure 1. Left inset: In a classic resonant cavity, the energy of the incident waves always exceeds that of the outgoing waves. We show in this work that this limitation can be overcome by scattering waves at a self-oscillating mode, leading to nonlinear wave-mode coupling. Right inset: Equations describing the nonlinear wave-mode coupling.

We envision that the quasi-passive realization of superradiance presented in this work will find application in flow-based acoustic metamaterials and topological insulators, which often suffer from dissipation losses. Furthermore, the proposed theory can model a wide variety of nonlinear scattering problems and may be used in the future to develop novel non-acoustic lossless scatterers and metamaterials by exploiting the energy supplied by a self-oscillating mode.

This project is funded by the Swiss National Science Foundation under Grant agreement 184617.

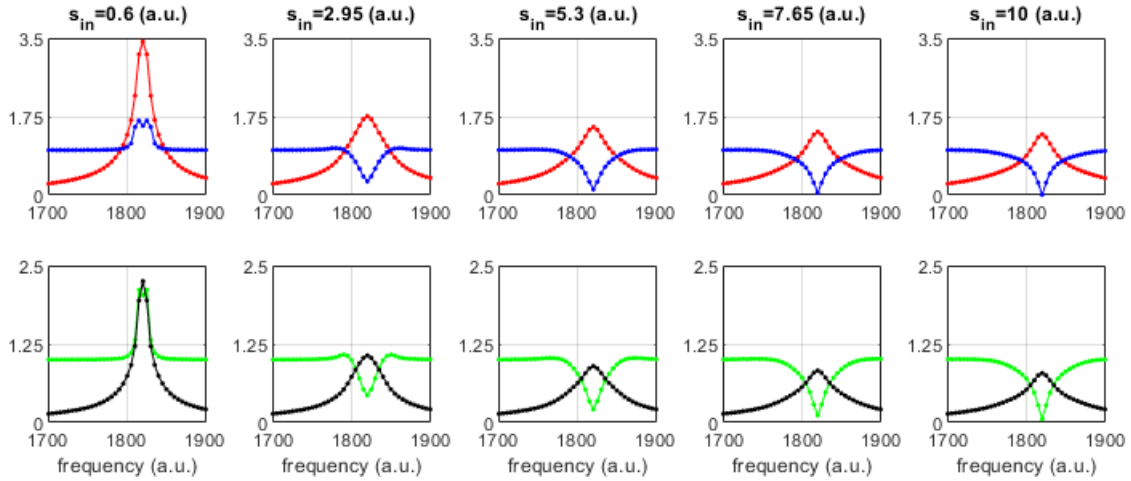

Figure 2. Theoretical prediction of the scattering matrix S. Shown are the entries S_{11} (red), S_{21} (blue), S_{12} (green) and S_{22} (black) over the incident wave frequency for different values of the normalized incident wave amplitude s_{in}.

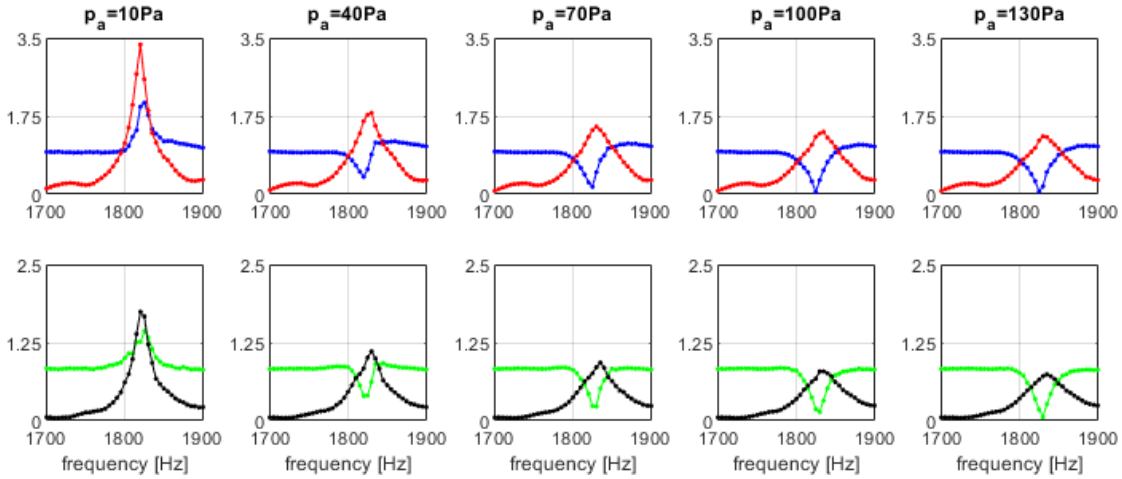

Figure 3. Experimental validation of the theoretical results shown in Fig. 2. The experiments were performed by sending acoustic waves to a whistling deep cavity in a wind channel biased by an imposed air flow. The acoustic amplitude of the wave just outside the cavity p_a was fixed for each measurement.

Introduction to Functionally Graded Unit Cell of Nonlinear Metamaterial that Controls Harmonic Responses of Elastic Waves

P. R. Ghodake

Department of Mechanical Engineering, Indian Institute of Technology Bombay, India
mech7pkumar@gmail.com

Abstract: A unit cell of nonlinear functionally graded metamaterial is exploited in this study through multiple computational experiments. The manipulative capabilities of the nonlinear functionally graded unit cell sandwiched between linear elastic materials of the same impedance are exploited to control harmonic responses. Sensitivities of the parameters that control the spatial distribution of the nonlinear parameters will help to design novel functionally graded nonlinear metamaterials using forward, and inverse design approaches.

Introduction

The presence of harmonically scattered waves and their sensitivities toward various parameters motivates exploiting harmonically scattered waves from functionally graded nonlinear inclusions[1]. Limitations of theoretical techniques and experimental developments in nonlinear ultrasonics exploring harmonic scattering encourage us to explore the domain through numerical perspective[2,3]. Numerical experiments are conducted in this study using the finite element method. A schematic of the numerical model is shown in Figure 1, and the multiple distributions of functionally graded material are shown in Figure 2. As the power of the spatial term changes from ¼ to 1 and then to 0, the area under the curves changes, as seen in Figure 2. Murnaghan hyperelastic material model is considered for modeling functionally graded nonlinear material.

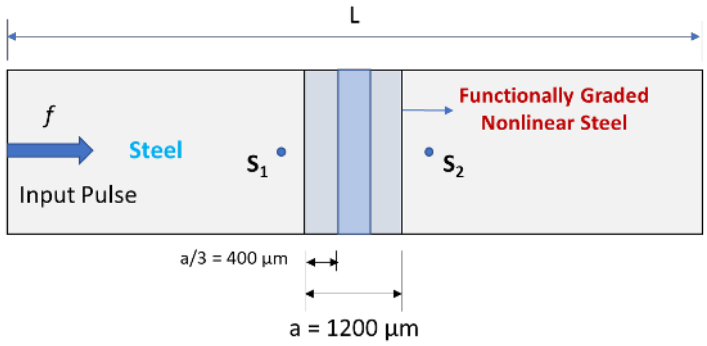

Figure 1. Schematics of three layered nonlinear functionally graded inclusion as a unit cell of the metamaterial to control nonlinear waves used for numerical modeling

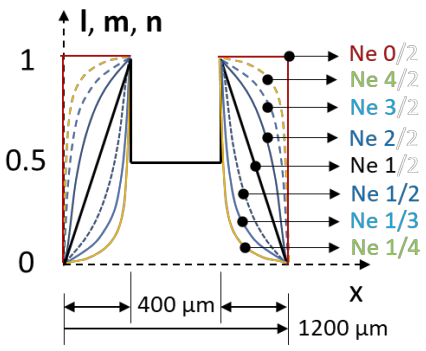

Figure 2. Multiple spatial distributions of nonlinear parameters over the length with different powers

Results and Conclusion

Static term (*0f* = 0 MHz) and 2nd harmonics (*2f* = 4 MHz) are generated due to harmonic scattering from a functionally graded unit cell. Figure 4 shows the increase in the amplitudes of 2nd harmonics and static term with a change in distribution curves from power Ne 4 to Ne 0. As the areas under curves increase from Ne 4 to Ne 0, amplitudes of harmonically forward (Figure 4) and backscattered (Figure 3) waves increase.

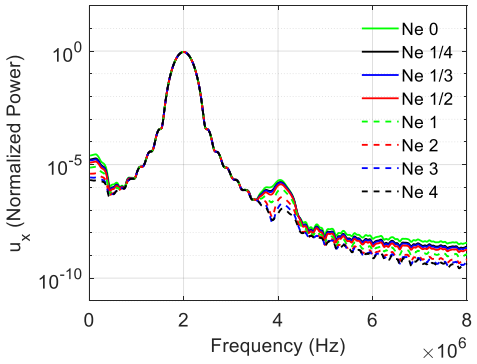

Figure 3. Harmonic responses of backscattered waves at S_1 with Ne 0 - 4 and 0.25(*l, m, n*) central layer

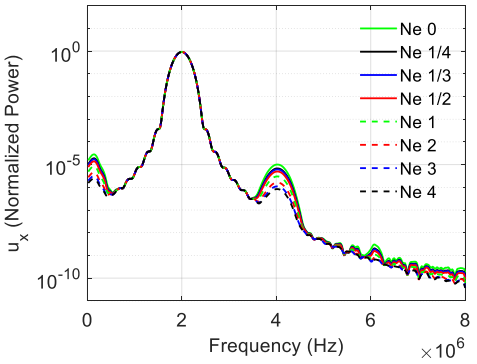

Figure 4. Harmonic responses of forward scattered waves at S_2 with Ne 0 - 4 and 0.25(*l, m, n*) central layer

Amplitudes of static terms (*0f*) of backscattered and forward scattered waves at any spatially distributed curves are the same, whereas amplitudes of 2nd harmonics of backscattered waves are always less than the forward scattered waves (Figure 3 and Figure 4). To understand the effect of the central layer of a unit cell, nonlinear parameters are varied from 0.25-1.00 multiples of (***l, m, n***). Amplitudes of forward scattered waves (*0f*, *2f*) increase (Figure 6) with an increase in the magnitude of middle layer nonlinear parameter from 0.25-1.00, whereas in contrast, the amplitude of 2nd harmonics (*2f*) of the backscattered wave decreases (Figure 5). But interestingly amplitude of the static term (*0f*) of backscattered waves increases (Figure 5) with an increase in parameter from 0.25-1.00, similar to forward scattered waves (Figure 6). These interesting behaviors will help us to design a unit cell by proposing novel functionally graded nonlinear metamaterials to manipulate nonlinear waves.

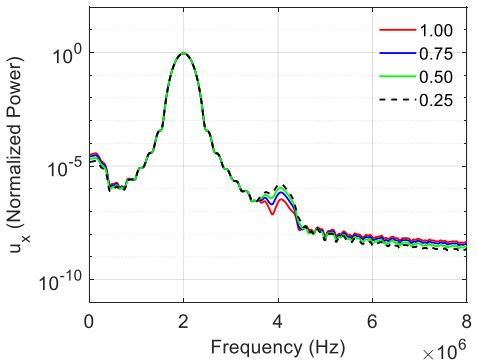

Figure 5. Harmonic responses of backscattered waves at S_1 with Ne 1/3 and various central layer parameters

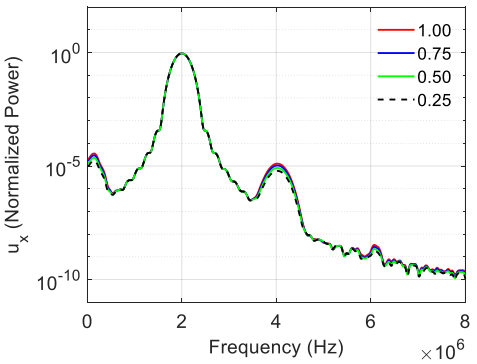

Figure 6. Harmonic responses of scattered waves at S_2 with Ne 1/3 and various central layer parameters

Fundamental Study of Elastic Wave Damping by Metamaterials with Local Resonant Structures in Electrical Systems

Kyogo SATO, Keisuke NISHIDA, Toshihiko SUGIURA*

Keio University, Japan
*corresponding author: sugiura@mech.keio.ac.jp

Abstract: Conventional acoustic metamaterials for elastic waves are mainly based on mechanical systems with local resonant structures, but this study aims to reduce vibration by replacing the unit cell with a resonant structure of a coupled electrical-structural system. As a basic study, we confirmed the vibration-damping property of acoustic metamaterials including electrical systems by numerical simulation and further clarified the resonance characteristics of unit cells by experiment.

1. Introduction

In recent years, acoustic metamaterials have been actively studied for waves in gases, liquids, and solids to help reduce noise [1]. Conventional research on acoustic metamaterials for waves in solids typically deals with vibration control methods that focus on the resonant structure of mechanical systems. However, we noted that such a system has installation restrictions on the structure and that it is necessary to change the resonant structure for each frequency to be attenuated. Therefore, we focused on coupled electrical and structural vibration systems based on resonant structures using electrical circuits and piezoelectric elements. In this study, we investigated the damping properties of acoustic metamaterials using electrical systems for wave propagation in solids by numerical simulation and the resonance properties of resonant structures by experiment.

2. Numerical simulation

Our metamaterial model consists of piezoelectric elements and resonant circuits periodically attached to the top surface of an aluminum beam, as shown in Figure 1. The thickness of the beam is 0.5 mm. The distance between the piezoelectric elements is also 0.5 mm, which is sufficiently shorter than the propagation wavelength. The resonant frequency of one circuit is set to 100.7 kHz. The resonant frequency of a unit cell was confirmed to be 101 kHz by eigenvalue analysis. In this model, the waves are transmitted in 10 kHz increments from 70 kHz to 160 kHz. The displacement of the top surface of the beam during wave propagation was determined by coupled electrical-structural finite element analysis and compared with the results for beams without piezoelectric elements and electrical circuits attached. Vertical displacements were obtained at three different locations on the top surface of the beam: point A, 100 mm from the transmission point and before the local resonant structure; point B, 170 mm from the transmission point and 100 unit cells away in the local resonant structure region; and point C, 200 mm from the transmission point and after passing the local resonant structure region.

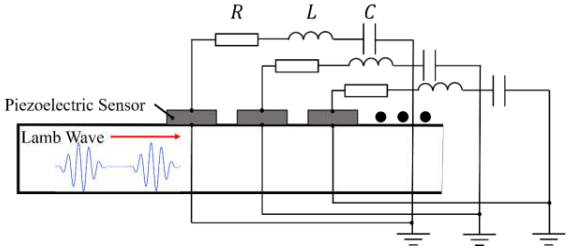

Figure 1. Periodic structures with local resonators as electrical systems

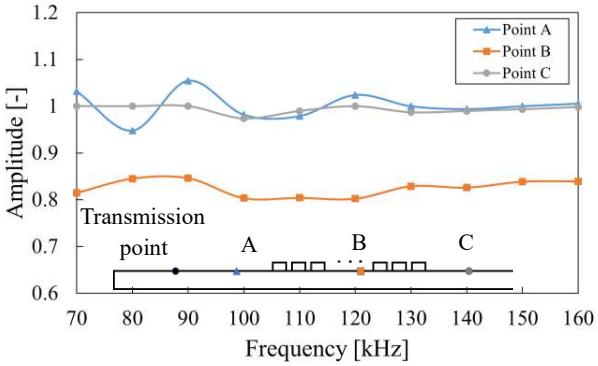

Figure 2. Amplitude of vertical displacement at three locations on the beam for each transmission frequency, obtained by FEM

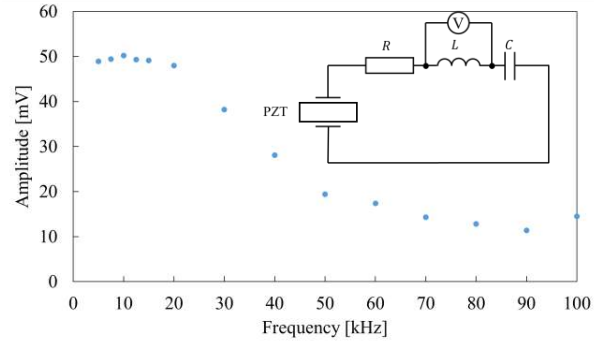

Figure 3. Measured amplitude of the electrical voltage depending on the frequency

Figure 2 shows amplitude of vertical displacement at three locations on the beam obtained by numerical simulation. The maximum amplitude on the vertical axis is the dimensionless value obtained by dividing by the maximum amplitude without the electrical system. The horizontal axis indicates the transmission frequency. As can be seen from this result, at point B in the local resonant structure region with the electrical system attached, the displacement amplitude is reduced by about 20%.

3. Experiment

In the experiment, 10 piezoelectric elements were placed on an aluminum plate at 5 mm intervals, and the resonant frequency of the circuit was set at 10.7 kHz. To investigate the resonant frequency of the coupled electrical-structural system, the voltage applied to the inductors of the circuit was measured. The measurement results obtained from the experiment are plotted in Figure 3, where the horizontal axis represents the excitation frequency, and the vertical axis represents the maximum amplitude of the voltage. The results show that the amplitude reaches its maximum value around 10 kHz, which is the resonant frequency of the circuit, and that the voltage amplitude is found to decrease in the frequency band away from this frequency. Thus, the voltage response due to mechanical excitation was confirmed and the resonance properties in the unit cell of the electrical metamaterial were also experimentally confirmed.

4. Conclusions

In the metamaterial containing a coupled electrical-structural system, numerical simulations confirmed the vibration-damping properties of the local resonant structure at locations near the unit cell. The resonance characteristics in the unit cell of the electrical system were also clarified by experiments.

High-resolution medical ultrasound focusing and temperature rise with acoustic metamaterial

Jiajie He[1], Xue Jiang[1*], and Dean Ta[1, 2]

[1] Center for Biomedical Engineering, School of Information Science and Technology, Fudan University, Shanghai, 200433, China.

[2] Department of Rehabilitation Medicine, Huashan Hospital, Fudan University, Shanghai, 200040, China.

[*]corresponding author: xuejiang@fudan.edu.cn

Abstract: We experimentally realize the medical ultrasound focusing based on the compact and passive metamaterial. The three-dimensional spot focusing is endowed with high spatial resolution (0.63λ FWHM and 2.75λ FLHM), broad effective bandwidth (0.5-1.4 MHz) and tunable focal length (18.5-71 mm). Ultrasound scalpel, which converge the acoustic energy within a sharp needle area, is demonstrated with an aspect ratio of 12.64. Additionally, we investigate the prominent temperature rise in the focal region and reveal the dependence on the ultrasound frequency.

Ultrasound focusing features superior penetrability, biocompatibility and non-radioactivity, enabling substantial applications in biomedical science and clinical medicine, such as medical imaging, non-invasive surgery and neurostimulation[1-3]. Conventional ultrasound focusing technologies face two urgent challenges. On the one hand, spatial resolution is the key indicator to evaluate the focusing performance. However, ultrasound has lower focusing resolution compared with light/electromagnetic wave. On the other hand, traditional ultrasound focusing relies on the active transducer array with complex circuit modulation, or curved lens with fixed focal length, which inevitably hinders the development of more precise and flexible focusing technology.

The advent of acoustic metamaterial/metasurface has provided new solutions to the freeform sound manipulation and improve focusing precision[4-7]. Currently, the metamaterial-based acoustic focusing is mainly implemented for airborne sound at a relatively low frequency (< 500 kHz). Due to the difficulties in the fabrication of complicated microstructures, underwater ultrasound focusing which plays a pivotal role in biomedical diagnosis and therapy still remains a challenging task.

In this work, we numerically and experimentally realize the underwater medical ultrasound focusing with sub-wavelength resolution and tunable focal length over a broad frequency band. The metamaterial is designed as an axisymmetric disk, which consists of spatially serrated units with specific tilted angles. Ultrasound energy is reflected by the structure and precisely converged at the target position, leading to the three-dimensional spot focusing and ultrasound focusing scalpel. Full width at half maximum (FWHM) and full length at half maximum (FLHM) are used to represent the spatial resolution. Figure 1 shows the measured underwater spot focusing, where the FWHM is 0.89λ and 0.63λ while the FLHM is 3.54λ and 2.75λ in measurements and simulations, respectively. Significantly, ultrasound focusing is effectively maintained within 0.5-1.4 MHz (1.5 octaves). The dynamic focal length presents an approximately linear relationship on the operating frequency. Ultrasound scalpel further enriches the focusing pattern by concentrating the energy inside a sharp needle area, with an aspect ratio of 12.64 in Fig. 2. Accompanied with the enhancement of ultrasound intensity, prominent temperture rise is also observed in the focal region. We investigate the simulated temperature rise and reveal the dependence on the ultrasound frequency in Fig. 3. Owning to the sub-wavelength focusing resolution, only the targeted focal region is heated by the ultrasound while the undesired region remains intact. Our proposal of the compact metasurface may offer a feasible approach for high-resolution medical ultrasound focusing, and possess fascinating prospects in biomedical imaging, diagnostic sonography and therapy.

Chiral and hyperbolic metamaterials

Spin-momentum locking breakdown on plasmonic metasurfaces

F. Lorén[1,2*], and L. Martín-Moreno[1,2]

Abstract: We have developed a detailed formalism to analyze the spin-momentum locking (SML) in structured plasmonic metasurfaces. It is valid for any unit cell where holes are placed at certain positions and angles. We can explain the SML emergence just from the unit cell configuration. Besides, there appear several breakdown terms spoiling the polarization landscape. We have studied systems with rotations along the unit cell but also with global symmetry of translation and rotation of the whole lattice, like Kagome lattice.

We revisit the optical properties of several plasmonic Berry metasurfaces. We focus on the spin-orbit coupling as a result of the local rotation of the coordinate system induced by the rotation of the nanoapertures, which is known to imprint a very strong polarization response in the far-field. In our work, we have studied a nanostructured metallic slab (gold), hosting certain nanoapertures or grooves configurations. The selection of a noble metal as the metallic slab is also important because they have positioned themselves as the most promising materials to host surface plasmon polaritons (SPPs) in the optical regime over the years. A properly hosting of these SPPs is fundamental for two reasons: the first one is because we want to use them to obtain a strong far-field response, and the second one is because we can place some 2D materials such as transition metal dichalcogenides (TMDs) above the metallic structure to enhance the coupling between the SPPs and the excitons from the TMDs. Finally, to trigger the spin-orbit coupling or spin-momentum locking, we have chosen two different configurations of grooves that lead to chiral behavior in the metasurface polarization response because of the positions and angles of their grooves.

To tackle theoretically this problem, we use the coupled-mode method, which consists of expanding the electromagnetic fields in a superposition of plane-wave modes in the region above the metasurface, and waveguide modes inside the sub-wavelength slits. We obtain the governing equations for the far-field landscape via the reflection coefficients, and we study in detail each element of these equations. We show that the interaction of the light with the metasurface allows for spin-to-momentum or momentum-to-spin conversions. We derive some selection rules which reveal a series of possible scattering processes for photons, that are associated with very specific changes in photon momentum and input/output polarizations. These selection rules are a theoretical confirmation of the spin-orbit Bragg's law, which is the momentum conservation of the spin-momentum locking. This is not the first time that a theoretical derivation for a system like this is implemented [1], but this is a simpler and more general way of exploring this kind of system. The most striking result is that the widely used spin-momentum locking is not perfect. We demonstrate that it suffers a breakdown. The circularly polarized photons that come in or out in the propagation direction get projected onto the planar metasurface, becoming elliptical in general. This breakdown causes more processes to be allowed and the polarization landscape to be spoiled. Besides, we observe that the less perpendicular-to-the-metasurface the propagation direction of the plane wave, the more relevant the effect, being critical when an SPP is excited.

The results for the first configuration are experimentally confirmed with Mueller polarimetry measurements, which allows for capturing the metasurface's full polarization, energy, and momentum response. Besides, these experimental results are

compared with numerical simulations and the agreement between both is excellent. Our results provide the much-needed microscopic understanding of this metasurface, which is already widely used for its distinct interaction properties with circularly polarized light. Furthermore, we have generalized the theoretical formalism and used it to explore the second of the configurations. This one is also called the Kagome lattice and it has been important in other works such as [1] because this distribution of grooves is invariant under combined translation and rotation of the whole lattice. We have found that the Kagome lattice also presents spin-momentum locking breakdown so, essentially, we demonstrate that the breakdown is ubiquitous and appears in any kind of nanostructured system.

These results are reported in [2] and are also under preparation for another paper.

Engineering of a THz time-reversal symmetry breaking chiral metamaterial

L. Graziotto[1*], J. Andberger[1], L. Sacchi[1], M. Beck[1], G. Scalari[1], and J. Faist[1]

[1]Institute for Quantum Electronics, ETH Zürich, Auguste-Piccard-Hof 1, 8093 Zürich, Switzerland

Abstract: A metamaterial of resonators capable of sustaining circularly polarized electromagnetic modes has been developed and it is reported to give rise to chiral light-matter hybrid states when coupled to the cyclotron resonance of a two-dimensional electron gas. The cavity design, which is crucial to ultra-strongly couple to the solid-state system, could potentially be implemented to manipulate topological properties of materials, or to affect their transport behavior, about which one can gain insights via a circuit model that we have developed.

Ultra-strong coupling (USC) refers to the regime of light-matter interaction in which the magnitude of the coupling is of the order of the bare electromagnetic mode frequency. When the matter platform consists of the cyclotron resonance of electrons confined in GaAs/AlGaAs quantum wells (two-dimensional electron gas, 2DEG) in a perpendicular magnetic field one obtains light-matter hybrid modes called *Landau polaritons* [1], which have been investigated in the THz region via the use of split-ring resonators [2]. It has been recently demonstrated [3] the possibility of achieving circularly polarized Landau polaritons, which in addition to the characteristic anti-crossing of their energy dispersions do exhibit an energy-shift caused by the interaction with the counter-rotating component of the electromagnetic field, the so-called *vacuum Bloch-Siegert shift*. The cavity design is what is crucial to enable such exotic quantum states at equilibrium [4], at variance with the driven Floquet-engineered states [5] that being out of equilibrium suffer from dissipation, decoherence, and other scattering mechanisms.

Here we report on the implementation of a THz metamaterial capable of harnessing the inherently chiral behavior of the 2DEG in a magnetic field, thus leading to light-matter modes which break time-reversal symmetry. The unit cell of the structure (Fig. 1a) consists of two pairs of orthogonal antennas whose electric fields at resonance oscillate with 90 degrees phase difference, such that at their intersection a circularly polarized mode is

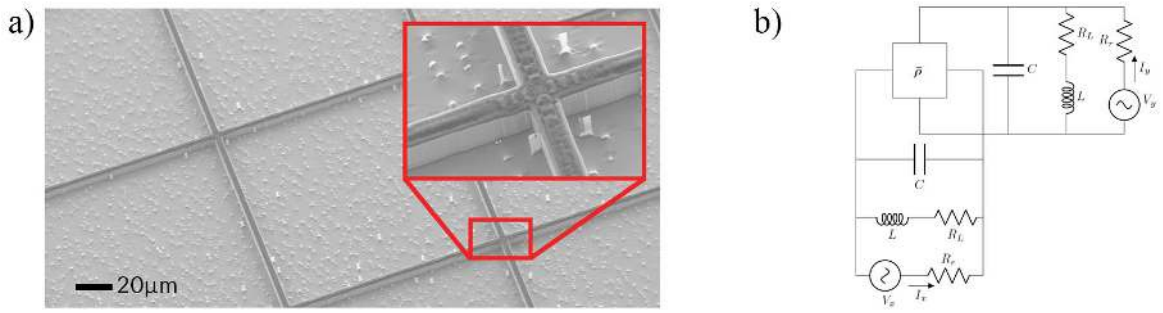

Figure 1. (a) SEM image of the chiral metamaterial. Inset: zoom in to the antenna gap, where the electromagnetic field interacts with the 2DEG. Notice the deep etch which suppresses the spurious capacitative effect. (b) Circuit model of the coupled system: the square represents the 2DEG, while the two antennas are represented by LC circuits.

sustained and coupled to the electron gas. We have characterized the system via THz time-domain spectroscopy (Fig. 2a): samples with different numbers of quantum wells have been investigated, and the coupling strength has been obtained by looking at the energy splitting at positive and negative magnetic field, which represents the hallmark of the chiral response. We have also developed a semi-classical circuit model (Fig. 1b) to get insights about the coupling mechanism and its limitations by cavity and material losses (Fig. 2b). The 2DEG gyrotropic response is calculated within Boltzmann's transport formalism, and the pairs of antennas are modelled via LC circuits. The model not only reproduces the results obtained via a formal Hamiltonian approach, but it is also applicable in general to planar resonators.

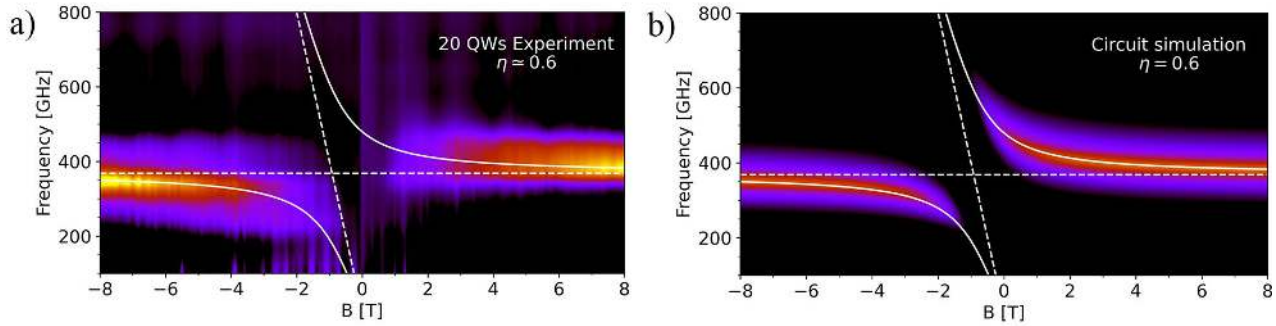

Figure 2. (a) Logarithm of transmission from a metamaterial sample coupled with 20 quantum wells, as a function of magnetic field and frequency of the excitation, as measured via THz time-domain spectroscopy. (b) Logarithm of transmission as simulated via a circuital approach. The dashed lines indicate the bare cavity frequency (horizontal) and cyclotron resonance (diagonal). η is the normalized coupling strength.

In conclusion, we have demonstrated a promising platform for exploring chiral states in condensed matter systems. Moreover, the cavity highly subwavelength interaction volume along with the strong polarizability of the solid-state platform pave the way for future magneto-transport experiments, which could access the USC ground state, whose chiral properties are still unexplored [6].

Abstract: We demonstrate an integrated deep-learning neural network that generates metasurface designs directly from independent polarization holograms, with a maximum of four different co- and cross- polarization conversion channels. This is achieved by extending the existing DeepCGH network with an inverse design component. Our approach enables a systematic design route for polarization holograms directly from an existing metamaterial library without requiring detailed knowledge of the constraints. Furthermore, it can be adapted for other multiplexing holograms that require automated designs.

Multiplexing holography with metasurfaces is a technology with emerging potential over a vast range of areas in science and technology, which include but are not limited to display technology and information storage [1]. Among different multiplexing approaches, polarization-multiplexed hologram is probably the most straightforward to use in practice. Recently, a planar metasurface has been demonstrated to increase the capacity for polarization multiplexing on various co-polarization channels by introducing the engineered noise [2]. However, such single-layered metasurfaces have a constrained form of Jones matrix being symmetric when expressed in terms of linear polarization: $t_{xy}=t_{yx}$. The incorporation of this degree of freedom (DOF) will further extend the usage of polarization holograms. On the other hand, the conventional iterative method for designing metasurface polarization holograms needs to consider the constraints on the multiple polarization channels, while it is not easily scalable to more variety of nanostructures (to break $t_{xy}=t_{yx}$) like the bianisotropic structures [3]. To overcome such issues and speed up the whole design process, it is beneficial to adopt a machine learning approach for generality.

Here, by extending the existing DeepCGH network [4] with an inverse design component, we developed a deep learning algorithm (DeepCGH-ID) to generate holograms and assist on the metasurface design. To fully utilize the polarization holograms, we take a bianisotropic metasurface as a template. As shown in the upper left panel of Fig.1(a), the designed bianisotropic structural unit with the silicon-made "fin" structure is embedded in glass in a square lattice of periodicity a = 1000 nm. The structure has two layers of L-shape bars (width w and thickness h = 250 nm) connected by a square pillar (width w and thickness t = 125 nm) in between. The two L-shapes break the mirror symmetry in the z-direction in generating bianisotropy. The size of the silicon structure in the y-direction is l = 637.5 nm. The vertical pillar is shifted by Δx and Δy relative to the two vertical middle planes of the unit cell (dashed line frames). This structure is defined as "right-handed", and the lower left panel in Fig.1(a) shows its mirrored structure (with mirror plane $x = y$), defined as the "left-handed" structure. The Jones matrix elements of the right-handed structure are obtained from simulations (with normal incidence (along positive z-direction) and a fixed wavelength of 1550 nm) with varied geometric parameters. All the phases can cover the full range of 2π, and t_{xy} is significantly different from t_{yx} as shown in the right panel of Fig.1(a). As the phase of t_{yy} does not change too much for the whole library, we add the orientation of the nanostructure as another geometric parameter, by rotating the structure in the counter-clockwise direction.

With the nanostructure library in place, an integrated deep neural network to design metasurface holograms is developed and shown in Fig.1(b). The whole network turns input target holograms B_{ki} (upper green box) to the

output geometric parameters of all nanostructures on the metasurface (the cyan box). Subscript k iterates the polarization channels (xx, xy, yx, yy or LL, LR, RL, RR for linear-polarization(LP) or circular-polarization(CP) holograms) and i iterates the pixels on the hologram. The decoder is pre-trained with supervised learning to turn geometric parameters to the Jones matrix elements. The encoder-decoder pair is an autoencoder variant to do inverse design of nanostructures from given Jones matrix elements. It is further embedded into the integrated network as an autoencoder in turning target holograms to geometry and to reconstructed holograms B'_{ki} with loss function being the reconstruction error. The integrated network trains the far-field predictor network and the encoder network with unsupervised learning [5]. Here, we generate 500 different configurations of polarization holograms with dice patterns (with the size of 64 by 64 pixels) to train the network, and each set consists of four independent holograms, which iterates four combinations of polarization conversion channels. After the network is well trained, a testing set with the dice patterns are chosen to test the network. The first row in Fig.1(c) lists the target holograms, and the second (third) row lists the generated holograms in the LP (CP) basis. Each column shows one of the four polarization channels with the first (second) arrow indicating the analyzing (incident) polarizations. The horizontal (vertical) arrow means x (y) polarization. The clockwise (counterclockwise) arrow means right (left)-handed CP. Pearson correlation coefficients between the reconstructed and the target holograms are shown in upper left corner of each hologram and are all higher than 0.8. It is worth to note that without detailed physical knowledge on the nanostructure constraints, this integrated network method can generate metasurface designs directly from the required complex polarization holograms.

Machine Learning Techniques and Practical Advice for the Free-Form Inverse Design of Nanophotonic Devices

Timo Gahlmann* **and Philippe Tassin**

Department of Physics, Chalmers University of Technology, SE-412 96 Gothenburg, Sweden
*corresponding author: timo.gahlmann@chalmers.se

Abstract: The free-form inverse design of nanophotonic metasurfaces can be solved with a modified CGAN machine learning method that balances the accuracy of desired optical properties with experimental feasibility.

We will present several machine learning techniques that can be used for the inverse design of free-form nanophotonic devices, i.e., devices for the manipulation of light with subwavelength patterning [1]. Such devices allow us to control light at unprecedented levels, resulting in nontrivial scattering response, e.g., for holograms and retroreflectors. A nanophotonic device often consists of an array of scattering elements, each of which needs to have a specific transmission (or reflection) amplitude and phase. The challenge is, then, to find the shape and materials of meta-atoms with the desired scattering response. This engineering problem is called inverse design.

In this contribution, we will discuss how it is possible to address the computational and methodological difficulties emerging when using neural networks for the inverse design of metasurfaces [2]. Neural networks provide the big advantage that they can quickly generate a design for a meta-atom with most desired transmission amplitude and phase once they are trained. The training of the neural networks still requires a large number of simulations of the nanophotonic device (with different geometries), but they can be run in parallel on high-performance computer clusters. We will provide guidance for best practice and an overview of techniques that work well, illustrated by examples.

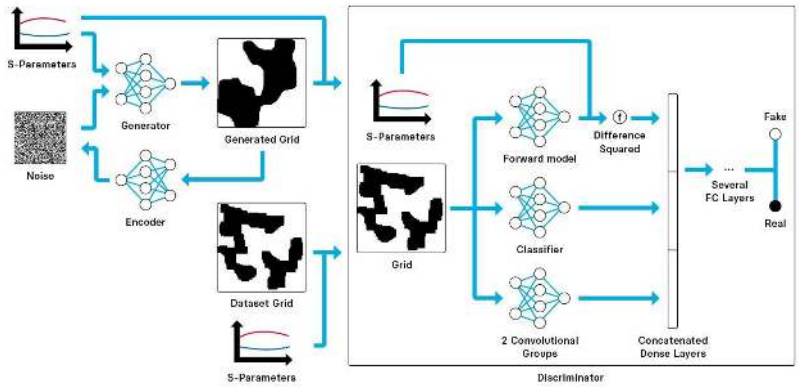

Figure 1: A conditional generative adversarial network model. The generator creates unit cell grids from noise and S parameters while the encoder prevents mode collapse. Two ”expert” networks (forward and classifier model) are integrated inside the discriminator.

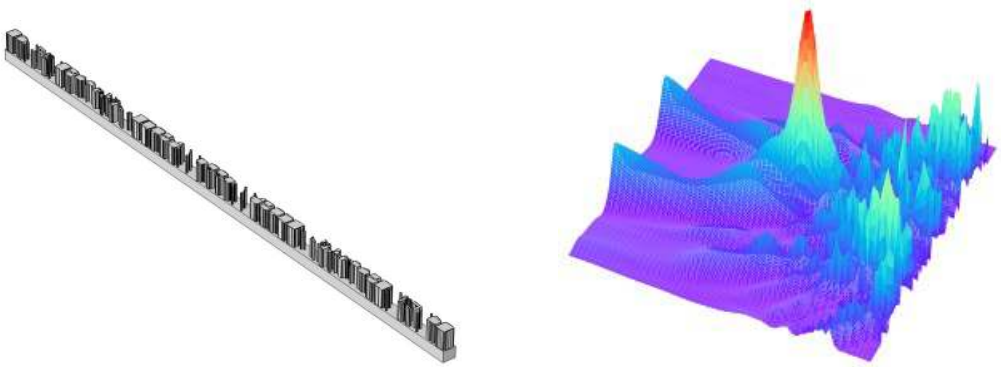

Figure 2: Left: Unit cell composition of a cylindrical lens as designed by the CGAN. Right: Intensity of the focused beam obtained from the CGAN-designed lens.

First we will show how to create a neural-network model mapping a random device geometry on an optical property of interest. Such a forward model is necessary as a surrogate model in the CGAN that we have built for the inverse design. Second, we will discuss methods to integrate fabrication feasibility into the inverse design method, e.g., by training a classifier network to distinguish between fabrication-feasible and unfeasible geometries. We will then proceed with presenting our CGAN model for the inverse design.

In a CGAN, a generator creates grids based on noise and labels (desired S parameters, aspect ratio, minimum resonances width and other criteria), while the discriminator is fed not only the grids produced by the generator and grids from the given data set, but also the respective labels. We will also show how the integration of "expert" networks into the discriminator can significantly improve the training speed and performance of the CGAN. Additionally, we will present a technique to prevent mode collapse in the generator, e.g., by using an additional encoder network. Finally, various other practical tricks to improve the stability, convergence, and outputs of the CGAN inverse-design network will be elaborated, e.g., data augmentation, use of dense ResNet [3], temporarily freezing the discriminator, data blurring, and noise to the different input channels.

Beyond Periodic pillar-wise library for metasurface: a stochastic approach

Loumi TREMAS[1*], and Mathys LE GRAND[1], Denis RIDEAU[2], Louis Henri FERNANDEZ-MOURON, Jeremy GREBOT, Bruce RAE, James DOWNING, Pascal URARD, Valérie SERRADEIL, Lucie DILHAN, Habib MOHAMAD, Gonzague DE CARPENTIER, Enrico Giuseppe CARNEMOLLA, Matteo FISSORE, Christophe SAUVAN

[1,2]STMicroelectronics, France [*]Corresponding author: loumi.tremas@st.com

Abstract: Most of the large scale metasurface are designed using pillar-wise periodic libraries [2]. However, in certain cases, resonances can appear which makes the relation between the desired phase and the corresponding pillar radius ambiguous. In the present abstract, we propose a new stochastic approach beyond pillar-wise periodic libraries.

The phase and transmission of the incident wave through the metasurface is studied with FDTD simulations. The studied systems are composed of pseudo-periodic assembly of pillars exhibiting a random radius variation obtained with a gaussian perturbation field (characterized by an RMS and a correlation length). Our metasurfaces are composed of scattering nano pillars. They are equally spaced on a grid and their radius can continuously vary in the interval $R \in [0.06; 0.18]\mu m$, their height is identical throughout all the experiment and have been simulated using a monochromatic source in the near infrared on a normal angle of incidence.

To study the impact of our system smoothness, a dataset of radius maps with different correlation length has been built. The correlation length translates how smooth the radius transition between neighboring pillars is. It is defined as $d_{corr} = N * \sigma$ where σ is the standard deviation of the gaussian perturbation and N the number of pillars. To create meta-surfaces with gaussian perturbations, a radius map M_i of NxN radii is generated from a uniform distribution. In this case $N = 21$. This radius map is then convoluted to several gaussian distributions parameterized by $\sigma = \{\sigma_1, \dots, \sigma_g\}\ with\ g \in \mathbb{N}$ to get g new

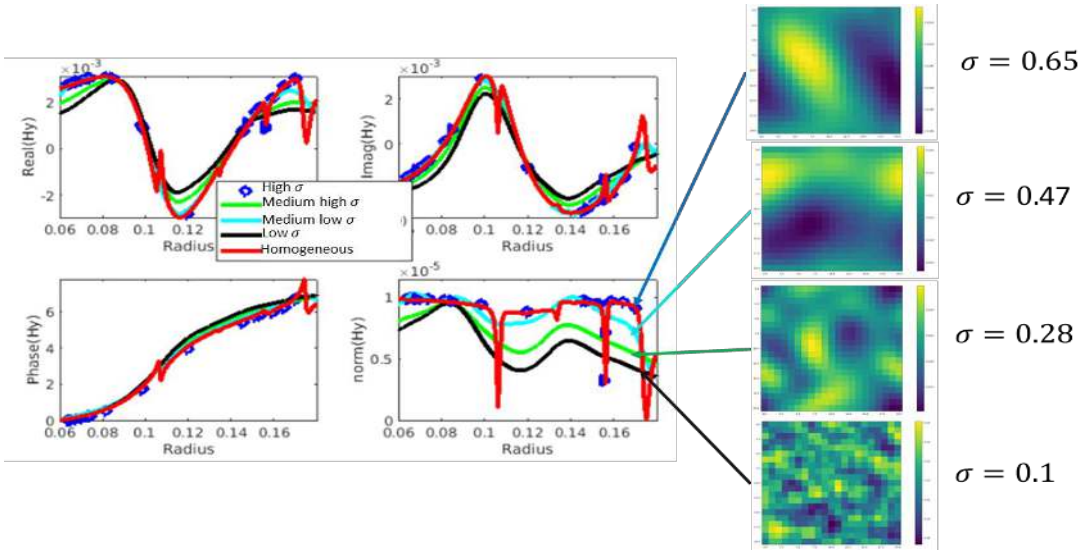

Figure 1: The relation between the phase and the radius is parameterized by the gaussian perturbation

ST Restricted

radius maps $M_i^{corr} = \{M_i^{\sigma_1}, \dots, M_i^{\sigma_g}\}$. By doing so with several M_i, a statical study on the correlation influence can be lead. Images on figure 1 show such radius maps.

Once the dataset inputs are generated, a Finite Time Difference Domain (FDTD) solver developed by Ansys to compute the near electromagnetic fields is used. The chosen nearfield distance for the study is 10 nanometer after the metamaterials in the z-axis.

The relation f between the pillar top radius and the local phase changed induced depends not only on the pillar parameters but also on the other pillars in his vicinity. There are electromagnetic couplings between pillars. And it is shown on figure 1 that when describing the neighborhood of a pillar with its correlation lengths, different relations f_{σ_i} are found. It appears that the resonance amplitudes decrease when the correlation lengths increase, and that the correlation length also affects the

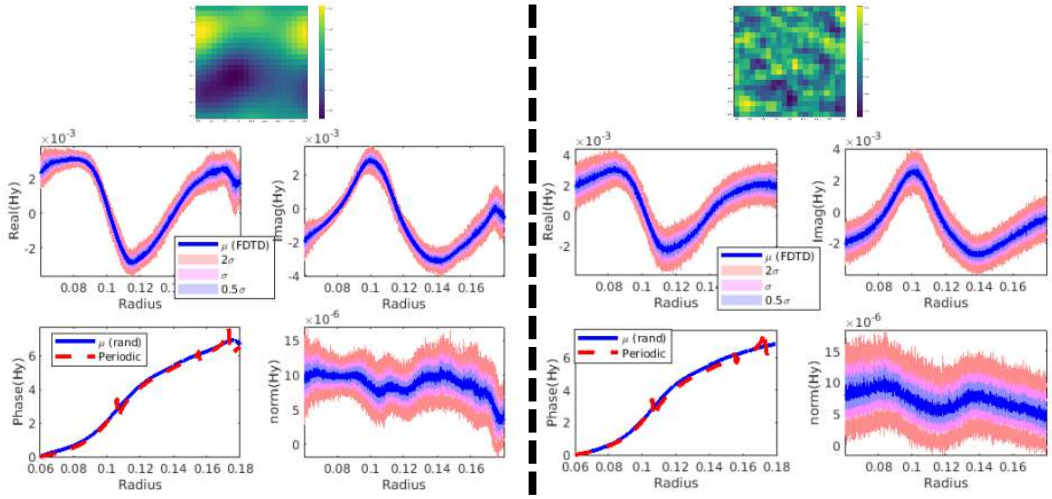

Figure 2:Statistical relation between phase/transmission and radius for two different perturbations

resonance localization [1-3]. This system makes possible a rigorous statistical analysis of the impact of neighboring pillars on a given individuation pillar. Additionally, an efficient AI-based convolutional model that can accurately reproduce the FDTD results (when these pseudo-random structures are correctly added in the training database) will be discussed in the conference. A further study has been conducted on the influence of the correlation length of a database on the training of an IA based solver with architectures like the ones introduced in [4-6].

Metamaterial-based devices

Design of a beam-modulable vertical cavity using a dielectric metasurface with a full phase change encircling an exceptional point

Jaewon Jang and Yeonsang Park*

[1]Department of Physics, Chungnam National University, Daejeon 34134, Korea
[2]Institute of Quantum Systems, Chungnam National University, Daejeon 34134, Korea
*corresponding author: yeonsang.park@cnu.ac.kr

Abstract: We suggest dielectric metasurfaces that can have a 2π phase with high reflection. Suggested dielectric metasurfaces are designed to have high reflection and simultaneously have a 2π phase with transmitted light by encircling the phase singularity point. We confirmed by simulation that a vertical cavity with high quality factor can be formed by using metasurfaces as a top reflector in the cavity, and the beam shape emitted from this cavity is modulated with ease with the help of metasurfaces.

The Huygens' metasurfaces are well-known for their high transmittance and phase gradient achieved through the resonant overlapping.[1] In addition, dielectric metasurfaces can work as high reflectors with a single layer effectively.[2] Recently, Song et al. demonstrated that the wavefront of the reflected wave can be modulated by using plasmonic metasurfaces with a 2π phase change protected topologically around the exceptional point.[3]

Here, we propose a dielectric metasurface that has a very high reflectivity at the target wavelength of 980 nm and simultaneously enables a 2π phase change for a small amount of transmitted wave. Contrary to the existing Huygens' metasurfaces which focus on enhancing transmission, we investigated the possibility of obtaining high reflection while also modulating the phase of a small amount of transmitted light for the application of a resonant cavity. Through FDTD simulation, we found out the presence of an exceptional point in a cross-shaped a-Si nanostructure as shown in Fig. 1, and that a 2π phase change of the transmitted light could be obtained by encircling this exceptional point.

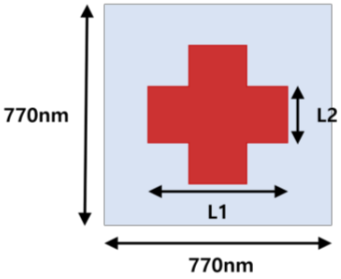

Figure 1. Schematic top view of a-Si nanostructure.

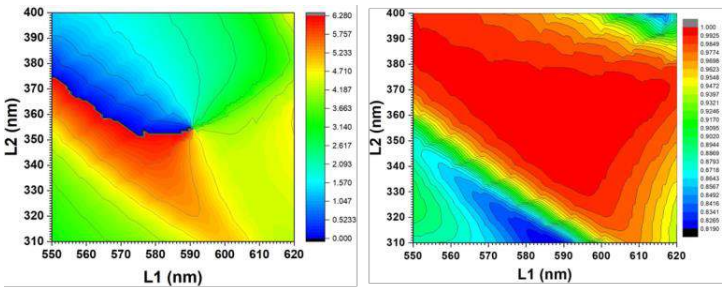

Figure 2. (a) Phase map and (b) Reflection map simulated while changing parameters of L1 and L2.

To confirm the function of the suggested metasurfaces, we simulated a metalens that shows high reflection to form the cavity with high quality factor and simultaneously controls the beam shape of the transmitted light. From Fig. 3, we could confirm that the most of light is reflected and a small amount of transmitted light is focused on the target focal distance with 20 μm. By integrating the simulated metalens with a bottom DBR, we developed a vertical cavity where the top DBR and the metasurface for controlling the emission beam shape are combined as a single layer. The suggested metasurfaces are expected to be used to form a vertical cavity as well as an external cavity for the application of optical communication, non-destructive biological imaging, endoscopy and beyond.

Abstract: Wireless technologies based on electromagnetic wave are crucial in the modern industry but nonoptimal in biomedical and underwater applications, where ultrasound has been proposed as an alternative approach. Here we construct a unified ultrasonic wireless infrastructure that supports multiple specific and separate functions, dubbed converged wireless infrastructure. The infrastructure based on ultrasound holography serves as the central hub to realize a series of wireless functions which is demonstrated with phased array and holograms.

The acoustic version of the wireless technology has been proposed and explored such as wireless powering. The piezoelectric energy harvesting of vibration [1] and ultrasound-based wireless power transfer (WPT) [2] are extended to be applied to charge biomedical electronics [3,4]. The existing research generally allows for single wireless function (e. g. wireless powering) and works for the single terminal. It is desired to develop a converged wireless infrastructure that integrates multiple mainstream wireless functions and allows the interaction among the various components, which yet remains an outstanding challenge. The difficulties lie in creating the complex control network and dynamically modulating the multiple control nodes.

Here we report the realization of acoustic-based converged wireless infrastructure by creating and modulating the control network consisting of multiple nodes with acoustic holography [5,6]. In the proposed wireless system, the holographic array serves as the central hub and integrates a series of mainstream wireless functions. We experimentally demonstrate those functions including the selective wireless power transfer, stable remote audio monitoring, dynamic programmable logic control, and parallel acoustic communication with 11 channels. The wireless system can also control multiple terminals even freely moving in 3D space. The immunity against EM and biological interference are also experimentally validated as unique features of acoustic wireless system. Considering the anti-interference performance and favorable underwater propagation ability, it is envisioned that the converged wireless system based on acoustic holographic array would perform a vital role in extreme environments such as the deep ocean. The converged wireless infrastructure represents a unified scheme to establish the integrated wireless network with different functions, which provides a promising strategy for wireless technologies performing in EM-restricted conditions.

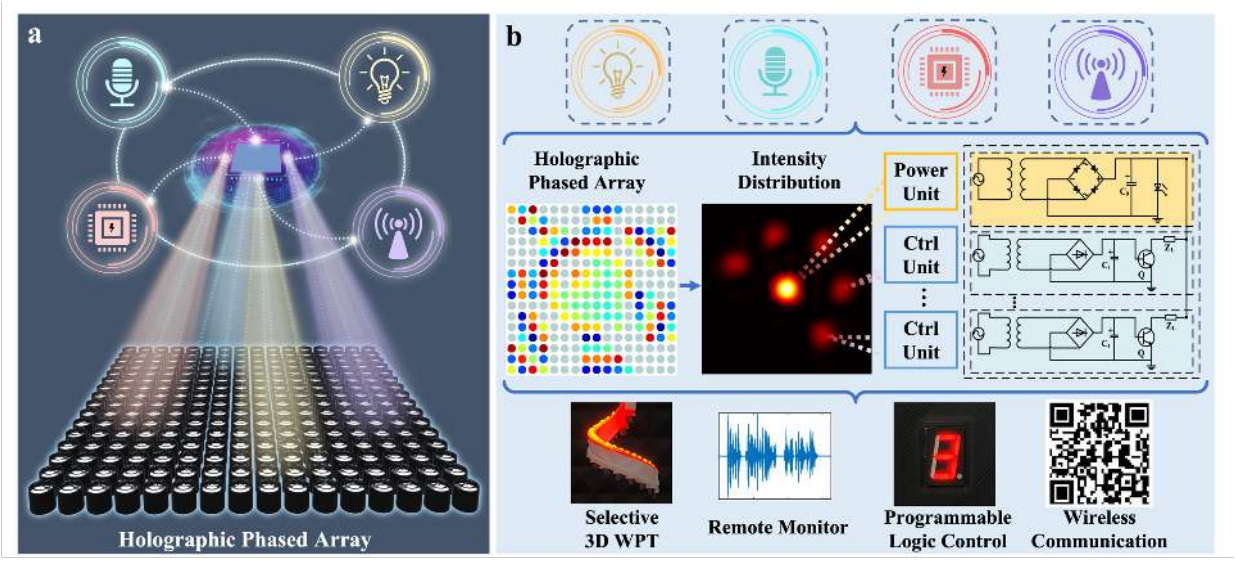

Figure 1. Converged wireless infrastructure based on acoustic holographic array. (a) Schematic of the converged wireless infrastructure which integrates mainstream wireless functions demonstrated in this work: selective 3D wireless powering of arbitrarily-distributed devices, remote audio monitoring, dynamic programable logic control of moving targets and wireless communication. Ultrasound holographic phased array (HPA) acts as the central hub to wirelessly assign commands and coordinate the individual devices. **(b)** Workflow diagram of the proposed acoustic wireless system. The HPA modulates control modes by specifying the acoustic intensity distribution according to the desired functions (top panel). Ultrasound energy is converted to the wireless power supplies by the power unit, or transferred into the control signals by the control unit, with the corresponding circuit diagrams shown on the right panel. Versatile wireless functions are realized by integrating those power and control units (bottom panel).

Atomic-level engineered transition-metal alloy photoanodes with record efficiency for solar water splitting

Fei Xiang[1], Ning Li[1], Arturo Burguete-Lopez[1], Zhao He[1], Maxim Elizarov[1], Andrea Fratalocchi[1*]

[1]PRIMALIGHT, King Abdullah University of Science and Technology (KAUST), Thuwal 23955-6900, Saudi Arabia

Abstract: We report a uniform transition-metal metamaterial alloy with atomic-level control on Si photoanodes for efficient and stable solar-assisted water splitting. This technique extends the lifetime of the photoelectrochemical device beyond 250 hours, achieving a record applied bias photon-to-current efficiency (ABPE) efficiency of 4.25%.

Harvesting solar energy for hydrogen production has attracted broad research interests as a sustainable conversion and storage pathway with zero carbon emission [1-3]. While the hydrogen evolution reaction at the device photocathode achieves high efficiency (ABPE up to 12% [4]), the water reaction at the photoanode suffers from poor kinetics, with best-reported ABPE efficiencies below 4% [4-6]. Studying new photoanodes with enhanced performances attracts the largest body of present research efforts [3, 7].

Besides the energy conversion efficiency, PEC photoanodes also need to improve their stability [8, 9]. For PEC devices with efficiencies above 3%, the reported stability under continuous working is generally below 100 hours [5]. For example, the a-Si/TiO_2 bilayer passivated n-c-Si/a-Si/TiO_2/Ni photoanode affords a ABPE of 3.9% with 30 hours stable operation [4]. The poor device lifetime for photoanodes originates from the structural instability of the semiconductor light absorber in the strong alkaline electrolyte (pH = 14) and the photo corrosion of the co-catalyst layer [7]. While additional protective layer coating, such as, e.g., SiO_x and Al_2O_3, prolongs the n-Si/Pt/Ni photoanode lifetime to around 200 hours, the water oxidation efficiency drops to 0.98% [6].

In this work, we report a conformal, atomic-level engineered nickel-iron (NiFe) metamaterial that simultaneously works as a co-catalyst and protective layer for the photoanodes (**Figure 1**). These self-protected photoanodes with 2 nm thickness of NiFe achieve an ABPE efficiency of up to 4.25% for the water oxidation reaction. Figure 1a-c report the scanning electron microscopy (SEM) and scanning transmission electron microscope (STEM) images of uniform and conformal coating of NiFe alloy deposited on the top surface of photoanodes. Figure 1d presents the *J-E* curves of fabricated PEC devices with varying thicknesses of NiFe. The best PEC device achieves a low onset potential of 1.08 V vs. RHE at the current density of 10 mA cm^{-2}. The system reaches a saturated current density I_{sat} = 39 mA cm^{-2}, close to the thermodynamic limit of the c-Si (Fig. 1d dashed line). Under continuous working conditions, the device operates with nearly 100% retention of its initial current for more than 40 hours (Fig. 1e). Figure 1f compares the performances of the NiFe PEC device implemented in this work against state of the art. These results open the design and implementation of highly efficient and durable PEC devices for large-scale solar hydrogen generation.

Breathalyzer-based Prompt Coronavirus Screening Test using Terahertz Spectroscopy of Viruses in LC-Resonant Metamaterial Nano-Antenna Array

Rudrarup Sengupta[1*], Heena Khand[1], and Gabby Sarusi[1]

[1]Department of Photonics and Electro-Optics Engineering, School of Electrical and Computer Engineering, Ben-Gurion University of the Negev, Beer Sheva, Israel. *corresponding author: rudrarup@post.bgu.ac.il

Abstract: We propose a tested, sensitive and prompt COVID-19 breath-screening method that takes less than one-minute. The non-biological method is based on detection of shift in terahertz resonance-frequency of a nano-engineered LC-resonant metamaterial chip, caused by viruses and related exhaled particles. The chip is enclosed in breathalyzer-like enclosure, which is shown to optically suppress Fabry-Pérot, for the first time. Low-scale clinical trials were conducted with asymptomatic, symptomatic coronavirus-patients and healthy individuals, where coronavirus-positive are effectively-screened with 87% accuracy, from healthy individuals.

Our proposed method is based on the detection of shift in resonance frequency of a nano-gap LC-resonant metamaterial chip, caused by viruses and mainly related exhaled particles, when performing a terahertz (THz) spectroscopy. The metallic nanostructure is physically designed as an inductor and capacitor element, where its fundamental resonant frequency is $F_0 = 1/2\pi\sqrt{LC}$. Here, L is the inductance and C is the capacitance. C is highly dependent on the effective dielectric constant (ε_{eff}) of the material introduced inside the capacitor gap. A change in the resonant frequency of the metamaterial structure can be brought about by any foreign substance deposited in the capacitive gap region, thereby changing the ε_{eff} and thus the capacitance, resulting in a redshift in the resonance frequency (ΔF) with respect to the pristine LC circuit in the array.

For the detection of COVID-19 carriers using metamaterial-based structures, we physically re-design the THz LC resonant geometry with the intention of maximizing the capacitor-gap-area. The capacitor gap (width) can be reduced in order in order to obtain the plasmonic enhancement that is associated with the nano-metric scale of such a capacitor gap. Placing the capacitor gaps at both geometric diagonals of a square inductor enables the exhaled viruses and particles to be detected in both S and P polarization states with a rectangular all-around singular inductor structure as shown in Figure 1(a, b), for its resonance detection. This improvement enables breathalyzer-based coronavirus and related particle detection by increasing the capacitive gap lengths compared to the basic SRR[1]; this effectively increases the sensitivity by increasing the probability of viruses/particles falling inside the capacitive gap and yet maintaining a sub-micron capacitor gap, thereby enabling pronounced resonance frequency shifts for breath samples even with a lower virus load. The 3D printed capsule enclosure for our metamaterial chip, is optically designed with layers having specific property to optically suppress the Si substrate's Fabry-Perot losses.

In our proposed coronavirus screening test with we detect a combination of viruses and related biological particles exhaled by an infected person, (e.g. virus debris, cytokines, cell debris and related proteins and fat molecules) which produces an effective change in dielectric constant of the resonant metamaterial at the capacitive gap regions. This phenomenon red shifts the resonance frequency (ΔF), which becomes the deterministic factor to effectively screen the infected patients from the healthy individual. We achieve a definite band of $\Delta F = 1.5\ GHz$ to $9\ GHz$ for infected individuals, with a linear relationship of increasing ΔF with increasing viral load as shown in Figure 2. In order to effectively differentiate between 'healthy' and 'SARS-CoV-2 infected' patients in terms of ΔF, we included only 'completely healthy' and 'sick of SARS-CoV-2' individual, in order to design a screening test only and not a diagnostic test. The simplicity of this cost-effective breathalyzer-based testing kit lies in its ease of handling, which does not require

a complex setup procedure. The entire testing and analysis are performed within 50 to 55 seconds, with 86.84% agreement with the RT-qPCR analysis (with both PPV and NPV values of 88.88%), based on the low scale verification clinical trials conducted at Soroka medical centre, Israel.

Electronic beam steering using a reconfigurable metasurface

N. Meftah[1], B. Ratni[1], M. N. El Korso[2], and S. N. Burokur[1*]

[1]LEME, UPL, Univ Paris Nanterre, F92410 Ville d'Avray, France

Abstract: A 2D reconfigurable reflective metasurface with individually addressable unit cells incorporating voltage-controlled varactor diodes is proposed. This metasurface illuminated by a primary source is used as a reconfigurable parabolic reflector antenna, enabling an electronic control of beam steering by assigning the appropriate phase profile along the metasurface through capacitance modulation.

Metasurfaces have attracted great interest due to their ability to manipulate electromagnetic waves, such as radiation control [1-3], wavefront shaping [1,4], and polarization conversion [5]. The concept of reconfigurable metasurfaces has emerged in recent years to satisfy the changing requirements in practical applications and enable the integration of multiple functionalities into a single metasurface. In this paper, a fully programmable metasurface with individually addressable unit cells, enabling between -180° and 180° phase coverage, is designed for operation around 2.3 GHz by incorporating varactor diodes. The metasurface associated with a primary source is used as a 2D reconfigurable parabolic reflector antenna to achieve complete elevation and azimuth beam scanning.

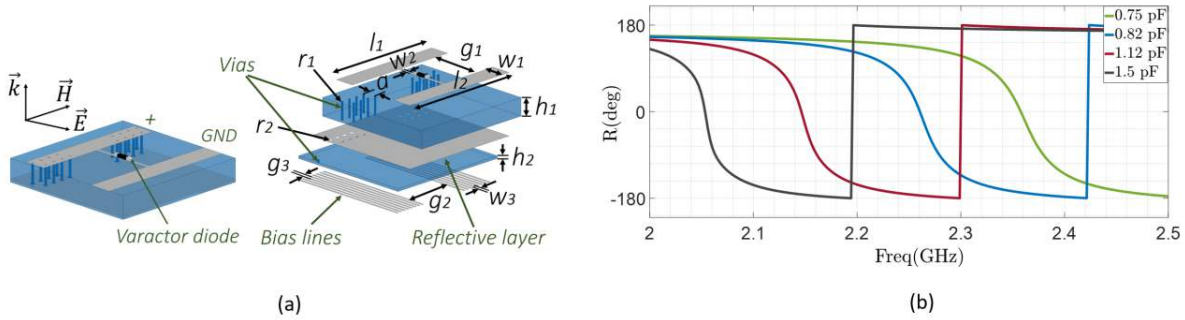

Figure 1. (a) Schematic design of the unit cell: l_1 = 24 mm, l_2 = 25 mm, w_1 = 4 mm, w_2 = 2 mm, w_3 = 0.4 mm, g_1 = 11 mm, g_2 = 9.85 mm, g_3 = 0.5 mm, a = 2 mm, r_1 = 0.4 mm, r_2 = 0.8 mm, h_1 = 3.5 mm and h_2 = 0.25 mm. (b) Simulated reflection phase responses for different capacitance values.

The proposed reconfigurable metasurface comprises 16x16 tunable unit cells. As shown in Fig. 1(a), the tunable unit cell is composed of three metal layers: the capacitive grid incorporating the varactor diode (SMV1405-040LF), the reflective ground plane and the voltage bias layer. The dielectric substrates used have relative permittivity ε_r = 2.2. 16 vias are integrated into the top dielectric substrate, where 15 are blind vias, and a single one is connected to the power supply to bias the varactor diode. From Fig. 1(b), it can be noted that the resonance frequency varies from 2.05 GHz to 2.36 GHz when the capacitance changes from 1.5 pF to 0.75 pF, enabling to achieve a phase gradient close to 360° at 2.3 GHz.

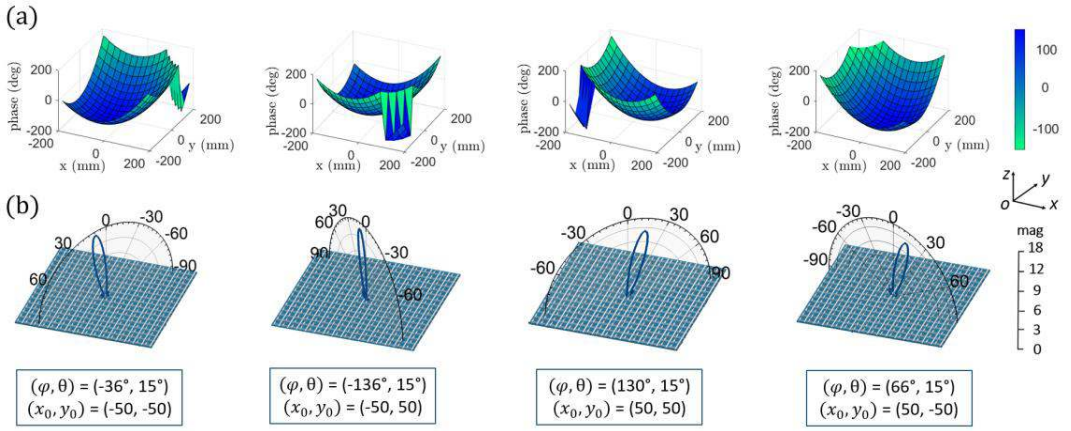

Figure 2. (a) 2D phase profiles for beam steering. (b) Simulated far-field radiation patterns for different (x0, y0) shifting.

The designed 2D reconfigurable metasurface is illuminated by a primary source to be used as a planar parabolic reflector to generate a fully controllable highly directional beam. The parabolic phase profile applied along the metasurface is calculated as:

$$\varphi(x,y) = \frac{2\pi}{\lambda}\left(\frac{(x-x_0)^2+(y-y_0)^2}{4F}\right) + \varphi_0 \qquad (1)$$

where λ is the free space operating wavelength, F (= 150 mm) is the focal distance, and φ_0 is the reflection phase at (x_0, y_0). A direct coaxial-fed microstrip patch antenna designed for 2.3 GHz operation is used as a primary source and is placed at the focal point. In order to control beam steering, the phase profile is electronically adjusted by shifting the reference reflection phase along the *x*-, *y*-direction or both, such that the feeding source is virtually displaced in the focal plane. The simulation results show directive radiation with more than 10 dB realized gain. A deflection of ±30° from the *z*-axis with 360° steering in the *xoy* plane (Fig. 2) is achieved.

The designed programmable metasurface has been used to design a 2D reconfigurable parabolic reflector antenna, where high directive beams and 360° beam steering flexibility and ±30° vertical scanning have been demonstrated in simulation by judiciously modifying the phase profile.

Modifying the integer quantum Hall effect with cavity vacuum fields

J. Enkner[1], F. Appugliese[1], G. L. Paravicini-Bagliani[1], M. Beck[1], C. Reichl[2], W. Wegscheider[2], G. Scalari[1], C. Ciuti[3], and J. Faist [1*]

Abstract: As reported by Appugliese et al. [1] as you immerse a Hall bar into the cavity vacuum fields of a 2-dimensional metamaterial, a split ring resonator (THz), the interaction with vacuum fields not only modifies the finite resistances of the Shubnikov de Haas oscillations in the diffusive transport regime [2], but it also breaks the topological protection in the integer quantum hall regime. We quantify this loss of quantization as vacuum field induced resistivity that is directly linked to the Rabi frequency.

As a topological insulator the quantum Hall system is paradigmatic for being robust under the influence of short-range perturbations. We observe the loss the zero-resistance states in the longitudinal traces and quantization of the Hall plateaus due to the cavity induced long-range perturbations. The accompanying picture is called "cavity mediated electron hopping" [3]. It shows that with an anti-resonant process we can lift an electron occupying the disordered state ϕ_λ^n in the nth Landau level into the state $\phi_{\lambda''}^{n+1}$ in the (n+1)th with the emission of a virtual photon. The inverse process then drops the electron back into the nth Level, but into a different disordered state $\phi_{\lambda'}^n$ at a different location as the virtual photon gets also re-absorbed. Effectively, with this process electrons can now scatter between the topologically protected edge states via the insulating bulk and break topological protection. The effective coupling $\tilde{\Gamma}_{\lambda,\lambda'}^{(n)}$ between the disordered states ϕ_λ^n and $\phi_{\lambda'}^n$ is given by the expression

$$\tilde{\Gamma}_{\lambda,\lambda'}^{(n)} = \sum_{\lambda''} \frac{\tilde{g}_{\lambda,\lambda''}^{(n,n+1)} \tilde{g}_{\lambda',\lambda''}^{(n,n+1)}}{\epsilon_{n,\lambda} - \epsilon_{n+1,\lambda''} - \hbar\tilde{\omega}_{\mathrm{cav}}} \qquad (1)$$

Summing over all N_{deg} disordered states, where N_{deg} is the degeneracy of the Landau band and $g_{\lambda,\lambda''}^{(n,n+1)}$ is the single electron Rabi frequency that that is calculated through the overlap of the electronic wave functions of state ϕ_λ^n and state $\phi_{\lambda''}^{n+1}$.

We quantitatively characterize this loss of quantization as vacuum field induced resistivity ρ_{vac}^{xx}, a parameter we get from performing an adapted Landauer-Büttiker formalism [4], that describes the scattering that is causing the deviation from perfect quantization with a finite transmission t_i of the highest populated edge state [5]. With extracting the longitudinal resistance R_{xx} at the middle of each quantized plateau we can fit a value for the vacuum field induced scattering ρ_{vac}^{xx}.

When we plot ρ_{vac}^{xx} as a function of the cyclotron energy, first we find that the absolute values are higher for odd states than for even. This can be intuitively understood with the fact that each time an electron crosses the gap via an anti-resonant process, it also suffers an energy penalty related to the gap spacing. Since the Zeeman-split states are energetically smaller, higher rates of scattering are a consequence. Secondly, both odd and even states follow the same exponential decay, the characteristic energy E_{char} that hints towards $g_{\lambda,\lambda''}^{(n,n+1)}$ being the

controlling parameter.
In a study we alter the geometry of both Hall bar and cavity (complementary split ring resonator [6]) in a way that guarantees us the same coupling strength but different Rabi frequency (Figure 1a).
Two different samples processed on the same heterostructure display an exponential decay that aligned with the prediction of the characteristic energy in this system, therefore reinforcing the connection to the rabi frequency.

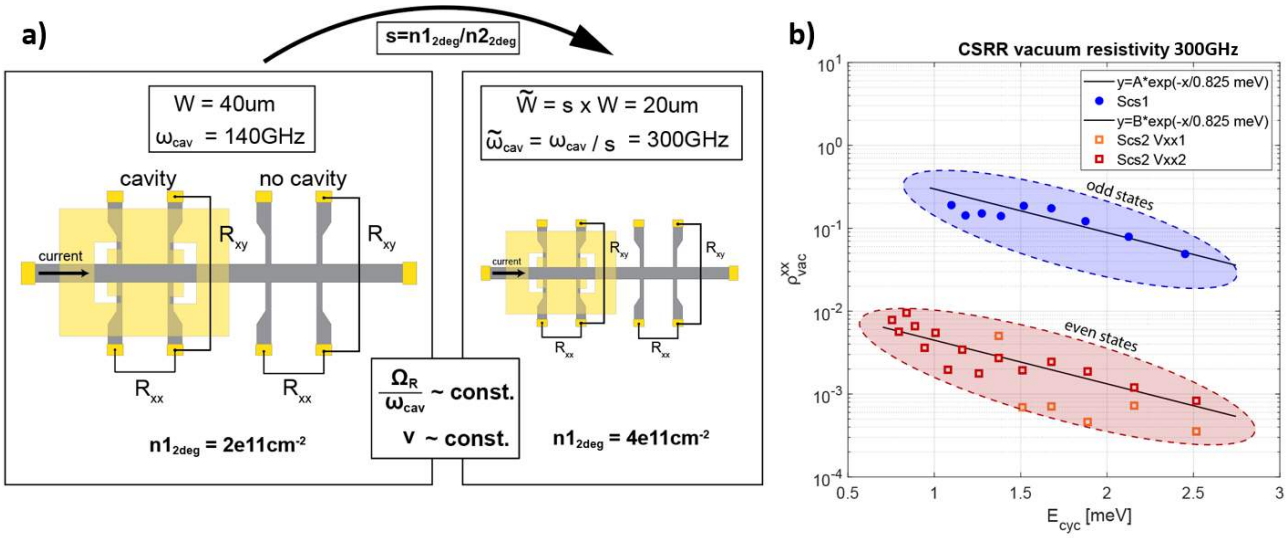

Figure 1: a) sketch illustrating the straight forwardness of scaling both Hall bar and CSRR down by factor 2, locking the coupling strength to the same value of Ω_R/ω_{cav} = 30% while keeping the field profile inside the cavity the same. The parameter changed is Rabi frequency Ω_R. b) two independent samples processed on the same heterostructure but with the same sample geometry and Rabi frequency now only display very comparable values for ρ_{vac}^{xx} but also show the same exponential decay, E_{char} =0.825, that again is directly proportional to the Rabi frequency.

In our work we present a deeper understanding and characterization of the effect reported in [1], while directly drawing the connection to the light matter coupled nature of the system.

Abstract: We have demonstrated the excitation of multipole plasmon modes in hybrid cavity consisting of a split ring resonator (SRR) in the vicinity of dipole cavity (hole array) via conductive coupling.

Localized surface plasmon resonances (LSPRs) are non-propagating surface plasmons, which can be excited via the interaction of electromagnetic wave with appropriately designed dipole cavities [**1**]. These plasmonic modes enhances the confinement of electromagnetic energy through strong light-matter interaction. Planar plasmonic structures support higher order plasmonic modes inherently but they consist of low scattering intensity in comparison to the dipolar plasmonic modes [**2**]. Hence, these higher order modes are not easy to excite in such structures. In this context, the coupling of dipole cavities with other plasmonic structures provides additional degree of freedom to tune the higher-order plasmon modes [**2-4**]. In the present study, we investigated the effect of conductive coupling of SRR and dipole cavity on the transmission characteristics of the hybrid structure.

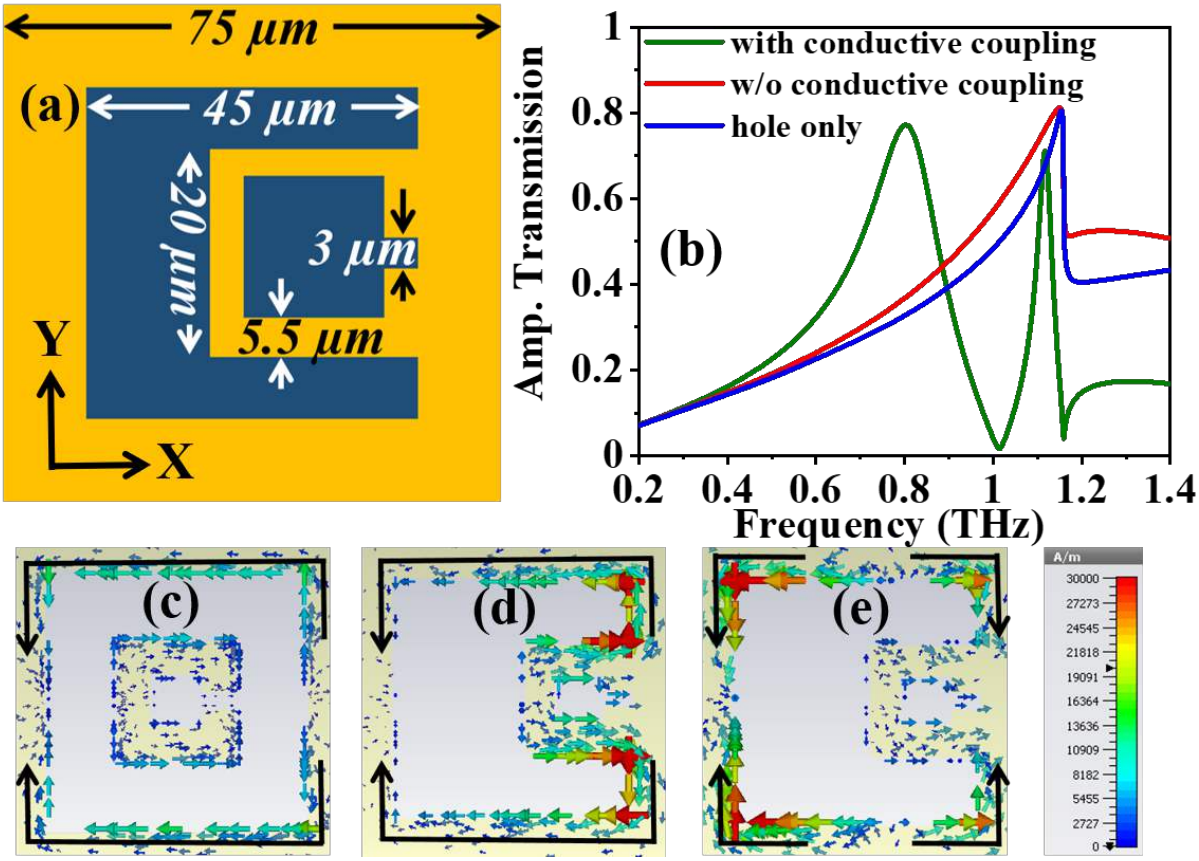

Fig. 1: (a) Unit cell of the proposed metamaterial structure displaying the geometrical parameters; (b) Transmission amplitude spectra depicting the evolution of new resonance peak for conductive coupling; Surface

current distribution (c) for "without" conductive coupling at $f = 1.15\,THz$; for "with" conductive coupling at (d) $f = 0.80\,THz$, and (e) $f = 1.12\,THz$.

The unit cell of the proposed structure along with the geometrical parameters is shown in Fig. 1(a). The structure is designed on an intrinsic silicon substrate of $25\,\mu m$ thickness. On the top of the Si substrate, a 200 nm thick perforated aluminum sheet consisting of a square cavity is placed and an SRR of same thickness is placed inside the cavity. We theoretically investigated the transmission characteristic of the hybrid resonant cavity for x-polarized terahertz radiations. The numerical analysis of the designed structure is done by using commercially available CST microwave studio. Unit cell boundary conditions are used in the x- and y-direction, whereas open boundary conditions are used in the z-direction.

Initially, we studied the transmission amplitude spectra of the uncoupled dipole cavity. As shown in Fig. 1(b), the transmission spectra of uncoupled dipole cavity consist of a dipole resonance peak at $f = 1.15\,THz$ due to the excitation of surface plasmons at metal-dielectric boundary. Subsequently, the SRR was introduced at the center of the cavity and the transmission spectra was recorded with x-polarized light. The structure is symmetric about x-axis, therefore the presence of SRR does not significantly affect transmission spectra (as shown in Fig. 1(b)) for x-polarized incident radiation. In order to introduce conductive coupling between the cavity and the SRR, the SRR is shifted along x-axis until it touches the cavity wall. The transmission spectra for such configuration (Fig. 1(b)) shows the excitation of an additional higher order plasmonic mode. The presence of higher order mode can be confirmed through surface current distribution at resonance frequency (Fig. 1(c-e)), where the direction of the surface current is indicated by the black arrows. Figure 1(c) shows the surface current distribution for the hybrid cavity at $f = 1.15\,THz$ where the SRR is placed at the center. It is clear from the figure that the contribution of SRR does not have significant contribution and the resonance peak is excited due to the cavity only. Figure 1(d, e) shows the surface current distribution for conductive coupling at $f = 0.80\,THz$ and $f = 1.12\,THz$, respectively. The current distribution shows the significant contribution of the SRR and cavity in the excitement of these resonance modes. The current distribution at $f = 0.80\,THz$ demonstrate a typical dipolar plasmon mode whereas, the current distribution at $f = 1.12\,THz$ confirms the excitation of quadrupole surface plasmon mode.

In summary, we demonstrated the excitation of the higher order plasmonic modes induced via conductive coupling between the SRR and the dipole cavity. Such higher order plasmonic modes may have various potential THz applications including filtering, sensing, spectral enhancement, etc.

Highly Sensitive Flexible Terahertz Metasensor for Thin Film Sensing

Parveen Joon, Sukhvinder Kaur, and R. K. Varshney*

Physics Department, Indian Institute of Technology Delhi, New Delhi-110016, India

* ravi@physics.iitd.ac.in

Abstract: We present a flexible terahertz metamaterial sensor that exhibits inductive capacitive (LC)/dipole resonance, and the effects of varying the thickness of a dielectric analyte on Split Ring Resonator/rod structure have been explored. The sensor is highly sensitive to even small (59.9 GHz/μm) environmental changes as the sensor's geometry results in enhanced localized electric fields.

Giving flexibility to metamaterials enables the wrapping of transparent and lightweight metamaterials around objects [1,2]. The dielectric environment present on the surface of the metamaterial structure affects the metamaterial's resonance frequency as it is highly sensitive to changes in the dielectric environment. The sensor is greatly miniaturized due to its subwavelength resonance, which also helps to increase sensitivity because high resonance is restricted to a small area [3]. Therefore, in the present study, we have studied the coupling of SRR and rod structure and demonstrated the excitation of LC/dipole resonance.

Our proposed terahertz metamaterial sensor consists of SRR/rod resonator unit and a flexible polyimide substrate. Figure 1(a) depicts the unit cell of sensing structure. The bottom is the dielectric flexible substrate of polyimide film (n=1.87), and the top is a metallic layer (Al) that produces electromagnetic resonance. The metallic layer encompasses SRR and rod structures. The dimensions are l_r = 20 μm, l_i = 45.5 μm, t_s = 25 μm and t_{al} = 0.2 μm (metallic layer thickness), t_r = 5.5 μm, g = d = 3 μm. The period is l = w = 75 μm and Δl is the change in length.

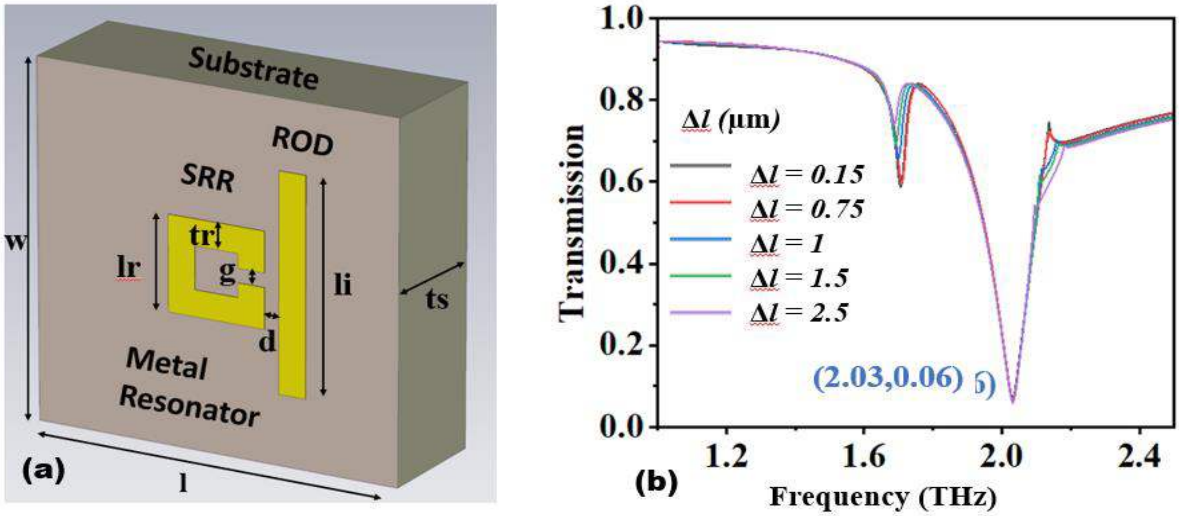

Fig.1. (a) Schematic diagram of SRR/Rod terahertz metamaterial sensor unit cell with parameters (b) Transmission spectra for change in dimensions of the SRR and rod

The transmission spectra, as shown in Figure 1(b), for change in length and width (keeping the area constant) of SRR and rod were obtained by using CST microwave studio to ascertain the flexibility of the structure. The dipole

and LC resonance appeared at 1.71 and 2.03 THz, respectively. It is evident from the transmission spectra that there is no significant shift in the resonance frequency on varying the length and width. Hence, the proposed structure is well-suited for applications that need conformal adhesion. Therefore, the terahertz metamaterial sensor was utilized for thin-film sensing of Mica with a constant refractive index (n)=2.44.

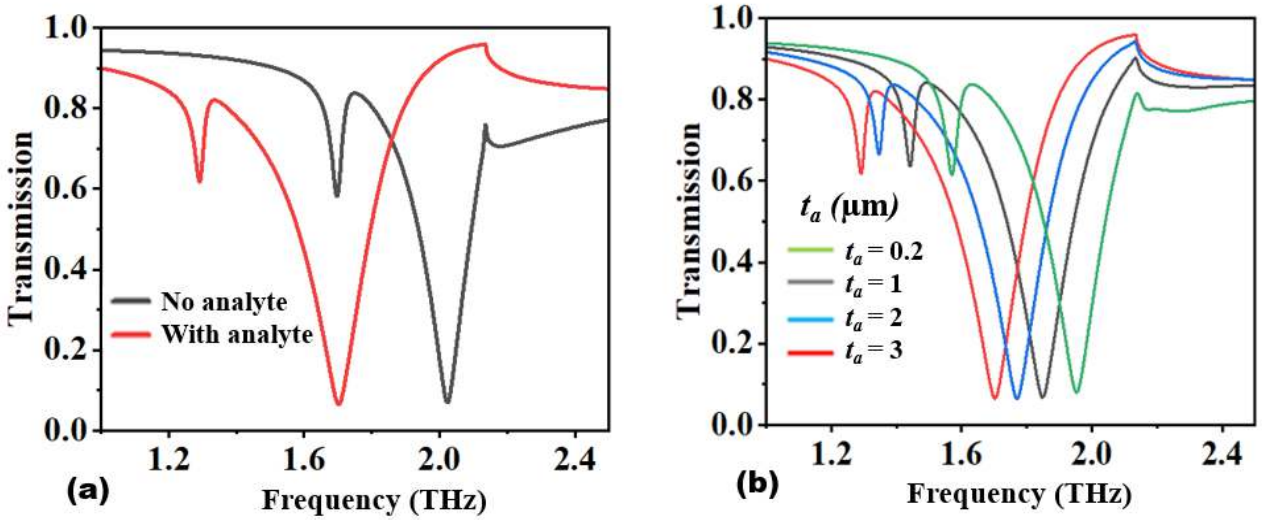

Fig.2. (a) Transmission spectra showing the shift of resonance frequency with and without analyte (b) Transmission spectra showing the shift in resonance frequency with change in Analyte thickness.

The transmission spectra were captured with and without an analyte, as shown in Figure 2(a). The shift in resonance frequency was found to be quite noticeable as evident from the plot. To comprehend the shift in resonance frequency with increasing analyte thickness, the thickness of the sample was increased from 0.2 to 3 μm. As the thickness of the analyte increases, effective capacitance of SRR increases, and hence the resonance frequency decreases leading to redshift [4] which can be seen in the transmission spectrum as shown in Figure 2(b). Hence, the proposed terahertz metamaterial sensor can be employed as thin film sensor and calculated sensitivity ($\frac{\Delta f}{\Delta t_a}$, where, Δf is change in resonance frequency and Δt_a is change in analyte thickness) is 59.9 GHz/μm, which is almost double of previously reported results.

Abstract: We develop a multifunctional metasurface platform that leverages the combination of loss-engineered substoichiometric titanium oxide (TiO_{2-x}) and the emerging physical concept of optical bound states in the continuum (BICs) to boost photoinduced charge transfer (PICT) and provide broad spectral tunability, making this semiconductor metasurface not only a competitive platform for surface photocatalytic investigations, but also a promising candidate for boosting sensitivities in in semiconductor-based surface-enhanced Raman scattering (SERS) applications.

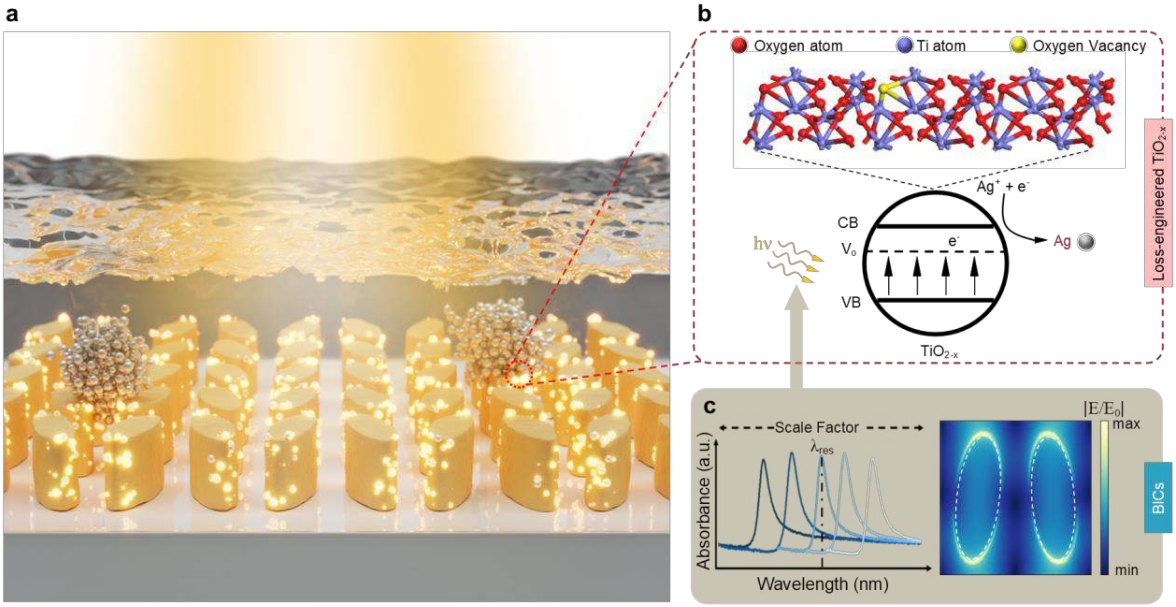

Figure 1. Catalytic metasurfaces driven by bound states in the continuum. a, Schematic of the TiO_{2-x}-based BIC metasurface platform for the photoreduction of silver ions. **b**, Schematic of oxygen vacancies acting as the defect energy level between the conduction band and valence band, which extends the light absorption to the visible region. The photo-excited electron exhibits strong reducing reactivity, resulting in the reduction of Ag^+ ions. **c**, The reduction rate of Ag^+ is increased via metasurface-enhanced light absorption at a given excitation wavelength. Spectral tunability of the catalytic metasurfaces is achieved by adjusting the scaling factor of the unit cell. Strong nanoscale light confinement and

enhancement of the local electromagnetic fields of the catalytic metasurface are provided by the BIC concept (right). This idea can be extended to other materials. Adapted from Ref. [5].

Recently, metasurfaces underpinned by the physics of photonic bound states in the continuum (BICs) with extremely high quality (Q) factors and strong enhancement of electromagnetic fields have received significant interest [1,2]. Most of the BIC-based systems demonstrated so far are constructed from high refractive index materials like Si [3], where pushing the operating range towards the blue part of the optical spectrum is still challenging due to significant dielectric losses associated with the band gaps. TiO_2 is a promising alternative because of its adjustable extinction coefficient [4], but has, so far, not been employed in the context of BIC-based systems.

Here, we present an ultrathin catalytic metasurface platform that leverages, the combination of loss-engineered substoichiometric titanium oxide (TiO_{2-x}) and the emerging physical concept of optical bound states in the continuum (BICs) to boost photocatalytic activity and provide broad spectral tunability (**Figure 1**). We demonstrate that our platform reaches the conditions of critical light coupling in a TiO_{2-x} BIC metasurface, providing at the same time a general framework for maximizing light-matter interactions in diverse photocatalytic materials. This approach can avoid long-standing drawbacks of many naturally occurring semiconductor-based ultrathin films applied in photocatalysis, such as poor spectral tunability and limited absorption manipulation [5].

Additionally, the enhanced photoinduced charge transfer (PICT) in TiO_2 metasurface systems reveals the great potential of this approach as a semiconductor SERS substrate, where PICT is shown to play a dominant role in our experiments. Significantly, we harness two additional benefits of our BIC platform: strong near-field electromagnetic field enhancement as well as broad spectral tunability, which are urgently needed for pushing the development of semiconductor SERS substrates.

Hence, our findings establish this multifunctional metasurface platform as a versatile and efficient means to enhance various photochemical processes and enable new opportunities for optoelectronic device applications.

Demonstration of an ultra-sharp bend in 1D grating waveguides based on inverse design

A. O. Sakin[1], A. C. Songur[1], H. A. Gunes[1], B. Akcay[1], and M. Unlu[1*]

[1] Dept. of Electrical and Electronics Engineering, TOBB University of Economics and Technology, 06510 Ankara, Turkey

[*]corresponding author: munlu@etu.edu.tr

Abstract: The design of sharp bends in 1D grating waveguides is a challenging problem as the Bloch mode profiles are being pushed towards the outer sidewall and becoming highly asymmetrical, as a result of the steep and high group velocity dispersion of the 1D grating waveguide. To overcome this problem, we propose a first-of-its-kind ultra-sharp bend design in an extensively corrugated 1D grating waveguide on silicon-on-insulator, based on pixelated metamaterials with an ultra-compact size of 2.1 × 2.2 μm^2.

Silicon Photonics Integrated Circuits (PICs) have been attracting tremendous interest due to their potential for meeting the growing need for ultra-high bandwidth data transmission, providing unique capabilities with their inherently broadband, high-speed, and low-loss nature. However, the challenge of achieving miniaturized, low-power photonic structures is ever-increasing as a result of the limitations of silicon, including the absence of a direct band gap and weak second-order nonlinearity, in response to the need for high-capacity photonic interconnects. An intriguing area of study in the field of photonics involves creating optical true time delay (TTD) lines for the purpose of steering antenna beams, modulating signals, and implementing advanced multiplexing techniques. In particular, the one-dimensional (1D) grating waveguide, comprising a periodically modulated pattern of index guiding in both vertical and horizontal directions, has been the focus of much attention as a consequence of its compact size, low loss, and ultra-high bandwidth [1-2]. For changing the direction of light propagation in 1D grating waveguides, sharp bends are an indispensable structure. The high refractive index contrast between the core and claddings in single-mode strip waveguides makes it simple to achieve ultra-sharp waveguide bends [3]. However, when it comes to bends in 1D grating waveguides, the scenario becomes notably different, resulting in both mode-mismatch loss and inter-mode crosstalk. This is because the Bloch mode profiles, a type of guided mode, are squeezed towards the outer sidewall and become highly asymmetrical due to the steeper dispersion relationship and higher group velocity dispersion of the 1D grating waveguide.

A widely used method for managing the difficulties posed by sharp bends in 1D grating waveguides is to gradually transform the taper from a 1D grating waveguide to a conventional strip waveguide at the bend and then tapering back to a 1D grating waveguide after the bend. Nevertheless, the tapering approach has the drawback of adding the extra loss and occupying valuable chip estate unnecessarily [4]. Additionally, the concept of bending in a 1D grating waveguide using modified Archimedean spirals with maximum radii of 59 μm has been proposed in order to achieve low excess losses and inter-mode crosstalk [5]. However, this method is only effective when the corrugation width is narrower, resulting in a more symmetrical Bloch mode profile with a lower group velocity dispersion [6]. Currently, the bends that have been shown are not sharp, and designing them with a wider corrugation to enhance group velocity dispersion is still not possible. Therefore, we propose, for the first time to the authors' best knowledge, an ultra-sharp bend based on pixelated metamaterials for an extensively corrugated 1D grating waveguide on silicon-on-insulator (SOI) with a footprint of only 2.1 × 2.2 μm^2. A sharp bend made of pixelated metamaterials is designed using a genetic algorithm, with the pixels being 100 nm by 100 nm. The material properties are binary, either silicon or silicon dioxide. As

schematically illustrated in Figure 1 (a), where turquoise pixels denote silicon dioxide cells, and the red area represents unetched silicon. These elements have been chosen after taking into account the feasibility of our electron beam lithography and dry etching processes. The metamaterial-assisted bends in Figure 1(a) have been optimized for 2.1 μm corrugation width, but they can also withstand narrower corrugations. Despite its ultra-compact design, the insertion loss is approximately -1.25 dB and tend to decrease when utilizing large footprints. Also, there exists no compromise of the high bandwidth characteristics of the 1D grating waveguide. The frequency response reveals that it can support ultra-wide-band operations over a 55 nm bandwidth range. (Ref. [7] contains the details and results of the 1D grating waveguide.) The fabrication process is still in progress, and the measurement results of the fabricated structure will be presented at the conference.

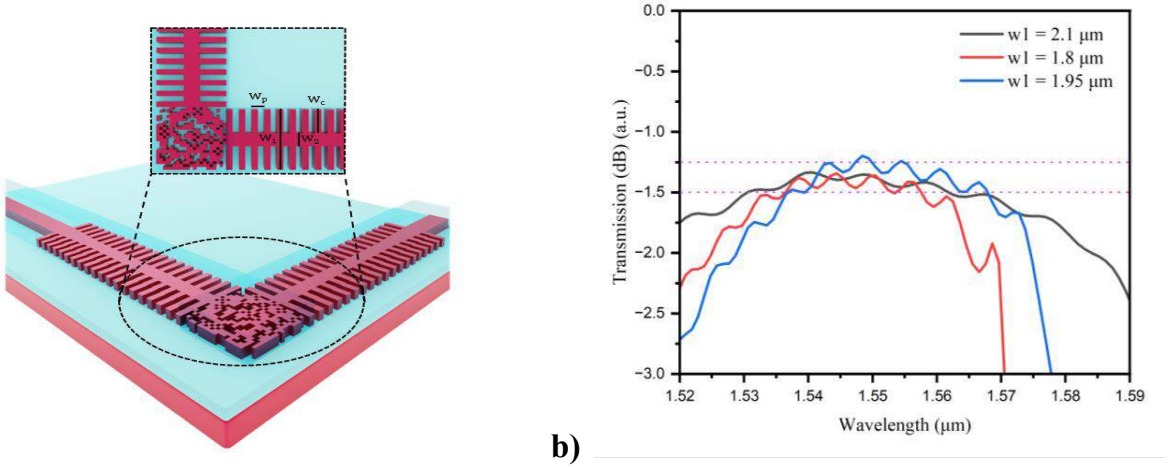

Figure 1. a) Schematic of ultra-sharp bend in the 1D grating waveguide and illustration of design parameters on the structure, **b)** The frequency response of the metamaterial-assisted bend structure, using 2.1, 1.8, and 1.95 μm corrugated grating configurations.

Metamaterial-Assisted Power Division: An Inverse Design Study in 1D Grating Waveguides

A. O. Sakin[1], B. Akcay[1], H. A. Gunes[1], A. C. Songur[1], and M. Unlu[1*]

[1] Dept. of Electrical and Electronics Engineering, TOBB University of Economics and Technology, 06510 Ankara, Turkey

Abstract: Power dividers are vital components playing a crucial role in facilitating signal merging, routing, and division to ensure the efficient functioning of multi-channel systems in photonic integrated circuits. However, the use of bulky power splitters can occupy a significant amount of space on the chip. Therefore, we propose the utilization of a metamaterial-assisted ultra-low-loss T junction power divider, which integrates an input and two output grating waveguides, with a size of just 2.1 × 2.1 μm^2.

Silicon photonic integrated circuits (PICs) have the potential to revolutionize high-speed communication, sensing, computing, and quantum technologies through their low power consumption, compatibility with CMOS technology, and broadband capabilities [1]. In recent years, microwave photonic (MWP) devices, a type of PIC application, have seen increasing interest due to their exceptional qualities when compared to traditional microwave technologies, with the high intrinsic bandwidth of optical signals being the primary reason for their superiority. In particular, the true time delay line (TTDL) is an essential component for signal processing in microwave photonics and optical communications, as it can be utilized in various applications such as optical beamforming in phased array antennas, generating arbitrary waveforms, and reconfigurable MWP filters. There are several methods for designing TTDLs, including photonic crystal waveguides, ring resonators, one-dimensional (1D) grating waveguides, and subwavelength grating waveguides. 1D grating waveguides are highly suitable for communication and sensing applications due to their compact design, high bandwidth, and Bloch mode capability to achieve highly localized modes that enhance modulation efficiency through Kerr and Pockels effects [2]. In addition, the compact size of 1D grating waveguides makes them well-suited for multi-channel operations that require precise control over the time delay between multiple optical signals, particularly in applications such as antenna beam steering. Nevertheless, in traditional photonic interconnects, bulky power splitters are often favored to separate the power and direction of channels, whether in vertical or horizontal directions. The utilization of bulky power splitters to separate the power and direction of channels in traditional photonic interconnects, whether in the vertical or horizontal direction, can occupy valuable chip estate, and the dispersion effect of a unit silicon path can cause pulse broadening significantly [3].

Recent studies have shown that utilizing directional couplers with sidewall corrugated subwavelength grating waveguides can split power effectively for broadband add–drop grating waveguide filters [4]. However, power splitting between two 1D grating waveguides in the same path has not yet been demonstrated due to the challenge of achieving a suitable match between the 1D grating waveguide's unique band structure using a splitting structure, particularly in a high group velocity dispersion configuration. To overcome this problem, we present utilizing a metamaterial-assisted T junction power divider that integrates an input and two output grating waveguides on a silicon-on-insulator (SOI) substrate, with a footprint of only 2.1 × 2.1 μm^2. Moreover, the proposed T junction power divider is capable of executing the necessary 90-degree turn for multi-channel photonic interconnections. The design of a metamaterial topology that is both highly symmetric and efficient has

been achieved by optimizing it with a genetic algorithm and utilizing 3D finite difference time domain solutions, on a 2 μm buried oxide layer with a top silicon layer of 220 nm thickness, and 1 μm cladding layer. The silica layer is indicated by the blue portion while the silicon layer is denoted by the white portion, as illustrated in Figure 1(a). By setting the corrugation width of the 1D grating waveguide to 2.1 um, a high group velocity dispersion has been achieved, which has posed a challenge for the design of the splitter. (Further information about the implementation of the 1D grating waveguide can be found in Ref. [5]) The transmission efficiency of the TE polarization state, assuming that the input is also in the TE polarization, is considered the figure of merit (FOM) for our device. The device has been discretized into 21 by 21 square pixels, each with a size of 100 nm by 100 nm. With a per-channel insertion loss of -3.28 dB, the power divider has a total insertion loss of -0.275 dB and is able to support an ultra-high bandwidth ranging from 1,500 to 1,600 nm, as shown in Figure 1(b). The fabrication process is still in progress, and the measurement results of the fabricated structure will be presented at the conference.

Abstract: The use of fishbone-like grating waveguides (FLGWs) in photonic integrated circuits (PICs) presents a challenge in terms of chip space utilization because it requires incorporating conventional, large components. Therefore, we propose the combination of three key elements - a long adiabatic waveguide taper, a power splitter, and a transition region for FLGWs - using digital metamaterials to allow for the effective utilization of FLGWs that are excited by ultrashort pulses in a compact footprint of only 5 × 14.1 μm^2.

Radio-over-fiber (RoF) technology, being the major branch of microwave photonics, provides high bandwidth, low-loss, and long-distance propagation capabilities, enabling a wide range of applications spanning from communications to wireless networks. The employment of ultrashort pulses as the optical carrier results in a further enhancement of the substantial capacity [1]. Moreover, in order to improve the capabilities of RoF systems, it is critical to design on-chip, compact, and high-performance electro-optic modulators (EOMs) and true time delay (TTD) lines excited by ultrashort pulses. Fishbone-like grating waveguides (FLGWs) have become increasingly popular in recent times as they have the potential to deliver a TTD, a broad bandwidth, and the ability to easily adjust the group velocity dispersion characteristic [2-3]. The relationship between the Bloch mode, a form of guided light in FLGWs, and the group velocity dispersion is interdependent and can be adjusted by changing the geometric parameters of the FLGWs [3]. This aspect is beneficial to both EOMs and TTD lines, due to the increased modulation efficiency and delay characteristic that can be achieved through the presence of highly localized modes in FLGWs [3-5]. Nevertheless, the use of FLGWs in photonic integrated circuits (PICs) is challenging from the perspective of chip estate utilization, as it requires the utilization of conventional, bulky components in terms of footprint size like a grating coupler (GC) to strip waveguide taper, power splitter, and transition region before the grating waveguide. As an example, to minimize loss during the transition between the classical GC and strip waveguide, the adiabatic waveguide taper must be at least 120 μm in length [6]. Additionally, the size of other components, such as the power splitter and the transition region of the grating waveguide, occupies a considerable amount of area on the chip.

The ever-increasing demand for higher integration density dictates more compact components. It is important to note that while various miniaturized grating couplers to taper & splitter designs have been proposed in the literature to reduce the footprint size [7-8], no solution has been found to connect an area-efficient grating coupler with FLGWs due to the complex and distinctive nature of its band structure and Bloch mode pattern that makes it challenging to match it with other components. Therefore, we present the merging of three key components - long adiabatic waveguide taper, power splitter, and transition region of FLGWs - by digital metamaterials to enable the efficient use of FLGWs excited by the ultrashort pulse in a compact footprint of only 5 × 14.1 μm^2. Hence, significant progress has been made in compensating for dispersion, specifically with ultrashort pulses, by utilizing a compact structure instead of larger silicon paths. In the study, we opt for larger grating coupler width (14 μm) compared to other studies [7-8] to assess the stability of the digitized metamaterial-based approach under non-optimal conditions. Decreasing the width of the grating coupler can also lead to an easier and more compact design of the structure with improved transmission characteristics. The

optimized design of the structure utilizing digital metamaterials has been accomplished using a genetic algorithm and includes 100 nm x 100 nm cells, which are compatible with the fabrication process. Algorithm decides whether a cell at a predetermined location should be SiO_2 or Si. The differential evolutionary approach of the algorithm creates unintuitive solutions to the determined figure of merit. As shown in Fig. 1 (a), the unified design does the work of 3 different on-chip components. The design is terminated with a fishbone waveguide and fishbone taper to a normal strip waveguide. According to Fig. 1 (b), the bandwidth of the design is greater than 100 nm and the transmission response of each channel is approximately -4.8 dB which is significantly high considering the ultra-compact topology.

Flexible metamaterial microwave absorbers with polymer nanocomposite as substrates

M. Anjali*, Kumaran Rengaswamy, Abhishek Ukey, Lincy Stephen, C. V. Krishnamurthy, and V. Subramanian

Microwave Laboratory, Department of Physics, Indian Institute of Technology Madras, Chennai 600036, India

*Email: anjalim@physics.iitm.ac.in

Abstract: In this work, we have demonstrated metamaterial absorbers operating at 9.88 GHz using novel epoxy/graphene nanoplatelets composites (E-GnP) as substrates. The substrate is systematically studied for different weight percentages of GnP in epoxy, which could result in variation of dielectric constant as well as loss tangent and hence the enhancement of bandwidth. Owing to the flexibility of the substrate, the metamaterial absorber could cater to conformal applications.

Using novel materials in the design of metamaterial microwave absorbers provides a holistic way of device design by leveraging the degrees of freedom in engineering unit cells. Polymer nanocomposites are useful in this regard as there are a variety of options to fabricate materials with desirable mechanical, thermal and dielectric properties depending on the choice of the matrix and filler. The present work involves the realization of flexible metamaterial absorber with epoxy/graphene nanoplatelets polymer composite (E-GnP) as substrates. The X-band dielectric permittivity varied from 3.4 for 1 wt% (E-GnP1) to 14.7 for 9 wt% (E-GnP9) of the composites. The absorption bandwidth of the metamaterial absorbers designed to operate at 9.88 GHz increased from 0.114 GHz for E-GnP1 to 0.350 GHz for the E-GnP9 substrate, owing to an increase in the substrate loss tangent. The user-controllable mechanical and dielectric properties of the E-GnP composites can overcome the constraints of commercial substrates and make them a good choice for designing metamaterial absorbers.

Active metasurface using Ag/ITO nano antenna for visible wavelength

C.-S. Hwang[1*], Y.-H. Kim, J. H. Yang, J. Y. Kim, K. H. Choi, J. Moon, J. H. Choi

[1]Electronics and Telecommunications Research Institute, S. Korea

Abstract: We propose double line nano antenna structure for the purpose of complex modulation in visible wavelength. RCWA simulation results show that the nano antenna with Ag/ITO outperform the stacked structure in that case the modulated active layers are vertically stacked.

We previously suggested the active metasurface for complex modulation in visible wavelength [1]. The structure consists of Al nano antenna and hyperbolic meta material including ITO/Ag multilayers as shown Fig, 1 (a). The carrier concentration of top and bottom ITO layers could be controlled independently to modulate the reflective wave for complex modulation. We suggest novel modification of the structure to enhance the modulation amplitude and to reduce the difficulties in fabrication. The voltage of each line of the antenna in Fig. 1 (b) and (c) could be controlled independently for the complex modulation. We found that the structure consists of double line of Ag nano antenna combined with patterned ITO layers (Fig. 1 (c)) results in better result compared with the structure consists of double Al nano antenna with un-patterned Ag layers. The performance of the structure, the modulated area in complex reflectance plane, was tested using RCWA simulation with the randomly distributed structure parameters [2]. As shown in Fig. 2, the performance of double line structure with Al nano antenna (double line type-1) was inferior to the single line structure, but the modified double line structure with Ag/ITO nano antenna (double line type-2) showed better performance.

Another merit of the novel structure is that the coupling with dielectric environment could be enhanced due to the strong local electrical field formed near the modulated region as shown in Fig. 3. The LC-coupled metasurface can be the example of the possible application with the double line metasurface [3].

Abstract: The COVID-19 pandemic increased the need for accurate and rapid detection of biomolecules, leading to the development of immunoassay-based biosensors. While label-binding can be time-consuming and costly, Label-free and highly sensitive biosensors using Mid-IR molecular fingerprint have been explored. Surface-Enhanced Infrared Absorption spectroscopy has emerged to enhance and measure vibrational modes in small amounts of analyte, and a metamaterial absorber was developed to increase the sensing area and enhance the SEIRA signal. SEIRA spectroscopy has the potential for biosensing device.

Due to the COVID-19 pandemic, there is a growing demand for the detection of biomolecules to identify infected individuals, particularly in high-risk areas like airports and medical facilities. It is crucial to detect biomolecules accurately and quickly to prevent the spread of infectious diseases. As a result, there is a rising interest in the development of immunoassay-based biosensors that utilize the antigen-antibody reaction for fast and precise biomolecule detection. The immunoassay approach allows for the identification and quantification of analytes using fluorescence or color change, with additional signal amplification through the binding of a label with an enzyme linked to the analyte. However, this label-binding process can be time-consuming and expensive, leading to the exploration of label-free and highly sensitive immunoassay-based biosensors. Label-free biomolecule sensing can be achieved through Mid-IR molecular fingerprint, which involves measuring the vibrational modes of different molecules, including biomolecules. These molecules have unique vibrational modes that can be used to determine specific molecular structures using spectroscopy.

Traditionally, molecular vibrational modes have been measured using spectroscopy with increasing interaction optical path as described by the Beer-Lambert law. However, this approach faces challenges in detecting small amounts of analyte in thin films due to the small scattering cross-section. To overcome this limitation, Surface-Enhanced Infrared Absorption (SEIRA) spectroscopy has been developed to enhance and measure vibrational modes in extremely small amounts of analyte. This technique involves analyzing the strongly coupled far-field spectra between the near-field generated by Localized Surface Plasmon Resonance (LSPR) and the vibrational mode of the analyte to identify and quantitatively measure the analyte. By spatially and spectrally overlapping the near-field and the vibrational modes of the analytes, the signal extracted from the spectrum can be enhanced. In this study, a metamaterial absorber (MA) was fabricated as a plasmonic resonance cavity with a vertical nanogap, and isotropic dry etching was performed to enhance the near-field generated by LSPR and increase the surface sensing area, thereby enhancing the SEIRA signal.[1] Using these biosensors, small amounts of biomolecules can be rapidly and accurately measured. As a result, SEIRA spectroscopy holds potential to become an important sensing device for preparing for future pandemics.

[Fig.1] (a) The schematic of antibody-antigen combined with MA. (b) SEM Image of MA fabricated by nano-imprint lithography. (c) The simulated near-field profile of undercut MA at resonance wavelength. (d) The spectrum of the undercut MA, SAM coated MA, antibody incubated MA, antibody-antigen incubated MA.

The immunoassay process involves combining the plasmonic MA structure with antibody-antigen for biomolecule detection. The schematic of the immunoassay process with Surface-Enhanced Infrared Absorption (SEIRA) is shown in Fig.1(a), while Fig.1(b) shows the scanning electron microscopy (SEM) image of the fabricated MA structure, and Fig.1(c) shows the simulated near-field distribution of the MA. The study increased the near-field enhancement and enlarged the sensing area by using MA fabricated through isotropic dry etching to undercut the spacer layer of the metal-insulator-metal structure. The SEIRA signal was confirmed by measuring the corona virus antibody and antigen with a peak splitting of 0.343μm. The concentration of antigen relates to the number of interacting molecules, and the peak splitting relates to the number of interacting molecules and effective mode volume. [2]

Metasurface Augmented Camera for General Optical Metrology Applications

A. Burguete-Lopez[1*], M. Makarenko[1], Q. Wang[1] , F. Getman[1] A. Fratalocchi[1]

[1]PRIMALIGHT, Faculty of Electrical Engineering; Applied Mathematics and Computational Science,

Abstract: We present a general optical metrology platform that employs an information processing metasurface as the means for the measurement of observables. The approach, consisting of combining an information processing metasurface with an off-the-shelf CMOS sensor, permits rapid characterization of the properties of materials in a cost-effective and mass-producible package. We present initial results on the fabrication of a prototype of this system.

The technology of metasurfaces has attracted great interest over the past decade, with numerous works showing that optical elements such as lenses [1], polarizers [2], filters [3] and holograms [4] can be realized in highly integrated and compact sheets. More recent works in the field have begun exploring the realization of metasurface based instruments, with demonstrations of metasurface chains for spectroscopy [5], [6], orbital angular momentum measurement [7] and Bell states measurements [8]. As metasurface based instrumentation is an emerging field, existing works have focused on the design of devices for highly specific tasks, with little work available on the development of general purpose devices.

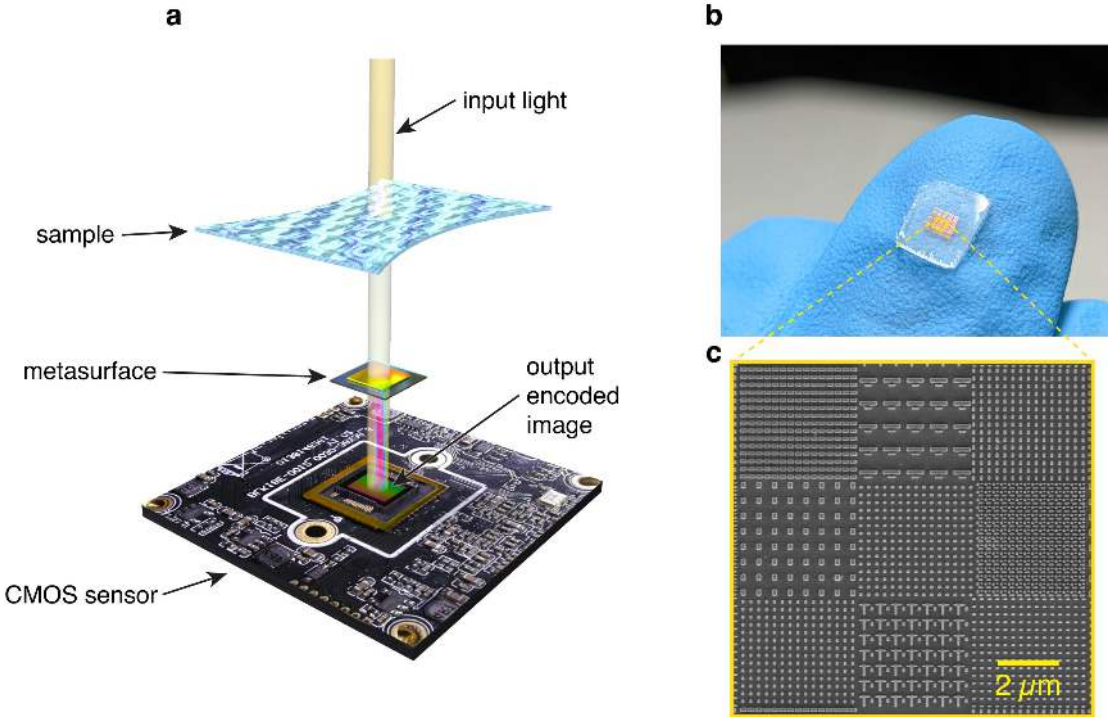

Figure 1: **Metrology system**. **a** An input light beam passes through a sample and propagates carrying information about the interaction. A suitably designed metasurface extracts this information, converting it to an encoded image that a CMOS sensor reads. **b** Photograph of fabricated information extracting metasurface. **c** scanning electron microscope image showing the structure of encoder arrays that conform the information processing metasurface.

In this work we aim to address this gap by introducing a general purpose metasurface based instrument for optical metrology. Figure 1a illustrates the concept. Light that interacts with a material, either through transmission or reflection, becomes a medium that carries information on the physical properties of the material. This information, encoded as amplitude, phase and polarization variations in the beam, can be extracted through the use of a suitably engineered metasurface sensitive to these changes. We design such metasurfaces following a data driven approach. Making use of an inverse design software that can

obtain designs for arbitrarily defined input-output optical responses. The metasurface converts the information encoded in the light beam into an intensity pattern, which is then read by a standard CMOS sensor as an encoded image.

Figure 1b presents a photograph of a prototype metasurface and fig. 1c a scanning electron microscope closeup of the metasurface structure. The design consists of a an array of nine patterns that repeats across the substrate area. These patterns are engineered to translate the information encoded in an input beam to amplitude signals. The metasurface is placed on the CMOS sensor in such a way that each of these patterns covers a sensor pixel, in a manner analogous to the Bayer array of color cameras.

Attribute of attenuation band in smart negative indexed mechanical metamaterials

Ankur Dwivedi[1*] and S. A. R. Horsley[1]

[1]University of Exeter, United Kingdom
[*]corresponding author: A.Dwivedi@exeter.ac.uk

Abstract: Unique tailored geometry and pattern of engineered mechanical metamaterials are essential to accomplish unusual properties which are seldom observed in natural materials. Here we study the characteristic of the attenuation band in smart mechanical metamaterial having negative stiffness and mass properties. We derive critical physical parameters, which are essential in the formation of locally resonant attenuation band. We found the higher attenuation (HA1) region in the attenuation band has different attributes in case of negative stiffness and mass metamaterials.

Elastic mechanical metamaterials are the exemplars of periodic structures that exhibit interesting frequency-dependent properties like negative Young's modulus and negative mass in a certain frequency band due to emergence of local resonance. The structural arrangement of the individual unit-cells define the property of the material system and material property of the base material has little influence. Their precise shape, geometry, size, orientation, contact property and arrangement gives them their properties capable of manipulating acoustic waves by blocking, absorbing, enhancing, bending waves, to achieve objectives that are unrealizable with conventional materials. Embedding of the piezoelectric material empowers such systema to harvest the vibrational energy effectively along with simultaneously vibration attenuation. Based on the interesting physical properties exhibited by the mechanical metamaterials, they can be categorized as negative mass [1], negative stiffness [2], and other combinations also as shown in Figure 1.

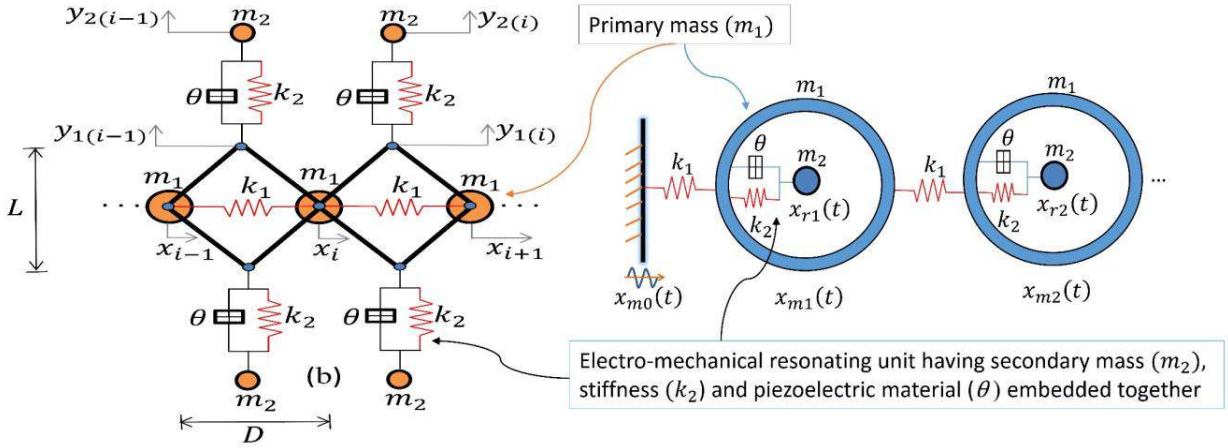

Figure 1: Piezo-embedded negative stiffness metamaterial (left), where a series of primary masses (m_1) attach to each other by springs and rocker mechanism (four rigid massless bars with friction revolute joints such that nodes connecting the primary masses traverse only horizontally). Piezo-embedded negative mass metamaterial (right), a mass-in-mass system where inside the primary mass (m_1) a resonating mass (m_2), is present. A piezoelectric material having an electromechanical coupling coefficient (θ) is embedded in the electromechanical resonating units in both metamaterials.

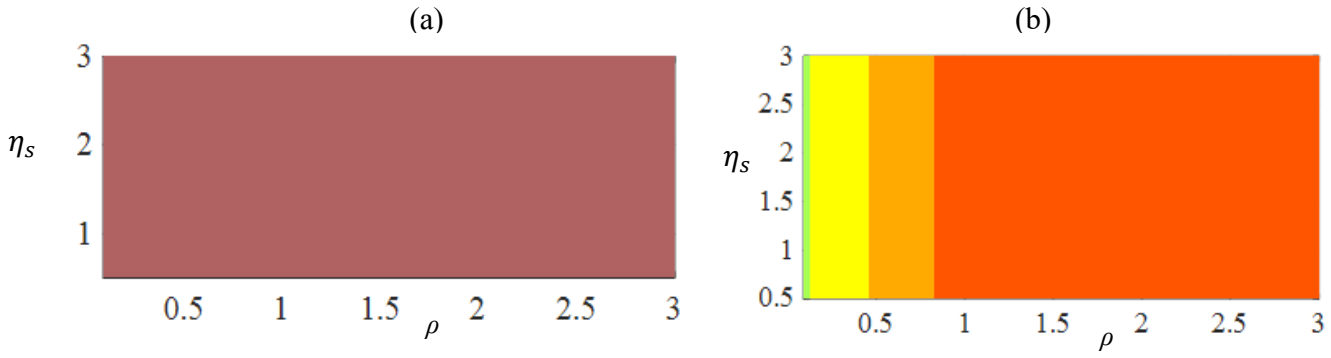

Figure: Contour plots for HA1, piezo-embedded negative (a) stiffness and (b) mass metamaterial for a set of value of capacitive parameter (c) and resistive parameter (r) in non-dimensional frequency domain (η_2).

The dynamics of piezo-embedded mechanical metamaterials gives the dispersion relationship which can be deduced by Bloch's formulation [3,4] and gives physical parameters stated in Eqn. (1).

$$\eta_s = \frac{\omega_2}{\omega_1}, \rho = \frac{m_2}{m_1}, c = \frac{\theta^2}{k_2 C^p}, r = \frac{R\omega_2\theta^2}{k_2} \tag{1}$$

where, ω = (k/m)$^{0.5}$ is natural frequency, R is resistance attached in the energy harvesting circuit and C_P is the capacitance of piezoelectric material.

We found for the negative stiffness metamaterial HA1 is independent of mass ratio (ρ) and structural frequency ratio (η_s), it depends only on the non-dimensional capacitive (c) and resistive parameter (r),whereas in case of negative mass metamaterial HA1 is constant for range of value of (ρ). Therefore, this investigation can suggest insight about identifying critical physical parameters and their range for optimal vibration attenuation and energy harvesting. It will be useful while designing the smart negative indexed mechanical metamaterials integrated with the piezoelectric material.

Scanning Reflectance Anisotropy Microscopy: strain mapping of metasurfaces and beyond.

Fabian Haake[1*]
Joan Sendra[1]
Henning Galinski[1]
Ralph Spolenak[1]

[1]Author: Department of Materials ETH Zurich, Switzerland
[*]Corresponding author: fabian.haake@mat.ethz.ch

Abstract: Elastic deformation of materials leads to breaking of the lattice symmetry. One consequence of the deformation is the emergence of optical anisotropy. However, the capabilities to map local strain fields by optical microscopy are currently limited. Here, we introduce a broadband reflectance anisotropy microscope as a phase-sensitive optical platform for the sensing of elastic strain in materials. We demonstrate non-destructive mechanical characterization of strained metasurfaces, which can serve as strain markers, and amorphous dielectric photonic-like crystals.

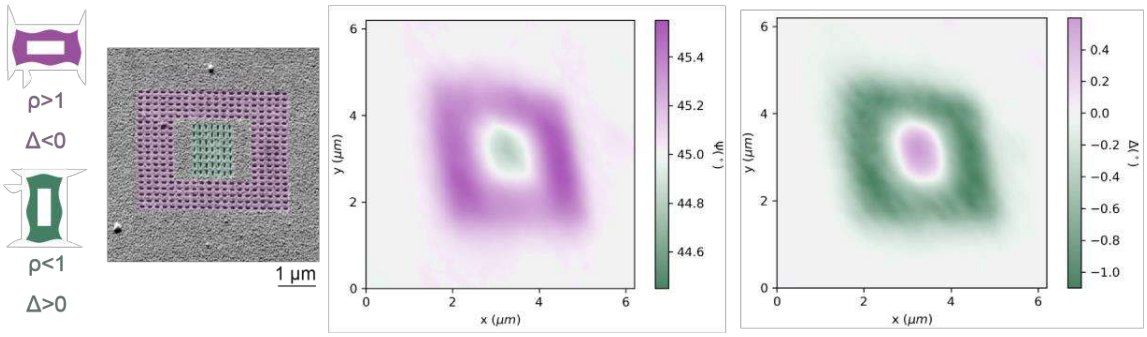

Figure 1: SEM image and SRAM measurements of a metasurface composed of dipolar slot antennas showcasing the sensitivity of the setup to the ellipsometric properties (phase Δ and amplitude Ψ) of the sample.[1]

Figure 1 shows a metasurface of nanoslot antennas (width: 100 nm height: 50 nm) that were milled with FIB in a 100 nm thick template stripped gold surface on polycarbonate. The SRAM measurements were carried out at the resonance frequency of the nanoslot array of 2.39 eV. These maps show the high phase sensitivity of SRAM at diffraction-limited resolution.[1]

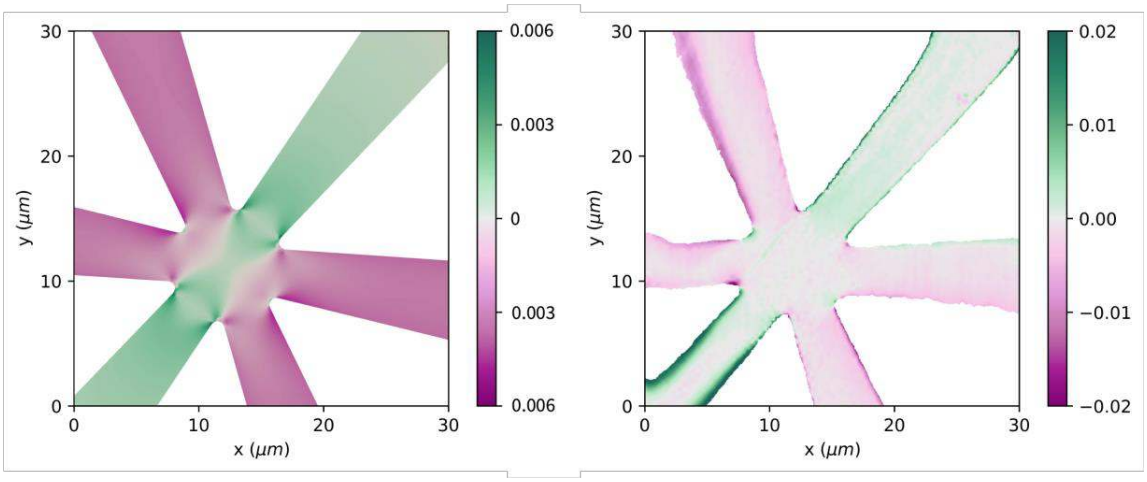

Figure 2: Simulated strain distribution ε_{xx}-ε_{yy} and measured SRAM map of an uniaxially strained photonic crystal-like structure.

Figure 2 shows the simulated strain distribution and measured SRAM map of a photonic crystal-like structure in a 500 nm thick amorphous germanium layer on Kapton. This structure consists of 6 concentrically aligned wedges that were milled with a FIB. A tensile stage introduces anisotropy between two wedges with a total strain of 0.2%. As shown the technique is able measure the local strain field distribution and can therefore be used for the optical characterization of large photonic crystals.

Line modes in elastic mechanical metamaterials

Ankur Dwivedi[1*] and S. A. R. Horsley[1]

[1]University of Exeter, United Kingdom
[*]corresponding author: A.Dwivedi@exeter.ac.uk

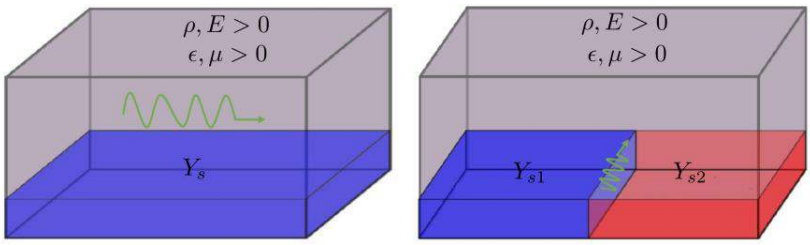
Abstract: The one dimensional analogue of surface modes - line modes - have been recently found in electromagnetic materials, existing at the interface between surfaces of positive and negative reactance. Here we consider the mechanical analogue of line modes. Analytically we find they exist at the interface between two surfaces respectively pinned in vertical and in-plane directions, and we examine the conditions for their existence using the finite element method, tuning the line mode eigenfrequencies by varying the density and elastic moduli of the materials.

Elastic surface waves (SWs) bound to a planar interface can take the form of Rayleigh waves when the surface is traction free. Analogously, electromagnetic (EM) waves at a free-space interface take either the form of a surface plasmon, or a surface magneto-plasmon, depending on the sign of the surface reactance. It was recently found that EM surface waves could be further confined to propagate in only one-dimension (as "line waves") with a metasurface containing an interface between regions where the reactance has opposite sign [1, 2] (see Fig. 1). In this work we investigate the existence and properties of line waves on mechanical metasurfaces (in contrast to the sub-wavelength guiding structures of [3, 4])

We define the elastic surface reactance Y at an interface via $\sigma.n = Y.u$, where $n.\sigma$ is the normal stress, and u is the displacement. It is not straightforward to directly translate results from EM to elastic waves, due to the absence of longitudinal EM waves. We first give a simple case where we can analytically demonstrate the existence of elastic line modes. As shown in [2], the interface between a PEC ($\boldsymbol{E}$ field normal to surface) and PMC ($\boldsymbol{E}$ field parallel to surface) supports an EM line wave. Assuming a pure shear wave in a bulk elastic medium, which obeys (ρ is mass density, G is the shear modulus, and ω is angular natural frequency)

$$\nabla^2 u_T + \frac{\rho\omega^2}{G} u_T = 0 \qquad (1)$$

we can see that the boundary conditions $n.u = 0$ and $n \times u = 0$ are exactly equivalent to PEC and PMC conditions respectively. Therefore, as described in [2] these boundary conditions must support a line wave of the form $u_x = K_{1/2}(\kappa r)cos(\theta/2)exp(ik_z z)$, where $K_{1/2}$ is a modified Bessel function.



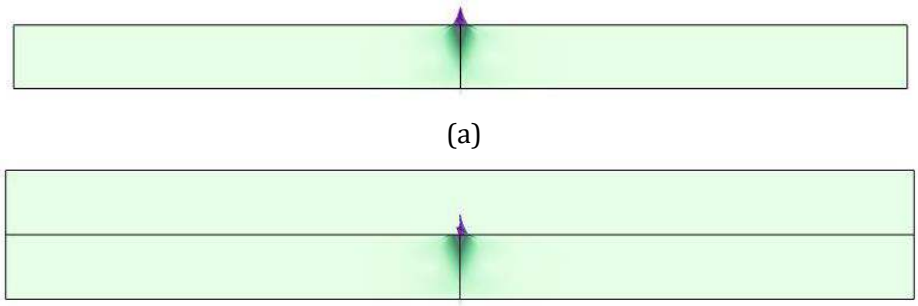


Figure 1: Both EM and elastic surface waves (SWs) can be seen (left) on an interface, with the properties of the SW depending on the surface admittance Y_s. The SWs turns to line wave (LW) at an interface between

surfaces of differing admittance.

We have further developed our understanding of elastic line modes via numerical simulations, varying both material parameters and boundary conditions. In Fig. 2 we show two examples where these modes are evident. we have taken fixed wave propagation constants $k_z > \sqrt{\rho\,\omega^2/G}$ along the z-axis and applied a fixed boundary condition along the edges of the simulation, mimicking the surface impedance conditions (1) with bulk media. We used an eigenmode analysis to solve for the frequency ω in a 2D model in COMSOL Multiphysics.

(a)

(b)

Figure 2: Eigenmodes shown for (a) two positive density materials with equal magnitude elastic modulus, but opposite sign. (b) three materials with upper material having positive density and elastic modulus. Lower two materials also have positive mass density but equal and opposite elastic modulus.

Abstract: Two-dimensional magnonic crystals (2D MCs) for forward volume spin waves were demonstrated using yttrium iron garnets (YIG) and copper disks. The 2D MCs with hexagonal lattice were fabricated on a 13 μm thick YIG on a gadolinium gallium garnet substrate by using photolithography and the wet etching and lift-off method. A bandgap was observed in a measured transmission spectrum. The frequency of the bandgap and the propagation band of spin waves were in good agreement with a calculation result.

Electronic devices have achieved high performance through miniaturization and high integration, but the growth rate of device performance is slowing down as the integration density approaches the physical limit. This is a problem arising from the principle of electronic devices that transmit information by transferring electric charges. For this reason, spin wave devices using phase waves created by magnetic moments are being developed as the next generation of information processing devices because of no charge transfer and functions utilizing the phase interference phenomenon. Recently, NAND devices based on spin wave interference have been demonstrated[1], and nano- and micro-scale integration technologies are being developed for chipping spin wave devices[2]. However, the technology to wire spin waves, like electrical wiring in electronic circuits, has not been established. Therefore, we have focused on magnonic crystals (MCs), in which the flow of spin waves can be controlled by using a periodic magnetic structure. MCs can be used to filter, confinement, and phase modulation for spin waves. These functions of MCs are essential for the development of spin wave integrated circuits, including logic gates. In these applications, the forward volume spin wave (FVSW) is suitable because of its in-plane isotropy. In addition, the waveguide comprising yttrium iron garnet (YIG) is useful because of the long propagation length of spin waves. One-dimensional (1D) MCs with a periodic magnetic structure have already been demonstrated as a configuration that can be chipped in principle, and the appearance of a bandgap has been observed[3]. However, two-dimensional (2D) MCs showing bandgaps for all directions in a plane need to be demonstrated to realize control of spin wave propagation in two dimensions. Hence, in this work, 2D MCs were fabricated using YIG, and non-magnetic metals and spin wave transmission spectra were measured.

First, 2D MCs were designed using a three-dimensional electromagnetic simulator (Dassault Systems, Simulia CST studio suite 2022) based on the finite integration technique. It was used because of its good agreement with experimental results in previous studies[2, 3]. The simulation model consists of a substrate with two microstrip lines (MSLs) and a YIG film placed on top of the MSLs. The substrate consists of a 170 mm × 170 mm × 0.6 mm glass epoxy (FR4) with an 18-μm thick Cu signal line (SL) on the top surface of FR4 and an 18-μm thick Cu ground plane on the bottom surface of FR4. The YIG is a 15 mm × 15 mm × 10 μm film. Cu disks with a diameter of 300 μm and a thickness of 1 μm were periodically located on the surface of the YIG between two SLs. A configuration type of 2D MC was a hexagonal lattice with a lattice constant of 450 μm.

30-nm thick Au films were located on one side of SLs to depress reflected spin waves from the edge of the YIG film[4]. The transmission spectra were calculated when the incident angles of the spin waves to the 2D MCs were varied by rotating the 2D MCs. The incident angle was varied from 0 to 30 degrees in a step of 5 degrees. Band gaps which were low transmission bands, were observed in the range of 10 to 30 degrees. And a frequency of the band gaps shifted to the lower frequency as the incident angle increased. At a frequency of 1.80 GHz, the band gaps were generated in the range of 10 to 30 degrees.

Based on the above calculation, 2D MC samples were fabricated on a 13 μm thick YIG on a gadolinium gallium garnet substrate by wet etching and lift-off method using photolithography. And a measurement system the same as the simulation model was constructed. The transmission spectra were measured using a vector network analyzer while applying a biased magnetic field perpendicular to the YIG film. A bandgap was observed in the measured transmission spectrum. The frequency of the bandgap and the propagation band of spin waves were in good agreement with the calculation result. From these results, 2D MC using YIG and non-magnetic metals was demonstrated.

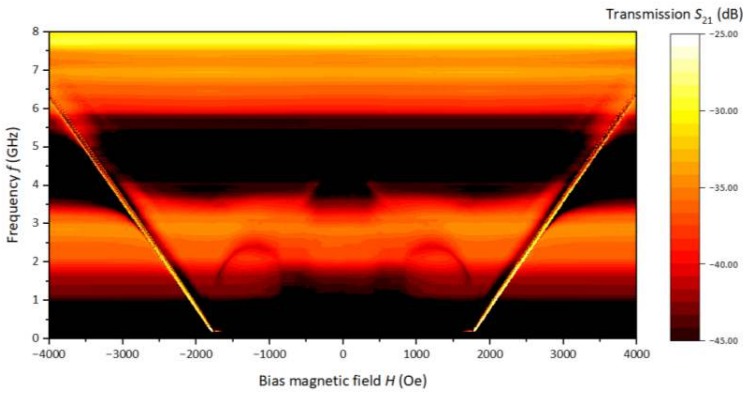

Figure 1. Measured spin wave spectroscopy when the incident angle was 5 degrees.

Abstract: The physics of time-varying media as a means of wave manipulation has resulted in the demonstration of several novel phenomena such as magnetic-free non-reciprocity, photonic time crystals, etc., to name a few. Here, we numerically demonstrate the excitation of BIC in a silicon metasurface without breaking the symmetry of the structure. By sinusoidally modulating the refractive index in time, using experimentally realizable parameters, we show the excitation, dynamic tuning, and restoration of BIC in mid-IR.

Introduction

Bound states in the continuum (BIC) are non-radiating localised waves coexisting within a continuum of propagating waves [1, 2]. Unlike a resonant state, a BIC cannot be excited using plane waves coming from infinity, i.e. BICs are dark states with infinite radiative lifetimes [3, 4]. Recently, there has been a growing interest in realizing an open cavity supporting a BIC that is accessible to broadband light for perpetual optical storage [5-7].

Here, we numerically demonstrate the excitation of BIC using an external broadband light source, in mid-IR, without breaking the structural symmetry. We perturb the BIC mode by modulating the refractive index of a silicon metasurface in time, using experimentally realisable modulation frequencies. The BIC can be dynamically tuned by changing the modulation frequency and hence can be used for optical trapping, sensing, etc.

Simulation and Results

The proposed structure consists of a 1 μm thick, two-dimensional silicon metasurface on a glass substrate ($\varepsilon_{SiO2} = 1.45$), as shown in fig. 1a. A unit cell of the metasurface consists of cylindrical nanoholes of diameter and height of 1 μm and an inter-cell periodicity of P_x and P_y in the x−, and y− directions, respectively. The structure is embedded in SiO_2 to provide a homogeneous environment. The permittivity of silicon is assumed to be dispersionless and taken to be $\varepsilon_{0,Si} = 11.9$ prior to modulation ($t < t_0$). We use the commercial FDTD solver, Lumerical FDTD™, to carry out the numerical study of the structure.

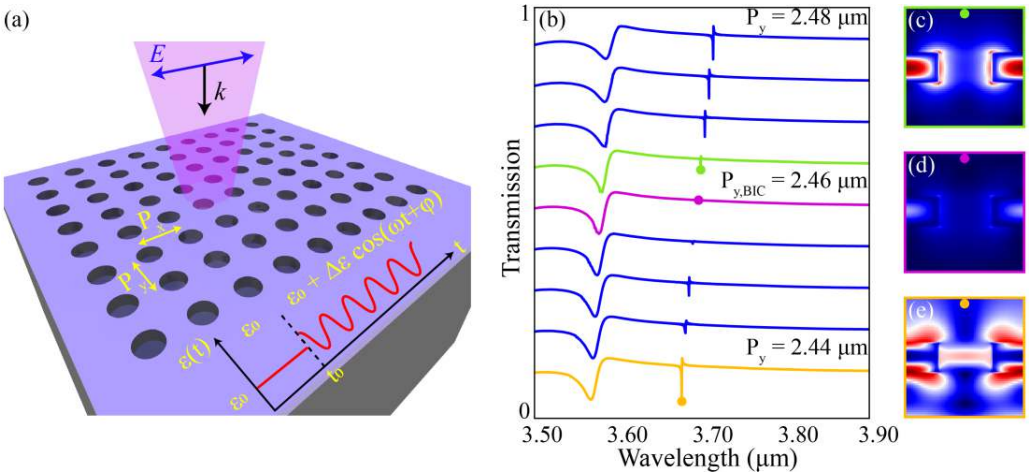

Fig 1: (a) Schematic illustration of 1 μm thick silicon metasurface on a glass substrate. The diameter of a cylindrical nanohole is 1 μm, with a periodicity of P_x and P_y in the respective directions. The scheme for permittivity modulation of silicon is shown in the figure. (b) The transmission spectra calculated for $P_x = 2.20$ μm and P_y varying from 2.44 μm to 2.48 μm. (c-e) Field profiles for (c) $P_y = 2.465$ μm, (d) $P_y = 2.46$ μm and (e) $P_y = 2.44$ μm.

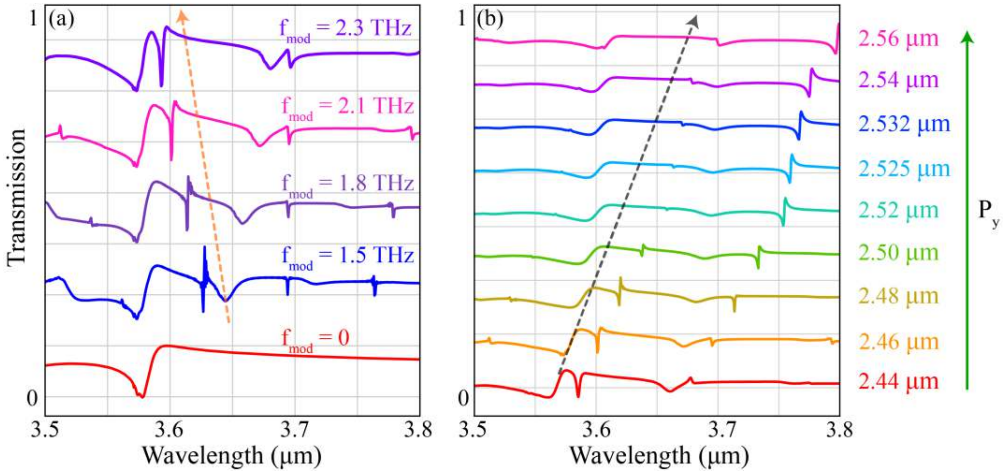

Fig. 2: (a) Transmission spectra as a function of wavelength and modulation frequency for a periodicity of P_x = 2.20 μm and P_y = 2.60 μm, and modulation depth of $\Delta\varepsilon$ = 0.5. (b) Transmission spectra for varying P_y when the metasurface is modulated at f_{mod} = 2.1 THz. The mode restores to BIC on varying P_y (dashed grey), thereby confirming the excitation of quasi-BIC in fig 2a (dashed orange).

The geometric parameters, P_x and P_y, are tuned to achieve the BIC condition. Figure 1b shows the evolution of normalised transmission spectra as a function of wavelength and periodicity P_y, with P_x = 2.20 μm. The incident beam is polarised along the x−direction for normal incidence. The figure shows two resonant transmission dips at wavelengths of 3.57 μm and 3.67 μm for P_y = 2.44 μm, with the dip at lower energy vanishing with increasing P_y. The BIC mode, therefore, occurs for a periodicity of P_x = 2.20 μm and P_y = 2.46 μm. The cross-sectional field profiles for P_y = 2.44 μm, 2.46 μm, and 2.465 μm are shown in Fig. 1c-e, respectively. The fields are highly localised within silicon for periodicities slightly detuned from the BIC (fig. 1c), are extremely leaky for periodicities away from BIC (fig. 1e), and vanish at BIC (fig. 1d).

We now modulate the permittivity of silicon in time with a modulation frequency f_{mod} and modulation depth $\Delta\varepsilon$ such that $\varepsilon_{Si} = \varepsilon_{0,Si} + \Delta\varepsilon \cos(2\pi f_{mod} t + \varphi)$ for $t > t_0$. Figure 2a shows the transmission spectra for modulated metasurface with the following parameters: $\Delta\varepsilon$ = 0.5, f_{mod} = 1.5 THz to 2.3 THz, and φ = 0. Compared to the unmodulated case (red curve), we see signatures of three distinct modes when f_{mod} = 1.5 THz. We focus on the transmission dip at 3.63 μm, which blue-shifts and broadens as f_{mod} increases. This dip corresponds to the perturbation of BIC and its subsequent conversion to a quasi-BIC mode. To verify that the excited mode is a quasi-BIC mode, we vary the periodicity P_y at a particular modulation frequency and observe the evolution of the mode. Figure 2b shows the transmission spectra at different periodicities for f_{mod} = 2.1 THz. As the periodicity increases, the mode at 3.58 μm red-shifts with reduced amplitude, vanishes for a periodicity of 2.52 μm and re-emerges on further increase in P_y. The mode restores to BIC on varying the periodicity, thereby confirming that the modulation resulted in excitation of a quasi-BIC mode.

In conclusion, we have demonstrated the coupling of BIC mode to external radiation by temporally modulating the refractive index of a silicon metasurface. The Q-factor of the mode can be controlled by varying the modulation frequency, and hence can be used for sensing, optical storage, etc.

Abstract: We propose a 3D lattice design (assembly of beams) that uses an optimization routine to generate forbidden frequency bands for all types of mechanical waves. The optimization step is performed using the Spectral Element Method (SEM) with a genetic algorithm. A specific example demonstrates the evolution of the unit cell structure over generations, resulting in a complete (relative to all wave polarizations) band gap opening. To verify the bandgap efficiency, wave propagation in an 8-unit cell periodic network is computed.

I. INTRODUCTION

Phononic crystals have demonstrated the effectiveness of Bragg or resonant band gaps in filtering, guiding, and manipulating acoustic waves [1]. Just like phononic crystals, lattice structures can be designed periodically to produce stopbands while ensuring good static rigidity [2]. A design study [3] showed that proper tuning of a 1D unit cell allows for the design of absolute bandgaps (i.e., relative to all mechanical wave polarizations). In this presentation, we propose the design of a 3D lattice unit cell modeled with SEM coupled with a genetic algorithm that searches for the optimal set of interconnected beams that opens the largest forbidden frequency band.

II. METHODOLOGY

We model the propagation of elastic waves in a set of interconnected beams using a semi-analytical computational algorithm called the Spectral Element Method (SEM). This algorithm provides exact theoretical frequency domain solutions and is faster than the finite element method, making it ideal for computing a wide variety of configurations [4]. The optimization is performed using a genetic algorithm. The cost function to be minimized is defined as the inverse of the frequency value of the largest bandgap calculated within the studied frequency range. The genes are linked to the ability to reshape the existing beams or add new ones.

III. RESULTS AND DISCUSSIONS

Figure 1 presents an optimization example. The first row shows the initial structure consisting of two beams on each side of the propagation axis. The flexural resonance of the lateral beams affects the propagation of torsional and bending waves, significantly reducing the structure's stiffness and thus the wave speed. We run the genetic algorithm for 14 iterations. After the fifth generation (second row in Fig. 1), the structure adopts a spring shape in the x direction, resulting in a significant drop in compressional (red dots) rigidity. The optimization lowers the propagation speed of compression waves, leading to the appearance of a complete forbidden frequency band. After 14 iterations (third row in Fig. 1), the structure remains similar to that of the 5th iteration, but the bandgap is significantly broader.

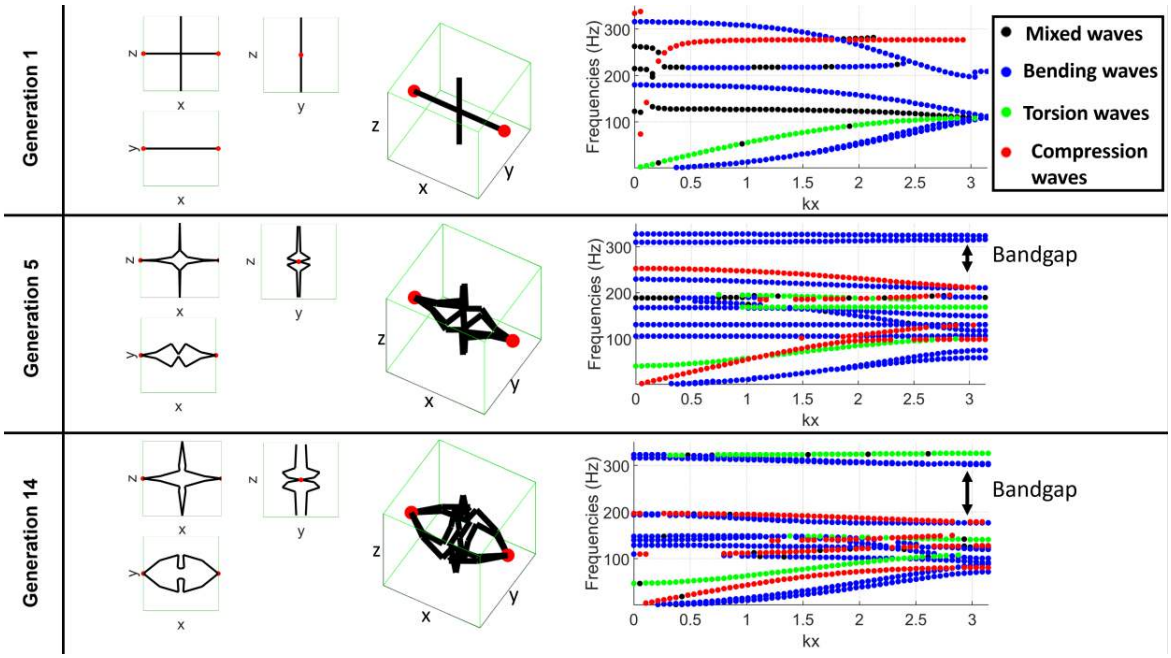

Fig. 1. The results of a genetic algorithm used to optimize a 3D structure composed of interconnected beams to maximize the stopband in a 1D periodic network are displayed on three lines, representing generations 1, 5, and 14 of the algorithm. On each line, the left side shows the different views of the unit cells selected at each generation. The right side of each line presents the dispersion diagrams associated with the unit cells computed with SEM. Each point on the diagram is colored according to the type of wave propagating in the network: compression waves are represented in red, torsion waves in green, bending waves in blue, and mixed waves in black.

IV. CONCLUSION

We have established a method that uses a genetic algorithm to modulate beam network structures to achieve forbidden frequency bands for all types of mechanical waves. The modeling was carried out semi-analytically using the Spectral Element Method (SEM), which allowed for faster computation than finite element methods. The presented optimization example shows the effectiveness of this method in achieving an absolute vibration filter and understanding how the structure evolves to control the propagation of mechanical waves within its periodic network. With the rise of additive manufacturing, this work will be extended to periodic networks that allow for multi-directional propagation of mechanical waves, with the goal of fabricating 3D-printed structural components that act as absolute vibration filters.

Numerical method for the inverse design of three-component metamaterial multilayers

T. Terao[1*]

[1]Department of Electrical, Electronic and Computer Engineering, Gifu university, Japan
[*]corresponding author: terao@gifu-u.ac.jp

Abstract: A numerical method for inverse design of three-component metamaterial multilayers was developed. Restart-tempering method was applied to optimize optical properties for three-component metamaterials multilayers. An algorithm suitable for accurately calculating the effective refractive index of these metamaterial multilayers was also demonstrated**.**

The design of metamaterials with arbitrary refractive indices is an important issue for the further practical development of metamaterial composites, and is useful for the creation of negative-refractive-index materials (NIMs) and epsilon-near-zero materials. In addition, it is also desirable to search for materials with the smallest possible imaginary part of the refractive index, as previously proposed metamaterial materials (especially in the optical domain) often have very strong optical absorption in the frequency region of interest. In my previous study,[1] I have proposed an original method called "restart tempering method", which is suitable for the inverse design of metamaterial multilayers consisting of two different types of layers with different dielectric constants and magnetic permeabilities. In this study, we discuss an inverse design method for a three-layer metamaterial multilayer film consisting of two different positive refractive index materials (PIMs) and a thin layer of PIMs or metals, in order to increase the degree of freedom in designing metamaterial composite materials (Figure 1).

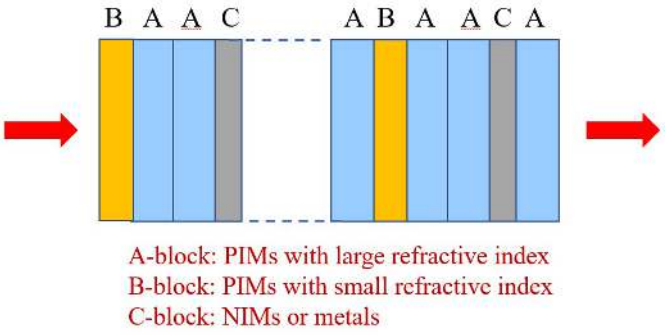

Figure 1. Metamaterial multilayers with three different components

Several attempts have been made to determine the (effective) complex refractive index n of the entire multilayer from the transmission coefficient t and reflection coefficient r of the multilayer. Experimental methods exist to determine the refractive index of a thin film, such as ellipsometry. In the case of conventional experimental refractive index measurement methods, the interior of the thin film is formulated as a homogeneous medium, but this is not strictly the same problem for metamaterial multilayers such as the present one, since the interior is not homogeneous. From the standpoint of numerical analysis, the method proposed by Ref. 2 is well known as a representative method. However, in this method, the complex refractive index is determined by inverse trigonometric functions which are multivalued functions. Therefore, there is a problem that the real part

of the refractive index is not uniquely determined, and no mathematical formula is given to give an integer that specifies the true solution from an infinite number of sequences. In addition, it is of interest to clarify whether the effective refractive index estimated for a metamaterial multilayer is transferable with respect to the angle of incidence.

In this study, the downhill simplex method was employed to estimate more accurately the effective refractive index n_{eff} of metamaterial multilayers and corresponding software to address the above problem. The problem of transferability of n_{eff} in multilayers was also numerically verified by comparing the case of perpendicular incidence with that of oblique incidence. In parallel, we extended the restart tempering method,[1] which was developed by our group, to the problem of three-component multilayer systems and applied it to the inverse design of these systems.

The author acknowledges the Supercomputer Center at the University of Tokyo, for the use of their facilities. This work was supported by JSPS KAKENHI Grant Number 20K11848.

Abstract: Polaritons – hybrid light-mater excitations – are very appealing for the confinement of light at the nanoscale. Recently, a particular interest has been focused on thin anisotropic slabs of van der Waals (vdW)[1,2] materials supporting anisotropic polaritons which exhibit ultra-high momenta and strongly directional in-plane[3]. Here we introduce a concept of vdW slabs-based twisted polaritonic crystals (PCs) – lattices with periods comparable to the polariton wavelength rotated with respect to the natural vdW crystal axes – to efficiently excite and control in-plane anisotropic polaritons.

In this work we focus our study on PCs made out of thin biaxial slabs, such as, for instance, hole arrays made directly in the slab[4]. The periodic structure gives rise to Bragg resonances whose properties can be extracted from the polaritonic bandstructure provided by our theory. Such Bragg resonances can be efficiently tuned in frequency by twisting the lattice with respect to the crystallographic axes. We develop a simple theoretical approach to treat the diffraction of light by the twisted PCs and demonstrate its validity for realistic structures (e.g., hole arrays) by comparing analytical results with full-wave electromagnetic simulations. Our results open up a new research area of twisted polaritonic crystals, including those that support nontrivial topological polaritons. PCs may be very attractive for some practical use, such as in tunable sensors or photodetectors in a plethora of possible optical setups.

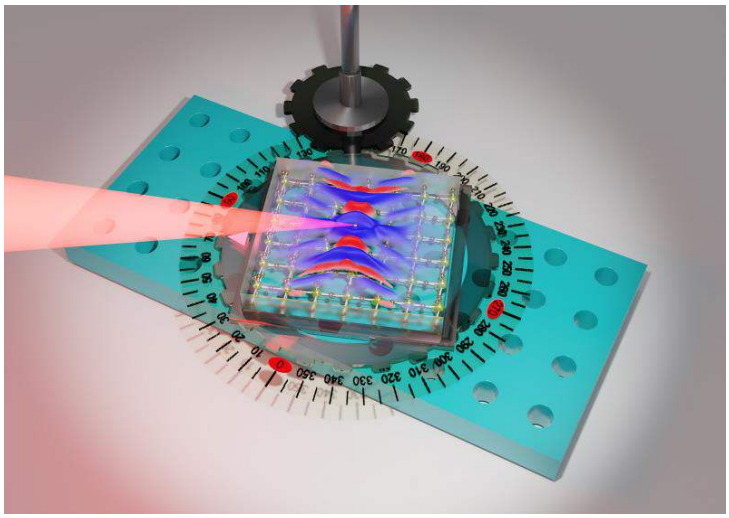

Figure 1: An artistic image of a potential twist-tunable PC structure. The polaritons inside the crystal can be efficiently controlled by twisting the axes of the periodic structure made in the substrate with respect to the natural axes of the anisotropic crystal slab.

Arbitrarily-broadband dispersion compensation with ultrathin multiresonant metasurfaces

Odysseas Tsilipakos[1*] and Thomas Koschny[2]

[1] Theoretical and Physical Chemistry Institute, National Hellenic Research Foundation, GR-11635 Athens, Greece

Abstract: We propose multiresonant metasurfaces exhibiting a broadband and purely quadratic spectral phase to be utilized for dispersion compensation and in general any application requiring temporal pulse shaping of broadband signals. The proposed metasurfaces require implementing a specific combination of Lorentzian resonances in the electric and magnetic surface conductivities. Our approach overcomes the fundamental limitations of both conventional, non-resonant approaches (too bulky) as well as modern, singly-resonant metasurfaces (too narrowband) and aspires to bring broadband dispersion engineering at ultrathin physical scales.

In recent years, metasurfaces (MSs) have been extensively studied for a myriad of applications. However, they have found limited use when it comes to broadband dispersion engineering and the temporal shaping of short pulses. This is because conventional, singly-resonant MSs are inherently narrowband and exhibit a specific spectral phase profile dictated by the resonance dispersion; for a single Lorentzian resonance centered at Ω it is of the form $\varphi(\omega) \propto \mathrm{atan}(\gamma(\omega - \Omega))$. The first example of a broadband, specifically-engineered spectral phase concerned a linear profile (spectrally-constant group delay), utilized to delay broadband pulses without distortion [1] and to perform achromatic wavefront manipulation (e.g., beam focusing and steering) [2,3]. However, a wider class of important applications requires a quadratic phase profile (linear group delay), namely, dispersion compensation, chirped pulse amplification, and more generally any application requiring control over the instantaneous frequency (chirp) and temporal duration of a broadband pulse through pulse chirping/de-chirping.

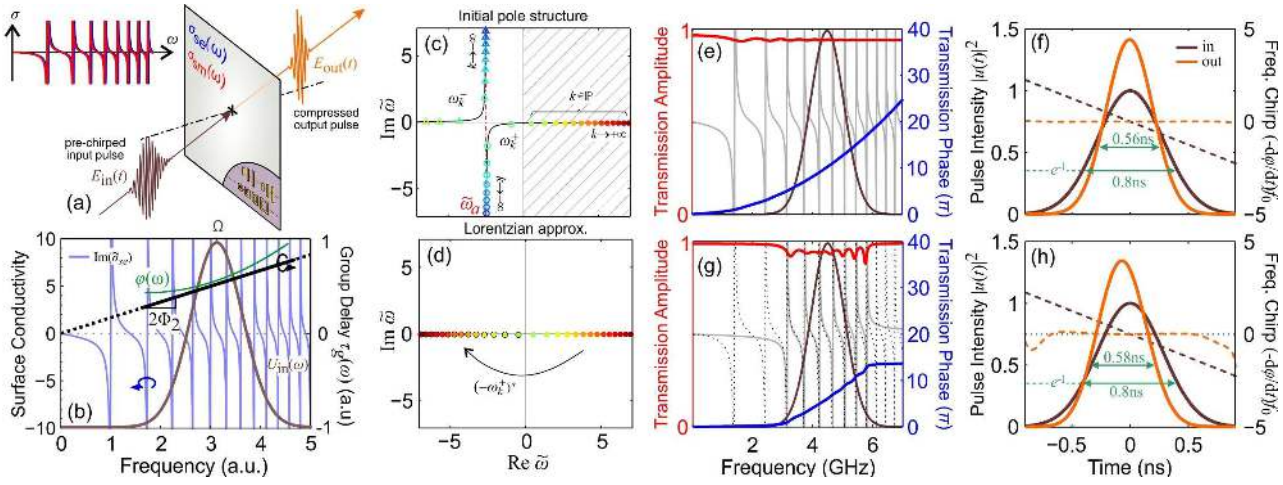

Figure 1: (a) Multiresonant metasurface with overlapping electric and magnetic surface conductivities for dispersion compensation in transmission. (b) The decreasing frequency spacing leads to positive group delay dispersion ($\Phi_2 > 0$). (c) Initial pole structure of required surface conductivity $\tilde{\sigma}_{se}(\omega)$. (d) Pole structure of the Lorentzian approximation $\tilde{\sigma}_{se}^{LA}(\omega)$. (e,f) Dispersion compensation example with an infinite Lorentzian resonance train. (g,h) The resonance train is truncated to seven resonances; the bandwidth becomes finite but the performance is not compromised.

Thus far, the approaches to dispersion compensation with MSs are either too narrowband or do not guarantee pulse integrity [4-6]. Here, we present a solution to this problem by constructing multiresonant MSs that implement a purely quadratic phase profile which is both arbitrarily strong (despite the ultrathin nature) and (almost) arbitrarily broadband, as controlled by the spacing and number of the implemented resonances, respectively. The main elements of our approach are illustrated in Fig. 1. A specific configuration of Lorentzian resonances in the electric and magnetic surface conductivities with decreasing(increasing) frequency spacing can lead to a purely quadratic phase $\varphi(\omega) = \Phi_2(\omega - \Omega)^2 + \Phi_1(\omega - \Omega) + \Phi_0]$ with positive(negative) group delay dispersion Φ_2 [Fig. 1(a),(b)].

In order to rigorously derive the required surface conductivities, we plug the desired transmission/reflection transfer function $H(\omega) = A\exp\{i\varphi(\omega)\}$ [$\varphi(\omega)$ is the quadratic phase and A allows for amplitude decay] in the expressions relating transmission/reflection plane-wave scattering coefficients with the surface conductivities of the MS [1]. The resulting prescription for the electric surface conductivity is found to be $\tilde{\sigma}_{se}(\omega) = -i\tan\{[\varphi(\omega) + i|\log A|]/2\}$. The poles of this complex function are depicted in Fig. 1(c). Subsequently, we keep only the poles with indices $k \in \mathbb{P}$ in Fig. 1(c) and complement them with their negative-conjugate counterparts [Fig. 1(d)] in order to end up with a Lorentzian approximation to the required conductivity. The Lorentzian approximation $\tilde{\sigma}_{se}^{LA}(\omega)$ is (i) characterized by poles residing only in the lower complex half-plane (as required by causality) and (ii) possesses the correct spectral symmetry (real part: even; imaginary part: odd) so that it translates into a real function in the temporal domain, as required for physical response functions.

As can be seen in Fig. 1(e), implementing the Lorentzian approximation $\tilde{\sigma}_{se}^{LA}(\omega)$ the metasurface can exhibit a broadband quadratic spectral phase with a fairly flat amplitude. This can be used for dispersion compensation of chirped signals [Fig. 1(f)]. For operation in transmission(reflection) electric and magnetic conductivities have to be spectrally overlapping(interleaved). In the example of Fig. 1(e),(f), the output pulse is completely de-chirped and compressed by a factor of $\sqrt{2}$, as intended. In practice, the resonance trains need to be truncated. Figure 1(g) investigates this scenario keeping seven resonances. The compression is only slightly affected and the residual output chirp is negligible along the duration of the output pulse [Fig. 1(h)].

ZrO_2 Holographic Metasurfaces for Biophotonics Applications

Mohammad biabanifard[1], Tomasz Plaskocinski[1], Jianling Xiao[1], and Andrea Di Falco[1]

[1]University of St Andrews, North Haugh, St Andrews, Fife, KY16 9SS, United Kingdom
*corresponding author: adf10@st-andrews.ac.uk

Abstract: We present zirconium dioxide holographic metasurfaces offering environmental independence operation, ease of fabrication, biocompatibility, and broadband functional nature. Here we show that this class of metasurfaces can be used for integrated optical trapping in the visible range.

Metasurfaces, artificial two-dimensional surfaces that are designed to manipulate the electromagnetic behavior of light, can be used to modulate the optical response of the incident light [1-2]. Holographic metasurfaces (MSs) have found utilization in virtual and augmented reality, encryption and security, sensing, imaging and digital art applications [3]. One of the key factors that determine the properties and scope of applications of metasurfaces-based devices is the material chosen for the meta-atoms. Titanium dioxide (TiO_2) and amorphous silicon are among the most prominent materials for practical metasurface applications in the visible range, due to their high refractive index and broadband transparency. However, they suffer from high-temperature fabrication (TiO_2) and low operational bandwidth in visible wavelengths (amorphous silicon).

Here, we discuss particularly the potential of zirconium dioxide (ZrO_2) as a suitable material for the practical use of metasurface technology, offering broadband operation across the whole visible range, as shown in Fig. 1a. Most importantly, ZrO_2 presents excellent resistance to corrosion and different chemicals, very high fracture toughness, high hardness and density, good frictional behavior, low thermal conductivity, and solid electrical insulation, which make it particularly attractive for real-world applications [4].

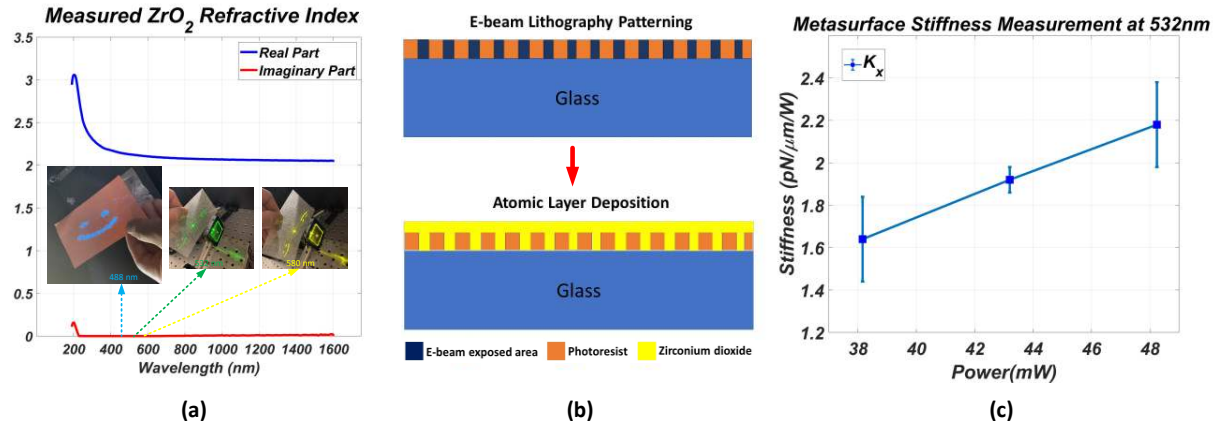

Fig. 1. (a) The measured refractive index of ZrO_2 with the inserted smile face holographic image working at 488nm, (b) the fabrication process, and (c) the measured trap stiffness operating at 532nm.

The platform was validated by fabricating holographic metasurfaces for on-chip optical trapping, which replaces the need for a costly and bulky high numerical aperture microscope objective. The meta-atoms were fabricated using electron beam lithography on a glass substrate, followed by low-temperature conformal coating of ZrO2 using atomic layer deposition, as depicted in Fig. 1b.

The design of the meta-atoms was optimized to cover a phase range of approximately 260 degrees at 532 nm, taking into account the refractive index of ZrO2 which is n=2.11. Although not complete, the achieved phase range was sufficient to design a high-quality focused spot with a focal distance of 40 micrometers and designed numerical aperture NA=1.2. The trap stiffness of a 2-micrometer silica particle trapped by a ZrO_2 MS, excited by a collimated beam at 532nm, is shown in Fig. 1c. These experimental results demonstrate the potential of ZrO_2 MSs for on-chip optical trapping applications.

The new fabrication technique used in this study does not require etching after atomic layer deposition, and it is a low-temperature process that results in a flat surface on top of the structure. These features make the technique particularly advantageous for biophotonics applications, where a smooth and uniform surface is often required. Additionally, the efficiency of the fabrication process could potentially reduce the cost and complexity of manufacturing metasurface devices for a variety of applications.

Ray-based design of hybrid metalens refractive imaging systems

Yijun Ding[1*] and Bryan D. Stone[1]

[1]Synopsys Inc., 199 S. Los Robles Ave. Suite 400, Pasadena, CA 91101, USA
[*]corresponding author: joyding@synopsys.com

Abstract: The complexity of the design workflow is one of the main roadblocks for the adoption of metalenses in a hybrid imaging system that include both metalenses and conventional refracting or reflecting optical elements. This complexity is caused by the two significantly different length scales of lenses (macro-optics) and meta-atoms (micro-structures). To bridge the gap between the two scales, we propose a ray-based approach for designing hybrid imaging system and provide design examples for this approach.

Metalenses have the potential to become a powerful new tool in an optical engineer's toolbox, in light of its potential applications in AR/VR, biomedical imaging, and wearable consumer electronics [1–3]. One of the main roadblocks for the adoption of metalenses in optical design is the complexity of the design workflow. This complexity is caused by the two significantly different length scales involved in the design of a metalens. Meta-atoms, with a length scale of a few hundred nanometers, are often simulated with rigourous coupled-wave analysis (RCWA) or finite-difference time-domain (FDTD) method. However, these simulation methods alone are not suitable for the design of mm-scale metalenses, as the memory and computation time required for the simulation is prohibitive. A ray-based metalens analysis tool can bridge the gap between the metalens and the optical property of the meta-atoms, hence reducing the complexity of the metalens design workflow.

Because of the length-scale of the meta-atoms, ray-based methods for analysis and optimization may not be considered to be appropriate. However, by treating the imparted phase appropriately, ray-based method can be used to design and analyze optical systems that incorporate one or more meta lenses. In order for ray-based design methods to be generally successful, they must account for angular and wavelength dependence of the meta-atom optical properties. Prior work on multiscale optimization of hybrid imaging systems has applied a simple phase surface [4], Sweatt model [5], or effective medium theory [6] to simulate a metalens. We treat a metalens similar to a conventional diffractive surface [7, 8]. Compared to prior work, our approach considers the optical property dependence on wavelength and field of view, and it works for varying meta-atom types.

In our approach, there are two pieces of information that are required by the ray trace:

1. The ray directions following the meta surface.
2. The amount of energy (also called efficiency) that propagates in each of these orders.

We use the discontinuities in the meta-atom parameter to determine the ray directions for the diffracted order and Fourier Optics [9] to estimate the amount of energy that goes into the various orders for a given incident ray. This allows the ray direction and energy to be dependent on the wavelength and angle of incidence. The ray-based approach can still take into account the wave-nature of light, but rays are used as an integral part of the design and analysis process.

Our approach is not limited to a particular type of meta-atoms. The optical properties of the meta-atoms can be

calculated with RCWA or FDTD algorithms using local periodic approximation [10]. By varying the design parameter(s) of the meta-atoms, a lookup table can be generated in the form of a transfer-function library [11]. The angular and wavelength dependence can be included in the meta-atom library and hence considered in the ray-based design approach. We have implemented a ray-based metalens design tool that links to such a meta-atom library.

The proposed methods can be applied to imaging systems or illumination systems composed solely of meta lenses, or systems that incorporate a mix of meta lenses and conventional refractive, reflective, or diffractive optical elements. In this paper we discuss this ray-based approach and offer design examples that are used to validate this approach. For the validation, we compare the results of ray-based analysis with those found by a more rigourous wave-based analysis. Note that the ray-based approach can still take into account the wave-nature of light, but rays are used as an integral part of the design and analysis process. We find that the design process is greatly simplified by using the ray-based approach and that there is excellent agreement between the ray-based predictions and the wave-based analysis.

Metasurface-based optical concentrators monolithically integrated with Barrier infrared detectors

T. Wenger, R. Muller, C. J. Hill, A. Fisher, D. Z. Ting, D. Wilson, S. D. Gunapala, and A. Soibel*

*asoibel@jpl.nasa.gov

Abstract: Recently developed metasurface technology enables optical concentrators that can be integrated with detectors. In this work we developed InAsSb-based infrared photodetectors monolithically integrated with metasurface lenses (metalenses) that act as optical concentrators. The metalenses are fabricated on the backside of a gallium antimonide substrate, and the photodetectors are fabricated on the frontside of the same substrate. The metalenses enhance the detector responsivity up to 10-fold and detectors retain the same detectivity at temperatures up to 40K higher.

Infrared (IR) detectors are widely used in medical, defense, and space applications. Recent IR detector advances such as nBn detectors have emerged with favorable high temperature performance. This makes them highly interesting for applications in space, especially for satellite concepts with small form factors where room for cooling hardware remains limited. Integration of photodetectors with optical concentrators enables detectors to collect a larger fraction of incident light, thereby increasing the responsivity of the detector and enabling operation at higher temperatures with the same performance. Such high-temperature detectors are attractive for instance in IR spectroscopy applications and gas analyzers.

We monolithically integrated metalenses as optical concentrators with single-pixel nBn detectors.[1] This was done by first fabricating the concentrators on the backside of a GaSb wafer with detector material grown on the frontside, followed by detector fabrication on the frontside. We investigated two separate metasurface designs, one annulus-shaped broadband design and one square narrowband design. Both metasurface designs are based on circular nanoposts, with post-post distance of 400 nm, that are etched 2 μm directly into the GaSb substrate. The metalens were designed to have a focal length of 500 μm (same as substrate thickness) for 4 μm light.

First, the detector material, $InAs_{0.915}Sb_{0.085}$, was grown using molecular-beam epitaxy (MBE) on the frontside of a GaSb substrate. Then metalens were fabricated on the backside of the detector wafer using electron-beam lithography and dry etching in both fluorine and chlorine chemistries. Next, the single pixel detectors with sides 100 μm were fabricated on the frontside using standard photolithography and a dry/wet etch. The metalens pattern contains alignment marks which were used for front-back alignment between metalenses and detectors. The alignment was performed with a maskless aligner.

We measured effective quantum efficiency (QE) for detectors with and without optical concentrators at T = 250 K. The bare detectors exhibit a fairly uniform response for 2−4 μm. Both metalens designs are effective in concentrating additional light onto the detector. The broadband design provides a more uniform performance enhancement, whereas the narrowband concentrator design has a peak in efficiency close to 4 μm. We found that QE enhancement is 3.5x for the broadband design and of 11x for the narrowband design. We evaluated the detectivity at the wavelength 3.75 μm with and without concentrators as a function of temperature. With the proper detectivity generalization, detectors with and without metalenses reach the same background-limited performance (BLIP) of 10^{12} cm Hz/W at low temperature. As the temperature increases, the dark current also increases and detectivity decreases. Importantly, the detectivity of the metalensed detectors falls off more slowly than detectors without metalenses, so these detectors can be operated at up to 40 K higher temperatures with the

same detectivity.

Abstract: Detection of the phase of an electromagnetic field is fundamental to applications including wavefront sensing in ophthalmology and precision telescopes as well as biological cell imaging. In contrast to readily detectable intensity variations, measuring phase usually requires more complex approaches. Conventional methods in this field suffer from drawbacks involving bulky and moving components, long propagation distances, computation time and energy consumption. Here we report on the use of nanophotonic devices used in transmission for phase-sensing and demonstrate their potential for ultra-compact wavefront recovery.

Detection of the phase of an electromagnetic field is fundamental to applications including biological cell imaging as well as wavefront recovery. While the intensity of a wavefield can be easily measured using conventional photodetectors, phase information is not directly accessible and requires application specific approaches. The field of wavefront sensing is concerned with extracting all relevant parameters of amplitude, phase, and polarisation from a wavefield. In this context, phase is for example used to draw conclusions about medical conditions in eye tests, or to compensate for aberrations in telescope images arising from atmospheric turbulences. A common approach to map phase modulations in the context of wavefront sensing is the use of Shack-Hartmann sensors as well interferometric approaches. Common methods for phase imaging in biology include Zernike phase imaging, DIC microscopy as well as other optical methods requiring computational post processing. These conventional phase detection methods commonly suffer from one or more disadvantages including bulky and moving components, macroscopic propagation distances as well as time and energy intensive computation. Recent work has demonstrated that all-optical image processing through meta-optical devices, including the visualisation of phase, has the potential to address these challenges [1]. These permit ultra-compact, real-time sensing of phase gradients via its conversion into readily measured intensity distributions. Initial demonstrations have demonstrated their applicability to phase imaging of unstained human cancer cells [2,3] as well as wavefront sensing [4]. We believe that nanophotonic approaches have significant potential to address the drawbacks of current phase sensing methods and we envisage new methods suitable for ultra-compact integration. Here we report on progress towards the application of meta-optical devices for all-optical, quantitative wavefront sensing. The quantification of phase can be used to determine quantities of interest such as the refractive index or dry mass of cells. We demonstrate recovery of the original wavefront through time-efficient computational post processing of the recorded data. We consider a subwavelength silver grating on top of a TiO_2 waveguiding layer sandwiched between a glass substrate and a PMMA superstrate (*c.f.* Fig. 1.a). This resonant waveguide grating device enables angle dependent coupling of incident radiation into guided modes, thereby filtering the spatial frequency content of the transmitted wavefield [2]. This permits optical computation of the first spatial derivative of the transmitted wavefield. For an incident wavefield with constant amplitude, but a modulation in phase, the intensity of the transmitted field is then proportional to the square of the first derivative of the phase. This all-optical conversion from phase into intensity underpins the

wavefront sensing method proposed here. In Fig. 1b first-order spatial derivatives along the *x*- and *y*-direction of an incident wavefield with a phase modulation in the shape of Zernike polynomials are optically computed by transmission through the device. Subsequently, we use the derivatives obtained along both spatial directions to computationally reconstruct the original wavefront through an iterative algorithm based on Fourier integration. Fig. 1.c shows a numerical example of reconstruction of the original wavefront from the spatial derivatives, as obtained upon transmission of the incident wavefield through the meta-optical device.

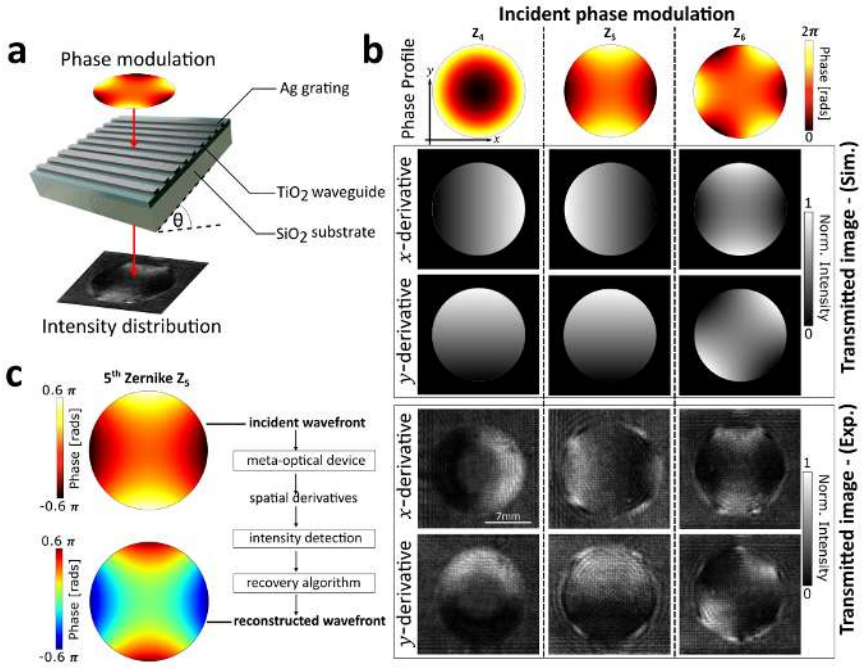

Fig.1 – a) Meta-optical device for phase visualisation in transmission at λ = 637 nm at a device tilt angle of θ = 3°. Subwavelength grating of Ag strips with period p = 400 nm on top of TiO_2 waveguid layer with a thickness of t = 150nm. b) Numerical and experimental optical computation of spatial derivatives of phase modulations along *x*- and *y*-direction via transmission through device using example of Zernike polynomials Z_4-Z_6. Experimental phase modulations of Z_4-Z_6 are imposed via a spatial light modultator (SLM) . c) Numerical simulation of meta-optical wavefront reconstruction based on integration of derivatives for the 5th Zernike polynomial Z_5.

In our presentation we will discuss application of the proposed method to quantitative phase-imaging of biological cells, and discuss devices that permit dynamic tuning of their processing capacity based on the incorporation of tuneable 2D materials.

Abstract: Edge and polarimetric imaging play an essential role in the enhancement of target detection and recognition performance. However, an imaging system with such multiple functionalities tend to be bulky and expensive because of the substantial footprint of their benchtop-based electronic and optical components. Here, we propose a multifunctional 3-in-1 microscope based on an ultrathin metasurface device which can concurrently perform polarimetric, edge and microscope imaging to visualize the multiple facets of transparent biological samples in real-time.

For microscopy imaging, typically biological samples are made very thin to avoid the scattering of light from various tissue structures. Without special image enhancement techniques, these tissue samples show little contrast under the conventional microscope, as these samples are usually transparent [1-3]. Precisely differentiating the edges, increasing the target detection, and enhancing the recognition performance of the imaging system are important for the study of such transparent biological samples [4-6]. The currently available imaging systems can only perform a single functionality at a time. In addition, only limited number of imaging systems are present to date which can perform multiple functionalities on the cost of expensive and substantial footprint of their benchtop-based electronic and optical components [7]. This reduces the portability and hinder their practical applications. Moreover, the application of standalone circular polarimetric microscopy in biological sciences is limited despite the useful information obtained from the circular polarization measurement. This is due to the challenging imaging techniques that require the frequent replacement of optical components for subsequent measurement for different polarization states [8].

To resolve the aforementioned challenges, here, a multifunctional 3-in-1 microscope is proposed based on a novel and compact optical device, which is impossible to achieve with conventional optical components. An ultrathin metasurface is incorporated into a microscopy setup, which can concurrently perform polarimetric imaging, edge imaging, and traditional microscope imaging. As a result, five images of the target sample are obtained with unique optical properties on the same imaging plane as shown in Figure 1. Although three different imaging functionalities are combined within the same microscope imaging system, the volume of the proposed 3-in-1 metasurface-based microscope does not increase. The proposed metasurface device is realized based on both spatial and polarization multiplexing techniques.

We experimentally demonstrate the capability of the proposed 3-in-1 metasurface-based microscope with various samples. Using the proposed device, the edge imaging enabled reliable and fast cell detection. The polarimetric imaging acquired the complete polarization information. This is used to resolve microstructures and

the anisotropic information, for example, their orientation and ordering. Edge and polarimetric information are complementary to that obtained through traditional microscopy imaging, allowing the visualization of multiple facets of the target samples in real-time.

Abstract: We present a method based on wave front engineering for rendering a Bessel Beam (BB) lattice with one single, flat, and lightweight optical element. According to this design, we fabricated and characterized a Silicon Nitride (SiNx) element using Meta-Surface (MS) technology encoding all the operations required to generate the designed BB lattice. Finally, we demonstrated its application in microscopy by integrating it along the excitation path of a light-sheet microscope (LSM) and recording neuronal activity from the zebrafish larva brain.

Laser beam shaping approaches are fundamental techniques adopted in a variety of applications such as microlithography, material processing, microscopy and optical tweezing, to increase the quality, the uniformity and speed of their beam-based processes by redistributing the irradiance and phase of the input beam[1]. Among the most frequently engineered and used beam shapes, Bessel beam profiles have been largely adopted due to their elongated depth-of-focus and self-healing features to drill high-aspect-ratio or narrow grooves[2,3], to manipulate microscopic particles[4], to illuminate samples with a thinner and wider light-sheet[5,6], and to produce patterns on glass[7].
Traditionally, arrays of Bessel beams are generated by combining an axicon phase profile and a spatial light modulator[8], or Dammann grating[9]. However, these approaches cannot avoid some of the following limitations, depending on the specific implementation: low numerical aperture (NA) of the single beams, a NA dependent on the grating orders and supercell period[9], the constraint of having all the beams in the array with the same optical features, the constrains of having a number of beams in the array limited by the grating order, the constraint on the input light polarization, or the limited intensity uniformity among all the beam spots included the zero-order one.
Here, we propose a method which exploits a novel, custom-designed Meta-Surface to generate an array containing an arbitrary number of BB with independent optical properties, focal position, and depth of focus. Finally, we show how we did integrate this novel Meta-Surface along an optical path to validate its performance in a challenging application: the recording of the neuronal activity from the zebrafish larva brain at cellular resolution.

Abstract: In this talk, we will give a demonstration, based on a recently-developed class of metalenses, of a prototype that alleviates the challenges of chromatic and coma aberrations within a single-layer device, and achieves color imaging over a field-of-view of $\sim 100°$. The proposed approach opens venues for translating this emergent technology into commercial products.

Flat optics holds the promise to replace conventional optics in many user devices, such as in smartphone cameras. However, challenges like chromatic and coma aberrations have hindered so far spectral broadband and large field-of-view (FOV) imaging performances in most of metalenses. Based on a recent class of metalenses, called quadratic metalenses [1–3], we provide here a solution that overcomes simultaneously both challenges. While quadratic metalenses are exempted from coma aberrations and thus provide naturally a large FOV [1–3], their inherent spherical aberrations (i.e. elongation of the focal spot along the axial direction), were seen so far as a limitation leading to non-diffraction limited focusing and lower focusing efficiencies. Here, we show that the depth-of-focus coming from these spherical aberrations allows for broadband focusing, and we leverage on this effect to design a set of three R,G,B quadratic metalenses whose working bandwidths match with the filter bandwidths present in a color camera, to demonstrate white light and large FOV imaging. Combined with our own post-processing deconvolution algorithm (called "EigenCWD"), this solution offers high contrast and good color reproduction capability and a spatial resolution that are sufficient for most smartphone camera applications [4]. Moreover, these three metalenses are fabricated on a same substrate with a same height, allowing to be fabricated upon a one-step photolithography suitable with mass-production.

Photonic bound states in the continuum in asymmetric bi-slot metasurfaces

Ti-Jung Hsu , Ruey-Lin Chern *

Institute of Applied Mechanics, National Taiwan University, Taipei 106, Taiwan
*corresponding author: chernrl@ntu.edu.tw

Abstract : We investigate the photonic bound states in the continuum (BICs) in dielectric metasurfaces composted of two asymmetric slots in the unit cell of a square lattice. Symmetry-protected (SP) BICs occur at the polarization vortex center (V point) with integer topological charge in the polarization state diagram when the structure is fully symmetric. By introducing the asymmetry between the two slots, accidental BICs or Friedrich-Wintgen (FW) BICs can be formed from the merging of two circular polarization points (C points) with half-integer topological charge.

Summary :

Bound states in the continuum (BICs) are non-leaky localized resonance modes that coexist with a continuous spectrum of radiating waves [1]. They are non-radiative waves and possess extremely large quality factors with vanishing spectral linewidths. As a concept introduced in quantum mechanics by von Neumann and Wigner in 1929, the existence of BICs was explained by Friedrich and Wintgen in 1985 as the result of destructive interference between two resonances coupled to the same radiation channel. In this study, we investigate the BICs in dielectric metasurfaces composed of asymmetric two rectangular slots in the unit cell of a square lattice. In particular, symmetry-protected (SP) BICs occur at the polarization vortex center (V point) with integer topological charge in the polarization state diagram when the two slots are identical, in which the topological charge is defined by the number of times the polarization vector winds around a BIC as [2]

$$q = \frac{1}{2\pi}\oint_C d\mathbf{k}\cdot\nabla_{\mathbf{k}}\phi(\mathbf{k}). \tag{1}$$

Here, $\phi(\mathbf{k}) = \arg[c_x(\mathbf{k}) + ic_y(\mathbf{k})]$ is the angle of the polarization vector, and C is a closed simple path in the momentum space that goes around the BIC in the counterclockwise direction. By introducing asymmetry between two rectangular slots, accidental BICs or Friedrich-Wintgen (FW) BICs can be formed by the merging of a pair of circular polarization points (C points) with half-integer topological charge [3], which is achieved by tuning the asymmetry parameter of the rectangular slot. In this situation, two modes are hybridized and the quality factors are greatly enhanced.

Abstract: Angle-multiplexed metasurfaces offer new degrees of freedom in multi-functional metasurfaces. However, they can suffer from trade-offs in transmission efficiency and angular sensitivity for paraxial rays. Here, we demonstrate a solution to the limitation by breaking mirror symmetries of single-layer metasurface structures. Using a theoretical model, we intuitively explain which material parameters affect the sensitivity and efficiency. Additionally, through the inverse design method, an angle-multiplexed beam deflector is proposed.

Angle-multiplexed metasurfaces have garnered much attention due to their ability to provide new optical functionalities that were not previously possible with conventional optical devices. Many studies have proposed angle-multiplexed metasurface designs with several different physical principles [1–2]. However, those proposals so far have a common problem that high angle sensitivity is achieved by at the expense of optical efficiency, especially for paraxial rays used in practical applications. Recently, we theoretically demonstrated that the problem is fundamental and inherent to angle-multiplexed metasurfaces with mirror symmetries, and proposed a new class of angle-multiplexed metasurface with broken mirror symmetry [3]. Here, we explicate the principle behind the proposed metasurfaces and show examples.

Assuming that the metasufaces consist of subwavelength fundamental building blocks and they are locally periodic, we can approximate each structure as a uniform anisotropic effective medium. In general, the effective optical axis of the material can be slanted with respect to axis normal to the substrate. The slanted crystal axis induces an off-diagonal component in the permittivity tensor, which can only be obtained by breaking the structural mirror symmetry. For two near-zero incidence waves propagating in the z-direction, Figure 1 compares complex transmission between anisotropic media with vertical and slanted crystal axes with varying a permittivity along the z-axis (ε_3). Most of points in the anisotropic medium with a vertical crystal axis have transmission amplitudes below the threshold despite certain permittivity values being able to produce a considerable phase difference (Fig. 1(a–b)). On the other hand, the medium with a slanted crystal axis can obtain both high transmission efficiency and large phase gradient for inputs. The medium can produce the phase difference of up to π while having transmission amplitudes above the threshold (Fig. 1(c–d)).

The reason behind this phenomenon is due to the dependence of the refractive index and wave impedance on incident angle and the permittivity (ε_3). Anisotropic media with a vertical crystal axis has a significant increase in the derivative of the refractive index with respect to incidence angle as the ε_3 approaches small values. However, the wave impedance and its derivative also increase dramatically, which makes it difficult to achieve both high angle-sensitivity and high transmission efficiency. In contrast, if the crystal axis is slanted, the changes in wave impedance and its derivative are less sensitive, allowing higher transmission efficiency (Fig. 1(e–f)).

Based on the theoretical analysis, we design the angle-multiplexed metasurfaces with high optical efficiency by spatially arranging the unit structures with broken mirror symmetry. We utilize a simple unit structure, slanted grating with a parallelogram-like cross section, which has minimal symmetry breaks. The angle-sensitive beam deflector is designed as an example of angle-multiplexed phase gradient metasurface (Fig. 2). The

optimized beam deflector directs the two incidence angles with a small angular separation, $\theta_1 = +5°$ and $\theta_2 = -5°$, in two very different directions, 39.2° and −7.3°, with a high relative transmission efficiency 93.8% and 88% (absolute efficiency: 83% and 56.3%) respectively. This indicates that not only the structures with broken mirror symmetries can induce large phase gradients at near-zero incidences, but they also can achieve asymmetric transmission with symmetric inputs.

Abstract: A morphogenesis-inspired technique for the engineering of electromagnetic components is under development and finds new applications in the procedural generation of radiating metasurfaces. This method simulates the growth of structures capable of spatially self-organizing to respond to electromagnetic constraints. An application is presented with the automated synthesis of a morphogenetic metasurface radiating a field distribution constrained in frequency, in space, and in polarization.

Many inverse design techniques rely on a guided exploration of huge component spaces to find the best candidates able to satisfy desired functionalities [1]. However, these approaches are constrained by the exploitation of gradient descent of non-convex cost functions and involving a large number of design variables [2]. Inspired by the structuring of living organisms and Alan Turing's pioneering work on its numerical modeling [3], morphogenetic engineering is based on a decentralization of the designer's role [4], trying to define local rules guiding the self-organization of complex systems and ensuring the emergence of the desired functions at the macroscopic scale. It is thus proposed to develop a model capable of generating radiating metasurfaces (Fig. 1), simulating the growth of spatial structures capable of ensuring an efficient conversion between a surface wave excited by a coaxial guide and spatially constrained radiated waves, in frequency and polarization.

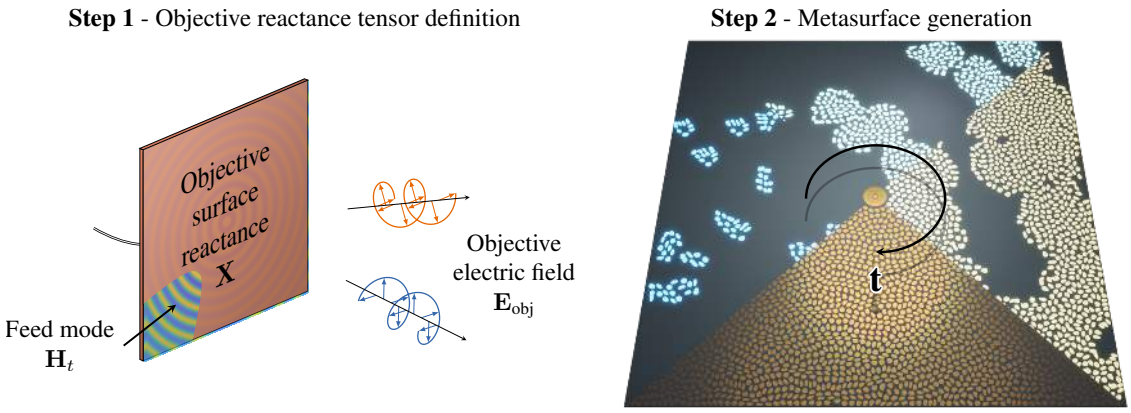

Figure 1: Design of a morphogenetic metasurface: (Left) Definition of electromagnetic constraints allowing the conversion of surface waves into radiated waves. (Right) Growth of elliptical patterns synthesizing the expected properties.

The generative model used here is based on the Gray-Scott reaction-diffusion model, defined by Eqs. (1) and (2), simulating the interaction between chemical species (called morphogens by Turing) progressively forming spatial structures used in this work. The synthesis of anisotropic properties required a modification of the original generative model, forcing the emergence of asymmetric patterns whose orientation can be controlled. Inspired by previous work on texture synthesis [5], the Gray-Scott system was thus altered as follows:

$$\frac{\partial \mathbf{U}}{\partial t} = \mathbf{d_u} \nabla \cdot (\underline{\underline{\mathbf{D}}} \nabla \mathbf{U}) - \mathbf{U}\mathbf{V}^2 + \mathbf{f}(1 - \mathbf{U}) \tag{1}$$

$$\frac{\partial \mathbf{V}}{\partial t} = \mathbf{d_v} \nabla \cdot (\underline{\underline{\mathbf{D}}} \nabla \mathbf{V}) + \mathbf{U}\mathbf{V}^2 - (\mathbf{f} + \mathbf{k})\mathbf{V}. \tag{2}$$

In this model, $\mathbf{U}$ and $\mathbf{V}$ represent the spatial concentrations of antagonistic morphogens, whose guided self-organization over time allows the formation of a metasurface. The resolution of this model by finite difference ensures the growth of spatial patterns controlled by the parameters $\mathbf{d_u}$, $\mathbf{d_v}$, $\mathbf{f}$, and $\mathbf{k}$. Finally, one can deform and control the local orientation of the generated patterns by modulating the anisotropy and the orientation of the eigenaxes of the tensors $\underline{\underline{\mathbf{D}}}$ guiding the diffusion of the morphogens. Following a characterization of the impedance properties synthesized using the finite element method, it was thus possible to directly convert the morphogenetic parameters guiding the emergence and the self-structuring of the patterns into electromagnetic properties. Fig. 2 depicts an holographic experiment based on the fabrication of a metasurface radiating a controlled field distribution at 20cm from the latter at 20.2 GHz. Following the radiation objectives translated into local rules guiding the morphogenetic synthesis, the measured electric field reveals both the letter "L" in left circular polarization and the letter "R" in right circular polarization.

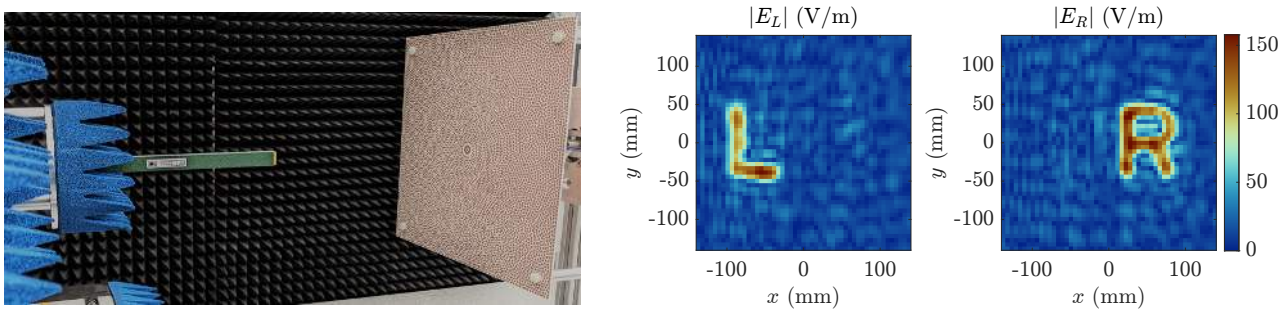

Figure 2: Fabrication and measurement of a morphogenetic metasurface generating a field distribution at 20.2 GHz revealing the letter "L" in left circular polarization ($|E_L|$) and the letter "R" in right circular polarization ($|E_R|$).

Many application perspectives of this generation technique still need to be explored, encouraged by the good performance of first demonstrations.

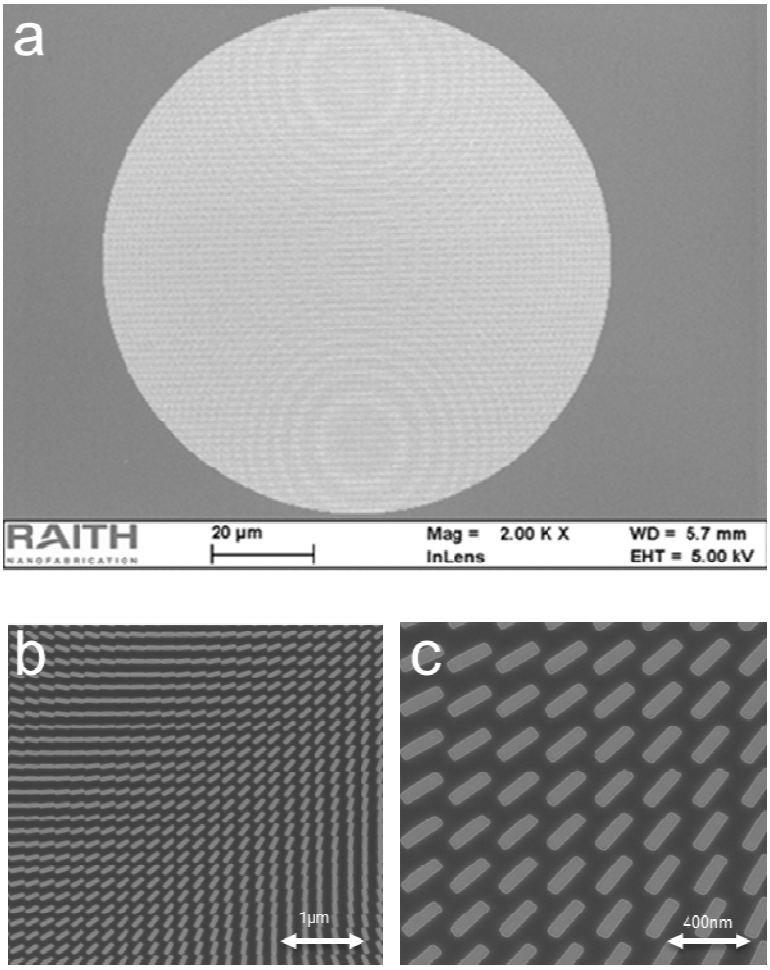
Enabling and perfectioning advanced large Area Metalens Nanofabrication by Electron Beam Lithography (EBL)

F. Nouvertné*, C. Aulbach, G. Piaszenski, J. Münchenberger and V. Boegli



Raith GmbH Dortmund, Konrad-Adenauer-Allee 8, 44263 Dortmund
*corresponding author: frank.nouvertne@raith.de

Abstract: The geometric nature of a large ~cm^2-sized metalense with its many unique and individual design elements can lead to corresponding design data file sizes of several hundreds of GB. This makes it extremely challenging if not impossible to be processed with conventional EBL nanofabrication systems. We present an enabling, innovative, and extremely efficient EBL workflow that circumvents the necessity for generating CAD-design-data for EBL by exploiting the algorithmic (formula-based) description of metalens patterns for "on-the-fly" EBL exposure pixel stream generation.

Metalenses are based on a new lens technology that is very promising for sensing and imaging in consumer electronics, medical applications, autonomous vehicles, AR/VR displays, and more. Metalenses are "flat" (2D) and made by optical components that use metasurfaces to focus light without the need for bulky classical optical lenses thus allowing for miniaturization of all devices mentioned above. Typically, metalens patterns extend over multiple 10mm^2 if not cm^2 and consist of an extremely high number of separate, irregularly and individually arranged unique design elements like small rectangles, circles, ellipses or similar with a few 100nm in size.

Corresponding CAD designs thereof, e.g. in GDSII format, the standard used in EBL nanofabrication, can grow up to data file sizes of several hundreds of GB making it extremely challenging if not impossible to be handled efficiently with conventional EBL systems. Exemplarily, for a metalens with ~1cm^2 diameter and ~200nm sized elementary functional elements like nanofins, the entire design consists of several hundred million unique design elements, that cannot be treated hierarchically or in a repetitive way within the EBL system´s data handling architecture. They rather need to be sequentially and individually processed (including design fracturing, data transmission and exposure pixel sequence calculation) within the entire data processing path of the EBL system. This requires highest computational power and most efficient data transmission capabilities in both the system´s workstation as well as in its pattern generator, something that is still very challenging even in view of modern and powerful electronic infrastructure embedded in nowadays EBL systems.

Here, we present a lean, fast and extremely efficient, new and innovative EBL workflow that circumvents the necessity for generating a flat GDSII design by exploiting the algorithmic (formula-based) description of the metalens pattern. The pattern information contained in the mathematical formula is translated into an EBL job, that directly creates the relevant pixel stream for the pattern generator "on-the-fly" only as soon as the exposure has been started. This results in almost zero overhead and eliminates time consuming generation of intermediate GDSII design or machine code files – while not suffering from potential file size limits regarding the metalens dimension.

Transmittance analysis of dielectric optical metasurfaces

Ivan Moreno*, Carlos Basilio-Ortiz

Universidad Autonoma de Zacatecas, Mexico
*corresponding author: imorenoh@uaz.edu.mx

Abstract: Metasurfaces that consist of a graded array of dielectric nano-posts arranged in a lattice are widely studied in optics and photonics. We analyze the light beam transmittance through such an optical metasurface at oblique incidences for visible wavelengths. We obtain the transmitted intensity through the dielectric metasurface versus the incident angle, for different phase gradients of the metasurface. These results are useful for designing efficient nonimaging metalenses. Finally, some concepts are presented for specifying directional transmittance of a dielectric metasurface.

Metalens technology based on dielectric metasurfaces is showing considerable optical performance while opening up new opportunities to thin, flat, lightweight optical devices [1,2]. Metalens applications in nonimaging optics require the optimization of the efficiency light propagation [3], and then to study the transmittance (transmitted intensity/incident intensity) of light beams at oblique incidence. Figure 1 shows the transmission of an input beam of light through a dielectric metasurface with constant phase gradient C, or phase profile $\Phi(x)=Cx$. This Figure shows a lateral view of a metasurface with nano-posts, and input angle θ_1 and output angle θ_2. Oblique incidence may introduce changes in the light propagation due to the finite height of the nano-posts, which height reduction is under research [4].

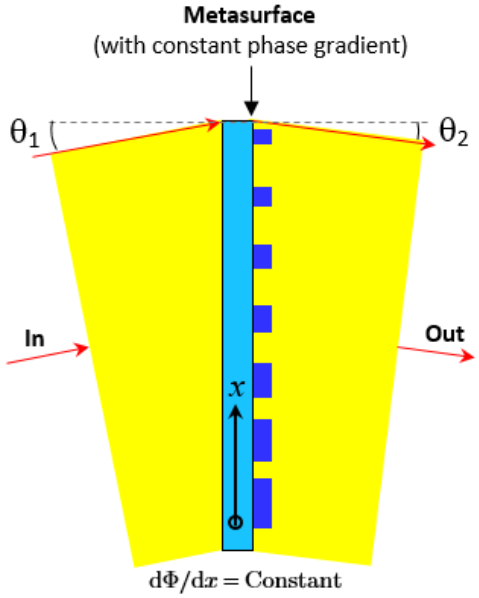

Figure 1: Transmission of an input beam of light through a dielectric metasurface with constant phase gradient C, or phase profile $\Phi(x)=Cx$. Figure shows a lateral view of a metasurface with nano-posts, and input angle θ_1 and output angle θ_2.

Therefore, here we analyze the light beam transmittance through an optical metasurface at oblique incidences for visible wavelengths. We obtain the transmitted intensity through the dielectric metasurface versus the incident angle, for different phase gradients of the metasurface. So that a relation between transmittance and phase gradient is obtained.

Abstract: Metalenses have great potential for miniaturizing imaging systems due to the ultrathin and flat features. However, besides reducing lens thickness, folding/compressing the space between lens and image is also a dominating factor to obtain the utmost compactness. This work proposes a pancake metalens that folds the optical path at will using a metacavity consisting of a bifacial metasurface and a mirror. This pancake meta-optics framework could enable miniaturization of imaging systems and would provide insights for meta-device applications.

Metalenses have arrested tremendous research interest due to its ultra-thin and flat architecture that favor the compact imaging systems [1]. Nevertheless, the lens thickness itself determines little the whole devices size indeed. The occupation mainly accounts for the imaging distance of a certain lens. Therefore, to ultimately reduce the size of an imaging system, one needs to greatly fold/compress the imaging distance but not purely reduce the lens thickness. Unfortunately, few works paid attention to this goal in previous researches about the metalens.

In this work, we propose an ingenious method for on-demand compression of imaging systems based on a metacavity consisting of a bifacial metasurface and a parallel mirror. We first employed chiral meta-atoms [2] to compose a supercell to access the bifacial metasurface with asymmetric and independent functions. Next, incorporating the metasurface with a mirror, light experiences three times of reflection and four times of spin flip within the meta-cavity. Simulations under both normal and oblique incidences are performed to exhibit the polarized space-folding effect. Finally, imparted with specifically designed phase both in transmission and reflection, *pancake metalenses* with ultrathin element features and on-demand working distance cut are constructed and demonstrated with relatively good imaging performances [3]. This kind of design can be scaled up to a larger size and other wavelengths to benefit applications like landscape imaging and favor plenty of miniaturized optical devices.

Abstract: In this study, we present the study of phonon-polariton bound states in the continuum (BIC) modes in an array of elliptical hexagonal boron nitride (hBN) nanoantennas. Using both theoretical analysis and experimental verification, we demonstrate the existence of a red-shifted quasi-BIC (Q-BIC) mode with a high-quality factor along the x-polarization. Additionally, we uncover a novel concept of a blue-shifted Q-BIC mode with a high-quality factor along the y-polarization, which we also verify theoretically and experimentally.

Bound state in the continuum (BICs) is a fascinating phenomenon in the field of physics that has garnered significant attention from researchers over the years [1]. BICs refer to a special class of localized modes in open systems that exhibits resonance frequencies embedded within the continuous spectrum but do not radiate energy into the surrounding continuum. The use of bound states in the continuum (BIC) is, in particular, a very active research topic in photonics. One promising approach is the use of dielectric metasurfaces, for sensing applications. In fact, one of the main challenges is improving the quality factor Q by confining BICs, which is defined as,

$$\text{Quality Factor } (Q) = \frac{\text{Central Frequency of the Resonance } (f_0)}{\text{Full Width Half Maximum (FWHM) } (\Delta f)} \qquad [1]$$

We modeled phonon polaritons in hBN through the Lorentz model including the matrix tensor equations of direction-dependent permittivity which defined different values in x and z directions because of the uniaxial in-plane isotropic crystal property of hBN ($\varepsilon_{xx}=\varepsilon_{yy}\neq\varepsilon_{zz}$).

The system in our model comprises two elliptical hBN resonators arranged parallel to each other along the y-axis. We started by simulating the system without any rotation of the ellipses to establish the baseline for the Q-BIC properties within a frequency range of 40THz to 45THz. The main resonance of hBN was observed at 43.60THz/1454 cm^{-1} along x-polarization and 42.3THz/1411 cm^{-1} along y-polarization, inside the upper reststrahlen band of $h^{11}BN$ (Type II hyperbolic polariton). Although the BIC mode was present at this stage, it was not visible due to its non-radiative nature. To demonstrate the Q-BIC modes, we considered a cell of two ellipses and broke the symmetry, and rotated them in opposite directions by 25 degrees a (Fig.1a). This resulted in a new Q-BIC mode with a redshift in the resonance frequency to 41.95THz/1399.3 cm^{-1} are shown in Fig. 1c, along with x-polarization as a low-frequency dark mode and an increase in the quality factor of the quasi-BIC mode.. We achieved the enhancement in quality factor from 161.5 (main resonance) to 233.05 (Q-BIC) by nearly 44% calculated from eq. 1 along with x-polarization and a new Q-BIC blue shifted mode occurs along y-axis polarization at 43.95THz/1466cm^{-1} in our simulations, which can be explained by the band structure folding in the Q-BIC hBN resonators.

We conducted an experimental study to confirm our simulated findings on the BIC and Q-BIC modes in hBN

nano-antennas. To create our sample, we exfoliated natural $h^{11}BN$ onto a CaF_2 substrate, chosen for its UV-IR spectrum transparency, and patterned the meta-surfaces of elliptical resonators with e-beam lithography. After fabrication, SEM images were taken and presented in Figure 1b, which shows elliptical hBN nano-antenna resonators with a period size of 1.7µm. We used FTIR spectroscopy to measure the transmission spectrum under the IR-transmission regime of 1300 cm^{-1} -1350 cm^{-1} with an aperture size of 20µm. Our results indicate the presence of the Q-BIC mode, which is red-shifted at a frequency of 1383 cm^{-1} along the x-polarization, as shown by the red solid line in Figure 1d. We used a polarizer to separate out both modes along the x and y polarization, as shown in Figure 1d. Our findings also provide experimental evidence of the presence of band structure folding along y-polarization, as the Q-BIC along y-polarization is blue-shifted to 1437cm^{-1}, as shown by the blue solid line in Figure 1d. Finally, we achieved nearly a 39% enhancement in the red-shifted Q-factor from 143 (main resonance) to 198 (Q-BIC) along the x-polarization. This project has received funding from the European Research Council (ERC) under the European Union's Horizon 2020 research and innovation program (Grant Agreement No. 948250)

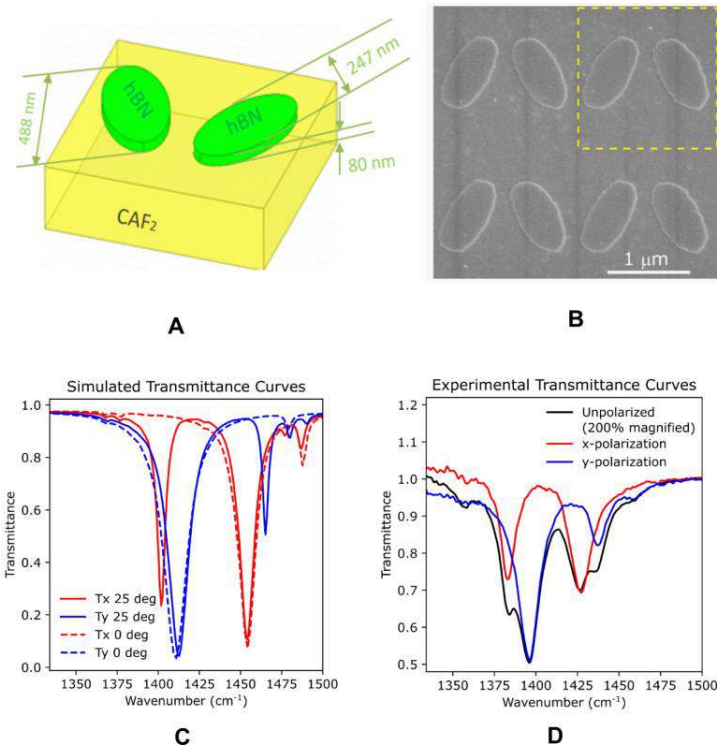

Figure 1 - hBN resonators with the major axis of 488nm, minor axis of 247nm, hBN thickness of 80nm over the CAF_2 substrate (1a), SEM image of the hBN resonators having a period size of 1.7µm with same measurements of simulated resonators (1b), Simulated transmitted curves shows the main resonances at zero degrees rotation by dotted lines and 25 degrees rotation curves by solid lines, red and blue color shows the x and y polarization respectively (1c), Experimental FTIR curves show by solid lines, black represents to the unpolarized curve (without polarizer), red and blue shows the transmission curves shows the x and y polarization respectively.

Polarization Dichroic Fabry-Perot Cavities Enabled By Metasurface Structures

B. Semnani[1,2*], M. Soltani[1,2], S. Kuru[1], and M. Bajcsy[1,2]

Abstract: Here we report on our experimental progress towards design, fabrication and experimental characterization of a new class of high performance confocal Fabry–Pérot cavities formed by dielectric metasurface structures. The metasurface structures are used to make the cavities stable, optimized their mode volume and also to make them polarization birefringent.

Fabry–Pérot cavities that operate in free-space are superb platforms to enhance light-mater interaction in various media, such as cold atoms and optically trapped single quantum emitters. Despite their significance, integrated confocal Fabry–Pérot cavities with accessible mode distribution in free space and ultra-stable behaviour have yet to be experimentally demonstrated [1,2]. In this work, we present new design strategies accompanied with our preliminary experimental results on confocal Fabry–Pérot cavities formed by (i) a pair of Pancharatnam-Berry phase reflecting metasurfaces [3] which reflect and focuses only one helical state of light and (ii) Multilayer polarization-birefringent metasurface structure which reflects one linear polarization state and transmits the orthogonal polarization state. The metasurface mirrors are vertically mounted in lithography-defined platforms with proper spacing to form confocal Fabry–Pérot cavities.

(I) Self-polarizing Chiral Cavity: The chiral metasurface structure is formed by a subwavelength array of 400nm tall round-corner rectangular nanofins arranged on one side of a 50nm thick Silver layer which plays the role of the back mirror (Fig.1a). The phase profile associated with a focusing mirror is imparted via rotation of each nanofin at a given coordinate (x,y) by an angle $\theta(x,y)=2\varphi(x,y)$ where φ is the desired phase . Since the array spacing is subwavelength, higher order Floquet modes can potentially excite lossy Plamsons. We thus introduce a thin layer of SiO2 to prevent field accumulation on the surface of the Silver. This minimizes depolarization (see Fig.1b) and loss. Therefore, higher Q factors can be achieved. Also, the design is optimized to maintain polarization purity for all rotation angles. Fig 1.b shows the geometric phase vs the angle of rotation for all nanofin ordinations. Another significant issue is the formation of nanoislands on the silver layer during PECVD deposition of amorphous Si. The film morphology spontaneously forms nanoislands. The nanoisland formation also occurs when the substrate temperature becomes high and local melting happens for the thin metal layer. It is a well-known process named "dewetting" [4]. To circumvent this issue, we used the magnetron sputtering method followed by a thin film of Silicon dioxide sputtering to prevent dewetting during the PECVD process of a-Si coating at high temperatures. The SEM images show the ability of this modified coating strategy compared to the conventional e-beam evaporation of Silver after the growth of 400nm a-Si using PECVD in 300C. So, not only the spacing layer prevents the field accumulation on the surface of Silver, it plays a crucial role in avoiding dewetting the thin Silver layer during PECVD deposition of amorphous silicon.

(II) Polarization-dichroic Fabry–Pérot cavity: Another cavity structure is formed by two vertically

mounted birefringent metasurface structures which operate in confocal lens/cavity modes. Each birefringent metasurface, as a whole, is composed of two flat planar dielectric structures with nano-scale patterns. The layers are responsible for polarization-selective reflection and focusing of light respectively. The phase-front of the light for the two orthogonal polarization states is independently controlled by using high aspect ratio symmetry broken dielectric metasurfaces [3]. A second layer of photonic-crystal slab acting as broadband dimerized high contrast grating (DHCG) [5] with near 100% polarization discrimination is used to switch between the lensing behavior to a metastructure which behaves as a focusing mirror. We used ray tracing to obtain independent phase profiles imparted by polarization dichroic metasurface so that the modes overlap properly. The cavity structure is used to build a single photon gate mediated by cold Cs atoms.

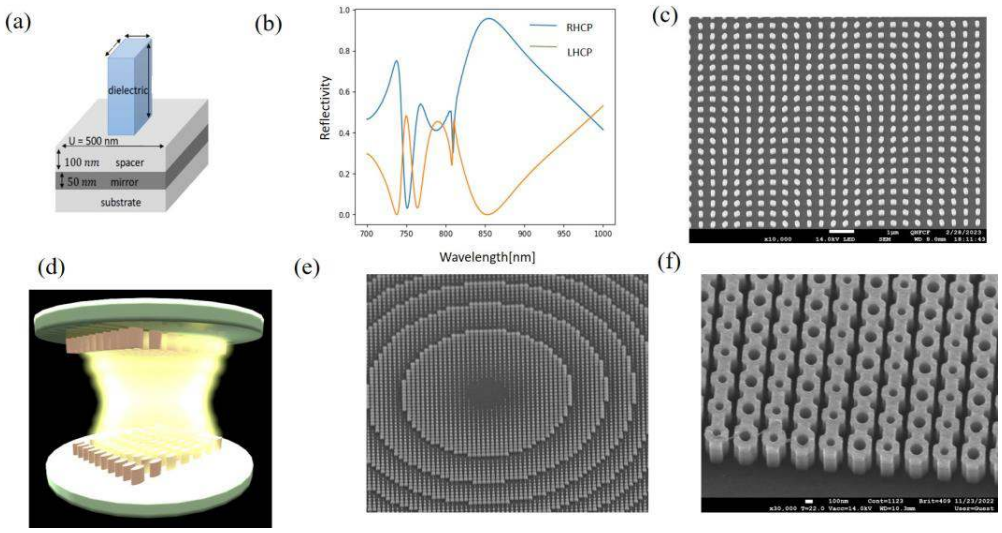

Figure 1. (a-c) Pancharatnam-Berry phase reflecting metasurfaces (a) Schematics of the multilayer metasurface. Nanofins are made of PECVD-grown α-Si.(b) Reflection spectrum upon purely right handed circularly polarized illumination. At 850nm the mirror becomes spin-preserving (c) fabricated metasurface **(d-f)** bilayer Polarization-dichroic metasurface structure (e) phase imparting layer (f) Dimerized high contras grating layer with near unity reflectivity discrimination for linear polarization of light.

Abstract: In this study, we proposed an optical system including metalens doublet which can generate focus at an arbitrary location in three-dimensional space by simply tuning their distance or orientation angles. For fully exploiting 2-polarization channels of the unitary symmetric metasurfaces, a built-in hologram is embedded in the remaining channel, which visually guides rotational and positional alignment between two metalenses in real-time, without additional fabrication cost. The suggested hybrid optical system could apply to and widen many other studies.

Active metasurfaces with reconfigurable and tunable properties have attracted a lot of academic and industrial interest. By controlling the properties of the constituent material or environment surrounding the metasurfaces, one can tune the response of the metasurfaces[1]. However, a significant challenge in achieving high performance is the requirement for the size of independently tunable pixels to be on the same scale as the wavelength. Accordingly, mechanical reconfiguration of multiple metasurfaces also has been studied because of its simple and macroscopic tuning mechanism[2].

Here, using the polarization-multiplexing characteristic of the unitary symmetric metasurfaces, we demonstrate that the metalens doublet can work as a three-dimensional varifocal device for right-circularly polarized (RCP) light and generate a visual alignment-guiding hologram for left-circularly polarized (LCP) light.

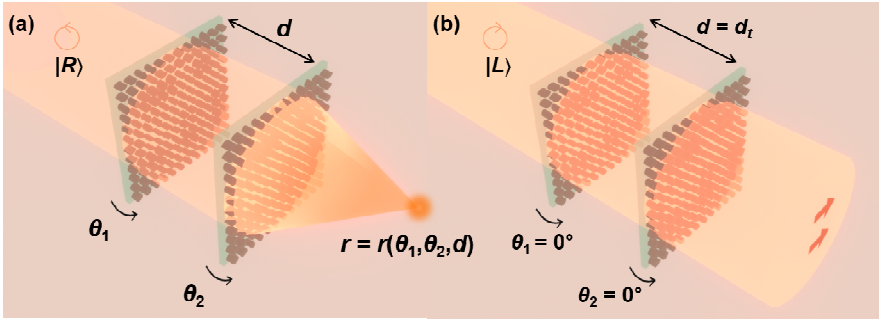

Figure 1. Schematic illustration of polarization-multiplexed metalens doublet. (a) Three-dimensional varifocal device for RCP incidence. The location of the hot spot can cover the three-dimensional space by simply rotating two metalenses or changing the distance between them. (b) Alignment-guiding hologram for LCP input light. Depending on the distance between two metalenses and the orientation of each metalens, the output holographic image is blurred, rotated, and shifted.

In Figure 1, The tunable metalens doublet consists of two optical elements, each of which is functionally a superposition of a beam-steerer and a lens for RCP incidence. According to imaging equation, the position of the hotspot can cover longitudinal displacement. The transversal displacement effect at the imaging plane can be analytically derived using Fresnel approximation, which is given as

$$\boldsymbol{\rho} = \frac{d_2}{k_0}\left(\boldsymbol{k}_{\parallel,2} + \frac{f_1}{d_1}\boldsymbol{k}_{\parallel,1}\right) \tag{1}$$

k_0 : vacuum wavevector
$\boldsymbol{k}_{\parallel,i}(i = 1,2)$: beam steering tangential wavevector of ith element
$\theta_i(i = 1,2)$: rotation angle of ith element

For LCP incidence, the first metasurface is designed to perform as a superposed device of a hologram and a convex lens, and the second metasurface is designed to be superposed of a concave lens, a grating, and a beam-steerer.

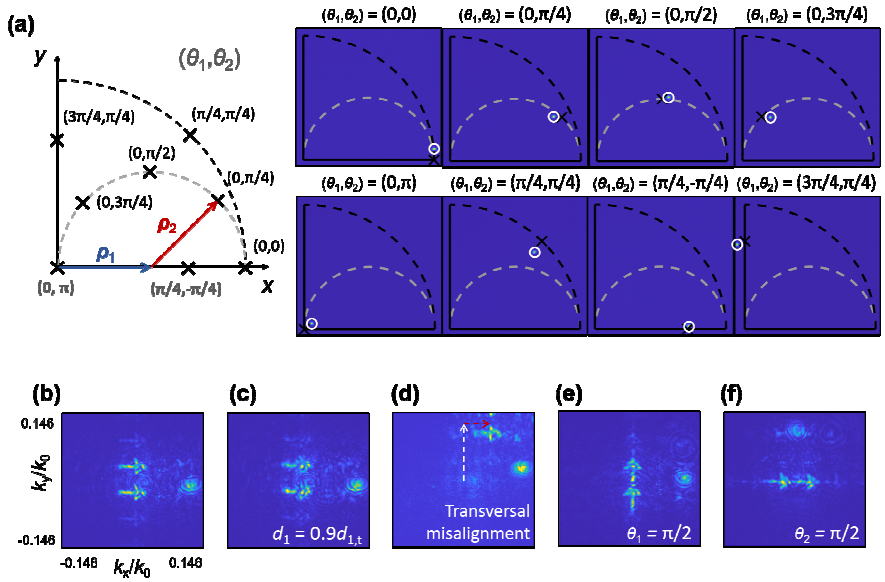

Figure 2. Experimentally measured device performance. (a) Transversal controllability of the hot spot. The left(right) panel represents the target(measured) focusing position. (b) Measured holographic image when the rotation angle of each metasurface is 0° and the metasurface aligned well to have target distance. (c-f) Measured holographic images with each kind of misalignment. (d) Measured holographic image with transversal misalignment along the vertical direction. The white arrow shows the intrinsic displacement caused by lens characteristics. The red arrow shows the extrinsic displacement caused by the spatially-varying beam-steering effect. This figure is adapted from Figure 5 and Figure 6 of reference 2.

We theoretically, numerically, and experimentally proved that by just manipulating their inter-distance and orientation angles, the resulting hot spot can be relocated arbitrarily. Figure 2(a) experimentally proves the transversal controllability of the focal spot and Figure 2(b)-(f) show the measured results of the built-in hologram. The tunable mechanism and the multifunctionality of our suggested device could be widely applied to a variety of research fields such as three-dimensional imaging, facial recognition, laser cutting, and distance sensing.

Abstract: A circular-polarization (CP) beam scanning metasurface is proposed to achieve fully transmission beam scanning of 28-degree for both positive and negative direction of the radiation pattern. The combination of plannar and non-plannar electromagnetic (EM) elements to enlarge the distance variation of spacing modulation metasurface for larger beam scanning range than the conventional active. The scanning ability is being controlled and optimized by integrated with the DC motor and is being verified through the numerical and measurement result.

Metasurface is the compose of periodic electromagnetic (EM) elements that can manipulate the electromagnetic wave. Recently proposed of reconfigurable metasurface has shown the limitations of integration functions for transmission beam scanning and polarization conversion due to the tuning ability [1], basing layer [2]. Phase and spacing modulation are two conventional designs for beam scanning metasurface that proceed by reconfiguring the phase delays and spacings between EM elements on a metasurface. Phase modulation metasurface commonly used active components to integrate with the FSS to adjust the phase delay of each unit cell (UC), which is costly and limited design. Therefore, spacing modulation is required, especially for transmission beam steering, and polarization conversion. In challenging to solve the design limitations for reconfigurable metasurface, we propose a transmissive CP metasurface with polarization conversion function that has large scanning range by the combination of planar and non-planar spacing modulation structure (Fig 1a).

Conventional spacing modulation metasurface has UC arrangement in planar where the distance variation is considered by the air gap between UC and ranging between the UC size at d = 0.5 UC size and the air gap where d > 0.5 UC size. To increase the distance variation range, we demonstrate rotatable UCs to achieve both plannar and non-plannar geometry for lowering the limited distance between UCs to smaller than the UC size (d < 0.5 UC size). Fig 1b shows the geometrical and characteristic of the distance variation and rotation angle of the rotatable UC.

To implementation the idea of the propose metasurface, we firstly designed a conventional 3-layer transmission polarization conversion UC to convert the EM wave polarization from Linear Polarization (LP) to CP and achieved 90-degree phase different at UC size of wavelength ($\lambda \sim 30$mm) at 10.5 GHz operation frequency. Fig 1c show the simulated average transmission magnitude over -3 dB and the phase shift of the 90-deg phase different UCs A, B, C, and D at different rotation state α = 0,10, and 20 deg. Fig 1d showing the simulated RHCP and LHCP beam scanning range from 22 to 50 deg of the metasurface in function of the distance variation. Respectively, the flip of the UC B and D could switch the RHCP and LHCP beam between positive and negative direction angle due to the phase gradient phenomena of the LP source [3]. Moreover, we measured the RHCP and LHCP beam angle at 22 and 37 deg and received good results confirming the performance of the proposed metasurface as shown in Fig 1e.

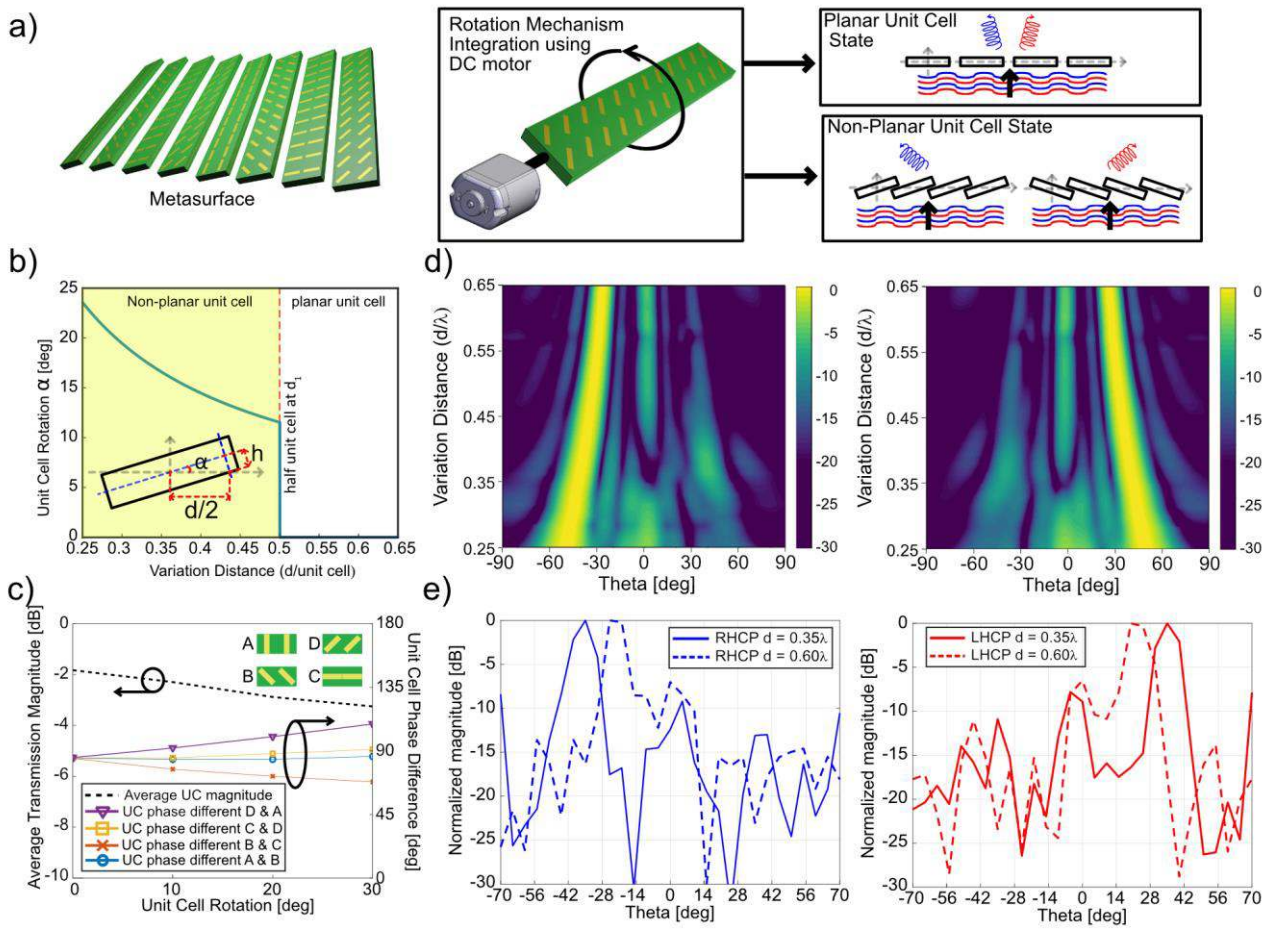

Figure 1 a) Metasurface illustration and mechanism. b) UC rotation and distance variation characteristics.
c) simulated UC average transmission magnitude and phase difference.
d) Simulated scanning range of RHCP (left figure) and LHCP beam (right figure)
e) Measurement result of RHCP (left figure) and LHCP (right figure) beam at 22 and 37-deg radiation angle

Inconclusion, in this summary we introduce a fully CP beam scanning transmission metasurface with mechanically integration of planar and non-planar UC reconfiguration that could achieved 28-deg transmission beam scanning range for either RHCP and LHCP in both positive and negative radiation pattern direction.

Abstract: In this paper, we propose a rigorous study on the angle-sensitivity of the extraordinary optical transmission resonances in subwavelength plasmonic silver nanogratings. The mechanism of angle sensitivity of the resonances is revealed in terms of the coupling between the cavity resonance and the propagating surface plasmon excitation. Based on the mechanism, strong and efficient monochromatic spatial filters are engineered by judicious tuning of the geometric parameters. The designed spatial filtering functions are also verified via experiments.

Plasmonic nanogratings have been widely studied over the decades since the first observation of the extraordinary optical transmission (EOT) resonances [1]. Majority of EOT research has been focused on understanding and utilizing complex spectral behaviors under a fixed incidence angle. In this paper, we suggest a rigorous study on incidence angle-sensitivity of the EOT and its use for resonant spatial frequency filtering [2, 3]. As can be seen in Fig. 1(a), according to the incidence angle, silver nanograting shows the strong angle-sensitivity with the red shift of the EOT (red box region in Fig. 1(a)). For the design of a finite Ag EOT nanograting with strong angle-sensitive cavity resonance, lowpass (Fig. 1(b)) and bandpass (Fig. 1(c)) spatial filtering is achieved at the different resonance wavelengths, respectively.

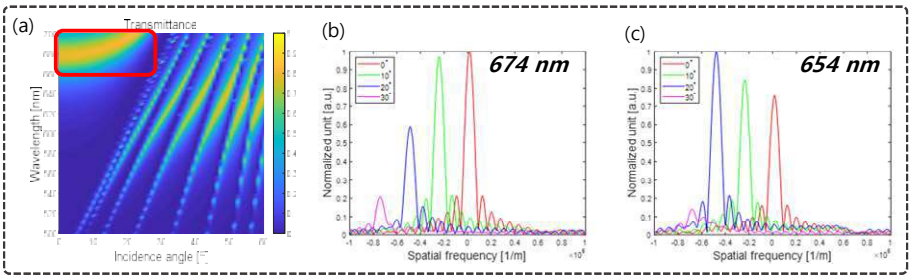

Figure 1. (a) Angle sensitive EOT spectrum. (b) lowpass and (c) bandpass spatial filtering at the wavelengths of 674 and 654 nm, respectively.

Abstract: We demonstrate a rapid and programmable amplitude modulator based on the thermo-optical effect by integrating transparent conducting oxide micro-heaters with metasurfaces. The system exhibits sub-millisecond rise-time and 9 folds of amplitude modulation.

Metasurfaces have attracted much interest recently because of their exceptional light-scattering properties, thanks to their ability to manipulate light-matter interaction through their geometrical parameters and material properties. Currently, there is a quest to enable dynamic tuning of metasurface properties, particularly with fast tuning rate and programmable across multiple pixels [1]. However, the fixed geometry of the metasurfaces has been an obstacle to the tunability of their scattering properties.

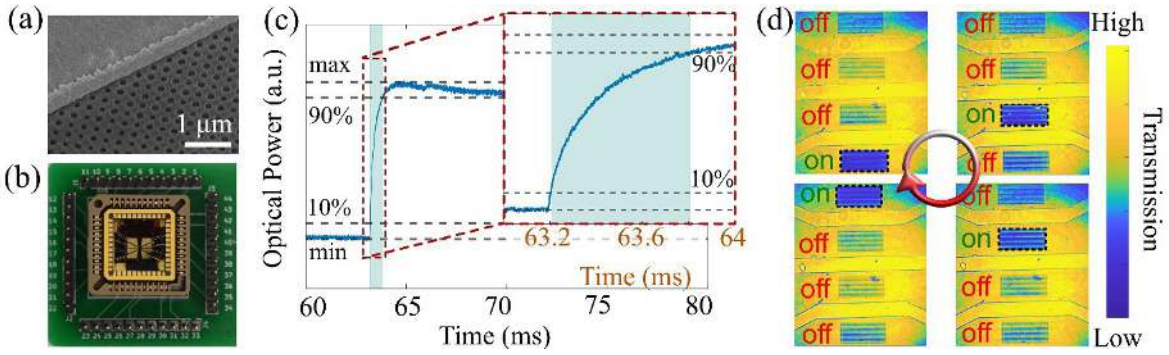

Fig. 1 (a) SEM of the Si hole-array metasurface embedded in ITO. (b) Picture of the printed circuit board (PCB) used for programming and electrically driving the metasurface. (c) Transmission intensity rise-time after electrically biasing the system. Insert is the magnified plot, indicating the switching rise-time (d) Addressable tuning of individual metasurfaces by controlling the micro-heaters.

Here, we demonstrate electrically tunable metasurfaces driven by thermo-optic effect and flash-heating in silicon [2]. Our device consists of a silicon hole array metasurface encapsulated by transparent conducting oxide as a localised heater (see Fig. 1a,b). We show a 9-fold change in transmission by < 5 V biasing voltage and the modulation rise-time of < 625 µs., which is about 20-fold faster than biasing the system with a step profile voltage

(Fig. 1c). As can be seen in Fig 1d, this method enables programming the spatially individual metasurfaces, on-demand. Some of the advantages of the proposed tuning method compared with other methods are the possibility to apply it for modulation in the visible and near-infrared region, large modulation depth, working at transmission regime, exhibiting low optical loss, low input voltage requirement, and operating with higher than video-rate switching speed. The device is furthermore compatible with modern electronic display technologies and could be ideal for personal electronic devices such as flat displays, virtual reality holography and light detection and ranging, where fast, solid-state and transparent optical switches are required.

Investigation of Field Effect Tuning of Refractive Index in Transparent Conducting Oxide Thin Film Fabry-Perot Cavity Structures.

Evan Roy[1], **Nishtha Shelly**[1], **Chris Murray**[1], **David McCloskey**[1]

[1]School of Physics, CRANN and AMBER, Trinity College Dublin, Dublin 2, Ireland

eroy@tcd.ie

Abstract: Electrical tuning of transparent conducting oxides (TCOs) can result in unity order change in refractive index at visible and NIR frequencies by blue shifting the plasma frequency ω_p within an interfacial accumulation layer. We used the Transfer Matrix Method (TMM) in MATLAB to simulate TCO heterostructures based on metal-insulator-metal (MIM) Fabry-Perot (FP) cavities. Our results demonstrate that large changes in transmitted and reflected light are achievable in MIM heterostructures in the visible at low voltages in the surface normal geometry.

Summary: A typical MIM FP device will have a thin transmissive metal on top to allow light in and another metal on the bottom to form two reflective surfaces. Different insulating or conducting layers can be added in between to manipulate the confined modes as well. By manipulating the thickness of these layers, one can fine tune the frequencies of the resonance modes and the internal field in the cavity. By simulating with the TMM in MATLAB we can predict the spectra of our heterostructures and fine tune them accordingly [1,2].

The placement of ultrathin (less than 10nm) absorbers like Mo, MoS_2, and Cr in the central high intensity region of the dielectric spacer helps to sharpen the MIM FP cavity resonance mode via coupling it with an additional absorption band. Mo and Cr are among the best broadband absorbers in the visible, reducing reflectivity and transmittance evenly across this range as a result. See figure 1(A, B). The idea of sharpening and suppressing higher order optical resonances using this particular MIM structure is based on the work of Korean researchers Junho Lee and Kyu-Tae Lee, among others, looking at high-color-purity structural color filters in transmittance and reflectance [3,4].

Indium tin oxide is a well-studied TCO that has shown promise in many different optoelectronic applications, including large field effect refractive index change. Recent literature has reported on unity order change in the local refractive index of ITO by applying an electrical bias up to 2.5 V across a metal-oxide-semiconductor (MOS) structure [5]. By applying a bias, an accumulation layer is created at the ITO-dielectric interface where the charge carrier density n can increase by factor of 10. Higher initial doping levels in the ITO shifts the strong refractive index change from the NIR to the visible range, creating greater sensitivity in the permittivity ε of ITO below 700 nm. See eq.(1) and figure 1(B, C).

$$\varepsilon = \varepsilon_\infty - \frac{\omega_p^2}{\omega^2 + i\omega\Gamma}; \quad \omega_p^2 = \frac{ne^2}{\varepsilon_\infty m^*} \tag{1}$$

Although a large change in the local refractive index is possible, the accumulation region in which this occurs is localized to within ~5nm of the ITO-oxide interface and is spatially characterized by a Poisson distribution. To create a large change in transmission or reflectivity upon bias there are two strategies that we used in tandem. The heterostructure can be optimized to enhance the matter light interaction by coupling an FP cavity mode to the absorption band of the central metal layer, and additional ITO and insulating layers can be added to multiply the effective shift in the spectra as shown in figure 1(E, F).

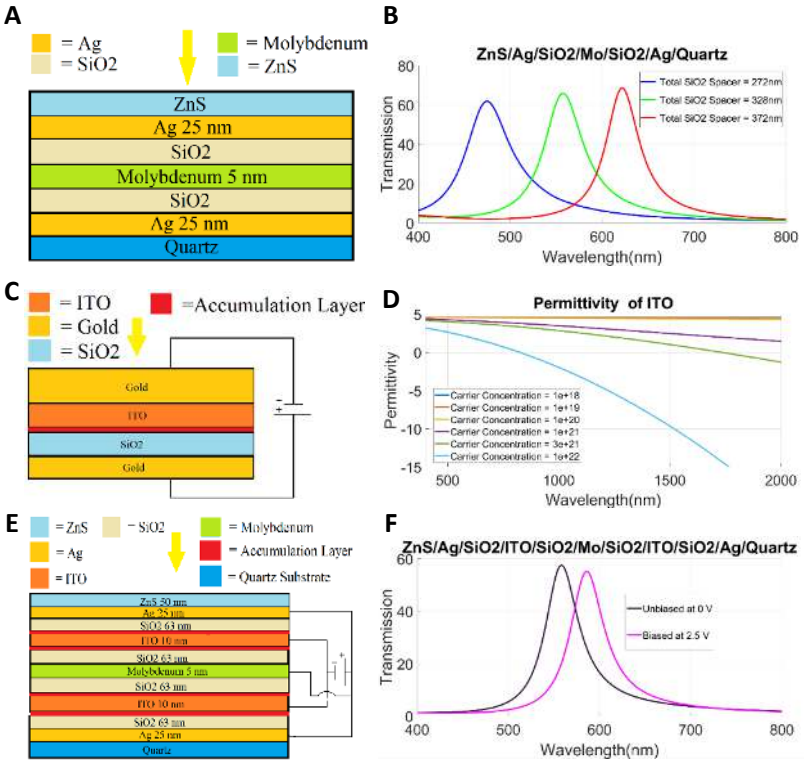

Figure 1(A, B). A MIM heterostructure with a 5 nm Mo layer central absorber. By changing the dielectric SiO_2 spacer thickness, the resonance peak position can be controlled. The result is a structural high-purity transmission filter, which can have useful applications in RGB display technology. Figure 1(C, D). The real permittivity of ITO in a MOS device relative to wavelength and carrier concentration as derived from the Drude-Lorentz model shown in equation (1). Changing n from $10^{21} - 10^{22}$ cm^{-3} creates a large change in ε in the accumulation layer in the visible range [5]. Figure 1(E, F). Simulated spectra of a large MIM FP heterostructure using a quartz substrate. The spectrum shifts when biased allowing for large change in transmission around the resonance mode peak.

Optical Metasurfaces for Grafted Vortex Beams Generation

Hammad Ahmed[1*], Muhammad Afnan Ansari[1], Xianzhong Chen[1]

[1]Institute of Photonics and Quantum Sciences, School of Engineering and Physical Sciences, Heriot-Watt University, Edinburgh, EH14 4AS, UK.

Abstract: Inspired by plant grafting, the act of placing a portion of one plant (scion) on a branch or root of another (rootstock), grafted vortex beams (GVBs) can be formed through grafting two or more helical phase profiles of optical vortex beams. GVBs have attracted much attention due to their unique optical properties and potential applications. Here, we propose and demonstrate the coaxial superposition of GVBs without relying on the complicated optical setup. The coaxial superposition of GVBs can generate asymmetric singularity distribution, which can be modulated by introducing an initial phase difference in the metasurface design. Our work has provided a compact metasurface approach to complete the sophisticated task that is extremely challenging or impossible with conventional optics, opening opportunities for the study and applications of GVBs in a wide range of areas.

In conventional optical vortices, the OAM distribution on the doughnut-shaped intensity ring is uniform. This uniformity is not suitable for applications where versatile OAM distributions are required, e.g., multiparticle trapping and manipulation. Therefore, noncanonical optical vortices (non-uniform hollow circular OAM distributions, spiral OAM distributions)[1] are proposed to tackle these challenges. However, these OAM distributions are strongly dependent on the intensity and the local OAM modulation is impossible. A GVB, which is generated through grafting two or more spiral phase profiles of optical vortex beams, has a controllable OAM distribution and constant intensity. Recently, GVBS have attracted much attention due to their unique optical properties (e.g., versatile OAM distributions) and potential applications (e.g., more options for particle manipulation) [2]. However, the generation and manipulation of GPVBs are more challenging and complicated due to the involvement of an additional phase profile of a lens and that of an axicon. The optical setups currently being used for generating GPVBs are complex, requiring numerous optical components, including spatial light modulators, lenses, pinhole filters, polarizers, and dichroic mirrors, which result in large space requirement and high cost[3, 4]. These optical systems are impractical for many applications, and hence there is a pressing requirement for a compact, simple, and efficient approach to generating and manipulating GVBs.

To tackle the fundamental and technical challenges in more conventional optics, we propose and experimentally demonstrate (as shown in Figure 1) a metasurface-based approach to generating and manipulating GVBs. To the best of our knowledge, this is the first time that a single metasurface has been used to generate various GPVBs and realize the coaxial superpositions, without relying on the complex conventional optical setup. The uniqueness of this method is that the superimposed GPVBs have nonuniform OAM and asymmetric singularity distributions, which can be modulated by introducing initial phase difference in the metasurface design. The proposed metasurface approach can facilitate system integration and device miniaturization and has strong potential for novel applications that may not be possible with conventional optics.

Abstract: A High Impedance Surface (HIS) metasurface has been designed to be combine with patch-based antennas to improve their radiation properties for the Electronic Travel Aid (ETA) application for which they are intended. A wearable patch and patch-HIS arrays antennas have been designed *ad hoc,* in the 24.05-24.25GHz frequency band. In order to evaluate the performance of the antennas, electromagnetic images have been obtained and a metric have been applied to compare their quality and evaluate their behavior for the application.

The traditional travel aids used by visually impaired people have been the white cane and the guide dog. However, these solutions are not enough for autonomous mobility. In this context, it seems that millimeter wave radars may be appropriate for obstacle detection, due to its great development in recent years and the relatively high frequency in which this technology operates, which allows obtaining compact radar modules. In order to improve the performance of the antennas (e.g., front-to-back ratio, gain, etc.), antennas surrounded by HIS unit cells have been proposed [1]. In this work, the effects of these nonideal radiators are analyzed for a short distance avoidance collision application. Electromagnetic images will be obtained by a flexible sum-and-delay algorithm:

$$\rho(\vec{r}) = \sum_{m=1}^{M}\sum_{n=1}^{N} S_r(m,n)\cdot e^{jk_m 2|\vec{r}-\overrightarrow{r_n}|} \quad (1)$$

Sr refers to the acquired data, *M* stands for the number of frequencies while *N* indicates the acquisition points. *km* represents the wavenumber at the m-frequency, $\vec{r}$ indicates the pixel where the reflectivity is going to be calculated and $\overrightarrow{r_n}$ refers to the n-measured position. This algorithm assumes that a perfect spherical wavefront is employed for calculating the reflectivity. However, if the waves are not created from the same position, dispersive behavior along frequency is expected, producing unwanted artifacts in images.

The performance of patch-based antennas, all of them designed in RO3003, have been analyzed for this application. A simple patch antenna (*Patch*), a two-element patch array with a wall of HIS unit cells between its elements to reduce the coupling (*Array-HIS Wall*) and including a row of unit cells surrounding the patches to reduce the possible surface waves (*Array-HIS Row*) have been evaluated. The fabricated prototypes are shown in Figure 1a. TABLE 1 summarizes the radiation properties of each antenna for the center frequency of the operating bandwidth. More details about the antennas and metasurface design can be found in [1].

Electromagnetic images have been obtained from a monostatic set-up (see Figure 1b). A simple target has been employed, as this kind of objects provides a simple response, which facilitates the analysis of the results. In this work a metal strip of 4x340mm is used as the target. It is placed over the antenna at a distance of 13.2cm, so that far-field conditions are met. The synthetic aperture length is set in 30 cm in the direction of the x-axis (see Figure 1b) and the sampling step has been established in order to satisfy the Nyquist theorem (~λ/4 at 24.25GHz). The data have been acquired with a Vector Network Analyzer (VNA) simulating a step-frequency continuous wave (SCFW) radar. Figure 1c, d and e show the electromagnetic images obtained with each antenna, where the contour of the object has been highlighted in magenta. In order to quantitatively compare the quality of the images

their entropy (IE) have been calculated according to [2], and the results are indicated in TABLE 1. The smaller the entropy value, the better quality of the image. It can be concluded that all the antennas detect the target (see Figure 1c, d and e). The *Array-HIS Row* design, which reduce the coupling between the array elements, improves the IE result with respect to the simple *Patch*. As it can be observed in Figure 1d, the spread energy around the target is lower than the other cases. However, surrounding the array by a row of unit cells does not improve the IE result obtained with the *Wall Array-HIS*, although it performs better than the *Patch*. Therefore, few unit cells in the middle of the array elements contribute to reduce the coupling between them, modifying the radiation diagram of the antenna, so that a better performance is reached for this application.

TABLE 1. Simulated and measured radiation properties of the antennas and TCR results.

	Simulated				Measured	IE
Antenna	G [dB]	D [dB]	η [%]	FTBR [dB]	G [dB]	
Patch	6.8	6.8	100	20.2	7.4	6.9
Array-HIS Wall	8	8	100	24.8	8.5	6.5

Silicon metalens using Fresnel zone plate with subwavelength gratings

W. Fraser[1*] and W. N. Ye[1]

[1]Silicon Micro/NanoPhotonics Group, Carleton University, Ottawa, Canada

Abstract: Beam focusing metalenses have become an enabling technology for flat optic-integrated imaging and free-space communication systems. Traditional metalenses comprised of periodically arranged subwavelength building blocks rely on custom fabrication practices. We present a 500 nm silicon-on-insulator-compatible metalens based on the Fresnel zone plate capable of subwavelength focusing with a peak efficiency of 42.7% over a 389 nm bandwidth in the *C*-band.

Summary: All-dielectric metasurfaces [1-4] have attracted great interest for imaging and free-space communication applications. Typical beam focusing metalenses form a hyperbolic phase profile spanning the 0 to 2π range which converts planar wavefronts into converging spherical waves. This is achieved by varying the geometrical properties of subwavelength scattering elements arranged in a periodic array [5-18]. Phase accumulation requires lens thicknesses that are close to the operating wavelength [17] unless complex resonances are exploited, sacrificing the bandwidth [18]. Consequently, conventional all-dielectric focusing metalenses are incompatible with public silicon-on-insulator (SOI) foundries which slows integration with photonic systems. In this work [19], we present the design and simulation of a novel compact metalens that can be fabricated with a single full etch step on the 500 nm SOI platform. The proposed design uses silicon subwavelength grating (SWG) structures to form a binary phase Fresnel zone plate (BPFZP) that produces a subwavelength focal spot across the *C*-band.

The binary phase Fresnel zone plate consists of a set of concentric annular regions forming a circular aperture. The radii of these so-called Fresnel zones are calculated a focal length, f, and the wavelength, λ, using equation 1 [20]:

$$r_n = f\sqrt{\frac{n\lambda}{f} + \left(\frac{n\lambda}{2f}\right)^2} \tag{1}$$

where n is an integer representing the order of the zones counting out from the center of the aperture. The radii are such that the optical path length difference to the focal point between adjacent zones is a half-wavelength. Introducing a phase profile that alternates between 0 and π according to the Fresnel zones produces constructive interference at the focal point.

A diagram of the proposed design presented in this work is shown in Figure 1. Trapezoidal segmented subwavelength gratings [21] are etched into the even-numbered Fresnel zones to spatially vary the equivalent refractive index over the surfaces of the lens.

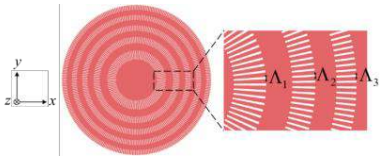

Figure 1. Top-view diagram of our proposed binary phase Fresnel zone plate using subwavelength gratings.

The duty cycle of the subwavelength gratings is optimized to satisfy the binary phase profile of the Fresnel zone plate. The circular symmetry of the lens enables polarization-insensitive operation. Near diffraction-limited focusing is demonstrated in simulations over a 389 nm bandwidth with a peak focusing efficiency of 42.7%.

Abstract: We propose and experimentally demonstrate a programmable matrix computation in the optical domain using a spatial light modulator (SLM) and a metalens array. Our scheme encodes the programmable matrix to the metalens array by superimposing multiple phase gradients. Meanwhile, the SLM produces a phase-controlled spatial illuminated light which acts as our input vector. Then, the result can be extracted from the far-field interference pattern constructed by different metalenses using a pattern recognition method.

Introduction

Over the past decade, metasurfaces have shown remarkable capabilities in wavefront manipulation for various optical applications. Metalens, one of the metasurface applications, enables focusing at multiple points in space unlike conventional lens. Recent works in the field include tunable metalens [1,2], applications for imaging [3], spectroscopy [4], and quantum source generation [5]. Our work demonstrates the programmable capability of metalens array for optical matrix computation. We use a geometric-phase metasurface to realize our metalens array, which encodes specific matrix operations simultaneously. Our implementation utilizes phase-modulated light as the input vector, and the resulting vector can be obtained by analyzing the interference pattern formed on the camera. Our demonstration of optical matrix computation can be developed for more sophisticated applications, such as neural network computation at the speed of light, which involves larger-sized matrices.

Programmable metasurface

Fig. 1 illustrates the scheme for optical matrix computation using a metalens array. A Spatial Light Modulator (SLM) is used to selectively illuminate the area on the metalens array using phase gradient and encodes the input vector as different phase profiles. Then, the metalens array transforms the input vector with the transform matrix, and the resulting vector can be obtained from the far-field interference pattern using a pattern recognition method.

Programmable operations can be achieved by choosing which lenses to excite with corresponding the input amplitudes and phases. For example, we have designed a metalens array that by exciting the 2-by-2 upper left lenses, we can get a Grover-search operation. On the other hand, by exciting the 2-by-2 bottom left lenses, we can get a 4-bit FT operation.

Our metasurface design is composed of a 3-by-3 lens array which acts as 9 different input ports. Each metalens can deflect the beam to 9 output ports (3-by-3 spots in the far field) with designed amplitude and phase. Therefore, our system is a 9-by-9 programmable matrix transformation via setting the entries of the transform matrix T. Eq. (1) gives the complex profile of our metasurface design.

$$E_i(x,y) = \sum_j T_i^j \exp\left[ik_x^j\left(i\left(x-x_i\right) + ik_y^j\left(y-y_i\right)\right)\right] \exp\left[i\,k_0\sqrt{\left(x-x_i\right)^2+\left(y-y_i\right)^2+f^2}\right] \quad \textbf{(1)}$$

Here, i denotes input lens index and j denotes the output port index. The origin for each lens is given by the coordinate (x_i, y_i), and the target deflection angle or far-field output port coordinate is related by $\left(k_x^j, k_y^j\right)$. Additionally, we also added a focusing profile with a focal length f to facilitate the limited numerical aperture of the objective lenses. The transform matrix T, which encodes both Grover-search and FT operations at once, is given by Eq. (2).

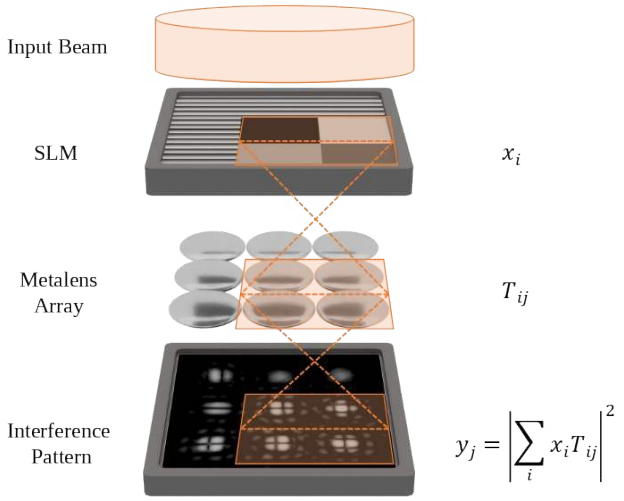

Figure 1. Schematic for optical matrix computation using metalens array for 4-bit Fourier transform computation.

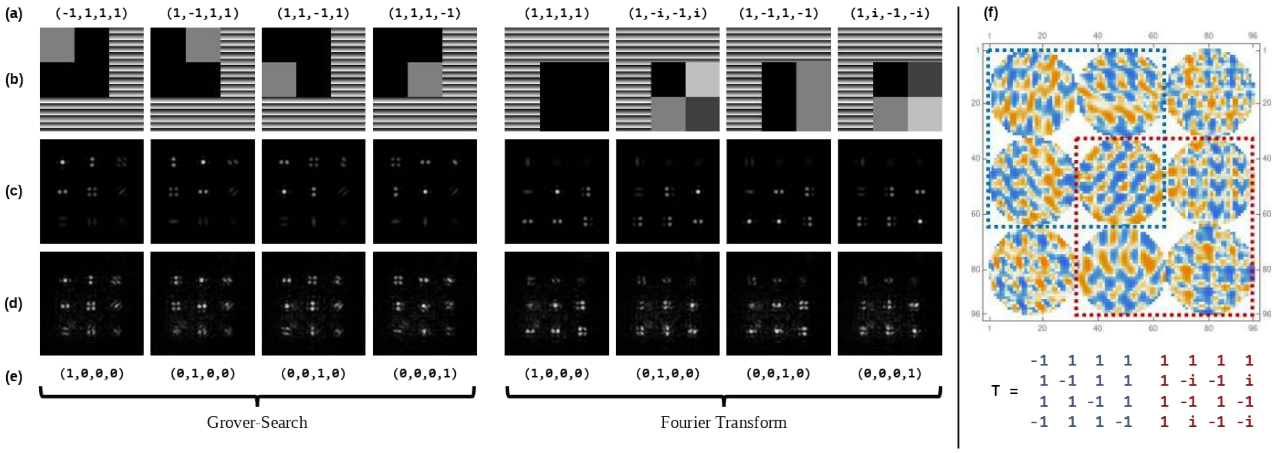

Figure 2. Experimental result for optical matrix computation using a programmable metalens array. (a) Input vector; (b) encoded SLM phase profile; (c) simulated far-field interference pattern; (d) experimental result; (e) normalized output vector (f) 96x96 unit cells metasurface design and transformation submatrices (blue: Grover-search, red: Fourier transform).

$$T = \begin{pmatrix} -1 & 1 & 1 & 1 & 1 & 1 & 0 & 0 & 0 \\ 1 & -1 & 1 & 1 & 1 & 0 & 1 & 0 & 0 \\ 1 & 1 & -1 & 1 & 0 & 0 & 0 & 0 & 1 \\ 1 & 1 & 1 & -1 & 1 & 0 & 0 & 1 & 0 \\ 1 & 1 & 0 & 1 & -1 & -1 & -1 & -1 & -1 \\ 1 & 0 & 0 & 0 & -1 & -i & 1 & 1 & i \\ 0 & 1 & 0 & 0 & -1 & 1 & -1 & -1 & 1 \\ 0 & 0 & 0 & 1 & -1 & 1 & -1 & -1 & 1 \\ 0 & 0 & 1 & 0 & -1 & i & 1 & 1 & -i \end{pmatrix} \quad (2)$$

The blue entries indicate the relevant submatrix for the Grover-search matrix, whereas the red entries indicate the submatrix for Fourier transform.

Experimental results

Fig. 2 shows the simulated and experimental result for different input vectors. Each column represents different input vector bases displayed by the SLM. After the transformation, the expected normalized output vector is either 1 or 0, corresponding to constructive or destructive interference at the center of each far-field spot. Constructive interference is represented by a single spot (bright center), while destructive interference is represented by multiple spots (dark center). In our experiment, we use a Single Photon Avalanche Diode (SPAD) camera to capture the interference patterns and analyze them to determine the output vector.

As an example, the first column in Fig. 2 is to illustrate one Grover-search operation, which is to find which variable in the input vector having an extra pi phase. In this case, we can focus only on the top-left part of the metasurface. We first encode the input vector $x = (-1,1,1,1)$ by taking its argument as the SLM phase profile. Then, we observe the patterns on the far field as: one constructive interference, followed by three destructive interference patterns; which yields the output vector $y = (1,0,0,0)$. For other input beams, we can determine the output vector by measuring the intensity at the center of each spot or by analyzing the interference pattern.

Conclusion

In conclusion, we experimentally demonstrate an optical matrix computation scheme using SLM and geometric-phase metalens array. The result can then be obtained by analyzing the interference pattern observed on the camera. Lastly, this scheme introduces the powerful capability of metasurface to the optical computational field. With a larger and more efficient metasurface, scaling up the size of the vectors will be possible, and further extension of this scheme can be applied for optical quantum computation and optical neural network.

Switching of Phase-Change Optical Metasurfaces via Remote Thermal Sources

G. Braid[1], C. Ruíz de Galarreta[1,2], A. Comley[3], J. Bertolotti[1], C. D. Wright[1*]

Abstract: The application space for optical metasurfaces is increased if they are actively controllable. This can be achieved by including a phase-change material, whose optical properties can be changed by thermal stimuli. Such stimuli are often provided by laser excitation of the metasurface, or by embedded micro-heaters within the surface. Some metasurfaces may however not be suited to such approaches. In this work we explore the provision of suitable stimuli using a thermal source that is physically remote from the metasurface.

Metasurfaces offer precise control of optical wavefronts, which has led to the development of compact optical devices for applications such as perfect absorbers, polarisers, beam deflectors, holograms, and lenses, to name but a few [1,2]. The range of possible applications is further expanded if the metasurface can be actively controlled. Many methods have been explored for achieving this control, and one of the most promising is the incorporation of a chalcogenide phase-change material (PCM) layer in the design [1].

Chalcogenide PCMs have two solid phases—amorphous and crystalline—with substantially different physical properties. Both phases are stable at room temperature, and each can be switched to the other by a thermal stimulus [1]. The switching of PCM regions embedded within optical metasurfaces is not, however, always straightforward. For certain designs, direct laser excitation of the metasurface may not be feasible (e.g., in cases where the PCM layer/region is embedded within other materials that absorb strongly at the laser excitation wavelength). Similarly, the integration of micro-heaters into some metasurface designs can pose a significant engineering challenge. Here, therefore, we explore an alternative approach, that of switching PCM-based metasurfaces via a thermal source that is physically remote (separated) from the surface itself.

Han et al. [3] recently demonstrated fan-shaped thermal metamaterial-type heat guide structures that can provide near-uniform heating over extended regions by directed conduction of heat from a remote source. Although Han's designs were on the macroscale (sizes in the cm range), the approach is readily shrunk down to the microscale, as shown in Figure 1. Indeed, similar control and transfer of heat from a remote source can be obtained using considerably simpler structures, ones potentially more suited to use with typical PCM metasurfaces. In Figure 2, for example, we show a design in which the heat sources are linked to a central metasurface-containing region by four straight metal (here tungsten) arms. Upon exciting the end of one or more of these arms using a laser pulse, heat is conducted to the metasurface and, with appropriate design, sufficiently high temperatures and cooling rates can be obtained for successful crystallisation and amorphisation of commonly used PCMs.

In summary, in cases where direct heating of a PCM metasurface is not straightforward, we have shown that switching of the PCM layer/region can be achieved by heat conducted from thermal sources placed remotely from the metasurface itself. Various devices based on this concept of the switching of PCM metasurfaces via remote thermal sources are in the process of being fabricated and experimentally characterised.

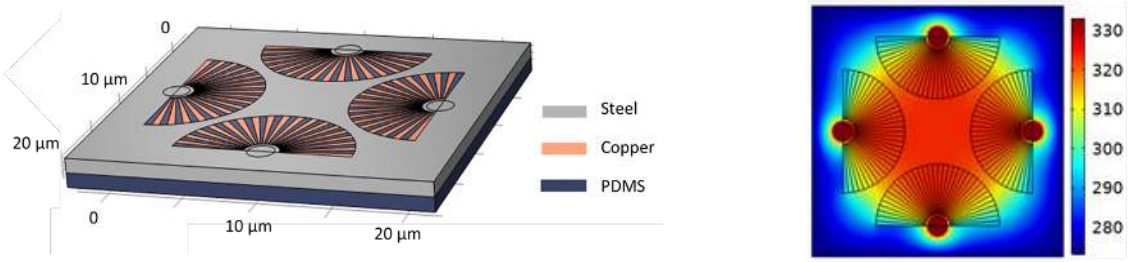

Fig. 1. (a) The fan-type thermal metasurface design from Han et al. [3] shrunk down to the microscale and providing uniform heating from remote heat sources (located in the circle at the base of each fan). (b) Finite-element (Comsol) simulated heat distribution for the structure in (a) with the heat sources assumed at a constant temperature of 333 K.

(a) (b)

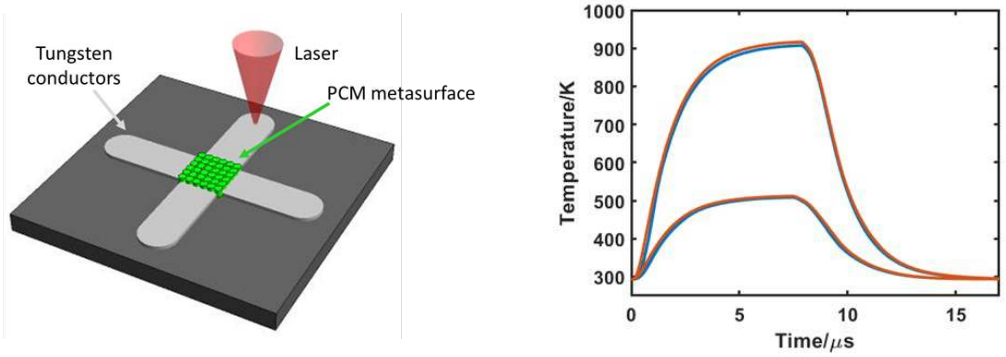

Fig. 2. (a) Schematic of a simplified structure for switching of a PCM metasurface via remote thermal stimulation. Lasers incident at the ends of the arms supply the heat needed to switch PCM. (b) Finite element simulation (Comsol) of the heating of a $Ge_2Sb_2Se_4Te_1$ (GSST) PCM metasurface (of the type used in [2]) via remote thermal excitation using a 400 nm laser. Temperatures suited to both fast crystallisation and to melting can be reached with practicable values of laser power. Moreover, cooling post-melting is relatively fast, implying successful amorphisation is achievable (for GSST) with the remote heating approach. Red and blue lines show maximum and minimum temperatures in the GSST regions of the metasurface (their closeness indicating uniformity of heating achieved).

Abstract: We present an integrated platform for ultrasensitive in-situ biospectroscopy by combining all-dielectric pixelated metasurfaces and machine learning. Specifically designed metasurfaces with advanced sampling techniques probe the real-time dynamics of lipid membrane photoswitching in an aqueous environment in the mid-infrared, overcoming sensitivity limitations and strong water absorption associated with conventional infrared spectroscopy. Our platform combines metasurfaces, optofluidics, and artificial intelligence (AI) to extend the capabilities of dielectric metasurfaces for analyzing complex biological entities.

Surface-enhanced infrared absorption spectroscopy (SEIRA) is an important method for studying the molecular composition of analytes, overcoming the challenges due to the size difference between mid-infrared (mid-IR) wavelengths and nanometer-scale molecules [1]. While previous SEIRA implementations based on plasmonic resonators can suffer from Ohmic losses, emerging directions involve the use of all-dielectric nanostructures that support bound states in the continuum (BICs) to enhance sensitivity. BIC-driven metasurfaces with ultra-sharp high-Q resonances enable precise control over resonance position, line width, and magnitude of near-field enhancement [2]. By implementing such metasurface approaches in a pixelated arrangement for molecular barcoding [3], an unambiguous mapping between spectral information and spatial information can be created.

This technique allows the imaging-based readout of biomolecular fingerprints, which could aid in the study of the photoisomerization dynamics and interactions between synthetic photoswitchable lipids, or photolipids, and other membrane components in a supported lipid bilayer (SLB) setting without the requirement of an additional spectroscopic label. Photolipids, which contain an azobenzene unit in the lipid tail, allow the reversible control of membrane properties, such as bilayer fusion [4]. Machine learning models have demonstrated great potential in addressing the complexity of data analysis in metasurface-enhanced bioanalytical studies [5].

Our integrated platform combines metasurfaces, optofluidics, and AI for the in-situ real-time investigation of the composition and switching dynamics of photoswitchable lipid membranes (**Figure 1**). We engineered all-dielectric metasurfaces that support high-Q BIC resonances in an aqueous environment in the mid-infrared to enhance the capabilities of studying the minute spectroscopic absorption variations between the two photolipid membrane states, trans and cis, such as around 1735 cm^{-1}. Furthermore, machine learning was implemented for rapid and reliable data analysis and optimization of the metasurface design.

By adapting the metasurface based on the AI model results, the integrated platform can be tailored to other molecular analytes, allowing for the study of more complex molecular systems and processes in biology and environmental monitoring.

Tuning optical properties of individual Sb_2S_3 nanostructures

P. Kepič[1,2*], P. Liška[1], B. Idesová[1], F. Ligmajer[1,2], and T. Šikola[1,2]

Abstract: Phase-change materials represent one of the main directions toward tunable nanophotonic devices. Even though a phase-changing antimony trisulfide (Sb_2S_3) has recently received tremendous attention due to its low absorption in the visible and near-infrared spectral region, its crystal phase transition is still not fully understood, especially at the nanoscale. Here, by observing the tuning of the optical properties of individual Sb_2S_3 nanostructures, we want to explain the gradual tunning of the future Sb_2S_3 metasurfaces.

Antimony trisulfide (Sb_2S_3) is a non-volatile phase-change material that goes through an amorphous–crystalline transition (~250°C) that can be achieved by simple heating and crystalline–amorphous transition (~600°C) that is based on a very fast (~10°C/ns) melt-quench process achieved by high-energy pulses [1]. Its most significant advantage lies in its lowest absorption and relatively large refractive index modulation in the visible and near-infrared spectral region. While several articles report tunable (multi-function) metasurfaces by continuously changing the phase of this or other phase-change materials [2, 3], those that describe if the tuning takes place at the nanostructure or is an average behavior of an array are missing. Observation of the transition in single and arrayed Sb_2S_3 nanostructures would help us better understand the phase transition process and its influence on the optical properties at the nanoscale.

First, we deposited a 160 nm Sb_2S_3 thin film on a fused silica substrate using a pulsed laser deposition. Before the investigation and crystallization, the film was coated by approx. 15 nm Al_2O_3 protective layer, using atomic layer deposition to prevent contamination and sulfur loss. The film was gradually crystallized on a 250°C hot plate and investigated in 30 s steps from amorphous to crystalline phase using microscopy images and spectroscopic ellipsometry. We observed a clear gradual crystallization during six crystallization steps (in 180s; see Figure 1a), where already after 60 s, more than 50% of the film was crystallized (Figure 1b). From the spectroscopic ellipsometry, we obtained the refractive index and absorption coefficient of each of these intermediate states (Figure 1c). Note that effect of individual anisotropic crystals is considered to be averaged. For the refractive index at 633 nm wavelength, we obtained the same S-shaped behavior as in the crystallized area graph (Figure 1b), in which curvature is most pronounced around 60 s of crystallization.

Using these gradually crystallized refractive indices, we simulated single scattering and absorption cross-section of Sb_2S_3 nanocylinders using FDTD simulation. In Figure 1d, we can see that the Mie resonance peak of the nanocylinder with a 200 nm diameter is transferred from one to the other when the film is continuously crystallized. However, this is just a simulation, and we would like to know if we can measure such gradual crystallization in individual Sb_2S_3 nanostructures. We fabricated single Sb_2S_3 nanostructures and nanostructure arrays in the same deposition process (160 nm film and 17 nm protective layer) to verify this hypothesis. We are about to crystallize and measure these nanocylinders using dark-field reflection spectroscopy. Whether the result is positive or negative, it will give a better inside into the crystallization process of phase-change tunable metasurfaces and ultimately improve such devices.

Efficient broadband mid-infrared linear-to-circular polarization conversion using a nanorod-based metasurface

H. Zou*, and G. R. Nash

Natural Sciences, University of Exeter, United Kingdom
*corresponding author: hz358@exeter.ac.uk

Abstract: In this work a nanorod-based metasurface is experimentally demonstrated to exhibit broadband linear-to-circular polarization conversion in the mid-infrared region of the spectrum. Measurement of the Stokes parameters confirms reflected light is circular polarization with average axial ratio of 0.75 across broadband from 3.5μm to 7.5μm. Such metasurfaces could not only replace conventional quarter wave plates, but also be used for circular dichroism spectroscopy allowing the characterization of important chiral molecules.

Circular polarization light is particularly useful for infrared circular dichroism spectroscopy. Under illumination with circularly polarized light, chiral molecules absorb different amounts dependent on their handedness, and important information about the structure of chiral biomolecules, such as proteins, can be obtained without labeling the analytes. This is particularly useful if this effect can be exploited in the infrared region of the spectrum, where many important biomolecules have strong vibrational fingerprints [1]. However, traditional quarter wave plate have fundamental problems including bulky size, single operating wavelength while metasurfaces have been investigated as a potential means of replacing bulk optic components due to their subwavelength thickness, and flexibly tailored operation wavelength. In addition, the strong near-fields associated with metasurfaces could also ultimately be exploited for high sensitivity biosensing.

Building on the work on metasurfaces for the terahertz region [2], a metasurface consisting of an array of nanorod resonators for efficient linear-to-circular convertor in the mid-infrared spectrum in reflection mode was investigated in this work [3]. Figure 1 (a) shows the schematic unit cell of metasurface with geometric parameters and a scanning electron microscope (SEM) photo of fabricated sample.

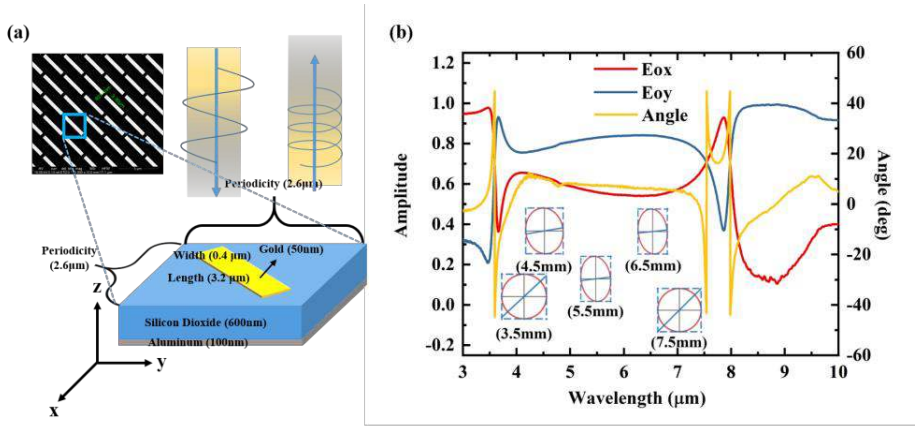

Fig. 1. (a) The schematic of one unit cell of nanorod-based metasurface. The device is placed on the x-y plane and light travels along z direction. Insert shows the SEM photo of fabricated sample. (b) Spectrum of ellipse parameters Eox Eoy and Angle of reflected beam. Inserts are polarization states of the beam at corresponding wavelength.

Samples were fabricated using electron beam lithography and characterized using a Fourier transform infrared (FTIR) spectrometer. The light source is filtered by a wire grid polarizer allowing only linearly polarized light to illuminate on samples. Reflected signal from the sample is collected by a liquid nitrogen cooled HgCdTe detector with a 2–12μm response at room temperature under ambient conditions. Ellipse parameters i.e. amplitude Eox, Eoy and Angle enabling to define the polarization of reflected beam can be calculated based on measured four Stokes parameters [4]. The calculated ellipse parameters as a function of wavelength is shown in Figure 1 (b). At resonances of 3.5μm and 7.5μm as indicated in inserts, the reflected beam is circular polarization with axial ratio of 1. The slope of Eox, Eoy and Angle show relatively flat features between 3.5μm and 7.5μm indicating that the polarization state keeps stable as elliptical with the evidence that the average axial ratio is 0.75. The insert ellipses show the polarization states are elliptical at 4.5μm, 5.5μm and 6.5μm, respectively. In conclusion, the rod-shaped metasurface features broadband linear-to-circular polarization conversion from 3.5-7.5μm. Compared with conventional bulky quarter wave plates, which only provide polarization conversion at a specific wavelength, the metasurface provides a working bandwidth of ~4μm, but with subwavelength thickness (~λ/4). Such metasurfaces could potentially be exploited for circular dichroism spectroscopy to characterize chiral molecules such as proteins in the mid-infrared region.

Complete linear control based on universal metasurfaces and their applications

Joonkyo Jung[1], Taeyong Chang[1], Sang-Hyeon Nam[1], Hyeonhee Kim[1], Jong Uk Kim[1], Nayoung Kim[1], Suwan Jeon[1], Minsung Heo[1], and Jonghwa Shin[1,*]

Abstract: By virtue of their high degrees of freedom in manipulating optical properties of an incident light such as amplitude, phase, and polarization, dielectric metasurfaces have attracted a lot of attraction from academia and industry. However, they still suffer from the lack of complete controllability of amplitude, phase, and polarization. Here, we have theoretically, numerically and experimentally proven that the complete linear control of those properties can be possible by using bi-layer dielectric metasurfaces, which we named universal metasurfaces.

During the last decade, metasurfaces comprised of arrays of nanostructures with subwavelength scales have attracted a lot of interest from both academia and industry because of their unnatural capability of controlling an incident wave. In particular, since dielectric metasurfaces have the advantage of higher transmission compared to metallic counterparts, and full 2π phase coverage over two different linear polarization states, many research groups studied dielectric metasurfaces for a variety of applications such as optical imaging, hologram, quantum photonics, and so on. However, the known metasurface technique still has limitations in the range of controllability and the complete control of amplitude, phase, and polarization all at once has not been demonstrated yet. In this paper, we proved that bi-layer dielectric metasurfaces, which we named universal metasurfaces, theoretically suffice to control the amplitude, phase, and polarization of the incident wave based on the Jones matrix analysis. To support this, we have conducted numerical simulations and experiments.

To begin with, we approached the extended controllability of universal metasurfaces using the analysis based on the Jones matrix, with which a single layer of dielectric metasurface can be approximated as a unitary symmetric matrix, U_S where U_S is a unitary symmetric matrix. By stacking two layers, a bi-layer structure is created and the Jones matrix at each position can be given as a unitary matrix, denoted as $U=U_{S,A}U_{S,B}$ where U is a unitary matrix and the subscript A and B represent bottom and top layers. In addition, based on the singular value decomposition, any arbitrary matrix can be decomposed into the sum of two unitary matrices, $A=1/2(U_1+U_2)$ where A is an arbitrary matrix, and subscripts 1 and 2 represent the position. To physically realize this matrix operation, we used spatial homogenization of two types of bilayer unit cell structures. The details of the structure are depicted in Figure 1(a). We have confirmed numerically that this suggested structure can achieve any Jones matrix as shown in Figure 1(b). Using the arbitrary Jones matrices that can be supported by universal metasurfaces, we have created novel hologram applications that surpass existing functionalities. As a representative example, two independent vector holographic images are presented in Figure 2, where a pseudo-color space is utilized to visually display complex polarization states.

In summary, we have established the theoretical, numerical, and experimental validity of universal metasurfaces. We hope that the exceptional controllability provided by our universal metasurfaces will lead to novel applications in many other research fields.

Abstract: Resistive frequency selective surface (FSS) based microwave absorbers have been widely reported but at lower frequency bands, reducing their unit cell size remains a challenge. In this paper, a resistive ink-based miniaturized passive metamaterial absorber is proposed for S- Band with stable absorption performance up to high oblique incidence angles. The periodicity of the unit cell is approximately λ/26 and the overall thickness is λ/20. The miniaturization of unit cell can be explained using effective medium theory.

The unit cell is based on a lossy cavity, in addition to conventional FSS. To fabricate the final prototype, resistive ink is to be coated on FR4 substrate stripes. The cavity can then be assembled by cutting narrow slits on these stripes and inserting them orthogonally through these slits to form a square shape. Resistive square ring metasurface patterns are printed separately and placed on the top of the cavities. A high absorption response is achieved which is stable up to 50º angle of incidence for both TE and TM mode. Use of spacing between FSS and ground plane reduces the periodicity as well as overall thickness of the absorber. Unlike conventional FSS, the resistive elements are designed on the transverse walls that ultimately results in an open cavity. This cavity-based structure is then merged with a resistive FSS top layer to control the resonance of overall structure. The unit cell diagram and absorption response for various oblique incident angles for TE mode are given in Fig 1.

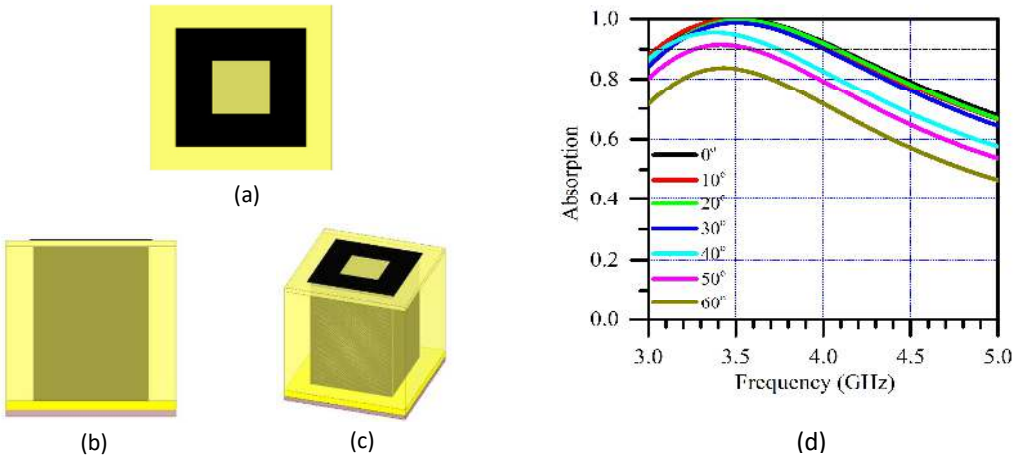

Fig 1: (a) Top view (b) Side view and (c) Perspective view of the miniaturized unit cell of the proposed microwave absorber for S-band and it's (d) Absorption response.

Metasurface-Based Radome for Wearable Antenna at 24GHz

M. E. de Cos Gómez[1*], A. Flórez Berdasco[1], and F. Las-Heras Andrés[1]

[1] TSC, Electrical Engineering Department. Universidad de Oviedo. Gijón, Spain
[*]corresponding author: medecos@uniovi.es

Abstract: A metasurface-based radome (metaradome) is designed to protect a wearable grid array antenna (GAA) for imaging applications in 24.05GHz-24.25GHz. It provides high transmission and low reflection within the GAA operation frequency band in a wide angular range under oblique incidence. The GAA with metaradome. preserves the GAA operation band and radiation parameters. The overall device' size is 40 x 40 x 3.162 mm^3. The envisioned application is collision avoidance in aid to visually impaired people at medium-long distance.

A radome should protect the antenna with minimal impact on its performance. Ideally it should be electrically invisible, that is, fully transparent and lossless. In practice a radome must ensure high transmission and low reflection and absorption within the antenna operation frequency band. In addition, radiation scattered from the radome may elevate antenna sidelobes, which can lead to reduction in gain and directivity. In recent years it has been proposed to use metasurfaces to be combined with radomes to reduce their negative effects on antenna performance, or even as radomes themselves [1], giving rise to the term metaradome or metadome [2]. In this work, a metasurface-based radome has been designed to be located much closer to the antenna than a radome of the same material and without degrading the performance of the antenna. In this way, the antenna is protected while maintaining a lightweight, compact and fully operational design for the intended application. Figure 1 shows the metasurface unit cell geometry and dimensions on RO3003 dielectric substrate, the simulation set-up using Floquet ports and master-slave boundary conditions and the retrieved transmission and reflection coefficient for both TE and TM polarized incident plane-waves. It can be highlighted that very high transmission and very low reflection is achieved in the band of interest (24.05GHz-24.25GHz), as intended.

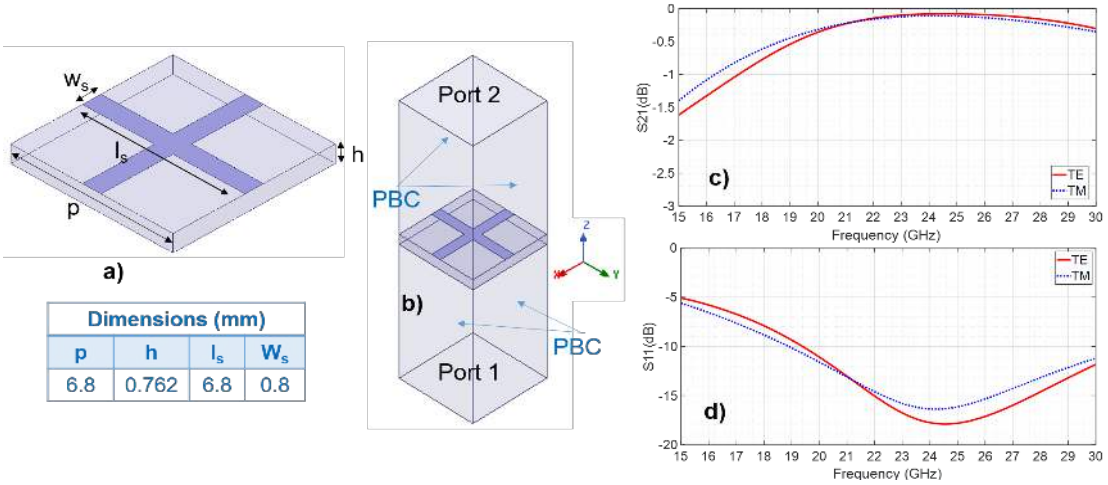

Figure 1. Metaradome: a) Unit cell; b) Simulation set-up; c) Transmission coefficient; d) Reflection coefficient

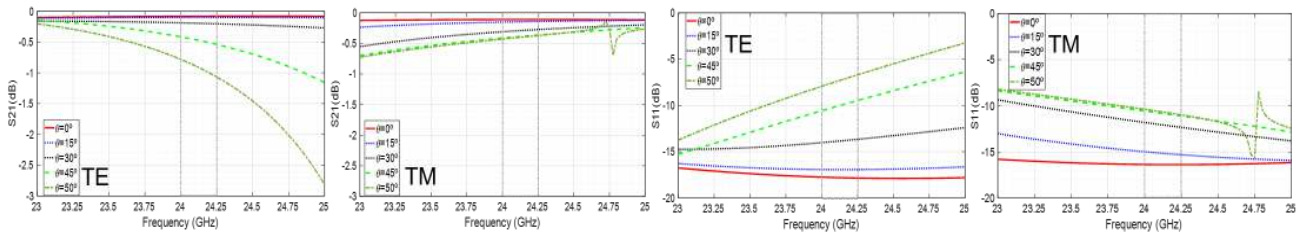
The angular stability of a metasurface usable as a radome is crucial. The designed metaradome is fully

angularly stable under oblique incident TE and TM polarized plane waves up to θ=45º and highly stable up to θ=50º, considering both transmission and reflection coefficients.



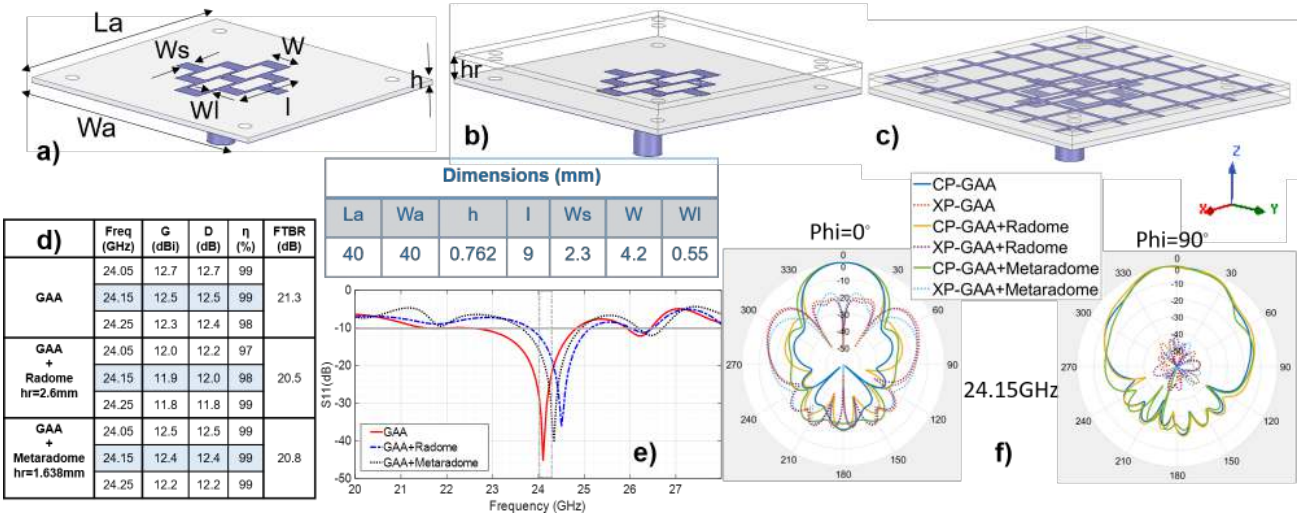


Figure 2. Angular stability of the metaradome for Phi=0º under TE and TM polarized incident plane waves

For the intended application a trade-off solution between-range and coverage area has to be adopted. A suitable Grid Array Antenna (GAA) [3] was designed on RO3003 substrate. In Figure 3 it can be observed that a metaradome can be arranged at closer distance from the GAA than a radome (1.638mm vs 2.6mm) and better preserving the operational properties of the GAA. Thus a protected and compact wearable antenna is achieved.

Active phase control with metasurfaces in the visible by electrochemistry

Junhyung Park[1], Min Gwan Jo[1], and Jonghwa Shin[1*]

[1]Department of Materials Science and Engineering, KAIST, Daejeon, Republic of Korea
[*]corresponding author: qubit@kaist.ac.kr

Abstract: Metasurfaces have been realized large control on properties of light, amplitude, phase, and polarizations with adequate design of meta-atoms. Nevertheless, such control is not yet fully achieved dynamically after fabrication. We show large dynamic change (over 180°) of phase of visible light with a single metasurface, which so far required the use of liquid crystals, based on simple electrochemistry. We believe our approaches will help realize dynamic beam control devices for visible light.

Temporal coupled mode theory, a simple and effective theoretical model for understanding optical scattering properties of resonators, provides viable design strategies for phase control of light with metasurfaces. ITO based active metasurfaces studies demonstrated that one resonator with background mirror can be simplified as one-port single resonance system and a small change of ratio between two resonator parameters, radiational loss and resistive loss, at perfect absorption condition will lead to large phase shift near 180° in the infrared [1]. Also, large resonance frequency changes can lead to large phase change with similar one-port single resonance systems, if the resistive loss is small[2]. In addition, achievable amount of phase change can be further increased over 360° with negligible amplitude change when the number of resonances increases [3]. There have been many papers that suggested and demonstrated large phase control up to 360° in the infrared with active materials. However, most of active materials used in for infrared active metasurfaces cannot be used for visible metasurfaces since their effectiveness becomes much smaller or material loss becomes too large in the visible regime. As a result, large dynamic phase control for visible light are typically done with liquid crystals, which are almost transparent and possess a large change of the refractive index depending on their orientation. Liquid crystals, however, suffer from pixel crosstalks due to coupling between neighboring liquid crystal molecules and have not achieved pixel resolution below 1μm, thus may not be suitable for high numerical aperture or large angle applications [4].

We suggest that by using electrochemistry approaches, large phase change of visible light can be achieved with metasurfaces with sub-micron unit cells. Electrodeposition, coating of metals by voltage appliance in electrolyte, and electrochromic materials, which change color or opacity when voltage and ions are applied, have mostly been used for dynamic color tunable metasurfaces [5], [6]. However, electrodeposition of metals, which have large optical losses at the visible regime, can effectively change resistive and radiational losses of nanoresonators, when it occurs between background channels and resonators. As a result, coupling condition of metausrfaces shifts during electrodeposition of metals and thus large phase shift follows as in ITO based dynamic metasurfaces in the infrared. Our suggested electrodeposition based metasurfaces can have further larger change of ratio between radiational and resistive loss, and thus perfect absorption at target wavelength is not necessary. When we design our metasurfaces to have perfect absorption at wavelength deviated from target wavelength and resonance frequency passing by target wavelength when resistive loss is smaller than radiational loss, our metasurfaces can have phase change larger than 180°, and smaller amplitude change. Secondly, we suggest one port double resonance reflective metasurfaces can be used in the visible regime to have phase change over 360° with well-known electrochromic materials, polyaniline. Phase-only change in double resonance system require the condition that each resonance frequency shifts with same direction, but different amount and thus one resonance

pass by the other resonance when material properties change. We designed such system by coupling Mie resonances and Fabry-Perot resonances. Resonance frequency shift is proportional to volume integral of multiplication of permittivity change and electric field intensity divided by mode volume. [7] Fabry-Perot resonances consist of active materials, polyaniline, dielectric Mie resonators are placed near Fabry-Perot resonances and both resonance frequencies are matched in the middle of permittivity change in our study and we achieved phase change over 360° with suppressed amplitude change even with material loss of polyaniline.

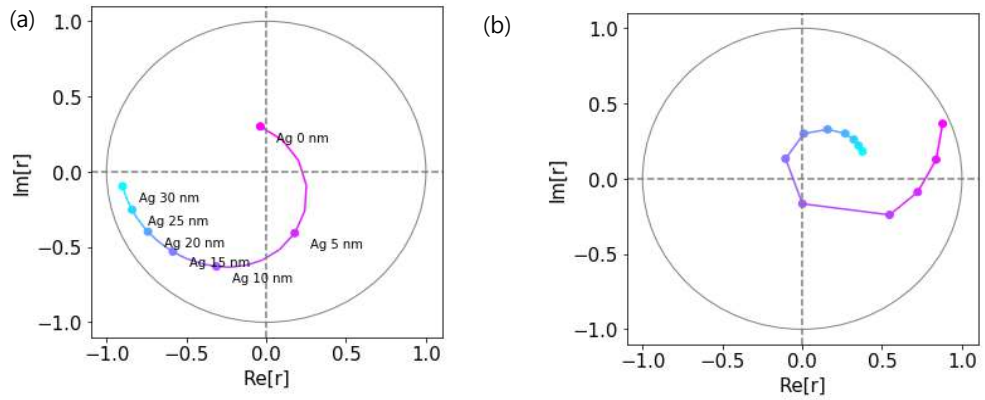

Figure 1: (a) Trajectory of reflection coefficients of electrodeposition based dynamic metasurfaces at 532nm (b) Trajectory of reflection coefficients of electrochromic material based dynamic metasurfaces at 545nm. Refractive index values are from 1.5 to 1.13 and intermediate index values are linearly interpolated [6]

Abstract: A one-dimensional all-metal, plasmonic metasurface absorber was fabricated from a compact disk by transferring a one-dimensionally patterned aluminium (Al) layer on transparent polymer. This plasmonic metasurface absorber was used for refractive index sensing in the mid-infrared region. A sensitivity of 10.708 µm/ RIU was achieved for the operating wavelength range 12-15 µm. This metasurface can be used in various photonics applications such as broadband light absorbers, filters, mode locking for mid-IR lasers, smart windows, photodetectors, etc.

Plasmonic multilayer structures having one-dimensional (1D) and 2D periodic nanostrucures are considered 1D or 2D plasmonic metasurfaces (PMs) [1]. PMs are used in various photonics applications such as refractive index (RI) sensors [2], surface enhanced IR absorption [3], light absorbers [4], etc. Generally, plasmonic metasurface absorbers (PMAs) are designed using a metal-insulator-metal (MIM) structure and the incident light gets absorbed in the insulator layer because of surface plasmon (SP) modes [5]. But the fabrication complexities of PMAs can be removed by designing all metal PMAs which support the confinement of light at the sharp edges of the plasmonic nanostructure [6]. Here, fabricated all-metal PMA was used for RI sensing.

A schematic of the fabricated PMA has been shown in Fig. 1 (a). The structure consists of 1D metallic aluminum (Al) grating lines having the period of 1450nm, grating width of 680nm, groove width of 770nm, and grating height of 120nm on a continuous Al layer which is 5 µm thick. The PMA has been fabricated using a commercially available compact disk (CD). PMA has been fabricated by transferring a one-dimensionally patterned aluminium (Al) layer on a transparent polymer. Fig. 1 (b), it has been shown the 3D top view of the fabricated all-metal PMA and it can be observed that the grating height is 120nm around; the period 1450nm; the grating width w=680nm; and the groove width a=770nm.

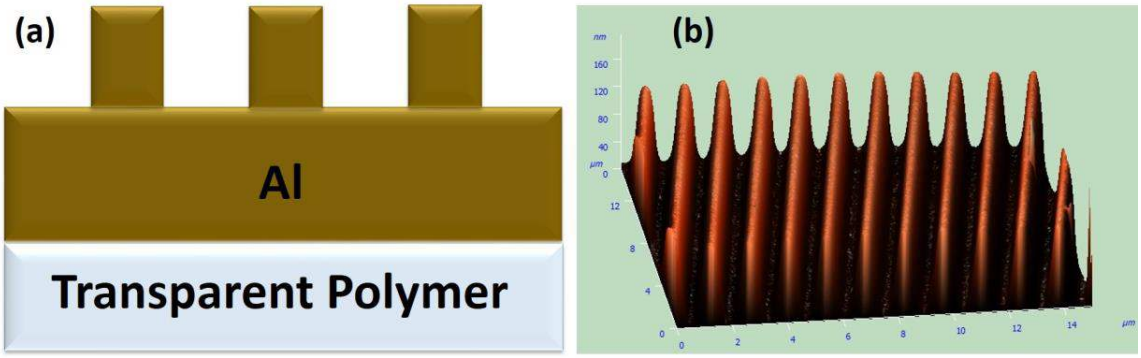

Fig. 1 (a) Schematic of the fabricated PMA, (b) 3D view of the PMA top surface by AFM characterization technique,

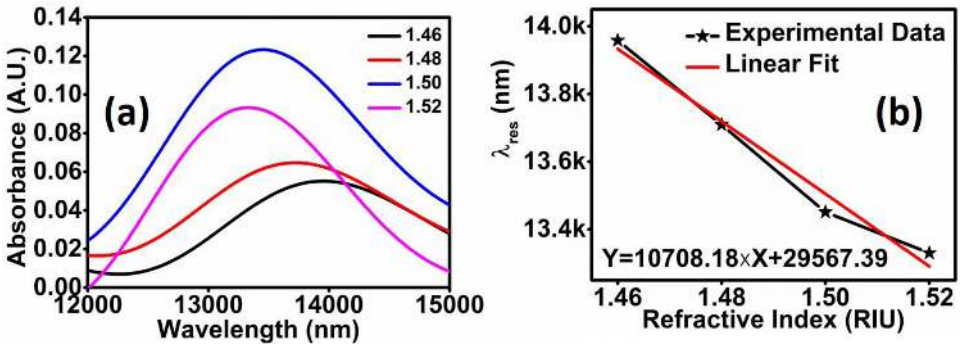

Fig. 2 (a) Absorption spectra for different RI of analyte medium, (b) Characteristics response curve of the sensor

Absorption of Mid-IR light in all metal PMA is achieved because of the confinement of light at the sharp edges of the plasmonic nanostructure and this confinement of light is due to SP modes which are excited at the metal-air interface. Fig. 2 (a), it has been shown an experimental absorption spectrum for different RI values of the analyte medium. The absorption spectra were recorded by using the Fourier transform infrared (FTIR) spectrometer integrated with an attenuated total reflection (ATR) accessory for TM polarized light. The absorption spectra for different RI values were recorded for the angle of incidence 83^0. It can be observed a blue shift in resonance wavelength ($\boldsymbol{\lambda}_{res}$) with the change of RI values from 1.46 to 1.52. The values of $\boldsymbol{\lambda}_{res}$ corresponding to different RI values have been extracted from Fig. 2(a) and plotted in Fig. 2(b). A sensitivity of 10.708 µm/ RIU has been estimated by linear fitting of the data points and calculating the slope.

In summary, an all-metal, flexible PMA has been fabricated as a wide-band absorber in the wavelength range of 12-15µm for refractive index sensing. A sensitivity of 10.708 µm/ RIU was achieved. This PMA can be used in various photonics applications such as Mid-IR photodetector, heat-absorbing flexible cover, biomedical sensors, etc.

Funding from MoE-STARS, and DST-BDTD grants are thankfully acknowledged. Sagar Kumar Verma thanks IITR and MoE for the Ph.D. fellowship.

Metasurfaces for illumination and light concentration

Ivan Moreno*, C. P. Castañeda-Almanza, and Thaire V. Galvan

Universidad Autonoma de Zacatecas, Mexico
*corresponding author: imorenoh@uaz.edu.mx

Abstract: We show some methods for designing metalenses that deal with the optimal transfer of light energy, i.e. for light concentration and illumination applications. Owing to its compactness, flatness, and high design flexibility, metasurface-based flat optics may solve some problems in the nonimaging optics field, which deals with light concentration and illumination. We report our latest advances on this topic. We discuss two algorithms for uniform illumination design with metasurfaces: ray mapping method, and Monge–Ampere equation method. And we discuss the string method for efficient light concentration with flat optics.

Metalenses are finding new applications as nonimaging metalenses [1-3]. Therefore, here we describe the design of some types of metalenses for illumination and light concentration applications. We resume a simple method to design a metalens for uniform illumination, which is based on the ray mapping algorithm between a point source and a target [2]. Also, we explain the Monge–Ampere equation method for metasurfaces, which preserves the energy through the light propagation [3]. In addition, we introduce the string method for designing light concentrators with metasurfaces.

Analysis of Reliability of Flexible Microwave Absorbing Meta-Surface under Bending Stress

Doo-Sun Choi[1], Ji-Youn Kwak[2], Jun Sae Han[1], Eun-Ji Gwak[1]and Eun-chae Jeon[3*]

Abstract: We developed a simple method to predict the performances of absorbing microwaves under bending stress, and applied the method to a flexible meta-surface for assessing their reliability in this study. Since bending stress made severe damage immediately after bending and some damages were recovered after removing bending stress in flexible meta-surfaces, the reliability of flexible meta-surfaces should be evaluated under bending stress.

Meta-surfaces for absorbing microwaves can be used in various fields such as electronics, optics and militaries [1, 2]. Flexible meta-surfaces have much wider applications than flat and rigid meta-surfaces. Since the flexible meta-surfaces is attached on the targets which should be protected from microwaves, the flexible meta-surfaces experience continuous bending stress during whole life-time. Generally, the flexible meta-surfaces are manufactured and their performances are measured under flat state with no bending stress. However, the performances should be varied when the bending stress is first applied and can be varied with time. It is hard to measure variation of their performances with time (as known as reliability) because we need a large anechoic chamber and expensive measurement systems. We developed a simple method to predict the variations of microwave absorbing performances under bending stress in a general laboratory and with a simple measurement system, and applied this method to a flexible meta-surface for assessing their reliability in this study.

First, we manufactured several flexible meta-surfaces using metal molds, TPU(thermoplastic polyurethane) films and carbon-based conductive ink. The precise patterns for absorbing microwaves on the metal molds were machined by ultra-precision cutting technology. The electric properties of the meta-surfaces were measured under flat state without bending stress in order to obtain reference data. Then, we installed the flexible meta-surfaces in a customized bending system having designed bending radii. The electric properties measured shortly after the installation showed large degradation, which meant that bending stress could make severe damage immediately in flexible meta-surfaces. We maintained the bending state for 1,000hr, and measured the electric properties after certain elapsed time. The degradation of the electric properties showed little change under continuous bending stress. When we removed bending stress after 1,000hr, some degradation was recovered. This meant that the properties of flexible meta-surfaces should be evaluated under bending stress because they are not same under bending stress and at flat state. In summary, we suggested a simple method to assess reliability of flexible meta-surfaces, and verified the validity of the suggested method in this study.

Abstract: The present paper describes the study and design of a Substrate Integrated Waveguide (SIW) Leaky Wave Antenna (LWA) that has a fixed frequency beam steering and is intended to be fabricated with microelectronic processes using polymers layers and metal deposition. The antenna is designed to operate between 58 GHz and 70 GHz, enabling MIMO communications. The radiation pattern of the antenna is reconfigurable using diodes connected to the capacitive gaps of Complementary Electric LC resonator (cELC) unit cells. The antenna is capable of scanning a beam range of 120° (-60° to 60°) and has a peak directivity of 9.13 dBi at 70 GHz, with a variation of less than 2 dB. The goal of the study is to design an integrated reconfigurable antenna.

Introduction: The rise of digital technology has led to a significant increase in data [1], requiring more transmission capacity to meet future needs. However, given the increased frequency range, such as mm-wave 5G or WiGig -around 60 GHz-, but also the terahertz range with 6G [2], short wavelengths require the design of miniaturized RF systems with low loss. Hence, the need to design efficient and agile antennas that can be integrated on-chips. In this article, we present a reconfigurable on-chip waveguide-fed cELC-based metasurface antenna, which operates in the 60 GHz range. The proposed antenna is composed of a SIW with resonant cells etched on its top with small lateral dimension ($< \lambda_0/5$, often $< \lambda_0/10$) and small distance between them ($\lambda_0/10$ to $\lambda_0/5$) of the free-space wavelength λ_0 [3]. It is crucial that each element couples weakly to the guided wave and do not contribute to the excitation of neighboring cells [4]. The antenna presented is designed on BenzoCycloButene (BCB) layer compatible with microelectronics processes [5,6], allowing a complete integration with existing microelectronics manufacturing.

Design and discussion: The scheme of the antenna is shown in Figure 1. On the top surface of the SIW, 18 cELC (2 x 9 cELC) are built as radiation elements with lateral dimensions of $\lambda_0/16$. The distance between each cell is about $\lambda_0/6$ at 60 GHz. The SIW is designed following the method presented in [7] on a BCB layer 60 µm thick. In order to add reconfigurability mechanism to the structure, varactor diodes are placed at both capacitive ends of each element. This allows to modify radiating properties by varying the capacitance of each unit cell. The bias via is located near the edge of the SIW to reduce its impact on the guided wave.

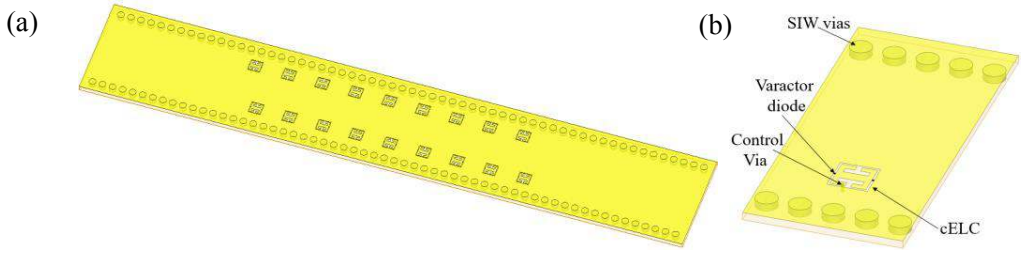

Figure 1: Schematic view of the design (a) SIW LWA, (b) cELC

EM simulations are carried out using HFSS software. The behavior of varactor diodes is emulated using the HFSS RLC boundaries. Figure 2(a) presents the radiation patterns at 60 GHz. We can observe that by varying the capacitance of the varactors, the radiation pattern, at a fixed frequency (60 GHz), can be steered up to 60°. Figure 2(b) presents the peak of directivity at different frequencies ranging from 58 GHz to 70 GHz with different steering angles. Antenna S-parameters are presented in Figure 3 and we can observe that for each case S_{11} is lower than -10 dB, thus ensuring the correct matching of the antenna. It should be noted that it is possible to lower the side lobe levels by applying a magnitude taper.

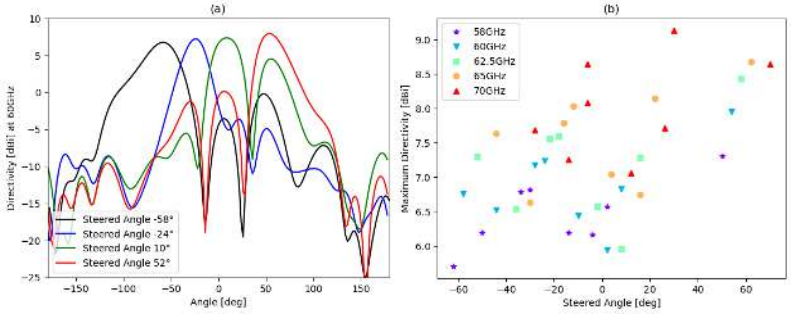

Figure 2: Radiation properties (a) Radiation Pattern at 60 GHz (b) Maximum Directivity Vs Steered Angle

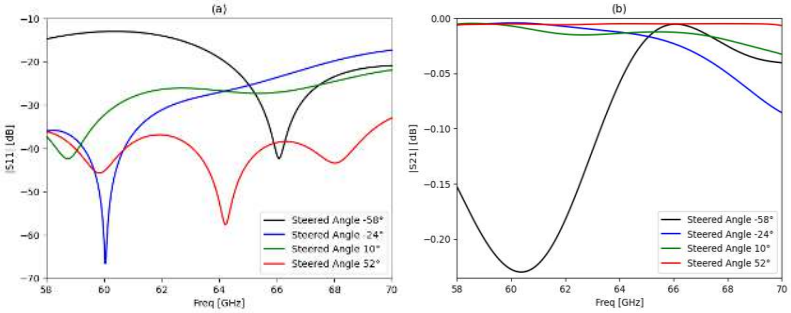

Figure 3: Scattering Parameters (a) $|S_{11}|$ (b) $|S_{21}|$

Conclusion: A reconfigurable on-chip antenna operating at 60 GHz is designed. The proposed antenna can allow to steer the main beam from -60° to 60° at different frequencies ranging between 58 and 70 GHz. Primary simulation results were presented to validate the structure.

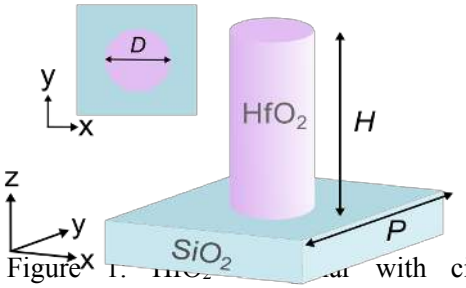
Abstract: Conventional optical elements used nowadays are usually bulky and heavy, while metasurfaces offer a promising solution allowing for miniaturization and multifunctionality. In this work, we use hafnium dioxide (HfO_2) for its high index of refraction and wide bandgap, both of which allow for fabrication of dielectric metasurfaces even for deep-UV wavelengths. We present a metalens and polarization beam splitter composed of high aspect-ratio nanopillars and analyze their functionality for wavelengths of 325 nm and 266 nm.

Manipulation of ultraviolet (UV) light presents a significant challenge for the optical industry not only due to inherent absorption present in the commonly used materials also for due to tight precision limits limiting fabrication of conventional optical elements such as lenses. Nanophotonics offers a promising solution in the form of metasurfaces, which are able to alter the phase, amplitude, and polarization of incident light [1]. The advantage of metasurfaces lies in their compact size, as well as in the possibility of implementation of multiple optical functions in a single device [2]. In order to sustain low absorption, which is the key requirement in many optical applications, dielectric Mie-resonant nanostructures are mainly used due to the significantly lower losses compared to the metallic plasmonically active nanostructures [3]. So far, for the UV wavelengths, HfO_2, Nb_2O_5, Si_3N_4 or AlN have been proposed as suitable materials. In this work, we choose HfO_2 for its high refractive index >2 and wide bandgap 5.7 eV, ensuring low losses down to the deep-UV wavelengths. Based on this material platform, metalenses, metaholograms and self-accelerating beam generators have been demonstrated [4], as well as integrated metalenses on a single-photon avalanche diode [5]. In our work, we demonstrate not only a prototypical HfO_2 metalens for UV, but also a polarization beam splitter suitable for wavelengths of 325 nm and 266 nm.



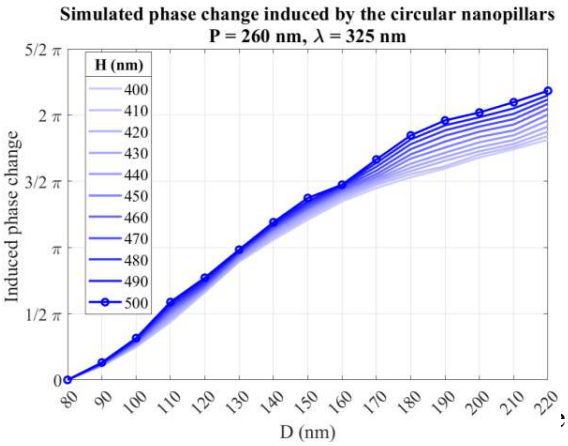


Figure 1. HfO_2 [illegible] with circular cross-section of height *H*, diameter *D,* and spacing between the nanopillars *P* on a fused silica substrate.

circular nanopillars with various diameters *D* and heights *H* when illuminated by a plane wave of 325 nm wavelength.

In the first step, finite-difference time-domain simulations were performed in order to estimate the phase of the light transmitted by the prospect metasurface building blocks — HfO_2 nanopillars with circular cross-sections on a fused silica substrate (Figure 1). In these simulations, we used periodic boundary conditions along the *x* and *y* axis, and perfectly matched layers in the *z* direction, while illuminating the nanostructure with a plane wave of 325 nm wavelength. The simulated phase alterations induced by such nanostructures of varying diameters *D* and heights *H,* with a constant spacing between the nanostructures (*P* = 260 nm) can be seen in Figure 2. The required 2π phase change, crucial for mimicking the phase profile of a lens, was reached only for nanostructures taller than 450 nm. These nanostructures of five different diameters were later considered in the metalens design shown in Figure 3. The subsequent fabrication of the metasurfaces consisted of multiple steps. In the first step, a resist mask with circular holes of the desired diameters was made via electron beam lithography into a positive resist. These holes were subsequently filled with HfO_2, employing atomic layer deposition, which ensures conformal coverage of the resist surface. In order to remove the resist in oxygen plasma, the top layer of HfO_2 must be etched away via argon ion etching. This fabrication process ensures high fabrication precision of the final nanostructures. Final metalens characterization was done by measuring the intensity profile of the focused spot. The design process of the polarization beam splitter, whose function schematic is shown in Figure 4, is very similar to the one of the metalens. The main difference is in the shape of the nanopillar cross-sections, which had to be rectangular in order to introduce the necessary polarization anisotropy. The phase profile of a beam splitter was then obtained through a geometric phase, where the individual building blocks were rotated to attain the desired phase profile.

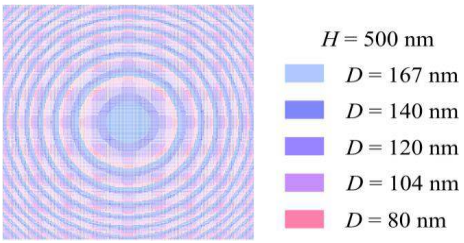

Figure 3: Proposed design of the final HfO_2 metalens based on nanopillars 450 nm tall with varying diameters *D*.

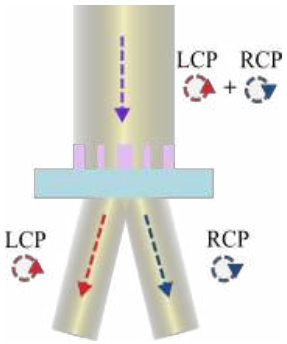

Figure 4: Schematics of polarization beam splitter employing HfO_2 nanopillars with a rectangular cross-section.

Epsilon near zero metasurfaces (ENZ) at visible wavelengths

I.R.Alhamdan[1], **S.A.Schulz**[2]

[1]University of Saint Andrews, United Kingdom
[2]University of Saint Andrews, United Kingdome
[*]Corresponding author: sas35@st-andrews.ac.uk

Abstract: Here we present an Epsilon near zero (ENZ) metasurface in the visible range using a multilayer structure of silicon oxide (SiO_2), gold nanoantenna, and Indium tin Oxide (ITO). ITO is an ENZ material with distinguished optical properties and can control antenna resonances. Finite difference time domain (FDTD) simulations show high efficiencies for the proposed design in transmission and reflection modes. Our metasurface has promising potential for augmented reality and chemical sensing due to the flexibility of ITO's plasma frequency.

Epsilon near zero (ENZ) materials have a vanishing permittivity around a spectral point known as the epsilon near zero wavelength (λ_{ENZ}). In general, ENZ materials are engineered and designed using different mechanisms. One of these is the media mixing of a multilayered design of dielectric and metal layers [1]. Some transparent conductive Oxides (TCOs) are naturally occurring ENZ materials, for example Indium Tin Oxide (ITO) which has an λ_{ENZ} in the near-infrared region. This fact makes TCOs highly desirable in telecommunication applications and beam steering. One of the most important implementations of ITO is controlling the localized surface plasmon resonance (LSPR) of plasmonic antennas without having to alter their size or shape [2].

Harnessing the distinguished optical properties of ENZ material for controlling the propagation of light in the visible range will open the frontier for augmented reality applications and chemical sensing. The λ_{ENZ} of ITO can be flexibly tuned by simply changing the fabrication parameters where the carrier concentration of ITO is altered and hence the plasma frequency [3]. Therefore, ITO represents an optimum platform for shifting the operating wavelength of the metasurface to the visible wavelength, enabling the creation of imaging and holographic devices with unprecedented resolutions and capabilities. Achieving this could lead to advanced virtual reality experience and medical imaging technology.

We conducted a finite difference time domain (FDTD) simulation using a commercial software (lumerical), to showcase an ENZ metasurface at the visible range that incorporate ITO. In the transmission metasurface design, a nanostructured antenna is positioned on top of a thin layer of ITO that lies on a glass spacer (Figure 1. (a)). Our simulations indicate high efficiency in transmission as evidenced by the spectrum Figure 1. (b). Other parameters such as the spacer thickness and antenna thickness are optimized via a sweep simulation.

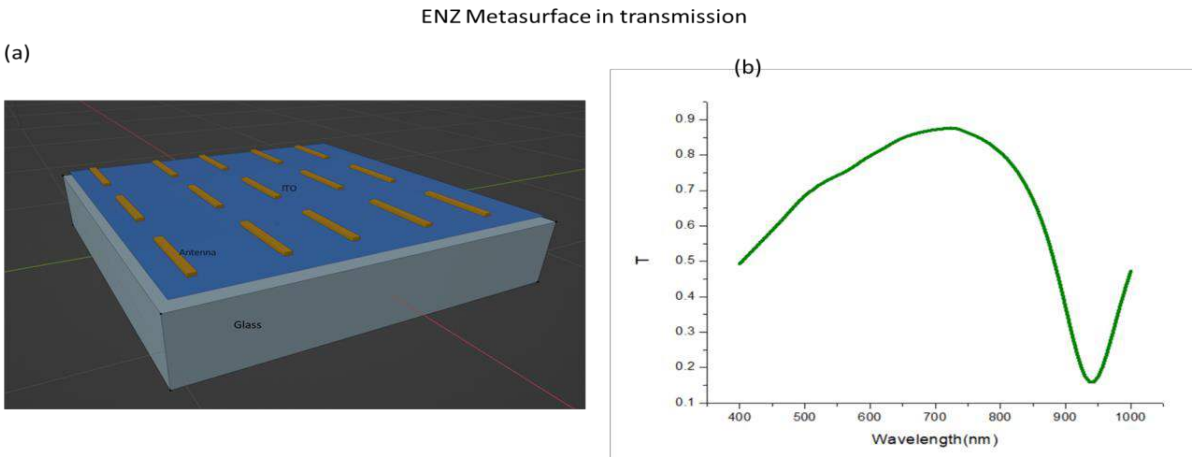

Figure 1: The metasurface in transmission as simulated in Lumerical (a) a perspective view of the design which contains an antenna nanostructure on a surface of an ITO and a glass spacer (b) the transmission spectrum of the structure.

In summary, the unique optical properties of ENZ materials hold great promise for manipulating light in the visible range, which can pave the way for the creation of highly advanced holographic devices. Our FDTD simulation has shown that our proposed metasurface design exhibits high efficiency, underscoring the potential of ENZ materials for use in augmented reality applications.

Supercell Metasurfaces: Hierarchical Designs and Experimental Validation

Tatiana Contino[1,2]*, **Michele Tamagnone**[1]

[1]Fondazione Istituto Italiano di Tecnologia, via Morego 30, 16163 Genova, Italy

[2]Dipartimento di Chimica e Chimica Industriale, Università di Genova, Genova, Italy

Abstract: In this work, we demonstrate a new concept of metasurfaces based on a generalization of supercells. In general, these supercells consist of a series of unit cells that combine with each other to achieve a specific function. We present hierarchical supercells (supercells of supercells) and we extend supercells to general 2D Bravais Lattice, providing a simple mathematical framework to describe the resulting metagratings.

Metasurfaces are artificial planar materials consisting of arrays of subwavelength-spaces nanostructures at an interface, allowing for unprecedented control over the properties of light like phase, amplitude, and polarization, and have allow multiple and versatile functionalities in a single device [1,2]. In general, metasurfaces are obtained through subwavelength unit cells designed to impart a local phase profile to light propagating through the cell. Multiple functions such as focusing, holograms, polarization functions, and beam shaping can be achieved by this technique. Using supercells (arrangements of multiple cells which can are optimized together in the design), it is possible to achieve multiple functions at same time[3]. When the supercell is repeated periodically, the device behaves as a grating, splitting the light in multiple diffraction orders (*metagrating*). The size of the supercells determines the number and direction of diffraction orders to be considered while the geometry of the nanostructures present in the unit cell determines the local effect of the metasurface on light.

In this work, we generalize the concept of supercells in two ways: (i) using hierarchies to create supercells of supercells and (ii) by means of general 2D integer Bravais lattices.

Hierarchies of supercells can be defined in the following way: starting from metasurfaces based on a single-unit cell that is repeated periodically on the plane, we define first-order supercells by joining several cells and then breaking the previous translational symmetry by creating differences among the various cells in the supercell. Second order supercells, similarly, are supercells of supercells, and so on for higher orders. Each time the supercell order is increased, new diffraction orders are obtained. By engineering the unit cells it is possible to obtain devices with different functions on each order (Figure 1A-C). The phase and amplitude of each order depend on the particular asymmetry introduced when the supercell is created, specifically the amplitude is proportional to the perturbation parameter in the small-perturbation limit.

In addition to considering supercells that extend horizontally or vertically on the plane, we consider here supercells that extend obliquely. It is possible to identify these supercells by means of an integer 2D Bravais lattice, defined by the points $\{n\bar{a} + m\bar{b}\}$, where $\bar{a}$ and $\bar{b}$ are 2D integer vectors. We can then define the supercell matrix L as

$$L = \begin{pmatrix} a_x & b_x \\ a_y & b_y \end{pmatrix} \in \mathbb{Z}^{2\times 2} \quad (1)$$

It is straightforward to show that the number of cells in the supercells is $|\det(L)|$. In Figure 1D,E we show an example of such a Bravais lattice (with $|\det(L)| = 4$), and we identify the associated supercell as a “Tetris-like” tile which fills the entire plane. The number of orders is also increased by a factor of $|\det(L)|$. Specifically, the diffraction orders for a metagrating with periodicity of P are given by:

$$\sum_{m,n} \delta\left(\bar{k} - \frac{2\pi}{P}\begin{bmatrix} m \\ n \end{bmatrix}\right) \tag{2}$$

while when the supercell is defined, the new diffraction orders (more numerous) are given by

$$\sum_{m,n} \delta\left(\bar{k} - \frac{2\pi}{P} L^{-1,H}\begin{bmatrix} m \\ n \end{bmatrix}\right) \tag{3}$$

In the presentation we will show concrete examples of devices based on these two concepts.

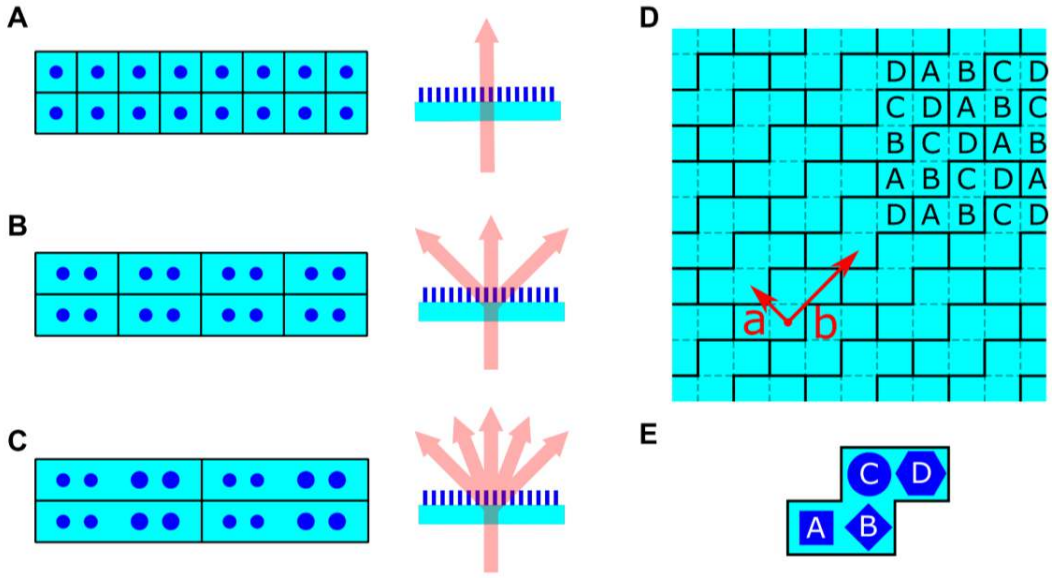

Figure 1: Generalized supercell metasurface concepts. A-C: Metagratings using supercells of increasing hierarchy. 0^{th} order supercells are just the unit cells of the metasurface, 1^{st} order are creating joining 0^{th} cells and so on. Increasing hierarchies generate an increased number of diffraction orders. **D**: An example of supercells based on a general integer Bravais lattice. **E**: Example of optical elements in a Bravais supercell.

Non-Uniform Array of Polarizable Particles as a Locally Linear Space Invariant (LSI) Metasurface

J. Dugan[1*], T. J. Smy[1], João G. Nizer Rahmeier[1], and S. Gupta

[1]Carleton University, Canada

Abstract: Non-uniform metasurfaces are often analyzed as a locally Linear Space Invariant (LSI) system where the effective parameters of the surface at any given unit cell are equal to the parameters of an equivalent uniform surface composed of only that unit cell. This is often treated as an approximate method for modeling non-uniform surfaces, however, in this work we demonstrate that a non-uniform array of electrically polarizable particles can in fact be modeled as a local LSI system.

Non-uniform metasurfaces are essential in several applications, such as wireless channel engineering as well as electromagnetic cloaking and illusions. Much work has been done on homogenizing uniform metasurfaces, with non-uniform metasurfaces being assumed to be locally space invariant (LSI), i.e., the effective parameters of the non-uniform surface at a given unit cell are the same as an equivalent uniform metasurface constructed using that cell. In much of the literature, the LSI nature of metasurfaces is treated essentially as a perturbative approximation based on the assumption that the coupling between unit cells for a non-uniform surface is approximately the same as for a uniform surface[1]. The local LSI assumption has been shown to provide excellent results even for highly non-uniform metasurfaces[2]. In this work, we will investigate the validity of this assumption.

Consider a uniform array of polarizable particles with a polarizability α and a separation of d, excited with normal incidence. Following the derivation by Tretyakov[3], we can write the field at a given dipole as

$$\boldsymbol{E} = \boldsymbol{E}_s + \beta \boldsymbol{p}, \tag{1}$$

where $\boldsymbol{E_s}$ is the source field, $\boldsymbol{p}$ is the induced dipole moment, and β is the interaction coefficient which is determined by summing the fields produced by each dipole in the array assuming each dipole has the same dipole moment. Further, if we now replace the dipoles with an equivalent spatially averaged current $\hat{\mathbf{J}} = j\omega\widehat{\mathbf{P}}$ where $\widehat{\boldsymbol{P}} = \boldsymbol{p}/d^2$, we can write the averaged field at each dipole as

$$\boldsymbol{E}_{\text{avg}} = \boldsymbol{E}_s - \frac{\eta}{2}\hat{\boldsymbol{J}}, \tag{2}$$

where η is the free space impedance. Using (1) and (2), and $p = \alpha E$, we can write,

$$\boldsymbol{E}_{\text{avg}} = \left[\frac{d^2}{j\omega}\left(\frac{1}{\alpha} - \beta\right) - \frac{\eta}{2}\right]\hat{\boldsymbol{J}} \tag{3}$$

Identifying, $\boldsymbol{E}_{\text{avg}} = \boldsymbol{Z}\hat{\boldsymbol{J}}$, we obtain the effective sheet impedance as:

$$\boldsymbol{Z} = \left[\frac{d^2}{j\omega}\left(\frac{1}{\alpha} - \beta\right) - \frac{\eta}{2}\right] \tag{4}$$

Now we want to extend our analysis to non-uniform surfaces where the polarizability is a function of the position on the surface $\alpha(r, \phi)$. Similar to (1), we can write the field at the dipole location as:

$$\boldsymbol{E}(r, \phi) = \boldsymbol{E}_s + \hat{\beta}\{\boldsymbol{p}\} \tag{5}$$

Where $\hat{\beta}$ is now an LSI operator which again, is found by summing the fields produced by each dipole; only now each dipole can have a different dipole moment. Now, the spatially averaged current is non-uniform so the averaged field will have the following form

$$\boldsymbol{E}_{\text{avg}}(r,\phi) = \boldsymbol{E}_s(r,\phi) + \hat{L}\{\hat{\boldsymbol{J}}(r,\phi)\} \tag{6}$$

where $\hat{L}$ is now referred to as the LSI propagation operator given by,

$$\hat{L}\{\hat{\boldsymbol{J}}(r,\phi)\} = -j\omega\mu \int_S \frac{e^{-jk(r-r')}}{|r-r'|}\left[\hat{\boldsymbol{J}}(r',\phi') + \frac{1}{k^2}\nabla'\nabla'\cdot\hat{\boldsymbol{J}}(r',\phi')\right] dS', \tag{7}$$

describing the fields produced by a current $\hat{\boldsymbol{J}}$ at the source location (r',ϕ'), at the observation (r,ϕ).
Given $\boldsymbol{p}(r,\phi) = \alpha(r,\phi)\boldsymbol{E}(r,\phi)$, and using (5) and (6), we can obtain the position dependent sheet impedance *operator* as:

$$\hat{\boldsymbol{Z}}(r,\phi)\{\hat{\boldsymbol{J}}\} = \left[\frac{d^2}{j\omega}\left(\frac{\hat{I}}{\alpha(r,\phi)} - \hat{\beta}\right) - \hat{L}\right]\{\hat{\boldsymbol{J}}\} \tag{8}$$

Where $\hat{I}$ is the identity operator, defined as $\hat{I}\{\hat{\boldsymbol{J}}\} = \hat{\boldsymbol{J}}$. For a uniform surface with an arbitrary incident field, we get the following impedance operator,

$$\hat{\boldsymbol{Z}}(r,\phi)\{\hat{\boldsymbol{J}}\} = \left[\frac{d^2}{j\omega}\left(\frac{\hat{I}}{\alpha} - \hat{\beta}\right) - \hat{L}\right]\{\hat{\boldsymbol{J}}\} \tag{9}$$

which can be easily verified to lead to (4) for a constant $\hat{\boldsymbol{J}}$ across the surface. Comparing (8) and (9), we observe that at any given point, (r,ϕ), on the non-uniform surface, the impedance operator is equal to an equivalent uniform surface made up of dipoles of the same polarizability, and not dependent on the polarizabilities of the neighboring particles. This indicates that for an array of electric dipoles, local LSI is thus not an assumption but rather a fundamental property of the array.

In future works, we will perform this investigation for a general bi-anisotropic surface, as well as for a surface containing higher-order multipoles. We will further perform numerical demonstrations to conclusively demonstrate the validity of the local LSI model. We believe this can prove to be an important realization about the non-uniform surfaces, as the ability to treat a surface as locally LSI may greatly simplify the design and analysis of general non-uniform metasurfaces.

Adjoint Optimized Mid-Wave Infrared Metalenses

J. Rollag[1,2], R. Wambold[1], R. Gibson[1*]
[1]Air Force Research Laboratory, Sensors Directorate, 2241 Avionics Circle, Wright-Patterson AFB, OH, 45433, USA

Abstract: Silicon metalenses with numerical apertures of 0.232 are designed for operation in the four to five micron wavelength range using adjoint optimization. The library element optimization allows for each freeform scatterer to be optimized for a given phase with feature size limitations suitable for standard fabrication. It is found that the silicon metalenses with the adjoint optimized scatterers perform better than traditional cylindrical scatterers in both bandwidth and focusing efficiency over the desired spectral range.

Many different optimization techniques for metasurface design have been studied recently. Broadly they fall in two categories where one can directly compute the performance of a particular meta-atom with an electromagnetic solver or rely on an inverse design technique [1]. While many variations of inverse design exist one that shows particular promise for metasurface design is adjoint optimization. Adjoint optimization has been used to enhance light extraction out of quantum emitters such as nitrogen vacancies in diamond [2] and increase coupling of defects in 2D materials coupled to photonic integrated circuits [3]. This technique has also been applied to develop robust metagratings that are insensitive to common fabrication imperfections [4] and with appropriate segmentation can be applied to freeform large-area metasurfaces [5]. This work is focused on adjoint optimization of individual freeform meta-atoms, or scatterers.

Using commercially available electromagnetic solver software [6] an algorithm is developed to optimize freeform meta-atom libraries. Each meta-atom is typically optimized in fewer than 400 iterations pushing the index of each meshed cell of the freeform element to either high or low index, corresponding to silicon or air, until the desired scattering phase is matched. The algorithm limits the feature sizes to be suitable for common fabrication techniques and from a desired phase profile distributes, the meta-atoms on a grid based on the scatterer phase nearest to that of the desired phase. The performance of metalenses with as few as four elements in the library show strong performance for millimeter scale apertures. While both the focusing efficiency and bandwidth improve with number of meta-atoms the trade-off between library size and performance levels off near 8 to 16 elements for silicon based MWIR lenses.

This method is shown to be an improvement over traditional cylindrical meta-atoms in terms of both bandwidth and focusing efficiency. This can be seen in Figure 1 where the electric field profile along the optical axis and at the focus are shown for an adjoint optimized metalens and a traditional cylindrical scatterer metalens, both constructed with eight meta-atoms and with NA ≈ 0.232. The focusing efficiency of the adjoint optimized metalens over the cylindrical scatterer metalens is 13.8% higher, where the focusing efficiency is defined at the percentage of $|E|^2$ within 3x the full-width half max [7], the FWHM at the focus is 13.9% smaller, and the average transmission 10.6% higher. Additionally, the transmission only varies by a few percent across the full-bandwidth for the adjoint optimized lenses whereas transmission varies by more than 15% for the cylindrical scatterer metalens. The adjoint optimized metalens outperforms in each of these metrics though a larger shift in the focal position across the $\lambda = 4 – 5$ μm range is observed. Larger aperture sizes, variations in NA, and variations in number of meta-atoms in each library will be presented for this design technique.

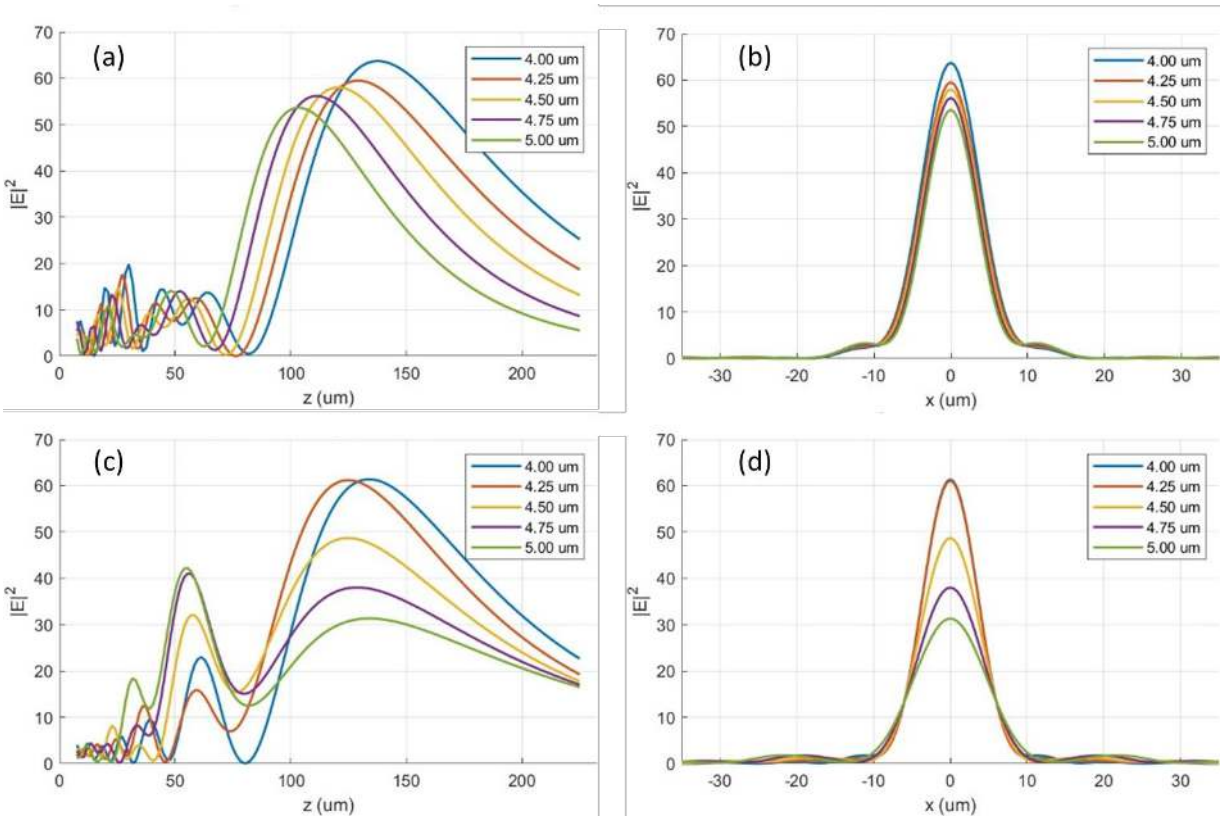

Figure 1. Comparison of performance in the λ = 4 – 5 μm range of metalenses designed by adjoint optimization (top row, (a) & (b)) and from direct computation (bottom row, (c) & (d)) with only eight elements each. The intensity profile along the optical axis is shown for the adjoint optimized design and direct computation in (a) & (c) while the intensity profile at the focus is shown in (c) & (d), respectively.

Self-assembly of magnetoplasmonic nanowires for structural colors and chiral metasurfaces

My-Chi Nguyen, Huu-Quang Nguyen, and Jaebeom Lee*

Department of Chemistry, Chungnam Nation University, Republic of Korea
*corresponding author: nanoleelab@cnu.ac.kr

Abstract: A template-free and one-step synthesis of metal core-magnetic shell Au@Fe_xO_y nanowires with high aspect ratio was introduced. The magnetic field-induced aligned array film presents unique iridescent structural coloration in different observation and polarization modes. Furthermore, a helical metasurface is assembled resembling Bouligand structure which exhibits circular dichroism tunable by adjusting the magnetic field strength, number of layers, and helical pitch angle. These results demonstrate the capability of self-assembly metasurfaces as groundwork for optical and sensing devices.

A facile one-pot solvothermal synthesis method was developed for growing an anisotropic hybrid nanostructure composed of magnetic oxide nanoparticles coated on plasmonic gold nanowires (Au@Fe_xO_y MagPlas NWs). The effects of reaction temperature, time, reducing agent and precursor as well as post-synthesis treatment were optimized to produce highly uniform NWs in the aspect ratio of 25 ~ 82. The synthesized structures inherited the magnetic properties from the iron oxide layer and anisotropic localized surface plasmon resonance (LSPR) of the gold nanowires, which are potentially useful for a wide range of optical and sensing applications.

Especially, by exploiting the interaction of NWs with an external magnetic field, MagPlas NWs were aligned into 2D photonic surfaces with high periodicity, which can generate distinctive structural colors that are uniquely iridescent and polarization-sensitive. Furthermore, we demonstrated the fabrication of a bioinspired Bouligand-type chiral cholesteric metasurface, by stacking the 2D aligned microchains continuously with a rotating pitch angle. This film displays remarkable sensing capability with circular dichroism spectroscopy, which could detect the change of surface alignments upon the addition of analyte molecules. These intriguing properties of MagPlas anisotropic NWs and their self-assemblies could be consequently valuable for developing photonic, catalysts, and sensing applications.

Dynamic phase-modulated metasurface for beam scanning antenna

Z. Zouhdi[1,2], B. Ratni[1], and S. N. Burokur[1*]

[1]LEME, UPL, Univ Paris Nanterre, F92410 Ville d'Avray, France

[*]corresponding author: sburokur@parisnanterre.fr

Abstract: A directional high gain reconfigurable planar antenna is designed based on a phase-modulated metasurface. A prototype that operates around 5 GHz is designed, fabricated and tested. The metasurface is dynamically controlled by different bias voltages applied to the incorporated varactor diodes, thus allowing to control its phase characteristics. Different phase profiles have been tested allowing to firstly achieve a highly directive boresight radiation and secondly, to steer the main radiated beam towards an off-normal direction.

Metasurfaces have attracted great interest due to their ability to manipulate electromagnetic waves, such as radiation control [1-3], wavefront shaping [1,4], and polarization conversion [5]. In the field of antennas, metasurfaces have allowed to reduce the dimensions, particularly when they are used as partially reflective surfaces (PRS) in reflex-type Fabry-Perot (FP) cavity antennas to achieve high directivity from a single radiating element [6]. Flat lenses [7] and leaky-wave antennas [8] have also been designed based on the use of metasurfaces. The concept of reconfigurable metasurfaces has emerged in recent years to satisfy the changing requirements in practical applications and enable the integration of multiple functionalities into a single metasurface. In this work, a dynamic metasurface loaded with varactor diodes is exploited as a reconfigurable planar reflector with a parabolic phase profile in order to design a highly directive antenna at 5 GHz. Such antenna allows reconfigurability in frequency and further allows to control the direction of the radiated main beam in order to achieve beam steering.

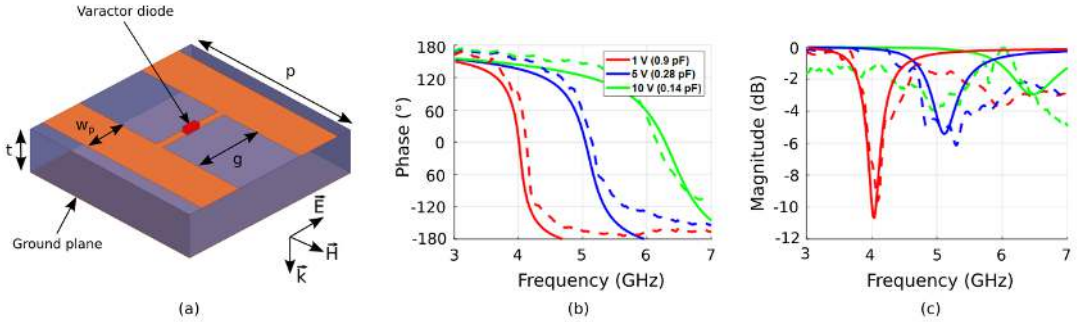

Figure 1. (a) Schematic design of the unit cell: p = 13 mm, w_p = 3 mm and g = 5 mm. The substrate used has a relative permittivity ε_r = 2.2 and a thickness t = 3 mm. Simulated and measured reflection responses for different applied stimuli signals: (b) phase and (c) magnitude.

The proposed reconfigurable metasurface comprises 30 columns, each containing 30 resonant unit cells (30 × 30 cells) and has lateral dimensions 390 mm × 390 mm. In this voltage bias configuration where a similar voltage will be applied to all the meta-atoms in a column, only a one-dimensional phase profile can be tailored. From Fig. 1(b), it can be noted that a high phase shift $\Delta\varphi$ (above 280°) is achieved within the 4.4 – 5 GHz due to the intrinsic design of the meta-atom.

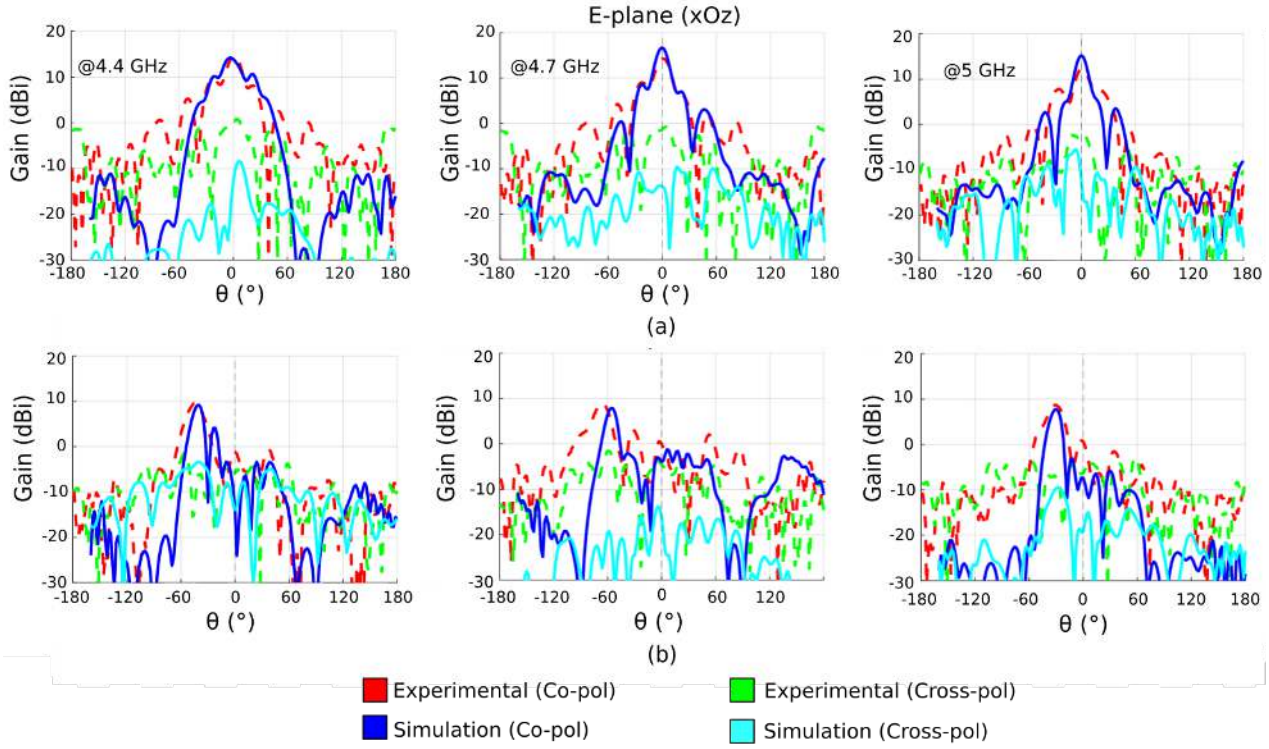

Figure 2. Simulation and experimental results. (a) Boresight radiation at different frequencies. (b) Beam steering (30°, 45° and 60°) at 4.7 GHz.

A Vivaldi radiating element is used to illuminate the metasurface reflector. This radiating element positioned at a certain distance in front of the metasurface will launch electromagnetic waves, which will be reflected by the meta-reflector. The cylindrical parabolic phase profile applied along the metasurface is calculated as:

$$\varphi(x,y) = \frac{2\pi}{\lambda}\left(\frac{(x-x_0)^2}{4F}\right) + \varphi_0 \qquad (1)$$

where λ is the free space operating wavelength, F (= 120 mm) is the focal distance, and φ_0 is the reflection phase at (x_0, y_0).

The cylindrical parabolic phase profiles allowing to obtain a boresight radiation at 4.4 GHz, 4.7 GHz and 5 GHz are applied to the metasurface by judiciously applying the correct bias voltage to each column of meta-atoms. The radiation patterns are presented in Fig. 2(a), and show a highly directive beam in the *E*-plane (*xOz* plane), where the phase profile is applied. The maximum gain reaches 16 dBi at the central frequency of 4.7 GHz. The half-power beamwidth of the antenna is found to be around 32°. The possibility of controlling the direction of the main radiated beam is also performed by introducing an offset x_0 in order to virtually move the parabola with respect to the source. In order to validate the beam-steering capabilities, the phase profile is shifted progressively. Three different beam steering angles (30°, 45° and 60°) are tested at 4.7 GHz. The results presented in Fig. 2(b) show high beam steering capabilities up to 60° with side-lobe levels (SLL) lower than 10 dB.

The resulting performances, particularly the directive nature of the antenna's radiated beam, open the way to several applications in the field of 5G, satellite, and naval communications. The high beam-steering capabilities allow a hemispheric coverage using a reduced number of antennas.

Abstract: Fano-type resonances in arrays of mirror-symmetric planar split-ring resonators (SRRs) are investigated using frequency-domain terahertz spectroscopy, numerical simulations, and analytical modeling. Special attention is paid to the guided substrate modes, which are responsible for the excitation of Fano-type peaks in the far-field transmission spectra. We find that the number, frequency, and amplitude of Fano resonances can be effectively tuned by varying the substrate thickness and array period.

Rapid progress in photonics and nanotechnology exposes many examples of resonant optical phenomena associated with Fano resonance [1]. Metasurface with mirror-symmetric SRRs serves as an excellent example of an artificial medium for Fano-type resonance to produce an appreciable transparency peak with enhanced quality factor [2]. In mirror-symmetric resonator array, Fano resonance emerges from the radiative coupling between resonators via the waveguide modes in a dielectric slab. In this work, to understand the behavior of Fano resonance in mirrored arrays, we investigate terahertz transmission of metasurfaces deposited on dielectric slabs of different thickness paying special attention to dispersion of the guided modes and configuration of electromagnetic fields in a dielectric substrate. We propose an original method – the analysis of the Fano resonance properties – to study the in-plane electromagnetic modes propagating along the substrate. We show a significant spectral narrowing and a rather large amplitude of Fano/EIT resonance in resonator arrays deposited on ultrathin dielectric films due to the reduction of ohmic and radiation losses. On the other hand, metasurface deposited on a thick dielectric substrate demonstrates excitation of higher-order guided modes resulting in multiple Fano resonances, which might be useful for various multichannel applications at terahertz frequencies.

The mirror-symmetric SRR array is shown in Fig. 1, and the relevant geometrical dimensions of the resonators are as follows: A = 500 μm, W = 50 μm, and G = 50 μm. The lattice constant L_y is changed from 525 to 800 μm, fixing all other parameters to study the dispersion of the diffracted waves along the dielectric plate. The substrate thickness d is varied in the range from 5 μm to 1200 μm. Numerical simulations are performed using a custom-made program based on the finite-difference time-domain method. An infinite metasurface is modeled by imposing the periodic boundary conditions at the sides of the unit cell. For experimental characterization, samples are fabricated

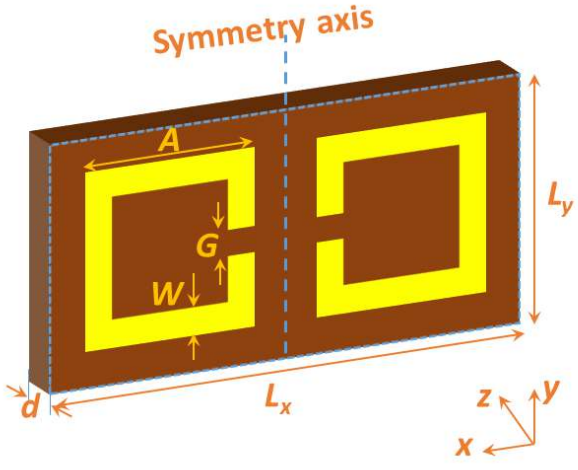

Figure 1. Schematic sketch of unit cell of mirror-symmetric SRR array. Period L_x is twice larger than L_y. Brown represents dielectric substrate, yellow indicates metallized surface.

on low-loss reinforced PTFE substrate of thickness 125 μm (Rogers RT/duroid 5880) and pure PTFE substrate of thickness 1000 μm. In the latter case, the PTFE substrate is metallized using SSAIL method [3]. Power transmission is measured using frequency-domain terahertz spectrometer Toptica Terascan 780. Metal resonators are patterned using conventional photolithography and wet etching techniques.

We observe that Fano-like resonance arises in the 200-300 GHz range due to the interference between the third-order plasmonic mode of SRRs and the guided substrate modes excited by the first-order diffraction of electromagnetic waves in the periodic resonator array [4]. We find that mirror-symmetric configuration of resonators allows excitation of fundamental guided mode in record thin ($\approx\lambda/40$) dielectric films. This is verified by the numerical simulation of electric and magnetic field amplitudes in the substrate. Also, the dispersion of Fano resonant frequency is studied analytically using the ray approach for guided modes and Fresnel formulas. The Fano frequency dispersion in the investigated structures is approximated using a modified waveguide dispersion model that includes an additional reflection phase shift at the substrate-resonator interface. The ultra-thin substrate is advantageous in that the coupling between the resonators is weak, leading to high Q factors and narrow Fano line widths.

On the other hand, as the substrate becomes thicker, the dielectric waveguide supports a more confined mode, resulting in stronger coupling between the resonators and stronger retardation of the in-plane electromagnetic modes, which lowers the Fano resonance frequency. In addition, the thick dielectric slab allows the propagation of higher-order guided modes that interfere with the plasmonic mode and induce three Fano peaks in the transmission spectrum. Theoretical simulations are confirmed by experimental results.

Abstract: We propose an all-dielectric metasurface supporting quasi-bound states in the continuum, by which terahertz emission is enhanced in a nonlinear lithium niobate ($LiNbO_3$) film under the excitation of femtosecond laser pulses. Our results show that the terahertz emission is enhanced up to 17 times by a silicon dioxide metasurface in the frequency range of 0.1–4.5 THz. This mechanism for the terahertz emission enhancement is attributed to the tight confinement of the pump field in the $LiNbO_3$ film.

Summary

In this study, we demonstrate an efficient terahertz emitter with an all-dielectric metasurface that enables up to 17 times enhancement of terahertz electric fields across a broad spectral range.[1] The metasurface is composed of patterned a silicon dioxide (SiO_2) layer and an $LiNbO_3$ film, supporting quasi-bound states in the continuum (BIC) induced by breaking the mirror and rotational symmetry.[2] The coupling between a magnetic-dipole mode and an electric-dipole one localizes the pump fields into the high-refractive-index $LiNbO_3$ film, and thus avoids the complicated process of $LiNbO_3$ etching.[3] As a result, the terahertz generation from $LiNbO_3$ is strikingly enhanced. Our work not only breaks the new ground for developing efficient broadband terahertz sources but also expands the application of all-dielectric metasurfaces.

The sample consists of an x-cut $LiNbO_3$ film on an insulating substrate (LNOI) capped a SiO_2 metasurface. We choose the x-cut LNOI to ensure that the orientation with the largest nonlinear coefficient (d33) is in-plane. The electric field of the pump light polarizes along the optic axis of $LiNbO_3$ (z-axis). As the metasurface building block, we select an L-shaped nanoresonator, formed by an in-plane perturbation on an $l \times l$ square (l = 250 nm) nanoresonator. An array of meta-atoms is arranged in a square lattice with the array pitch of p = 480 nm.

To reveal the mechanism of the THz emmission, we first calculated the electromagnetic eigenmodes of the unperturbed square nanoresonators. The square metasurface (SMS) supports a BIC (Mode 1) with an infinite Q factor at the point of the first Brillouin zone. The electric field distribution of Mode 1 presents a magnetic dipole nature polarizing along the x-axis (M_x). The BIC mode is prohibited from coupling with external electromagnetic waves and thus does not contribute to the enhancement of terahertz emission. An electric-dipole mode (mode 2) exists near the BIC mode, polarizing along the z-axis (P_z) with a finite Q factor (1758). The electric dipole mode nearly cannot boost the terahertz generation due to symmetry constraints, though it can slightly confine the pump fields inside the $LiNbO_3$ film.

In next, the L-shaped metasurface (LMS) is designed to break the mirror symmetry, resulting in the coupling between Mx and Pz. We calculated the eigenmode of the LMS. Two hybrid modes (Modes 3 and 4) are formed with both magnetic and electric dipole features. Mode 3 has a finite Q factor of 13768 at the Γ point of the

Brillouin zone, indicating that it is a quasi-BIC. The Q factor of the quasi-BIC approximately scales as an inverse square law with the asymmetry degree of the LMS, which is consistent with the previous report.[4] The quasi-BIC confines and enhances the optical electric fields inside the $LiNbO_3$. The enhanced optical electric field can enhance terahertz nonlinear polarization in $LiNbO_3$, which is the dominant mechanism for enhancing terahertz generation.

Finally, we illuminated our samples ($LiNbO_3$, $LiNbO_3$+SMS, and $LiNbO_3$+LMS) prepared by electron-beam lithography (EBL) technique, with NIR laser pulses (central wavelength 800 nm, repetition rate 80 MHz, duration 70 fs) and measured the terahertz generation by our homemade terahertz time-domain spectroscopy. We perform the Fourier transform of the terahertz pulses to investigate the enhancement further. Our results show that the enhancement of the terahertz amplitude spans the entire operating bandwidth of the detector (0.1–3 THz), but the detection frequency range is restricted by the thickness of ZnTe (2 mm). Utilizing a thinner ZnTe crystal (300 μm) as a detector, the detected enhanced bandwidth of the terahertz emission approaches 4.5 THz. The enhancement factor, terahertz amplitudes divided by the terahertz amplitude of $LiNbO_3$, reaches 17 around 0.7 THz for the LMS+ $LiNbO_3$ sample. Inversely, the enhancement factor for the SMS+ $LiNbO_3$ sample almost maintains 1 in the entire bandwidth of the detection. All of these findings show that our BIC-based all-dielectric metasurface can efficiently boost terahertz emission in the broadband range.

In conclusion, our experiment demonstrates that constructing metasurfaces on the $LiNbO_3$ film is an effective method to manipulate nonlinear processes, further releasing the potential of LNOI in nonlinear micro-nano photonics. The mechanism for enhancing terahertz generation is ascribed to the quasi-BIC induced by symmetry breaking, which strongly confines the pump electric fields in the $LiNbO_3$ films. The all-dielectric metasurface-based terahertz emitter features broadband, high efficiency, and small dimension, which paves the way for highly compact terahertz systems.

Nonlinear Effects of Linear Time-Dependent Metamaterials

P. R. Ghodake

Department of Mechanical Engineering, Indian Institute of Technology Bombay, India
mech7pkumar@gmail.com

Abstract: Nonlinear responses of linear time-dependent elastic metamaterials are demonstrated in this study through computational experiments. Manipulation capabilities of the time-varying metamaterials such as harmonic generation, controlling frequency combinations due to monochromatic wave and two-wave mixing by varying parameters time-dependent material property is explored in depth.

Introduction

Wave propagation in time-varying metallic materials is studied through a numerical perspective using the finite element method in this article. Recent developments in the photonics of time-varying media and multi-dimensional metamaterials motivated this research[1,2]. A Schematic of a numerical model is shown in Figure 1. The Young's modulus of the elastic material varies with respect to time (t) between t_1 and $t_2 + t_{pw}$, where t_1 and t_2 are the time required for the elastic waves to reach sensors S_1 and S_3, respectively, t_{pw} is the pulse width of the input monochromatic ($f = 2$ MHz) pulse, and f_0 is the oscillating frequency of the time-varying Young's Modulus (E) an elastic material property.

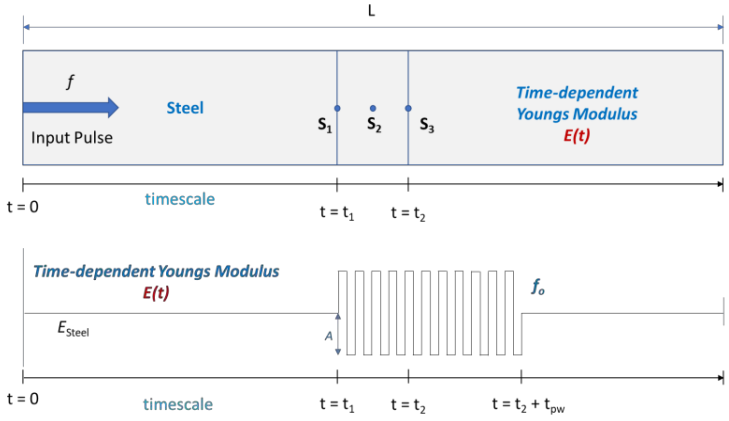

Figure 1. A schematic of the numerical model used to study the interaction of the elastic wave with the time-dependent metamaterial. The time variation of E_{steel} from t_1 to $t_2 + t_{pw}$ is shown.

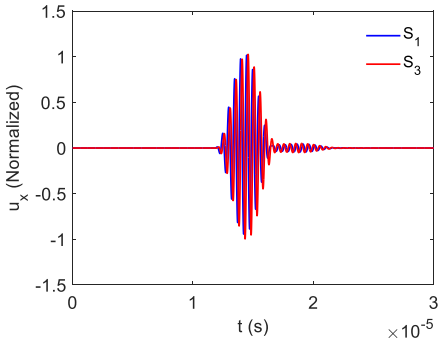

Figure 2. Time responses at S_1 and S_3 at amplitude $0.1E_{steel}$ (A) of the time-dependent material property when $f_0 = f$

Results and Discussion

Figure 2 shows the presence of scattered waves due to time-varying media and the input signal at both the sensors S_1 and S_3. Frequency responses from Figure 3 clearly show the presence of higher harmonics like $f + f_0 = |f - 3f_0| = 2f = \mathbf{4}$ MHz, $f + 3f_0 = |f - 5f_0| = 4f = \mathbf{8}$ MHz, and $|f - f_0| = \mathbf{0}$ MHz (static term) at low amplitude ($0.02E_{steel}$) of time-varying media. Interestingly as the amplitude of time-varying media increases from $0.02E_{steel}$ to $0.1E_{steel}$ the other frequency combinations like $f + 2f_0 = 3f = \mathbf{6}$ MHz shows their presence dominantly. Nonlinear harmonic responses of the linear time-varying materials show that linear materials behave as nonlinear materials due to the interaction of elastic waves when they are time-dependent.

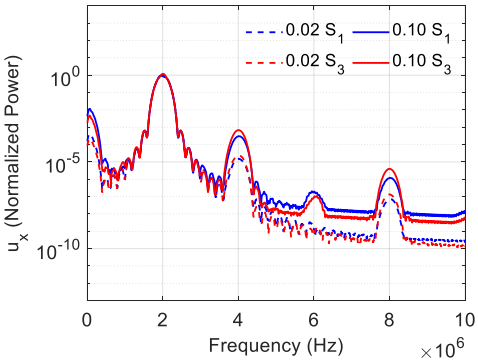

Figure 3. Frequency responses of the waves at S_1 and S_3 at $0.02E_{steel}$ and $0.10E_{steel}$ amplitudes (A) of time-dependent material properties when $f_0 = f$

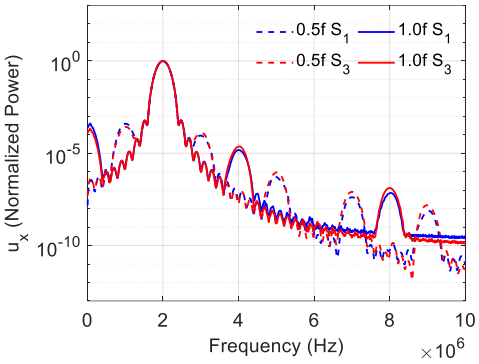

Figure 4. Frequency responses of the waves at S_1 and S_3 at $0.02E_{steel}$ amplitude (A) of time-dependent material properties and at $f_0 = 0.5f$ & $f_0 = 1.0f$

Similarly, when we change f_0 to $0.5f$, the different frequency combinations are observed such as $f + f_0 = |f - 5f_0| = 1.5f =$ **3** MHz, $f + 3f_0 = |f - 7f_0| = 2.5f =$ **5** MHz, $f + 5f_0 = 3.5f =$ **7** MHz, $f + 7f_0 = 4.5f =$ **9** MHz, and $|f - f_0| = |f - 3f_0| =$ **1** MHz as seen from Figure 4. Interestingly the static term ($0f =$ **0** MHz is not present when $f_0 = 0.5f$) only because of these particular combinations of the f and f_0 in comparison with when $f_0 = f$. Similar responses at $f_0 = 0.8f$, along with the frequency combinations during one-way two-wave mixing, are shown in Figure 5 and Figure 6. An increase in the amplitudes of all the frequency combinations during one-way two-wave mixing due to an increase in the amplitude (A) of the time-dependent material property from 0.02 to 0.10 can be seen in Figure 5. This study clearly shows the nonlinear manipulation of linear time-varying media that can be used as a nonlinear metamaterial to control elastic wave's harmonics. This study will help to expand the universe of time-dependent linear and nonlinear mechanical metamaterials to exploit their novel capabilities.

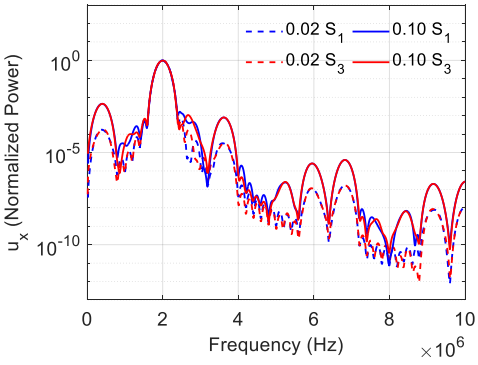

Figure 5. Frequency responses of the waves at S_1 and S_3 at $0.02E_{steel}$ and $0.10E_{steel}$ amplitudes (A) of time-dependent material properties when $f_0 = 0.8f$

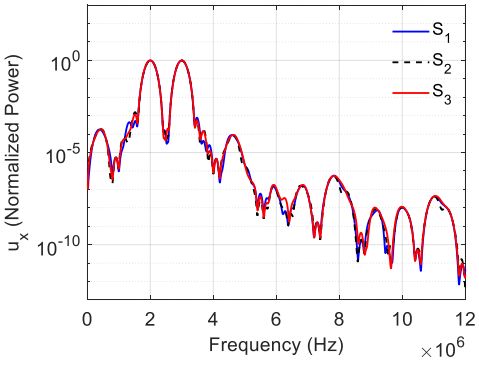

Figure 6. Frequency responses of the waves at S_1 and S_3 due to one-way two-wave mixing at $0.02E_{steel}$ amplitude (A) when $f_0 = 0.8f$

Nonlinear optics of quasistatic origin from a deep-subwavelength metallic meta-atomical system

Avi Niv[1]

Abstract: Surprisingly, the exact macro-world nonlinear mechanisms known for decades are also invoked in nano-scale nonlinear optics. In this talk, we will present a nonlinear optical mechanism that can only be found once the spatial dimension of a system is below the electromagnetic penetration depth. We will describe our experiments with the second harmonic generation (SHG) and optical rectification and discuss future research directions such as third-order effects, high harmonic generation, and chaos.

Nonlinear optics (NLO) is a vibrant indispensable research field. Nonetheless, the fundamental mechanism responsible for parametric frequency mixing has been known for decades. These exact mechanisms are also considered in the nano-scale. An essential aspect of second-order optical nonlinearity is the necessity of inversion symmetry violation. Combined with the conventional view of NLO, only negligible nonlinearity is expected from systems whose spatial dimensions are below the electromagnetic penetration depth. This vanishing effect applies to bulk nonlinearity due to the system's inability to support the required field gradients or to the net response from surface sources due to the lack of a phase lag and the ensuing canceling effect at opposite-facing surfaces.

Recently we have studied a metallic dimer whose spatial dimensions are ~30nm – comparable to the EM penetration into its comprising silver and gold [1-3]. To our surprise, an appreciable SHG emerged and showed a qualitatively different behavior than what the existing theory predicts in this case. This observation promoted us to consider the consequence of an extreme subwavelength system: Since there is no possibility for an appreciable phase difference, charges in each material domain of the dimer oscillate uniformly – a fact that is also confirmed with simulations. In addition, since the entire dimer is also deeply subwavelength, quasistatic Coulomb interaction emerges. Under these circumstances, the inter-dimer interaction assumes the following form:

$$\propto \frac{Q}{\Delta^2(t)}, \qquad (1)$$

where Q is a fixed-charge-related property and $\Delta(t)$ is the instantaneous separation between the two bodies of oscillating charges. Notice that this Coulomb interaction differs from what is usually foreseen for a dipole interaction where the separation is fixed, and the charge-related property oscillates. The dynamic denominator of Eq. (1) endows a coupled oscillator model with such coupling a significant nonlinear character. NLO, in this case, emerges from the *interaction* between two optical systems that are otherwise strictly linear in their response to an external field due to their extreme subwavelength dimensions.

Figure 1(a) shows full-wave simulation results for a deep subwavelength silver-silver (Ag-Ag) dimer in blue, silver-gold (Ag-Au) dimer in green and gold-gold (Au-Au) in orange. The simulation of our most advanced understanding of the SHG from a dimer system predicts that the Ag-Ag dimer should have the upper hand in SHG, followed by the Ag-Au case and ending with the Au-Au dimer. In addition, the spectral lineshape follows the dimer's

linear absorption spectra (not shown). Fig. 1(b) shows the measured SHG from corresponding samples. It is seen that the Ag-Au dimer substantially surpasses the other cases in terms of its SHG strength and, in addition, has a spectral peak - both indicating that the dominant NLO mechanism is not as predicted. The results of an oscillator model with coupling terms following Eq. (1) are shown in a solid black line for the Ag-Au case and a dashed black line for the Ag-Ag and Au-Au cases. It is seen that an interaction-based model captures both Ag-Au supremacy and its spectral peak. We have also studied other NLO effects; Fig. 1 (c) shows the DC potential from a sample configured for parametric optical rectification in blue and the prediction of the interaction model in green. The model reproduces the measured signal, including the non-quadratic trend at the strong-excitation regime, which is not thermal. On the contrary, the conventional theory shown in the orange line is limited to quadratic lineshapes that missed essential aspects of the light-matter interaction in this case.

In summary, we discuss experimental proof for a nonlinear optical mechanism beyond what is considered conventional. In the talk, we will present our methods of investigation and discuss the unique properties of interaction-based nonlinear optics for third-order processes, high harmonics, and optical chaos.

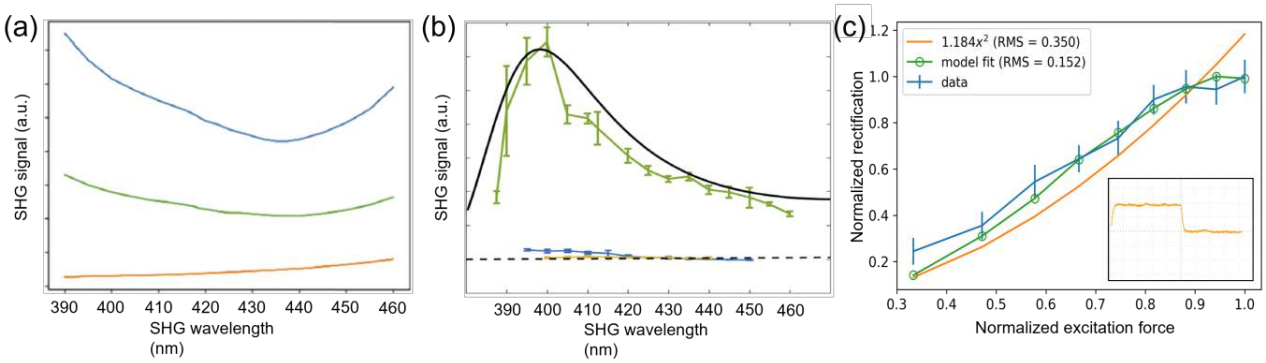

Figure 1: (a) Full-wave simulation of the dimer's SHG with blue, green, and orange lines depicting Ag-Ag, Ag-Au, and Au-Au dimers, respectively. (b) The experimental results from corresponding dimers. Notice that the Ag-Au case surpasses the Ag-Ag and the Au-Au dimers in contrast with the simulation results. Black lines depict the interaction model prediction for the Ag-Au case (solid) and for the Ag-Ag and Ag-Au cases (dashed). The proposed interaction-based nonlinear model reproduces the Ag-Au supremacy and its distinctive SHG peak. (c) Parametric rectification signal Vs. laser excitation force. Experimental results are shown in blue, the interaction model predictions are in green, and the best-case scenario of a conventional optical nonlinearity is in orange. It is seen that the model reproduces the non-quadratic trend of the rectified signal, which is a genuine interaction-based nonlinear effect and not a thermal one. Inset shows the parametric rectification signal for a single On-Off sequence of the excitation laser.

Controlling High-Q Lattice Resonances in Bipartite Plasmonic Arrays through Nanoparticle Geometry and Orientation

Timo Stolt[1*], Jussi Kelavuori[1], Ali Panahpour[1] and Mikko J. Huttunen[1]

[1]Photonics Laboratory, Physics Unit, Tampere University, FI-33014 Tampere, Finland
[*]corresponding author: timo.stolt@tuni.fi

Abstract: We numerically investigated plasmonic nanoparticle (NP) arrays with bipartite lattice configuration. The lattice periodicities were selected to give rise surface lattice resonances (SLRs) at two separate wavelengths in the near-infrared region. We show that the quality factors of the SLRs can be considerably improved by modifying the NP geometry and mutual orientation. NP modification also impacted the local-field distributions associated with SLRs, which is expected to have a significant impact on the nonlinear responses of the studied structures.

Periodic arrays of plasmonic nanoparticles (NPs) show potential for realizing novel photonic devices, such as microscopic lenses, lasers, and nonlinear components [1-3]. The optical responses of such structures can be enhanced through collective resonances known as surface lattice resonances (SLRs), which are narrowband collective excitations associated with high quality-factors (Q-factors) and strong local-field enhancements [4]. Recently, structures exhibiting multiple SLRs have shown promise for tunable nonlinear metasurface devices [5,6]. However, different SLRs in such multiresonant designs often occur for orthogonal polarization states. This results in poor spatial overlap between different SLR modes, and consequently, weakened light–matter interaction. Here, we address this issue by designing plasmonic bipartite NP arrays exhibiting two SLRs for the same incident polarization. We show that by changing the NP geometry and orientation, the Q-factors and mutual mode-overlaps of the occurring SLRs can be improved, which is essential for enhancing nonlinear processes taking place in such NP arrays.

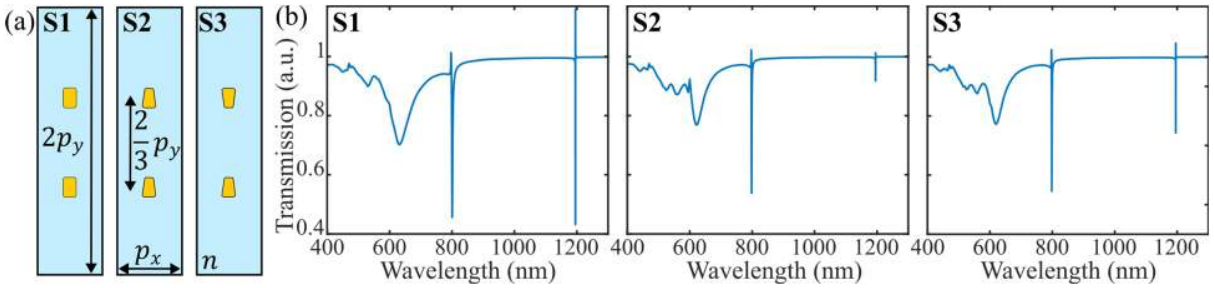

Figure 1: (a) The studied metasurface designs S1–S3 consisted of gold nanoparticles arranged in bipartite lattice. The arrays were embedded in homogeneous glass surroundings with refractive index $n = 1.45$. (b) Transmission spectra for x-polarized light for the studied sample designs. With p_y = 825 nm, the bipartite metasurfaces exhibit two SLRs near λ_1=800 nm and λ_2=1200 nm, respectively.

We numerically investigate (COMSOL Multiphysics) the optical properties of three metasurface designs consisting of gold NPs embedded in homogeneous glass surroundings ($n = 1.45$). Sample S1 consisted of rectangular NPs with thickness of 40 nm, length of 120 nm, and width of 80 nm (see Fig 1a). These NP dimensions give rise localized surface plasmon resonance (LSPR) near 625 nm (see Fig 1b). For samples S2 and S3, the width on one of sides of the NPs was shortened by 30 nm. In S2, the NPs were oriented in the same direction, while in

S3, every second NP was flipped so that the narrow ends of the NPs would point to each other. The narrowing of the NPs slightly blueshifts the LSPR to 620 nm and make it slightly narrower. The flipping of the NPs had no visible impact on LSPRs.

For all three designs, the lattice configuration was the same. Along the x-axis, each unit cell had one NP and periodicity of p_x = 400 nm. Along the y-axis, the total periodicity was $2p_y$ and two NPs were separated by $2/3p_y$ (see Figure 1a). With p_y= 825 nm, this lattice configuration gives rise two SLRs, named SLR1 and SLR2, near λ_1 = 800 nm and λ_2 = 1200 nm, respectively (see Figure 1b). The NP geometry and orientation do not significantly change these resonance wavelengths, but rather the Q-factor associated with the SLRs (see Figure 2). First, the narrowing of the NPs increases the Q-factor of SLR1 from 300 for S1 to roughly 1000 for S2 and S3. However, only narrowing the NPs decrease the Q-factor of SLR2 significantly: for S1 it is approximately 50 000, while for S2 it has decreased significantly to approximately 12 000. Interestingly, this effect can be compensated by flipping every second NP in the array. Thus, for S3, the SLR2 has a considerably high Q-factor of roughly 30 000. Furthermore, S3 has improved mode overlap between the two analyzed SLR modes, which is expected to boost nonlinear frequency-conversion processes, such as sum-frequency generation, difference-frequency generation, and four-wave-mixing.

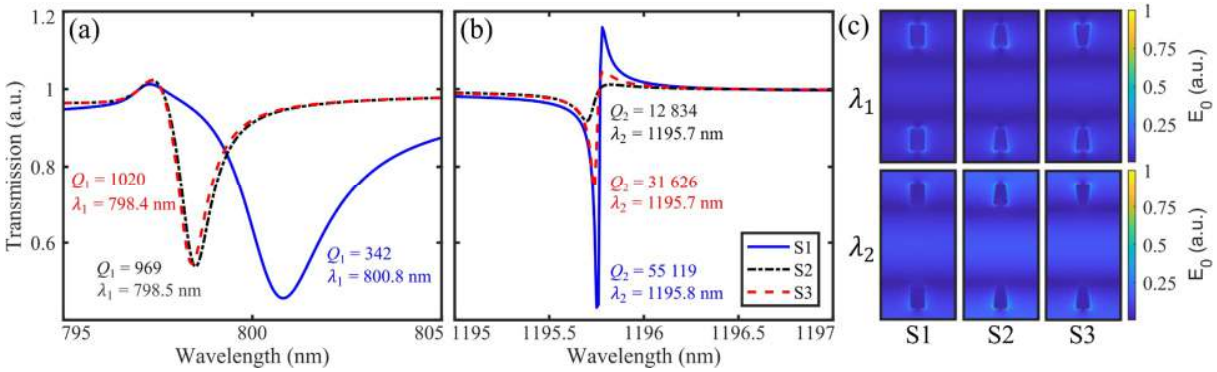

Figure 2: Transmission spectra for the investigated designs S1–S3 near (a) SLR1 wavelength $\boldsymbol{\lambda_1}$ and (b) SLR2 wavelength $\boldsymbol{\lambda_2}$. (c) Near-field distributions at $\boldsymbol{\lambda_1}$ and $\boldsymbol{\lambda_2}$.

Abstract: Many outstanding properties of halide perovskites provided their applications in optoelectronics. Perovskite films demonstrate outstanding nonlinear properties with large optical nonlinearities comparable to the nonlinear constants of conventional semiconductor materials. Meanwhile, nonlinear properties can be enhanced by the metaphotonic approach. Here we demonstrate a two-order enhancement of fifth-harmonic generation in halide perovskite nonlocal metasurfaces due to high-quality resonance at the generated harmonic wavelength in the visible frequency range.

Halide perovskites have many outstanding properties such as a tunable bandgap, pronounced exciton at room temperature, and high photoluminescence quantum yield [1]. Moreover, methylammonium lead halide perovskites have large nonlinear constants compared with conventional semiconductor materials [2] which provide a promising application for nonlinear metaphotonics. Their strong nonlinearities have provided high multiphoton absorption [3] and third-harmonic generation [4]. Engaging of metaphoric approach led to significant enhancement of two-photon photoluminescence and made it comparable to linear one [5]. Meanwhile, broken-symmetry nonlocal Si metasurfaces supporting a BIC demonstrated enhancement of high-harmonic generation [6]. Herein, we implement metaphotonics approach for the fifth harmonic generation in halide perovskite.

We designed and fabricated $MAPbBr_3$ metasurface that consists thin slab placed on a glass substrate and patterned with a shallow grating. Obtained metasurface supports two modes, a bound state in the continuum and guided-mode resonance, in the visible range. By pumping in the mid-IR range we observed third-harmonic generation in the near-IR range and fifth-harmonic generation in the visible range. The fifth-harmonic signal provided enhancement up to 90 in the range of pump wavelengths that generate harmonic in the visible range near the structure resonance of the metasurface. Our nonlinear simulations confirmed that the observed enhancement is due to the excitation of both modes of the structures. We believe our work paves the way toward efficient perovskite nonlinear metaphotonic devices.

Optical bistability in Su-Schrieffer-Heeger lattice with Kerr nonlinearity

Ghada Alharbi, Sang Soon Oh*

School of Physics and Astronomy, Cardiff University, Cardiff CF24 3AA, UK
*E-mail: ohs2@cardiff.ac.uk

Abstract

We present a nonlinear 1D Su–Schrieffer–Heeger model that models an array of coupled ring resonators with Kerr nonlinearity. We theoretically demonstrate that spontaneous symmetry breaking can be observed by symmetrically pumping the array in the clockwise and counterclockwise directions. The optical bistability can be attributed to the different shift of resonance frequencies between the two counter-propagating modes.

In the recent years, the study of photonic topological insulators has rapidly grown as an interesting subject in the fields of nanophotonics and quantum optics. Researchers have applied topological insulator models to various photonic platforms, e.g., an array of optical waveguides and microring resonators, to explore unique properties related to zero-energy modes [1, 2, 3]. Topologically protected localization at one edge of the system is the unique characteristic of topological insulators. So far, most of studies have considered the photonic topological insulators in the linear regime with weak field intensities. This is partly due to the complexity in modelling nonlinear responses together with modulated couplings. In this work, we study optical bistabilities coming from the Kerr nonlinear effect in a one-dimensional lattice model, called Su-Schrieffer-Heeger (SSH) model.

First, we implement the SSH model in a photonic system by arranging coupled microring resonators with alternating coupling coefficients, v and w. Then, we introduce the Kerr nonlinearity in each ring resonator that leads to the change of refractive indices, called self-phase modulation (SPM) and cross-phase modulation (XPM). The first ring resonator in the array is pumped by the two input sources with the same amplitudes S_{in} in the opposite directions. Fig. 1(a) shows the SSH model consisting of $(N+1)$ unit cells, and each unit cell has two sites: a and b.

To theoretically describe the model, we use the temporal coupled mode theory where the time evolution of the circulating field amplitudes a_n and b_n are calculated in the time domain. Here, we consider the intensities of the modes circulating in the clockwise $(+)$ and counterclockwise $(-)$ directions at each ring resonator [4, 5].

$$\begin{aligned} \frac{da_{n,\pm}}{dt} &= -i\Big[\omega_0 + i\omega_0\kappa(|a_{n,\pm}|^2 + 2|a_{n,\mp}|^2) - i\gamma_n\Big]a_{n,\pm} + \gamma_c s_{in} + ivb_{n,\mp} + iwb_{n-1,\mp}, \\ \frac{db_{n,\pm}}{dt} &= -i\Big[\omega_0 + i\omega_0\kappa(|b_{n,\pm}|^2 + 2|b_{n,\mp}|^2) - i\gamma'_n\Big]b_{n,\pm} + iva_{n,\mp} + iwa_{n+1,\mp}, \end{aligned} \tag{1}$$

where n denotes the index site. Here, the parameters γ_n and γ'_n are defined as $\gamma_n = \gamma_0 + \gamma_c\delta_{n,1}$ and $\gamma'_n = \gamma_0$, where γ_0 is the damping coefficient and γ_c is the coupling coefficient between the input waveguide and the first ring resonator. $\omega_0 = \omega + \Delta$ is the resonance frequency, here ω is laser frequency and Δ is detuning. On the right hand side of Eq. (1), the first term describes the detuning, the second and third are nonlinear terms with Kerr coefficient κ and the fourth is a damping term. The fifth term is the input field that appears only for the first ring resonator because it is the only one pumped directly by the input sources. The other terms are related to the coupling between the ring resonators.

For convenience, we normalize the coefficients in Eq. (1) with respect to the damping coefficient γ_0. Then, the equation can be written as :

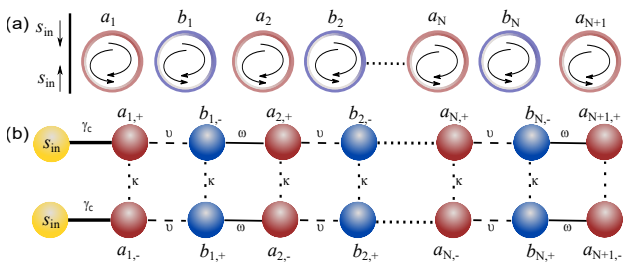

Figure 1: (a) A 1D array of coupled ring resonators with alternating gap sizes. (b) A schematic of the SSH model with resonators with Kerr nonlinearity coefficient κ.

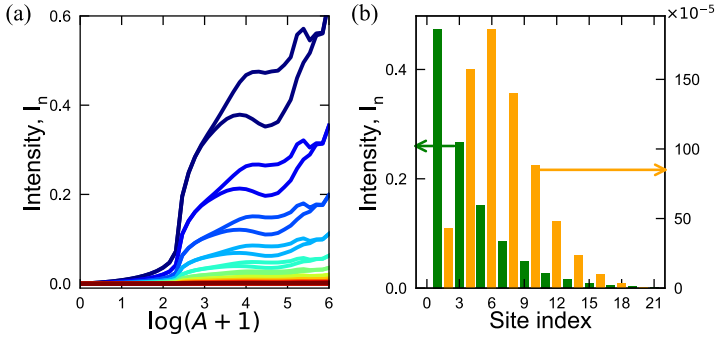

Figure 2: (a) Bistability observation for $M = 21$ ring resonators with detuning $\tilde{\Delta} = 1.85\tilde{\gamma_c}$, $\tilde{\gamma_c} = 10$, $\tilde{\kappa} = 10$ and $\gamma_0 = 0.001$. (b) The distribution of intensity on sites for $\log(A+1) = 4.15$ for odd sites (green color) and even site (orange color).

$$\begin{aligned} \frac{da_{n,\pm}}{d\tilde{t}} &= -\tilde{\gamma}_n - i\Big[1 + i\tilde{\kappa}(|a_{n,\pm}|^2 + 2|a_{n,\mp}|^2)\Big]a_{n,\pm} + \tilde{\gamma_c}s_{in} + i\tilde{v}b_{n,\mp} + i\tilde{w}b_{n-1,\mp}, \\ \frac{db_{n,\pm}}{d\tilde{t}} &= -\tilde{\gamma'}_n - i\Big[1 + i\tilde{\kappa}(|b_{n,\pm}|^2 + 2|b_{n,\mp}|^2)\Big]b_{n,\pm} + i\tilde{v}a_{n,\mp} + i\tilde{w}a_{n+1,\mp}, \end{aligned} \tag{2}$$

where the tilde denotes normalised quantities and we set the normalized frequency as the unity. Note that Eq. (2) is the Lugiato-Lefever equations [6] modified with additional couplings between the ring resonators and the input waveguides.

The circulating intensities for each ring resonator at different input amplitudes A are illustrated in Fig. 2(a). We observe the symmetry breaking of light intensities at the pump amplitude between $\log(A+1) = 3$ and $\log(A+1) = 5.8$. When the pump intensity goes above a certain level, the Kerr nonlinear effect shifts the resonance frequency of the modes and, along with some detuning, results in the optical bistabilities. As shown in Fig. 2(b), the field intensity becomes significant for odd sites only (sublattices a) and decreases exponentially in the right direction, which is the signature of the zero-energy edge modes.

In conclusion, we have theoretically shown that the spontaneous symmetry breaking in intensity between circulating optical modes can occur in a nonlinear coupled ring resonator even when symmetrically pumped in the clockwise and counterclockwise directions. We have shown that the Kerr effect starts to induce the resonance frequency shift between circulating modes at a certain value of the incident amplitude,

Abstract: We report a combined experimental/theoretical investigation on second and third harmonic generation from a plasmonic gold nanograting, resonant in the near infrared. The intense field localization leads to significant enhancement in nonlinear optical processes, more than three orders of magnitude herein, compared to flat gold nanolayer. The spectral and angular dependence (qualitative and quantitative) of the harmonics were experimentally recorded and validated within the framework of our microscopic, hydrodynamic model for linear and nonlinear material dispersion mechanisms of metals.

Theoretical and experimental study of nonlinear optical properties of metals, arches back to the beginning of nonlinear optics. Despite their high absorption in the visible and near infrared spectral ranges, metals are highly nonlinear materials and the study of NL optics from metal surfaces combined with plasmonics is a very active field of research with important applications in the fabrication of functional nano-photonic devices. However, the efficiency of harmonic generation from gold nanolayers and nanostructures is generally very low and is strongly limited in the wavelength range where absorption is present. Also, most of experimental results presented in literature often show only qualitative aspects of this enhancement, do not quantify the efficiency (presenting only arbitrary units) and are not in good agreement with the theoretical models set forward. It is crucial to understand and exploit the properties of light propagation and localization at the nanoscale to successfully design nano-antennas, filters and other devices whose geometrical features approach atomic size. At this scale light matter interaction display completely new and interesting physical phenomena and may not be well explained by conventional approximations.

Previously we were able to observe second (SH) and third harmonic (TH) generation from 20 nm and 70 nm-thick gold nano layers, to extract the basic physical intrinsic properties of the material [1]. Now we head towards structured nanomaterials, hence the grating, which promises enhanced nonlineartiy and more practical applications such as sensors, photonic circuits, high resolution imaging etc. Our approach consists of an expanded hydrodynamic model [2] that accounts for surface, magnetic and bulk nonlinearities extracted from equations of motion arising from free (Drude model) and bound electrons (Lorentz model) and contains different nonlocal effects such as convection and hot electrons.

The theoretical spectral response of the grating in reflection is calculated by means of rigorous coupled wave analysis (RCWA), also verified experimentally, and the reflectance map is shown in Figure 1(b). We fix the input wavelength at 800 nm, mapping the resonance at 16° incident angle (Figure 1(c)) for further measurements. The plasmonic structure confines the fields near the surface, producing an intense field close to the corners (Figure 1(d)), which in turn is responsible for pump absorption (resulting in near zero reflections) and the simultaneous enhancement of nonlinear interactions. Given the grating periodicity of ~610 nm, the SH (400 nm)

and TH (266 nm) produce several diffraction orders. The reflected SH efficiency from the grating, when summed over the different orders, is around 1.5×10^{-9}, which is about 1400 times the total SH efficiency from the planar gold part. Similarly, as shown in Figure 1(e), the total enhancement factor for the TH is of nearly 4000.

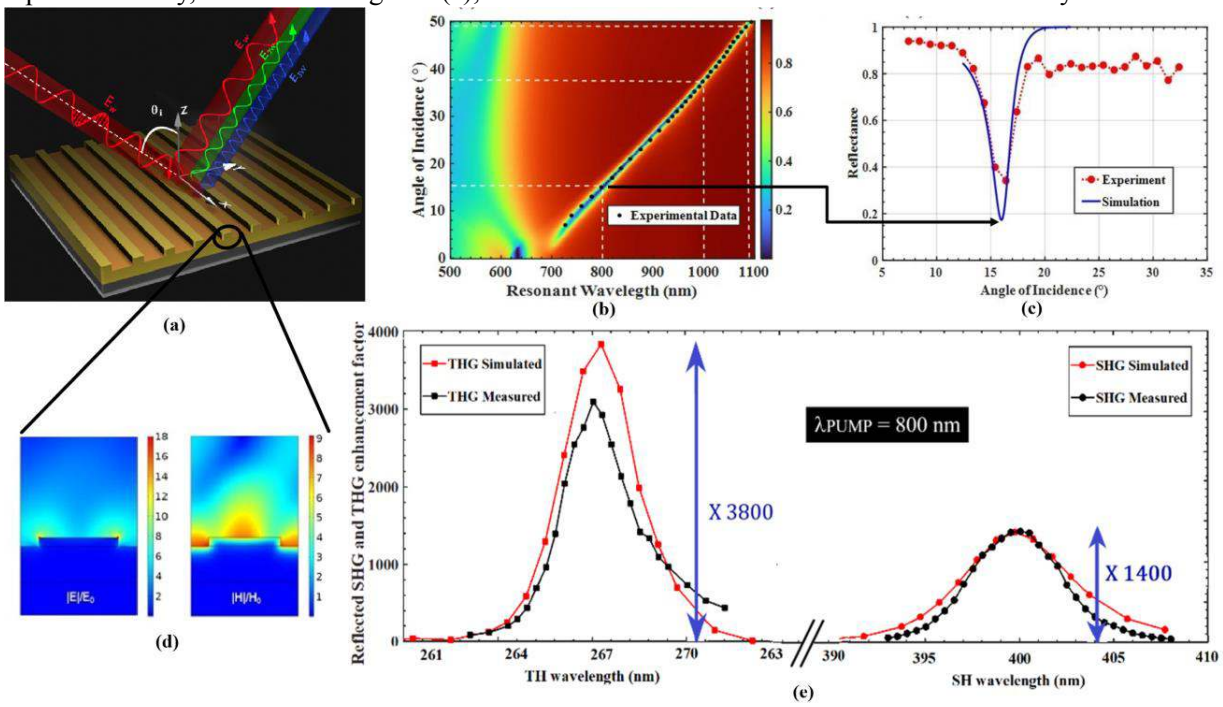

Fig. 1 (a) Schematic idea of the project. (b) Grating reflectance map, for TM incident polarization, as a function of incident angle and wavelength. The reflectance is normalized to 1 (100% reflection). Experimental measurements are shown as black dots on top of the simulations. (c) Reflectance as a function of incident angle for carrier wavelength tuned at 800 nm, normalized to the value obtained from the unpatterned gold layer: simulation (solid blue curve) and experimental measurements (dashed curve with red dots). The resonance is centered at 16º (d) Electric and magnetic field distributions at 800 nm and 16º angle of incidence around a single groove, normalized with respect to the incident electric and magnetic field amplitudes. (e) Simulated and measured enhancement of reflected SHG and THG, while pump wavelength is tuned at 800 nm and incident on the sample at 16°.

The reflected SH efficiency (0^{th} diffraction order) were also measured around 1000 nm (resonance at 37°), and around 1100 nm (resonance at 50°). The combined results of the three measured wavelengths depict conversion efficiencies of the same order of magnitude, although varying slightly due to different lab environments, different incident angles and penetration depths into the metal.

Based on the theoretical model, a large set of simulations were carried out, to obtain both SH and TH enhancements, varying incident pulse durations (FWHM) and using different grating geometries (channel and ridge widths). The results clearly show near-perfect agreement between theory and experimental observations of shape, spectral width, and maximum amplitude of the spectral response, and ways to enhance further the performance of the grating. The novelty of this work relays on the demonstration that a "mere" grating contains and displays a constellation of linear and nonlinear effects that require complex models, and should not be explained away using "effective" dielectric constants that may fit the observed spectra. Our results are not at all speculative, but demonstrate accurately a very good qualitative, and most importantly, quantitative agreement with our experimental results.

Abstract: Photonics is a promising solution to meet the growing demand for data in defense, aerospace, and telecommunication sectors. However, current linear optical systems face limitations in performance and applicability due to the lack of nonlinear elements required for generalized computation. To address this challenge, that combines an ENZ film with a metasurface exhibiting a surface-lattice-resonance (SLR) has been developed. Simulations suggest that on optical excitation, the transmission of the film can be modulated by over 150% (27% to 71%).

The defense, aerospace and telecommunication sectors have a growing demand for data due to new edge technologies like 5G and AI, which is putting pressure on underlying technologies to scale [1]. To address this challenge, new methods of transmitting and processing information, such as quantum and neuromorphic systems, are being explored, with a promising approach being the use of optical technologies. Photonics offers fast terahertz-level computation, high parallelism, and direct compatibility with several optical technologies such as imaging systems, optical fibers, and numerous sensors. In essence, they offer the potential to exceed the performance of conventional systems by 1000× while reducing size, weight, and power constraints [2,3]. However, current linear optical systems face limitations in performance and applicability due to the lack of nonlinear elements required for generalized computation.

This work directly addresses this problem, by realizing a device that combines an epsilon-near-zero film (ENZ) with a metasurface exhibiting a surface-lattice-resonance (SLR). The large nonlinearities observed in ENZ films coupled to the highly sensitive SLR resonance offers a path towards realizing a nonlinear activation function at sub-GW/cm^2 levels, opening the potential for excitation with laser diodes and fiber optic systems.

The proposed nonlinear activation function (Fig. 1) is implemented via a plasmonic metasurface exhibiting high-Q (>500) surface lattice resonances (SLR), which are a hybridization between the localized surface plasmon resonances (LSPR) and propagating Rayleigh anomalies (RA). The designed metasurface consists of a rectangular array (1060 nm by 500 nm) of rectangular gold nanoantennae (150 nm by 160 nm) on a 65-nm thick ITO film on a glass substrate, cladded by oxide (Figs. 1(a,e)). The targeted SLR resonance occurs at a wavelength of 1550 nm, with a FWHM of 8 nm (Figs. 1(b,c)). Upon pumping the metasurface on resonance (incident peak power ~10 GW/cm^2), a 30x enhancement in pump absorption is observed along with detuning of the resonance which leads to a change in probe (1570 nm) transmission intensity (Fig. 1(d)) of over 150% (27% to 71%). The index change of the ITO film is a result of generation of hot electrons in the conduction band, which increases the average electron effective mass. This results in a more dielectric film (index increases), causing the SLR to red shift. The large modulation achieved with THz scale bandwidth, provides an avenue towards the realization of a low-cost and high-performance nonlinear activation function, an essential building block for the construction of true optical computing systems.

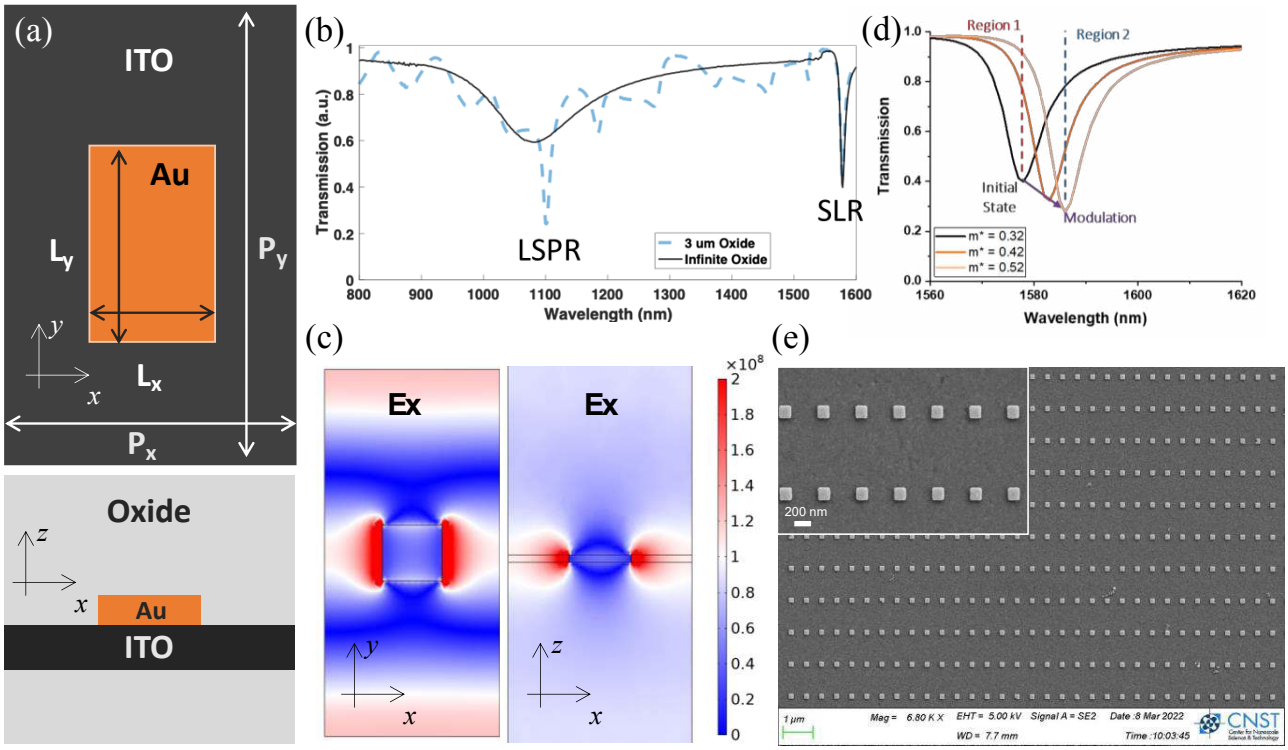

Figure 1: (a) Schematic of the SLR metasurface, top view and side view. Metasurface consists of Au nanoantenna (NA) fabricated on top of an ITO layer and cladded by an SiO_2 layer of thickness of a few microns. Abstract: We show the possibility of using photonic crystals to counteract the spatial Kerr effect, thus suppressing filamentation. Fine control of the spatial dispersion can be achieved by tuning the photonic crystal geometry and projecting to the appropriate Bloch mode branch. Chirped photonic crystals can be engineered with such geometry that the designed diffraction compensates for nonlinear focusing, suppressing beam filamentation.

Nonlinear propagation of intense ultrashort laser pulses in transparent materials produces a unique and spectacular phenomenon termed femtosecond filamentation. Femtosecond filamentation arises from a complex interplay between linear and a variety of nonlinear effects, which become coupled in space and time through material nonlinearity. This leads to a transformation of an ultrashort-pulsed laser beam into a light filament, which possesses an ultra-broadband spectrum, termed supercontinuum. In a sole spatial domain, the light filament emerges is a self-sustained structure that carries a limited amount of energy and power, which is of the order of critical power for self-focusing. In wide bandgap solid-state dielectric materials, in the near-infrared, P_{cr} is of the order of several MW [1]. However, many applications require high spectral energy density and high peak power, which is well above the typical values contained in a single filament.

Here we propose and substantialize an alternative idea that photonic crystals can efficiently suppress the emerging filamentation. It is well known that photonic crystals, can affect the overall diffraction of the beam [2]. The self-collimation effect is a thoroughly studied example of the effect of a photonic crystal on beam diffraction. This effect is caused by the flattening of the spatial dispersion curves that can be obtained for some photonic crystal geometries. Though this is of no particular use when it comes to suppressing filamentation, different geometries can be used to obtain other spatial dispersion regimes. For example, the reduced or increased curvature corresponds to weakened or strengthened diffraction. Another possibility is obtaining a spatial dispersion curve with a negative curvature corresponding to anti-diffraction. Considering this, we can infer that it is possible to devise a photonic crystal with such a geometry, that results in a spatial dispersion regime that can compensate for the nonlinear Kerr focusing of the beam, thus effectively suppressing filamentation.

Numerical simulations were performed using a forward beam propagation method, which approximates the envelope of the beam propagating in a slowly varying medium. The profile of refractive index modulation is chosen to be harmonic in both the transverse X and the longitudinal Z directions as shown in Figure 1a. The periodicities in both directions were varied to determine an optimal geometry, with the longitudinal period being tied to the transverse period through the Talbot length. It is convenient to introduce the geometric constant Q which is the inverse of the longitudinal period normalized to the Talbot length, the length at which self-imaging occurs:

$$Q = \frac{d_{Talbot}}{d_z} \cong \frac{2{d_x}^2}{\lambda d_z}$$

In the general case, for a photonic crystal with constant period and for all values of the geometric constant Q

that are close to 1, there are multiple dispersion curves corresponding to different Bloch mode branches. This is often undesirable since it makes it impossible to precisely control the diffraction of the beam, however this issue can be overcome by introducing an adiabatic chirp to the longitudinal period of the photonic crystal as seen in Figure 1a. We do this by starting at a longitudinal period corresponding to a geometric constant Q sufficiently far from 1 and slowly approaching the desired Q.

From the beam diameter evolutions shown in Figure 1b, we can see that in the homogeneous case (blue lines) the beam diameter first increases, but eventually the beam starts to converge and collapses at z = 2.84 mm. Using those same beam parameters but this time in a photonic crystal (yellow lines) we can see that the beam diameter again initially increases, however this time the beam does collapse, instead the beam converges only a little and the beam diameter asymptotically approaches some value for which the diffraction and nonlinear focusing are balanced. The initial divergence of the beams is likely because the initial beam used is elliptical.

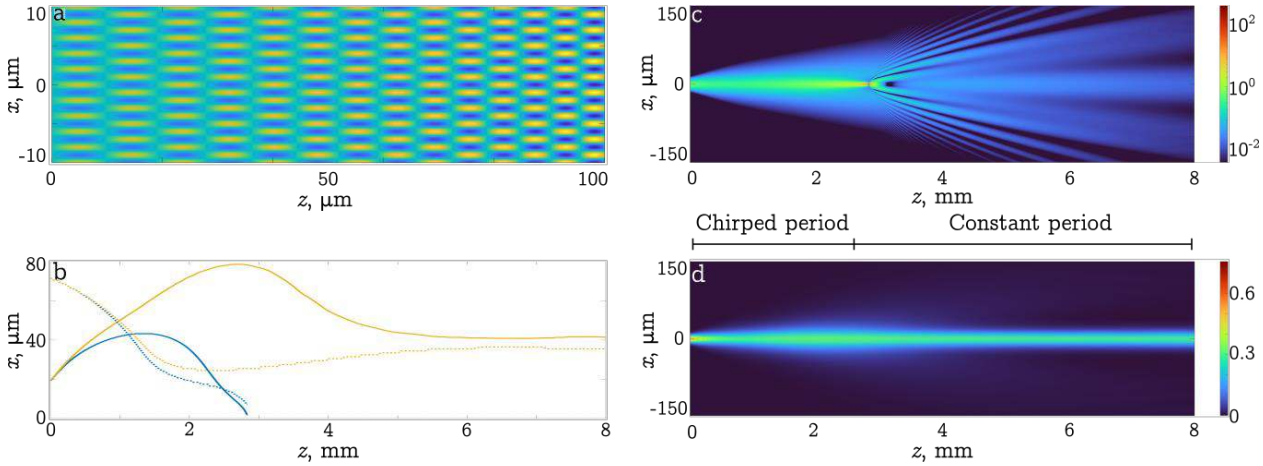

Figure 1. a – cross-section of the refractive index distribution in the modulated plane. b – beam diameter measured at e^{-2}; blue – unmodulated, yellow – modulated; solid – modulated plane, dotted – perpendicular plane. c and d – intensity distribution of the beam propagating in a homogeneous medium and photonic crystal, respectively.

The results show that using a photonic crystal with a geometry characterized by a value of Q close to 1 gives the desired result. In addition, using positive and negative chirp, both increased diffraction ($Q > 1$) and anti-diffraction ($Q < 1$) can be achieved.

In perspective, the current work created the framework for choosing advanced meta-structures that will be useful for super-continuum generation applications. Monolithic and compact devices that might replace the multi-plate systems might be enabled via future experimental tests.

This work has received funding from the Spanish Ministerio de Ciencia e Innovación under Grant PID2019-109175GB-C21, and the European Social Fund (Project No 09.3.3-LMT-K-712-17-0016) under a grant agreement with the Research Council of Lithuania (LMTLT).

Abstract: New stable periodic solutions are uncovered in the fractional complex Ginzburg-Landau equation with the introduction of non-Hermitian potentials. This equation is known to be a general model for extended dissipative systems. A thorough analysis of the dynamics and stability of the system is conducted. The stabilisation is proven to be robust in a wide area in the parameters space, with potential applications to other physical systems. As an example the study provides results on the stabilisation of Class B lasers.

In this work we uncover new periodic solutions in non-linear dissipative systems. The study is based on the universal Complex Ginzburg Landau Equation (GCLE) and extended to its fractional counterpart and to more realistic models such as Class B lasers. We show how the introduction of a non-Hermitian (complex) potential can effectively stabilise these states for a wide range of parameters. In these systems, turbulence is a challenging subject not only for its theoretical understanding but for the practical consequences. For instance, for lasers, turbulence represents one of the main aspects limiting the output power. Different attempts to control the turbulence have been proved. From the introduction of a global delayed feedback on the system [1] or the effect of a gradient [2] to the recently proposed unidirectional mode coupling through the introduction of spatiotemporal non-Hermitian potential [3].

The current work consists on another approach. Here we propose the stabilisation of specific stationary solutions of the different systems by the addition of a complex spatial modulation. In optics, the introduction of this potential corresponds to a harmonic modulation of the gain and refractive index of the system in the form: $V(x) = \cos(2\pi x/L)e^{-i\vartheta}$. In Fig. 1a) we can see a selected family of unstable periodic solutions of the unmodulated CGLE and in b) the evolution of the turbulent field with the dynamic introduction of a modulation for a fixed value of φ. We see how the field gets fully stabilised after a transient state. In Fig. 1c) we display the amplitude of the modulation, m, and the growth rate of the stationary solution that gets stabilised as a function of time. Note that stable solutions correspond to $\Re(\lambda) \leq 0$.

The results show extended stabilisation areas for a wide range of periodicities L. Stabilisation is found even for every tiny modulation of the gain and refractive index, up to only a 5% modulation amplitude for some cases. This stabilising effect is proven for different parameters (higher nonlinearity and different fractional dispersion) and holds for higher dimension of the system [4].

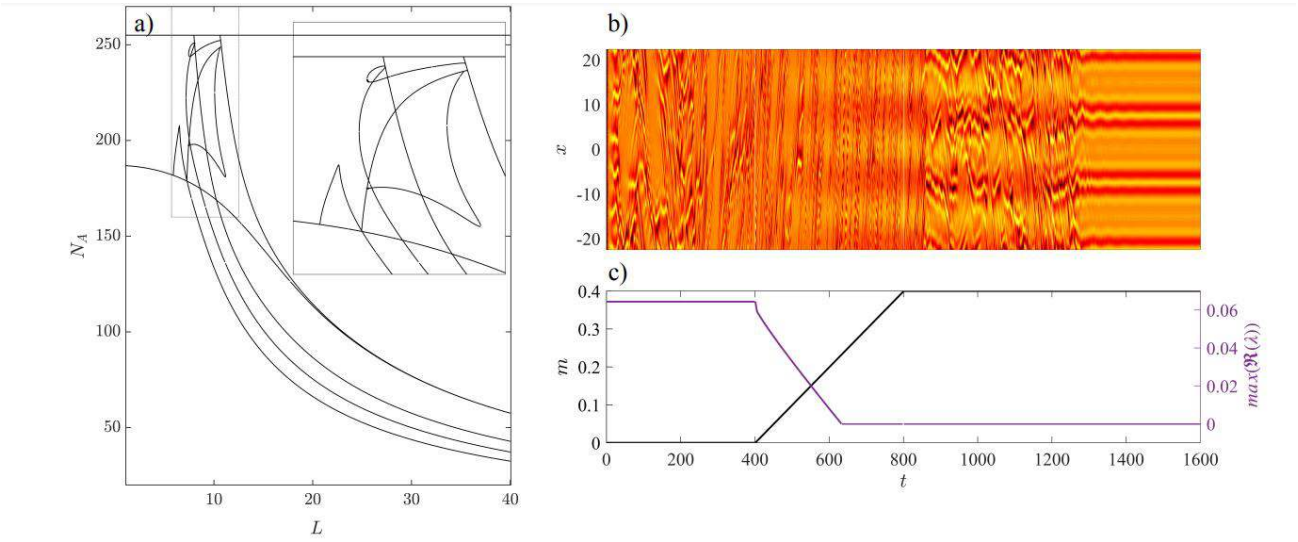

Fig. 1 a) Picture of the complexity of the unstable periodic solutions of the unmodulated CGLE. Inset corresponds to a zoom of some of the branches that are stabilised with the introduction of the non-Hermitian potential. NA corresponds to the norm of the solution. b) Transient evolution of the field profile from a turbulent state to the stable stationary state when the potential is applied. c) Profile of the potential amplitude and growth rate of the stationary solution

Moreover, the proposal holds also for Ginzburg-like models describing actual physical systems, for instance a 1D Vertical External-Cavity Surface Emitting Lasers, for which the dynamics of both the field and the carriers is considered. For this Class B lasers, the introduction of the non-Hermitian potential has shown to effectively stabilize the emission for highly unstable parameter ranges creating a large attractor basin.

Abstract: In this work we show the employment of a novel design photonic crystal (PhC) cavity in hybrid external cavity laser (HECL) configuration for refractive index sensing applications, with high sensitivity (145nm/RIU) and low detection limit (~10^{-5} RIU). The HECL RI sensor configuration exhibits a 16x improvement in the detection limit compared to the stand-alone photonic crystal cavity. In addition, the sensor is characterized by its compactness, high-power output, simplicity in fabrication, compatibility to integration process, and multi-sensing capability.

Recently optical biosensors have been developed to sense different analytes in real-time with high sensitivity and integration capabilities. For biomedical research, healthcare and environmental monitoring, the detection of ultralow concentrations of harmful compounds to human health is important. Therefore, sensors with detection limits (DLs) down to femtolitre [1] are very attractive for optical sensing applications.

In this work, we designed a novel PhC cavity based in 1D structure and optimized the cavity to work as laser mirror with very high Q-factors. Hence, by combining this 1D PhC cavity with III-V gain chips a new type of laser can be developed called Hybrid External Cavity Lasers (HECL). The HECL consists of a 250µm III/V reflective semiconductor optical amplifier (rSOA), and a Silicon Nitride (Si_3N_4) reflector. The reflector, consisting of a ridge waveguide and a side-coupled 1D PhC, is butt-coupled to the rSOA. To maximize optical coupling between the two components, the bus waveguide is designed with dimensions that match the area of the rSOA waveguide mode. This butt coupling approach has the advantage of designing, fabricating, testing, and optimizing the two components separately, ensuring optimal performance of both devices before packaging the laser. The laser characteristics were measured, and Figure 1 (a) shows the Light-Current (LI) curves for drive currents ranging from 0 to 100 mA, indicating high output power and low laser threshold. More than that, the HECL exhibits a mode-hop-free single-mode regime at telecom wavelengths for a wide range of drive currents (Figure 1 (b)), which is an important advantage for telecom and datacom applications.

As the laser mirror works as wavelength-selective feedback, the wavelength of the HECL is controlled by the 1D PhC cavity, and since part of mode supported by the PhC cavity exists in the cladding material, the lasing wavelength is strongly affected by the cladding refractive index (RI), making the laser a very precise RI sensor with high sensitivities [2]. The operation of the HECL as a RI sensor was studied by measuring the lasing wavelength shift in the presence of different upper-cladding materials (deionized water, i.e., "DI water", and sugar solution). Figures 1 (c) and 1 (d) demonstrate the experimental data of both optical spectral response, and calibration curve in terms of Δ_λ of the sensor with the standard deviations, respectively. Each data point was repeated multiple times to ensure the results repeatability. The HECL sensor exhibits a linear response when the

RI of the upper-cladding material increases. Furthermore, due to the lasing linewidth of the HECL being much narrower than that of the passive PhC resonance linewidth, the HECL improved the DL by a factor of ~16 to $6.6*10^{-5}$ RIU (limited value by the OSA resolution). We believe this is one of the first demonstrations using HECL for RI detection in which the experimental DL is much lower than the DL of its passive optical cavity, i.e., to the stand-alone photonic crystal cavity [2]. This promising result reinforces the advantage of hybrid lasers for refractive index sensing and not only for telecom/datacom applications. Moreover, the HECL-based RI sensor does not need an external light source, unlike the MMR RI sensor, which significantly reduces the system size and provides a better performance in terms of integration density.

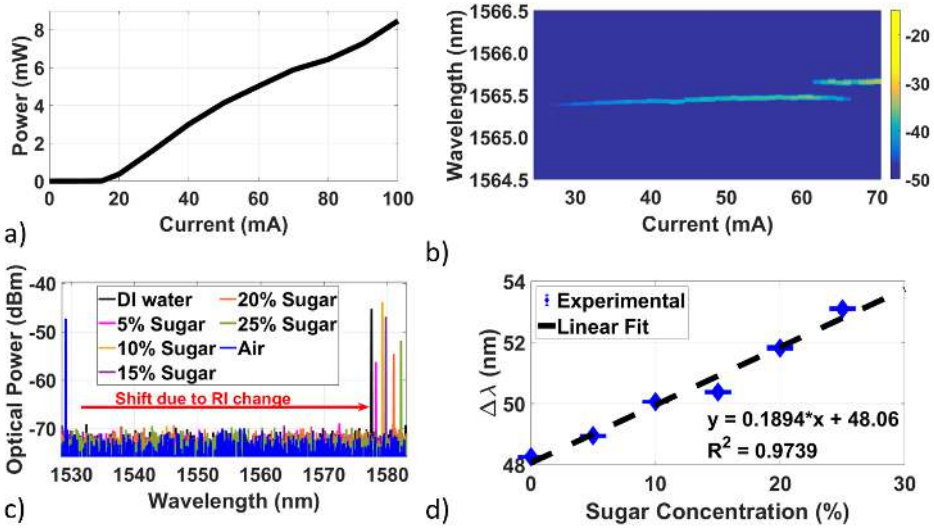

Figure 1. a) optical spectrum of the laser with different bias current; b) LI curve of the HECL; c) optical spectra of the sensor in the presence of different upper claddings; d) lasing wavelength shift when the upper cladding RI increases.

The main advantages that make HECL-based RI sensor attractive for optical biosensing can be summarized as follows: portability (lab-on-a-chip) and compactness, high power (mW range), high sensitivity, label-free detection (femtoliter detection), and simplicity in design and manufacturing (compared to 2D PhC). In addition, the HECL sensor presents important aspects from a commercialization point of view. These include the compatibility to integration process as Micro-Transfer Printing (mass sensor manufacturing capability) and the transparency from the visible to the NIR spectrum due the Si_3N_4 material, which opens the window for having sensors at different wavelengths on the same chip (multi-sensing capability).

Abstract: A promising approach towards the next generation of computing architectures are all-optical logic gates[1]. Strong light-matter coupling based free space all-optical transistors have recently demonstrated showing ultra-fast switching at room-temperature[2]. Here, we use silicon-on-insulator high index contrast grating microcavities to demonstrate polariton condensation and strong light-matter interaction on a chip. This opens the door for integrated all-optical transistors with scalability towards more complex optical logic circuits operating at room temperature.

Summary: Today, one of the most important technological challenges consists in the development of alternatives to CMOS-based computers. In this sense, one of the potential technologies, which could outperform the classical transistor in terms of switching speed and energy efficiency, is photonic transistors[1]. Microcavity exciton-polaritons (polaritons) provide the physical properties required for an ultra-fast transistor[2], as they inherit the speed from their photonic component and the non-linear interaction from the excitonic part. Nevertheless, up to now, no device capable of operating at room-temperature with a THz switching frequency has shown the capability of being scalable on-chip[2]. Here, we use a Silicon-On-Insulator (SOI) platform to realize High Contrast Grating (HCG) microcavities[3] (Figure 1) that support strong light-matter coupling[4], and which could serve as building-block for realizing integrated all-optical circuits. We demonstrate on-chip strong light-matter interaction and polariton condensation by means of HCG cavities filled with optically active polymer material.

The HCG structures are realized by patterning an SOI wafer with electron beam lithography and reactive ion etching. The planar nanophotonic Fabry–Pérot-like resonator is then constituted by two arrays of silicon pillars which provide the micron-sized lateral light confinement due to constructive and destructive interference given by the refractive index contrast provided by the metamaterial. The vertical confinement is achieved by total internal reflection from the spin-coated MeLPPP (methyl substituted ladder-type polymer) layer, which serves as organic semiconductor.

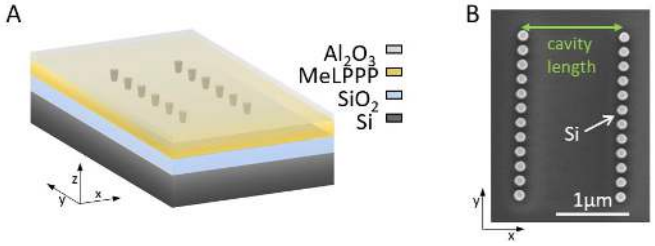

Figure 1. A) Top-view SEM image of an HCG cavity. B) Schematic of the HCG cavity.

We excited the cavities with a picosecond pulse at 400 nm in a micro-photoluminescence (µPL) setup. By varying the excitation fluence, we were able to observe polariton condensation, which gives rise to a narrow peak in the spectrum. Light-in-light-out characteristics (Figure 2.A) measured on a sample with cavity length L=1.82µm displays a polariton condensation threshold defined (grey bar at ≈81µJ/cm^2) by change in the slope.

Below the threshold, just PL is observed (violet in inset). Above threshold, a peak emerges on top of the PL signal, indicating polariton condensation (red in inset).

We fabricated multiple devices with different cavity lengths, allowing us to tune the cavity resonance and therefore the condensation energy (Figure 2.B). Comparing the experimental results (red circles) with Rigorous Coupled Wave Analysis (RCWA) simulations of the reflection of HCG cavities we observed that the experimental data and the RCWA simulation (solid yellow lines) are inconsistent for the weak light-matter coupling or purely photonic regime. By considering of the whole MeLPPP refractive index dispersion, the experimental data are well described by the RCWA simulation (greyscale map), showing anti-crossing of different longitudinal modes (i.e. lower polariton branches) at the excitonic energy (2.72 eV, dashed white line). This is an evidence of strong light-matter interaction regime. Furthermore, the definition of the resonances over a broad range of wavelengths (390-560nm) highlights the robustness of this metamaterial-based microcavities. The coupling-strength shows a record high value for MeLPPP-based cavities ($2\hbar\Omega$=350meV). The Hopfield coefficients, which determine the excitonic and photonic fractions of the constituting polaritons, are ~50%, establishing a record-high excitonic fraction for polariton condensates with this organic semiconductor.

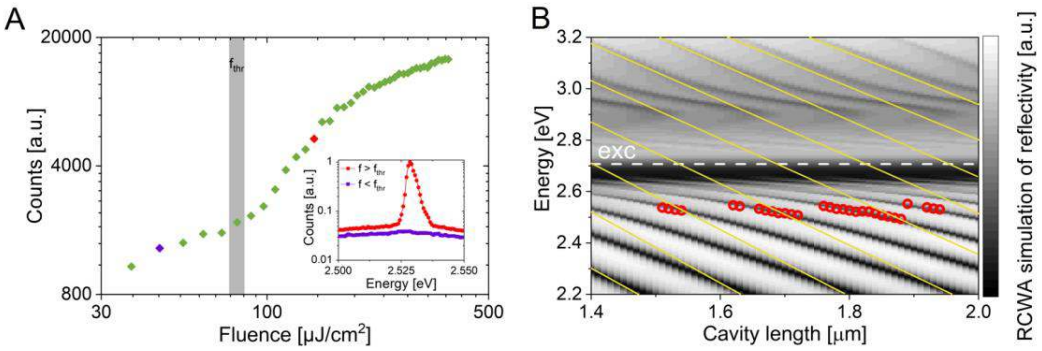

Figure 2. A) Light-in-light-out characteristic with polariton condensation above threshold. The inset shows the emission spectra below (violet) and above (red) threshold. B) RCWA simulations showing strong-coupling regime in the cavity detuning plot.

Conclusion: We have shown room-temperature polariton condensation on a photonic chip, paving the way to scalable polariton-based transistors. Progress of investigations of the coupling between multiple HCG cavities, which is central for establishing transistor action, will be reported.

Integrated Q-switched lasing element in the NIR with transition metal dichalcogenide gain and graphene saturable absorption

Abstract: We propose and analyze an integrated passively Q-switched lasing element in the NIR based on a nanophotonic disk resonator and enhanced with the contemporary MoS_2/WSe_2 TMD hetero-bilayer and graphene monolayer to provide the optically-pumped gain and saturable absorption, respectively. The configuration is rigorously evaluated utilizing a temporal coupled-mode theory framework. Following a meticulous design process, the pulsed lasing source delivers mW peak power and ps duration pulses, with a repetition rate of tens of GHz for sub-mW pump power.

The development of highly efficient, monolithically integrated light sources in the technologically mature silicon-on-insulator (SOI) platform constitutes a key scientific and technological goal for future high-density integration photonic circuitry. A new avenue towards this goal has been opened by the exploitation of the novel luminescence and nonlinear properties of two-dimensional (2D) materials, such as the semiconducting transition metal dichalcogenides (TMDs) and the semi-metallic graphene [1]. In this work, we propose and computationally examine an integrated passively Q-switched lasing component in the near-infrared (NIR), based on a nanophotonic disk resonator where both the gain and the saturable absorption (SA) mechanisms are provided by 2D materials. The contemporary MoS_2/WSe_2 TMD hetero-bilayer is selected as the gain medium; it emits light at 1128 nm (1.1 eV) after being optically pumped at 740 nm (1.675 eV). To enhance the efficiency of the light source, the gain medium is pumped by appropriately exciting a whispering-gallery mode of the cavity near the pump wavelength using guided light. A graphene monolayer is additionally utilized to harness the required ultrafast and low-saturation-intensity SA effect. To numerically analyze and design the proposed light source, we rigorously develop a temporal coupled-mode theory (CMT) framework [2, 3], fed by linear finite element method (FEM) simulations. The lasing and pumping transitions of the three-level gain medium (MoS_2/WSe_2 heterostructure), are described by induced electric polarization fields which are incorporated in the CMT framework employing first order perturbation theory. The polarization fields follow equations of homogeneously broadened Lorentzian oscillators and the carrier dynamics are described by appropriate semiclassical rate equations. The latter are introduced in the CMT framework using only the standard slowly-varying envelope (SVEA) and rotating-wave (RWA) approximations. Overall, the developed CMT framework is capable of accurately evaluating the fundamental lasing characteristics, including the lasing frequency and the dynamic response, and allows to extract useful practical design guidelines as well as conduct a linear stability analysis to identify operation regimes of the pulsed lasing structure.

The proposed Q-switched lasing configuration is depicted in Figure 1(a) and consists of a silicon-rich nitride (SRN) disk resonator on silica substrate. A double bus waveguide scheme is employed to efficiently excite the pumping mode and extract the emitted light from the lasing mode. The MoS_2/WSe_2 bilayer and graphene monolayer are patterned in disks matching the resonator and placed on top of it, separated by a 60-nm layer of hexagonal boron nitride (h-BN). The geometric parameters of the structure are marked in Figure 1(b). The

heights of the disk resonator and the h-BN layer have been judiciously selected, in order to allow for the lasing mode to interact strongly with both the TMD bilayer and graphene monolayer, which is a key prerequisite for the lasing element to operate in the pulsed regime. Concurrently, the employed configuration enables the pumping mode to interact strongly only with the TMD bilayer, hence, leaving unaffected the nonlinear response of graphene. This is schematically illustrated in Figure 1(c, d), where the norm of the tangential to the 2D materials electric field is depicted in the $x-y$ plane for the two modes. Due to the highly efficient pumping scheme and the strong light-matter interaction between the 2D gain medium and the lasing mode, the lasing threshold is only $26\ \mu W$. In Figure 1(e) we depict the output peak power, the full-width half maximum (FWHM), and the repetition rate of the obtained Q-switched pulses as a function of the pump power. By increasing the pump power, the pulse width decreases, while the peak power and the repetition rate increase. The proposed Q-switched lasing element is capable of delivering pulsed light inside an integrated bus waveguide with mW peak power, ps duration and GHz repetition rate even for sub-mW pump power, rendering it promising for optical communication and sensing applications in the NIR. An individual Q-switched pulse for $P_p = 0.5$ mW is depicted in the inset of Figure 1(e), which has an asymmetric lineshape with slightly longer leading edge.

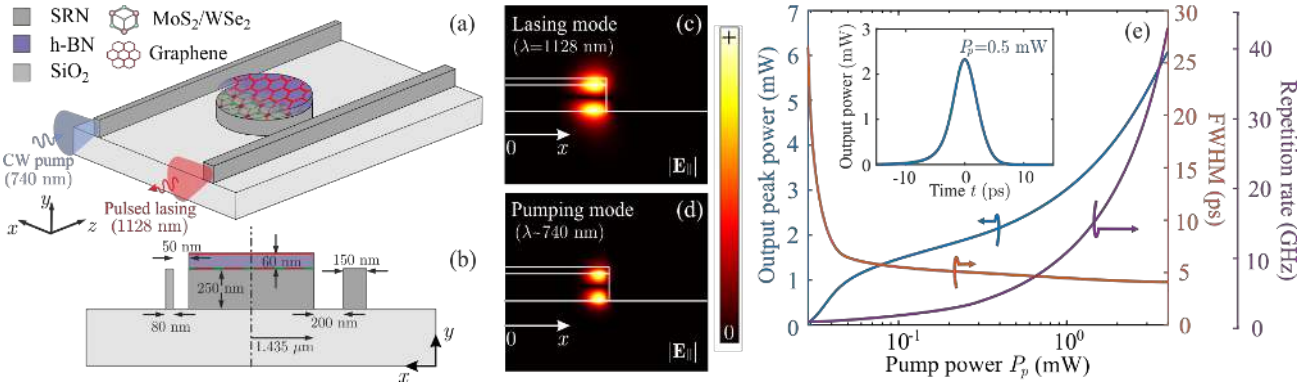

Figure 1. (a) Schematic of the proposed Q-switched lasing element consisting of a disk resonator comprising a MoS_2/WSe_2 TMD hetero-bilayer (gain) and a graphene monolayer (SA). The cavity is side-coupled to two dissimilar bus waveguides. (b) xy-plane cut of the structure with the geometric parameters. (c, d) Norm of the tangential to the 2D materials electric field for the (c) lasing and (d) pumping mode. (e) Output peak power, FWHM and repetition rate of the Q-switched pulses as a function of the pump power P_p. Inset: Individual Q-switched pulse for $P_p = 0.5$ mW.

Abstract: To obtain and control remarkable polarization properties of light, we consider a self-organizing, one-dimensional photonic potential inside a liquid crystal optical microcavity. Anisotropic modulation of the refractive index gives rise to two separated band structures for orthogonal, linear polarizations of light that interact with each other through spin-orbit coupling. The soft matter approach allows for efficient tuning of the bands with an external electric field.

Optical anisotropy in photonic structures typically grants greater control over system parameters, e.g. photon energy. In this case, the additional degree of freedom related to the polarization of light also distinguishes directions. Breaking the symmetry can lead to the spontaneous appearance of chirality in a system [1]. The introduction of an additional photonic potential may result in the appearance of photonic band gaps and states of light that inherit the polarization properties of the system [2].

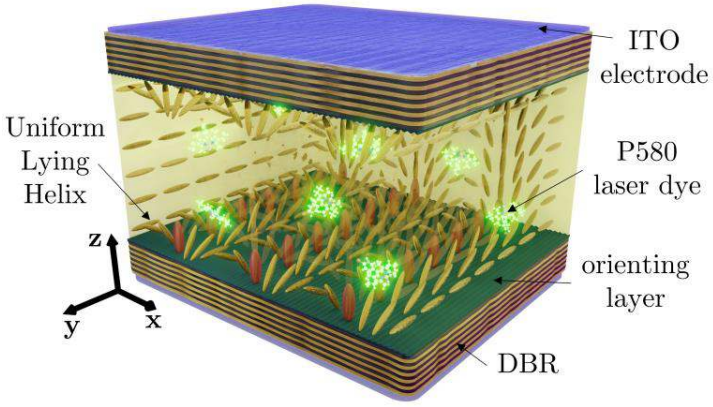

Figure 1. Schematic representation of the dye-doped optical microcavity with a stabilized ULH structure embedded within.

In this work, we propose a dye-doped liquid crystal optical microcavity with a built-in uniform lying helix (ULH) structure (Figure 1) that was induced in a chiral nematic liquid crystal matrix. Due to the birefringence of liquid crystals, a one-dimensional periodic modulation of the refractive index leads to the formation of two separate band structures with orthogonal linear polarization of light (Figures 2a, 2b). The inclination of the helix with respect to the plane of the cavity gives rise to the appearance of Rashba-Dresselhaus spin-orbit coupling for light, which couples the two bands together. As a result of the coupling, new states with strong circular polarizations are formed (Figure 2c).

An important aspect of the system is its technological advantages. A self-assembled one-dimensional well-oriented photonic potential based on ULH is formed in a macroscopic area (tens of micrometers). A special benefit of the use of soft matter is the easy dynamic tunability of the helix pitch (that is, the period of the

photonic potential) with an external electric field. In addition, due to doping the structure with light emitters, the system can transit to a non-linear regime with the laser light emitted from the sample [3].

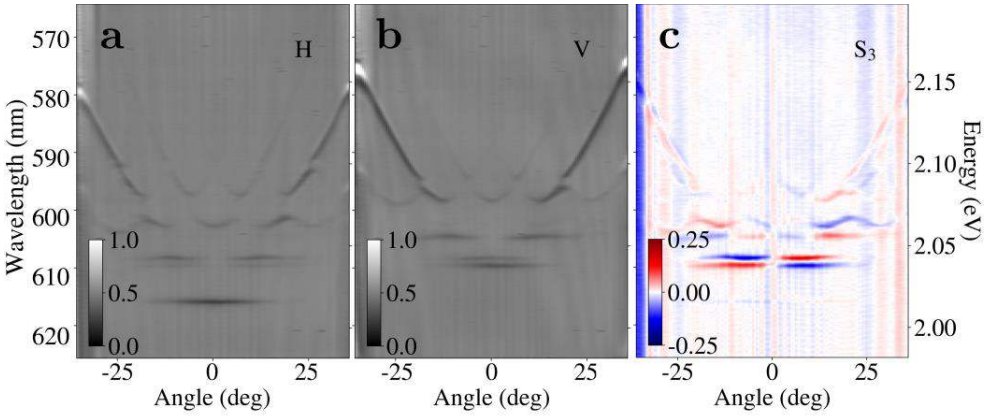

Figure 2. Angle-resolved reflectivity spectra of well-organized ULH in liquid crystal optical microcavity. Dispersion relation measured for orthogonal linear (a) horizontal H and (b) vertical V polarization of detected light. (c) Stokes parameter S_3 shows circularly polarized states of light caused by Rashba-Dresselhaus spin-orbit coupling.

To describe the dispersion relations observed experimentally, we propose a theoretical model based on effective Hamiltonians, which can be successfully applied to other optically anisotropic periodic structures. We believe that the phenomena presented here can be interesting and easily adapted not only in liquid crystal optical microcavities but also in fields such as photonics, metamaterials, or strong light-matter coupling.

Silicon Nitride Ring Resonators operating at 450nm

S. Jastan[1,2*], S. Iadanza [3], and L. O'Faolain[1,2]

[1]Munster Technological University, Ireland

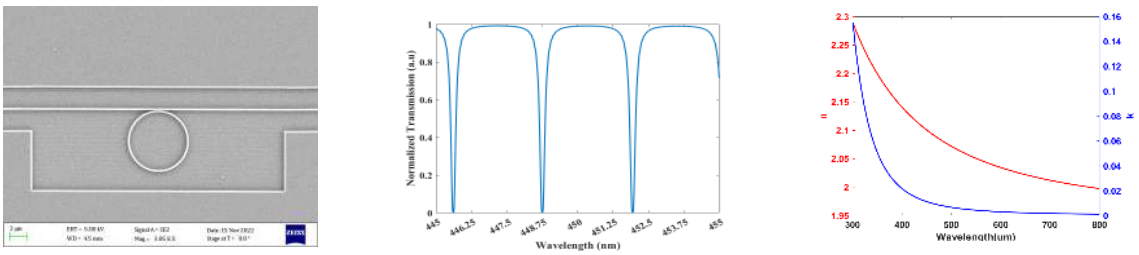
Abstract: This study utilizes Low Pressure Chemical Vapor Deposition (LPCVD) to deposit a 190 nanometer layer of Silicon Nitride (Si_3N_4) on Silicon Dioxide (SiO_2) for the purpose of fabricating Micro Ring Resonators (MMRs). The MMRs are designed to operate in the deep blue wavelength region, specifically at 450 nm. The compact design of the MMRs, characterized by their small radius on the order of a few microns, allows for a reduced device footprint.

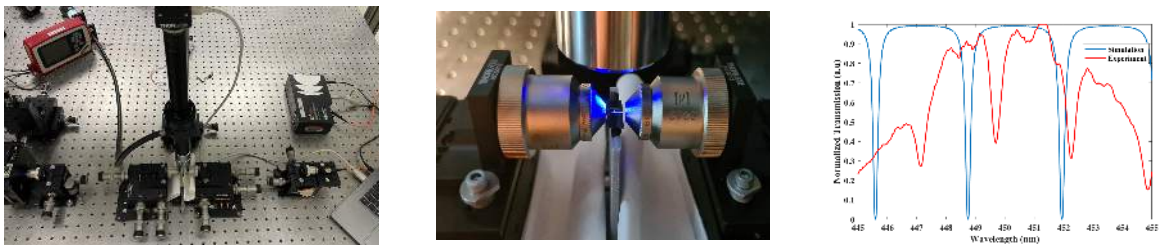


Recently, integrated ring resonators have gained popularity in the field of integrated optics and are now widely used in various applications. Their major application is for optical filtering and modulation. In addition, when combined with a broadband reflector, they can function as a wavelength-selective filter. A hybrid laser can be realized by coupling such a filter with a reflective semiconductor optical amplifier (RSOA) that will lase light at the same wavelength as the resonator. In order to obtain a narrow bandwidth laser, it is necessary to implement frequency-selective optical feedback, and a high Q factor ring resonator can fulfill this function. In this study, we are focusing on this application to develop narrow bandwidth lasers operating at 450 nm. Narrow linewidth light sources in the blue wavelength range are vital to applications ranging from Quantum Photonics to Raman spectroscopy to medical diagnostics. In particular, lasers at the wavelengths 461, 422, 407 and 396nm are important to compact atomic clocks, a rapidly emerging market, in which a narrow line-width blue laser source is used to target the atomic cooling transition. For designing the rings, we started with calculating the appropriate radius of the rings for 450 nm wavelength. In order for light to interfere constructively inside the ring resonator, the circumference of the ring must be an integer multiple of the wavelength of the light,

$$2\pi r n_{eff} = m\lambda \tag{1}$$

In this equation *r* is the ring radius, *m* is an integer, λ is our desired wavelength where we want to have a resonance, and n_{eff} is effective refractive index of the propagating mode. The quality factor (Q-factor) of a ring resonator is a parameter that determines how sharp the resonance is at the operating wavelength. If we define the resonance width as $\delta\lambda$, the Q-factor can be calculated using the following equation [1,2],

$$Q = \frac{\lambda}{\delta\lambda} \tag{2}$$



Utilizing VarFDTD module of the Lumerical software, we conducted simulations of the ring resonators. The Scanning Electron Microscopy (SEM) image of the ring structure (Figure 1a) and the transmission spectrum of the designed rings are depicted in Figure 1, illustrating our simulation outcomes. The challenge of working in the shorter wavelength range is due to the high loss characteristics of many materials in this spectrum. To assess material loss prior to fabrication, we deposited 190nm of SiN on Silicon Dioxide and conducted ellipsometry measurements. This allowed us to determine the absorption coefficient, as depicted in Figure 1c. Due to demand for high resolution, we employed Electron Beam

(a) **(b)** **(c)**

Figure 1: (**a**) SEM image and (**b**) Transmission spectrum of the designed ring resonator. (**c**) Ellipsometry data for loss calculation

Lithography (EBL) for fabrication and utilized a plasma etcher for the etching process. To characterize the fabricated rings, we used an endfire characterization setup which is shown in Figure 2. Also, Figure 2b shows the coupling method of light to the waveguides. In this setup, we used a broadband supercontinuum light source (400-2400 nm) which can be operated by a filter with tunability of 10 nm to 100 nm. In this experimental configuration, the light emitting from the

(a) **(b)** **(c)**

light source is coupled to the objective lens and propagates through the waveguides and ring resonators. On the opposite side of the chip, a second objective lens collects the light, which is then guided to a spectrometer for spectral analysis. The initial experimental results for the rings are presented in Figure 2c and compared to the simulation outcomes. The experimentally measured Q-factor was 1184, and the simulation Q-factor is 2000. These values are extracted directly from the FWHM of the resonance shape and using equation (3). Further enhancements will be pursued by modifying the ring structures and optimizing the fabrication process.

In summary, we have developed a simple method for fabrication and characterization of ring resonators that operate at 450 nm. The simulation of the ring resonators is described, which includes the display of the transmission spectrum of the designed rings. Additionally, the outcomes of the fabricated rings from experimentation are presented and compared to the simulation results. The initial results of the Q-factor of the ring structure are reported.

Abstract: We present an interlayer exciton laser composed of a MoS2/WSe2 heterostructure integrated with a silicon photonic topological microcavity with a quality factor of up to 10^4. We achieve excitonic lasing with ultra-low threshold, high side-mode suppression ratio and the longest emission wavelength to the telecommunication O-band.

Atomically thin heterostructures have attracted substantial attention in recent years due to their novel electronic and optical properties, and their ability for band structure engineering. Interlayer excitons (IX) with electrons and holes separated in different layers possess a long lifetime and have been used as an efficient gain medium for lasing [1,2]. However, IX lasing in optical communication wavelength has not been realized. Here, we report a room-temperature single-mode IX laser operating in the O-band (1260 – 1360 nm) [3]. Our observation is enabled by integrating a type-II heterostructure (MoS2/WSe2) with large band offset with a high-quality-factor topological silicon nanobeam cavity. We observe a single-mode lasing emission at 1320 nm with a linewidth of <~0.1 nm, the narrowest value reported for 2D material-based lasers. We highlight that the spectral resolution of our measurement setup limits the experimentally observed linewidth. Our work establishes IX as a practical gain medium for telecom lasing emission and highlights its potential for on-chip integration with silicon photonics platforms to develop compact, low-power, and high-speed optical communication systems.

Photonic bandgap structures

Fabrication of All-Garnet Bragg Mirror using Cerium Substituted Yttrium Iron Garnet

Yuki Yoshihara[1,2], Pang Boey Lim[2], Mitsuteru Inoue[1], Kazushi Ishiyama[1] and Taichi Goto[1]

[1]Research Institute of Electrical Communication, Tohoku University, Japan

Abstract: A multilayer sample comprising cerium substituted yttrium iron garnet layer and gadolinium gallium garnet layer, which can act as a magnetooptical Bragg mirror, was fabricated on the yttrium aluminum garnet (YAG) substrate. The sample was fabricated by the ion beam sputtering method. Crystalline, optical, and magnetooptical properties were measured. The three-pair periodic structure was epitaxially grown on the YAG substrate with a lattice relaxation. An optical bandgap at a wavelength of 960 nm was observed, and magnetooptical responses were measured.

Magnetooptical Q-switch is a futuristic technology and is anticipated to realize high-power, tiny, and active Q-switched laser. Recently, the spin-controlled laser (SCL), which composed of a magnetooptical Q-switch and neodymium-doped $Y_3Al_5O_{12}$ (Nd:YAG) laser crystal, was demonstrated [1, 2]. Integration of components in the SCL is desired for the development of further practical devices. One of the great candidate materials for the integration of magnetooptical Q-switch is cerium-substituted yttrium iron garnet (Ce:YIG). Doped Ce into YIG enhances Faraday rotation angle at near-infrared wavelength region, which operates YAG laser with low optical absorption [3]. Ce:YIG has $a = 1.243$ nm lattice constant which is larger than $a = 1.201$ nm of YAG laser crystal. Such a large lattice mismatch between the film and substrate is supposed to involve dislocation defects and decreases magnetooptical behavior when Ce:YIG is grown directly on YAG. To prevent this issue $Gd_3Ga_5O_{12}$ (GGG) should be an effective material as the seed layer with $a = 1.238$ nm. Moreover, the Bragg mirror can be constituted by a difference in refractive index between Ce:YIG and GGG. In this report, we designed a three-pair periodic structure of Ce:YIG and GGG seed layer, working as a Bragg mirror, and fabricated it using by ion beam sputtering (IBS) method. Crystalline, optical, and magnetooptical properties of the fabricated sample were measured.

The periodic structure of $(Ce:YIG/GGG)^3/YAG$ substrate was designed by the matrix approach method [4]. Optical thicknesses of each layer d were determined so that the $\lambda = 4nd$, where λ is the center wavelength of the bandgap (1000 nm), n is the refractive index of the materials for each layer. From the calculation, d was determined as 132.3 nm and 113.6 nm for GGG and Ce:YIG, respectively. Ce:YIG and GGG films were deposited by a radio-frequency (RF) IBS system (RMTec, RM17-0010) on the YAG substrate. The substrate dimension was 10 mm x 10 mm x 0.5 mm with (111) surface orientation. The substrate temperature was held at 900°C during the deposition. The thickness of the film was measured by a stylus profilometer (Bruker Dektak XT-A). The crystalline structure was measured by an x-ray diffractometer (XRD, Rigaku Smartlab). Optical transmissivity was measured by spectrophotometer (Shimadzu UV-3150). The magnetooptical property was measured as Faraday rotation angle by the magnetooptical measurement system (JASCO J-1700FK).

The reciprocal space map (RSM) around the (336) diffraction point of the fabricated sample, which is shown in Figure 1, was measured to observe crystal structure. There are two films' peaks with the same in-plane q_x(-1

-1 2) coordinate, which means the in-plane lattice is well-matched between Ce:YIG and GGG. Although two film peaks deviated from the YAG substrate peak both in- and out-of-plane with broad peak supposed to lattice relaxation of the film from the substrate. Rocking curve measurement around (444) substrate peak was also performed, and there were no other peaks. The measured total thickness of the deposited film was 745 nm. Based on the single layer thicknesses of GGG and Ce:YIG deposited under the same condition, the expected thickness for GGG was 141.1 nm and for Ce:YIG was 112.3 nm. The transmissivity of the sample was 59% at the center wavelength of a bandgap of 960 nm. The Faraday rotation angle of the sample was –0.19° at λ = 1000 nm, 3.0 times larger than the epitaxial Ce:YIG film on YAG substrate. These results showed that a $(Ce:YIG/GGG)^n$ periodic structure can be grown epitaxially on a YAG substrate, and exhibits both magnetooptical response and Bragg mirror functionality. This suggested that the structure has the potential to be used in the development of integrated magnetooptical laser devices.

Morphogenetic Design of Self-Organized Correlated Disordered Media

F. Chehami[1*], C. Decroze[1], and T. Fromenteze[1]

[1]University of Limoges, XLIM, UMR 7252, F-87000 Limoges, France

Abstract: Recently, a new class of materials referred to as correlated disordered structures has emerged and gained growing attention offering a significant improvement in the control of scattering, transport and localization of light in matter. So far, the different protocols proposed to design such arrangements consist on gradient descent methods requiring high computational efforts. In this paper, we propose a new simple method, inspired by the Turing's morphogenesis theory, for designing self-organized correlated disordered media exhibiting isotropic photonic band gaps.

In the context of the emergence of structures exhibiting a correlated disorder, several numerical approaches have been proposed to generate such media [1, 2]. However, most are based on gradient descent algorithms evaluated on non-convex cost functions defined over extensive set of design parameters. In this paper, we propose a new design method inspired by the morphogenesis theory introduced by A. Turing [3], in an attempt to explain the formation of structure in nature. This generative technique defined as a *reaction-diffusion* system, is a mathematical model only following local interaction rules, making it easily adaptable to complex geometries and scalable to large domains. The Gray-Scott reaction-diffusion model [4] is considered in this work, based on a simple system of two chemical species diffusing and interacting with each other, governed by the two following differential equations defining the evolution of the concentration of each chemical species over time :

$$\frac{\partial A}{\partial t} = \left(d_A \nabla^2 A - AB^2 + f(1-A)\right) \qquad (1)$$

$$\frac{\partial B}{\partial t} = \left(d_B \nabla^2 B + AB^2 - B(f+k)\right) \qquad (2)$$

A and B correspond to the concentration of two chemical compounds considered, which Turing defined as morphogens. The parameters f and k control the spontaneous generation and extinction of A and B, respectively, determining population equilibria forming spatial clusters. We focus in this work on a specific class of Turing patterns forming circular spots. Their synthesis is provided by solving Eqs. (1) and (2) by the finite difference method (Fig. 1), revealing a self-replicating dynamic similar to mitosis.

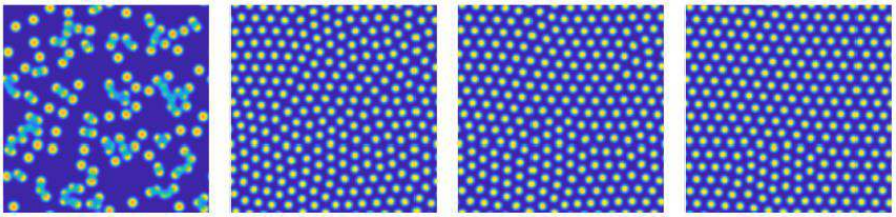

Figure 1: Generation steps of the self-replicating spots at different temporal iterations

Once the available space is filled with spots, the latter tend to optimize their compactness as the model iterates, transitioning from a disordered distribution to a quasi-crystalline arrangement. This model thus offers a way to generate disordered media whose degree of spatial correlation can be controlled. The self-structuring capability is

thus obtained through simple interaction rules defined at a local scale, without any form of cost function optimization.

To illustrate the ability of this generative model to synthesize correlated disordered media, an experiment of isotropic electromagnetic band gap formation is reproduced using this new technique [6] (Fig. 2).

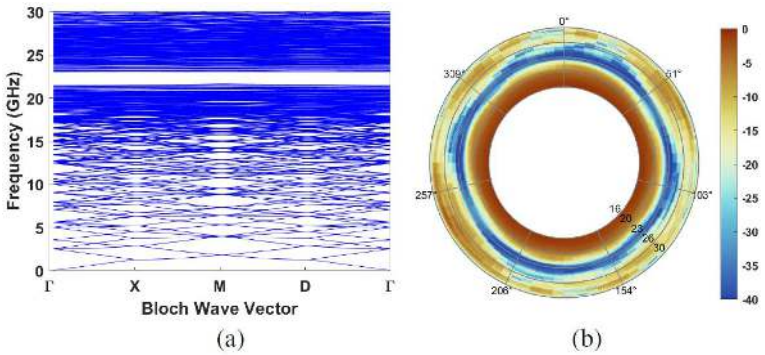

Figure 2: (a) Dispersion diagram and (b) Transmission measurements, over all incident angles, of the morphogenetic correlated disordered structure.

The computation of dispersion diagrams using the plane wave expansion method allowed the dimensioning of a structure based on acrylic rods of 3 mm radius (ϵ_r = 3), ensuring the formation of a band gap in the 18-26 GHz band. This structure was fabricated using commercial lollipop sticks of 15 cm length. A transmission measurement by means of a lens system forming a Gaussian beam allowed the extraction of attenuation coefficients in magnetic transverse excitation. Rotation of the sample revealed the formation of a quasi-isotropic band gap, characteristic of a structure with both periodic and random material properties.

This new morphogenetic generation method may offer flexibility, freedom and simplicity in the design of many components for applications in wave control devices such as freeform waveguides, polarizers and optical cavities with high quality factors.

Abstract: We measure near-field directional emission in a terahertz photonic crystal slab near its quasi-TM band edge. We find that the direction of the emitted field dramatically differs for two neighbouring channels (0.445 THz and 0.465 THz) due to the underlying band structure, in agreement with simulations. We also find that the field is enhanced on the slab surface indicating a concentration of radiation. This platform has potential applications in alignment-free, chip-based 6G technologies.

Technologies operating at terahertz frequencies (i.e., sub-millimeter waves) will demand waveguides for chip-based connectivity to support emerging applications in 6G telecommunication, biosensing and spectroscopy [1]. On-chip waveguides can provide diffraction-free propagation, but coupling efficiency is sensitive to alignment. Photonic crystal (PHC) slabs and anisotropic metamaterials can support alignment-free self-collimation and directional emission via a tailored local density of states [2-5], but such effects have only been measured at near-IR and microwave frequencies [4-7].

Here we experimentally demonstrate directional emission in a terahertz PHC slab near its quasi-TM band edge through near-field excitation and imaging. Figure 1(a) shows a micrograph of the PHC, which is composed of a silicon slab (refractive index: n = 3.4; thickness: 250 µm) containing hexagonally arranged voids (pitch a=240 µm; radius r=0.3a). Figure 1(b) shows a detail of the experiment, where a *x*-polarized near-field terahertz emitter and moveable detector [8] (Protemics) are placed on each side of the PHC. The calculated band structure of the PHC (Fig. 1(c)) shows a quasi-TM band gap near ~0.45 THz (dashed line). An *x*-polarized electric dipole, placed externally to the PHC slab, most efficiently excites quasi-TE Bloch modes that have a wave vector component in *y*, and which are close enough to the light line that they can be excited. Figure 1(d) shows isofrequency contours at 0.435THz and 0.455THz, indicating that at each frequency emission direction of the Bloch modes (perpendicular to the contour) strongly differ. This highlights the sensitivity of PHCs to changes in frequency and the potential of harnessing their band structures for specific device applications, e.g., frequency selective signal routing.

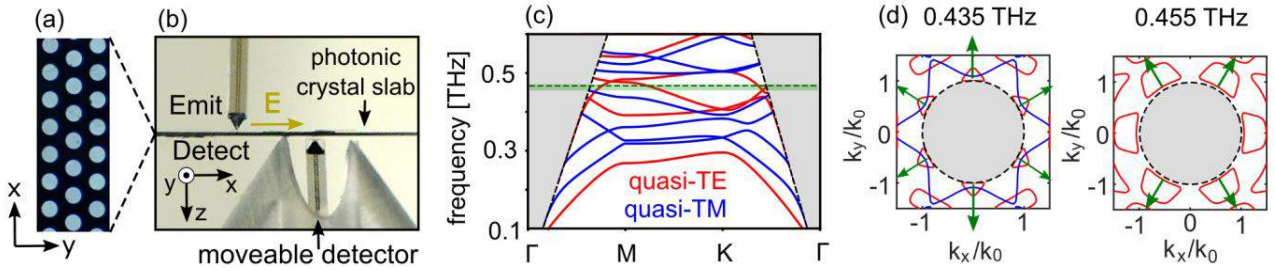

Figure 1. (a) Photonic crystal micrograph. Black: silicon; white: air. Period: a=240 µm; hole radius: r=72 µm. (b) Photograph of the terahertz emitter and detector on either side of the PHC slab. Yellow arrow: electric field direction. (c) Calculated photonic crystal band structure in the first Brillouin zone. (d) Calculated isofrequency contours (COMSOL) at 0.435 THz and 0.455 THz. Green arrows indicate preferred emission direction for the quasi-TE Bloch modes that are close to the light line (dashed line) to which we couple in our experiment.

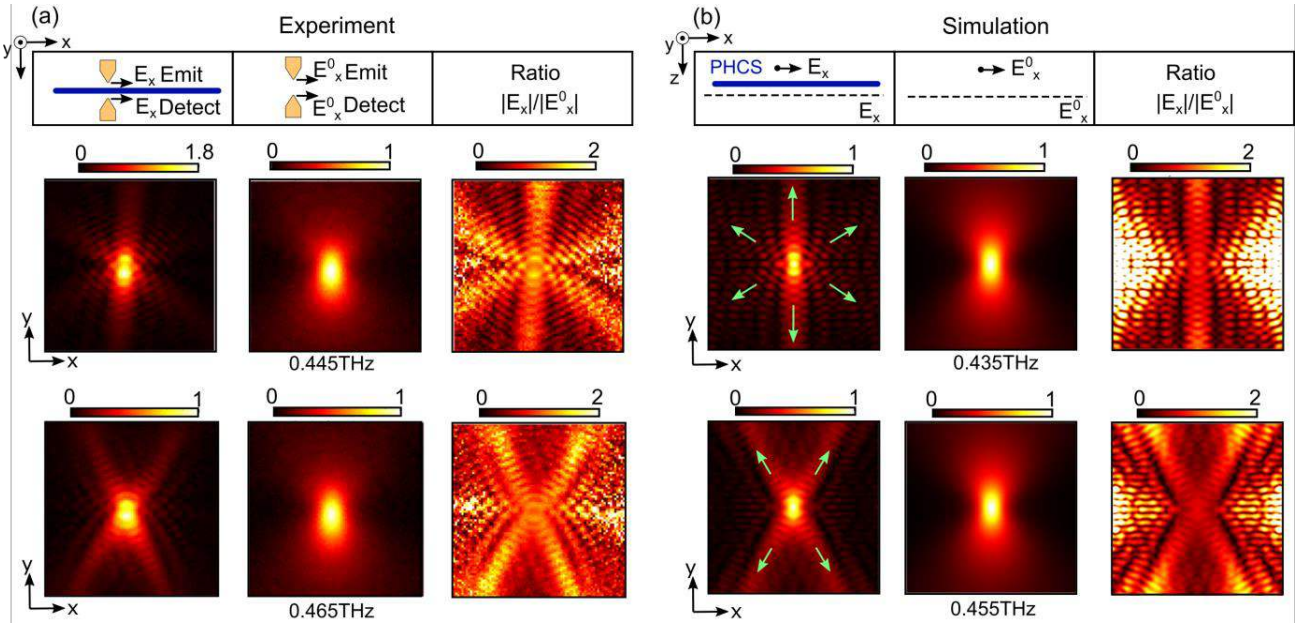

Figure 2. (a) Experiments of the transmitted electric field magnitude of an *x*-polarized electric dipole in near-contact with a PHC slab (left), without the slab (middle) and their ratio (right). (b) Corresponding simulations (CST). Green arrows are oriented as per Fig. 1(d).

Figure 2(a) show the experimental results: in the left column we show the *x*-polarized electric field magnitude distribution measured by scanning the moveable detector in *x* and *y*, transmitted by an *x*-polarized antenna located on the opposite side of the PHC, for two frequencies neighboring 0.45THz. The middle column shows the same experiment with the PHC removed. As expected from Fig 1(d), the field at lower frequency preferentially propagates along the *y* axis but splits in two across the diagonal at the higher frequency. The ratio between the first and second columns (third column) shows that for the same excitation, fields are locally increased due to the PHC in the vertical/diagonal regions of directional emission. FDTD simulation results, shown in Fig. 2(b), are in excellent agreement with simulations, with the same overall behaviour at frequencies within 2% of expectation. These experiments reveal that silicon photonic crystals can be harnessed to support frequency-selective directional emission of two neighboring sub-millimeter channels across spatially distinct pathways. We believe that this work provides a valuable addition to the limited library of chip-based functionalities of 6G technologies.

Nonlinear 2D Photonic Crystal Tunable Switch

A. Bounouioua[1*], A. Benmerkhi[1], and M. Bouchemat[1]

[1] Laboratoire de Microsystèmes et Instrumentation, Electronics Department,
Frères Mentouri Constanine1 university, Algeria

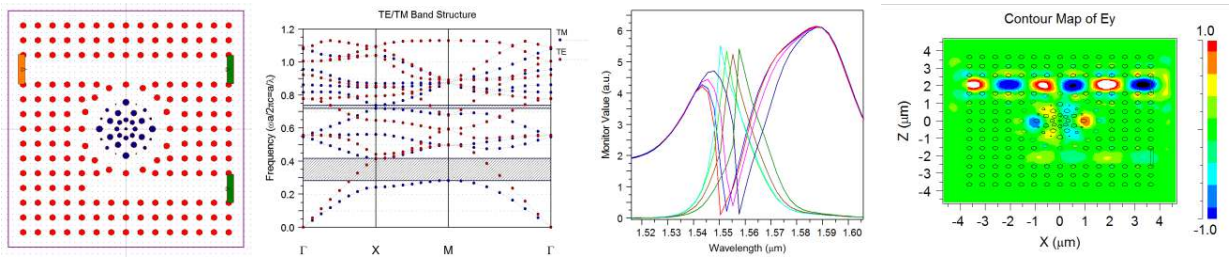
Abstract: In this study, we explored the effect of different tuned parameters in a 2D photonic crystal structure for all-optical switching based concept. The design based on a defect nonlinear ring resonator in a square lattice of silicon rods in air background is analyzed numerically. The outcomes of this investigation reveal very interesting switching characteristics by fitting the radius and position of the rods surrounding the center of the resonator. Furthermore, the device has multi-wavelength operation regime and fast response time with compact size.

NUMERICAL STUDY

In order to achieve the propagation of light with the c-band wavelength, we insert waveguides and ring resonator into the initial platform. The switching mechanism relays on the third order nonlinearity of a Kerr-like medium.

The calculation of band structure and simulation of the propagation of optical waves in the proposed structure were carried out using the plane wave expansion (PWE) and the finite difference time domain (FDTD) methods respectively. Simulation parameters such as the mesh sizes Δx and Δz in both X and Z directions and time step Δt were assumed $\Delta x = \Delta z = 50$ nm and $\Delta t = 0.1$ fs.



RESULTS AND DISCUSSION

Our platform is a square array of 15×15 silicon rods in air background. The Kerr-like medium is placed in the core of the ring resonator.

A photonic band gap (PBG) for TM mode was obtained in the range of $0.282 < a/\lambda < 0.417$.

By adjusting the radius and position of the rods surrounding the center of the resonator, we were able to adjust the operating wavelength to the desired point and produce a multi-wavelength operating design.

The effect of the previous parameters reveals the switching power threshold (<0.5w/µm), the response time (<1ps), the contrast ratio (>80% margin for logic 1).

(a) (b) (c) (d)

Fig. 1 (a) proposed structure, (b) Band diagram, (c) adjusting operating wavelength, (e) field propagation

CONCLUSION

By analyzing the obtained results and in comparison with works presented in the literature where for non-exhaustive example some focused on compactness of their structure [1] and some rather played attention to performing the switching parameters [2], we can say the one proposed in this paper gives a trade-off between all that and so it reveals a new area for 2D photonic crystal switches with tunable features.

Nanophotonics with stratified architecture for bright phosphor-based nano LEDs.

Debapriya Pal[1*], Femius Koenderink[1]

[1]AMOLF, Amsterdam, The Netherlands
[*]Corresponding author: d.pal@amolf.nl

Abstract: In pc-LEDs, phosphor blends are illuminated by a blue “pump” LED (GaN die) to achieve the desired spectrum. Nano LEDs are envisioned as pixels for display. This constrains the lateral size and the distance between the phosphor layer & GaN die. We design thin spacers inserted between the phosphor and GaN die, which recover the waveguiding characteristics of the phosphor layer at emission wavelengths and facilitate the use of nanophotonic strategies to increase light absorption and extraction in specific directions.

In current phosphor-converted LEDs, white light is generated efficiently by using a blue "pump" LED to illuminate a phosphor blend that emits longer wavelengths. The phosphor materials absorb part of the incident blue photons and re-emit at larger wavelengths for, e.g., white light emission. Nanophotonic strategies, such as diffractive metasurfaces, to enhance pump absorption and emission directivity in this scenario work since the phosphor is far away from the blue emitting GaN, thereby avoiding that phosphor emission disappears into the LED [1]. In this work, we study the much more complex scenario of nano-LEDs, which are typically envisioned as pixels in a display. This constrains the lateral size and the distance between phosphor layer & GaN die, which is highly disadvantageous for light extraction.

We claim geometries in which the phosphor is concentrated in submicron sized layers and separated from the blue die chip by either (a) a micron-sized dielectric spacer with a refractive index lower than that of the phosphor (low index normal dielectric spacer) or (b) by a 1D dielectric multilayer stack of materials of alternating refractive index (Bragg stack dielectric spacer) as shown in Figure 1. The proposed geometry works via (A) recovering the waveguide mode characteristics of the phosphor layer, (B) avoiding tunneling of emission directly into GaN die, thereby promoting emission into the air, and (C) accelerating emission into the guided modes of the phosphor through the Purcell effect at expense of undesired emission into GaN. This geometry can be combined with plasmonic and dielectric nanophotonic strategies to increase pump light absorption and extract the guided light into specific directions in a nano-LEDs device architecture setting.

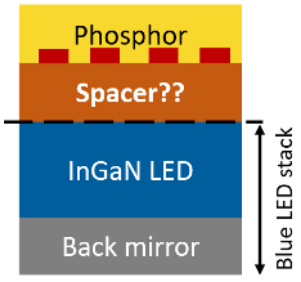

Figure 1: Schematic representation of the spacer inserted in between the phosphor layer and blue LED stack

with embedded corrugation (shown in red).

We present rigorous theoretical calculations to design the spacers which promote emission into the guided modes. We perform experiments confirming the benefits of inserting thin low index spacers combined with periodic corrugation to couple out those guided mode emission to far field using angle-resolved fluorescence microscopy experiments.

Emerging applications

Theoretical study of optomechanical effects by luminescence-induced optical force on micromechanical membranes

H. Arahari[1*], S. Konishi[2], S. Akita[2] and H. Ishihara[1]

[1]Dept. of Materials Engineering Science, Osaka University, Toyonaka, Osaka, 560-8531, Japan

Abstract: We have assumed a square-type optomechanical resonator formed with the luminescent nanofilm and a metallic mirror substrate, and then theoretically evaluated the luminescence-induced optical force (LiOF) on the emitting film. LiOF is enhanced at a specific cavity length due to the optical confinement effect of the resonator. We have shown theoretically that the enhanced LiOF could induce the mechanical frequency shift of the oscillator. This research provides new insights into the development of optomechanics using luminescence.

Light has momentum, and hence, force is exerted on the matter when the light is scattered or absorbed. This mechanism has been used for motion control of small particles in a wide range of fields, including molecular biology [1,2], photochemistry [3,4], and optomechanics [5]. 'Luminescence' of materials also causes a force on the matter. However, if it occurs isotropically, the exerted force is negligible. However, if the luminescence occurs anisotropically, it contributes to the motion of emitters. In this contribution, we focus on such luminescence-induced optical force (LiOF) causing mechanical motion, namely, we study an optomechanical cavity structure formed by a luminescent nanofilm and a metallic mirror substrate, as shown in Fig 1. We theoretically demonstrate that luminescence causes the mechanical motion of the emitters. If quantum states of the emitters can be coupled to mechanical modes via luminescence, we can realize quantum systems to control the luminescence properties of materials such as lasing [6].

As shown in Fig 1, we assumed organic-inorganic layered perovskites PhE-PbI_4 [7,8] as the luminescence film. This material is one of the promising light-emitting materials. By fabricating the luminescent film on a silicon nitride (SiN) membrane and transferring it onto the Al mirror substrate, the cavity structure is constructed. Here, the photoluminescence (PL) electric field in the cavity is enhanced or suppressed depending on the distance L between the film and the mirror due to the optical confinement effect. LiOF is caused by the spatial anisotropy of the PL electric field surrounding the emitter.

We evaluated the LiOF F_z^{inc} exerted on the luminescent film assuming the situation where only LiOF was exerted on the film by giving steady excitation energy to the luminescent film (see Fig. 2). As the steady-state excitation energy, we gave the interaction energy between the exciton polarization and the excitation light that corresponded to the energy when the luminescent film was irradiated

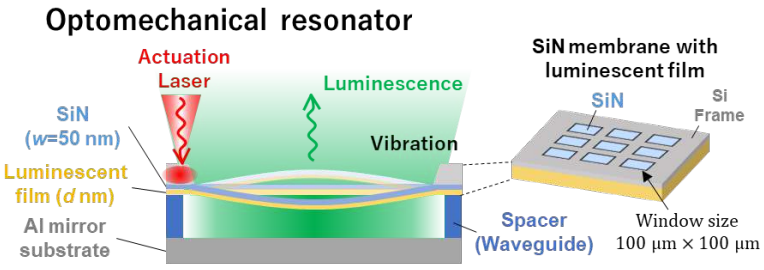

Figure 1. Model diagram of the optomechanical resonator. The size of the membrane window is 100 μm ×100 μm. As the luminescent film, we assumed organic-inorganic layered perovskites $(C_6H_5C_2H_4NH_3)_2PbI_4$, abbreviated here as PhE-PbI_4. The system is assumed to have a mechanical frequency $f_m = 1$ MHz and a film thickness of d=130 nm.

with excitation light of intensity I. Fig. 2 shows that, at a specific cavity length, the LiOF is enhanced. Such LiOF enhancement occurs at half the emission wavelength period (≅263 nm). The red line in Fig. 2 shows that the enhanced LiOF induces the mechanical frequency shift f_{opt} of the luminescent film from the given parameter f_{m} = 1 MHz,

$$f_{\mathrm{opt}} = f_{\mathrm{eff}} - f_{\mathrm{m}}, \ldots (1)$$

$$f_{\mathrm{eff}} = f_{\mathrm{m}}\sqrt{1 - \frac{\nabla_z F_z^{\mathrm{inc}}}{m_{\mathrm{eff}}\omega_{\mathrm{m}}^2}}, \ldots (2)$$

which is known as the optical spring effect [9]. We can confirm that LiOF influences the mechanical motion of the emitter by observing this effect in experiments.

The results of demonstrations indicate the potential of LiOF for unconventional optomechanical applications that convert the modes of luminescence into mechanical vibrational modes. We can use this mechanism to transmit the quantum properties of emitters to other quantum systems with different frequency regimes via the induced vibrational modes.

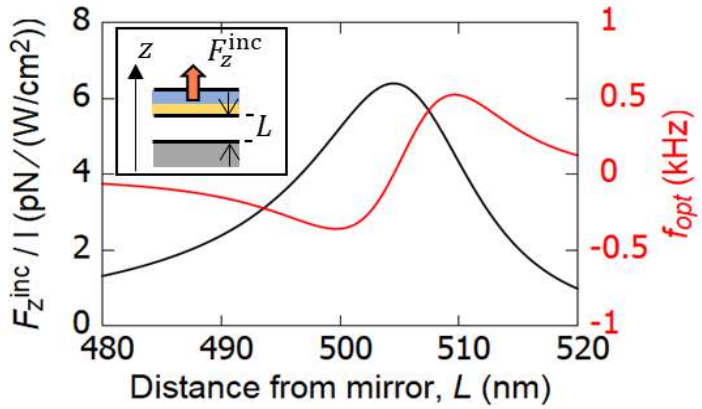

Figure 2. Black line: Cavity length L-dependence of LiOF F_z^{inc} when the luminescent film is given steady excitation energy. The results are normalized by I. Here, the excitation energy is the interaction energy between the exciton polarization and the excitation light field that corresponds to the energy when the luminescent film is irradiated with excitation light of intensity I. Red line: Mechanical frequency shift f_{opt} induced by LiOF under I=100 W/cm^2.

Inverse design of fabrication-compatible monolithic metasurfaces for optically interfacing deeply embedded solid-state qubits

Amelia R. Klein[1*], Nader Engheta,[1] and Lee C. Bassett[1]

[1]Department of Electrical and Systems Engineering, University of Pennsylvania, Philadelphia, PA 19104, USA
[*]corresponding author: amklein@seas.upenn.edu

Abstract: We use adjoint shape optimization to design monolithic metasurfaces tailored exactly to maximize photon collection from a specific solid-state defect into a particular free-space collection angle. Our shape optimization manifestly adheres to fabrication constraints at every iteration. We show that our highly-tailored objective criteria result in performance superior to a structure optimized as a conventional focusing metalens. This flexible design approach will help realize scalable interfaces for developing quantum technologies.

Solid-state spin defects such as the nitrogen-vacancy (NV) center in diamond are platforms for many emerging quantum technologies. Applications of these systems require their single-photon emission to be collected as efficiently as possible. For deep defects (which are desirable for their improved spin and optical properties being free from surface interactions), total internal reflection at the surface of diamond is commonly overcome with a spherical solid immersion lens (SIL). However, fabricating SILs involves a complex etching process, and they must be combined with high-numerical aperture (NA) free-space optics. As a more scalable alternative, a metasurface fabricated on the diamond surface could collect light directly into an optical fiber. Recent work demonstrated such a metalens, using conventional phase-shift approximation techniques to design an array of pillars that approximate a Fresnel lens[1]. However, the metalens performance was limited due to the conventional, approximate design strategy. In the present work, we leverage modern photonic inverse design techniques tailored to the problem of maximizing the broadband photon collection efficiency from a NV center into a multi-mode optical fiber of given NA, while manifestly preserving manufacturing constraints through the constrained parameterization of our structure.

Inverse design photonics using adjoint-based gradient descent have been used extensively for a number of applications in nanophotonics. Topology-based adjoint methods in particular have recently been applied to related problems of enhancing collection from NV centers[2,3]; however, these designs focused on shallow defects, where the metastructure modifies both the near- and far-field emission properties. Moreover, obtaining fabricable structures from topology optimization requires a significantly longer computation time due to successive phases in the computational process of gradually applying filters to guarantee material binarization, smoothness, and a minimum feature size. With challenges of diamond fabrication in mind, we instead choose to perform a novel type of constrained shape optimization such that our design is composed only of elementary structures that remain within our chosen fabrication constraints at every iteration in the optimization.

Our design process uses custom code built on top of an existing open-source inverse design package for Lumerical FDTD[4]. Our metasurface is parameterized as an array of elliptical pillars of uniform height, each defined by five variable parameters: two center coordinates, two axes lengths, and an angle of rotation. Since the position of these pillars is variable as well as their size, we are still able to explore a broader possible design space than static unit-cell based designs. Fabrication constraints are made explicit via lower bounds on the pillar sizes and constraint functions between adjacent pillars that ensure a minimum spacing between them.

With a dipole source at the position of a desired NV center, the photon collection efficiency expressed is in

the objective function as the total normalized power above the diamond surface, filtered to include only the component propagating within a given acceptance angle. This function is also spectrally weighted according to the NV center's room-temperature emission spectrum. We include in Figure 1 a small-scale demonstrative example designing a 2µm x 2µm metasurface in diamond collecting from a 2µm-deep dipole into an acceptance NA of 0.2. We also perform a second optimization on the same initial geometry to design a more conventional lens that focuses a plane wave to a 2µm deep spot. Both are performed over the 600-800nm wavelength range. Tailoring our optimization for one mode of operation or another results in very different structures; each significantly outperforms the other in their designed use cases. Beyond the NV center, our technique is easily adapted to any choice of substrate, collection angle, emission spectrum, and dipole orientation.

Applications of Eutectic Materials for 5G Technology

Hamid Reza Darabian[1]*, Jerzy Krupka[2], Bartłomiej Salski[3], Dorota Anna Pawlak[1,4,5]

Abstract: We utilize the micro-pulling down solidification technique with different pulling rates to tailor the dielectric permittivity and tangent loss for combination of TiO_2 and MgO for 5G applications. A set of measurements such as XRD and SEM have been conducted to study structural properties. The SEM images exhibit different crystalline sizes with the pulling rates. In addition, the dielectric permittivity measurements in the GHz range have been carried out for the samples revealing a dielectric dependency with pulling rates.

The growing interest in creating an internet-based network of different devices demands faster and more efficient communication. Such communications need to work at GHz and THz ranges [1]. Therefore, they trigger research areas for fabricating optimized dielectric materials which are the backbone of wireless communication [2]. Materials with minimum tangent loss, high-quality factor and high thermal stability are highly desired.

Recently eutectic materials attract lots of attention as materials for different applications including energy [4], metamaterials [5], plasmonics [6] and others [7]. In this work we investigate the potential of eutectic materials for the 5G Technology, particularly effects of growth parameters on dielectric values and losses.

TiO_2 is one the well-known dielectric materials due to its high permittivity and low loss [8]. Additionally, it has been shown that combination of TiO_2 with other oxides such as MgO and Al_2O_3 improves the thermal stability and reduces the loss.

In this project, we utilize the micro-pulling down solidification technique to control crystalline phases and interfaces and ultimately to reduce the tangent loss. TiO_2 and MgO have been selected as precursors and the composition percentages are selected based on two eutectic points in the phase diagram. The growth has been done at different pulling rates. A set of measurements have been conducted after the crystal growth, to study structural and dielectric properties. XRD measurements show the formation of TiO_2 and $MgTi_2O_5$ crystals. The SEM images exhibit partially formation of eutectic structures and different shapes with the pulling rates. In addition, the dielectric permittivity measurements in GHz range have been done for the samples showing a trend in the loss and permittivity values with pulling rates.

Abstract: We present a novel laser nano-lithography method inside the bulk of silicon. We exploit nanosecond laser pulses of 1.55-μm wavelength which are modulated with a spatial light modulator. The created Bessel beams enable direct and highly-controlled subsurface fabrication capability in Si. Using this technique, we demonstrate for the first time, the fabrication of sub-wavelength nano-modifications deep inside Si. We further illustrate nano-patterns of 200-nm width and of sub-micron separation. Such 3D control on sub-wavelength structures inside Si offer exciting possibilities for Si-photonics devices, meta-material and meta-surface in-chip technologies.

Direct laser writing (DLW) approaches have been widely used for 3D-structuring of transparent materials in recent years due to ease-of-operation, maskless nature, and rapid processing. Among different dielectrics, the high refractive index, low loss, and wide transparency window of silicon (Si) make it a great candidate for fabricating infrared sub-wavelength and resonant devices, potentially compatible with established electronic and photonic technologies. We recently demonstrated first subsurface Si photonics functionality and complete 3D fabrication capability with a resolution of 1 μm, created directly inside Si [1]. Numerous optical functionalities were shown in Si at this (or lower) resolutions [2], motivating us to overcome the challenges towards subsurface, sub-micron Si structuring. In order to accomplish this goal, we exploited nanosecond modulated beams. In spite of the progress made in nano-machining of other materials using femtosecond Bessel beams [3], attempts to apply this technique to Si have been unsuccessful due to limitations in the energy deposition of ultrafast pulses within the material [4].

Here we demonstrate volumetric (bulk) nano-structuring of Si using nanosecond Bessel beams, exploiting a spatial light modulator (SLM). The applied conical phase profile is in the form of $\phi(r) = e^{\pm\left(i2\pi\frac{r}{r_0}\right)}$, in which the r_0 parameter is correlated to conical angle of a physical axicon. The modulated beam is demagnified by a 4-*f* system and an aspheric lens with a focal point of 4.5 mm, and then directed to the wafer. Changing the applied phase pattern to the SLM, corresponding to different conical angles, and exploiting various polarization and pulse energies, we achieve sub-wavelength feature sized subsurface modifications, along with strong control on their position, feature size and architectures. By scanning the sample in a direction perpendicular to the laser propagation direction, planes with nano-scale one-dimensional-confinement are created inside Si (without altering the wafer surfaces). An optional selective chemical etching process reveals the nano-patterns. A representative cross-section SEM image of nano-scale lines with sub-micron separation is given in Figure 1(a). The nano-pattern is created with Bessel beam of $r_0 = 7$ pixels and pulse energy of $E_p = 5$ μJ. To reveal the nano-structures, the sample is briefly etched with a selective etchant [1]. The histogram shows the size distribution of these structures (Figure 1(b)).

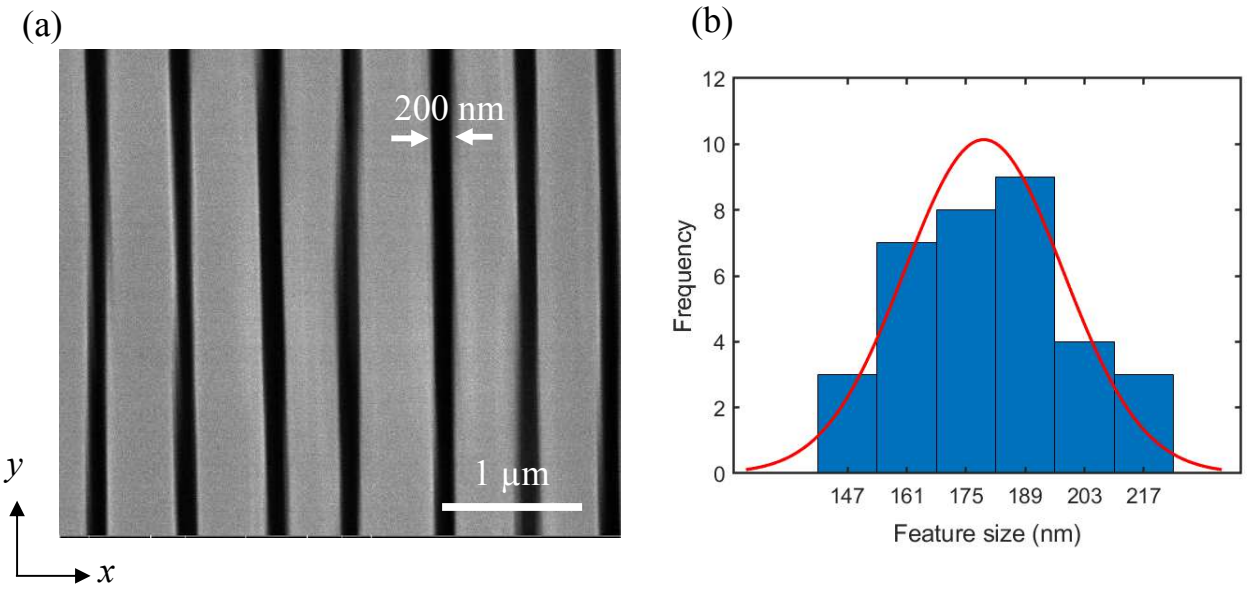

Figure 1. (a) Representative SEM image of nano-patterns created directly inside Si. The Bessel-type beam of y-polarization propagates along *z*-axis, whereas Si is scanned along *y*-axis. $r_0 = 7$, $E_p = 5$ μJ, and scanning speed = 1 mm/s. **(b)** Histogram of measured feature sizes indicates an average feature size of 180 nm ± 19 nm.

This new laser nano-structuring capability is unique, as the nanopatterning is performed directly and buried inside the Si wafer, with no surface damage. Such lithographic patterns can potentially be used as building blocks of sub-wavelength near- and mid-infrared photonic elements (potentially inside the bulk, or on the wafer surface). We anticipate that one may fabricate structures thinner than the current limit of 200 nm in Si with optimized parameters, leading to first subsurface sub-diffraction optical elements in Si, with significant consequences for sub-wavelength nano-photonics, metamaterials or metasurfaces.

MBE substrate deoxidation surveillance via RHEED image analysis with Deep-Learning

Abdourahman Khaireh-Walieh[1], Alexandre Arnoult[1], Sébastien Plissard[1] and Peter R. Wiecha[1]

akhairehwa@laas.fr

Abstract: In Molecular Beam Epitaxy (MBE), monitoring of the substrate deoxidation and in general, the entire crystal growth is crucial for precise crystal growth. Reflection High-Energy Electron Diffraction (RHEED) is a standard tool in MBE in-situ monitoring, providing complex real time information about the crystal surface. However, the diffraction patterns are often difficult to interpret, requiring experienced human operators[1]. We present an approach to automate the substrate deoxidation detection by analyzing RHEED video sequences by a deep-learning model.

Substrates used for crystal growth (gallium arsenide, GaAs, in our case) have usually a narrow layer of native oxide on their surface. This needs to be removed by heating before any crystal growth process can be done[2]. The deoxidation moment detection is crucial in order to avoid excessive heating and not to damage the substrate. RHEED is an in situ control method for MBE. An electron beam is directed towards the substrate surface under a narrow angle of a few degrees. The patterns on the RHEED screen are a result of diffraction of the electrons on the the crystal lattice at the substrate's surface, and thus contain information about the surface quality. RHEED is generally used to detect the deoxidation moment, but the exact deoxidation moment is not known in advance, and also the visual interpretation of the transition from oxidized to deoxidized in RHEED images is not trivial. Finally, the substrate is generally rotating, and the diffraction pattern is not necessarily visible at every rotation angle.

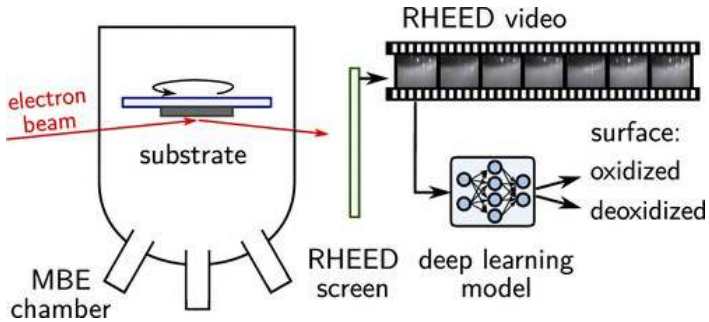

Figure 1: The e-beam is diffracted on the substrate surface forming a diffraction pattern on a fluorescent screen. Video sequences of these patterns are interpreted by a neural network.

The goal of our paper is to automate the deoxidation detection with a deep neural network model for the analysis of RHEED patterns. By analyzing sequences of images we furthermore

render the detection robust for rotating samples.
Our approach involves a two stage process. The first step consists in an autoencoder. During training, the input image is reconstructed through a bottleneck latent space by a decoder with the goal to minimize a loss function comparing the initial image and its reconstruction. After training, the encoder is used to extract the relevant information from the input image into a latent vector. These latent vectors will be stacked into sequences, representing the condensed content of entire video sequences. Those latent-sequences are finally fed into a convolution neural network classifier. We demonstrate that deoxidation detection works faithfully on experiments performed up to half a year after the training data acquisition, end despite visible RHEED screen deterioration[3].

Abstract: A laser heating technique was used to selectively anneal a magnetic garnet film in a vacuum, which can be useful for integrating devices with other electronic or optical devices. The film was deposited on a synthetic fused silica substrate, and the laser was scanned in-plane to anneal the sample. Two types of periodical Ce:YIG structures were fabricated using the constructed laser annealing system, which could provide additional functionalities.

Magnetooptical (MO) effects exhibit many functionalities and have been applied in various devices, such as magnetophotonic crystals [1], magnonic crystals, MO isolators [2], MO spatial light modulators, and MO Q-switches. In these devices, MO garnet crystals or ceramics are widely used as MO materials because of their large MO response with low absorption. However, the high-temperature fabrication process of MO materials, which can reach over 700°C, is often an issue when integrating these devices with other electronic or optical devices. To address this issue, a laser heating technique can be used, which enables selective heating of a specific area. In this paper, we demonstrated the selective annealing of magnetic garnet film using a laser in a vacuum.

A 339-nm-thick film was deposited on a 5-mm square synthetic fused silica substrate using a radio frequency (RF) ion beam sputtering system with a sintered cerium-substituted yttrium iron garnet (Ce:YIG) target. The film thickness was measured by a stylus profilometer. The sample was placed on a sample stage in a vacuum chamber where no gases were introduced, and the pressure was 20 Pa. To anneal the sample, a laser was illuminated the sample, and the sample was scanned in-plane by the computer-controlled stage. The laser used for sample annealing was a continuous wave oscillation type, and an optical shutter was used to control the on/off timing of the laser annealing. The laser wavelength was 532 nm with a power of 2.0 W. The laser scanned the sample at the speed of 200 μm/s. Two types of laser scanning were conducted for annealing. The surfaces of the annealed samples were observed by microscopes, and magnetooptical responses (Faraday rotation angle) were measured.

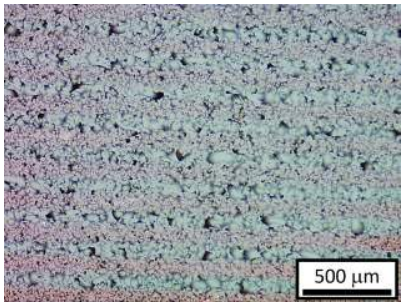

Figure 1. Microscope image of the stripe-type Ce:YIG surface annealing by scanning laser.

Figure 1 shows the stripe-patterned Ce:YIG structure. The bright area shows the crystallized part by the laser, and the dark parts are amorphous. The width of the stripe was about 100 μm, close to the spot size of the laser on the sample surface. The Faraday rotation angle was 0.27 degrees at a wavelength of 532 nm, 67% of the former-reported Ce:YIG film. Black points show the clacks or the pealed area of the sample because of the large difference in thermal expansion between the film and the glass substrate.

To decrease the clack or breakoff of the film, the stage temperature was increased by a heater at 200°C. The Faraday rotation angle was increased up to 0.34 degrees, corresponding to 0.1 degrees/micron. Figure 2 shows the periodical Ce:YIG dots fabricated by the constructed laser annealing system, combined with the optical shutter and the scanning stage. The laser was illuminated on one spot for 1 second, the optical shutter was closed, the sample was cooled for 10 seconds, and then the sample was moved at a 120 μm pitch. This sample is expected to work as two-dimensional magnetophotonic crystal or spatial light modulator by integrating with electronics.

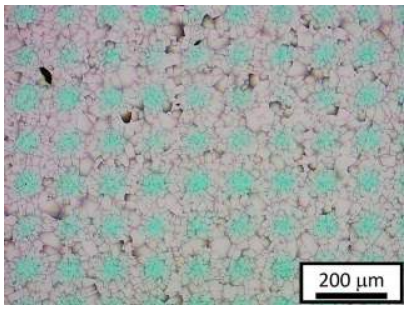

Figure 2. Periodical Ce:YIG dots fabricated by heater-assisted laser annealing.

Two types of periodical Ce:YIG structures were fabricated using a laser annealing system in this paper. The constructed laser annealing system would provide further complicated structures, demonstrating additional functionalities. In the symposium, the details of the magnetooptical responses will also be discussed.

Dyes emission mediated by plasmonic nanostructures revealed by SNOM

A. Mercedi [1*], L. Litti[1]

[1] Department of Chemical Sciences, University of Padova, v. Marzolo 1, 35131 Padova, Italy

Abstract: Looking at an object is the most direct approach to define and describe it. Scanning near field optical microscopy (SNOM) is part of the Scanning Probe Microscopy techniques. Its unique characteristic is to shed light in the nanoscale, overcoming the diffraction limit while simultaneously providing topographical images[1]. These reasons make this technique a powerful tool to directly correlate the complex mechanisms and structure/activity relationships that affect the emission properties of a fluorescent dye located in close proximity to a plasmonic nanostructure.

The interaction between a fluorescent dye and a plasmonic surface, can lead to a variety of different phenomena, such as Surface Enhanced Raman Scattering (SERS)[2,3], Surface Enhanced Fluorescence (SEF)[4], or even Surface Plasmon Amplification by Stimulated Emission of Radiation (SPASER)[5]. All these effects are most commonly studied in the far field regime, but they are strongly dependent on various local factors. For example, the distance between the fluorophore and the nanoparticle, the particles aggregation, as well as shape and composition of the plasmonic substrate. All these variables can be studied by SNOM techniques directly at the nanoscale. A direct correlation to the emission properties of the dyes is therefore eventually obtained. This could provide new insights into optical properties at the nanoscale and pave the way for new developments.

Abstract: Various researches have studied volume grating made of photo-reactive materials for optical elements due to their diffractive characteristics. However, investigation of optical features of volume grating still relies on the conventional Kogelnik's theory. Here, we analyzed the optical behaviors in detail and found out the conditions for noise-free diffraction by using Fourier-optics and computational simulations. Finally, we defined the optical Fourier volume (OFV) which has clear diffraction and experimentally validated our analytical results by using both photopolymer and photoaddressable polymer.

Since volume holograms were first developed by Gabriel Lippman (1), recording methods and recording materials of optical diffractive elements made of volume gratings have been extensively studied by many researchers. Currently, volume holograms are used in important components of AR/VR devices and Head-up-display not only simple optical elements such as lens and mirror.

The diffraction behaviors of volume grating such as transparency, diffraction efficiency and full-wave-half-maximum (FWHM) can be predicted by conventional coupled-wave theory (Kogelnik's theory). From Kogelnik's diffraction theory, we already knew that modulation range of refractive index (Δn) inside the volume grating and thickness determine the efficiency of first-order diffraction and FWHM. However, there are no established clear study for the condition of volume grating having noise-free ideal diffraction without interference of uninterested other frequencies. Thus, we analyzed the volume grating in perspective of Fourier Optics by using Fourier frequency analysis and rigorous coupled-wave analysis (RCWA) simulation, and then, we defined the Optical Fourier Volume (OFV) which exhibits the ideal diffraction behaviors (3).

In Fourier optical perspectives, one sine-wave component from Fourier decomposition of refractive index profile inside the volume grating leads to the one diffraction mode (4,5). In case of binary n profile that looks like a single grating lattice, it is decomposed into countless sine-wave functions by Fourier decomposition. Thus, those sine-wave functions produce the frequency interference from many diffraction modes (Fig. 1a). Additionally, in case of too large Δn, excessive phase accumulation of light inside the volume hologram can occur, then it results in decrease of diffraction efficiency and interference of frequencies (Fig. 1b). In conclusion, we found out that sine-wave n profile and proper phase accumulation determined by Δn and thickness are essential for ideal noise-free single diffraction of volume grating.

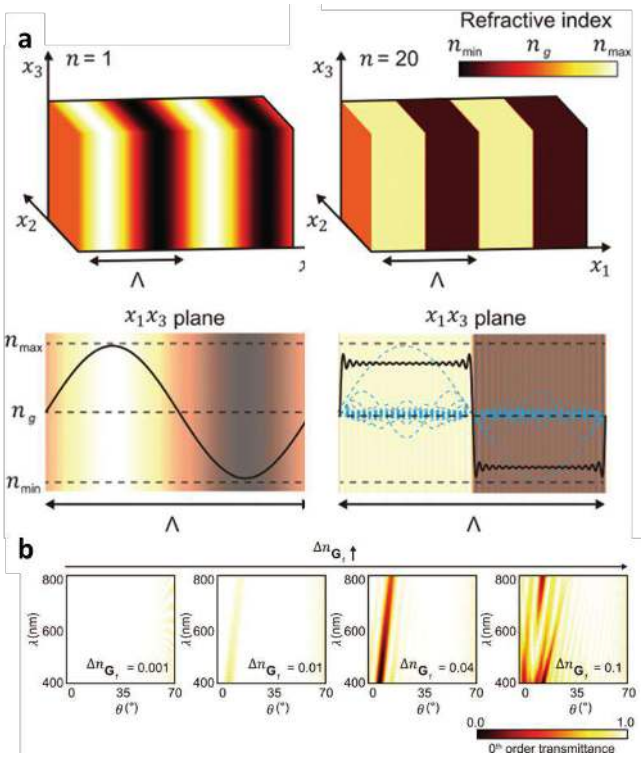

Fig1. a) The grating lattices having sin-wave and binary *n* profiles. b) Diffraction behaviors according to Δ*n*.

We experimentally validated our theoretical analysis of OFV by using two representative holographic polymers such as photopolymer and photoaddressable polymer. We confirmed that volume holograms made of both two holographic polymers exhibit the ideal OFV characteristics due to the sin-wave profile of *n* and under πd/2 value of phase accumulation. Some cases of photoaddressable polymers having high phase accumulations due to the thick film show the little degeneracies and frequency interferences.

Abstract: Holographic Optical Elements (HOEs) based on the Fourier transform have to consist of the structures with sinusoidally modulated refractive index changes to avoid the mixing of undesired frequencies that can act as noise for the devices. In terms of the structure concepts, the optical Fourier volumes are appropriate for the HOEs due to their high diffraction efficiency, narrow angular selectivity. In this works, we synthesized the photoaddressable polymers and inscribed the optical Fourier volumes to confirm their properties as HOEs.

Holographic Optical Elements (HOEs) have used in many AR/VR devices to control the light to desired pathways. Among many types of holographic gratings, optical Fourier Volumes have appropriate structures to use as HOEs due to their high diffraction efficiency, narrow angular selectivity and enabling the control of the light with diverse pathways. However, in generally, optical Fourier Volumes have binary modulated structures produced by the lithography which can occur the noise appeared by mixing of undesired frequencies for the devices. In this reason, the optical Fourier Volumes are required to have sinusoidally modulated profiles of the refractive index to make higher signal-to-noise ratio. (Fig.1) [1]

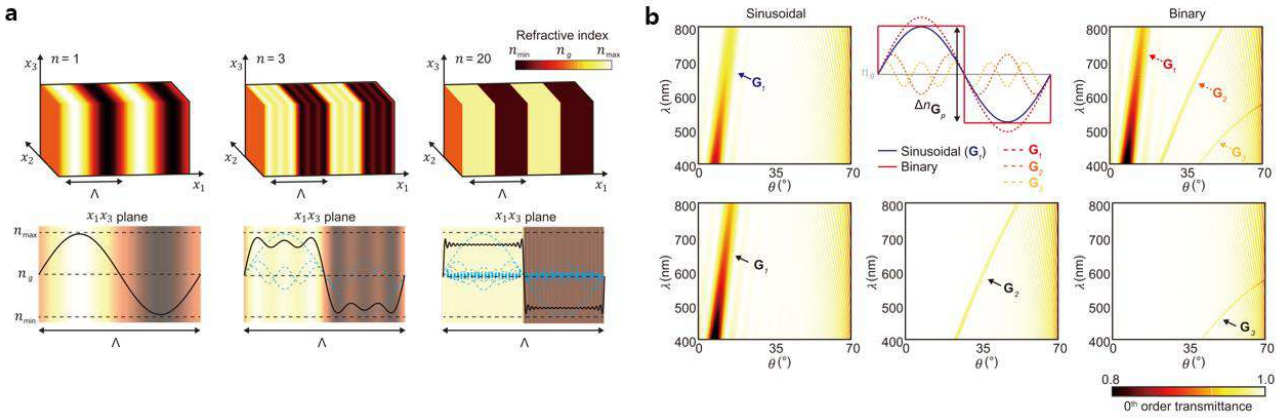

Fig. 1. The numerical calculations about 1D optical Fourier volumes through rigorous coupled-wave analysis (RCWA). (a) the spatial profiles of the refractive index according to the numbers of wave to be mixed. (b) The analysis of diffraction behaviors about sinusoidally and binary modulated optical Fourier volumes with the same values of the refractive index change through monitoring the 0th order transmission.

In this works, we synthesized the photoaddressable polymers consisting of azobenzene and liquid crystals to inscribe sinusoidally modulated optical Fourier Volumes and confirmed their properties as HOEs. The light-driven reorientation of the azobenzene molecules induced by the photochemical trans-cis-trans isomerization generates the sinusoidally modulated molecular alignments across the polarization directions of the interference pattern of two circular polarized lights.[2] The molecular alignments of the azobenzene molecules cause the refractive index changes sinusoidally and amplify them through the cooperative motions to align the neighboring liquid crystal molecules.[3]

We experimentally inscribed the two types of the sinusoidally modulated optical Fourier volumes, the transmissive and reflective volume gratings, and measured their characteristics such as diffraction efficiency, angular selectivity, and photonic band gaps which show that they can act as the optical Fourier volumes. (Fig.2) Each type of inscribed volume gratings has specific diffraction behaviors which well-match the Fourier spectrum without the noise from unwanted frequencies.

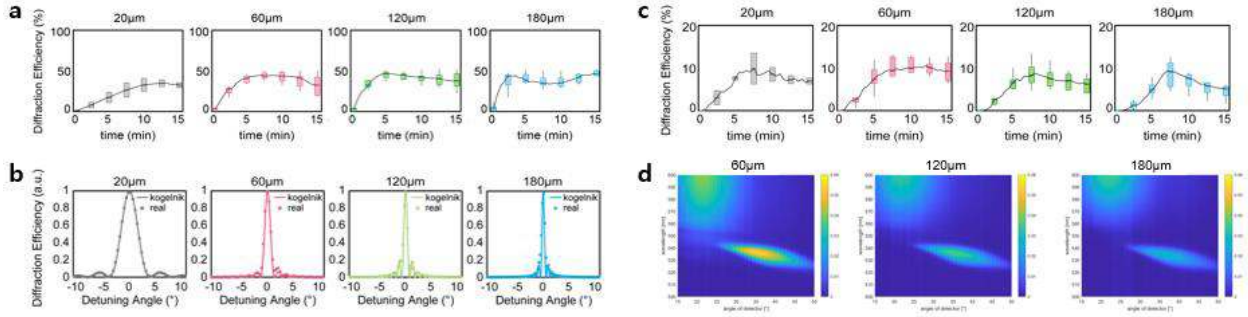

Fig. 2. The characteristics of each type of volume gratings. Abstract: Optical Fourier surfaces (OFSs), which are surface gratings having sinusoidally modulated profiles, can be minimized optical loss due to preventing the mixing of waves with undesired frequencies. In this work, we introduce a novel fabricated method for the perfect OFSs. Our method can generate perfect sinusoidal gratings with high throughput because it is based on holographic mass migration. Furthermore, we demonstrate that our OFSs can reach the theoretical upper limit of diffraction efficiency in the whole visible wavelength range.

Surface gratings, which are basic elements of diffractive optical elements (DOEs), have been widely used for various optical applications, especially augmented reality (AR) and virtual reality (VR) technologies. For the application of these optical devices, these diffractive gratings should be minimized optical loss. To this end, sinusoidally modulated surface profiles were required to prevent the mixing of waves with undesired frequencies. In terms of Fourier optics, diffractive gratings composed of entirely sinusoidal profiles can be categorized into optical Fourier surfaces (OFSs) [1].

Sinusoidally modulated surface profiles can be generated through lithographic approaches; recently, OFSs were successfully generated by scanning probe lithography (SPL) [2]. However, these conventional lithographic methods have limitations in fabricated area and throughput because of additional processes. In this work, we present a novel method for the fabrication of perfect OFSs through holographic mass migration rather than lithographic etching. In this process, the OFSs could be generated in a large area with high throughput compared to other fabricated methods [3,4].

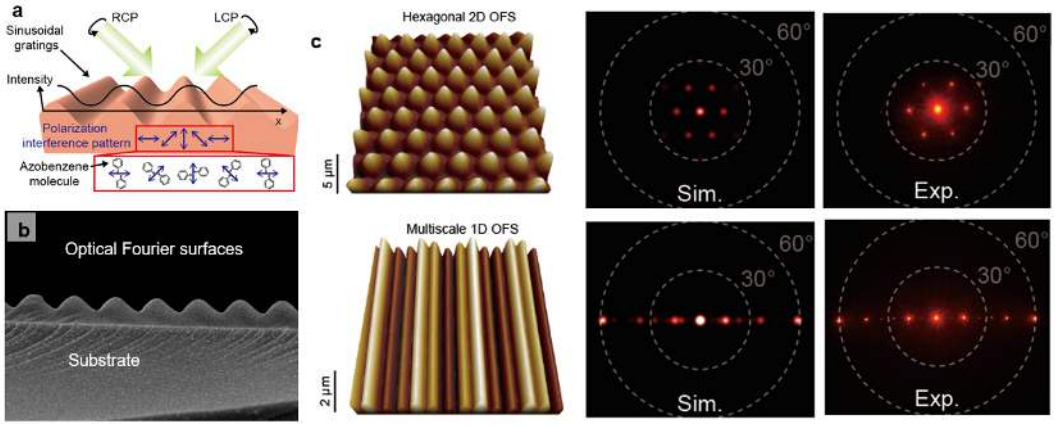

Figure 1. Optical Fourier surfaces (OFSs) through holographic mass migration. a) Schematic for holographic

mass migration. b) Scanning electron microscopy image of the perfect sinusoidally modulated profile of OFSs. c) Atomic force microscopy images and Fourier spectrum of complex 2D OFSs.

By the holographic inscription as depending on mass migration, we fabricated OFSs having a perfect sinusoidal profile which can be minimized the mixing of undesired frequencies. As a result, the experimental Fourier spectrums of not only 1D OFSs but complex 2D OFSs designed based on Fourier synthesis exactly match with numerical calculation (Figure 1). Another advantage of our OFSs was that can be easily transferred to other polymers, especially transparent materials with a high refractive index at visible wavelengths. We demonstrated that OFSs can reach the theoretical upper limit of diffraction efficiency in the whole visible wavelength range (Figure 2).

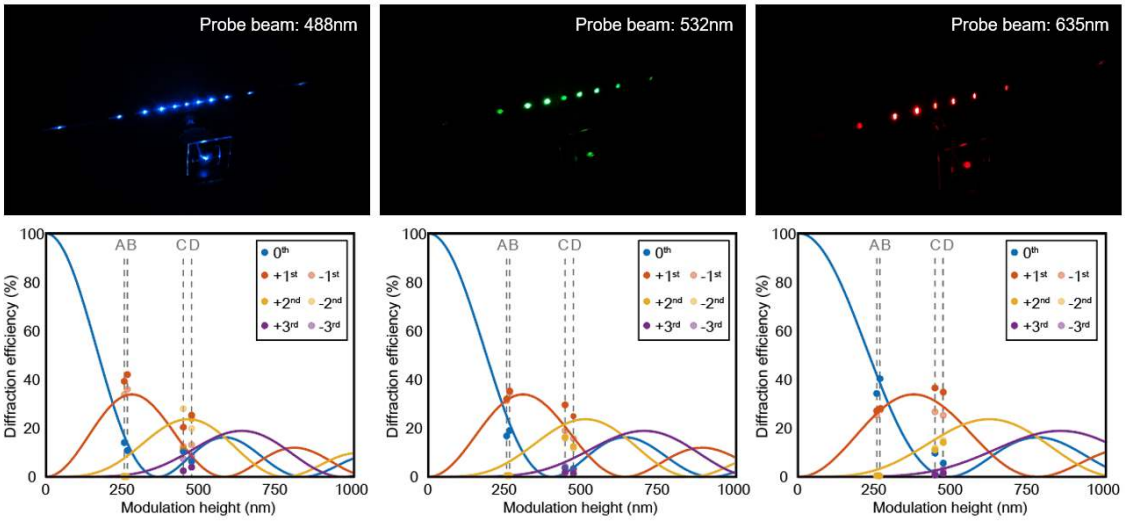

Figure 2. Full-color diffraction of OFSs reaching the theoretical upper limit of diffraction efficiency.

Characterizing Far-Field Plasmonic Resonances of Au and $AuAl_2$ Structures using Dark Field Spectroscopy

T. McCaughery[1], A. Maity[1], R. Bowman[1]

[1]Queen's University, Belfast. United Kingdom

Abstract: Plasmonic materials such as Au and $AuAl_2$ have the ability to facilitate nanoscale heat generation and have attracted attention due to their relative availability [1,2]. In this work, these materials were patterned into various geometries. Dark field spectroscopy (DFS) was used to measure the far-field response of particles, along with 3D-FDTD modelling which calculated the field enhancement present within the structures. The experimental and simulated DF results were compared and showed good agreement for Au.

Au and $AuAl_2$ were fabricated by PVD (co-)sputtering sheet films onto a p-type silicon substrate, with subsequent photolithographic patterning and dry etching carried out, resulting in structures consisting of two 200nm discs connected by a nanowire (known as 'nanowire-bridged dimers'[3]). Single-particle DFS showed a spectral resonance at a wavelength of 668nm for the Au structure (see Fig. 1(a)). A monitor which was placed 5nm above the 'nanowire bridge' within the 3D-FDTD model showed a circular region of enhancement.

Having characterized the Au structure, the aim is to explore the effects of introducing Al into the system, maintaining the nanowire-bridged dimer design. Room temperature $AuAl_2$ has been co-sputtered and ellipsometry has been taken for both Au and $AuAl_2$ as shown in Fig.1(b). $AuAl_2$ nanowire-bridged dimers will be patterned and analyzed with increasing vacuum anneal temperature, in order to observe thermal robustness.

Abstract: One of the major concerns of the today's society is related to environmental monitoring and food safety, which have a great impact on the citizens well-being and health. In particular, food contamination is regarded as a severe public health problem due to the constant increase in food-borne diseases. A natural toxin, produced by living organisms and toxic to humans when ingested, is formaldehyde (FA), also known as formalin (37 % formaldehyde aqueous solution), which is a colour-less, highly volatile, with an irritating odour gas.

In this context, this work aims to develop and implement a new innovative miniaturized portable sensing platform for the dual-modal Surface Plasmon Resonance (SPR) – Surface Enhanced Raman Spectroscopy (SERS) detection of FA in beverages. Specifically, a sensor architecture is designed by combining the advantages of polydimethylsiloxane (PDMS), such as flexibility, optical transparency and chemical inertness, and gold thin films for FA monitoring by means of portable plasmon-based detection technologies. The developed flexible chip allows the efficient optical detection of glucose *via* SPR, but also its specific identification through SERS, by the modification of the PDMS' surface micro-roughness through an innovative simple method of micro-imprinting of the three-dimensional (3D) matrix of filter paper, thus, upon the deposition of the gold thin film, a rough surface suitable for SERS is obtained. Upon the optimization of the gold thin film thickness, the SPR and SERS sensitivities are evaluated using a well-known Raman reporter, specifically, 4-mercaptobenzoic acid. Further, the plasmonic platform will be functionalized with biomolecules in order to obtain at its surface primary amino groups, which are known to transform in imine groups as a result of their interaction with aldehydes, FA included. The dual implementation of SPR and SERS analysis techniques ensures both high sensitivity and specificity of the as-developed FA sensor, promoting portability and fast on-site detection capabilities, contributing thus to the progress of food pollutant monitoring by providing a real-world solution for the determination of life-threatening amounts of hazardous materials.

Ion beam doping of phase-change materials: a platform for active metasurfaces

Martin Hafermann, Robin Schock, Annkathrin Köhler, Jacob Grandmontagne, and Carsten Ronning

Institute of Solid-State Physics, Friedrich Schiller University Jena, 07743 Jena, Germany

Abstract: Phase-change materials (PCMs) have emerged to serve as active media for tunable plasmonic and photonic devices. They provide the ability of reversible, repeatable, and rapid switching between amorphous and crystalline states accompanied with drastic changes in the electronic and photonic properties. Impurity doping by means of ion implantation can be used to tailor the crystallization kinetics of PCMs. Here, we demonstrate that spatially selective ion beam doping of PCMs can serve as a platform in designing active metasurfaces.

The integration of active media into conventional metasurface designs enables the ability to control the optical response in-operando leading to dynamic switchable, tunable, and reconfigurable optical functionalities. While multiple material classes have been demonstrated to serve as such active media, particularly chalcogenide-based phase-change materials, such as $Ge_2Sb_2Te_5$ (GST), have emerged as one of the most promising materials for tunable plasmonic and photonic devices[1,2]. They provide the ability of reversible, repeatable, and rapid switching between amorphous and crystalline states upon external optical, electrical, or thermal stimuli and accompanied with drastic changes in the electronic and photonic properties.

In this work, we present that impurity doping via ion implantation can be utilized to modify the crystallization process of GST thin films[3]. Two opposing effects occur for the implantation of group V elements into GST thin films, which can be seen in Figure 1a. First, the crystallization process is facilitated by the reduction of homopolar bonds caused by ion beam induced lattice damage for low doping concentrations. This was corroborated by noble gas irradiations of as-deposited GST films, as no impurity doping effect is expected. Moreover, it was found that heavier ions have a more pronounced damaging effect that is accompanied with a higher reduction of the homopolar bonds destabilizing the amorphous phase. Second, the crystallization is retarded by higher contents of impurities, while various effects are proposed for different ion species. While light ions, like nitrogen, may induce a strain field due to their localization at tetrahedral interstitial sites, heavier ions may be able to substitute atoms from their lattice sites or fill the inherent vacancies in GST, which leads to the formation of additional covalent bonds inhibiting the crystallization process. Repeated re-amorphization via noble gas ion irradiation and thermal annealing of doped GST films was performed. The effect of induced lattice damage becomes similar for all ion species, as after multiple cycles only the contribution of Ar^+-ion irradiation used to re-amorphize GST is dominant. While the doping effect of the lighter ions diminishes, it is roughly constant for the heavier ions upon cycling. Enhancing the doping effect within As^+-doped GST by the introduction of a more uniform box-like implantation profile leads to well separated transitions of intrinsic (re-amorphized) and doped GST already for doping concentrations of 2 at.% (compare Figure 1b).

We further demonstrate how ion beam doping of GST combined with masking can serve as a platform for designing active photonic devices. As shown above, doping of GST with e.g. As can be utilized for stabilizing the amorphous phase by increasing the crystallization temperature. Thus, spatially selective doping based on ion implantation through lithographically patterned masks yields the ability to shift the crystallization temperature in

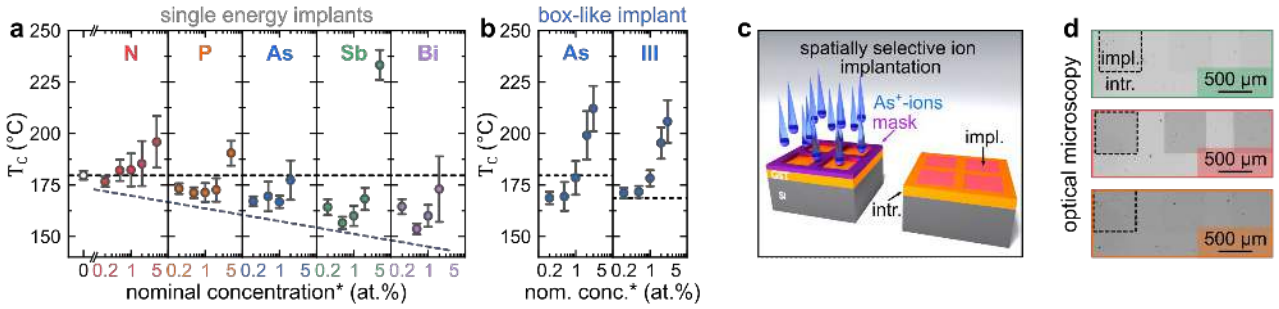

Figure 1 (a) Critical temperatures for crystallization T_C of various group V ion implanted GST thin films on Si substrates as a function of nominal dopant concentration for all ion species. Nominal concentration values correspond to peak values of ion depth distribution. Error bars correspond to the respective phase-transition width. (b) Critical temperatures for crystallization T_C of box-like As^+-ion implanted GST films as a function of nominal concentration. Subsequent to the first annealing step, each sample was repeatedly amorphized (using Ar^+-ion irradiation) followed by additional annealing steps (only step III shown). (c) Schematic of spatially selective ion implantation of As^+-ions through a lithographically patterned mask into GST film on Si. (d) Optical microscopy images of an area-selectively implanted GST film in the amorphous (orange box; both regions amorphous), partially annealed (red box; intrinsic is rock-salt, implanted is amorphous) and completely annealed (green box; both regions crystalline) states.

pre-defined, restricted regions (see Figure 1c). The separation between the phase transitions of intrinsic and implanted regions shown in Figure 1b was utilized to achieve artificial phase coexistence within a spatially selective implanted GST thin film by heating the sample to a temperature that is between the phase-change regimes of intrinsic and implanted regions. This was observed within an optical microscope, which is depicted in figure 1d for the three different states: amorphous (orange box; both regions amorphous), partially annealed (red box; intrinsic is rock-salt, implanted is amorphous) and completely annealed (green box; both regions crystalline). While the square structures are barely visible in the amorphous and completely annealed case, they are clearly distinguishable in the partially annealed state due to the distinct different reflectance of amorphous and crystalline GST in the visible spectral region.

Finally, we use e-beam lithography as masking technique that facilitates implanted regions with subwavelength dimensions. Appropriate switching between the states of these implanted and intrinsic regions enables active tuning of a lateral phase coexistence that can be accompanied with in- and out-tuning of an optical functionality. By this means, we demonstrate that spatially selective ion beam doping of a phase-change material can serve as a platform for designing active optical metasurfaces that are reconfigurable, switchable, and inherently flat.

Abstract: The development of focused ion beam (FIB) has reached a point where its resolution and time-consumption are suitable for the fabrication of nanostructures. Various 100 nm diameter dumbbell-shaped pits were fabricated with FIB automation controlling the positions, depth, and gap of the dimer systems (Fig.1). Filling well-organized pits with gold nanoparticles (NP), can relieve whether random positioned NP can be a better solution for surface-enhanced Raman spectroscopy (SERS) than periodical positioned, and other related questions.

Abstract: In this work the conformal deposition of high refractive index thin films on periodically micro-structured surfaces was investigated. The optical response of fabricated single-layer photonic structures demonstrates sharp sensitivity in both angle and wavelength domains, allowing to perform narrow-band spatial filtering and manipulate light polarization.

The modern tendency to miniaturize laser systems and enhance its laser power, evokes the need to create novel optical elements with periodically modulated inner nanostructure, such as photonic crystals. Artificially created refractive index modulation in such structures forms the allowed and forbidden energy bands, that are useful to manipulate light propagation in various ways. And yet, when the required periodicity of refractive index decreases to nano-scale, the possibilities of state-of-the-art lithography to fabricate such photonic crystals are restricted. Therefore, multidimensional photonic crystals are quite rare in practice.

One of the alternative fabrication methods is a conformal deposition of thin films on a structured surface, where every layer repeats initial surface modulation. The practical value of such complex multilayer nanostructures has been demonstrated in Ref. [1], however sharp optical characteristics deviate from theoretical predictions, due to various reasons, such as modulation extinction after the thickness of deposited layers reaches several microns, distortion of modulation form etc.

This work demonstrates the investigation of analogical structure, but consisting of a more simple architecture - of high refractive index single-layer deposited on a periodically modulated surface. When the periodically modulated single-layer structure with a high refractive index is surrounded by a low refractive index media, as shown in Fig. 1(a), it features Fano-like resonance phenomena due to the coupling of thin film waveguided modes with Fabry-Perot modes [2]. This phenomenon results in the appearance of extremely low transmittance lines in the transmittance (Θ, λ) maps, which are sensitive with respect to the angle and the wavelength of the incident light (Fig. 1(b)).

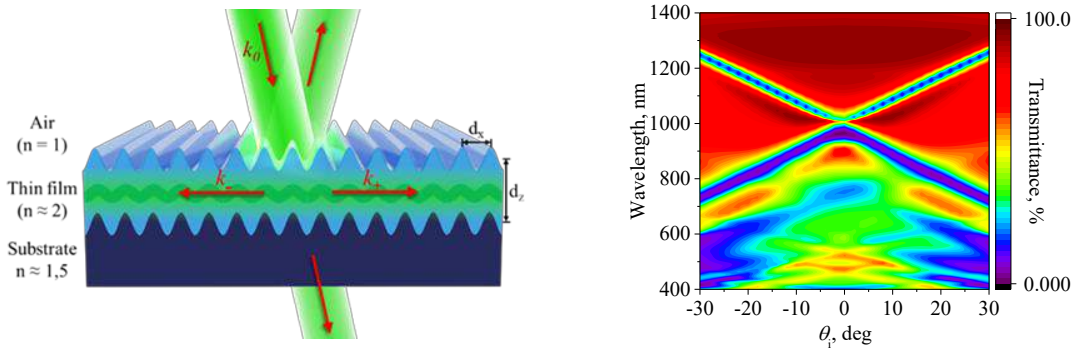

Figure 1. (a) The schematic representation of Fano-like resonance in periodically modulated single-layer photonic structure; (b) Transmission map in a plane (Θ, λ) for 0.2 μm thick tantalum oxide structured layer [2].

Moreover, as the fabricated single-layer photonic structure has refractive index modulation only in one direction, its optical response is also polarization dependent. As will be discussed during the presentation, the proposed single-layer photonic structure, featuring Fano-like resonances, can be considered as a potential spatial filtering or light-polarizing optical element suited for micro-laser systems.

This work received funding from the European Social Fund (Project No. 09.3.3-LMT-K712–17-0016) under grant agreement with LMTLT.

Laser-Induced Nanostructuring of Material Phase and Shape for 3D Light Control

M.S. Elizarov*, N. Li, A. Fratalocchi

PRIMALIGHT, Faculty of Electrical Engineering, Applied Mathematics and Computational Science,
KAUST, Thuwal 23955-6900, Saudi Arabia
*corresponding author: maxim.elizarov@kaust.edu.sa

Abstract: We introduce a three-dimensional nanostructuring platform that utilizes light-induced control over nanomaterials' phase and geometry. We employ a heterogeneous oxide-polymer nanostructure as the fundamental component of our approach. By applying low-power (up to 15mW) CW lasers of varying intensity and exposure time, we achieve photothermal passivation and reshaping of the initial material. Resulting structures possess modified spectral response, enabling us to develop a technology for large-scale structural color laser printing with widest gamut reported.

The development of new nanofabrication techniques for controlling light at the nanoscale attracts considerable interest in research[1]. Recent advances in state-of-the-art methodologies, including nanopatterning, additive nanomanufacturing, and lithography, focus on processing specific geometrical patterns in a given material. Phase-changing media, on the contrary, have been reported to enhance the performance and response attainable at optical frequencies significantly. However, a technique that allows point-to-point controllability over the material phase and geometrical shape is unavailable. Addressing this problem can open new pathways for controlling materials' optical response, leading to new levels of performance of photonic devices.

Here we present a nanostructuring platform in which we explore nonlinear light-matter interactions to alter the material geometry and phase controllably. The cornerstone of this approach is laser-induced passivation and reshaping of oxide-polymer heterostructures deposited on rigid and flexible substrates. Figure 1a shows a cross-sectional TEM image with corresponding EDX elemental mapping for the initial heterostructure composed of polymer nanosphere with deposited partially oxidized material on top. Upon exposure to a tightly focused laser diode, we observe structural change involving polymer melting with the formation of fully oxidized hollow core-shell geometry (Fig.1c). Elemental mapping of this area (Fig.1d) confirms that the cavity of the newly formed nanostructure is void. We observe that the phase transition in these structures is a gradual process dependent on laser intensity and exposure time. The transformed system with partial to fully passivated material exhibits resonant behavior in the optical response. In the case of closely-packed two-dimensional arrays of an initial heterostructure, successive exposure to laser illumination over the larger sample area results in the generation of structural coloration at the microscale. We control this process by various parameters, including the laser power, exposure area, and exposure time.

We demonstrate this nanomaterial platform's effectiveness in the inkless laser color printing field, which recently attracted significant interest[2]. While resonant laser printing on a preprocessed photoactive material achieved subdiffraction limit resolution, it still lacks a wide color gamut and requires nonintegrated, high-energy, and high cost pulsed lasers. By using a low-power (15 mW) laser diode, we achieve laser printing at high-resolution (33000 DPI) images with the broadest gamut

reported. To the best of the authors' knowledge, the controllable gamut of color obtained with this technique also exceeds the best results currently available with inverse design. This new platform can open new applications of nanomaterial engineering for controlling light with nanoscale resolution[3].

Abstract: Magnetic garnet films have been widely used in magnetooptical devices because of their large Faraday rotation angle and low optical loss. For the development of magnetooptical devices such as spatial light modulators and spin-controlled lasers, controlling the magnetic domains is essential. However, predicting the behavior of magnetic domains can be challenging. In this research, we calculated the magnetic domains in the magnetic garnet film using a micromagnetic simulation.

Magnetic garnet films are widely used in magnetooptical devices because of their large Faraday rotation angles and low optical absorption. Cerium-substituted yttrium iron garnet (Ce:YIG, $Ce_1Y_2Fe_5O_{12}$)[1] particularly well-suited for use in magnetooptical modulators such as magnetooptical spatial light modulators[2] and magnetooptical Q-switch[3], due to its excellent magnetooptical response at near-infrared wavelengths. To be effective in such applications, Ce:YIG needs to exhibit perpendicular magnetic anisotropy in order to quickly control the magnetization direction. However, Ce:YIG films often exhibit magnetic domains with varying sizes and shapes, which presents a challenge in designing magnetooptical modulators. To address this issue, we used a large-scale parallel computing technique to perform micromagnetic simulations and calculate the magnetic domain structures of Ce:YIG films.

We employed a commercial micromagnetic simulator (EXAMAG, Fujitsu) to conduct our simulations, using a total of five nodes for parallel computing. The simulation process utilized 128 cores and 750 GB of memory. The model size was 5 microns × 5 microns × 0.2 microns (as shown in Figure 1) with a cell sizeof 10 nm × 10 nm × 10 nm. The entire model comprised 2.6×10^7 cells.

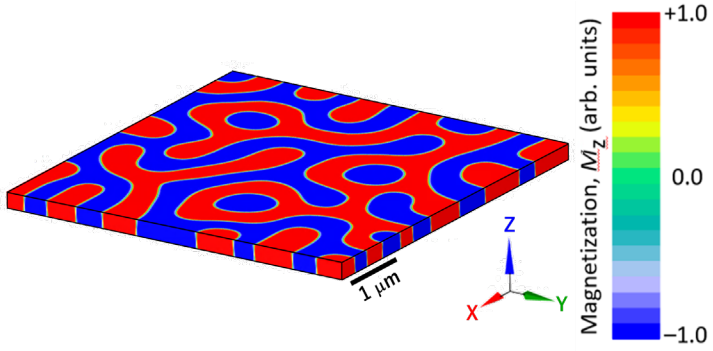

Figure 1. Steady simulation result of Ce:YIG, showing the perpendicular maze-like magnetic domains.

To obtain the initial magnetization state of the Ce:YIG film, we conducted simulations without an external magnetic field. We then utilized the energy minimization method to obtain a stable state of the magnetic moments, whereby the position and direction of magnetic moments are calculated so that the total energy of the entire model is minimized. In the simulation, we set the saturation magnetization of Ce:YIG to 225 mT and the exchange coupling constant to 3.5 pJ/m. The anisotropic magnetic field was set to 398.8 mT, with the field direction perpendicular to the film surface. These parameter values were determined based on experimental measurements.

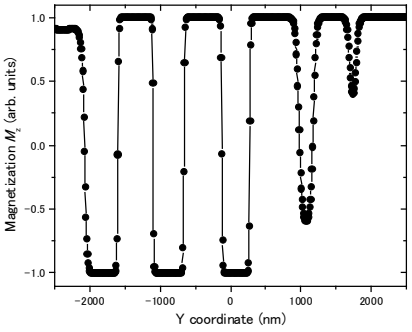

Figure 2. The plot of Z-component magnetization in Y direction.

Figure 1 shows the calculated result of the initial state of magnetization in the Ce:YIG. The maze-shaped magnetic domains were observed, with an average size of approximately 0.5 microns. Figure 2 shows the *z*-component of magnetization along the *y*-direction, where the average magnetic domains width was approximately 480 nm and the average domain wall width was approximately 12 nm. The observed domain wall type was the Bloch wall. These results suggest the presence of perpendicular maze-like magnetic domain in Ce:YIG. The next step is to calculate its magnetic properties and hysteresis loop. At the conference, we will report on the calculation of magnetic properties and other parameters, as determined from samples on another substrate.

Abstract: Thermally activated delayed Fluorescence (TADF) mechanism can occur by a complicated and fascinating route involving the triplet manifold. Here, we report a computational approach based on *Time Dependent Density Functional Theory* (TD-DFT) to shed light on the anomalous response of a phenothiazine derivative exhibiting efficient TADF only upon aggregation. The strong red-shifted peak in the photoluminescence spectrum of the molecule dispersed in a non-polar solvent (i.e. cyclohexane) is explained in terms of aggregation of monomers and dimer formation.

Molecular fluorescence is conventionally interpreted as a two-step process. An initial absorption induces an electronic transition to a singlet excited state of the quantum system, which then decays radiatively into the electronic ground state, with a certain quantum efficiency. In 2012, Adachi and co-workers [1] introduced the term TADF to indicate the phenomenon for which the singlet state can be populated-back by electrons coming from the nearest triplet state, according to what is called a reverse intersystem crossing (rISC) process. In order to achieve good TADF performance, an emitter must ensure a small enough triplet-singlet energy gap (less than 0.1 eV), [2] which allows to maximize the opportunity of harvesting triplet state by thermally activating the rISC process, i.e. high RISC rate in conjunction with minimum phosphorescence (k_P) and non-radiative (k_{ISC}) decay. Moreover, a high *Photo Luminescence Quantum Yield* is ensured trough a larger transition dipole moment between the singlet excited state and the ground state. The reduction of the singlet-triplet gap it has been shown to be achieved by charge transfer states that minimizes the exchange energy.

In this work, we investigated the TADF performance of a phenothiazine derivative consisting of a strong donor (phenothiazine) and an acceptor (fluorenone) in the quasi-equatorial conformation [3], see Fig. 1(a).

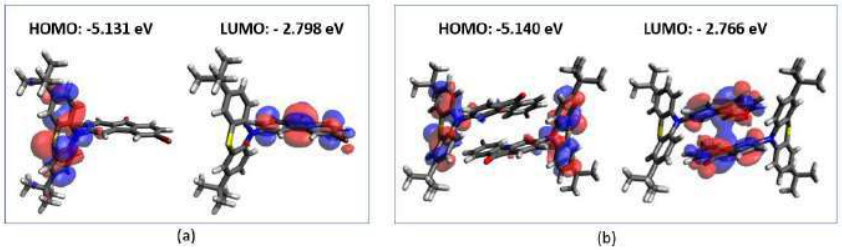

Fig. 1 (a) HOMO and LUMO orbitals of the phenothiazine derivative in the quasi-equatorial conformation. (b) HOMO and LUMO orbitals of the phenothiazine derivative excimer in the quasi-equatorial conformation relaxed in the dimer ground state.

All simulations were performed by using the ORCA 5.0 package. The geometry of the ground state was optimized in the gas phase by employing the B3LYP functionals and a TZVP basis set, with the def2/*J* auxiliary basis set for the RIJCOSX approximation to the Coulomb integrals [4]. Electronical and optical properties were analyzed for the monomer in the cyclohexane solvent, allowing identification of the first singlet (S_1) and triplet (T_3) charge transfer states. Coherently with experiments, revealing the appearance of a two-peak structure for the photoluminescence spectrum of the molecule in cyclohexane, we found out different TADF properties for the analyzed molecule in the monomer and excimer arrangements.

We performed several DFT simulations to select the most stable dimer conformation (relative orientation and distance between monomers), see Fig. 1(b), and compared its behavior to the monomer. A promising change in the relative position of the electronic states of interest for TADF and a red-shift of the emission peak, this being coherent with the appearance of an extra peak in the experimental PL spectrum (about 1 eV red-shift with respect to the monomer). The hypothesis of the formation of a dimer electronic state would, thus, explain the dependence of the TADF performance for such kind of phenothiazine derivative on the molecule concentration and aggregation conditions. This study could open new perspective toward an on-demand control and activation of the TADF phenomenon in molecules of interest for optoelectronics and nanomedicine applications.

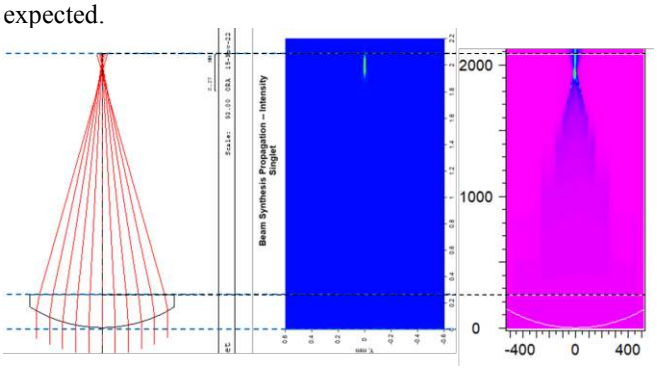
Abstract

The first fully automated design tool, MetaOptic Designer (MOD) [1] has been extended to design hybrid optical systems that combine metalenses with refractive lenses. In addition to metalenses, MOD can also model refractive lens accurately and efficiently. Hence, it can be used to design metalenses that correct various aberrations in existing optical system or to replace several refractive lenses in the system.

1. Introduction



Because of their great potential to revolutionize optical products by replacing bulky curved lenses with thin, flat surfaces, metalenses have become a key enabling technology for the next generation of compact imaging, sensing, and display applications [2]. Because of the challenges in design and fabrication, however, it is difficult to replace traditional refractive lenses completely, especially for multi-functional optical systems like imaging lens systems which require both achromaticity and wide-angle. Therefore, adding metalenses to an existing optical system or partially replacing several of the bulky refractive lenses are now feasible solutions for correcting various aberrations or miniaturizing the optical system, as exemplified by Samsung [3] and LG [4].

Because of multi-scale optics involved, designing such hybrid optical systems is a challenging task. Synopsys provides leading design tools for both ray optics and electromagnetic optics and has developed a unique and proprietary technology to interface between the two optical domains seamlessly to model optical systems that combine metalenses and refractive lenses [5]. Refractive lenses designed in CODE V [6] can be directly loaded into MOD, and metalenses can be optimized subsequently within the hybrid lens system. In the following sections, we will first validate this hybrid algorithm, then apply it to hybrid optical systems.

2. Validation

The accuracy of MOD for metalenses/metasurfaces has been fully validated against rigorous FDTD for different applications [1]. Its handling of traditional refractive lenses, however, has not been verified. Therefore, it is necessary to validate MOD for refractive lens systems before applying it to hybrid optical systems.

We first apply MOD to a single plano-convex spherical lens as shown in Figure *1*. As indicted from the simulation results by different methods, the simple spherical lens suffers various aberrations and doesn't focus well as expected.

(a) (b) (c)

Figure 1: Simulation results of a simple spherical lens (a) Ray-tracing; (b) BSP; (c) MOD.

To make a quantitively comparison, the focus shift calculated by different methods is shown in Figure *2*. It is indicated that the MOD results are the same as BSP (Beam Synthesis Propagation) 0 results because both methods are based on physical optics with different base functions.

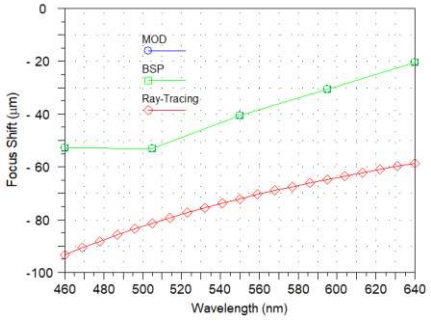


Figure 2: Focus shift of the spherical lens by different methods.

Compared with ray-tracing results, however, some discrepancy is observed. That is because different merit functions are used. In MOD and BSP, the intensity peak is used to determine the focal position, while wavefront error is used in ray-tracing. Hence, their results may differ, especially for systems with imaging aberrations.

The defocusing can be viewed more clearly in top-views zoomed around the focal position, as shown in Figure *3*. As can be observed, the simple spherical lens does not focus well over the entire visible range.

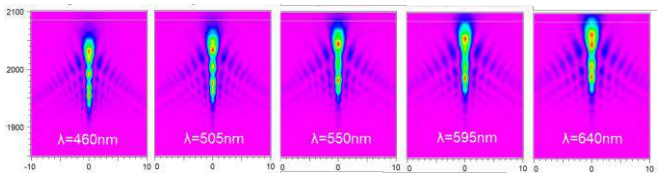

Figure 3: Defocusing over the at different wavelengths.

3. Metacorrector

To correct the chromatic and spherical aberrations, a metasurface is introduced into the optical system as shown in Figure *4*.

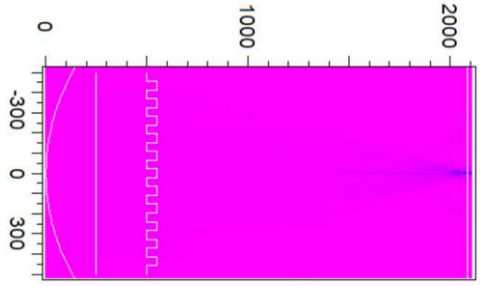

Figure 4: Hybrid optical system with both metalens and refractive lens.

A portion of the layout of the optimized metacorrector is shown Figure *5*.

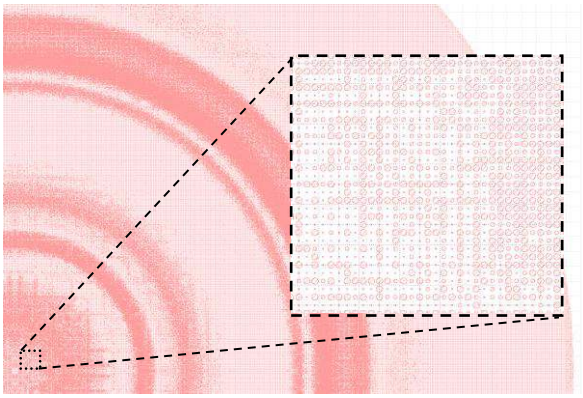

Figure 5: Layout of the optimized metacorrector.

Shown in Figure *6* are the focusing behavior of the hybrid optical system. Compared with Figure *3*, it shows the metacorrector improves the focusing significantly.

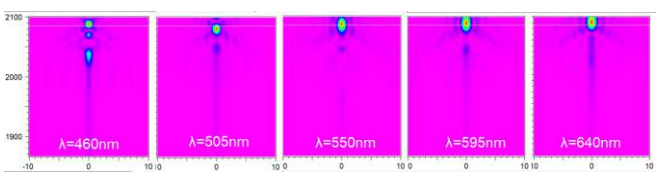

Figure 6: Focusing improvement with the metacorrector.

The focusing improvement can be compared quantitatively in focus shift as shown in Figure *7*. As observed, the metacorrector corrects both chromatic and spherical aberrations dramatically.

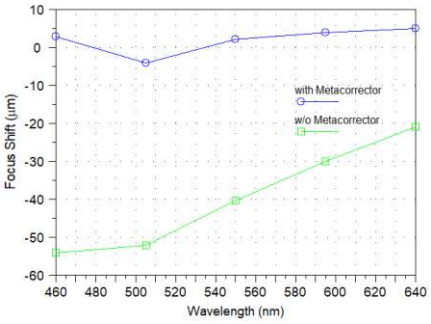

Figure 7: Comparison of the focus shift with and without metacorrector.

4. Conclusions

In summary, we have extended our inverse design tool, MetaOptic Designer to hybrid optical systems which includes both metalenses and refractive lenses. The validation showed MOD can handle refractive lenses well and that an optimized metalens can improve image quality significantly over a range of wavelenths. Furthermore, this approach can be applied to large and complex optical systems, such as those used in cellphone cameras.

Level-set optimization of non-reciprocal media

C. M. Cisowski[1*], R. Bennett[1]

[1]School of Physics and Astronomy, University of Glasgow, Glasgow, UK
[*]Corresponding author: clairemarie.cisowski@glasgow.ac.uk

Abstract: Non-reciprocal photonics holds transformative potential for energy harvesting and optical information processing. While computer assisted design techniques have become widespread approaches for tailoring and enhancing optical devices, devices based on non-reciprocal media constitute a missing entry in the growing catalogue of inverse-designed technology. In this work, we exploit a Green's tensor formalism to introduce a level-set method for the inverse design of a non-reciprocal material for the example of a point-based intensity optimization problem.

Inverse design engineering generates structures based on a set of desired properties and characteristics; it has gained in popularity in recent years due to its capacity to outperform traditional numerical techniques [1]. The majority of inverse design algorithms developed for optics exploit Lorentz reciprocity to reduce the time of the optimization process, making its implementation for non-reciprocal media an arduous process.

We propose a solution to this problem by basing our algorithm entirely on the use of electromagnetic dyadic Green's tensor, $\mathbf{G}(\mathbf{r},\mathbf{r}',\omega)$ which describes the propagation of a plane-wave electric field of frequency ω from a source point $\mathbf{r}'$ to an observation point $\mathbf{r}$ [2]**.** This method was introduced in [3] in the context of atomic interactions in external environments. Here we show that this method is particularly effective for tailoring non-reciprocal media. Using the finite difference time domain techniques, we demonstrate how our approach can be implemented to solve a three-dimensional point-based intensity optimization problem for the case of a gyrotropic medium. The inverse design technique used in our study is a topology optimization method.

This work unlocks new avenues for enhancing and tailoring nonreciprocal effects, enabling the development of a new set of optical devices with outstanding performances and functionalities, including optical isolators and circulators for photonics integrated circuits [4].

Abstract: In order to enhance the light collection and absorption of III-V photovoltaic, the optimal cell geometry has been the subject of continuous research. For example, solar concentrators have been one of the attempts to increase the density of incident photon flux. However, as optic elements such as mirrors and lenses are inevitably required, There was an issue that not only the volume of the entire system but also the thermal density increased. In this work, we suggest the strategy to the optimal light-trapping structure for monolithic III-V double junction solar cell implemented with luminescence solar concentrator by systematic analysis, integrating ray-optical analysis with Shockley-queisser limit.

Luminescent Solar Concentrator has been attracting attention as an excellent alternative to solar concentrators. Unlike optical solar concentrator, it adopts luminophores that emit light omni-directionally in the multi-mode slab waveguide, so it does not only require bulky sun-tracker system and thermal cooler, but also it is much more advantageous in module assembly and shows excellent light collecting power in diffused sun light.

However, when this Luminescent Solar Concentrator was applied to double junction III-V, it suffered loss in photon energy due to energy downshifting, and it was difficult to achieve a great improvement in the increase of the collective output current of series-connected subcells.

In this study, we extend the geometrical optical absorption criterion of solar cells proposed by E. Yablonovitch to a structure containing a Luminescent Solar Concentrator, building a model based on ray optics, we could get a clue how the geometry and refractive index of a multimode slab waveguide affect the distribution of rays in the overall system[1].

Furthermore, we determined the quantum efficiency, absorption wavelength and emission wavelength of the luminophores to match the subcell absorption region of the double-junction solar cell while reflecting the full spectrum of sunlight and found the structural optimization conditions for the structure of the double junction III-V solar cell with Luminescent Solar Concentrator. This was possible through not only rigorous ray optical, but also the detailed balance analysis with our integrated modeling which can convert the light flux on photovoltaics into the electric properties of device, such as the short-curcuit current, open-circuit voltage and fill factor, etc[2].

As a result, the multi-junction solar cells were arranged co-planar with the multimode slab waveguide so that they could simultaneously take the directly illuminated solar photon flux and the light emitted from the luminophores. Then the thickness and refractive index of each slab were adjusted, the wave guided light was appropriately induced to the sub cell[3].

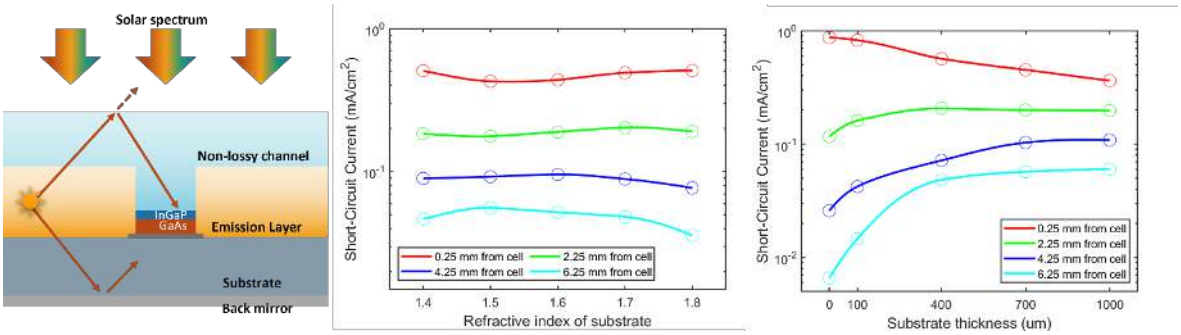

Figure 1: (a) Schematic of III-V Photovoltaic with Luminescent Solar Concentrator that condenses light from direct sunlight and luminophores. (b) Short circuit current increase due to induced light according to the refractive index of the substrate layer. (c) Short circuit current increase due to induced light according to the thickness of the substrate layer.

Band gap tuning based on adjustable stiffness of local resonators

H. Alimohammadi[1*], K. Vassilyeva[1], H. HosseinNia[2], and E. Petlenkov[1]

[1]Computer Systems Department, Tallinn University of Technology, 12618 Tallinn, Estonia

Abstract: This research explores the feasibility of using a cantilever-type resonator beam to achieve tunable and real-time control of vibration suppression. By varying the center of mass of the attached masses, the bandgap and transmittance response can be significantly impacted. The results suggest potential for improving resonator performance and optimizing metamaterial beams for vibration suppression applications.

Summary:

The method involves analyzing the propagation of acoustic waves through a phononic structure with one, two, and four beams connected to a non-uniform beam-type resonator. The frequency response of the tip of the Euler-Bernoulli beam is monitored to verify the outcomes found in the dispersion curves. The equation of motion is solved using a harmonic input force, with periodic boundary conditions and Floquet periodicity taken into account for accurate results. The study demonstrates the feasibility of using a cantilever-type resonator instead of a lumped mass spring for examining other modes of the resonator and tuning and controlling the bandgap characteristics of the beam in real-time experiments. A simulation is performed using finite element software.

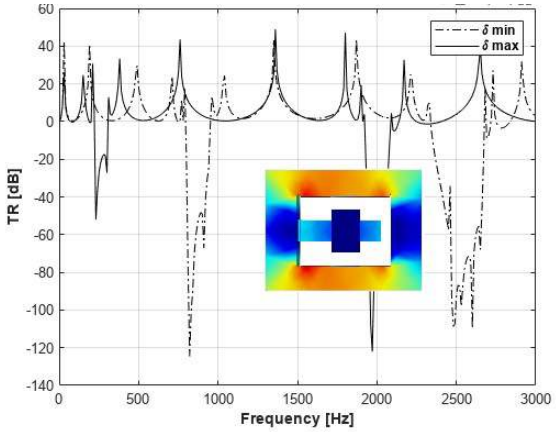

Fig.1. Transmittance responses of the first and second mode of resonator with μ=0.9 for different δ.

By using a cantilever-type resonator instead of a lumped mass spring, it becomes feasible to examine other modes of the resonator. Fig.1 shows the transmittance responses of the first and second mode of the resonator with a high mass ratio of μ=0.9 for different values of resonator center of mass (δ). The second mode is observed in the transverse vibration of the beam, and the attached mass on the resonator material is replaced from PLA to steel to decrease the natural frequency of the resonator to the desired frequency range. The result shows the same behaviour in the second mode as well, and the variation of δ changes the bandwidth and edge of bandgap similar to first mode.

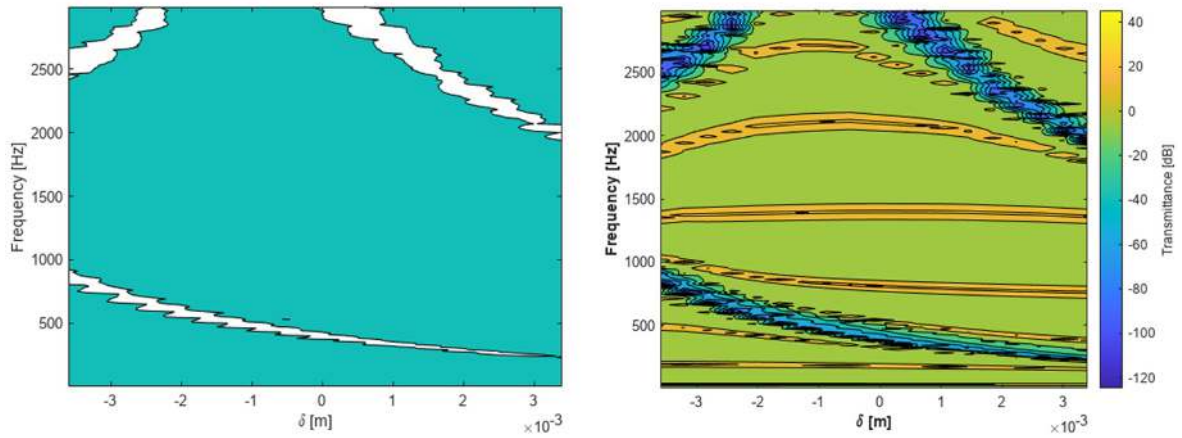

Fig.2. Contour and Image binarization of the transmittance using -40 dB as reference in response to the variation of δ, and μ=0.9.

Fig.2 shows the binary representation of the transmittance contour pattern evolution with changes in δ for a high mass ratio of μ=0.9. The image binary contour of the transmittance for μ=0.9 and -40 dB as reference is shown in Fig.2. The second mode of resonator creates an additional gap in higher frequencies, as shown in the top part of Fig.2. This result suggests that using a cantilever-type resonator instead of a lumped mass spring allows the study of other modes of the resonator. Moreover, the change in attached mass and mass ratio allows for tuning and controlling the bandgap characteristics of the beam in real-time experiments.

In conclusion, this research has examined the possibility of tuning the band gap of beam-type resonators based on adjustable stiffness to achieve broadband vibration suppression. Through the analysis of dispersion relations and the binary representation of transmittance contour patterns, it has been demonstrated that the center of masses of attached masses does not significantly affect the vibration suppression performance of the metamaterial beam. However, by using a cantilever-type resonator instead of a lumped mass spring, it has become possible to examine other modes of the resonator and to tune and control the bandgap characteristics of the beam in real-time experiments. This study has provided valuable insights into the design and optimization of graded metamaterial beams for vibration suppression applications.
