SPONSORS I EXHIBITORS

Gold Sponsor

Raith develops leading edge lithography systems enabling compound semiconductor customers to drive innovation and production. Our maskless electron beam, laser beam and focused ion beam patterning solutions cover the full range, from µm structures to sub 10 nm critical device fabrication. The Raith product portfolio is being complemented by automated SEM based chip analysis and process control systems. Our worldwide service and customer support structures are backed by experienced experts in our international applications and development centers. We are fully committed to further push the limits of nanofabrication in close collaboration with our outstanding customer base.

Silver Sponsor

The Synopsys Optical Solutions Group provides design tools that model all aspects of light propagation. Our innovative software packages include CODE V® imaging design software, LightTools® illumination design software, the LucidShape® products for automotive lighting, and the RSoft™ Photonic Device Tools for passive and active photonic devices. And our optical measurement solutions give customers access to precision light scattering data for materials and media used in optical systems.

At META 2023, Synopsys will demonstrate MetaOptic Designer, an unprecedented inverse design tool that takes user-specified criteria and generates metalenses/metasurfaces for optimal design performance. Metalens design traditionally requires extensive physics knowledge and many hours of development. MetaOptic Designer removes these barriers with exclusive AI that automatically yields the best metalens designs as fast as possible.

PHASICS, founded in 2003, offers state-of-the-art optics metrology and imaging solutions, from standalone SID4 wavefront sensors to fully automated test benches, Kaleo MTF, Kaleo MultiWAVE, and a fully modular metrology solution, Kaleo Kit. This range of wavefront measurement systems and quantitative phase imaging solutions is based on innovative, high-resolution wavefront-sensing technology. PHASICS' unique, patented wavefront sensing technology is called QuadriWave Lateral Shearing Interferometry (QWLSI). This technology was developed to overcome the Shack- Hartmann limitations: it offers ultra-high resolution, high sensitivity (sub-nanometric), and a wide dynamic range (hundreds of microns).

PHASICS has a strong customer focus and cares about satisfying all its customers' needs. Its robust R&D team develops innovative features, explores new applications, and customizes standard configurations to customers' requests. Thanks to these large innovative projects, PHASICS covers a wide range of applications, including laser testing, adaptive optics, lens alignment and quality control, refractive index mapping in materials, quantitative phase imaging for biology, and plasma and gas density measurements.

ENSEMBLE3 is a newly established Centre of Excellence in nanophotonics, advanced materials and technologies based on crystal growth. The Centre was established under the "Teaming for Excellence" program funded by the European Commission and the "International Research Agendas" program funded by the Foundation for Polish Science and works in collaboration with renowned national and international scientific institutions.

The Centre works on the development of new material technologies and advanced materials with exceptional electromagnetic properties that can be applied in areas such as photonics, optoelectronics, telecommunications, solar energy conversion, medicine, aeronautics, security and defense.

Other Partners

Université Paris-Saclay is a research university based in Paris, France. Université Paris-Saclay offers a comprehensive and varied range of Undergraduate, Master's and PhD degrees, renowned internationally thanks to the University's reputation for research excellence and the commitment of its academic staff. The University's constituent faculties, institutes and component institutions all contribute to the curricula with cutting-edge specialised courses in Science and Engineering, Life Sciences and Health, and Social Sciences and Humanities.
Université Paris-Saclayis ranked 1st in France and 13th in the world according to the Academic Ranking of World Universities (ARWU).

AEM - Advanced Electromagnetics is a peer-reviewed, Gold Open Access journal. It covers recent international research results in the general field of Electromagnetic Waves, Antennas and Propagation. Authors of articles published in Advanced Electromagnetics retain the copyright of their articles and are free to reproduce and disseminate their work (under a Creative Commons Attribution License). AEM is widely indexed and has a Scopus CiteScore of 2.2 (2021).

ACS Photonics is an interdisciplinary forum to communicate on the latest advances in the field of photonics, all the way from basic research to applied research and technology. Embracing the transversality of photonics, it connects scientists and technologists from a broad scientific spectrum, at the interface between physics, chemistry, biology, and engineering. It also aims at bridging the gap between the academic and industrial worlds.

Nanophotonics (De Gruyter) covers recent international research results, specific developments in the field and novel applications. It publishes all article in a Gold Open Access model and belongs to the top journals in the field. Nanophotonics focuses on the interaction of photons with nano-structures, such as carbon nano-tubes, nano metal particles, nano crystals, semiconductor nano dots, photonic crystals, tissue and DNA.

PLENARY SPEAKERS

Andrea Alù

City University of New York, USA

Extreme Control of Light and Sound with Metamaterials

Andrea Alù is a Distinguished Professor at the City University of New York (CUNY), the Founding Director of the Photonics Initiative at the CUNY Advanced Science Research Center, and the Einstein Professor of Physics at the CUNY Graduate Center. He received his Laurea (2001) and PhD (2007) from the University of Roma Tre, Italy, and, after a postdoc at the University of Pennsylvania, he joined the faculty of the University of Texas at Austin in 2009, where he was the Temple Foundation Endowed Professor until Jan. 2018. Dr. Alù is a Fellow of the National Academy of Inventors (NAI), the American Association for the Advancement of Science (AAAS), the Institute of Electrical and Electronic Engineers (IEEE), the Materials Research Society (MRS), Optica, the International Society for Optics and Photonics (SPIE) and the American Physical Society (APS). He is the President of Metamorphose, a Highly Cited Researcher since 2017, a Simons Investigator in Physics, the director of the Simons Collaboration on Extreme Wave Phenomena Based on Symmetries, and the Editor in Chief of Optical Materials Express. He has received several scientific awards, including the NSF Alan T. Waterman award, the Blavatnik National Award for Physical Sciences and Engineering, the IEEE Kiyo Tomiyasu Award, the ICO Prize in Optics, the OSA Adolph Lomb Medal, and the URSI Issac Koga Gold Medal.

Extreme Control of Light and Sound with Metamaterials
In this talk, I discuss recent developments in this field of research, with an emphasis on the role of symmetries in establishing emerging optical responses for metamaterials based on otherwise simple constituents. Geometrical rotations, suitably tailored perturbations, and broken time reversal symmetry can be carefully engaged to tailor waves in robust and efficient ways, control their propagation, break Lorentz reciprocity and enable topological order and phase transitions.

Nader Engheta

University of Pennsylvania, USA

Structuring light with media with higher dimensions: space, time, and more

Nader Engheta is the H. Nedwill Ramsey Professor at the University of Pennsylvaniain Philadelphia with affiliations in the Departments of Electrical and Systems Engineering, Physics and Astronomy, Bioengineering, and Materials Science and Engineering. He received his BS degree from the University of Tehran, and his MS and Ph.D. degrees from Caltech. His current research activities span a broad range of areas including optics, metamaterials, electrodynamics, microwaves, photonics, nano-optics, graphene photonics, imaging and sensing inspired by eyes of animal species, microwave and optical antennas, and physics and engineering of fields and waves. He has received several awards for his research including the 2023 Benjamin Franklin Medal in Electrical Engineering, Election to the American Academy of Arts and Sciences (2023), Caltech Distinguished Alumni Award (2023), the 2020 Isaac Newton Medal and Prize from the Institute of Physics (UK), the 2020 Max Born Award from the OPTICA (formerly Optical Society), the 2019 Ellis Island Medal of Honor, the 2018 IEEE Pioneer Award in Nanotechnology, the 2022 Hermann Anton Haus Lecture at MIT, the 2015 SPIE Gold Medal, the 2014 Balthasar van der Pol Gold Medal from the International Union of Radio Science (URSI), the 2017 William Streifer Scientific Achievement Award, the Canadian Academy of Engineeringas an International Fellow the Fellow of US National Academy of Inventors (NAI), the IEEE Electromagnetics Award, the Vannevar Bush Faculty Fellowship Awardfrom DoD, the Wheatstone Lecture in King's College London, 2006 Scientific American Magazine 50 Leaders in Science and Technology, and the Guggenheim Fellowship. He is a Fellow of nine international scientificand technical organizations, i.e., IEEE, OPTICA, APS, MRS, SPIE, URSI, AAAS, IOP and NAI. He has received the honorary doctoral degrees from the Aalto University in Finland in 2016, the University of Stuttgart, Germany in 2016, and Ukraine's National Technical University Kharkov Polytechnic Institute in 2017.

Structuring light with media with higher dimensions: space, time, and more

In this talk, I will present some of our most recent results on exploring light-matter interaction in material media with high degrees of freedom and dimensions including spatial and/or temporal inhomogeneities, and other degrees of freedom such as anisotropy, ellipticity, and hyperbolicity. We show how light manipulation with such metastructures with high degrees of freedom can lead to exciting novel wave phenomena with potential applications in wave-based reconfigurable analog computing, 4D optics, and other optical devices and components.

Sylvain Gigan

Sorbonne Université, France

Imaging and Computing with disorder

Sylvain Gigan is professor of physics at Sorbonne Université in Paris and group leader in Laboratoire Kastler-Brossel at Ecole Normale Supérieure. His research interests range from fundamental investigations of light propagation in complex media, biomedical imaging, computational imaging, and signal processing, to quantum optics and quantum information in complex media. After graduating from Ecole Polytechnique (Palaiseau France) in 2000 and a Master specialization in optics from University Paris XI (Orsay, France), he obtained a PhD in physics in 2004 from University Pierre and Marie Curie (Paris, France) in quantum and non-linear Optics. From 2004 to 2007, he was a postdoctoral researcher in Vienna University (Austria). from 2007 to 2014, he was at ESPCI ParisTech as Associate Professor, and started working on optical imaging in complex media and wavefront shaping techniques, at the Langevin Institute. Dr. Gigan is also the cofounder of a spin-off called LightOn (www.lighton.ai), aiming at performing optical computing for machine learning and big data. He was awarded the Fabry de Gramont Prize of the French Optical Society in 2016, The Joseph Fourier ATOS prize in 2018, the Jean Jerphagnon Prize in 2019.

Imaging and Computing with disorder

Light propagation in complex media, such as paint, clouds, or biological tissues, is a very challenging phenomenon, encompassing fundamental aspects in mesoscopic and statistical physics. It is also of utmost applied interest, in particular for imaging. Although this scattering process seems to mix and completely destroy all information, thus preventing imaging or communication, a different approach has emerged. I will discuss how this powerful concept has recently triggered a wealth of advances in imaging and computing.

Marin Soljačić

Massachusetts Institute of Technology (MIT), USA

Nanophotonics for tailoring radiation from fast electrons

Marin Soljačić is a Professor of Physics at MIT. He is a founder of WiTricity Corporation (2007), LuxLabs (2017), as well as Lightelligence (2017). His main research interests are in artificial intelligence as well as electromagnetic phenomena, focusing on nanophotonics, non-linear optics, and wireless power transfer. He is a recipient of the Adolph Lomb medal from the Optical Society of America (2005), and the TR35 award of the Technology Review magazine (2006). In 2008, he was awarded a MacArthur fellowship “genius” grant. He is an international member of the Croatian Academy of Engineering since 2009. In 2011 he became a Young Global Leader (YGL) of the World Economic Forum. In 2014, he was awarded Blavatnik National Award, as well as Invented Here! (Boston Patent Law Association). In 2017, he was awarded "The Order of the Croatian Daystar, with the image of Ruđer Bošković", the Croatian President’s top medal for Science. In 2017, the Croatian President also awarded him with "The Order of the Croatian Interlace" medal. He was also Highly Cited Researcher according to WoS for 2019, 2020 and 2021.

Nanophotonics for tailoring radiation from fast electrons

Nanophotonic methods provide intriguing options for manipulating scintillation phenomena. We will outline recent developments in this domain, along with our theoretical framework for modeling these occurrences, supported by our experimental findings. Additionally, Smith-Purcell radiation, characterized by fast electrons interacting with nano-structured materials to produce light, offers a broad spectrum of possibilities for creation of novel light sources. We will discuss our new theoretical framework designed to comprehend and tailor such phenomena, as well as our techniques for boosting Smith-Purcell radiation.

Isabelle Staude

Friedrich Schiller University Jena, Germany

Active photonic metasurfaces empowered by 2D semiconductors

Isabelle Staude is professor at the Institute of Solid State Physics at the Friedrich Schiller University Jena, Germany. She studied physics at the University of Konstanz, Germany, received her Ph.D. degree from the Karlsruhe Institute of Technology, Germany, in 2011, and spent several years as a postdoc at the Australian National University, Canberra, Australia. She received an Emmy-Noether Grant from the German Research Foundation and the Hertha Sponer Prize 2017 from the German Physical Society. She is a member of the German Young Academy (Junge Akademie) and a Fellow of the Max Planck School of Photonics..

Active photonic metasurfaces empowered by 2D semiconductors

This talk reviews our recent and ongoing activities in hybridizing optical metasurfaces composed of resonant metallic or dielectric building blocks with 2D-TMDCs. We demonstrate that the ability of the nanoresonators to concentrate light into nanoscale volumes can be utilized to carefully control the properties, such as pattern and polarization, of light emitted by 2D-TMDCs via photoluminescence or nonlinear optical processes. Furthermore, we investigate the ability of tailored nanostructures to interact selectively with exciton populations located at inequivalent conduction band minima at the corners of the 2D-TMDC's Brillouin zone.

Jelena Vuckovic

Stanford University, USA

Scalable classical and quantum photonics

Jelena Vuckovic (PhD Caltech 2002) is the Jensen Huang Professor in Global Leadership in the School of Engineering, and Professor of Electrical Engineering and by courtesy of Applied Physics at Stanford, where she leads the Nanoscale and Quantum Photonics Lab. She is also the Fortinet Founders Chair of the Electrical Engineering Department at Stanford, and was the inaugural director of Q-FARM, the Stanford-SLAC Quantum Science and Engineering Initiative. Vuckovic has received many awards and honors including recently the Vannevar Bush Faculty Fellowship (2022), the Mildred Dresselhaus Lectureship from MIT (2021), the James Gordon Memorial Speakership from the OSA (2020), the IET A. F. Harvey Engineering Research Prize (2019), Distinguished Scholarship of the Max Planck Institute for Quantum Optics (2019), the Hans Fischer Senior Fellowship from the Institute for Advanced Studies in Munich (2013), and Humboldt Prize (2010). She is a Fellow of the APS, of the Optica (OSA), and of the IEEE, and an associate editor of the ACS Photonics.

Scalable classical and quantum photonics

Novel computational techniques such as photonics inverse design, along with new nanofabrication approaches, play a crucial role in building scalable integrated classical and quantum photonics. Inverse design, a departure from the traditional photonics design approach, can lead to photonics much better than state of the art in many metrics (smaller, more efficient, more robust, a much higher density of integration). This is enabled by development of a computer software which efficiently searches through the space of all possible and fabricable photonic geometries, in any material of interest. On the other hand, future photonic systems also require integration and fabrication of traditional and non-traditional photonic materials, including silicon, silicon-carbide, diamond, sapphire, and strong electro-optic materials such as lithium niobate, strontium and barium titanate.

KEYNOTE SPEAKERS

Harry Atwater

California Institute of Technology, USA

Active Metasurfaces in Space and Time

Harry Atwater is the Otis Booth Leadership Chair of the Division of Engineering and Applied Science, and the Howard Hughes Professor of Applied Physics and Materials Science at the California Institute of Technology. Atwater's scientific effort focuses on nanophotonic light-matter interactions. His work spans fundamental nanophotonic phenomena and applications, including active wavefront shaping of light using metasurfaces, optical propulsion of lightsails, quantum and 2D nanophotonics as well as solar energy conversion.

Atwater was an early pioneer in nanophotonics and plasmonics and gave a name to the field of plasmonics in 2001. He is Chair of the LightSail Committee for the Breakthrough Starshot program. Currently Atwater is also the Director for the Liquid Sunlight Alliance (LiSA), a Department of Energy Hub program for solar fuels, and was also the founding Editor in Chief of the journal ACS Photonics. Atwater is a Member of the US National Academy of Engineering, a Web of Science Highly Cited Researcher, and the recipient of the 2021 von Hippel Award of the Materials Research Society.

Active Metasurfaces in Space and Time
Active dielectric and plasmonic metasurfaces enable new modalities for spatiotemporal beam control for beam steering and wavefront shaping at multiple frequencies. In this talk, I will discuss metasurfaces with high quality factor, local, resonant elements capable of two-dimensional phase gradient generation, in both passive and active metasurface designs. I will also describe active metasurfaces with both spatial and temporal phase gradients, and an active metasurface as a lens-less imaging system, and compare the characteristics to conventional lens-coupled image sensors.

Alexandra Boltasseva

Purdue University, USA

Crossroads of Nanophotonics and Machine Learning

Alexandra Boltasseva is a Professor at the School of Electrical & Computer Engineering at Purdue University. She received her PhD in electrical engineering at Technical University of Denmark, DTU in 2004. Boltasseva specializes in nanophotonics, nanofabrication, optical materials, plasmonics and metamaterials. She is 2018 Blavatnik National Award for Young Scientists Finalist and received the 2013 IEEE Photonics Society Young Investigator Award, 2013 Materials Research Society (MRS) Outstanding Young Investigator Award, the MIT Technology Review Top Young Innovator (TR35), the Young Researcher Award in Advanced Optical Technologies from the University of Erlangen-Nuremberg, Germany, and the Young Elite-Researcher Award from the Danish Council for Independent Research. She is a Fellow of the Optical Society of America (OSA) and Fellow of SPIE. She served on MRS Board of Directors and is Editor-in-Chief for OSA's Optical Materials Express.

Crossroads of Nanophotonics and Machine Learning
We report on advancing machine-learning-assisted optical inverse design optimization for metasurfaces with applications in thermophotovoltaics, reflective optics, and lightsail technology as well as for on-chip quantum photonic components and super-resolution imaging.

Mark Brongersma

Stanford University, USA

Flat Optics for Dynamic Wavefront Manipulation

Mark Brongersma is the Stephen Harris Professor in the Departments of Materials Science and Applied Physics at Stanford University. He leads a research team of ten students and five postdocs. Their research is directed towards the development and physical analysis of new materials and structures that find use in nanoscale electronic and photonic devices. He is on the list of Global Highly Cited Researchers (Clarivate Analytics). He received a National Science Foundation Career Award, the Walter J. Gores Award for Excellence in Teaching, the International Raymond and Beverly Sackler Prize in the Physical Sciences (Physics) for his work on plasmonics, and is a Fellow of the OSA, the SPIE, and the APS. Dr. Brongersma received his PhD from the FOM Institute AMOLF in Amsterdam, The Netherlands, in 1998. From 1998-2001 he was a postdoctoral research fellow at the California Institute of Technology.

Flat Optics for Dynamic Wavefront Manipulation
In this presentation, I will highlight our recent efforts to realize electrically-tunable metasurfaces employing nanomechanics, microfluidics, phase change materials, and atomically-thin semiconductors. Such elements are capable of dynamic wavefront manipulation for optical beam steering and holography. I will also discuss how the nanostructured, planar optical elements can be fabricated by scalable fabrication technologies, opening the door to a wide range of commercial applications.

Demetrios Christodoulides

University of Southern California, USA

Optical thermodynamics of highly multimode nonlinear photonic systems

Demetrios Christodoulides is an Endowed Chair Professor in the Department of Electrical and Computer Engineering at the University of Southern California. He received his Ph.D. from Johns Hopkins University in 1986. After earning his doctorate degree, he joined Bellcore as a postdoctoral research fellow, and was a faculty member in the Department of Electrical Engineering at Lehigh University from 1988 to 2002. Between 2002 and 2022 he was a Pegasus Professor and the Cobb Family Endowed Chair at CREOL–The College of Optics and Photonics at the University of Central Florida. Christodoulides' contributions have been in the general field of optics and photonics. Among them is the first prediction of discrete self-trapped states in optical lattices, Bragg solitons in nonlinear gratings, vector solitons, and the development of the theory describing nonlinear optical interactions in soft matter and biological colloidal systems. His group proposed and demonstrated optical accelerating beams, which today find applications in microscopy and nonlinear optics. In the last ten years or so, his work has focused on the ramifications and applications of some special symmetries in optics, such as those of parity-time symmetry and supersymmetry. Most recently he has been exploring new theoretical avenues in describing the complex dynamics of highly multimode nonlinear photonic systems by means of optical thermodynamics. He has served as an associate editor for the IEEE Journal of Quantum Electronics and JOSA B. He is a Fellow of APS and Optica. He is the recipient of the Optica's 2011 R.W. Wood Prize and 2018 Max Born Award, and of the 2023 Arthur L. Schawlow Prize in Laser Science of APS.

Optical thermodynamics of highly multimode nonlinear photonic systems
In this talk, a thermodynamic theory capable of describing complex, highly multimoded, nonlinear optical systems is presented. It is shown that the mode occupancies in such nonlinear multimode arrangements follow a universal behavior that always tends to maximize the system's entropy at steady-state. This thermodynamic response takes place irrespective of the type of nonlinearities involved and can be utilized to either heat or cool an optical multimode system. Aspects associated with adiabatic compressions and expansions will be discussed along with the possibility for all-optical Carnot cycles.

Javier García de Abajo

ICFO-Institut de Ciencies Fotoniques, Spain

Quantum optical phenomena in two-dimensional materials

Javier García de Abajo received his PhD from the University of the Basque Country in 1993 and then visited Berkeley National Lab for three years. He was a Research Professor at the Spanish CSIC and in 2013 moved to ICFO-Institut de Ciencies Fotoniques (Barcelona) as an ICREA Research Professor and Group Leader. He is Fellow of both the American Physical Society and the Optical Society of America, and he has co-authored 300+ articles on different aspects of nanophotonics, atomic physics, surface science, and electron microscope spectroscopies. See http://www.nanophotonics.es for more details.

Quantum optical phenomena in two-dimensional materials
We discuss new approaches to the synthesis, design, and exploitation of two-dimensional materials for nanophotonics, including plasmonics in ultrathin crystalline metals, a disruptive class of quantum-phase materials, recent advances in the solution to the problem of coupling between free-space light and ultraconfined optical excitations, and the application of these developments to the study of ultrafast nonlinear phenomena and quantum optics at the atomic scale.

Wolfgang Fritzsche

Leibniz Institute for Photonic Technology, Germany

Bioanalytics using plasmonic nanostructures

Wolfgang Fritzsche is heading the Nanobiophotonics Department at the Leibniz Institute for Photonic Technology (IPHT) in Jena, Germany. His scientific interest is in localized surface plasmon resonance, focused on novel effects in the interaction of molecular components with plasmonic nanostructures, with a special emphasis on biosensing. Here, multiplexed assays based on imaging spectrometry readout are targeted, in order to allow for the paralleled monitoring of molecular binding reactions for potential bioanalytical applications.

Bioanalytics using plasmonic nanostructures
The effect of localized surface plasmon resonance (LSPR) on chemically synthesized gold nanoparticles is utilized to setup a biosensing platform with the potential for sensitive and specific detection of biomolecules of interest such as biomarkers. This principle is demonstrated both on a single particle level for DNA detection, then extended also to proteins, and to arrays of particles. In order to readout the arrays, imaging spectrometer were developed.

Sven Höfling

University of Würzburg, Germany

Semiconductor quantum dot based quantum technologies

Sven Höfling received his Ph.D. degree from Würzburg University. He was with the Fraunhofer Institute of Applied Solid-State Physics, Freiburg, Germany from 2001 to 2002 working on blue and white light emitting diodes. From 2006 to 2013, he was head of the Optoelectronic Materials and Devices Group at Technische Physik, Würzburg University. Sven Höfling was a full professor at the University of St Andrews, Scotland from 2013 to 2021. In 2015 he rejoint the University of Würzburg, Germany as a professor of physics and as the Head of the Chair of Applied Physics and the Gottfried-Landwehr-Laboratory for Nanotechnologies. He is running a 550 sqm clean room with a full chain of semiconductor growth, processing and characterization tools. Dr. Höfling is a member of German Physical Society (DPG), a Senior member of IEEE and SPIE, and a fellow of the Institute of Physics (IOP) and Optica.

Semiconductor quantum dot based quantum technologies
We will summarize recent progress made within our group on self-assembled quantum dot device,development for quantum repeater and quantum computer applications. A particular emphasis will be on,semiconductor quantum dots embedded in circular Bragg grating cavities. For scalability, spatially deterministic, placement of quantum dots in bullseye cavities is pursued and tuning by electric and strain fields are,implemented. To apply electric fields, a new device design for electrically contactable circular Bragg grating,cavities in labyrinth geometry is employed.

Jiří Homola

Institute of Photonics and Electronics of the Czech Academy of Sciences, Czech Republic

Plasmonic biosensors for biomedical applications

Jiří Homola is Deputy Director and the Head of Optical Biosensors research group at the Institute of Photonics and Electronics of the Czech Academy of Sciences. He received his PhD (1993) from the Czech Academy of Sciences. From 1993 to 1997 he worked at the Institute of Photonics and Electronics, Prague as a Research Scientist. From 1997 to 2002 he was with the Department of Electrical Engineering, University of Washington, Seattle (USA), since 2001 as a Research Associate Professor. From 2003, he has been with the Institute of Photonics and Electronics in Prague and has been responsible for the optical biosensors research program. In 2009, he received his DSc. degree in technical sciences from the Czech Academy of Sciences and in 2014 he became Professor of physics at Charles University in Prague. From 2009 to 2019, he was Affiliate Professor at the University of Washington, Seattle. He has received the Roche Diagnostics Prize for Sensor Technology, Award for Outstanding Research of the Ministry of Education of the Czech Republic, among other awards. He has been elected Fellow of the Learned Society of the Czech Republic and Fellow of the International Society for Optical Engineering (SPIE). He serves as associate editor of Biosensors and Bioelectronics (Elsevier).

Plasmonic biosensors for biomedical applications
Optical biosensors hold potential for applications in numerous important areas. Herein, we discuss the main challenges in developing plasmonic biosensors for applications in biomedicine and present selected advances in biosensor research that aim to address these challenges. We cover advances in plasmonic nanostructures, sensor instrumentation, transport of target molecules in microfluidic systems, functional coatings, and detection assays. We also highlight applications of plasmonic biosensors related to the investigation of biomolecular interactions related to Alzheimer's disease and diagnosis of Myelodysplastic syndromes.

Mercedeh Khajavikhan

University of Southern California, USA

Micro- and Nano-lasers: From One to Many, Unleashing Endless Possibilities

Mercedeh Khajavikhan is a Professor of Electrical and Computer Engineering at the University of Southern California. She has also a joint appointment at the Department of Physics & Astronomy at USC. She received her Ph.D. in Electrical Engineering from the University of Minnesota in 2009. Subsequently, she joined the University of California in San Diego as a postdoctoral researcher, where she worked on the design and development of nanolasers, plasmonic devices, and silicon photonics components. Prior to joining USC, she was a faculty at the College of Optics and Photonics (CREOL) at the University of Central Florida (UCF), working primarily on unraveling novel phenomena in active photonic platforms. She is the recipient of the NSF Early CAREER Award in 2015, the ONR Young Investigator Award in 2016, the DARPA Young Faculty Award in 2018, the University of Central Florida Reach for the Stars Award in 2017, UCF Luminary Award in 2018, and DARPA Director's Fellowship in 2020. She is a fellow of Optica (formerly known as Optical Society of America OSA).

Micro- and Nano-lasers: From One to Many, Unleashing Endless Possibilities

Micro- and nano-lasers form a crucial category of optical components with significant scientific and technological implications. In this presentation, I will discuss the utilization of non-Hermiticity, supersymmetry, and topology principles to design arrays of these devices, resulting in intriguing and unexpected lasing phenomena. By considering the interaction between cavity modes, array geometry, and both short- and long-range coupling among the array elements, we can achieve novel laser phase locking regimes, high radiance emission, rapid beam steering, photonic spin machines, and unidirectional lasing.

Tobias J. Kippenberg

EPFL, Switzerland

Ultra low loss nonlinear integrated photonic circuits: from soliton microcombs, traveling wave parametric amplifiers, chip based Erbium amplifiers to cryogenic quantum interconnects

Tobias J. Kippenberg is Full Professor in the Institute of Physics and Electrical Engineering at EPFL in Switzerland since 2013 and joined EPFL in 2008 as Tenure Track Assistant Professor. Prior to EPFL, he was Independent Max Planck Junior Research group leader at the Max Planck Institute of Quantum Optics in Garching, Germany. While at the MPQ he demonstrated radiation pressure cooling of optical micro-resonators, and developed techniques with which mechanical oscillators can be cooled, measured and manipulated in the quantum regime that are now part of the research field of Cavity Quantum Optomechanics. Moreover, his group discovered the generation of optical frequency combs using high Q micro-resonators, a principle known now as micro-combs or Kerr combs. For his early contributions in these two research fields, he has been recipient of the EFTF Award for Young Scientists (2011), The Helmholtz Prize in Metrology (2009), the EPS Fresnel Prize (2009), ICO Award (2014), Swiss Latsis Prize (2015), as well as the Wilhelmy Klung Research Prize in Physics (2015), the 2018 ZEISS Research Award and 2020 OSA R. Wood Award. Moreover, he is 1st prize recipient of the "8th European Union Contest for Young Scientists" in 1996 and is listed in the Highly Cited Researchers List of 1% most cited Physicists in 2014-2019. He is founder of the startup LIGENTEC SA, an integrated photonics foundry.

Ultra low loss nonlinear integrated photonic circuits: from soliton microcombs, traveling wave parametric amplifiers, chip based Erbium amplifiers to cryogenic quantum interconnects
Recent advances in attaining ultra low loss highly confining silicon nitride waveguides with loss in the dB-meter range, and their heterogeneous integration with MEMS and Lithium Niobate have opened up novel applications that exhibit both low cost, and scalable manufacturing but also performance that is on par or exceeding that of legacy optical systems. I will describe a range of novel advances, including photonic integrated circuit based frequency agile lasers, wave amplifiers, as well as soliton frequency combs.

Naoto Nagaosa

RIKEN Center for Emergent Matter Science (CEMS), Japan

Chirality and nonreciprocal responses in quantum materials

Naoto Nagaosa was born in Hyogo Prefecture in 1958, and graduated from Department of Applied physics, The University of Tokyo in 1980. From 1983 to 1986, he was a research associate in Institute for Solid State Physics, Univ. Tokyo, and received a D.Sci from Univ. Tokyo in 1986. From 1988 to 1990, he worked as a visiting scientist at Department of Physics, Massachusetts Institute of Technology, before joining the Department of Applied Physics in Univ. Tokyo, where he is now a professor. From 2013 he has joint appointment with the Deputy Director of the RIKEN Center for Emergent Matter Science (CEMS). He is now serving as Senior Advisory Group (SAG) Scientist of APCTP, and also the chairman of c5 commission (Low Temperature Physics) of IUPAP. His research field is theoretical condensed-matter physics, especially involving the strong electron correlation, optical responses of solids, topological aspects of condensed matter, and superconductivity. For his accomplishments, he has received the Yukawa Prize, Japan IBM Prize, Nissan Science Prize, Nishina Memorial Prize, Fujihara Prize, Purple Ribbon, Benjamin Lee Professorship, and is now a Foreign member of National Academy of Science.

Chirality and nonreciprocal responses in quantum materials
We study the chiral dynamics and consequent nonreciprocal responses in quantum materials, where the most fundamental principles in physics manifest themselves, i.e., the symmetries especially the time-reversal and spatial inversion, dissipation, quantum-classical crossover/transition, quantal Berry phase and topology, and many-body correlation effects. They include (1) magnetochiral anisotropy of semiconductors, Weyl semimetals, and superconductors, and (2) the photovoltaic effect, e.g., the shift currents under photo-excitations.

Dragomir Neshev

Australian National University, Australia

Dielectric metasurfaces with fast and ultra-fast tunability

Dragomir Neshev is the Director of the Australian Research Council Centre of Excellence for Transformative Meta-Optical Systems (TMOS) and a Professor in Physics at the Australian National University (ANU). He received a PhD degree from Sofia University, Bulgaria in 1999. Since then, he has worked in the field of optics at several research centres around the world and joined ANU in 2002. He is the recipient of several awards and honours, including a Highly Cited Researcher (Web of Science, 2022 and 2021), a Queen Elizabeth II Fellowship (ARC, 2010), and a Marie-Curie Individual Fellowship (European Commission, 2001). His activities span over several branches of optics, including periodic photonic structures, singular optics, plasmonics, and optical metasurfaces.

Dielectric metasurfaces with fast and ultra-fast tunability
This talk will overview the recent advances and challenges in tunable metasurfaces. I will discuss metasurface tunability through several mechanisms, including electrical and all-optical drives. Such drives allow for fast and ultrafast responses with high modulation strength. We demonstrate how all-optical control can lead to and high ultrafast transmission modulation of 80%. The presented developments hold promise for real-world applications of active meta-optics.

Sir John Pendry

Imperial College London, UK

Extreme time modulation of material properties and Hawking radiation

John Pendry is a condensed matter theorist working at Imperial College London. His early work addressed electronic and structural properties of surfaces developing the theory of low energy diffraction, EXAFS, and of electronic surface states later moving on to studies of transport in disordered systems. In the mid 1990's he turned his attention to metamaterials and proposed several structures which radically influenced the development of the field leading to the experimental discovery of negative refraction by the Smith group and later, also in collaboration with David Smith, the design of a cloak of invisibility. His investigation of negative refraction led to the discovery that it is theoretically possible to design a lens whose resolution is limited only by the perfection of manufacture, not by the well known Abbé law which limits resolution to the order of the wavelength. The technique of transformation optics which he pioneered has led to many applications in the field of plasmonics, particularly building on the perfect lens concept and showing how to concentrate light into sub nanoscale volumes. His most recent work moves the study of metamaterials on to structures that vary in time as well as in space, invoking quantum aspects of metamaterials.

Extreme time modulation of material properties and Hawking radiation
Experiments demonstrating extremely rapid modulation of the permittivity have been performed by exploitingthe enhanced non-linear effects possible in the presence of plasmonic resonances. These experiments measure anextreme rise time by exploiting the analogy between Young's slits which produce diffraction in momentum space,and closely spaced time windows which produce diffraction in frequency space.

Luca Razzari

Centre Energie, Matériaux et Télécommunications (INRS-EMT), Canada

Structured surfaces for enhanced radiation-matter interaction and nonlinear optics

Luca Razzari is a Full Professor at Institut National de la Recherche Scientifique – Centre Energie, Matériaux et Télécommunications (INRS-EMT) in Montreal, Canada, since 2020. He received his Laurea (2001) and PhD (2004) degrees from the University of Pavia, Italy. He completed part of his PhD research at Institut d'Optique in Orsay, France (2004). He then had three postdoctoral experiences: from 2005 to 2006, he worked at the Institute for Complex Systems (CNR-ISC) in Rome, Italy. From 2006 to 2010, he made his first move to Canada as a Marie Curie Fellow at INRS-EMT. From 2010 to 2012, he was with the Italian Institute of Technology (IIT) in Genoa, Italy. In November 2012, he finally joined the INRS-EMT as a junior faculty member. Dr. Razzari's research interests include nanoscale light-matter interactions, metasurfaces, nonlinear optics, as well as terahertz science and technology. He has been recently elected a Fellow of Optica (2023).

Structured surfaces for enhanced radiation-matter interaction and nonlinear optics
In this talk, I will review our main results regarding the exploitation of nanoresonators and,metasurfaces for: (i) enhanced terahertz spectroscopy of low-dimensional materials; (ii) nanoscale phonon strong coupling; and (iii) nonlinear wavelength conversion.

Mikael Rechtsman

Pennsylvania State University, USA

Quantized Fractional Thouless Pumping of Solitons

Mikael Rechtsman is an Associate Professor of Physics at the Pennsylvania State University in the US. His research group studies different aspects of nonlinear optics and photonics, with a focus on topological structures and devices. He is the recipient of the Packard and Sloan Fellowships, the Office of Naval Research Young Investigator Award, and the ICO prize of the International Commission of Optics.

Quantized Fractional Thouless Pumping of Solitons
I will present my group's recent work on the fractional pumping of solitons in photonic Thouless pumps. Specifically, I will show that the displacement (in unit cells) of solitons in Thouless pumps is strictly quantized to the Chern number of the band from which the soliton bifurcates in the low power regime, whereas in the intermediate power regime, nonlinear bifurcations lead to fractional quantization of soliton motion. This fractional quantization can be predicted from multi-band Wannier functions.

Moti Segev

Technion, Israel

Photonic Time-Crystals

Moti Segev is the Robert J. Shillman Distinguished Professor of Physics and Electrical Engineering, at the Technion, Israel. His interests are mainly in photonics, solitons, lasers, and quantum optics. He won numerous international awards, among them the 2007 Quantum Electronics Prize of the EPS, the 2009 Max Born Award of the OSA, and the 2014 Arthur Schawlow Prize of the APS. In 2011, he was elected to the Israel Academy of Sciences, in 2015 to the National Academy of Science of the USA. In 2014 he won the Israel Prize (highest honor in Israel). Above all his achievements, Moti takes pride in the success of his graduate students and postdocs, among them are currently 23 professors in the USA, Germany, Taiwan, Croatia, Italy, India, China and Israel, and many holding senior R&D positions in the industry.

Photonic Time-Crystals
Time-Crystals (PTCs) are materials in which the refractive index varies periodically and abruptly in,time. They conserve momentum but not energy, and display momentum bands separated by gaps. The,fundamentals of PTCs will be presented, with an emphasis on light-matter interactions ranging from light,emission by atoms and free electrons to superluminal k-gap solitons and recent experiments.

Vladimir M. Shalaev

Purdue University, USA

Near-Zero-Index Materials for Nonlinear Optics and Beyond

Vladimir M. Shalaev, Scientific Director for Nanophotonics at Birck Nanotechnology Center and Distinguished Professor of Electrical and Computer Engineering at Purdue University, specializes in nanophotonics, plasmonics, and optical metamaterials. Vladimir M. Shalaev has received several awards for his research in the field of nanophotonics and metamaterials, including the Max Born Award of the Optical Society of America for his pioneering contributions to the field of optical metamaterials, the Willis E. Lamb Award for Laser Science and Quantum Optics, IEEE Photonics Society William Streifer Scientific Achievement Award, Rolf Landauer medal of the ETOPIM (Electrical, Transport and Optical Properties of Inhomogeneous Media) International Association, the UNESCO Medal for the development of nanosciences and nanotechnologies, OSA and SPIE Goodman Book Writing Award. He is a Fellow of the IEEE, APS, SPIE, MRS and OSA. Prof. Shalaev has authored three books, thirty invited book chapters and over 500 research publications.

Near-Zero-Index Materials for Nonlinear Optics and Beyond
We discuss Near-Zero-Index (NZI) materials based on transparent conducting oxides (TCOs) that open new avenues in nonlinear optics including exotic time-varying media phenomena, such as negative refraction, time refraction/reflection, and photonic time crystals.

Kerry Vahala

California Institute of Technology, USA

High-Q photonics

Kerry Vahala is Professor of Applied Physics at Caltech and holds the Jenkins Chair in Information Science and Technology. His research on chip-based high-Q optical resonators and related low-power nonlinear optical devices has advanced miniature frequency and time systems, microwave sources, parametric oscillators, astrocombs and gyroscopes. Vahala also made early contributions to the subject of cavity optomechanics and demonstrations of chip-based devices to cavity QED phenomena. A member of the National Academy of Engineering and Fellow of the IEEE and Optica, he received the IEEE Sarnoff Medal for research on quantum-well laser dynamics, the Alexander von Humboldt award and MPQ Distinguished Scholar Award for work on ultra-high-Q optical microcavities, a NASA achievement award for application of microcombs to exoplanet detection, and the Optica Forman Team Engineering Excellence Award for a 2-photon optical clock. Vahala is the Executive Officer of the Department of Applied Physics and Materials Science at Caltech.

High-Q photonics

After a brief overview of their history, I will review recent applications. These include Sagnac gyroscopes, microwave signal sources, clocks, and high-coherent sources. The current and possible future limits of microresonator performance, and untapped application areas, will also be discussed.

Xiangrong Wang

The Hong Kong University of Science and Technology, Hong Kong

Recent progress in magnetic skyrmion physics

Xiangrong Wang is a full professor in the physics department of The Hong Kong University of Science and Technology (HKUST). He obtained his PhD in 1990 from University of Rochester and joined the Physics Department of HKUST in 1992. Professor Wang is a condensed matter theorist and is interested in revealing the physics principles behind the novel physics phenomena. Currently, he is working on the interplay of charges, spins, and phonons in nano-systems and devices. His current research focus on topological states of matter, magnetization dynamics, and spin/charge transport. The research topics include skyrmion physics, magnonics, magnetic domain wall motion, spin current generation and detection, and magneto-effects.

Recent progress in magnetic skyrmion physics

In this talk, I will discuss several progresses made in our group about fundamental properties of skyrmions in chiral magnetic films. These include 1) skyrmion sizes in isolated, in crystal, or in stripy forms, 2) skyrmion nucleation, formation, and potential barrier energies, 3) the roles of magnetic field in skyrmion crystal formation, 4) the stability and existing conditions of composite skyrmions such as target skyrmions and skyrmion bags/cluster, 5) topological equivalence of stripy phases and skyrmion crystals.

Martin Wegener

KIT, Germany

Roton-like dispersion relations in metamaterials

Martin Wegener is Professor at the Institute of Applied Physics at KIT and one of the Directors of the Institute of Nanotechnology at KIT. He is also spokesperson of the Excellence Cluster "3D Matter Made to Order". He initiated (2006) and co-founded (2007) the company Nanoscribe GmbH. His current research interests are in 3D additive manufacturing driven towards the nanometer scale and applications thereof, for example in 3D metamaterials.

Roton-like dispersion relations in metamaterials
We review our work on mimicking the dispersion relation of rotons in liquid helium in different systems (acoustic, elastic, and electromagnetic waves) and using three different strategies (nonlocal metamaterials, chiral metamaterials, and monomode metamaterials).

Gary Wiederrecht

Argonne National Laboratory, USA

Ultrafast Optical Studies of Hybrid Nanomaterials of Interest for Optoelectronic and Energy Conversion Applications

Gary Wiederrecht is currently the Deputy Division Director and Senior Scientist in the Nanoscience & Technology (NST) Division at Argonne National Laboratory. He received a B.S. degree in chemistry from UC Berkeley in 1987 and a Ph.D. in physical chemistry from MIT in 1992. He moved to Argonne National Laboratory as a postdoctoral fellow in 1992, working with Michael Wasielewski on molecular photonics, and became a scientific staff member in 1995. His research interests center on the photochemistry and photophysics of hybrid nanostructures, photochemical energy conversion, quantum science, biomimetic materials, and the ultrafast optical responses of nanoparticles and nanoparticle assemblies. He is also working to develop novel approaches to time-resolved optical microscopy and imaging applications. He has received an R&D100 award, the DOE Young Scientist Award, the Presidential Early Career Award for Scientists and Engineers (PECASE), and the Argonne National Laboratory Distinguished Service Award. He has authored or co-authored approximately 165 peer-reviewed research articles and has several patents. He is a Fellow of the American Physical Society.

Ultrafast Optical Studies of Hybrid Nanomaterials of Interest for Optoelectronic and Energy Conversion Applications
Ultrafast optical spectroscopy is used to monitor energy flow in nanostructures of interest for optoelectronic and energy conversion applications. The impact of hybrid nanostructures on aiding in the efficiency of desired energy flow outcomes following the absorption of photons is further described. Using ultrafast spectroscopy to probe hybrid structures designed to increase light-matter interactions, such as through optical cavities, is also discussed.

Eli Yablonovitch

UC Berkeley, USA

The Challenge of Photonic Crystals (and Meta-Materials) is Inverse Electromagnetic Design (Aperiodic)

Eli Yablonovitch is a Professor of Electrical Engineering and Computer Sciences at UC Berkeley, where he holds the James & Katherine Lau Chair in Engineering. He is the Director of the NSF Center for Energy Efficient Electronics Science (E3S), a multi-University Center headquartered at Berkeley.

Prof. Yablonovitch introduced the idea that strained semiconductor lasers could have superior performance due to reduced valence band (hole) effective mass. With almost every human interaction with the internet, optical telecommunication occurs by strained semiconductor lasers. He is regarded as a Father of the Photonic BandGap concept, and he coined the term "Photonic Crystal". The geometrical structure of the first experimentally realized Photonic bandgap, is sometimes called “Yablonovite”. In his photovoltaic research, Yablonovitch introduced the 4(n squared) (“Yablonovitch Limit”) light-trapping factor that is in worldwide use, for almost all commercial solar panels. His mantra that "a great solar cell also needs to be a great LED”, is the basis of the world record solar cells: single-junction 28.8% efficiency; dual-junction 31.5%; quadruple-junction 38.8% efficiency; all at 1 sun. His startup company Ethertronics Inc., has shipped over one billion cellphone antennas.

Prof. Yablonovitch is elected as a Member of the National Academy of Engineering, the National Academy of Sciences, the American Academy of Arts & Sciences, and is a Foreign Member of the Royal Society of London. He has been awarded the Buckley Prize of the American Physical Society, the Isaac Newton Medal of the UK Institute of Physics, the Rank Prize (UK), the Harvey Prize (Israel), the IEEE Photonics Award, the IET Mountbatten Medal (UK), the Julius Springer Prize (Germany), the R.W. Wood Prize, the W. Streifer Scientific Achievement Award, and the Adolf Lomb Medal. He also has an honorary Ph.D. from the Royal Institute of Technology, Stockholm, & the Hong Kong Univ. of Science & Technology, and is honorary Professor at Nanjing University.

The Challenge of Photonic Crystals (and Meta-Materials) is Inverse Electromagnetic Design (Aperiodic)
Inevitably, in electromagnetics, there is a goal, and it may be that the goal is best achieved by an,aperiodic rather than a periodic design. Then there is a universal question: What is the best design to achieve,a specific goal?

Nikolay Zheludev

University of Southampton, UK and NTU, Singapore

Continuous Time Crystals on Opto-Mechanical Platform

Nikolay Zheludev’s research interest are in nanophotonics and metamaterials. He is the Deputy Director of the Optoelectronics Research Centre in Southampton University, UK and co-Director of The Photonics Institute at Nanyang Technological University, Singapore.

Prof. Zheludev is elected as a Fellow of the Royal Society (UK) and Member of the USA National Academy of Engineering. He is a Fellow of the European Physical Society (EPS), the Optical Society (OSA) and the Institute of Physics (London). He has been awarded the Michael Faraday Gold Medal, Thomas Young Medal and President of Singapore Science and Technology Award.

Continuous Time Crystals on Opto-Mechanical Platform
We overview recent developments in the field of photonic time crystals, a state of matter with broken time-translation symmetry.

TUTORIALS

Prof. Philippe Lalanne

Institut d'Optique d'Aquitaine - CNRS, France

Wednesday 19st July
14:00 - 15:00 — Amphi Fournel

Disordered optical metasurfaces

Philippe Lalanne is a CNRS Research scientist. Optician by adoption, he is an expert in nanoscale electrodynamics. His first works with Pierre Chavel at Orsay focused on optoelectronic machines for implementing neural networks operating by simulated annealing at video rate. After a sabbatical year at the Institute of Optics (Rochester), he undertook work in the field of diffractive optics. At the Laboratoire Charles Fabry in Palaiseau, he then designed the first high-efficiency metasurfaces, gave general rules for designing microcavities with high quality factor and explained the role of plasmons in the extraordinary optical transmissions. At the Laboratoire Photonique, Numérique et Nanosciences in Bordeaux, he is currently studying the non-Hermitian dissipative coupling of light with nanoresonators and the properties of disordered optical metasurfaces. From 2018 to 2022, he was director of the GDR Ondes. He received several distinctions, including a 2022 ERC Advanced grant. He is associate editor of the journal Optica and is a fellow of IOP, SPIE and OPTICA.

Disordered optical metasurfaces
Shaping the far-field radiation diagrams of surfaces engraved with high-index subwavelength structures belongs to a longstanding and fundamental ambition of wave science. The problem comes in different forms, but generally consists of angularly and spectrally controlling polychromatic light scattering with nanostructures smartly arrayed on a surface. We discuss important challenges in the emerging field of disordered metasurfaces to address applications such as light focusing, light extraction and detection, color and appearance creation.

Dr. Anja Wecker

Editor in Chief of Advanced Optical Materials (WILEY), Germany

Thursday 20th July
14:00 - 15:00 — Amphi Bezier

Publishing Research with Impact in the Optics and Photonics Field

Anja Wecker studied chemistry at Saarland University in Saarbrücken where she completed her diploma as well as well as her PhD thesis in the field of physical chemistry. She joined Wiley in 2012.

Publishing Research with Impact in the Optics and Photonics Field
For researchers, it's a long road from the idea to the published article. Producing great research results does not necessarily mean they will automatically be appreciated by the community. Choosing the right journal, convincing editors and reviewers, and making work visible to others are essential steps on the way to success. In this tutorial talk, I will give an insight into publishing opportunities in relevant journals and the related peer review process. From an editorial perspective, I will provide some guidance on how to best pass peer review and maximize success in scientific publishing.

INDUSTRIAL WORKSHOPS

SYNOPSYS®

18th & 19th July, 16:40 - 17:40 — Salle des Conseils

Automated Inverse Design Solution for Metalenses

Chenglin Xu, Maryvonne Chalony, Yijun Ding

To help researchers design metalenses easily and quickly, Synopsys has developed MetaOptic Designer, a fully automated design tool for metalenses. Based on a few inputs from designers, such as a pre-built metaatom library and basic lens configuration, MetaOptic Designer generates an optimized design to meet all design targets. Synopsys will introduce and demonstrate MetaOptic Designer in two workshop sessions at META 2023.

On July 18, we will provide a general overview of the MetaOptic Designer optimization algorithm, followed by quick demonstrations of the tool's capability.

On July 19, we will demonstrate advanced metalens applications with tips and tricks; applications will include:

- Achromatic metalens
- Wide-angle metalens
- Chiral hologram
- Reflective metalens
- Hybrid optical system with both metasurfaces and traditional refractive lenses

The workshop is free and open to all META conference attendees.

GUIDELINES FOR PRESENTERS I **IN-PERSON**

In-person Oral Presentations

Each session room is equipped with a stationary computer connected to a LCD projector. Presenters must load their presentation files in advance onto the session computer. Technician personnel will be available to assist you.

Scheduled time slots for oral presentations are 15 mn for regular, 20 mn for invited presentations, 30 mn for keynote talks and 35 mn for plenary talks, including questions and discussions. Presenters are required to report to their session room and to their session Chair at least 15 minutes prior to the start of their session.

The session chair must be present in the session room at least 15 minutes before the start of the session and must strictly observe the starting time and time limit of each paper.

In-person Poster Presentations

Presenters are requested to stand by their posters during their session. One poster board, A0 size (118.9 x 84.1 cm), in portrait orientation, will be available for each poster. Pins or thumbtacks are provided to mount your posters on the board. All presenters are required to mount their papers 30mn before the session and remove them at the end of their sessions. Posters must prepared using the standard AES poster template (available on the conference website).

GUIDELINES FOR PRESENTERS I **ONLINE**

All Oral presentations will be in person with option for remote viewing via Zoom.

Poster sessions will be hybrid, consisting of both in person and virtual presentations. Instructions for **virtual poster presenters** can be found here: guidelines).

Nanophotonics for tailoring radiation from fast electrons

Marin Soljačić

Physics Department, Massachusetts Institute of Technology, Cambridge, MA, USA
soljacic@mit.edu

Abstract: Nanophotonic methods provide intriguing options for manipulating scintillation phenomena. We will outline recent developments in this domain, along with our theoretical framework for modeling these occurrences, supported by our experimental findings. Additionally, Smith-Purcell radiation, characterized by fast electrons interacting with nano-structured materials to produce light, offers a broad spectrum of possibilities for creation of novel light sources. We will discuss our new theoretical framework designed to comprehend and tailor such phenomena, as well as our techniques for boosting Smith-Purcell radiation.

Structuring light with media with higher dimensions: space, time, and more

Nader Engheta[1]

[1]Department of Electrical and Systems Engineering, University of Pennsylvania, Philadelphia, PA 19104, USA
*corresponding author, E-mail: engheta@seas.upenn.edu

Abstract

In this talk, I will present some of our most recent results on exploring light-matter interaction in material media with high degrees of freedom and dimensions including spatial and/or temporal inhomogeneities, and other degrees of freedom such as anisotropy, ellipticity, and hyperbolicity. We show how light manipulation with such metastructures with high degrees of freedom can lead to exciting novel wave phenomena with potential applications in wave-based reconfigurable analog computing, 4D optics, and other optical devices and components.

Scalable classical and quantum photonics

Jelena Vuckovic

Stanford University, CA, USA
*corresponding author: jela@stanford.edu

Abstract: Novel computational techniques such as photonics inverse design, along with new nanofabrication approaches, play a crucial role in building scalable integrated classical and quantum photonics. Inverse design, a departure from the traditional photonics design approach, can lead to photonics much better than state of the art in many metrics (smaller, more efficient, more robust, a much higher density of integration). This is enabled by development of a computer software which efficiently searches through the space of all possible and fabricable photonic geometries, in any material of interest. On the other hand, future photonic systems also require integration and fabrication of traditional and non-traditional photonic materials, including silicon, silicon-carbide, diamond, sapphire, and strong electro-optic materials such as lithium niobate, strontium and barium titanate.

Active photonic metasurfaces empowered by 2D semiconductors

Isabelle Staude

Friedrich Schiller University Jena, Institute of Solid State Physics, Max-Wien-Platz 1, 07743 Jena, Germany
*corresponding author: Isabelle.staude@uni-jena.de

Abstract: Optical metasurfaces, namely two-dimensional arrangements of designed nanoresonators, have been in the limelight of nanophotonics research during the last decade. Such metasurfaces can impose a spatially variant phase shift onto an incident light field, thereby providing control over its wave front. As such, metasurfaces have been suggested for numerous wavefront-shaping applications, including lensing, beam shaping, and holographic imaging [1]. However, most metasurfaces realized so far were passive and linear, and their optical response was permanently encoded into the structure during fabrication. Recently, a growing amount of research is concentrating on the integration of active materials, in particular emitters, optical nonlinearities, and responsive materials into the metasurface architectures. The resulting active, i.e. light-emitting, nonlinear, and tunable, metasurface systems can provide many functionalities beyond pure wavefront shaping, and are of huge interest for a large range of potential applications.

While many different active materials have been explored in the context of creating active metasurfaces, the semiconducting representatives of the family of two-dimensional transition metal dichalcogenides (2D-TMDCs) stand out by their unique optoelectronic properties, including a strong direct bandgap photoluminescence in the monolayer phase, excitonic-dominated properties at room temperature, strong second-order nonlinear susceptibility, strong spin-valley coupling and associated chiral photoluminescence emission, as well as tunability of their optical response by electronic gating. Furthermore, due to their flat nature, their integration with likewise flat optical metasurfaces is particularly intuitive [2].

This talk reviews our recent and ongoing activities in hybridizing optical metasurfaces composed of resonant metallic or dielectric building blocks with 2D-TMDCs. We demonstrate that the ability of the nanoresonators to concentrate light into nanoscale volumes can be utilized to carefully control the properties, such as pattern and polarization, of light emitted by 2D-TMDCs via photoluminescence or nonlinear optical processes [3,4]. Furthermore, we investigate the ability of tailored nanostructures to interact selectively with exciton populations located at inequivalent conduction band minima at the corners of the 2D-TMDC's Brillouin zone. Finally, we suggest that resonant nanoantennas can be used to probe the nature of chiral emission from 2D-TMDCs. Altogether, our results contribute to a better fundamental understanding of coupling of photonic nanostructures to excitons in 2D-TMDCs and are an important step towards the realization of future miniaturized active metasurface and valleytronic devices.

Imaging and Computing with disorder

Sylvain Gigan
Laboratoire Kastler Brossel, Sorbonne Université, Ecole Normale Supérieure-Paris Sciences et Lettres (PSL) Research University, Centre Nationale de la Recherche Scientifique (CNRS) UMR 8552,Collège de France, 24 rue Lhomond, 75005 Paris, France
sylvain.gigan@lkb.ens.fr

Abstract: Light propagation in complex media, such as paint, clouds, or biological tissues, is a very challenging phenomenon, encompassing fundamental aspects in mesoscopic and statistical physics. It is also of utmost applied interest, in particular for imaging. Although this scattering process seems to mix and completely destroy all information, thus preventing imaging or communication, a different approach has emerged — exploiting this apparently detrimental effect to one's advantage by processing information carried by waves. I will discuss how this powerful concept has recently triggered a wealth of advances in imaging and computing.

META 2023, PARIS - FRANCE, JULY 18 – 21, 2023

Extreme Control of Light and Sound with Metamaterials

Andrea Alù
Photonics Initiative, Advanced Science Research Center, City University of New York
Physics Program, Graduate Center, City University of New York
Department of Electrical and Computer Engineering, City College of New York
85 St. Nicholas Terrace, New York, NY 10031, U.S.A.
aalu@gc.cuny.edu, http://alulab.org

Abstract: The field of metamaterials, artificial materials engineered at the nanoscale, has been rapidly evolving in the past two decades, demonstrating extreme optical and acoustic phenomena and unprecedented control over wave propagation. In this talk, I discuss recent developments in this field of research, with an emphasis on the role of symmetries in establishing emerging optical responses for metamaterials based on otherwise simple constituents. Geometrical rotations, suitably tailored perturbations, and broken time reversal symmetry can be carefully engaged to tailor waves in robust and efficient ways, control their propagation, break Lorentz reciprocity and enable topological order and phase transitions. In particular, the use of strongly coupled wave and matter interactions in polaritonic systems enables extreme responses at the nanoscale, well suited for classical-wave and quantum applications. In my talk, I will discuss the underlying physical principles that span over a wide range of frequencies, and their impact on practical technologies, from imaging, energy and sensing to computing and communications..

Ultra low loss nonlinear integrated photonic circuits: from soliton microcombs, traveling wave parametric amplifiers, chip based Erbium amplifiers to cryogenic quantum interconnects

Tobias Kippenberg

EPFL, Switzerland
*corresponding author: tobias.kippenberg@epfl.ch

Abstract: Recent advances in attaining ultra low loss highly confining silicon nitride waveguides with loss in the dB-meter range, and their heterogeneous integration with MEMS and Lithium Niobate have opened up novel applications that exhibit both low cost, and scalable manufacturing but also performance that is on par or exceeding that of legacy optical systems. I will describe a range of novel advances, including photonic integrated circuit based frequency agile lasers with fiber laser phase noise, parametric traveling wave amplifiers, Erbium amplifiers on chip, as well as soliton frequency combs.

Quantized Fractional Thouless Pumping of Solitons

Marius Juergensen[1], Sebabrata Mukherjee[1,2], Christina Joerg[1,3], and Mikael C. Rechtsman[1]

[1]The Pennsylvania State University, University Park, PA, USA 16802
[2]Indian Institute of Science, Bangalore, India
[3]Technical University of Kaiserslautern, German

[*]corresponding author: mcrworld@psu.edu

Abstract: I will present my group's recent work on the fractional pumping of solitons in photonic Thouless pumps. Specifically, I will show that the displacement (in unit cells) of solitons in Thouless pumps is strictly quantized to the Chern number of the band from which the soliton bifurcates in the low power regime; whereas in the intermediate power regime, nonlinear bifurcations lead to fractional quantization of soliton motion. This fractional quantization can be predicted from multi-band Wannier functions associated with the states of the pump.

META 2023, PARIS - FRANCE, JULY 18 – 21, 2023

Photonic Time-Crystals

Mordechai (Moti) Segev

Technion, Israel

Abstract: Time-Crystals (PTCs) are materials in which the refractive index varies periodically and abruptly in time. They conserve momentum but not energy, and display momentum bands separated by gaps. The fundamentals of PTCs will be presented, with an emphasis on light-matter interactions ranging from light emission by atoms and free electrons to superluminal k-gap solitons and recent experiments.

Optical thermodynamics of highly multimode nonlinear photonic systems

Demetrios Christodoulides

University of Southern California, USA
*corresponding author: demetri@usc.edu

Abstract: The past few years have witnessed a resurgence of interest in multimode structures, predominantly driven by the ever-increasing demand for higher information capacities. This renaissance, in turn, incited a flurry of activities in the general area of nonlinear multimode optics. The sheer complexity associated with the presence of hundreds or thousands of nonlinearly interacting modes that collectively act as a many-body system, has led to new opportunities in observing a multitude of novel optical effects that would have been otherwise impossible in single-mode settings. In this talk, a thermodynamic theory capable of describing complex, highly multimoded, nonlinear optical systems is presented. It is shown that the mode occupancies in such nonlinear multimode arrangements follow a universal behavior that always tends to maximize the system's entropy at steady-state. This thermodynamic response takes place irrespective of the type of nonlinearities involved and can be utilized to either heat or cool an optical multimode system. Aspects associated with adiabatic compressions and expansions will be discussed along with the possibility for all-optical Carnot cycles.

META 2023, PARIS - FRANCE, JULY 18 – 21, 2023

Dielectric metasurfaces with fast and ultra-fast tunability

Dragomir Neshev
ARC Centre of Excellence for Transformative Meta-Optical Systems (TMOS), Department of Electronic Material Engineering, Research School of Physics, Australian National University, Canberra, Australia
*corresponding author: Dragomir.Neshev@anu.edu.au

Abstract: This talk will overview the recent advances and challenges in tunable metasurfaces. I will discuss metasurface tunability through several mechanisms, including electrical and all-optical drive. Such drives allows for fast and ultrafast response with high modulation strength. We demonstrate the how all-optical control can lead to and high ultrafast transmission modulation of 80%. The presented developments hold promises for real-world applications of active meta-optics.

Optical metasurfaces are sub-wavelength patterned surfaces that interact strongly with light. The field has been driven by the key advantages of this technology, including the ultimate miniaturization of optical elements, empowering novel functionalities that process hidden modalities of light, and the opportunity to tune their properties on demand. Several exciting applications have been demonstrated over the past years, including high-efficiency metalenses and holograms. However, many exciting new applications require metasurfaces with dynamically reconfigurable and programable functionalities. Such applications include 3D imaging, holographic displays, and light detection and ranging (LIDAR). This talk will overview the recent advances and challenges in reconfiguring optical metasurfaces. I will discuss metasurface tunability by utilizing different control mechanisms to tune the properties of the constituent elements. In particular, I will present the development of optically and electrically driven metasurfaces to perform fast amplitude modulation. We demonstrate the highest ultrafast modulation of over 80% and multi-pixel operation with over 70% transmission modulation. The presented developments aim to advance the field of tunable optical metasurface for real-world applications of active meta-optics.

Semiconductor quantum dot based quantum technologies

Abstract: We will summarize recent progress made within our group on self-assembled quantum dot device development for quantum repeater and quantum computer applications. A particular emphasis will be on semiconductor quantum dots embedded in circular Bragg grating cavities. For scalability, spatially deterministic placement of quantum dots in bullseye cavities is pursued and tuning by electric and strain fields are implemented. To apply electric fields, a new device design for electrically contactable circular Bragg grating cavities in labyrinth geometry is employed.

In this presentation, we will summarize recent progress made within our group and plans on device development with self-assembled quantum dots intended for quantum repeater and quantum computer applications [1]. A particular emphasis will be on semiconductor quantum dots embedded in circular Bragg grating cavities [2,3]. For scalability, spatially deterministic placement of quantum dots in bullseye cavities is pursued and techniques for tuning by electric and strain fields are implemented. To apply electric fields, a new device design for electrically contactable circular Bragg grating cavities in labyrinth geometry is employed [4]. We report on the challenges experienced in obtaining high performance devices based on circular Bragg grating cavities and figures of merits achieved, outlining the prospects for these devices in quantum technology applications.

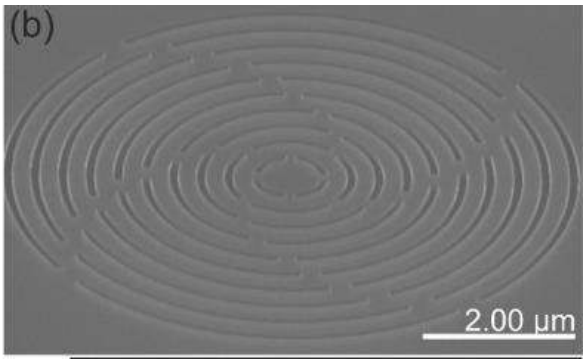

Figure 1 Circular Bragg grating cavity in labyrinth geometry for electrical contacting.

Recent progress in magnetic skyrmion physics

Xiangrong Wang[1,2 *]

[1]Physics Department, The Hong Kong University of Science and Technology, Clear Water Bay, Kowloon, Hong Kong

[2]HKUST Shenzhen Research Institute, Shenzhen 518057, China

[*]corresponding author: phxwan@ust.hk

Abstract: In this talk, I will discuss several progresses made in our group about fundamental properties of skyrmions in chiral magnetic films. These include 1) skyrmion sizes in isolated, in crystal, or in stripy forms; 2) skyrmion nucleation, formation, and potential barrier energies; 3) the roles of magnetic field in skyrmion crystal formation; 4) the stability and existing conditions of composite skyrmions such as target skyrmions and skyrmion bags/cluster; 5) topological equivalence of stripy phases and skyrmion crystals.

The summary Magnetic skyrmions have attracted much attention in recent years for their academic interest and potential applications in information technology [1]. They are two-dimensional magnetic solitons with localized topological spin textures which can move and be manipulated by external forces. Various aspects of magnetic skyrmions have been extensively and intensively studied, including characterizations, generations, control, etc. With all advances in skyrmion physics, many fundamental properties of skyrmions were not adequately known, such as the role of magnetic field in skyrmion crystal (SkX) formation, relationship between SkXs and stripy spin structures that often appear together with SkXs, parameter dependences of skyrmion size in isolated circular skyrmions, in SkXs, and in stripe skyrmions, skyrmion nucleation energy, skyrmion energy barrier and skyrmion energy. Other than different elementary skyrmions, many localized magnetic structures, topologically different from the elementary skyrmions and with arbitrary integer skyrmion numbers, were found in

the past eight years. The increasing number of newly discovered topologically non-trivial localized spin structures in chiral magnetic films reminisces the discovery of a huge number of elementary particles in the first half of last century that resulted in the quark model of elementary particles. It calls for a “quark model” to properly organize these newly discovered topological magnetic structures. This talk shall address above mentioned fundamental issues related to magnetic skyrmion physics.

We use a perpendicularly magnetized chiral magnetic film as a model to demonstrate these progresses. The films are characterised by a Dzyaloshinskii–Moriya interaction (DMI) and normal ferromagnetic exchange interaction characterized by parameter D and A, respectively, as well as magnetic anisotropy measured by K and magnetic field H.

We show that only skyrmions with positive formation energy are intrinsically circular [2-5]. Allowed spin structures are fully determined by parameters defined as $\kappa \equiv (\pi D)2/(16AK)$ and $\kappa' \equiv (\pi D)2/(16A\mu_0 M_s H)$. Critical κ and κ' separates isolated circular skyrmions from condensed stripe skyrmions [3]. The natural morphology of skyrmions of negative formation energy are stripes of well-defined width. Condensed stripy skyrmions, ranging from irregular maze to periodically arranged helical states, is the preferred thermodynamic equilibrium state [5] when skyrmion-skyrmion separation is much larger than the stripe width. It is generally believed that helical states and SkXs are topologically unconnected \cite{roadmap}, and transformations from stripy states to SkXs are phase transitions, even though stripy states are the precursors of SkXs. However, these beliefs are inconsistent with recent findings that skyrmions at lower density have stripe morphology in their condensed phase [4,5]. The irregular stripy phases transform smoothly into SkXs as stripe width increases via material parameter engineering or as the skyrmion density increases through thermal agitations and/or the assistances of external forces [4,5]. Thus, SkXs and helical states are topologically connected.

We show that the stability and properties of various types of composite skyrmions are very sensitive to κ and κ'. Magnetic skyrmions show strong particle-continuum-medium duality. As particles, one or many circular and stripe skyrmions can be embedded inside another larger skyrmion, which act as a glue or a bag, to form a skyrmionium or skyrmion bag/cluster. The embedding can continue layer by layer to form all kinds of target skyrmions and cascade skyrmion bags. In the absence of the external magnetic field and for $\kappa \leq 1$ where isolated circular skyrmions are metastable and $\kappa > 1$ where condensed stripe skyrmions are stable. 1) Topologies of stable static magnetic textures are fully determined by κ, and A/D defines their length scale. 2) The maximal number of cascade layers in target skyrmions for $\kappa \leq 1$ increases monotonically from 1 at $\kappa=0.7$ to 2 at $\kappa=0.8$, and to 4 at $\kappa=0.94$, and eventually diverges at $\kappa=1$ for an infinite large system. 3) An

unstable target skyrmion or skyrmion bag for $\kappa < 1$ can be stabilized by inserting enough skyrmions inside the innermost bag and/or the next innermost bag. The maximal number of skyrmions needed to stabilize a skyrmion bag decreases from a larger value at small κ, say 4 at $\kappa=0.7$, to the lowest possible 1 when κ approaches 1. This number increases also as the number of cascade layers increases. Furthermore, skyrmion size inside the innermost bag increases with the number of skyrmions inside the bag, and approaches the size of isolated elementary skyrmions. 4) For $\kappa>1$, the number of target stripe skyrmions and cascade stripe skyrmion bags can be any number as long as the average space-size occupied by each skyrmion is larger than twice of elementary stripe width. Furthermore, stripe width and stripe spin profile of any target stripe skyrmions and cascade stripe skyrmion bags are the same as those of elementary stripe skyrmions. 5) When the average skyrmion-skyrmion distance inside a stripe skyrmion bag is comparable to the elementary stripe width for $\kappa>1$, stripe skyrmions in the innermost layer become disk-like objects and form an SkX.

In conclusion, I will present several progress made in our group about some fundamental properties of skyrmions in chiral magnetic films. Depending on skyrmion formation energy, a magnetic skyrmion is a circular object for a positive formation energy, and irregular stripe for a negative formation energy, in contrast to the common belief that stripy spin textures are topological trivial objects. In fact, many spiral/helical/cycloid orders are skyrmions, siblings of circular skyrmions in skyrmion crystals (SkXs) and cousins of isolated circular skyrmions. At the extreme of one or a few skyrmions in the whole sample, the skyrmion is a ramified stripe. As the skyrmion number density increases, skyrmion shapes gradually change from ramified stripes to circular objects, forming SkXs. Skyrmion size in a SkX has a different parameter dependence as those for isolated skyrmions and stripes, and size formulas in three different cases are obtained. A generic theory about SkX formation in chiral magnetic thin films and its fascinating thermodynamic behaviours will be presented. The lowest energy state in the presence of an external magnetic field has a finite skyrmion density. This explains why a chiral magnetic film is often in a stripy state at a low field and a SkX only around an optimal field when an important parameter, called κ, is above a critical value. Both stripy states and SkXs are skyrmion condensates and they are topologically equivalent. By gradually tuning the stripe width, the morphology of a skyrmion condensate transforms smoothly and continuously from various stripy phases to crystals. A huge number of all kinds of topologically protected localized magnetic solitons observed in experiments and simulations can be understood from the duality of particle and elastic continuum-medium nature of skyrmions. Skyrmions can be building blocks for cascade skyrmion bags and target skyrmions. They can also act as bags and glues to hold many other skyrmions together. The principles and rules for stable composite skyrmions are explained and presented, revealing their rich and interesting physics. In summary, recent progress shows that magnetic skyrmions have very rich and interesting physics.

Chirality and nonreciprocal responses in quantum materials

N. Nagaosa*
RIKEN Center for Emergent Matter Science (CEMS), Japan
*corresponding author: nagaosa@riken.jp

Abstract: We study the chiral dynamics and consequent nonreciprocal responses in quantum materials, where the most fundamental principles in physics manifest themselves, i.e., the symmetries especially the time-reversal and spatial inversion, dissipation, quantum-classical crossover/transition, quantal Berry phase and topology, and many-body correlation effects. They include (1) magnetochiral anisotropy of semiconductors, Weyl semimetals, and superconductors, and (2) the photovoltaic effect, e.g., the shift currents under photo-excitations.

When the system lacks both parity and mirror symmetries, it is called “chiral” and can be classified into right-handed and left-handed materials. Chirality is one of the most fundamental issues in many branches of sciences [1]. This is on the structure of the system, while we are interested in the dynamics particularly the flow of the particles in solids here. In that case, the time-reversal symmetry is also important, and the nonreciprocal responses are classified into 4 categories according to the
(a) linear or nonlinear, and (b) with and without the time-reversal symmetry breaking [2].

(1) The magnetochiral anisotropy of quantum materials:
Under the external magnetic field which breaks the time-reversal symmetry, the band dispersion becomes asymmetric between k and -k in noncentrosymmetric materials, which results in the nonreciprocal response of the resistivity called “magnetochiral anisotropy”, where the resistivity contains the term expressed by the product of the magnetic field B and the current I. We employed the Boltzmann transport theory to analyze the magnetochiral anisotropy in BiTiBr, which shows the giant bulk Rashba splitting [3]. This effect is found to be enhanced by the chiral anomaly in Weyl semimetals [4]. Even larger magnetochiral anisotropy is observed experimentally in superconductor MoS2. We have constructed the Ginzburg-Landau free energy functional which contains the third order terms in the momentum of the order parameter, and calculated the nonlinear paraconductivity due to the fluctuating order parameter. This theory explains the huge enhancement of the nonreciprocal resistivity [5].

(2) Photovoltaic effect in noncentrosymmetric materials:
The spontaneous creation of the bulk photocurrent induced by the irradiation of light without the external bias is called photovoltaic effect. We have formulated this effect in terms of the Floquet theory combined with the Keldysh Green’s function to reveal the role of relaxation [6]. Furthermore, we have extended this formalism to the electron-phonon coupled system, and predict the direct current production in ferroelectric insulator by exciting phonon, which is observed experimentally in BiTiO3 [7].

aeb@purdue.edu

Abstract: Advancing optical inverse design via machine learning promises to enable the next generation of efficient on-chip circuitry, high-resolution imaging and sensing, sustainable energy concepts, and quantum information technology. In this talk, we discuss photonic design approaches and emerging material platforms for showcasing machine-learning-assisted topology optimization for metasurface designs with applications in thermosphotovoltaics, reflective optics, and lightsail technology. We demonstrate the effectiveness of autoencoders for compressing the vast design space of metasurfaces into a smaller search space. By employing global optimization via adjoint methods or quantum annealing, one can find the optimal metasurface designs within the smaller space constructed by the autoencoder. The quantum-assisted machine learning framework, named bVAE-QUBO, presented in this work is the first demonstration of a generic machine learning framework that compresses an arbitrary continuous optimization problem into an Ising-model formalism for quantum sampling. When compared to other global optimization techniques, bVAE-QUBO has the potential for quantum speedups and achieving higher quality designs than traditional adjoint optimization methods. The techniques employed in this work extend well beyond the metasurface optimization space and into many inverse design problems for engineering and physics.

Active Metasurfaces in Space and Time

Harry A. Atwater[1]

[1]California Institute of Technology, USA
*corresponding author: haa@caltech.edu

Abstract: Active dielectric and plasmonic metasurfaces enable new modalities for spatiotemporal beam control for beam steering and wavefront shaping at multiple frequencies.

Electro-optically tunable active metasurfaces that enable dynamic modulation of reflection and transmission amplitude, phase, and polarization using resonantly excited materials and phenomena are powerful design elements for meta-imaging and computation. As flat, low-profile optical elements, active metasurfaces have potential serve as cascadable, programmable components in optical meta-imaging systems, such as lens-less cameras and single-photon imaging systems.

Active metasurfaces that enable dynamic complex index modulation to vary the amplitude, phase and polarization have been recently explored using several active materials and modulation phenomena, including carrier index in plasmonic ENZ structures, reorientation of liquid crystal molecules, electrooptic effects in quantum well heterostructures and polar perovskite materials, as well as index changes in phase change materials. Recently also, metasurfaces that employ dielectric phase-gradient elements with high quality factor non-local as well as local resonances have expanded the design space for active metasurfaces by enabling silicon and other more conventional dielectric materials with modest values of index change to be utilized.

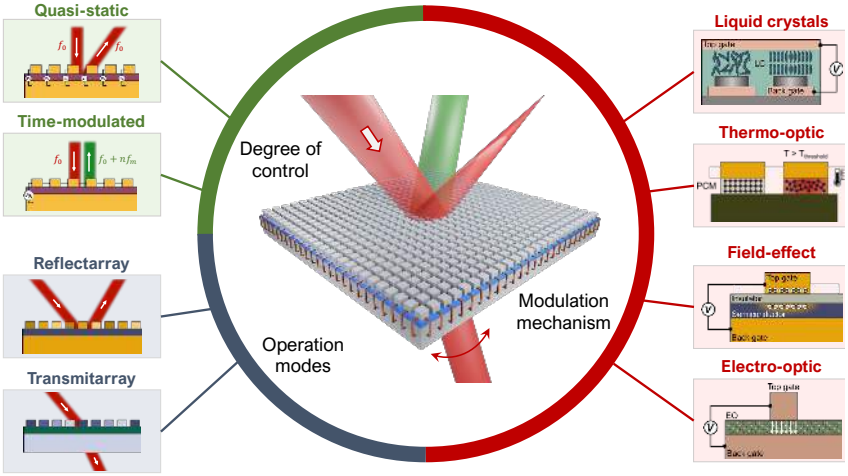

Figure 1. Active metasurface configurations (left) and physical mechanisms for modulation(right). (image credit: P. Thureja)

We can develop a taxonomy for active metasurfaces based on the attainable degree of spatial and temporal control. The spatial phase gradient arising from phase-reconfigurable array elements can enable continuous phase gradient tuning for beam steering or varifocal lensing. The degree of temporal control is connected to the reconfiguration timescale: In *quasistatic* metasurfaces, temporal gradients are slow compared to the period of electromagnetic waves, while *time-modulated* structures feature temporal gradients modulated fast enough to alter the frequency of the scattered beam. This opens the possibility to frequency multiplex scattered beams from active metasurfaces to facilitate harmonic beam steering in which a single active aperture steers scattered beams for different frequencies at independent angles.

In this talk, I will discuss metasurfaces with high quality factor, local, resonant elements capable of two-dimensional phase gradient generation, in both passive and active metasurface designs. I will also describe active metasurfaces with both spatial and temporal phase gradients, and an active metasurface as a lens-less imaging system, and compare the characteristics to conventional lens-coupled image sensors.

Continuous Time Crystals on Opto-Mechanical Platform

Nikolay I. Zheludev[1,2]

[1]University of Southampton, UK; [2]Nanayan Technological University, Singapore
zheludev@soton.ac.uk

Abstract: We overview recent development in the field of photonic time crystals, a state of matter with broken time-translation symmetry.

Recent advances in picometer scale visualization and localization techniques with electron beams [1] and topologically structured light [2] allow the detection of atomic level displacements in opto-mechanical systems and the study of dynamics and statistics of their picometre scale thermal and driven movements. This opens opportunity to develop pico/nano-opto-mechanical systems, in particular flexible plasmonic metamaterial arrays as a powerful platform to investigate classical many-body effects in the strongly correlated regime induced by light that complements the cold atom and spin platforms where many-body quantum states of bosonic or fermionic matter can be studied.

Among these many-body strongly correlated systems is the time crystal that is an eagerly sought phase of matter with broken time-translation symmetry. Quantum time crystals with discretely broken time-translation symmetry have been demonstrated in trapped ions, atoms and spins while continuously broken time-translation symmetry has only been observed in an atomic condensate inside an optical cavity.

We have demonstrated [3] that a classical metamaterial nanostructure, a two-dimensional array of plasmonic metamolecules supported on nanowires, exhibit complex picometer scale dynamics in presence of light. It can be driven to a state possessing all the key features of a continuous time crystal: continuous coherent illumination by light resonant with the metamolecules' plasmonic mode triggers a spontaneous first order phase transition to a superradiant-like state of transmissivity oscillations, resulting from many-body interactions among the metamolecules, characterized by long-range order in space and time. The continuous time crystal state results from synchronization of picometer scale stochastic thermal movements of the nanowires that is driven by light-induced interactions of plasmonic metamolecules. In interpretation of these experiments, we discuss different routes to synchronization including the Kuramoto-like mechanism that rely on nonlinearity of the mechanical sub-system of the array and the mechanism involving non-reciprocal non-Hamiltonian forces of light pressure.

We argue that the continuous time crystal state is of interest to applications in all-optical modulation, frequency conversion, timing and all-optical computing.

Disordered optical metasurfaces

Philippe Lalanne
Institut d'Optique d'Aquitaine - LP2N, France
philippe.lalanne@institutoptique.fr

Abstract: Shaping the far-field radiation diagrams of surfaces engraved with high-index subwavelength structures belongs to a longstanding and fundamental ambition of wave science. The problem comes in different forms, but generally consists of angularly and spectrally controlling polychromatic light scattering with nanostructures smartly arrayed on a surface. We discuss important challenges in the emerging field of disordered metasurfaces to address applications such as light focusing, light extraction and detection, color and appearance creation.

Hybrid Nanomaterials and Metastructures for Photonics, Sensing and Energy

Ultrathin Suspended Chiral Metasurfaces for Enantiodiscrimination and Circularly Polarized Luminescence

Artificially designed chiroptical metasurfaces can exhibit a strong circular dichroism, but they are usually limited by the complicated fabrication procedure and alignment errors. Here, we demonstrate a new type of self-aligned suspended bilayer metasurface with only one-step electron beam lithography exposure [1,2]. A significant optical chirality of 221° μm^{-1} can be realized using suspended metasurfaces with a thickness of 100 nm. Furthermore, we demonstrate that 1) such suspended chiral metasurfaces can be utilized for label-free discrimination of the chiral molecules at zeptomole level, exhibiting a much higher sensitivity (orders of magnitude) compared to the conventional circular dichroism spectroscopy [1]; 2) such suspended chiral metasurfaces can be utilized to induce strong circularly polarized luminescence from achiral nanocrystals including both upconversion nanoparticles (UCNPs) and quantum dots (QDs) [2,3]. Due to the giant chiroptical response, the proposed metadevice may offer promising applications for ultrathin circular polarizers, chiral molecular discrimination, imaging and sensing, etc.

Abstract: Using a scanning tunneling microscope, the radiative recombination yield of excitons in a laser-excited two-dimensional semiconductor is locally and electrically controlled.

Monolayer transition-metal dichalcogenides (TMDs)[1,2] are direct-bandgap two-dimensional (2D) semiconductors that have potentially groundbreaking applications in nanodevice technologies thanks to their unique optical and electronic properties. Even at room temperature, the photophysics of monolayer TMDs is governed by the exciton dynamics, i.e., the dynamics of bound electron-hole pairs that can diffuse in the 2D lattice and interact with each other or with charge carriers. Manipulating the elementary excitonic processes (i.e., exciton creation, diffusion and recombination) is key for the performance of TMD-based devices. In particular, the control of the luminescence quantum yield is a long sought-after goal in 2D optoelectronics and nanophotonics.[3] Attempts to control trion formation in monolayer TMDs on the nanoscale have been reported, e.g., using the plasmonic tip-substrate nanocavity of an atomic force microscope.[4] Nevertheless, distinguishing charge injection and electromagnetic effects in such plasmon-based experiments is challenging. Moreover, most of the techniques to locally control or excite excitons in 2D materials that are based on a scanning probe (or a focused electron beam) provide virtually no direct information about the diffusion and local recombination processes of these excitons,[5,6] a key aspect for the integration of these materials in realistic devices.

In this communication, we introduce a new method to locally and electrically control the radiative quantum yield of monolayer TMDs on transparent electrodes (i.e., indium tin oxide-coated glass) using the tip and the tunneling current of a scanning tunneling microscope (STM).[7] Via a combination of STM and wide-field photoluminescence microscopy, we uncover the effects of the biased tip-sample junction on the excitonic properties a WS_2 monolayer. The radiative quantum yield is modified in two ways, both of which are shown to be reversible. First, the near-field electromagnetic non-radiative transfer of energy from excitons to the non-plasmonic tungsten tip of the STM quenches the photoluminescence in an almost diffraction-limited area just below the tip. Secondly, bias and current-dependent photoluminescence quenching and enhancement occur within micrometer-scale areas around the tip position. We ascribe such "long-range" effects to lateral spatial gradients in the charge carrier density in the monolayer, which presumably modify the relative contributions of neutral and charged excitons to the photoluminescence and the radiative quantum yield of the excitons. Such doping gradients result from electron tunneling between the tip and the semiconductor and a partial electronic decoupling of the monolayer from the underlying conducting substrate.[7]

Photoluminescence Engineering with Surface Lattice Resonances

S. Murai*

Department of Material Chemistry, Graduate School of Engineering, Kyoto University, Japan
*Corresponding author: murai@dipole7.kuic.kyoto-u.ac.jp

Abstract: We combined a luminescent layer or substrate with metallic or dielectric nanoantennae to harness the photoluminescence into a specific direction predefined by the antenna design. A notable (> 10 times) enhancement in in radiation intensity into a designated direction is demonstrated. We describe the mechanism using a simple analytical model. We also fabricated "nanoantenna sticker" where the nanoantenna is embedded in a flexible polymer. The sticker can be stacked on any clean surfaces and act as nanoantenna.

Nanoantenna is a periodic array of scattering elements that can harness light into a specific direction. Combination of nanoantenna with phosphors enables spatial and spectral control over the luminescence (Fig. 1) [1-3]. In this presentation, we use several sets of nanoantennae (metallic or dielectric) and phosphors (organic or inorganic) to demonstrate the luminescence control. Typical nanoantenna consists of aluminum [1], silicon [2], and titanium dioxide [3]. We will discuss the difference of conversion efficiency from blue excitation to yellow-red luminescence for the metallic and dielectric nanoantenna.

We also introduce the nanoantenna stickers, which are the nanoantenna embedded in the flexible polymer [4]. We place this sticker on top of the luminescent layers to modulate their emission directionality. Because of its flexibility, the sticker gives control over luminescent directionality via stretching/compressing it.

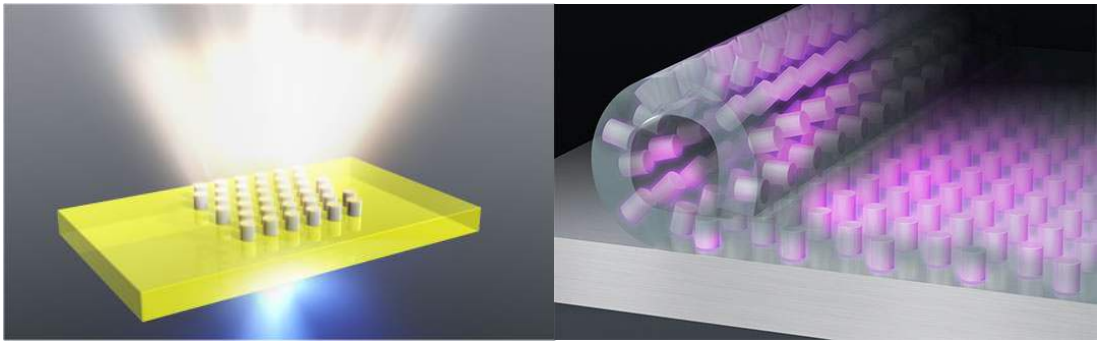

Fig. 1: (left) Sketch of the nanoantenna phosphor, converting a blue light into yellow photoluminescence with a directionality. (right) Sketch if the nanoantenna sticker, which is flexible and can be attached to any clean surfaces.

DNA Origami as a Versatile Method for Bottom-Up Fabrication of Plasmonic Metamaterials

Christoph Sikeler[1*], Susanne Kempter[1], Franziska Haslinger[1] and Tim Liedl[1]

[1]Ludwig-Maximilians-Universität, Germany
[*]corresponding author: C.Sikeler@physik.uni-muenchen.de

Abstract: In this work, we exploit the flexibility of DNA origami to create different kinds of metamaterials. DNA origami structures are created in a bottom-up, self-assembly process and plasmonic nanoparticles can be attached at predesigned locations. This can be used to create periodic lattices in solution as well as on a surface.

DNA origami is a very versatile technique to fabricate arbitrary nanostructures in a bottom-up, highly paralyzed manner. It utilizes the specificity of Watson-Crick base pairing to assemble designed structures from a long single-stranded DNA strand (scaffold) and multiple short oligonucleotides (staples). The desired geometry is built from multiple DNA double helices, which can be approximated by a cylindrical shape and are tightly connected by repeating DNA crossover motives[1].

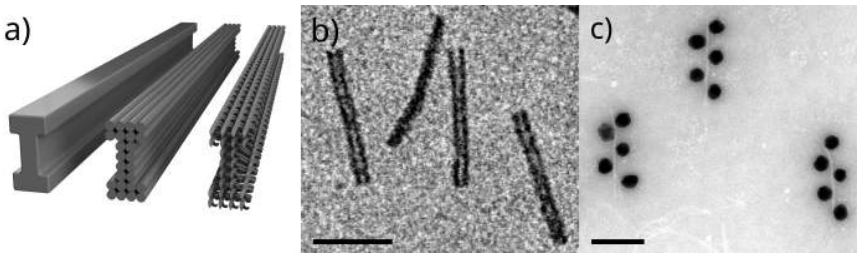

Figure 1: *Left: Illustration of an H-beam. Middle: Illustration of an H-beam structure filled with cylinders. Right: Illustration of an H-beam build from DNA double helices. (b) TEM image of an H-beam DNA origami structure. (c) TEM image of an H-beam DNA origami structure to form a zigzag pattern with five attached gold nanospheres.*

There are many ways to chemically modify DNA strands. Therefore, a large variety of molecules and particles can be functionalized with DNA. By extending staple strands in the DNA origami structure with a sequence that is complementary to the sequences of strands that are conjugated to the molecules of interest, it is possible to introduce these guest molecules at specific locations on the DNA origami structure (Figure 1). Guest molecules can for example be metallic nanoparticles, quantum dots, fluorophores or proteins. Consequently, DNA origami structures decorated with metallic nanoparticles can be used to build plasmonic systems with high accuracy and without the need for lithography.

On the other hand, one can use e-beam lithography to arrange DNA origami structures on a surface[2]. Once attached to the surface, the origami structures can be used to capture metallic nanoparticles like gold nanospheres, see Fig. 2 a and b. The specific interaction between the DNA origami structure and the nanoparticles allows for a very precise positioning. Therefore, e-beam lithography combined with DNA origami enables us to build functional surfaces with metallic nanoparticles whose geometry would be difficult to produce with lithography.

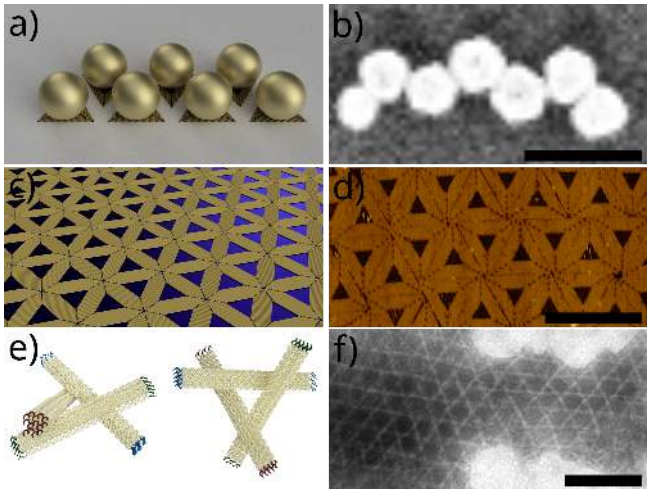

Figure 2: *Illustration and experimental implementation of DNA origami structures. (a) Illustration of gold nanospheres arranged in a zigzag pattern using DNA origami and e-beam lithography. (b) SEM image of gold nanospheres arranged on DNA origami structures in a zigzag pattern. (c) Illustration of a periodic DNA origami surface. (d) AFM image of triangular origami structures forming a closed packed pattern on a mica surface. (e) Illustration of a DNA origami structure which can be multimerized to build a rhombohedral crystal. (f) TEM image of a rhombohedral crystal formed by DNA origami.*

Furthermore, periodic surfaces can be created even without any lithography. Under certain conditions the DNA origami structures accumulate at the surface. In order to fit as many DNA origami structures to the surface as possible, the structures will arrange in a closed packed pattern[3]. For example, incubating a triangular DNA origami structure at a surface will result in a hexagonal pattern, see Fig. 2 c and d. Each of the origamis can subsequently capture guest molecules. Hence, a periodic pattern of plasmonic particles can be created completely by a bottom-up, self-assembly process.

DNA origami can also be used to build periodic crystals in liquid. By employing the specificity of DNA base pairing, DNA origamis can be programmed to attach to each other. Therefore, a single DNA origami structure forms a unit cell which multimerizes into a large periodic lattice[4], see Fig. 2 e and f. Again, this lattice can bind guest particles at predesigned locations in each unit cell. As a result, one ends up with a periodic one-, two- or three-dimensional array of plasmonic particles.

Oriented Colloidal Quantum Wells:
Pushing the Limits, Breaking Records

Hilmi Volkan Demir
NTU Singapore – Nanyang Technological University, School of Electrical and Electronic Engineering, School of Physical and Mathematical Sciences, School of Materials Science and Engineering, Singapore

Bilkent University UNAM, Department of Electrical and Electronics Engineering, Department of Physics, Institute of Materials Science and Nanotechnology, National Nanotechnology Research Center, Ankara, Turkey
hvdemir@ntu.edu.sg, volkan@bilkent.edu.tr

We introduce a powerful, large-area self-assembly technique for orienting colloidal quantum wells in all face-down configuration. We demonstrate three-dimensional constructs of such oriented self-assemblies with monolayer precision. We present the most recent examples of LEDs and lasers using these oriented assemblies for lighting and displays. Here we also show record high efficiency from their LEDs and record thin gain medium from their laser structures. These solution-processed quantum wells hold great promise to challenge their epitaxial thin-film counterparts in semiconductor optoelectronics.

Guided mode resonance enhanced upconversion luminescence of upconversion nanoparticles for immunoassay with ultralow limit of detection

Abstract: A low refractive index resonant waveguide grating (RWG) is integrated with up-conversion nanoparticles (UCNPs) to from a sandwich type immunoassay. Guided mode resonance enhanced evanescent field is formed atop of the RWG to enhance upconversion luminescence of UCNPs in aqueous and the detection sensitivity of the bioassay is greatly increased. The limit of detection of the bioassay is 0.42 fg/mL for the detection of cardiac troponin I, which is 6 orders lower than acute myocardial infarction threshold value (~28 pg/mL).

In this work, a novel sandwich type immuneassay, based on the integration of a low refractive index resonant waveguide grating (low-n RWG) and upconversion nanoparticles (UCNPs), hereafter called as low-n RWG + UCNPs sandwich bioassay, is presented for the detection of the concentration cardiac troponin I, (cTnI). Figure 1 displays the structure of a 3x3 sandwich type low-n RWG + UCNPs bioassay. In each pixel, capture antibodies (anti-cardiac troponin I) are immobilized on the low-n RWG surface to seize cTnI. UCNP-conjugated detection antibodies are bound to cTnI to form a sandwich structure. The use of UCNPs in the assay provides the following advantages: (1) no background luminescence is generated from the carrier fluid or the assay biochemistry because UCNPs are excited with near-infrared (NIR) light. It can significantly reduce the limit of detection (LOD) to a value much lower than those of conventional assays. (2) The upconversion luminescent (UCL) properties of UCNPs are inert to the environment. The detection process is not influenced by the sampled fluid and the variation of environmental sampling conditions. In our previous investigation, we found that as the low-n RWG is illuminated by NIR light with resonant excitation configuration, i.e. incident light matching with guided mode resonance (GMR) condition, strong local field can be formed atop of the low-n RWG. As a result, UCL of UCNPs can be greatly enhanced [1-3], and thus significantly improves the detection sensitivity of the low-n RWG + UCNPs bioassay.

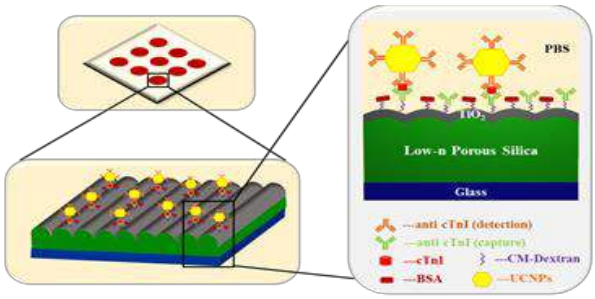

Figure 1 Schematic diagram of a 3x3 sandwich type low-n RWG + UCNPs bioassay

Figure 2 (a) shows UCL spectra of the low-n RWG + UCNPs bioassay with cTnI concentration of 1 pg/ml obtained with two different excitation angles $\theta=22^0$ (resonant excitation) and $\theta=0^0$ (non-resonant excitation). The result confirms that the resonant excitation indeed can greatly enhance UCL intensity of UCNPs. The inset shows UCL images of the low-n RWG + UCNPs bioassay taken with the aforementioned excitation angles. Figure 2 (b) shows UCL spectra at 450 nm of low-n RWG + UCNPs bioassays varying with concentrations of cTnI in PBS obtained under resonant excitation condition ($\theta=22^0$). As displayed, the UCL intensity increases as the concentration of cTnI increases. Figure 2 (c) plots UCL peak intensity at 450 nm versus the concentration of cTnI obtained by three different chips. From the plot, the LOD of the bioassay for the detection of cTnI was found to be 0.42 fg/mL. The bioassay offers the detection range over 7 orders of magnitude of cTnI concentration from 1 fg/mL to 1 ng/mL. To address the challenges of matrix effects and interference, two human sera were diluted 100 times with PBS and spiked with known cTnI concentrations as internal controls. Their recoveries are 113.2% and 96.3%. Our results confirm that the low-n RWG+UCNPs sandwich bioassay indeed can improve LOD to fg/ml level, about three to five orders lower than those of obtained by other techniques. Therefore, the low-n RWG + UCNPs sandwich bioassay should be useful for detecting very low concentration of biomarkers in blood.

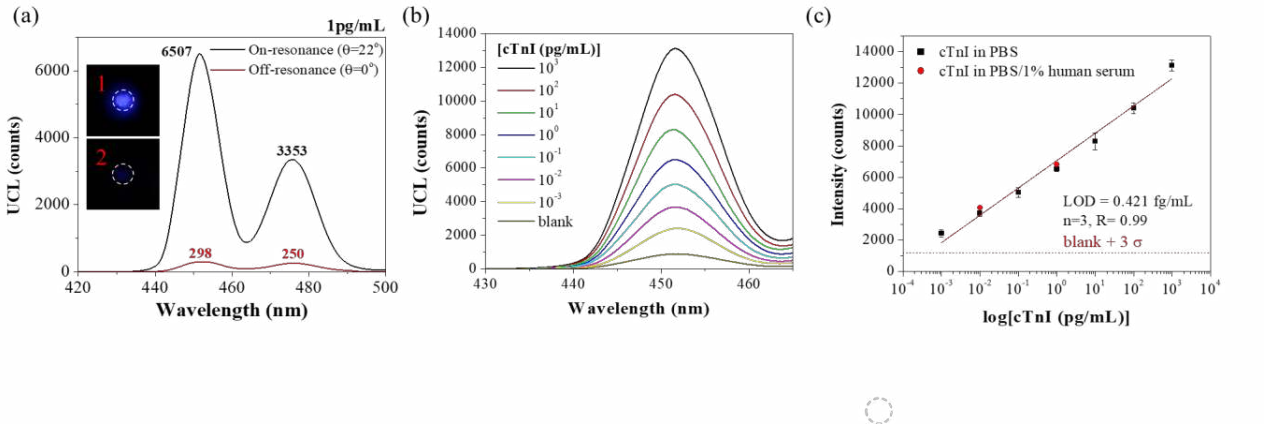

Figure 2 (a) UCL spectra of the low-n RWG + UCNPs bioassay with cTnI concentration of 1 pg/ml obtained with $\theta=22^0$ and $\theta=0^0$. (b) UCL spectra at 450 nm of the low-n RWG + UCNPs bioassays varying with concentrations of cTnI in PBS obtained with $\theta=22^0$. (c) UCL peak intensity at 450 nm versus the concentration of cTnI obtained by three different chips.

Abstract: When a chiral nanomaterial is irradiated by circularly polarized light, the material in general exhibits chiro-optical effects. The chiro-optical effects appear as various forms. Here we report chiral optical gradient force observation on chiral nanoparticles and nanoscale imaging of chiro-optical force fields.

When a chiral nanomaterial is irradiated by circularly polarized light, the material in general exhibits chiro-optical effects. The chiro-optical effects appear as various forms, typified by circular dichroism (CD) and optical rotation (OR). When a small particle is illuminated with strong focused laser beam, the particle is trapped at the focal point due to the optical gradient force, which is known as optical trapping. Chiral nanoparticles are expected to exhibit chiro-optical trapping effects. That is, the optical gradient force exerted on the chiral particle depends, when trapped by circularly polarized light, on the handedness of the circular polarization. In this paper, we report studies related to chiro-optical effects on the optical gradient forces on chiral nanostructures.

Chiral optical gradient force on chiral nanoparticles. We investigated the chiral characteristics of gradient force for chiral nanoparticles, which has not previously been studied experimentally. Three-dimensional helicoid-shaped chiral gold nanoparticles[1] (Fig. 1) were trapped by circularly polarized light and the characteristics depending on the handedness of the trapping light and on the handedness of the particle were examined.[2] The colloidal solutions of the chiral nanoparticles showed strong CD (and OR) bands in visible to near-infrared region, in resonance with the surface plasmon modes. We trapped the particles in water with loosely focused circularly polarized laser beam in the wavelength region near the plasmon resonance (680-720 nm).

The experimental results showed that the gradient force depended on the handedness of the CP of the trapping light and the particle chirality. The wavelength dependence of the gradient force tends to follow the CD spectrum of the colloidal solution rather than the OR, and this result indicates that the spectral features of the chiral gradient

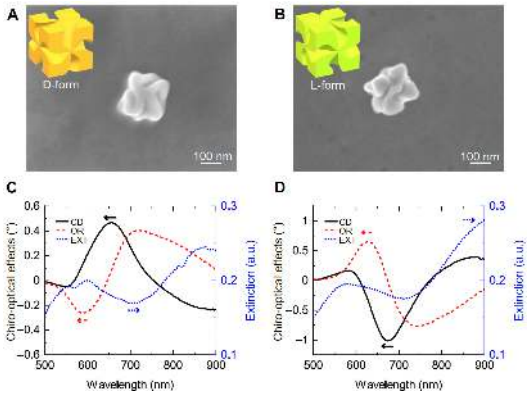

Fig. 1 SEM images (A,B) and CD, OR, and extinction spectra (C,D) of D-form (A,C) and L-form (B,D) helicoid gold nanoparticles.[2]

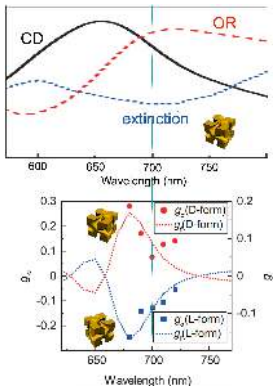

Fig. 2 Optical spectra of the colloidal solution of D-form particles (top) and experimental (dots) and simulated (curves) wavelength dependences of gradient force dissymmetries (bottom).[2]

force are influenced not only by the real part of the refractive index but also by the electromagnetic field perturbed by the chiral particle. This is in sharp contrast to the well-known behavior of the gradient force, which is governed by the real part of the refractive index. The extended aspect of the chiral optical force obtained here can provide novel methodologies on chirality sensing, manipulation, separation, enantioselective biological reactions, and so forth.

Nanoscale imaging of chiro-optical force. Atomic force microscopy is based on detection of forces between the probe tip and the matter to be observed. This principle can be applicable to optical forces due to interaction between dipoles on the probe and on the sample, induced by irradiation of light. This method of microscopic imaging has been known as photoinduced force microscopy. By detecting difference between the force under left- and right-handed circularly polarized illumination with the photoinduced force microscopy, we can expect to visualize chiral optical fields on the sample under irradiation of light.

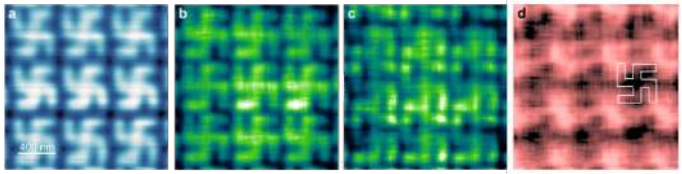

Fig. 3 (From left to right) AFM image, photoinduced force images under right- and left-circularly polarized light at 785 nm, and the differential image between the two photoinduced force images, for right-handed gold gammadion array structure. The unit cell size is 540 nm.

We thus developed an experimental system for nanoscopic observation of chiro-optical force and imaging of chiral optical fields on the samples, based on photoinduced force microscope. We adopted gold coated AFM tip as the probe to detect interaction with the sample induced by irradiation of the system by circularly polarized light. Heterodyne frequency modulation technique[3] was utilized to eliminate the thermal effects by the light. The photoinduced force images under illumination of left- and right-circularly polarized light were recorded, and the chiro-optical image was obtained as the difference between the two. As the test sample, we fabricated left- and right-handed gold gammadion structure arrays by electron-beam lithography method. The result of chiro-optical image of the sample is demonstrated in Fig. 3. We succeeded in visualizing nanoscale chiral optical fields in the vicinity of the nanostructures. It is seen that the local chiro-optical effect is prominent at the corners of each gammadion. The technique provides a new method to investigate chiral optical near-fields and paves the way for revealing the physical phenomena of nanoscale chiro-optical effects and technological development based on that.

Abstract: Recent investigations have demonstrated the strength of investigating the interactions occurring between plasmonic materials and molecules at the nanoscale to elucidate the richness of reactivity offered by plasmon−driven photocatalysis. In this talk, I will present a photochemical nanoscopy technique that enables the 2D mapping of plasmonic reaction products, and thus of the hot carriers driving photocatalysis, with subwavelength resolution. This approach opens the way to a deeper understanding of how photonic low-dimensional materials drive chemical transformations.

Abstract: We show both experimentally and theoretically that the photodynamics of quantum emitters (NV colored centers in nanodiamonds), accurately positioned by AFM nanoxerography in the near field of silicon dimer nanoantennas, can be controlled by these simple high-index dielectric nanostructures. Then, in order to go a step further and control the directive emission of such quantum sources, we explore numerically and optimize with an evolutionary optimization algorithm, the geometry of silicon nanoantennas, made of a limited number of building blocks.

Introduction

Improving the brightness and efficiency of single photon sources by the mean of optically resonant nanostructures is a major stake for the development of efficient nanodevices for quantum communications.

For a couple of decades, these resonant nanostructures have mainly been made of noble metal that sustain strong localized resonances (LSPR) that can be used to manipulate, concentrate or redirect visible light. Such properties have led to numerous actual or potential applications in integrated optics, sensors, nonlinear optics, field-enhanced spectroscopies, or photovoltaics. Recently, an alternative emerged with high refractive index dielectric nanostructures, which offer the same range of applications as plasmonics by manipulating Mie optical resonances instead of LSPR [1].

These resonances can be efficiently tuned by modifying the size, shape, and material of those nanostructures (e.g. silicon, n ~ 4) [2]. Furthermore, high index dielectric nanostructures offer several key advantages when compared to their metallic counterparts: absorption losses are far weaker for wavelengths longer than the direct band gap, access to semiconductor (CMOS) technology for nanostructure fabrication, and presence of intrinsic strong magnetic and electric resonances, providing an unique opportunity to spatially separate and redistribute the energy of the magnetic and electric parts of the electromagnetic field in the near field, otherwise inextricably connected in the far field [3].

Discussion

We discuss here the effect of simple high index dielectric nanoantennas on the spontaneous emission of model quantum emitters. First, we accurately positioned arrays of nanodiamonds hosting NV colored centers in the gap of silicon dimer nanoantennas, using atomic force microscopy (AFM – [4]) nanoxerography [5]. The NV center is an ideal model system exhibiting single photon emission properties at room temperature, which is well adapted for proof of concept experiments in quantum nano-optics. Since the emission rate of the emitters, and therefore the local density of photonic states (LDOS), are modified by the nanostructure, we show by the mean of time-resolved photoluminescence acquisitions that the photodynamics of these electric dipoles can be enhanced by the coupling to the nanoantenna down to the single photon emission regime [5]. Our experimental results are in good agreement with multipolar analysis and numerical simulations based on the Green Dyadic Method - GDM.

Second, in order to go a step further, we explore numerically the control of the directive emission from quantum dipolar sources by the mean of complex Si antennas. The latter, made of a given number of building (nano)blocks, are optimized by an Evolutionary Algorithm (EA). The geometries obtained allow to tailor the emission direction of a single dipolar source, maximizing the intensity of the emitted light within a given solid angle. Our numerical experiments demonstrate the efficiency of such EA-optimized antennas.

Novel Second Harmonic Rayleigh and Mie scattering chiroptical effects

Ventsislav K. Valev[1,2,3]
1 Centre for Photonics and Photonic Materials, University of Bath, Bath, BA2 7AY, United Kingdom
2 Centre for Nanoscience and Nanotechnology, University of Bath, Bath, BA2 7AY, United Kingdom

Abstract: Following our recent discovery of the Hyper Rayleigh Scattering Optical Activity (HRS OA) [1,2], we report both novel forms of harmonic chiroptical scattering and novel materials in which these effects can be observed. The new effects are enable chiroptical characterization in tiny volumes of illumination. They are also highly sensitive and capable of characterizing the chirality of a single metal nanoparticles, floating freely in an isotropic liquid environment.

Chirality – the geometric property of breaking mirror-symmetry – is omnipresent in nature. It is exhibited in the spiral shapes of galaxies in motion, in the storm systems of planetary atmospheres, in the shape of human hand, the shells of many snails, in the twist of seeds and bacteria, as well as in molecules, such as DNA, proteins, sugars and amino acids. In molecules, the handedness (i.e. their direction of twist) is extremely important as it can determine the nature of chemical reactions or the expression of genes. Circular dichroism and optical rotation are among the main chiral optical (chiroptical) techniques that serve to routinely characterize the handedness of chiral molecules and inorganic particles. However, these optical effects are considered intrinsically weak, and, in order to accumulate a large measurable signal, they rely on large illumination volumes and large amounts of chiral analytes.

By contrast, in the case of nonlinear chiral optical method, the effects are orders of magnitude more pronounced. These effects are usually limited in space to the only the focal point of illumination. The caveat is that such nonlinear chiral optical methods have been considered technologically complex and their applications beyond the laboratory environment have been limited.

To cite a few examples, second harmonic generation circular dichroism[3] and second harmonic generation optical rotation [4] were the first nonlinear chiroptical effects reported but they are based on symmetry breaking interfaces and are therefore not suited for investigating chirality in liquids, such as water – the medium of life. For such isotropic liquids, chirality can be characterized by sum frequency generation.[5,6] This technique is a good example of the technological complexity often associated with nonlinear chiroptical methods – it requires it requires two light pulses on two non-collinear beam paths, with different polarization to be superimposed at the same point, both in space and in time. Going to higher nonlinear chiroptical effects (those that engage the third susceptibility, or second hyper-polarizability), good examples are nonlinear circular dichroism or optical rotatory dispersion [7]. These methods are measured against the background of linear effects, which is also the case for Polarimetric z-scan [8], where the linear optical effect serves to calibrate the nonlinear method.

In 2019, our team reported the first experimental observation of the effect – Chiroptical Harmonic Scattering – at the second harmonic, from Ag nanohelices[1]. This paper settled the 40-year old scientific question. We later reported the effect from chiral Au nanocubes [9], from semiconductor (CdTe) nanoparticles [10] and at the third harmonic wavelength (together with Andrews) [11]. In [9], we also set a sensitivity record, reporting the first chiroptical characterisation of a single nanoparticle floating freely in a liquid environment, a sensitivity that was further confirmed in [12].

Here, we report chiroptical Mie scattering at the Second Harmonic and chiroptical second harmonic Rayleigh scattering in a class of materials where the effects had not been seen before.

Chiral Generation of Hot Carriers Towards Enantioselective Plasmonic Photocatalysis

Miguel Comesaña-Hermo

Université Paris Cité, CNRS, ITODYS, F-75013 Paris, France
*corresponding author: miguel.comesana-hermo@u-paris.fr

Abstract: We present the synthesis of inorganic assemblies composed by the adsorption of Au nanoparticles onto chiral silica nanostructures in order to study the features of non-thermalized charge carriers obtained under circularly polarized radiation. We demonstrate that such materials can be implemented as photocatalytic platforms in polarization-dependent chemical reactions.

It has been recently predicted that the formation of plasmonic assemblies with chiroptical activities can induce an asymmetric response on the hot charges generated via electromagnetic excitation of the plasmonic component.[1,2] In this manner, hot electrons and holes could be used for the development of polarization-sensitive photochemistry. In the present work we use silica-Au nanoribbons as chiral templates for the controlled assembly of plasmon-based photocatalysts, leading to the formation of hybrid materials with asymmetric catalytic features. More precisely, we demonstrate that an improved reaction yield can be obtained when the helicity of the circularly polarized light used for the activation of the plasmonic component matches the handedness of the chiral substrate.[3] Subsequently, we take advantage of this feature to investigate the photo-induced growth of a metal onto the chiral substrate. The photo-reduction of metal ions induced by the photo-generated charge carriers can lead to the formation of a chiral plasmonic system with novel morphological and optical features.[4]

Abstract:

In this work, we observe near-infrared plasmon induced hot electron extraction in a heterostructure between indium tin oxide nanocrystals and monolayer molybdenum disulphide. We excite the sample at 1750 nm, resonant with the indium tin oxide plasmon and we observe the excitonic features of molybdenum disulphide in the visible range, close to the exciton of molybdenum disulphide. Such phenomenon can be ascribed to a charge transfer between indium tin oxide nanocrystals and monolayer molybdenum disulphide upon plasmon excitation.

Alternative ways to produce energy from the Sun also include plasmon induced hot electron extraction based solar cells [1,2]. In 2016, Reineck[3] et al. have demonstrated photon-to-electron conversion efficiency by employing a solar cell with an interface between gold nanoparticles and titanium dioxide. Visible light excites the gold nanoparticles generating hot electrons. Such hot electrons are higher in energy with respect to the bottom of the conduction band of titanium dioxide.

With materials that show the plasmonic resonance in the visible it is possible to observe plasmon-induced hot electron extraction[4]. In recent years the attention on plasmons in heavily doped semiconductor nanocrystals has increased. Doping levels around 10^20-21 cm^-3 place their plasmon resonances in the near infrared. Of particular interest are transparent conducting oxide nanocrystals

Herein, we show plasmon-induced hot electron extraction in an indium tin oxide nanocrystal / monolayer molybdenum disulphide structure (Figure 1a). By exciting the heterostructure at 1750 nm, where molybdenum disulphide is not absorbing light and indium tin oxide shows a strong absorption, we observe the excitonic feature of molybdenum disulphide. We ascribe this phenomenon to plasmon-induced hot electron transfer between indium tin oxide nanocrystals and monolayer molybdenum disulphide.

In figure 2a, we show the MoS2 transient signal excited below the bandgap at 1750 nm (0.7
eV), which is much lower with respect to the optical bandgap. We have chosen 1750 nm to ensure that even by two-photon absorption we could not reach the excitonic energy that is around 660 nm (1.87 eV). In this case, we can only see an artifact at zero-time delay between the pump and probe. Finally, in Figure 3d, we show the results of the heterojunction of ITO and MoS2 excited at 1750 nm. After the coherent artifact, we observe the fingerprint of the exciton around 630 and 660 nm. We assign this to an ultrafast plasmon induced hot electron transfer from ITO to MoS2. The high energy tail of the hot FD distribution has enough energy to overcome the Schottky barrier and jump to the MoS2. When now the probe arrives, we have created a different dielectric environment for the MoS2 having those charges in the valence band.

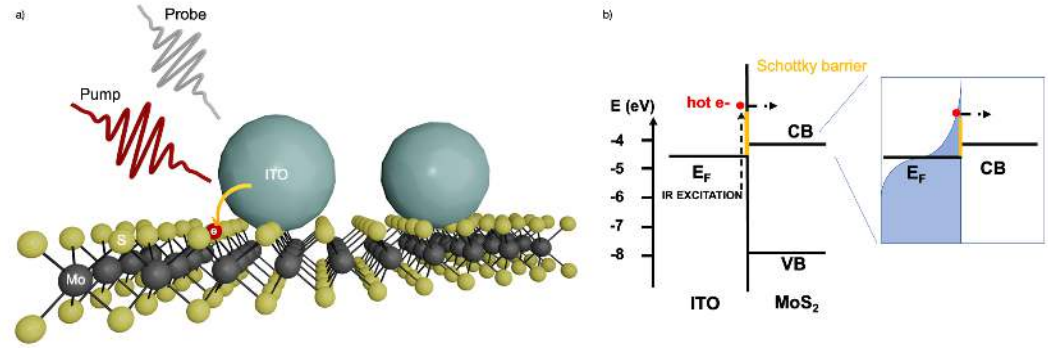

Figure 1 a) ITO/MoS2 heterojunction sketch; b) Band alignment between ITO and MoS2, on the right-hand side we have the sketch of the hot Fermi Dirac Distribution and Schottky barrier.

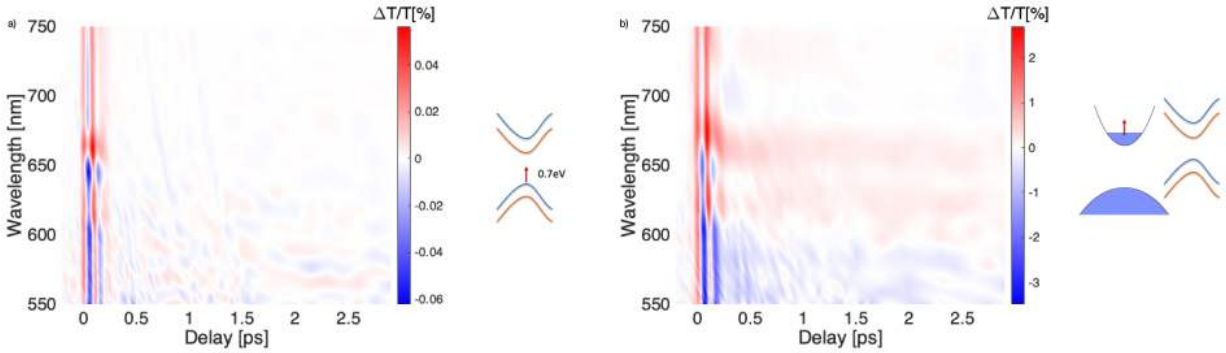

Figure 2 a) Pump probe map of bare MoS2 excited in the NIR at 1750nm b) Pump probe map of the heterostructure ITO/MoS2 excited in the infrared at 1750nm

In conclusion, we have used ultrafast spectroscopy to see charge transfer processes from indium tin oxide to a single layer MoS2 heterojunction excited resonant to the plasmon at 1750 nm.

Abstract: The impulsive photoexcitation of nanoparticles kicks off the time-dependent re-equilibration of the electron gas, ion lattice, and environment. For better understanding and harnessing these processes, for thermoplasmonics or photocatalysis applications, it is paramount to know the dynamic, time-dependent evolution of the temperature of each system subcomponents. We report two different methods to directly deduce the temporal evolution of the electronic and lattice temperature of plasmonic Au nanoparticles excited by ultrashort laser pulses on the fs-ps time scale.

Following the impulsive photoexcitation of bulk materials and nanoparticles (NPs), a non-thermal electron population is generated. The nonthermal gas internally thermalizes on a sub-picosecond time scale via electron–electron (e-e) collisions, giving rise to a hot electron gas that subsequently releases its energy to the lattice by means of electron–phonon (e-p) collisions, on the few-ps time scale. Once electron gas and ionic lattice are in mutual thermal equilibrium, heat is dissipated to the environment via phonon–phonon (ph-ph) interactions within few hundred ps.

These dynamic processes and the energy redistribution among the system's degrees of freedom following the photoexcitation lie at the very heart of several highly-intriguing light-induced physical phenomena, such as photocatalysis, thermoplasmonics and solar energy conversion. Highly energetic non-thermal electrons (available in the first few hundreds of fs following the excitation), in particular, play a pivotal role in determining the final outcome of photocatalytic reactions, whereas the lattice-temperature evolution is instrumental for thermoplasmonics heating. In any case, knowing the electron and lattice temperature throughout the relaxation process paves the way to a better understanding of the physical processes occurring during the energy relaxation. We report the direct, model-independent measurement of the electronic and lattice temperature of impulsively excited Au plasmonic nanoparticles, on a time scale ranging from the hundred-fs to the hundred-ps regime.

The ultrafst-electron temperature (T_e) measurements were performedby means of ultrafast, high-resolution photoemission spectroscopy, on ensembles of plasmonic gold NPs, laid onto a transparent conductive oxide substrate [1]. Experiments were performed in pump-probe configuration by photo-exciting the NPs close to the LSP resonance and collecting ultrafast time-resolved photoemission spectra (tr-PES) by means of ultrashort energetic light pulses obtained by high-harmonic generation from the pump beam (Fig.1, left).

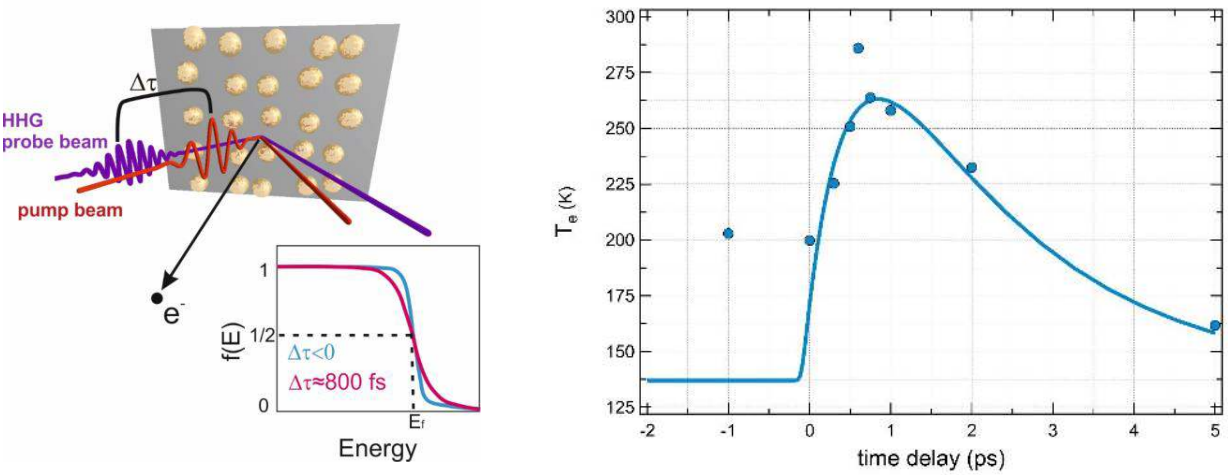

Figure 1: Left: experimental configuration for the ultrafast pump-probe photoemission experiment. Right: evolution of the electronic temperature as a function of the time elapsed since the photoexcitation.

T_e was evaluated exploiting its own definition expressed by the Fermi distribution function, without resorting to any kind of model. Its temporal evolution showed a marked increase up to 800 fs, followed by a gradual relaxation toward environment temperature (Fig. 1, right). The deviations of the electronic distribution function with respect to the Fermi-Dirac were below experimental sensitivity.

At longer delays time, where electron gas and ion lattice are in thermal equilibrium, the nanoparticle temperature was deduced by means of a direct comparison between the differential absorbance of the excited system recorded in a femtosecond- transient absorption spectroscopy measurement, and the differential absorbance recorded in a static thermo-optical experiment [2]. The overlap between time-dependent spectra and temperature-dependent spectra allows to reconstruct the temperature evolution of the nanoparticles in the 20 ps-300 ps time interval, whereupon the relaxation towards ambient temperature is almost complete.

Abstract: Metasurfaces supporting bound states in the continuum (BICs) have emerged as a powerful nanophotonic platform because of their exceptional resonance control and large field enhancements ideal for light-matter coupling. Van der Waals (vdW) materials are particularly interesting for nanophotonics because of their unique optical and electronic properties. This talk will introduce BIC-driven metasurface concepts based on the prominent vdW materials hexagonal boron nitride and the transition metal dichalcogenide WS_2, demonstrating broad spectral tunability, ultrasharp resonances, and strong light-matter coupling.

The introduction of the physical concept of bound states in the continuum has sparked a revolution in nanophotonics, enabling breakthrough applications ranging from ultrasensitive biospectroscopy to efficient higher harmonic generation and beyond. Because of their exceptional control over high-Q resonances accompanied by large field enhancements, symmetry-protected BIC-driven metasurfaces have seen particular interest for enhancing and probing light-matter interactions. Many realizations of such metasurfaces have so far relied on established nanophotonic materials such as silicon, germanium, or titanium dioxide. Layered materials composed of individual atomic planes bonded together by weak van der Waals (vdW) interactions can open exciting new perspectives for nanophotonic light-matter coupling because of their unique optical and electronic properties, especially for on-chip quantum optics and optoelectronics.

In my talk, I will introduce several recent examples of BIC-driven metasurface concepts based on vdW materials such as hexagonal boron nitride (hBN) and the transition metal dichalcogenide (TMDC) WS_2, demonstrating broad spectral tunability throughout the visible wavelength range, high resonance quality factors, and strong light matter coupling [1,2]. Uniquely, these concepts leverage material-intrinsic BICs, where the vdW structures themselves act as the optically active materials. We harness WS_2-intrinsic BIC modes with sharp and tailored linewidths to tune the resonances over the WS_2 exciton, resolving the distinct anti-crossing signature of strong coupling with large values of the Rabi splitting of 116 meV that can be precisely controlled by modifying the metasurface geometry. Material-intrinsic BIC platforms are broadly applicable for a multitude of vdW materials, where they can deliver both basic insights and practical polaritonic device applications.

Abstract

Plasmonic systems can act as photocatalysts, with energy deposited in their resonant modes driving local chemical reactions. Furthermore, the spatial inhomogeneity of the local response of a plasmonic nanostructure can be used to tailor its properties as a nanoantenna, perhaps most notably through the creation of electromagnetic hot spots. Such locally differentiated response can be combined with circularly polarized light to create and amplify local chiral symmetry of the particle-light system. We present computational results suggesting the potential for developing chiral plasmonic nanostructures from achiral templates by exploiting this phenomenon.

Abstract

Chiral excited electronic states of molecules have an intrinsic sense of handedness, or twist, and are the active component in energy efficient display technologies and in new photosynthetic routes to produce pharmaceuticals. Creating chiral states is achieved by manipulating the "twistiness" of the geometric molecular structure. This is a demanding problem adding complexity due to the need to precisely control molecular geometry. Here we demonstrate a novel concept for creating chiral excited states which does not rely on molecular structure. Instead, it depends on hybridising a non-chiral molecule with a chiral electromagnetic field, producing a hybrid light-matter chiral polariton state. This is achieved by a symmetry-controlled strong chiral-light–matter interaction between an electromagnetic mode of a chiral nanocavity and an achiral molecule, a concept referred to as the electromagnetic-enantiomer. This electromagnetic mechanism simplifies the creation of chiral electronic states since it is far less demanding in terms of materials design. We have illustrated the concept using an exemplar system relevant to organic optoelectronic technology, producing efficient circularly polarised emission from a non-chiral emitter molecule.

Enhancing Light-Matter Interaction in MoS_2 Monolayer deposited on Metalic Nanostructures

M. F. Sousa Lemes [1], G. M. Marega[2], R. Chiesa[2], A. Kis[2] and E. Marega Jr.*[1]

Abstract: Monolayer transition metal dichalcogenides (TMDs) with a direct bandgap hold enormous potential for designing novel electronic and optoelectronic devices. However, their atomic-thin thickness leads to inefficient light-matter interactions and hinders more versatile applications. One promising solution to overcome this problem is hybridizing the 2D-TMDs with plasmonic structures to increase the optical absorption of the monolayer materials.

Since the discovery of graphene in 2004, an impressive development of other 2D materials has followed. Some examples are transition metal dichalcogenides (TMDs), e.g. molybdenum disulfide (MoS_2), molybdenum diselenide ($MoSe_2$), tungsten disulfide (WS_2), hexagonal boron nitride (h-BN), and many others. However, monolayer TMDs have a low optical cross-section due to their atomic thickness, which results in low light absorption and hinders their systematic use in light harvesting and conversion applications. Various designed systems have been studied to improve the light-matter interaction in 2D materials, such as chemical treatment (1) and quantum doping (2), but they suffer from a high degree of complexity for practical implementation. One effective way to enhance the optical response of monolayer TMDs relies on using plasmonic metal nanomaterials that localize and enhance the electromagnetic field within their proximity (3-4). Here, we report on the fabrication of MoS_2-coated metallic nanostructures and their characterization by Confocal photoluminescence microscopy and lifetime image measurements (Figure 1). Confocal photoluminescence microscopy analysis at room temperature was employed to understand the influence on the emission properties of the MoS_2 (figure 2) when deposited on top of a metallic nanostructure. When the microscopy incident photon energy is above the bandgap of the MoS_2 (excitation at 405 nm), the PL radiative emission is greatly enhanced, ~400-fold, at the Au grating region (red square) and quenched outside (blue square). However, when the excitation is below the bandgap (excitation at 800 nm), the emission at the Au grating is also enhanced 120-fold, and it shows different behavior that can attribute to the absorption of light by the plasmonic metal nanostructure, its conversion into hot electron-hole pairs, and subsequent excitation transfer into MoS_2 layer. In the blue square region in figure 2c again, a quenching in the photoluminescence is observed. It is important to note that the quantum yield of the two-photon

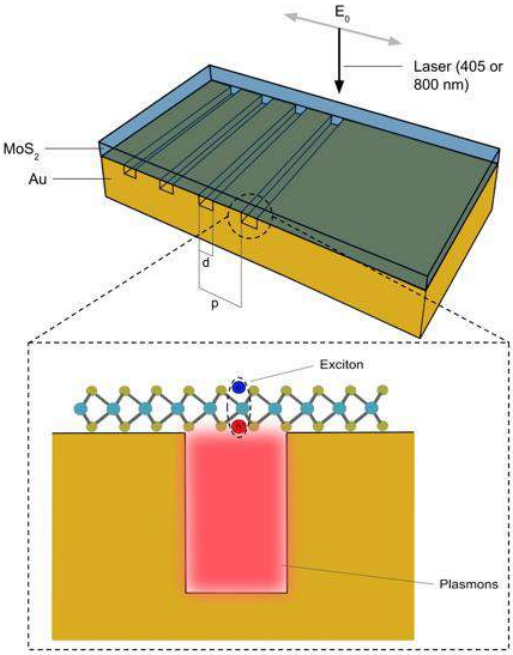

Figure 1 - Schematic diagram of MoS_2 deposit on metallic nanostructures.

absorption of the MoS_2 is extremely low.

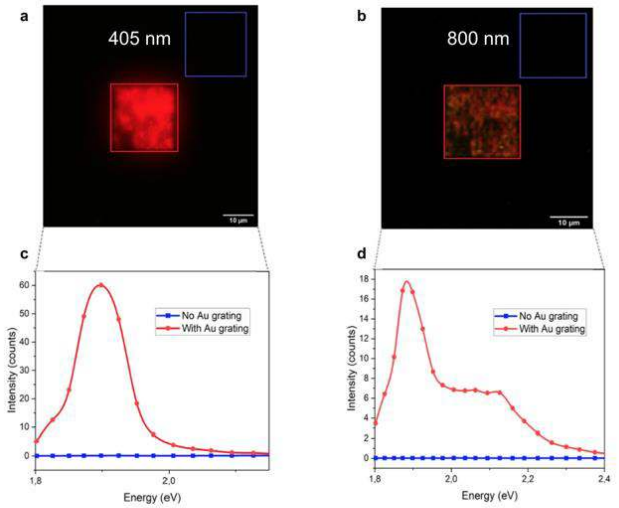

Figure 2 – a) and b) confocal spectral images of 20x20μm square metallic grating with slits separated by 400nm and a width of 50nm. c) and d) spectral deconvolution of the red and blue square regions.

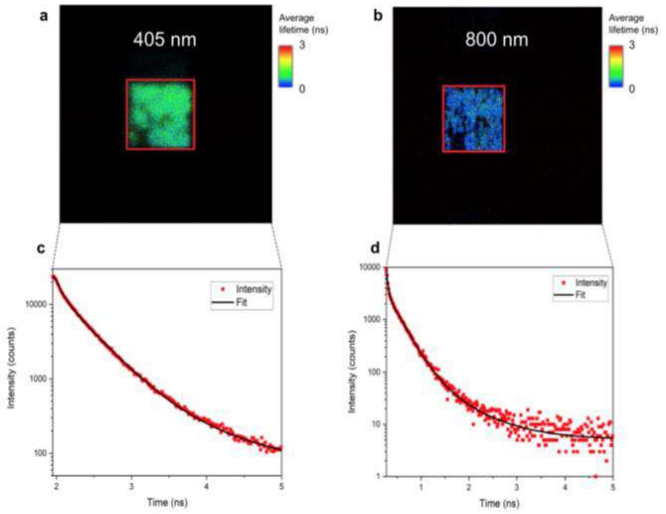

Figure 3 – a) and b) Fluorescence lifetime confocal images of the same structures as in figure 2. c) and d) the average time decay of the red square region.

Fluorescence lifetime images were performed to investigate the mechanisms between the emission properties at the two incident photon energies (see figure 3). The average lifetimes on the Au grating structure are significantly larger when the excitation is at 405 nm compared with the 800nm excitation. This shows that the recombination mechanisms happen faster for plasmon-mediated processes and must be considered when designing optoelectronic devices operating in this energy range.

This study can provide a new understanding of the plasmonic-excitonic interaction in these hybrid metal/semiconductor devices and paves the way toward implementing plasmon-enhanced transition metal dichalcogenide photodetectors, sensors, and emitters.

Abstract: Being able to control the excitonic flux is a mandatory step for the development of future room-temperature excitonic quantum devices. Transition metal dichalcogenides (ML-TMD) with stable and mobile excitons are highly attractive in this prospect. However, generating an efficient and controlled exciton diffusion over long distances has proven quite complex. Here we demonstrate that ML-TMD based lateral heterostructure (MoSe2/WSe2) acts as an efficient excitonic diode[1], with an excitonic flux that can be controlled through near-field engineering.

In our work, we investigate experimentally and theoretically the effect of atomically sharp $MoSe_2/WSe_2$ lateral heterostructure (LH) over the exciton diffusion. Using Tip Enhanced Photoluminescence measurements (TEPL), in combination with a modified diffusion theory[2], we show that at the steady state, due to the presence of the excitonic asymmetric potential at the interface, an area is formed in which the diffusion properties are modified becoming strongly asymmetric. This partition zone is extending hundreds of nanometers away from the LH forcing excitons to move, toward the junction, up to five time their diffusion length (LD) before recombining without affecting neither the potential, recombination rate, or mobility of the propagating quasi-particles. Furthermore, we performed time dependent PL imaging experiments that show that in WSe_2, LD is strongly dependent on the excitonic density (n). By comparing the diffusion properties of fully h-BN encapsulated LH and h-BN supported LH, without top h-BN layer, we demonstrate that the diffusion properties of the LH can be tuned by increasing the excitation laser power or by modifying the optical near field configuration[3] (at constant laser power).

Abstract: To increase the efficiency of energy harvesting, technologies that can utilize weak thermal energies existing in environments are in demand; however, conventional technologies fail to realize this objective because energy accumulation does not occur in them. Herein we propose a metamaterial thermal engineering technique by which thermal energy can be accumulated from the surrounding environment and can be converted into electricity.

Thermal energies existing in the environment are one of the reliable energy resources. Technologies that can utilise weak such thermal energies are needed to satisfy the demands for increased energy utilisation. However, thermal energies are emitted from objects into the atmosphere, e.g. cars, machines, and buildings, and are present in extremely diluted form in the atmosphere, making it difficult to accumulate and utilise the energies.

Herein we propose metamaterial thermal management that can be used to accumulate diluted thermal energies existing in ambient air. Using the metamaterial thermal engineering, we realised a thermoelectric device that can produce electricity even in a uniform-temperature environment. We attached a metamaterial absorber (MA) on the surface of one of the thermoelectric device edges (Fig. 1(a,b)) and kept the device in a uniform-temperature environment. Using the large difference in absorptivity of the device edges produced by the MA, a temperature gradient is produced even when the device is subjected to uniform and isotropic thermal radiations, leading to thermoelectric generation (Fig. 1(c)).

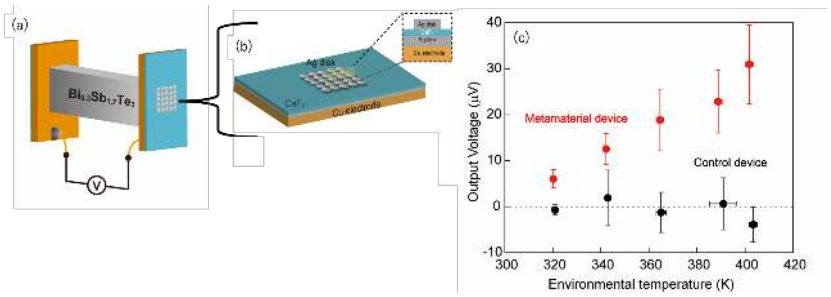

Fig. 1 Schematics of (a) a thermoelectric device loaded with the metamaterial electrode and (b) metamaterial array. (c) Dependence of the output voltages generated on the metamaterial device (red) and a control device (black) on the measured environment temperatures.

Hyperbolic meta-antennas: magnetic and electric modes

Sema Ebrahimi,[1,2,3,*] Alina Muravitskaya,[2,3] Ali M. Adawi,[2,3] Anne-Laure Baudrion,[1] Pierre-Michel Adam,[1,*] Jean-Sebastien G. Bouillard[2,3,*]

Abstract: Coupling hyperbolic metaparticles is the next step in metamaterial applications, providing tunable electromagnetic properties on demand. Here we present the magnetic and electric modes in hyperbolic meta-antennas arising from the coupling of metaparticles. We show the existence of two coupling regimes for the magnetic modes, and demonstrate a fine control over the electrical field spatial distribution, opening the route towards a wide range of applications from magnetic nanolight sources and magnetic forces engineering, to single photon sources, and subwavelength lasers.

Metamaterials, by providing custom engineered optical properties, offer new ways of manipulating electromagnetic waves. Hyperbolic metamaterials specifically can support high-k modes, large increases in photonic density of states, and high refractive index structures beyond what is available in nature, therefore enabling new ways to engineer light-matter interactions.[1,2] It is therefore not surprising that HMM have found a vast range of applications encompassing single-antenna biosensing, plasmonic-based lasing, photovoltaics, and hot-electron generation technologies.[3-5]

Hyperbolic metaparticles, created by nanostructuring hyperbolic metamaterials, represent additional possibilities to bulk metamaterials, and have therefore been at the center of recent research with the promise of many exotic applications. Hyperbolic metaparticles built from alternating metal-dielectric multilayers support two well-separated electric and magnetic resonances. However, the study of hyperbolic nanostructures has so far focused on isolated metaparticles, despite the fact that mode coupling in metamaterial nanostructures will pave the way for novel optical phenomena unavailable in isolated metaparticles and allow to fully capitalize on their many opportunities.

Here we introduce a new class of hyperbolic bowtie meta-antenna based on a type II hyperbolic bulk metamaterial. The meta-antenna is constructed from a gold-titanium dioxide multilayer system, in which both the geometrical and material parameters are kept within the possibilities of current experimental nanofabrication techniques. Using finite difference time domain (FDTD) simulations, we explore the mode structure supported by such a hyperbolic system and evidence the existence of both electric and magnetic coupling in those meta-antennas.

After identifying the modes supported by this type of meta-antenna, we compare the optical behaviour of full multilayer geometry to the corresponding effective medium system for a range of filling factors. We then study the mode coupling inside such a meta-antenna by fully exploring the parameter space, including the gap size, filling factor, and incident polarisation. Whereas the coupled electric mode results in a field enhancement along the height of the meta-antenna nanogap, the magnetic coupling, on the other hand, follows two regimes depending on the interplay of the individual magnetic dipole moments. With both coupling controllable through the effective permittivity, gap size, and incident polarization, such novel hyperbolic meta-antennas open the

route for applications in optical sensors, single photon sources, sub-wavelength meta-cavity lasers, as well as magnetic nanolight sources, chiral quantum optics, magnetic forces engineering, active control of metamaterial nanostructures, and quantum interfaces for non-reciprocal processing of light.

Abstract: Hot carriers photoinduced by fs-laser pulses in photonic nanostructures have been widely investigated. In most of the works a spatially homogeneous excitation pattern is assumed. Here we show how ultrafast hot carrier spatial inhomogeneities at the nanoscale can manifest and even dominate the transient transmission of photonic metasurfaces. An inhomogeneous version of the three-temperature model has been validated on pump-probe spectroscopy measurements in plasmonic metasurfaces. Our results pave the way for the design of novel ultrafast nanophotonic devices.

Hot carriers photoinduced by intense laser pulses in nanomaterials have been the subject of intensive research, both for fundamental aspects and novel applications. Among the latter, ultrafast all-optical modulation of light has recently attracted a strong interest (see, e.g., Refs. 1, 2 for an overview). However, despite the many papers published so far in the field, it is only until very recently that spatial inhomogeneities of the photogenerated hot electrons have come into play [2-10].

Here we report on an agile modeling approach based on an extended, inhomogeneous, version of the more classic three temperature model (I3TM) [1,2], capable of grasping the key phenomena involved in the spatio-temporal dynamics of hot carriers photogenerated at the nanoscale. The theoretical predictions of the I3TM have been validated on ultrafast broadband pump-probe measurements of gold metaatoms.

We then show how it is possible to engineer the metaatom configuration so to exploit these spatial transients for novel functionalities. In particular, we demonstrate unprecedented ultrafast reconfiguration of giant dichroism by simply acting on the polarization of the fs-laser control pulse in plasmonic metasurfaces with Au nanocross metaatoms [8]. Moreover, we highlight the key role of spatial inhomogeneities on the temporal dynamics of the ultrafast reconfiguration for plasmonic metaatoms with high aspect ratio. Pronounced discrepancies between homogeneous and inhomogeneous models are indeed retrieved, possibly resulting in opposite signs for the predicted transient signal even for relatively low fluences (~mJ/cm^2 level) [9].

Finally, we show how a similar modeling approach can be applied to all-dielectric nanomaterials, and provides the capability to explain the origin of the picosecond time delay with which the peak of the transient optical response is observed in AlGaAs nanopillars excited with ~100 fs laser pulses [10].

This work is part of the METAFAST project that received funding from the European Union Horizon 2020 Research and Innovation program under grant agreement no. 899673.

Ultrafast phenomena at the interface of plasmonic/semiconductor hybrid systems

M. Zavelani-Rossi[1,2]

Abstract: Hybrid plasmonic/semiconductor junction allow providing and controlling interesting physical functionalities, such hot-electron charge transfer or plasmon induced resonance energy transfer. Ultrafast transient absorption spectroscopy is an effective tool to study the junction behavior. Here, gold plasmon nanostripes coupled to a 2D transition metal dichalcogenide (MoS_2) and silver nanoparticles decorating ZnO nanorods are considered. Experimental data together with an analytical model and crossed results, allow disclosing the physics of the systems, providing important information for fundamental knowledge and future applications.

Targeted design of plasmonic/semiconductor hybrid assemblies can promote new physics and new high-performance functionalities in optoelectronic devices. In particular, the interaction of the electromagnetic optical field with a structure composed by a low dimensional plasmonic noble metal coupled to a semiconductor can give rise to various physical phenomena, that can be exploited for energy harvesting, photocatalysis and biological sensing, to mention a few examples.[1–2] The strong light interaction, induced by plasmonic effects, fosters several unique phenomena such as electric field enhancement, tunable light absorption (from visible to infrared region) and generation of hot-electrons. The study of the carrier redistribution after photo-excitation in a plasmonic/semiconductor junction is crucial to determine the physical process, to assess the relaxation routes and to characterize the time-scale of the phenomena involved. This knowledge is beneficial both for fundamental physics of hybrid systems and for practical applications.

Among various interesting systems, the junction between a noble metal plasmonic object and a semiconductor is particularly interesting because hot-electrons generated in the metal can possibly overcome the barrier offset and travel into the conduction band of the neighboring semiconductor. The physics is very intriguing and highly debated because different routes mechanisms can take place, like direct electron transfer, or plasmon induced resonance energy transfer.[3,4] These processes occur on an ultrashort time scale, ranging from a few tens of femtoseconds to a few picoseconds.

Here, I will discuss two notable examples. The first one consisting of a 2D transition metal dichalcogenide (TMDs), a few-layer MoS_2, coupled to gold plasmonic nanostripes (NSs);[5,6] the second consisting of ZnO nanorods (NRs) decorated with silver plasmonic nanoparticles (NPs).[7] I will show the ultrafast transient absorption dynamics, obtained on a wide spectral range (350-700 nm), with high temporal resolution (<100 fs), and tunable pump excitation (in the near UV-visible spectral region). Experimental results are compared with an analytical model and with other data. A comprehensive scenario of the charge/energy transfer is thus provided.

For the Au NSs/MoS_2 architecture, multiple transient absorption measurements are presented (Figure 1a), enabling quantitative comparison between the ultrafast behavior of metal nanostructures, TMDs, and their assembly. This allows providing the evidence of plasmon-enhanced charge injection from Au NSs to the 2D semiconductor, which occurs in less than 200 fs. Numerical modeling corroborates the charge transfer mechanism.

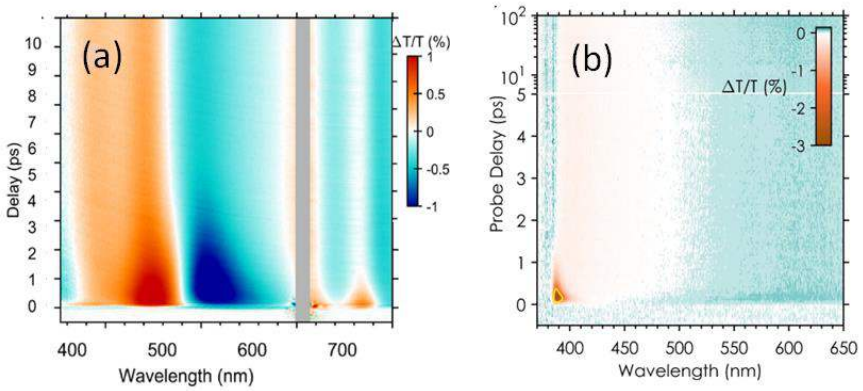

Figure 1: Transient absorption maps, (a) Au NSs/MoS_2, (b) Ag NPs/ ZnO NRs.

For the Ag NPs/ ZnO NRs system, a comparison is made between decorated and non-decorated NRs. Photoluminescence, transient absorption (Figure 1b) and photoresponse are studied. Following photo-excitation of the system, a fast electron redistribution is evidenced, favored by the tiny energy difference between the conduction band of ZnO and the Fermi level of Ag. Moreover, a fast and effective population of ZnO NRs trap states, mediated by Ag NPs plasmonic response, appears. All together, the whole set of data indicate a non-radiative optical field coupling mechanism of Ag NPs with ZnO, with hot-electron injection, that takes place in less than 500 fs.

Overall, it appears that ultrafast transient spectroscopy is an effective tool to shed light on the physical processes in metal plasmonic/semiconductor systems. It is noteworthy to mention that these results can be applied to different hybrid architectures.

Nanophotonic Tools for Lipid Membrane Sensing and Manipulation

T. Lohmüller[1]

[1] Photonics and Optoelectronics Group, Nano-Institute Munich, Department of Physics, Ludwig-Maximilians-Universität (LMU), Königinstraße 10, 80539 Munich, Germany
*corresponding author: t.lohmueller@lmu.de

Abstract: A new approach is presented for monitoring the photoisomerization dynamics of photolipid bilayer membranes on the nanoscale using plasmonic sensing. The azobenzene group in photolipids enables optical control over various membrane parameters, such as lipid mobility and thickness, but measuring the switching dynamics in a bilayer is challenging. We demonstrate that plasmonic sensing with single gold nanorods allows for analyzing membrane photoisomerization and corresponding changes in bilayer thickness with high spatio-temporal accuracy.

Synthetic lipid bilayer membranes are a key model system to study and emulate the physical properties of native plasma membranes. However, controlling membrane dynamics and reorganization with high spatio-temporal resolution is challenging and often involves drastic changes in experimental conditions. At the same time, lipid bilayer properties are mostly characterized by fluorescence techniques, which provide high sensitivity but require a fluorescent label that itself might interfere with bilayer properties. To overcome these limitations, we developed nanophotonic tools that enable precise control and monitoring of membrane properties at fast time-scales.

We used photolipids containing an azobenzene group in their lipid tails, which undergoes a conformational change upon illumination with UV and visible light, as a model system[1]. Introducing this lipid photoswitch into a bilayer membrane provides optical control over a variety of membrane parameters, including fluidity[2], mechanical properties[1], and thickness, among others[3,4]. However, analyzing the fast switching dynamics in the bilayer, which is only ~4 nm thin, is challenging due to a lack of sensitive tools. X-ray scattering (e.g. SAXS) is widely used, but it does not provide sufficient time resolution to monitor fast switching dynamics.

To address this challenge, we conducted an experiment using plasmonic gold nanorods deposited on a glass substrate and coated with a supported photolipid bilayer. We demonstrate that analyzing the scattering spectra obtained from single nanorods makes it possible to resolve the dynamics of the azobenzene switch between *cis* and *trans* isomer. We found that membrane photoisomerization leads to a reversible shift of the plasmon resonance over many switching cycles, which highlights the potential of plasmonic nanoparticles as sensitive probes to study the dynamics and photostationary states of lipid bilayer membranes with high accuracy and within nanoscale environments.

Our results demonstrate the potential of using hybrid nanosystems of photolipid molecules and plasmonic nanoparticles as light-sensitive nanoagents for controlling biological systems in space and time. By enabling precise control and monitoring of membrane properties, these nanophotonic tools can offer new insights into the behavior of biological membranes and pave the way for the development of new therapeutic and diagnostic applications.

Photodoping of plasmonic doped metal oxide nanocrystals for the direct storage of solar energy

Ilka Kriegel

[1]Functional Nanosystems, Italian Institute of Technology, via Morego 30, Genova, Italy

[*]corresponding author: ilka.kriegel@iit.it

Abstract: We are currently investigating novel processes that work towards the direct storage of solar energy by investigating nanomaterials that act as light-charged (nano-)capacitors. In this talk, I will present our work towards the understanding of the fundamental processes underlying this novel concept. I will present our endeavors in the production of novel nanomaterials, their photophysical and theoretical characterization. Finally, I will give insights into the challenges of device fabrication for this novel system.

Energy from sunlight is a promising alternative solution for the global sustainable energy crisis. However, there is a significant drawback related to the intermittency of the Sun. Potential solutions relate to the use of solar energy to produce useful chemicals, i.e. photocatalysis. Alternatively, novel technologies are developed that permit the direct storage of solar energy. A promising approach towards the latter is the photodoping of plasmonic, doped metal oxide nanocrystals, such as indium tin oxide or doped zinc oxides. The fundamental physical process initiates with the absorption of photons with light beyond the bandgap. An electron hole pair is created. When the hole reacts with sacrificial hole scavengers, such as ethanol, the extra electrons remain stored within the nanocrystal. This process can be repeated multiple times accumulating up to hundreds of electrons per nanocrystal,[1, 2] thus, photodoping displays the potential to combine light absorption, charge separation, and accumulation in the same set of materials.[3] Capacitance values, comparable to commercially available supercapacitor materials have been reported for this light-driven charging process.[4] Within this talk I will give fundamental insight into the mechanism of charge storage within metal oxide nanocrystals. I will further discuss open questions with regards to their implementation as novel light-driven multi-charge accumulation components in the next generation of solar energy devices.

For this work, the authors acknowledge the support of both European Union's Horizon 2020 European Research Council, under grant agreement no. 850875 (Light-DYNAMO) and European Union's Horizon 2020 Research and Innovation program under grant agreement no. 101017821 (LIGHT-CAP).

Abstract: The careful geometrical design of plasmonic nanocrystals (NCs) allows not only to manipulate their optical response, but also to generate heat efficiently. Here we present a opto-thermal study of plasmonics NCs but with complex shapes. We use a two-temperature model to study the ultrafast photothermal responses, and we solve for the lattice and the electronic temperatures. We observe the creation of local modifications of the dielectric function via the temperature, which leads to the thermal imprint of plasmonic hotspots.

Abstract: Detecting molecular chirality is crucial in biochemistry. It is, however, limited by low sensitivity at low concentrations. I will discuss our progress to push the limits of chiral sensing by exploiting semiconductor nanophotonics.

Chirality plays a pivotal role in the functionality of biomolecules such as proteins, amino acids, and carbohydrates. Circular dichroism can distinguish enantiomers thanks to a small difference in the absorption of circularly polarized light. However, chiral sensing faces significant limitations due to inherently weak chiroptical signals. It is thus severely limited by low sensitivity and low spatial resolution. As a result, it is challenging to resolve the chirality of individual nanoscale objects using light for critical applications such as detecting protein aggregates linked to various diseases. In this presentation, I will discuss our progress in pushing the sensitivity limits of optically resolvable chirality by exploiting semiconductor nanophotonics. I will show several strategies to optimize chiral molecular sensors based on silicon metasurfaces to detect low molecular concentrations. Specifically, I will present our recent results on tailoring silicon nanostructures to enhance polarized fluorescence [1, 2] and Raman spectroscopies, increase optical chirality and maximize chirality transfer [3, 4]. Our results promise an increase in sensitivity towards the detection of single chiral molecules compatible with high-resolution imaging.

Top-down and bottom-up fabrication of electro-optic flat photonic devices

R. Grange*[1]

[1]ETH Zurich, Optical Nanomaterial Group, Institute for Quantum Electronics, Department of Physics, 8093 Zurich, Switzerland
*corresponding author: grange@phys.ethz.ch

Abstract: We will demonstrate the fabrication of devices with lithium niobate and barium titanate material for applications in telecommunication and quantum optics.

Nonlinear and electro-optic devices are present in our daily life with many applications: light sources for microsurgery, green laser pointers, or modulators for telecommunication. Most of them use bulk materials such as glass fibres or high-quality crystals, hardly integrable or scalable. Even the fast developments of thin film lithium niobate face the challenging etching of metal-oxides. Therefore, the quest for a non-centrosymmetric material system, easy to fabricate and to scale up while maintaining its functionality is still ongoing. Here we will present our recent advances in top-down fabrication of lithium niobate devices[1], and bottom-up assemblies of randomly oriented nanocrystals to produce electro-optic, nonlinear and parametric down conversion signals[2]. First, barium titanate metalenses synthesized by a sol-gel technique will be demonstrated. Then, we will show how the electro-optic response in assembled nanostructures can be as strong as certain other perfect crystalline structure. Finally, we will generate photon pairs from free-standing lithium niobate microcubes through the spontaneous parametric down-conversion process[3].

Abstract: Collective lattice excitations known as surface lattice resonances (SLRs) enable to realize high-Q factor metasurface resonators. Here, we show how multiple high-Q SLRs can be utilized to realize flat resonators with a potential of increasing the nonlinear optical responses of metasurfaces. We will also theoretically demonstrate an approach towards ultra-high-Q SLRs (Q>10 000) by studying hybrid metasurface–waveguide structures.

Nonlinear optical processes provide the basis for many photonic applications, such as all-optical switches and frequency comb-based spectroscopy. Current trend in improving energy-efficiency of such nonlinear devices is to move towards small-scale and integrated devices. But it is challenging to realize strongly nonlinear integrated components by using conventional nonlinear materials, which motivates the search for alternative material platforms. Nonlinear metasurfaces have recently emerged as an interesting candidate to enable nanoscale/flat nonlinear optics [1–3]. Despite steady progress, the so far achieved conversion efficiencies have not yet rivalled conventional material platforms [4], motivating to increase the achievable conversion efficiencies of metasurfaces by increasing their associated Q-factors.

We will present our recent works to develop more efficient nonlinear metamaterials exhibiting high-Q-factor SLRs [1–3]. These resonances are associated with very narrow spectral features, showing potential to dramatically boost nonlinear processes via resonant light–matter interactions [2]. We will first discuss of our recent experimental demonstrations of multiply-resonant metasurfaces [3], and demonstrate that the lattice-sum approach (LSA) is a simple yet powerful method to understand the optical responses of SLR-supporting metasurfaces. Then, we will discuss of our recent theoretical work where we extend the LSA formalism to multipartite arrays, arbitrary incidence angles, and hybrid metasurface–waveguide structures. In particular, we show how placing metasurfaces inside waveguiding structures, the coupling between nanoparticles can be dramatically increased providing a clear route towards higher Q-factors. Even more interestingly, the associated waveguide modes become strongly dispersive near their cut-off frequencies, which provides a new mechanism to further increase the attainable Q-factors. This is particularly interesting, since it may enable to experimentally realize ultrahigh-Q-factor metasurfaces (Q>10 000) with smaller number of nanoparticles.

Chiral plasmonic metasurfaces self-assembled from non-chiral metallic nanowires and nanorods

W. Wu, V. Lemaire and M. Pauly*
Université de Strasbourg, CNRS, Institut Charles Sadron, Strasbourg, France
*corresponding author: matthias.pauly@unistra.fr

Abstract: Large-area chiral multilayer thin films are prepared by combining Grazing Incidence Spraying and Layer-by-Layer assembly from anisotropic plasmonic nanoparticles. The resulting giant chiroptical properties can be finely tuned over a broad wavelength range using simple design principles, reaching ellipticity values higher than 13° and g-factor values up to 1.6 in the visible and near-IR range. The chiroptical properties of helicity-preserving chiral mirrors will also be discussed.

Chiral assemblies of plasmonic nanoparticles have attracted increasing attention over the last years due to promising applications in fields such as molecular sensing or as optical circular polarizing elements.[1] Metamaterials that can control the flow of electromagnetic waves in unprecedented ways need to have subwavelength dimensions, i.e. in the range of tens of nm for optical applications, and their properties are not only governed by the constitutive materials but also often depend on the nanoscale structure and hierarchical organization of the individual building blocks. Such metamaterials have mostly been manufactured by top-down technologies that have the disadvantage of being expensive and slow. Obtaining large areas and regular (3D) ordering is difficult, and nanoparticle self-assembly is a promising alternative. A big challenge resides in the hierarchical organization of the nanoscale building blocks into two- or three-dimensional structures with well-controlled location and orientation across multiple length scales.

In this talk, I will present how Grazing Incidence Spraying can be used to assemble anisotropic nanoparticles as mono- and multilayer thin films[2-3] on large areas with tuneable particle density and orientation (Fig. 1a). Furthermore, the combination with the Layer-by-Layer assembly technique[4] allows building helical (and thus chiral) multilayer large-area thin films in which the composition and orientation can be controlled independently in each layer (Fig. 2b, c).[5]

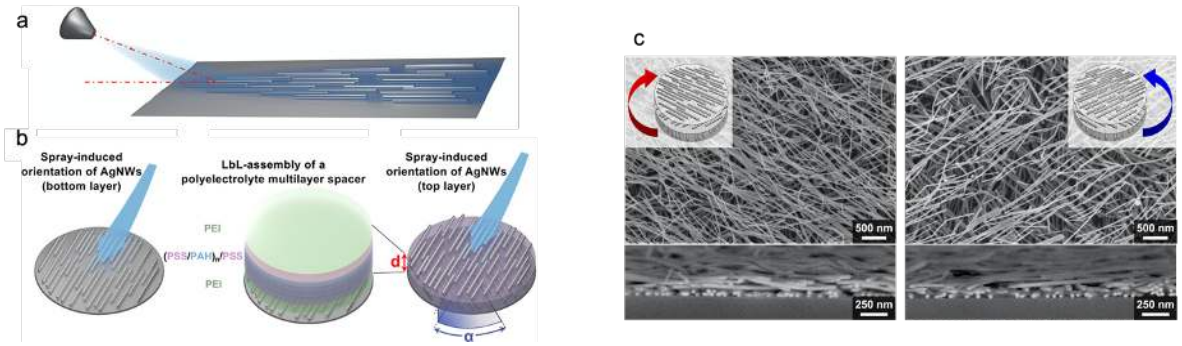

Figure 1: a) Schematic of the spray-induced orientation of nanowires. b) Schematic of the Layer-by-Layer assembly of oriented nanowire layers to prepare chiral Bouligand metasurfaces. c) SEM images (top-view and cross-section) of left-handed and right-handed 3-layer silver nanowire metasurfaces.

These films display very high chiroptical activity over a broad wavelength range (Fig. 2a) with g-factor values up to 1.8 in the near IR range (Fig. 2b).[6] The optical properties (polarized transmittance, CD spectroscopy and Mueller Matrix Polarimetry) as function of the thin film geometry will be detailed, with a special emphasis on how the chiroptical properties depend on the architecture of the assembly. The properties of chiral mirrors built from these assemblies will also be discussed.

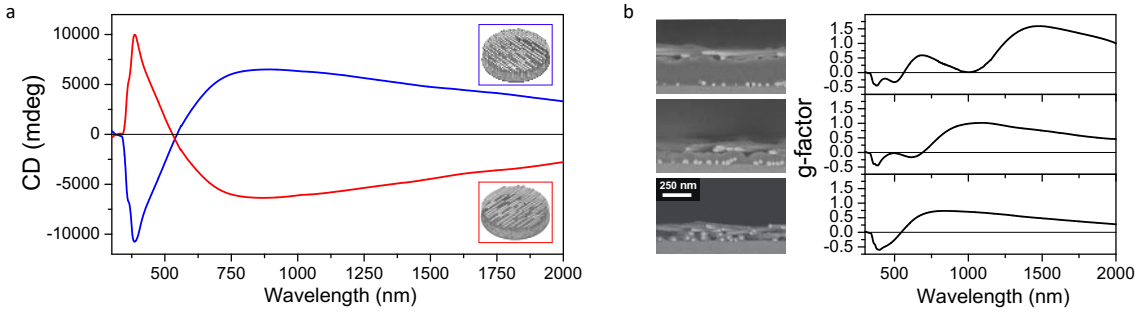

Figure 2: a) CD spectra of left-handed and right-handed chiral plasmonic nanostructures. b) Cross-section SEM images and g-factor spectra of chiral plasmonic thin films of increasing interlayer spacing.

Abstract: talk discusses how photonic cavities can be coupled to an infrared nanocrystal film not only to reshape the absorption but also to achieve new properties such as bias reconfigurable response.

To motivate this work, I will start by a few words regarding the integration of infrared nanocrystal as active material for infrared sensing and imaging [1]. In particular I will discuss how nanocrystal ink have dramatically simplify the coupling between the active layer and the at circuit making pixel pitch reduction possible.

In spite of this success, current devices still present a poor coupling to the incident light and most of it is generally not absorbed, limiting the overall device performance. This raises the need for a control of the light matter coupling though the coupling of the film to photonics cavity. I will review some of the development made in the group [2] relying on grating used both as cavity and contact electrodes. Though the initial goal was to boost the absorption and photoresponse of device we also have realized that it enables the design of bias reconfigurable photoresponse [3]. Two key ingredients are required which are (i) an inhomogeneous absorption generated by the cavity and (ii) a bias dependence diffusion length which comes for free thanks to hopping conduction. I will discuss some development that we have made in this direction starting from observation of small bias induced shift up to the development of structure where broad spectral window can be turned on and off

E-mail : shuwen.zeng@utt.fr

Abstract: Surface plasmon resonance sensors are commonly used an effective tool for real-time monitoring biomolecular interactions. The sensing mechanism is based on the evanescent field perturbation at the metallic sensing substrate induced by the binding of chemical and biological molecules. Molecular binding interactions could be measured from the signal of reflected light, under the condition that the surface plasmon resonance is excited by the incident light. In this talk, I will present the use of hybrid 2D nanomaterials-based metasurface nanostructure as an enhanced sensing substrate. The thickness of the plasmonic sensing substrate is tuned in an atomic scale and optimized to improve the sensing capability. Here, both a sharp phase signal change and phase-related Goos-Hänchen signal shift were achieved due to the strong resonance at the surface of the sensing film. The enhanced plasmonic sensitivities of 2D nanostructures were systematically investigated. It is worth noting that the tunability of atomic layer led to the sensing substrate optimized with a narrow scale < 1 nm. Through a precise engineering of the metasurface substrates, 3 orders of magnitude improvement of the sensitivity were demonstrated compared to the one with pure gold sensing substrate. This hybrid 2D nanomaterial-based metasurfaces would provide a good opportunity for developing portable theranostic devices in clinical applications.

Active control of the nanoparticle self-assembly for photonic applications

T. Erdem[1*]

[1]Department of Electrical-Electronics Engineering, Abdullah Gül University, Erkilet Bul. Sumer Campus, Kayseri Turkey
[*]corresponding author: erdem.talha@agu.edu.tr

Abstract: Colloidal nanoparticles enable collective utilization of the inherent properties of the nanoparticles. Furthermore, their collective optical response can be fine-tuned employing DNA-driven self-assembly. Here, we present that the optical transmission of self-assembled DNA-functionalized gold nanoparticle network can be actively manipulated using an external optical excitation. We also show control of optical polarization of emitted light from semiconducting supraparticle networks hybridized with magnetic supraparticles. These results prove the potential of programmed nanoparticle self-assembly in tailoring optical features of colloidal systems.

Conventional technologies of fabricating optical materials are usually complex, costly, and energy consuming. Chemical syntheses and functionalization of colloidal nanoparticles, which may possess semiconducting, metallic, or dielectric characteristics, offer solutions to some of these problems. Especially, programmed self-assembly of the nanomaterials using DNA-DNA interactions allows for obtaining optical features that cannot be easily obtained using conventional micro- and nanofabrication methodologies. We now add another functionality to the optical systems made of colloidal nanoparticles. Our idea relies on tailoring the structure of the colloidal nanomaterial network using external means leading to controlling the optical features of these systems.

In our first study, the temperature dependence of DNA-DNA interaction was utilized. A double-stranded DNA molecule consists of two different single-stranded DNA molecules with complementary base chains linked by hydrogen bonds. When the temperature of the environment increases, the hydrogen bonds break and the double-stranded DNA molecule splits into two single-stranded DNA molecules. When the temperature decreases, recombination occurs. In our study, we focused on controlling the binding-unbinding process of the nanoparticles with the help of an external light source and tailoring the light transmittance, not by changing the temperature on a macroscopic scale [1]. For this purpose, gold nanoparticles with a diameter of 20 nm were synthesized, and then single-stranded DNA molecules functionalized with thiol groups were attached to these particles. The nanoparticle sample was split into two groups such that complementary DNA strands were attached to the nanoparticles in each group. Next, a nanoparticle network was successfully produced from these materials by mixing DNA-functionalized gold nanoparticles. Then, using a green handheld laser, the nanoparticle network was successfully heated locally, enabling the separation of the gold nanoparticles that had formed a nanoparticle network. As a result, the optical transmittance of the structure was increased by 30%. Furthermore, clear openings were detected using an optical microscope in the regions illuminated by the laser beam.

In another study [2], which aims to actively control optical properties, supraparticles were formed from semiconductor quantum dots and magnetic nanoparticles. Complementary single-stranded DNA molecules were attached to these particles via copper-free click chemistry. By mixing the two types of supraparticles, magnetic supraparticles were connected to supraparticles containing semiconductor quantum dots. Thus, a hybrid particle

network was formed. By applying an external magnetic field to this particle network, the magnetic particles were forced to line up in the direction of the magnetic field. In this way, the linear polarization of the light emanating from the semiconductor quantum dots was successfully changed and the polarization ratio was increased to 1.9. In this study, it has been successfully demonstrated that radiation can be actively controlled by an external effect.

We expect our work, briefly summarized above, to open the door to innovative fabrication methods and innovative applications of nanophotonic structures.

We are grateful to Tübitak for 2247-A Program Grant No. 120C124.

Abstract: The need for photon and electron transport is necessary for quantum information, although very difficult in practice due to the different scales involved. In this work, we propose two different approaches to tackle this problem. The first consists of a hybrid plasmonic nanosystem comprising two types of nanosources placed strategically on a nanowire electromagnetic waveguide. The second is based on the integration of a single photon source, with a photonic structure consisting of optical waveguide used in photonics integrated circuits.

For nanophotonics and quantum photonics, it is of paramount importance to be able to efficiently couple nanoemitters and quantum emitters with photonic structures such as photonic waveguides[1], in order to be able to scale-up for any practical purposes. As a proof of concept, we use colloid semiconductor nanocrystals[2] (NCs) as nanosources of light which are also capable of single photon emission. At first, we couple different NCs on the same plasmonic structure based on a silver nanowire (Ag-NW) waveguide[3]. We then move on to another photonic platform which compatible on a larger scale with standard photonics (such as optical fibers) using ion exchanged waveguides (IEW).

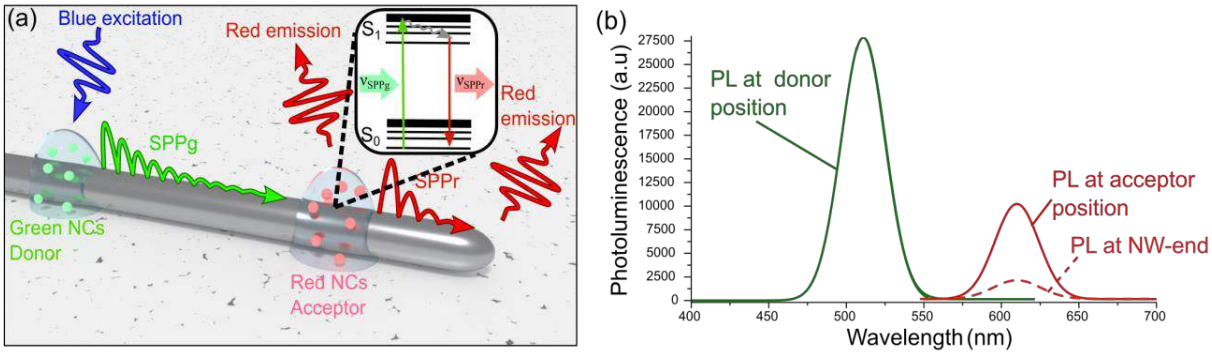

Figure 1-a Artistic view of a hybrid plasmonic nanosystem, -b PL spectra of emission on different zones. 405 laser focused on the intersection of the lines containing green QDs and the NW – donor position.

In the first case, using silver nanowires, we realize efficient acceptor-donor hybrid nano-systems where different nano-nodes can interact with each other as depicted in Fig.1-a, where 'green' surface plasmon polaritons are transformed into red plasmon polaritons at controlled sites of the silver plasmonic nanowaveguide, as a result of a plasmon-polariton conversion. Fig.1-b shows the photoluminescence (PL) obtained at different locations of the nanowire for excitation of donor NCs via a 405 nm laser. We demonstrate that Ag-NW nanowaveguides can support multi-mode propagating surface plasmon polaritons and thus defining a fundamental building block for plasmonic/nanophotonic integrated circuits.

To go even further, a single photon emitter NC was coupled to a glass waveguide connected to an optical fiber. Fig. 2-a provides a schematic of our system where we have the photonics structure made of a semi-buried IEW and a single NC as a quantum emitter on top of it. In between, a secondary waveguide has been fabricated in order to have a smooth adiabatic coupling of the NC with the micro-size waveguide. The NC emitter was then tested to demonstrate single photon emission as depicted in Fig. 2-b by the second order correlation function $g^{(2)}$ where the lowered central peak is a clear evidence that we have a single photon source from a single NC emission and this was obtained after connecting the glass waveguide to an optical fiber.

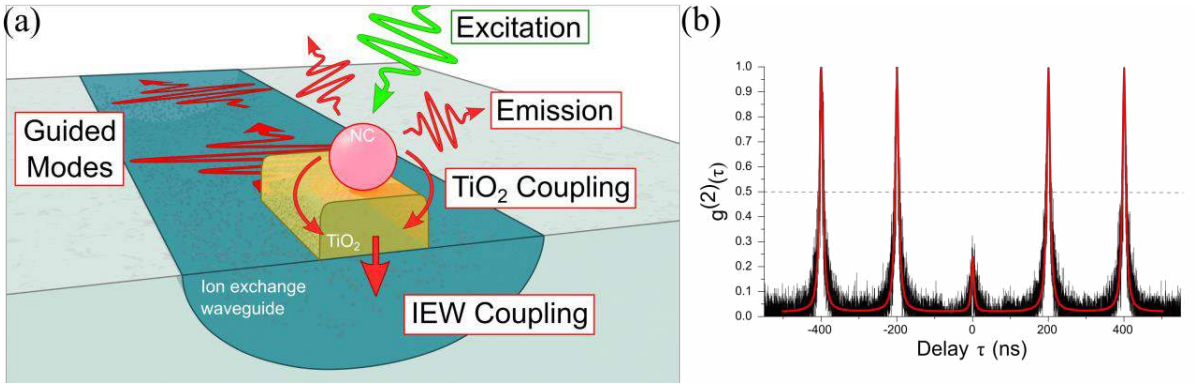

Figure 2 (a) Artistic view a single photon source integrated on Ion Exchange Waveguide. (b) Second order correlation function for the single NDs on the IEW/TiO_2 with a pulsed excitation laser at 532 nm.

We demonstrate in this that it is possible to effectively couple and control the position of nanoemitters to different photonic structures. Perspectives of this work are to optimise the coupling of nanoemitters to photonic structures as well as the use of color centres in nanodiamonds[4] as nanoemitters which are more compatible with more complex quantum photonic networks[5].

Abstract: Integrated photonics is a remarkable platform for the realization of quantum computations due to its flexibility and scalability. Here we propose a novel paradigm exploiting twisted waveguides as a building block for polarization-encoded quantum photonic computations on a chip. We unveil a transformation (gate) matrix in the closed form and demonstrate that twisted waveguides can implement arbitrary Bloch sphere rotations. The outcomes of this research may open a new direction in the development of quantum computing architectures on a chip.

To encode information in a single photon one must use its physical degrees of freedom such as path, momentum, angular momentum, and polarization. For reaching a higher information processing capability per chip footprint it is desirable to make use of the maximum possible number of them. Photon polarization is an always-available natural degree of freedom and is thus among the most widely used encoding mechanisms. To benefit from using an integrated platform it is crucial to perform most or ideally all light manipulations on a chip as most losses occur at a stage of coupling light into a chip or from a chip. However, despite the recognized strength of integrated photonics in controlling light, manipulation of polarization on a chip yet remains elusive.

Although integrated photonic polarization-encoded CNOT gate has been demonstrated in laser-written chips, the polarization manipulation in the reported works [1]–[3] was performed using either bulk or fiber optics. On-chip polarization manipulation schemes based on tilted basis waveguides are typically used serving as waveplates [4], [5] where the waveguide symmetry axis is the optical axis. Such schemes, however, suffer from a number of drawbacks: they are extremely sensitive to fabrication intolerances and due to the cross-section mismatch with normal waveguides exhibit significant coupling losses [6].

Here we report general polarization transformation with twisted waveguides. We note that twisted waveguides are capable not only to rotate the linear polarization but also to cause the polarization transformation due to their structural elliptical birefringence. Therefore, twisted waveguides can be suggested as arbitrary unitary gates in polarization-encoded quantum information processing circuits.

Results

Using modal expansion in helical reference frame and perturbation theory we have obtained an analytical expression for the transmission matrix of a twisted waveguide which is a general Bloch sphere rotation [7]. The main conclusion is that twisted waveguides can approximate arbitrary unitary operations with arbitrary precision and reasonable design constraints. Our results pave the way to robust yet simple building block for integrated photonic polarization-encoded quantum information processing with twisted waveguide architectures. Figure 1 summarizes the results of the investigation.

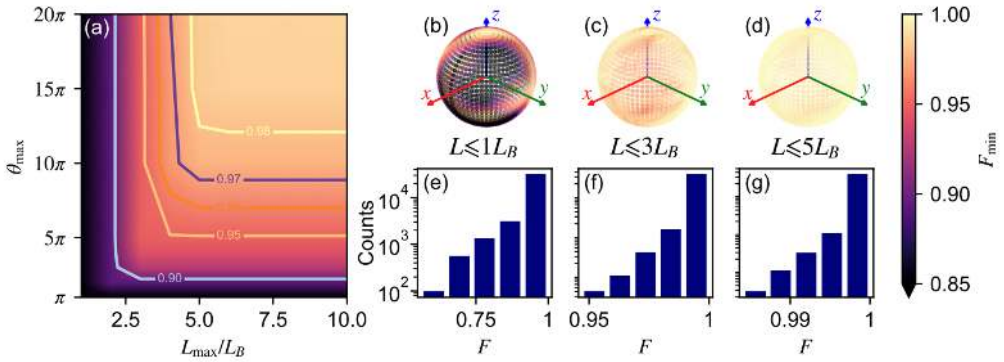

Figure 1. Twisted waveguide approximation of arbitrary single-qubit gates. (a) shows worst fidelity $F_{\min}$ over all single qubit gates as a function of twisted waveguide design constraints, where $\theta_{\max}$ is the maximum twist angle, $L_{\max}$ is the maximum twist length measured in terms of linear beat lengths L_B. (b-d) show the worst fidelity over rotations around a given axis with $\theta_{\max} = 20\pi$ and three different $L_{\max}$ constraints, histograms (e-g) below the spheres visualize the distribution of approximation fidelities. *Cited from* [7].

Abstract: In this work, we investigate the photothermal heating of asymmetric nano-crosses by ultrashort light pulses. We show experimentally and numerically that non-thermal energy density and temperature inside the two arms of the crosses can be controlled with the polarization of the pump pulse. We also demonstrate the importance of considering non-thermal electron ballistic displacement to reproduce the measured experimental data.

Nanoparticles (NPs) can absorb and convert light into heat, making them useful as localized sources of heat [1]. However, the dynamics of heat distribution inside NPs must be better understood and modeled. This is a challenging task due to the time and space scale involved in the photothermal process (femtosecond and nanometer scale). Firstly, we have developed a two-temperature model for uniform gold film [2]. In this work, we go further and realize pump-probe spectroscopy on cross-shaped gold nanoparticles on gold film (see figure 1 a-b). We predict with our numerical model heat transfer inside the nanoparticles and confirm it with experiments [3]. This NP geometry is known to support polarization-dependent localized plasmonic resonance (LSPR) along each of its branches (see figure 1-c). Here we obtain two resonances around 600 nm for the TM polarization and 680 nm for TE polarization. By selectively exciting one LSPR, we can heat only one branch, then, the heat will propagate along the other branch.

By measuring the temporal delay between the modulation of LSPR intensity of each branch with pump-probe setup, we put in evidence the thermal transport inside the cross-shaped NP. The measured optical response delay between the longitudinal and transverse LSPR of the nanocross was around 140 ± 50 fs, in agreement with the simulated one (100 fs). More details on the numerical model as the experiments are provided in [3]. We also demonstrate the importance of considering a non-thermal ballistic electron displacement inside the improved two-temperatures model to match the experiment.

Abstract: The refractory character of plasmonic transition metal nitrides[1] and their growth predominantly by reactive sputtering are simultaneously blessings and curses[2], as they limit the fabrication of nitride plasmonic nanostructures to top-down processes, which is time consuming, costly, and of limited scalability. In this work, alternative routes of fabrication of TMN nanostructures are critically reviewed and presented. We focus on the fabrication of nano-islands by nanosphere lithography[3], dichroic nanowires by glancing angle deposition[4], and colloidal nanoparticles laser ablation in liquids.

Abstract: We present here a subwavelength imaging approach that is based on the interaction between the highly exalted near-field of chiral nanostructures and an azobenzene molecule (DR1, disperse red 1) grafted to a polymeric chain (i.e., PMMA). The aim of the study is to experimentally demonstrate the visibility factor.

Under illumination, the azobenzene molecules (DR1) undergo photo-isomerization cycles, which induce a displacement of matter inducing measurable topographical modifications that can be tracked using atomic force microscopy [1]. Therefore, we obtain in the polymer a map of the near-field of the chiral nanostructures . We recently demonstrated that chiral effects in plasmonic nanostructures can be imaged with this technique [2]. Here, we apply photochemical imaging to chiral metallic nanostructures composed of two coupled gold nanorods. Each rod has a length of 140 nm, a width of 70 nm and a height of 50 nm. They are separated by a 40 nm wide gap and are shifted with respect to each other by a distance '**s**' along their long axis. We show that the near-field chiral response can be imprinted in the photopolymer (figure 1.a-b). It is shown that it is possible to experimentally map the near-field dissymmetry factor, which is the contrast in the local near-field response of the object under RCP and LCP excitation (figure 1.c) [3].

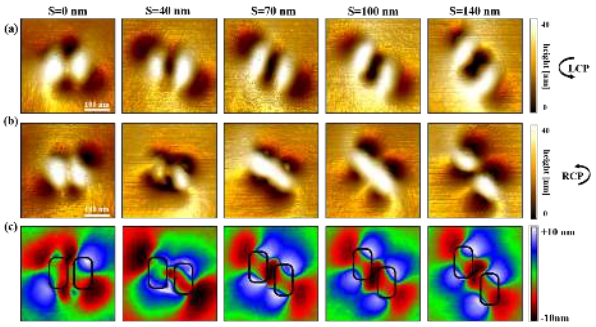

Figure 1 : (a,b) AFM images after irradiation by the left (LCP) and right (RCP) polarization. (c) V-factor maps.

Unidirectional ultracompact self-assembled optical antennas

Maria Sanz-Paz[1], Fangjia Zhu[1], Mauricio Pilo-Pais[1], Guillermo Acuna[1]*

[1] Department of Physics, University of Fribourg, Chemin du Musée 3, Fribourg CH-1700, Switzerland
*corresponding author: guillermo.acuna@unifr.ch

Abstract: We report unidirectional emission of a single fluorophore using an ultracompact optical antenna. The design consists of two side-by-side gold nanorods self-assembled via DNA origami, which also controls the positioning of the single-fluorophore. Our results show that when a single fluorescent molecule is positioned at the tip of one nanorod and emits at a frequency capable of driving the antenna in the anti-phase mode, unidirectional emission with a forward to backward ratio of up to 9.9 dB can be achieved.

Optical antennas have been widely used for manipulating light-matter interactions at the nanoscale in order control the emission intensity, lifetime and directivity of single molecules [1], [2]. In particular, increasing the directionality of single emitters takes on crucial significance, for example in the context of future integrated optical circuits or quantum communication and computing schemes, which hold potential for lower energy consumption and higher efficiency using states that can be controlled up to the fundamental quantum limit [3], [4]. To date most efforts were focused on designs adapted from the Yagi-Uda antenna that can reach high directionality with a significant number of elements spanned over approximately a wavelength [5]. Despite this tremendous proof of concept, further development of these antennas is hindered by the challenges involved in the fabrication and positioning of the single emitters and metallic elements that limits the coupling control and performance that can be achieved.

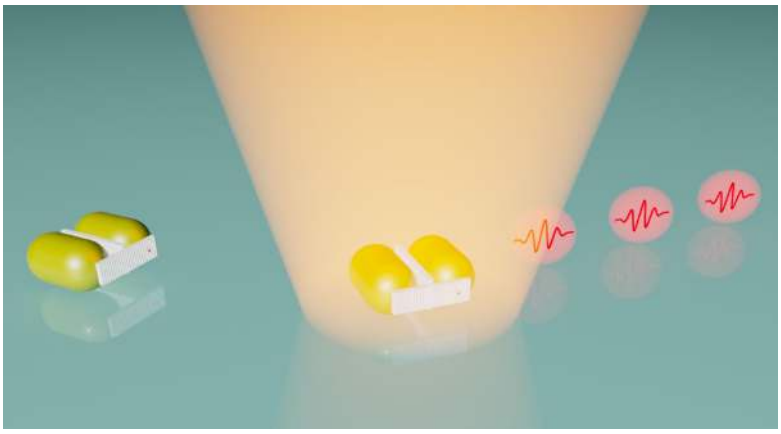

Fig. 1: sketch of an ultracompact antenna showing unidirectional emission

In this contribution, we report on the realization of ultra-compact directional antennas for single photon emitters by means of DNA self-assembly. Adapting the design proposed by Pakizeh et al. [6], we used the DNA origami technique [7] to place two gold nanorods in a side-to-side (or end-fire) arrangement with an overall footprint an order of magnitude smaller than the optical Yagi-Uda antenna. By coupling a single fluorescent molecule to one of the nanorods, unidirectional emission is registered red-shifted from the bonding mode [8], when the nanorods are driven close to the antiphase mode

Abstract: In this talk, we discuss growth strategies to produce transparent and conductive silver layers by physical vapor deposition in the presence of nitrogen additive. We use a combination of *in situ* and real-time diagnostics (substrate curvature measurements, surface differential reflectance spectroscopy, grazing incidence x-ray diffraction, and grazing incidence small-angle x-ray scattering) during deposition, which provides valuable insights into the effects of nitrogen additive on the early-film-formation stages and related optical properties.

Ultrathin silver films with thickness below a few nanometers are interesting candidates for use as transparent conductive electrodes in flexible optoelectronic devices [1]. However, early growth stages of Ag films deposited by 'conventional' physical vapor deposition on weakly interacting substrates are dominated by a natural tendency to form disconnected 3D islands, which manifests itself in high electrical resistivities and broad absorption bands in the visible range due to the excitation of localized surface plasmons. Growth strategies to produce continuous, ultrathin and ultrasmooth Ag films without compromising their electrical conductivity and optical transparency have lately been deployed. Among them, the use of gaseous additives, such as nitrogen or oxygen, appears to be an effective means of promoting wetting of Ag on the substrate surface, resulting in the formation of a continuous layer at a lower nominal Ag thickness [2-4]. However, understanding the impact of additives on the early-growth stages of ultrathin Ag films, in terms of both structural and optical/electrical properties, requires the implementation of *in situ* and real-time diagnostics.

In the present work, we study nitrogen-mediated growth of Ag on weakly-interacting amorphous carbon and SiO_x substrates. We explore the influence of nitrogen addition on the evolution of the film morphology, crystal structure, stress development, and optical response by coupling complementary *in situ* and real-time observations during the deposition by magnetron sputtering or electron-beam evaporation. Laboratory-scale real-time studies include substrate curvature measurements together with surface differential reflectance spectroscopy to determine the morphological transition thicknesses (percolation and continuous formation thickness) [5] as a function of nitrogen partial pressure. These investigations are augmented by real-time synchrotron experiments at SOLEIL (SIXS beamline) combining simultaneous grazing incidence small-angle x-ray scattering (GISAXS), grazing incidence diffraction (GID), and substrate curvature measurements. This enables us to monitor the evolution of the island morphology (size and shape), texture and stress, from the initial growth stages until the formation of a continuous layer, as well as during growth interruptions.

Foerster-Type Nonradiative Energy Transfer in Media with Complex Permittivity

Pedro Ludwig Hernandez-Martinez [1], Abdulkadir C. Yucel [1], and Hilmi Volkan Demir [1,2]

[*]corresponding author: pedro@ntu.edu.sg

Abstract: We present the effects of the complex permittivity of a background medium on Foerster-type nonradiative energy transfer (FRET) and the changes in FRET as a function of the relative permittivity of the medium. We discuss examples of enhanced FRET via tuning the complex permittivity of the medium and illustrate that FRET can significantly increase when the denominator of the FRET screening factor approaches zero.

The Foerster-type nonradiative energy transfer (FRET) is a crucial proximity effect that strongly modifies the emission kinetics of nano-emitters serving as donors and acceptors and has numerous applications such as color tuning, biosensing, light-harvesting, and light-generation. FRET strongly depends on the distance between the donor and acceptor pair, limiting its applications. Two main approaches have been used to boost FRET: the dimensionality effect from the change in the exciton confinement due to the difference in the nanostructure geometry [1] and the local electric field enhancement from a localized surface plasmon (LSP). However, these approaches have their limitations, and in the case of LSP, the lossy properties of the plasmonic nanostructure can decrease FRET if it is not appropriately designed. FRET can be significantly enhanced by using artificially engineered materials of complex dielectric medium with carefully tuned permittivity [2]. In such a medium, the FRET pair can effectively confine and guide the electromagnetic energy within them, owing to their low wavenumber and very large wavelength in the medium, introducing the proximity effect in the long-range interactions, leading to a dramatic increase in FRET. To illustrate the effects of the background medium's permittivity, we discuss examples where the background medium is tuned to enhance FRET.

Vacuum Ultraviolet Light Generation and Circular Polarization Control Using Dielectric Nanomembranes

Kuniaki Konishi

Institute for Photon Science and Technology, The University of Tokyo, Japan
kkonishi@ipst.s.u-tokyo.ac.jp

Abstract: We have demonstrated that dielectric free-standing thin film (Nanomembranes) with a thickness of several-hundred nanometers can generate coherent vacuum ultraviolet (VUV) light efficiently and tunably based on third harmonic generation (THG). We have also demonstrated the generation of circularly-polarized VUV THG in a dielectric nanomembrane with a square periodic lattice of circular hole. The presented results show that nanomembranes and their nanostructures are an effective new way to generate and control vacuum ultraviolet coherent light.

Vacuum ultraviolet (VUV) coherent light sources have been used for many applications for probing the electronic states of excited atoms and molecules and for controlling chemical reactions, time-resolved angle-resolved photoemission spectroscopy, and circular dichroism measurement of biomolecules. For such applications, it is important to develop a method for simple light generation for VUV spectroscopy. Though third or higher harmonic generation from gases has been used to generate vacuum and extreme-ultraviolet light, it is still more practical and convenient to use solids for wavelength conversion. Recently, new types of solid nonlinear materials for VUV generation, such as dielectric metasurfaces [1], which are artificial nanostructures with sizes comparable with or smaller than the light wavelength, have been proposed and demonstrated, but it is required to increase the intensity and control the polarization state of generated VUV coherent light for practical spectroscopic application.

We have developed that dielectric free-standing thin film (Nanomembranes) with a thickness of several-hundred nanometers or less can generate coherent VUV light efficiently and tunably based on third harmonic generation (THG) [2]. We evaluate that THG in SiO_2 nanomembranes excited at 470 nm enables VUV radiation at 157 nm with photon flux (10^{10} photon per second), which is sufficient to be used for spectroscopic application. We also demonstrate the generation of circularly-polarized VUV THG in a photonic crystal nanomembrane with a square periodic lattice of circular hole (Fig. 1) [3]. It is known that the rotational symmetry of the structure allows for a nonlinear optical response of circularly polarized light, [4], and we demonstrate that it is also applicable to rotational symmetry of periodic all-dielectric nanostructures, i.e., photonic crystals.

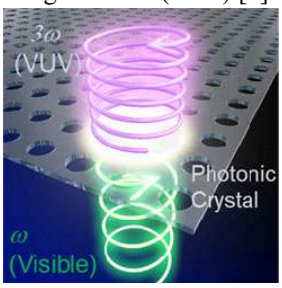

Fig. 1 Schematic of vacuum ultraviolet circular polarization wavelength conversion using a photonic crystal nanomembrane.

The presented results show that nanomembranes and their nanostructures are an effective new way to generate and control vacuum ultraviolet coherent light.

Abstract: The development of semiconducting thin films represents a large and important area of research, due to their interesting optical and electrical properties. Metal oxide (MO) films are indeed used in a wide range of applications, including photodetectors, gas sensors, biosensors or photocatalysis.
Near infrared (NIR) laser annealing was successfully used to crystallize TiO_2 thin films from a sol-gel solution deposited on gold nanoparticle arrays (AuNPs). The AuNPs were used as nano-heaters allowing a local temperature increase up to 500°C in the film. The temperature reached under laser is deduced from the presence of the anatase phase in the samples obtained by laser exposure, showing that crystallized TiO_2 can be obtained by thermoplasmonic effect. Different analytical techniques supported this study, such as grazing X-ray diffraction (GIXRD), UV-visible and Raman spectroscopy. The temperature increased was confirmed by a numerical model that emphasized the role of NPs coupling in the thermoplasmonic effect. Direct laser patterning by NIR laser and in combination with Deep-UV photolithography (DUV) has also been demonstrated. This fabrication method opens new perspectives in applications such as photonics, photocatalysis or biosensing.

Chiral Nanostructures

Y. K. Gun'ko*

School of Chemistry and CRANN, Trinity College Dublin, Dublin 2, Ireland
*corresponding author: igounko@tcd.ie

Abstract: Our primary aim is to create novel chiral nanostructured materials that exhibit optical activity and chirality, and to investigate their properties, nature, and potential applications. The chiroptically active nanostructures have unique physical and chemical properties that have attracted significant attention in recent years. Here we present the progress in various approaches for the synthesis of these nanostructures. The study of chiral nanostructures is an exciting and rapidly growing field with promising future prospects for various technological advancements.

Our primary aim is to create novel chiral nanostructured materials that exhibit optical activity and chirality, and to investigate their properties, nature, and potential applications. As part of our efforts, we have successfully synthesized new types of chiral nanomaterials, such as chiral II-VI semiconducting quantum dots and chiral nanoparticles of metal oxides that are of significant technological importance. Furthermore, we have shown that chiral quantum dots have promising applications in chiral recognition and luminescent chemo- and bio-sensing. Chiral nanostructures have unique physical and chemical properties that have attracted significant attention in recent years. They have potential applications in various fields such as optics, electronics, catalysis, and biomedicine. Chiral nanostructures can be synthesized using various techniques, and researchers are continually exploring new ways to create and control their chirality to optimize their properties [1-4]. The main goal of our work is to develop new types of technologically important inorganic nanosteuctured materials possessing optical activity and chirality, study their properties, investigate their nature and explore their potential applications (Figure 1).

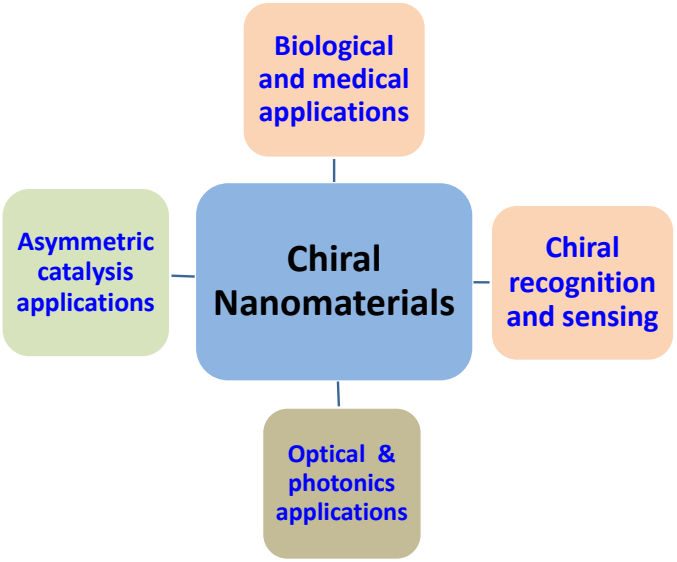

Figure 1. Potential applications of chiral nanomaterials.

We have developed new chiral nanomaterials including a range of chiral semiconducting nanoparticles (quantum dots) and chiral nanoparticles of technologically important metal carbonates, transition metal dichalcogenides and oxides. In addition, we explored the properties of new anisotropic chiral nanomaterials [5-7]. The new nanomaterials have shown a very interesting optical activity and unusual chiral morphologies which were confirmed by various instrumental techniques. The use of chiral ligands enabled us to transfer these nanostructures into aqueous phases and enhance their chiroptical activity. We have also demonstrated potential applications of chiral quantum dots for chiral recognition and luminescent chemo- and bio- sensing. We have also found that live cells demonstrate an enantioselective uptake of chiral quantum nanostructures. It is expected that chiral nanomaterials will find applications in sensing, nanomedicine, asymmetric synthesis, catalysis and other areas.

Abstract: In this work, we demonstrate the possibility of the local functionalization of gold nanoparticle surface using metal-induced diazonium salt polymerization for spatial control of quantum dot deposition. Varying the wavelength of excitation of gold nanoparticles, we can choose the polymerization mechanism, which leads to different polymerization pattern.

Hybrid metal-semiconductor nanostructures are of a great importance as promising elements of integrated photonics.[1] Successful implementation of hybrid structures into real applications depends on the efficiency of plasmon-exciton coupling in them. Plasmonic nanoparticles can significantly alter the optical and electronic properties of semiconductor nanocrystals (e.g. quantum dots, QDs).[2] However, the main problem during the fabrication of hybrid systems remains a poor control over semiconductor nanocrystals deposition in the vicinity of plasmonic structures. Since the enhanced field is not eventually distributed around a metal nanoparticle, for the efficient plasmon-exciton coupling an attachment of QDs in hot spots is required. Chaotic deposition of QDs reduces “beneficial” effect of plasmonic nanoparticles leading to a loss in the efficiency of the hybrid system.

In this work, we demonstrate the advantage of using metal-induced polymerization of diazonium salts to create anchoring sites for QDs in plasmonic hot spot. Diazonium salts, molecules containing easily removed N_2-group, have been widely used for electrochemical grafting of electrodes.[3] The large choice of substitution groups in these molecules allows binding varied molecules or particles to the grafted layer via electrostatic interaction or covalent bonding.[3] There are two possible pathways of dediazonation and therefore polymerization of diazonium salts (Fig. 1a). The first mechanism goes through the formation of a cation, which then interact with negatively charged surface, and is initiated by heating. Another mechanism requires electron transfer and goes through the radical formation step, which can further easily attach to any surface.

The ability of gold nanoparticles to generate under irradiation both local heat and hot electrons allow us to induce the both mechanisms of polymerization of diazonium salts resulting in different spatial image. Under the excitation that matched interband transition, we observe polarization-independent thermal growth of polymer on the gold nanoparticle surface (Fig. 1c). At the same time, the excitation of the plasmon resonance of the gold nanocube (Fig. 1b) leads to the polymerization pattern corresponding to hot spots (Fig. 1d). Further electrostatic interaction of negatively charged diazonium structures with positively charged QDs leads to controlled QD attachment in plasmonic hot spots.

Figures 1: (a) Schematic representation of possible polymerization pathways of diazonium salts in the presence of a metal nanoparticle; (b) FDTD simulated extinction spectrum of a gold nanocube; (c) and (d) SEM-images of gold nanocubes after polymerization of diazonium salts at the 514 nm and 633 nm excitation correspondingly.

The kinetics of plasmon-induced chemical reactions studied by surface-enhanced Raman scattering (SERS) and X-ray photoelectron spectroscopy (XPS)

Abstract: The rate constants of plasmon-induced transformation of brominated adenine and thiophenol derivatives is studied by SERS and XPS. We identified relevant parameters determining the reactivity of molecules on plasmonic nanostructures, among them the material and size of nanoparticles, as well as the local density of states. Furthermore we attempt to exploit these systems for site-selective functionalization of nanoparticles and radical induced polymerization reactions.

Plasmonic nanoparticles such as gold and silver nanoparticles absorb visible light very efficiently through excitation of their surface-plasmon resonance (SPR). The SPR can decay into ("hot") electron-hole pairs that are able to induce chemical reactions in adsorbed molecules by a charge transfer. In the case of the transfer of an electron the chemical processes occurring in the adsorbed molecules can be described by dissociative electron attachment (DEA). This opens the new field of plasmonic chemistry, which promises new chemical pathways and selectivities in bond breaking/activation through low-energy electrons.[1] We have investigated this process in brominated Adenine and Guanine on Au and AgNPs using surface-enhanced Raman scattering (SERS), which allows to determine the kinetics of the electron-induced debromination reaction by monitoring the vibrational fingerprint of reactants and products.[2,3] The same technique has been applied to a range of thiophenol molecules, and along with synchrotron XPS measurements we were able to identify important parameters determining the reactivity of molecules towards electrons released from the nanoparticle surface.[4-6] Currently, we are exploring possibilities to apply the gained mechanistical knowledge to modify nanoparticles site-selectively using plasmon-induced reactions, and to create light-controlled polymers using controlled radical polymerization.

Support by the European Research Council (ERC) is gratefully acknowledged (Consolidator Grant 772752).

Non-Thermal Activation of Reactants in Plasmon-Assisted Chemical Reactions: Roles of Molecular Structure and Metal-Molecule Contact

Zee Hwan Kim*
Department of Chemistry, Seoul National University, Seoul 08826, Korea
E-mail: zhkim@snu.ac.kr

Recent studies on plasmon-assisted chemical reactions postulate that the hot carriers of plasmon-excited nanostructures may induce a non-thermal vibrational activation of metal-bound reactants. However, a quantitative validation at the level of molecular quantum states is currently missing. In this talk, I will present our recent spectroscopic studies on metal-bound reactants, which proves the non-thermal vibrational molecular excitations caused by plasmons: We find that such a plasmon-induced vibrational excitation causes hyper-thermal vibrational population distribution of a specific molecular vibrational mode, and bring significant population in overtone-excited states. Such excitation is found to be critically dependent on the metal-molecule chemical contact. The inelastic molecule-electron scattering model could fully explain what are observed. The result provides the physical basis for the plasmon-assisted chemical reactions and paves the way for controlling chemical reactions on metal surfaces.

Ultrafast Optical Studies of Hybrid Nanomaterials of Interest for Optoelectronic and Energy Conversion Applications

G. P. Wiederrecht[1*]

[1]Center for Nanoscale Materials, Argonne National Laboratory, Lemont, IL, 60439, USA
[*]corresponding author: wiederrecht@anl.gov

Abstract: Ultrafast optical spectroscopy is used to monitor energy flow in nanostructures of interest for optoelectronic and energy conversion applications. The impact of hybrid nanostructures on aiding in the efficiency of desired energy flow outcomes following the absorption of photons is further described. Using ultrafast spectroscopy to probe hybrid structures designed to increase light-matter interactions, such as through optical cavities, is also discussed.

Ultrafast spectroscopy is useful for monitoring various pathways for energy flow following the photoexcitation of a nanomaterial. The ability of modern ultrafast laser systems to excite and probe over a broad spectral range, from ultraviolet through terahertz energies, allows for monitoring energy and charge flow within and between nanostructures, as well as to their local environments. Such capabilities enable the study and optimization of optically-induced processes that impact the efficiency of optoelectronic and light harvesting/energy conversion materials. With that said, ultrafast spectroscopy remains challenging and frequently very time-consuming for a number of reasons, such as phototoxicity of many materials (particularly under ambient conditions) and high optical scattering that can limit signal to noise in a pump-probe or time-resolved emission experiment.

Hybrid nanomaterials represent an additional handle with which to impact pathways of photoinduced energy flow and dissipation, through coupling that can modify both radiative and nonradiative processes. In this talk I describe our recent efforts to time-resolve energy flow in hybrid plasmonic and excitonic nanomaterials. I also describe our recent efforts to improve the rate of data acquisition of time-resolved optical studies in these and similar nanostructures, which can potentially have the added benefit of enabling a larger range of materials to be studied since less exposure time to illumination enables more photosensitive materials to be studied. Time-resolved studies of collective nanostructures designed for light harvesting and energy conversion are also described. Finally, the dynamics of excitonic-plasmonic hybrid nanostructures in which the plasmonic material functions as an optical cavity to alter radiative rates are discussed. For example, the dynamics of nanomaterial photoprocesses as a function of photon energy relative to the cavity resonance is explored in detail and impact on applications is described.

Bioanalytics using plasmonic nanostructures

S. Kastner, E. Podlesnaia, F. Seier, Y. Luximun, A. Dietel, M. Urban, A. Csaki, W. Fritzsche*

Leibniz Institute of Photonic Technology (IPHT) Jena, Germany

Abstract: The effect of localized surface plasmon resonance (LSPR) on chemically synthesized gold nanoparticles is utilized to setup a biosensing platform with the potential for sensitive and specific detection of biomolecules of interest such as biomarkers. This principle is demonstrated both on a single particle level for DNA detection, then extended also to proteins, and to arrays of particles. In order to readout the arrays, imaging spectrometer were developed.

Today, innovative tools for diagnostics and bioanalytics are needed. They should be able to detect molecules of interest with sufficient sensitivity, preferably label-free and multiplexed, to be usable outside of dedicated laboratories and with less qualified personnel, at minimal costs.

Plasmonic nanostructures promise to provide sensing capabilities with the potential for ultrasensitive and robust assays in a high parallelization and miniaturization, and without the need for markers. When functionalized with certain biomolecules (such as single-stranded DNA or antibodies) which bind the target molecule of interest (e.g., a biomarker like DNA or a protein), they should capture this target molecule with high specificity. Upon binding of target molecules, the localized surface plasmon resonance (LSPR) of these structures is changed, and can be used as sensoric readout [1]. This is possible even on a single nanostructure level, using optical darkfield detection introduced more than 100 years ago [2], as demonstrated for DNA detection [3]. In contrast to SPR, LSPR senses only in a very thin layer (on the scale of the particle diameter), resulting in an efficient background suppression [4,5]. Only molecules bound directly at the surface contribute significantly to the signal, but much less molecules farer away.

In order to multiplex this approach, imaging spectrometer setups, e.g. based on a Michelson interferometer or multiple LEDs have been developed, able to readout a whole array of sensors in one step [6,7]. On the sensor side, microarrays of gold nanoparticle spots were fabricated using spotting of pre-synthesized gold nanoparticles [8]. Such chemically synthesized particles allow for a cost-efficient generation of highly crystalline particles as nanosensors; by using microfluidic approaches, a higher quality and reproducibility can be achieved [9]. Using this microarray approach, a multiplex DNA-targeting detection of fungal pathogens involved in sepsis could be demonstrated [10]. DNA-based signal amplification, e.g. by hybridization chain reaction, improves the sensitivity [11. Beyond DNA detection, LSPR sensing is also applicable for the detection of protein targets, such as CRP [5].

In conclusion, the results demonstrate the potential of this LSPR-based array platform for molecular detection of biomolecules of interest, with possible applications in bioanalytics and diagnostics.

Abstract: Photon emission from gold has recently received increased attention, particularly in the context of nanoplasmonics. However, this signal's origin remains unclear. Here we study photoluminescence from ultrathin monocrystalline gold flakes, allowing us to decouple nanoscale from plasmonic effects. We explain our measurements through first-principles theory accounting for electronic and optical properties of the gold films. Our results resolve a fundamental scientific debate and provide insight for the exploitation of photoluminescence as a probe of light-matter interactions in metals.

Photon emission from gold was first observed in 1969 [1], and has since received increased interest from a number of fields that employ gold nanostructures, including fundamental nanoscale studies [2,3], monitoring surface and electronic temperature [4–6], and probing gold-molecule interactions in plasmonic picocavities [7]. Despite its usefulness, significant uncertainty surrounds the origin of emitted light in different structures, especially whether it is due to inelastic Raman scattering or recombination of hot electrons and holes [3,8–11]. This is further complicated by enhancement of emission at specific wavelengths due to plasmonic resonances and spatial confinement effects in nanostructures.

Here we present photon emission measurements from monocrystalline gold flakes with 14 nm to 110 nm thicknesses. Uniquely, our flakes have atomically flat, clean surfaces and, at the time of writing, they have the world's best aspect ratio [12]. This enables us to probe the relationship between photon emission and spatial confinement directly as a function of sample thickness and temperature at varying excitation wavelength and power. We reveal that long-wavelength photon emission is independent of excitation wavelength: conclusive evidence that this signal is due to photoluminescence (PL) rather than Raman scattering. We also demonstrate that photon re-absorption plays an extremely significant role in gold PL, which has previously not been fully understood. We use photon re-absorption to spatially resolve the origin of PL from within the flakes, revealing that there is minimal charge transport prior to PL. We reproduce experimental signals with first-principles calculations based on density functional theory. Finally, we show that PL can be used to probe local temperature without the need to measure the anti-Stokes components [5], enhancing the possibilities of gold thermometry. Our study provides crucial insight into the nature of light emitted from gold, decoupling spatial confinement from plasmonic enhancement, and paves the way to probing hot carriers in a wide variety of devices.

Abstract: The need to manufacture plasmonic materials with absorption in the Near-Infrared window is imperative even today for biomedical applications due to the efficient absorption and heating when at the same time the use of Traditional plasmonic metal nanoparticles have failed. We could pave the way by the controlled fabrication of refractory transition metal nitrides nanoparticles, such as Titanium Nitride, by pulsed laser ablation process in solvents.

Plasmonics is one of the most dynamic and fast-developing scientific and technological fields nowadays. Metal nanoparticles (NPs) with plasmonic response in the Near-Infrared (NIR) spectral range can be applied for biological applications due to the efficient absorption and heating at extremely confined volume in the vicinity of the NPs. “Traditional” plasmonic metal NPs, such as Au and Ag, fail to endure high temperatures and/or the high electric fields of NIR concentrated light, required for biological applications [1]. We could pave the way to emerging plasmonic bio-applications by the fabrication of refractory transition metal nitrides NPs, such as Titanium Nitride (TiN), whose plasmonic performance can extent into the NIR spectral range by varying their stoichiometry or via alloying to form ternary systems [2]. The most promising route to fabricate plasmonic TiN NPs, in terms of reproducibility and ease process upscaling, is by pulsed laser ablation in solvents (LA). As the NIR plasmonics are extremely sensitive to the stoichiometry and/or doping of TiN, LA emerges as the undisputed method of choice, because the ablated NPs retain in the elemental composition of the solid target.

In this work, we present the controlled fabrication of functional refractory and stable plasmonic TiN NPs with absorption in the NIR biological window by LA. The initial targets have been developed by reactive Magnetron Sputtering at room temperature while the final shaping of the colloidal NPs was performed through a laser ablation process by the 532 nm beam of a picosecond laser system and/or by 1064 and 532 nm beam of a nanosecond Nd:YAG pulsed laser system. TiN NPs structure and morphology as well as the quality of the materials have been analyzed by XRD, SEM, EDX, AFM and XPS. The optical properties of the TiN target materials have been evaluated by NIR-Vis-UV Spectroscopic Ellipsometry, while an optical absorbance characterization was performed on the colloidal TiN NPs. The photothermal properties of these colloidal NPs have also been investigated, and preliminary biocompatibility tests have been carried out using proteins such as albumin and fibrinogen in PBS solvent.

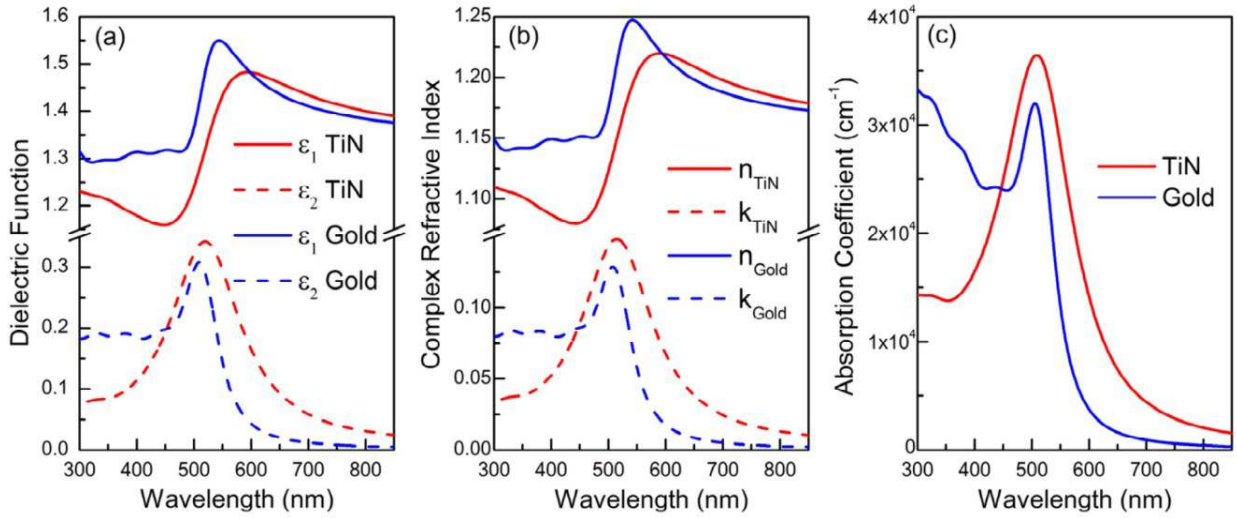

Figure 1. The predicted plasmonic performance of TiN NPs and 40 nm gold NPs [1].

Abstract: Nanostructures with chiroptical properties highly desired for photonic technologies. Here, we present endeavors towards achieving nanostructured chiral thin films, which show tunable, highly dissymmetric optical properties. Namely, chiroptical properties of gold or semiconductor nanocrystals are induced by mixing them with (chiral) liquid crystals. Owing to the soft character of liquid crystals, these nanocomposites exhibit durability, tunability and strong dissymmetry (g-factor up to 0.1) attractive for real world applications.

Thin films exhibiting plasmonic chirality or circularly polarized luminescence hold a great potential for photonic technologies relying on the emission or detection of circularly polarized light. However, most approaches of chiroptical thin films fabrication focus on top-down methods yielding static structures. To fully capitalize on the potential of chiral photonic materials the bottom-up fabrication of switchable films, showing high optical dissymmetry desired for applications, is required.

Recently, we proposed an efficient method for the preparation of chiral assemblies of nanoparticles which combats switchability and dissymmetry issues in thin films. The proposed method relies on melting and freezing a mixture of liquid crystal (LC) and either gold or semiconductor nanoparticles (NPs). Particularly, we proposed using LC that forms helically twisted fibers, that serves as a chiral matrix for guiding the assembly of NPs.[1,2] This way, we induce chiroptical properties of NPs.

From the perspective of the organic LC matrix, it's worth noting that upon cooling in the film state, the molecular architecture of the achiral LC supports the formation of layered assemblies that twist into helical nanofibers. These fibers grow dendritically from crystallization points, preserving their. This mechanism results in local symmetry breaking, that is mm-scale domains of both handedness are formed. It is possible to achieve macroscopic symmetry breaking by adding small amounts of a chiral, molecular dopant. To induce helical assembly of NPs within such LC films NPs need to mix well with LC in the melted state (at an elevated temperature), while on freezing they should be selectively pushed to the boundaries of the helical nanofibers. It is thus crucial to endow NPs with chemical compatibility to the matrix. For this purpose we cover gold and semiconductor NPs with organic ligands that are structurally similar to the LC compound.

The major contributions achieved using our methodology revolve around structure and optical properties of LC/NP composites, probed with e.g. TEM, AFM, XRD, CD, CPL methods and explained with modelling. Our films show a highly hierarchical structure of double helical assembly of NPs. This results in uniform composites, translating to strong optical dissymmetry of the films. Namely, for assemblies of spherical and rod-like gold NPs with sizes up to 50 nm, we recorded circular dichroism featured with dimensionless g-factor values of absorption on the state-of-the-art level of 0.1.[3] Similarly, when using InP/ZnS semiconductor NPs circularly polarized luminescence with strong dissymmetry was detected.[4] Importantly, the proposed method enables tuning of the chiroptical response into different parts of the visible spectrum by the choice on NPs and LC design.[5,6] A unique feature of the films is their thermal responsiveness driven by the soft character of LC matrix. It enables dynamic

switchability of the structure endowing the formed films with actively controlled chrioptical properties.[4,5] It is also worth to note that the described method for chiroptical film formation is highly scalable and energy efficient, increasing it's applicative potential.

In summary, the developed methodology of co-crystallization of liquid crystals and nanoparticles allows to realize chiral plasmonic and circularly polarized luminescent thin films with strong optical dissymmetry, precisely controlled structure, and (actively) tunable optical properties. These properties are achieved for thin films exhibiting high durability and scalable fabrication, which makes us believe that the described method may unlock the full potential of chiral photonics in the aspects of e.g. increasing the speed of data transfer.

Abstract:

Electro-optic modulators (EOMs) are one of the vital elements in optical communications for digitalizing optical signals through electric driving signals. Most of current EOM devices are targeting on-chip integrations, which routinely suffer from high coupling losses, complex optical alignments and single-band operations. Here, we report that a lumped EOM device is fully integrated on the single-mode optical fiber tips for fast amplitude modulations. Profiting from ultrathin and high quality-factor plasmonic metasurfaces, nanofabrication-friendly and highly efficient EO polymers and coupling-free connections with fiber networks, our EOM is demonstrated to allow dual-band operations (telecom O band and S band) and high-speed modulations (~ 1 GHz at a bias voltage of ± 9 V). This work offers an avenue to 'plug-and-play' implementations of EO devices and ultracompact "all-in-fibers" optical systems for communications, imaging, sensing and many others.

Conducting polymers as optical actuators for addressable structural colors

S. Rossi[1], **M. P. Jonsson**[1*]

[1]Laboratory of Organics Electronics, Department of Science and Technology, Linköping University, Sweden

[*]corresponding author: magnus.jonsson@liu.se

Abstract: Conducting polymers change their electronic and optical properties when doped with counter-ions. The doping process can be dynamically and reversibly done electrochemically, exposing the polymer to an electrolyte. The permittivity and thickness change upon redox cycling changes the effective refractive index. We demonstrate an application to tune the color of reflective optical nanocavities in all the visible spectrum, using a low-bandgap conducting polymer. The outcome is promising for reflective displays but can be extended to other active nanophotonic systems.

Summary

Many modern optical and optoelectronic devices require to be actively addressable, changing dynamically their response to an electric stimulus. Nanophotonics has been revolutionizing the optical field, with many new applications and opportunities given by the light-matter interaction at the subwavelength scale. However, the active tunability of those systems is still a technological challenge and new strategies and materials for optical actuation are needed. In our recent works, we focused on addressable structural colors for application in color reflective displays with ultralow power consumption. **The aim was to integrate metal-insulator-metal reflective optical nanocavities** that we developed in our previous work [1] **with conducting polymers for active electrochemical color tuning** [2]. Those materials are conjugated polymers that can be doped with counter ions to induce charge carriers in the polymeric chains. The doping process can be done by exposing the polymeric film to a suitable electrolyte in an electrochemical cell and is reversible by redox cycling. Conducting polymers have been having a fundamental role in the development of organic electronics and have shown great potential for photonics. They have been applied for solar cells, organic light-emitting diodes (OLED), electrochromic windows and displays, but only recently have found applications in optics. When charges (holes or electrons, depending on if p- or n-type) are injected in the polymeric chains applying a potential difference between the polymer and a counter electrode, counter-ions need to diffuse in the polymeric matrix to maintain charge neutrality. This causes swelling and thickness change, coupled with permittivity variation due to the modulation of the electronic properties of the

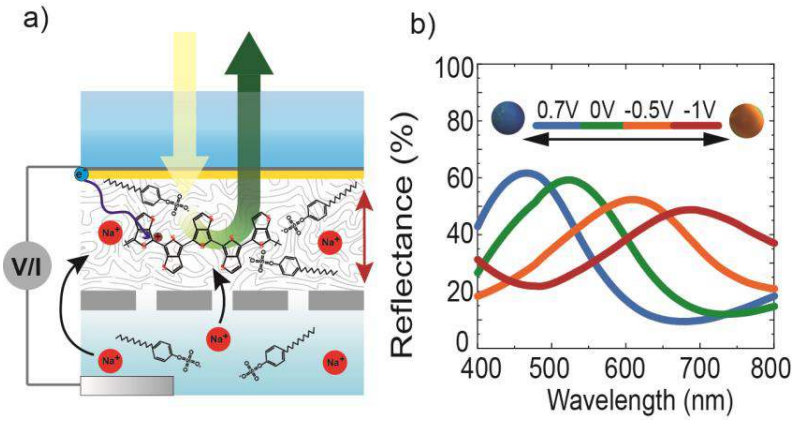

Figure 1. Electrochemically tunable reflective optical nanocavities. **a)** Schematic of the nanocavities integrated in the electrochemical cell. **b)** Experimental reflectance spectra at different potentials.

conjugated chains, leading to an effective refractive index variation that can be exploited for optical actuation. **We focus here on our recent efforts in studying and exploiting conducting polymers for electrochemically addressable structural colors**. We showed that a low-bandgap polymer, thienothiophene, exhibits a relatively low absorption in the visible for all the redox states, which makes it a good candidate for actuating reflective structural colors. We integrated thienothiophene as the spacer of optical nanocavities and placed the sample in an electrochemical cell with a water-based electrolyte (Fig. 1a). We achieved complete coverage of the visible spectrum, maintaining a high reflectance for all the colors while using a low voltage range (Fig. 1b). This was made possible by a synergistic combination of the variation of the optical properties and thickness change of the polymeric spacer. We attributed the actuation of the optical nanocavity mainly to the thickness variation of the polymeric spacer due to electrolyte swelling. The low-bandgap of the material ensured to obtain similar reflectance values for all the colors, in contrast with most conducting polymers, because the absorption peak is in the near-infrared for both the reduced (undoped) and oxidized (p-doped) states. The addition of nanoholes to the fully reflective mirror, further improved the ion diffusion, extending the wavelength tunability up to 400nm. Those cavities can be considered as the proof of concept of a "monopixel" that can cover the entire visible spectrum. The samples suffered from low color uniformity and limited cycling stability, but we expect that those issues can be solved by the lateral microstructuration of the nanocavities to lower the ionic diffusion path. **Therefore, conducting polymers have the potential to be used in hybrid nano-optical systems to actively address structural colors.** Besides optical nanocavities**,** they can also be applied to plasmonic nanopixels [3] and photonic crystals, Moreover, we demonstrated UV-patterning possibilities by using a different thin film deposition method based on vapor phase polymerization [4], which is promising for display applications. Those materials have also recently found application in actively addressable metasurfaces for beam steering [5] and holography [6] when coated over optical nanoantenna, extending their optical actuation capabilities beyond structural coloration.

Abstract: We use Au@Pd core-shell nanorods self-assembled into supercrystals as plasmonic photocatalysts for the Suzuki C-C coupling reaction between bromobenzene and m-tolylboronic acid under simulated sunlight. Such plasmonic device is an interesting model system to understand the relative importance that the electromagnetic field enhancement generated via plasmonic coupling between nanorods, the photogenerated hot charge carriers and the temperature rise may have on this particular reaction.

With the aim of benefiting from the synergistic effect between the optical properties of plasmonic nanoparticles and the well-known catalytic features of palladium, we synthesize Au@Pd core-shell nanorods (NRs) as efficient plasmonic photocatalysts.[1] The use of an evaporation-induced self-assembly method allows us to obtain the well-organized packing of Au@Pd NRs into supercrystals (SCs) by drop-casting a concentrated solution of the resonators on a silicon substrate.[2] Such nanoarchitectures enable us to induce plasmonic hot spots thanks to the coupling between the tips of the particles, generating, at the scale of the SC, a homogeneous enhancement of the electric field over a large area.

In order to investigate the photocatalytic features of our plasmonic device, we perform the Suzuki-Miyaura C-C coupling, a well-established method for carbon-carbon cross-coupling between an organoboron species and an aryl halide in the presence of a base, as model reaction.[1] This reaction usually requires an energy input in order to overcome the activation barrier, being usually performed at elevated temperatures (>50 °C) and using a palladium species as catalyst.[3] In this work we demonstrate that our Au@Pd SCs are efficient photocatalysts to drive this organic transformation, modulating chemical reactivity under irradiation thanks to the unique characteristics of the plasmonic objects and their collective features.[4],[5]

In this context, the relative importance of the different processes behind plasmonic photocatalysis (electromagnetic field enhancement, photogenerated charge carriers and photothermal effects) is also discussed.[6] Our experimental data is complemented by thermal simulations of the thermal contribution of the system under study.

Abstract: The control of optical properties at the nanoscale is a current topic of intense research. It has been shown recently in our group that the regular arrays of Co nanoparticles obtained by electron-beam lithography present intense plasmon resonances in the visible range of electromagnetic spectrum. In this work, we purpose to focus our attention on the study of the optical properties of colloidal Co nanoparticles synthesized by the polyol process. The nanoparticles obtained present an anisotropic shape in the form of nanorods and are relatively polydisperse in length while their thickness remains very homogenous (Figure 1a). FDTD simulations show that Co nanorods of thes dimensions have a plasmon resonance in the visible range, as shown in Figure 1b. Subsequently, the plasmonic properties of Co nanoparticles are characterized experimentally by electron energy loss spectroscopy (EELS) at the single-nanoparticle level, allowing us to take into consideration the polydispersity at the sample. Our finding highlights the potential of such objects as a new platform for studying light-matter interactions at the nanoscale.

Abstract: We analyze the plasmonic response of aluminum nanorods using both optical and electronic spectroscopies. We experimentally evidence a strong coupling phenomenom between the multiple orders of the nanorod's plasmonic resonance and the interband transition of aluminum. The resulting hybrid modes are analyzed using a model for strong coupling to extract the Rabi energies.

Aluminum is an appealing plasmonic material, combining a broadband metallic behavior, a wide availability and CMOS compatibility [1]. Here, we study the optical properties of aluminum nanostructures using electron energy-loss spectroscopy (EELS), a powerful technique allowing direct imaging and spectroscopy with nanoscale spatial resolution [2]. We focus on the coupling between the plasmonic modes of an Al nanorod and the interband transition of aluminum. Using both EELS and optical spectroscopy, we experimentally evidence a strong coupling between the antenna's plasmonic resonances and the interband transition (Fig. 1). This interesting phenomenon (as the antenna couples *with itself* to create hybrid modes) is analyzed using a model for strong coupling.

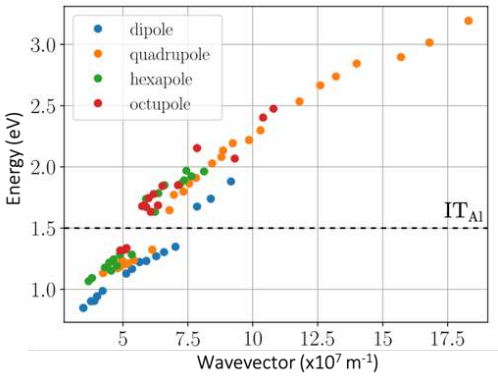

Figure 1: Dispersion curves of the plasmonic resonances of an Al nanorod, as obtained from EELS measurements. The horizontal dotted line denotes the position of the interband transition at 1.5 eV. A clear energy gap is observed around the interband, associated with strong coupling (Rabi splitting).

Light-matter-coupling effects in pentacene thin films on nanorod antenna arrays

C. P. Theurer[1], F. Laible[1], J. Tang[1], K. A. Broch[1], F. Schreiber[1], and M. Fleischer[1*]

[1]Institute for Applied Physics and Center for Light-Matter-Interaction, Sensors and Analytics LISA+, Eberhard Karls University Tübingen, Tübingen, Germany
[*]corresponding author: monika.fleischer@uni-tuebingen.de

Abstract: By harnessing light-matter coupling in optical cavities, the chemical and photophysical properties of organic semiconductor films can be tailored without the need for chemical modification. Here, strong coupling is demonstrated in polycrystalline pentacene thin films on top of silver nanorod antenna arrays. Such an open configuration offers advantages in view of device applications. Simultaneous coupling of the two Davydov transitions to surface lattice resonances is observed.

Under the influence of strong light-matter coupling within cavities exciton-polariton quasi-particles can form in organic semiconductors [1.]. While most studies so far consider either single crystals or diluted molecules in closed cavities between two mirrors for maximum effect, open cavities and polycrystalline thin films can have practical advantages in terms of applications. Strong coupling has been demonstrated e.g. in organic crystals on plasmonic nanorod arrays [2., 3.]. Such arrays offer the possibility to excite surface lattice resonances that present excellent spectral tunability and narrow bandwidths [4.-7.].
In the present work, pentacene thin films are prepared on silver nanorod arrays by organic molecular beam deposition. Pentacene is chosen as a common organic semiconductor with the added feature that it presents a singlet fission material [8.]. Singlet fission, i.e. the spontaneous splitting of an excited singlet state into two triplet states, is of considerable interest since it leads to a duplication of the excitons in a material. The singlet fission dynamics can be accelerated by strong light-matter coupling [9.]. The present work shows that the two Davydov transitions couple to surface lattice resonances excited in the nanorod array with different coupling strengths. The resulting energy splitting is evident when the system is compared to an inert polystyrene reference film with a comparable refractive index on the same arrays (see Figure 1). The strong coupling regime is reached for the lower transition in pentacene, leading to a reduction of the energy gap to the triplet pair state [10.].

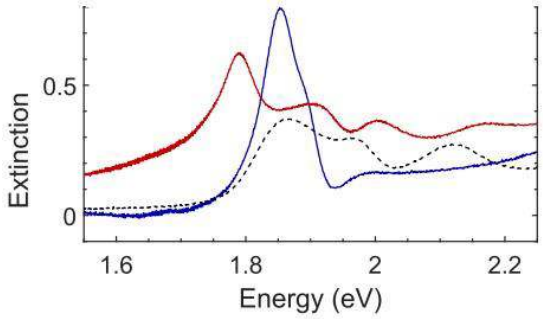

Figure 1: Extinction spectrum of a plasmonic silver nanorod array covered with a pentacene thin film (red) in comparison to the same array covered by a polystyrene reference film (blue). The black line shows the extinction of the bare pentacene film.

Optoelectronic properties of FeSe nanomaterials with diverse dimension

Hyojin Kang[1] and Jaebeom Lee[1,2*]

[1]Department of Chemical Engineering and Applied Chemistry, Chungnam National University, Republic of Korea[2] Department of Chemistry, Chungnam National University, Republic of Korea
[*]corresponding author: nanoleelab@gmail.com

Abstract: Metal chalcogenides, such as molybdenum sulfide (MoS_2), nickel sulfide (Ni_3S_2), and copper-based chalcogenides, are mainly a two-dimensional structure and have been studied in various fields for the past 10 years. Herein, we report dimension-controlled FeSe nanomaterials (0D, 1D and 2D) to have unprecedented electron structure using absorption coefficient driven by investigating transmittance spectra via Fourier-transform infrared spectroscopy, breaking conventional charge-phase transition. This approach could be applied as a next-generation electronic device due to its specific band gap and photo-reactivity.

The discovery of two-dimensional atomic crystals with rich photonic and optoelectronic properties has sparked renewed interest in next-generation optoelectronic devices. Among them, FeSe superconductors and related systems corresponding to transition metal chalcogenides have received particular attention due to their simple crystal structures and unique electronic and physical properties[1]. However, recently, studies on FeSe quantum dots as semiconductor light emitting materials have been actively conducted.[2] These quantum dots showed multi-colored excitation dependent emission (MEDE) characteristics that only appear in organic quantum dots, and this was reported to be caused by unusual electronic states that appear in semiconductors and Mott physics. In this study, various sizes and morphologies of FeSe nanocrystals were utilized to investigate and compare their anomalous band gaps and optical properties. 0D FeSe QDs were synthesized with chiral ligands of L-, D-cysteine (Cys), resulting in MEDE characteristics controlled by ligand-induced interlayer distance change. In addition, the inorganic MEDE is predicted to originate from the strong correlation effect in the local impurity state of the band edge occurring in the Fe-3d-orbital, where the interlayer extension by the Cys ligand promotes the MEDE degree of the FeSe NPs.

In the size/shape-dependent properties of FeSe, a new type of room temperature phase transition is clearly observed, including band gap instability seen in strongly correlated d-p orbital interaction effects. In particular, an unusual situation was found in the synthesis of FeSe nanospheres (d. 3.6 nm) and 2D nanoplates (l. 20, 500 nm). The optical coefficient spectra show significant bandgap differences in both, which are predicted to be attributed to the reduced bandgap by possible quantum confinement and electrical continuity in the first and second dimensions, respectively. This approach can be applied to analyze the electronic band structure of other relevant systems, disrupting the existing charge phase transition and achieving a feasible approach for electronic devices.

Abstract: The plasmonic photothermal effect can be used as an efficient heat source due to enhanced light-matter interaction. This talk will introduce recent advances in plasmonic photothermal effect-driven motion. Also, we will discuss the chiral photothermal effect and chiral optofluidics induced by chiral plasmonics.

The plasmonics photothermal effect is an emerging field in photonics that aims at harnessing the kinetic energy of light to generate heat at the nanoscale.[1] Meanwhile, along with the expanding application of circularly polarized light, a growing number of investigations on chiral plasmonic metasurfaces have been conducted.[2] This talk aims to introduce recent advances in chiral photothermal effect and their applications.

First, we will introduce the concept of the chiral photothermal effect. The chiral photothermal effect is a phenomenon that the process of different heat generation, conduction, and dissipation after circularly polarized light is absorbed by chiral materials.[3]

Second, we will introduce a theoretical conception of chiral optofluidics induced by the chiral photothermal effect.[4] As shown in figure 1a and figure 1b, the proposed metasurface exhibits giant circular dichroism in absorption and thus leads to a strong photothermal effect. Based on the multiphysical analysis, including optics, thermodynamics, and hydrodynamics, we propose a concept of chiral spectroscopy termed optofluidic circular dichroism. Our results show that different fluid velocities of thermally induced convection appear around a chiral plasmonic metasurface under different circularly polarized excitation. The chiral fluid convection is induced by an asymmetric heat distribution generated by absorbed photons in the plasmonic heater. This concept can be potentially used to induce chiral fluid convection utilizing the chiral photothermal effect. Our proposed structure can potentially be used in various optofluidics applications related to biochemistry, clinical biology, and so on.

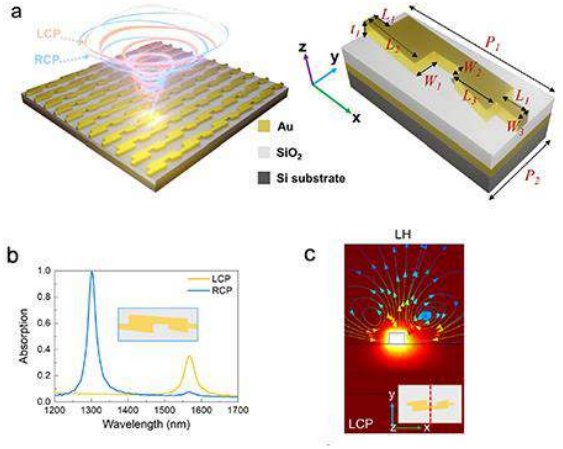

Figure 1. (a) Schematic of the chiral metasurface consisting of Au nanoantenna arrays and a bottom Au film separated by a SiO_2 layer; the geometry of a unit cell in the chiral metasurface. The thicknesses of the top Au chiral structure and bottom Au layer are 55 and 100 nm, respectively; the thickness of the SiO_2 spacer is 150 nm. For the top

resonator: L1 = 100 nm, L2 = 350 nm, L3 = 200 nm, W1 = 100 nm, W2 = 50 nm, W3 = 61 nm, P1 = 800 nm, P2 = 350 nm. (b) Simulated optical response of RH metasurface under RCP illumination. (c) Thermal-induced chiral fluid convection of the RH metasurface.

In the end, we summarize chiral photothermal phenomena and discuss their potential applications.

Abstract: The metasurfaces consist of arrays of sub-wavelength nanostructures, called meta-atoms. The periodic arrangement of these meta-atoms plays a key role in determining the functionality of the metasurface device.[1] In this project, Si nanoparticles are synthesized in solution[2] and assembled by a capillary force-based technique,[3] overcoming some of the drawbacks of the top-down approach. Furthermore, the metasurface structure assembled by Si NPs with high refractive index can realize strong magnetic field response with low loss.[4]

We have demonstrated the development of an aggregation-free colloidal dispersion of Si NPs with spheroidal shape using a kitchen blender,[2] based on exfoliation processes without addition of any surfactant. We obtained crystalline Si NPs with diameters controlled in the range of 45−250 nm. Nanoholes with different sizes were obtained by e-beam lithography (EBL). After a silanization reaction, Si NPs were filled into the hole with the help of capillary force using SmartForce. Finally, PMMA is removed by acetone and a certain size of nanoparticle metasurface can be obtained.

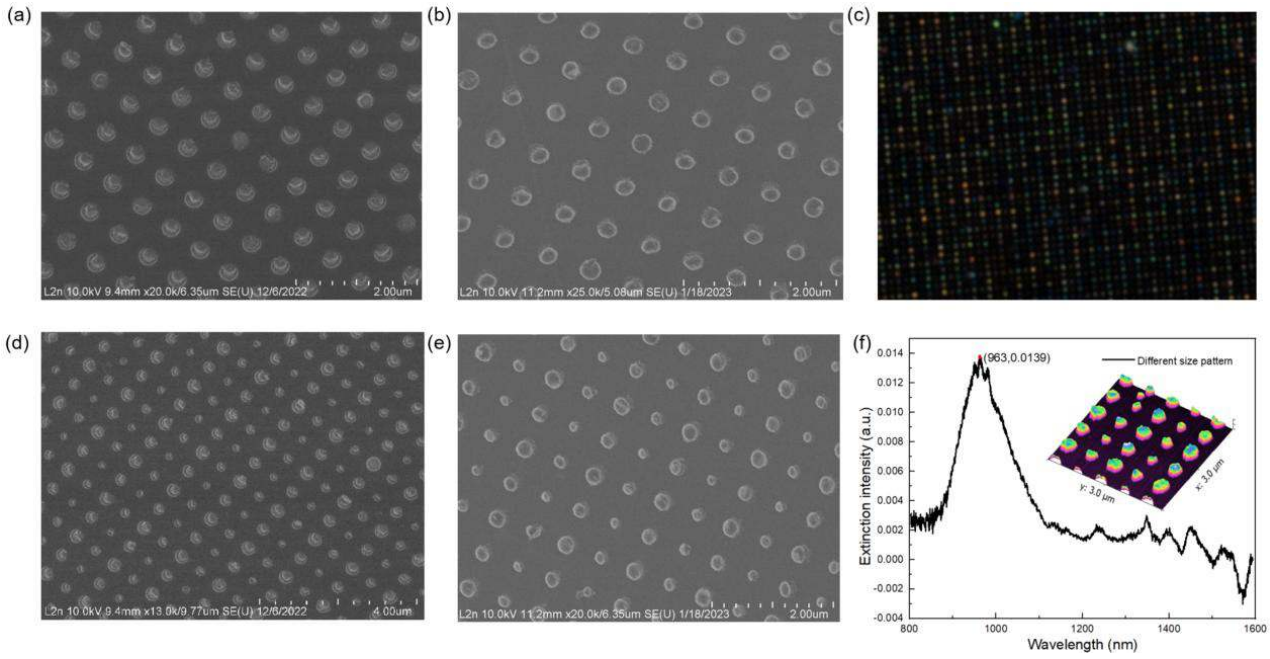

Fig. 1 NP assembly. SEM micrograph of a randomly selected assembly area 1 showing the deposition of single NPs (a) with PMMA matrix and (b) after removing the mask. (c) Dark field optical image of a randomly selected assembly area after removing PMMA mask. SEM micrograph of a randomly selected assembly area 2 showing the deposition of single NPs (d)

with PMMA matrix and (e) after removing PMMA. (f) Extinction spectrum of area 2 assembled by SmartForce after removing PMMA. The inset picture is the corresponding AFM image for this area.

We present a microfluidic platform to produce a pattern with particular size design within a microchannel, based on sequential capillarity-assisted Si nanoparticles assembly. The NPs assembly result is shown in Fig.1, the SEM micrograph of a randomly selected assembly area 1 and area 2 showing the deposition of single NPs is presented. The filling rate is almost 100%, and the Si NPs arrays stays well organized on the substrate after removing PMMA. This is also confirmed by AFM image shown in Fig.1 (f inset). First transmission optical measurement has been obtained and presented in Fig.1 (f) and shows an optical resonance in NIR. Other optical measurements on a larger range are in progress and will be presented.

The polarization, phase and amplitude of incident light can be controlled by the metal metasurface composed of metal structural elements. With the research of metasurface entering the near-infrared and visible wavelengths, the intrinsic loss of metals becomes increasingly prominent and cannot be ignored. The proposed dielectric metasurface avoids the loss problem of metal metasurface and the structural and functional design of dielectric metasurface is based on Mie scattering. Using a dielectric material in place of the plasmonic one, it will be possible to explore new optical and thermal properties. With the plethora efforts of researchers, we believe optical metasurfaces would spread through in our life sooner or later.

Abstract: Plasmonic surface lattice resonance-based (SLR) nanolasers are attractive because of their small mode volumes and footprint, ultrafast dynamics, and good beam directionality.[1] Underlying plasmonic nanocavities are usually produced by conventional lithography processes. We have developed a deposition method to arrange monodisperse, colloidal nanoparticles onto macroscopic, patterned substrates, otherwise metasurfaces, with a high assembly yield.[2,3] Furthermore, we have shown that the SLR can drive the lasing modes from the fluorescence spectra of the organic dye when pumped with ultra-short laser pulses.
This research was performed within a project LaSensA under the M-ERA.NET scheme.

Biocompatible fluorescent carbon dots nanoparticles used for anti-counterfeiting of cultural artefacts

Abstract: In this work, fluorescent biocompatible carbon nanoparticles were synthesized using high-pressure bottom-up synthesis. The influence of the different synthesis parameters was studied to investigate the formation mechanism of this method and their influence on the photophysical properties of the nanoparticles.
The carbon dots formed by this method were then integrated into various mediums to produce safe anti-counterfeiting markings used to protect cultural artefacts discovered in archaeological sites with a high risk of looting.

For many years, cultural property in general and archaeological artefacts especially have been liable to be stolen during and after the excavation process to be introduced to the black market. Globally, it is commonly estimated that the illicit trafficking of cultural heritage ranks among the biggest illicit trade in the world, grossing several billion dollars[1].

To tackle this problem a safe technical solution is needed to trace stolen archaeological artefacts. Biocompatible fluorescent nanoparticles can be used to produce original anti-counterfeiting markings that are safe for use without training and hard to reproduce by looters.

In 2004 Xu et al[2] discovered nanoparticles composed of carbon that produced blue photoluminescence. Carbon dots are a 0D nanomaterial made of a hybrid structure with graphene-like clusters of sp2 carbon linked within a shell of amorphous sp3 carbon comprised of organic functional groups on its surface. They present properties ideal for anticounterfeiting applications such as biocompatibility[3], stability and narrow fluorescence that can also be dependent on the excitation wavelength.
Since they are mainly composed of carbon, they constitute a safer alternative to heavy metal quantum dots and allow us to avoid trace contamination before analysis. As of today, carbon black is the basis of the black inks currently used for marking and it is chemically identical to Carbon Dots.
Various structures of carbon dots can be synthesized by bottom-up high-pressure synthesis from organic precursors. Conditions of pressure and temperature as well as the precursors used in the synthesis are chosen by investigating the emission properties and the quantum yield of the carbon dots. Structural characterizations such as FTIR and Raman spectroscopy are also investigated to bring new information on the origin of the fluorescence in their structure.

As a proof of concept, carbon dots synthesized from 1,6-dihydroxynaphtalene using a protocol developed by Yan et al.[4] were synthesized. After purification by silica column chromatography, we obtained a colloidal solution with a fluorescent emission at 590nm under UV or green excitation. This solution showed an absolute quantum yield of 22.6% under 530nm excitation. Integration of these nanoparticles inside commercial clear nail

polish used by archaeologists for protection of artefacts was performed by drying and redispersion in ethyl acetate. The coatings produced were unrecognizable from usual protection coatings with the naked eye but fluoresce under the correct excitation allowing for identification of the cultural artefact.

Abstract: We report the DNA-mediated assembly of gold nanoparticles into 3D superlattice crystals and their subsequent stabilization using carbazol-mediated DNA cross-linking. The visible-near infrared optical properties of the gold-DNA superlattice crystals is shown to be mediated by a broad spectrum of higher order Mie resonances.

Bottom-up approaches for developing new types of hybrid nanomaterials using DNA-mediated assembly are of great interest for their ability to encode the hierarchical structuring through the microscopic building blocks. In recent work our team has established methods for stabilization of the resulting superlattice structures using reversible DNA cross-linking via carbazole groups incorporated into the oligonucleotide structure.[1]

In this work we explore the optical response of three-dimensional Au superlattices mediated by DNA-assembly and carbazole cross-linking, down to the level of single isolated crystals using hyperspectral imaging and micro-spectroscopy. A broadband optical microscopy setup was constructed equipped with a supercontinuum laser as the main light source, a Si and InGaAs photodetectors for signal detection enabling a broad range from 400 nm to 1700 nm. As for the measurement we use a NA, 0.5, 100x objective to focus the light source on to the sample plane, resulting a diffracted limited spot with a diameter equal to the optical wavelength. An identical 100x objective was used to collect the transmitted or scattered light from the sample.

The originally prepared superlattice crystals are kept in a colloidal solution. A small amount (~ 10-20 µl) of the solution was drop casted on a freshly cleaned microscope glass slide and then let to dry overnight. Figure 2a shows the bright field image and the corresponding darkfield image under white lamp (focused laser spot is seen as a bright spot). As seen from the images the crystals on the film tend to form mostly aggregates but there are regions also where they are dispersed and isolated.

A hyperspectral imaging map is generated by scanning the laser focus over the dotted area in Figure 1a. The result under bright field illumination is shown in Figure 1b. The map looks like the exact replica of the digital image shown in Figure 1a expect that now each pixel in such a map contains detailed spectral information as shown in Figure 1c. The transmittance spectra show features around 650-700 nm due to plasmon resonance

effects. Also, the supercrystals exhibit features at higher wavelength >1000 nm which we attribute to the Mie-type resonances of the supercrystals.

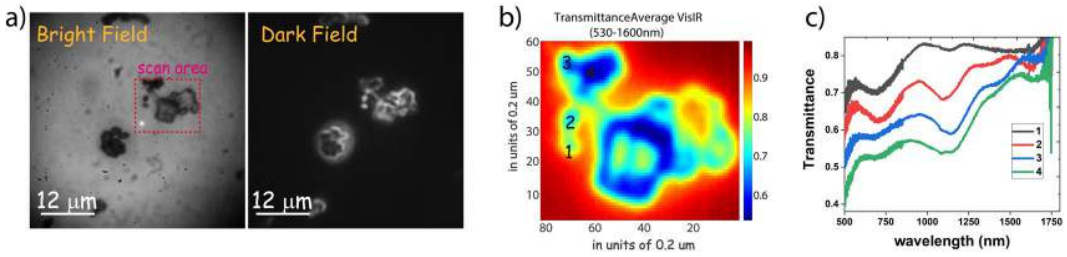

Figure 1. (a) Bright field and dark field images of Au superlattice crystals drop casted on a glass slide. (b) Hyperspectral map (scanned area in (a)) for average transmittance measured under bright field configuration. (c) Transmittance spectra corresponding to points marked in (b).

The setup allowed us to reveal a polarization-insensitive optical response with distinct scattering features in the visible and near-infrared range. The experimental observations were supported by detailed numerical simulations of the microcrystals under a resonant effective medium approximation in the regime of capacitively coupled nanoparticles. The study identifies a universal characteristic optical response which is defined by a band of multipolar Mie resonances, which only weakly depend on the crystal size and light polarization.

The authors acknowledge support from Dstl through a PhD studentship of ADF and The Leverhulme Trust through research grant RPG-2018-251.

Far-field optical methods are hindered by the optical diffraction limit. This is probably one of the reason of the success of electron-based optical spectroscopies available in a Scanning Transmission Electron Microscopy (STEM) such as Electron Energy Loss Spectroscopy (EELS) and Cathodoluminescence (CL), among others. One objective of the last decades is to unveil information about the electric field polarization of various excitations (plasmons, excitons, phonons, etc.) using Electron Microscopy, and measure the linear and the circular dichroism as it can be achieved in Optics. A first method to access this information is to measure, in EELS, the Orbital Angular Momentum transfers between the electron beam and the excitations to probe the near-field polarization. A second way to access the polarization measurement in the far-field, is to study the polarization of photons emitted by the sample after having been exited by the electron beam using CL. Some experiments have already combined the use of energy-filtered and polarized light and Scanning Electron Microscope to study achiral and chiral objects [1-3]. One object of interest is a well-known system called a Born-Kuhn System (BKS). This complex nanoparticle exhibits two plasmonic modes which have opposite chirality. This property already has been studied in optics on BKS networks [4] but has never been observed on a single nanoparticle. In this seminar, we discuss the way to perform such an experiment on BKS using a STEM, what are the limitations we can face of and what are the considered solutions to overcome them.

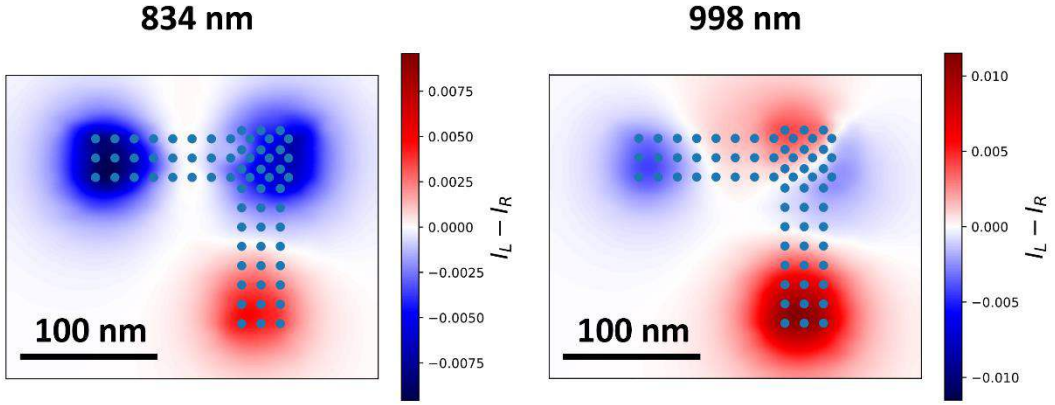

Figure : Simulated Right (R) and Left (L)-handed polarized cathodoluminescence on a gold BKS structure. Each arm has a length of 150 nm and a width of 50 nm. (pyGDM2)

New trends in nanophotonics and advanced materials

Active aerosols to control the propagation of light

Jake Fontana[1*], Chuck A. Rohde[1], Kristin M. Charipar[1], Paul Johns[1], Ashlin G. Porter[1] and Nicholas J. Greybush[1]

[1]U.S. Naval Research Laboratory, 4555 Overlook Ave. SW, Washington, DC 20375, USA

Abstract: This work connects the fields of active plasmonics and aerosols to establish an active aerosol. We report the experimental dynamics and control of ensembles of gold nanorods suspended in air by varying the magnitude and frequency of externally applied electric fields, thereby demonstrating an active aerosol. We further show light filter, valve and gradient-index responses, demonstrating active aerosols as a novel type of optical element we define as component-less optics.

Aerosols commonly impede the propagation of light and the ability to make observations in a variety of research fields, from cosmic dust in astronomy, to clouds in climate science and fog in navigation. Traditionally, aerosols have been regarded as passive, disordered media. If aerosols can be actively ordered, then spatial, spectral and temporal windows of opportunity may open to govern the propagation of light in air. External fields are regularly used to order individual aerosol particles. Though, control of an ordered aerosol ensemble of particles and resultant macroscale optics has yet to be realized, generally due to the need for significant coupling of the external field to a large number of particles in low pressure environments to overcome the disordering forces of Brownian motion.

Experiments were carried out to guide the optical response of an aerosol ensemble and understand the dynamic anisotropic properties of these materials in air when placed in external fields. Plasmonic nanorods were aerosolized into the gas state [1] and coupled to external electric fields [2], as conceptually illustrated in Figure 1.

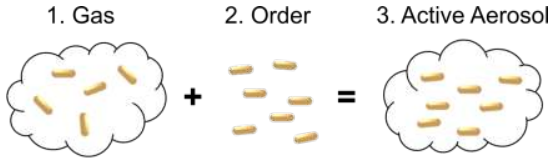

Figure 1. Active aerosol: Electric field induced order in plasmonic aerosols. Reprinted with permission from [3] © The Optical Society.

Active aerosols are shown as three illustrative optical elements, we term component-less optics [3]: (i) The absorption spectrum of gold nanorods in air is shown in Figure 2(a), with longitudinal and transverse absorption peaks at 1020 nm and 520 nm respectively, showing a stop-band light filter element at the absorption peak wavelengths. (ii) The orientational order of the ensemble of gold nanorods suspended in air is controlled by placing an AC electric field across the aerosol, aligning the longitudinal axis of the nanorods in the applied field direction, resulting in a light valve response, Figure 2(b). (iii) The positional order of the aerosol is modulated by introducing a DC electric field, pushing/pulling the nanorods in the field direction, and demonstrating a mechanism to create a gradient index behavior from the aerosol, Figure 2(c).

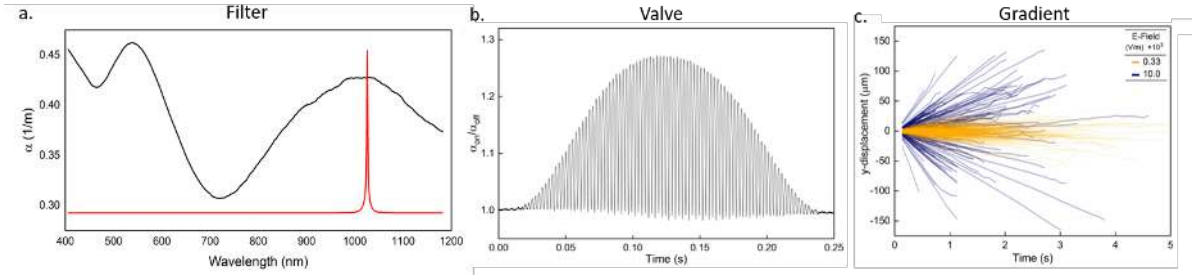

Figure 2. Component-less optics: light filter (a) valve (b) and gradient-index (c) responses. Adapted with permission from [3] © The Optical Society.

Integrated 2D GaGeTe Electro-Optic Phase Shifter in Silicon Photonics

S. R. Tamalampudi[1], G. Dushaq[1], J. E. Villegas[2], and M. S. Rasras[1*]

[1] Department of Electrical Engineering, New York University Abu Dhabi, UAE

[2] Department of Electrical and Computer Engineering, New York University Tandon School of Engineering, NY, 11201, Brooklyn, USA

Abstract: We present a high-speed and compact optical phase-shifter using multi-layered GaGeTe hybrid integrated on silicon micro-ring resonator (Si-MRR) structure. Under static DC bias, a blue-shift of wavelength is observed for both the Transverse Electric (TE) and Transverse Magnetic (TM) polarizations corresponding to -1.78 pm/V and - 6.65 pm/V, respectively. The device showed a remarkable tuning speed of 2.1 MHz with low optical insertion losses <0.25 dB. The Pockels effect is expected to dominate the observed phase shift.

The two-dimensional (2D) multi-layered GaGeTe crystals are a non-centrosymmetric structure Recently, those crystals have gained a lot of attention due to their superior electrical and optical properties. They also exhibit high chemical stability under ambient conditions[1-5]. The GaGeTe crystals are part of the MXTe 2D layered group made up of stacks of monolayers connected by weak van der Waals interactions [5].

In this work, we present an electro-optic device based on the hybrid integration of GaGeTe into a silicon micro-ring resonator (Si-MRR). Figure 1 (a) inset shows a schematic of the device, and optical image of the device. A compact phase shifter is used with a total length of 28µm. The device operates in the O-band centered at the telecom wavelength of 1310 nm. As shown in Fig. 1(a and b), for the TE polarization, a blue shifted phase of -1.78pm/V is observed which is attributed to changes in the real part of the index of refraction. A higher blue shift of -6.65 pm/V is observed for devices operating in the TM mode. We expect this blue shift with the positive applied bias to be due to the Pockels effect.

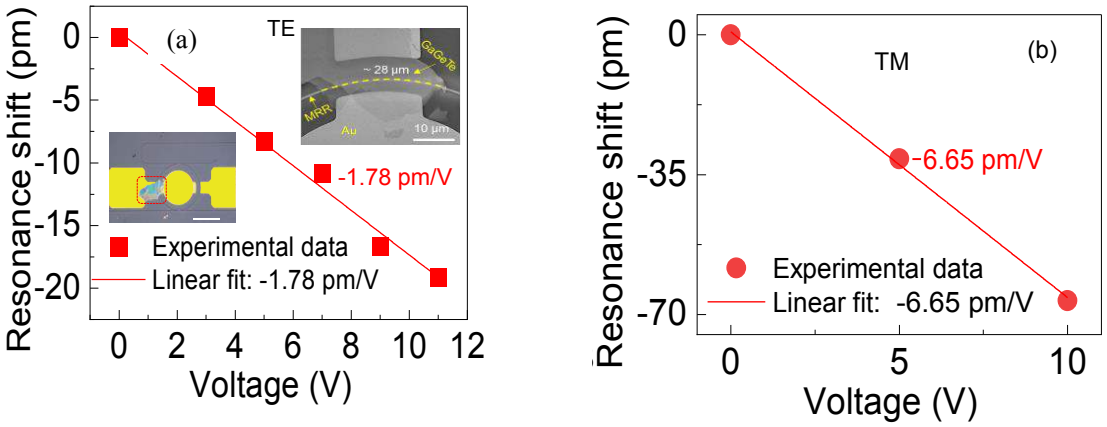

Fig. 1. The electro-static response of the hybrid Si-MRR/GaGeTe flake for TM mode with coverage lengths of 28 µm for different DC voltages. The measured resonance shift versus applied voltage (a) TE mode (b) TE mode.

In summary, the hybrid integration of GaGeTe on Si waveguides expands the silicon photonics device library by introducing a new class of highly tunable and linear electro-optical materials. The proposed structure can be used to construct optical phase shifters, high-speed modulators, small-footprint switches, and a variety of other active integrated photonic devices.

Acknowledgements, this work was supported by NYUAD Research Enhancement Fund. The experimental characterization was conducted in the NYUAD Photonics Lab and simulations were performed on the NYU IT High-Performance Computing resources given its services and staff expertise.

Abstract: Two-dimensional photonic crystal (PhC) in a planar geometry has enabled many sophisticated photonic functions and devices, such as PhC phosphors, photonic Anderson localizations, random lasers, and topological lasers, all demonstrated by the author's group. It is expected to continue to play pivotal roles in photonics. In this talk, some of the salient features and properties of those devices will be presented.

Two-dimensional (2D) photonic crystals (PhCs) have been exploited to demonstrate various important concepts and devices in nanophotonics, which include nanocavities with extreme Q factors, nanowaveguides with negligible bending-loss or cross-talk, zero or negative dispersions, nanolasers, etc. The author's group also has been working on both pure and applied physics based on the 2D PhCs with the emphasis on photonic band-edge modes. As for pure physics, photonic band-tail states manifested in composition-disordered PhCs and their relationship to photonic Anderson localizations were clarified [1]. For applications, a number of technologically important milestones in nanophotonic devices have been achieved, including PhC-based random lasers prepared by a top-down approach (Fig. 1) and the active controls on their modal properties [2], PhC phosphors with unprecedentedly high color-conversion efficiency [3], and topological PhC lasers that are immune to structural imperfections and irregularities [4]. This talk will summarize the concepts and characteristics of those devices, along with the future perspectives.

Plasmon and Graphene-based Nano-tweezers for Raman Imaging

Changjun Min[1*]

[1]Nanophotonics Research Centre, Institute of Microscale Optoelectronics, Shenzhen University, Shenzhen, China
[*]corresponding author: cjmin@szu.edu.cn

Abstract: To enhance the optical trapping precision and functions, we propose two new nano-tweezers technologies, including the plasmonic-thermoelectric tweezers and the graphene-based opto-thermoelectric tweezers. The plasmonic-thermoelectric tweezers offer both high trapping stability and high electric-field enhancement, and achieves Raman imaging with resolution of ~λ/4.5 by dynamically scanning a single metallic nanoparticle. The graphene-based opto-thermoelectric tweezers significantly reduces the required incident power and extends the working bandwidth, and shows great application potential in intracellular Raman spectroscopic detection.

Optical tweezers and associated manipulation tools have had a major impact on scientific and engineering research by offering precise manipulation of small objects. More recently, the use of surface plasmon techniques enables excitation of hotspots much smaller than the free-space wavelength; with this confinement, the plasmonic tweezers could achieve trapping of various nanostructures and materials with higher precision, and thus have contributed to various applications such as nanoparticle (NP) transport and sorting, biomanipulation, and spectrographic sensing and imaging [1].

Surface-enhanced Raman spectroscopy (SERS) technology usually uses metallic nanoparticles to enhance Raman scattering signals, thereby adding significantly to molecule-level recognition and detection. However, realization of nanometre-scaled SERS imaging in liquid environments is extremely difficult due to the requirements of both precise scanning of single metallic nanoparticle and high enhancement field, and thus has never been achieved before. To overcome this obstacle, we propose and demonstrate an immersive nanometre-scaled SERS mapping technology, based on dynamic scanning of a single metallic nanoparticle with a plasmonic-thermoelectric tweezers (PTT) system [2], as shown in Figure 1. The PTT is based on the combination of plasmonic focus and thermoelectric effect, and is demonstrated to possess both high trap stability and Raman enhancement. The results indicate that, for a trapped gold NP of radius 100 nm, its range in fluctuation shrinks sharply to 1/10 of the size observed within traditional focused plasmonic tweezers. By scanning the trapped NP over a molybdenum disulfide (MoS2) sample, two-dimensional Raman imaging with a deep-subwavelength resolution of 118.5 nm is achieved, thereby breaking the diffraction limitation significantly. This enables exciting new functionalities for optical tweezer systems, for example, imaging and detection of biological samples, plasmon-mediated photocatalysis, molecular detections, and many others.

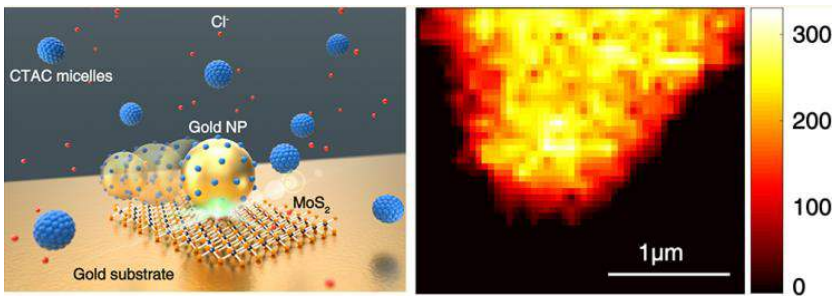

Figure 1. Schematics of SERS imaging based on the PTT system, and the resultant Raman imaging of the MoS_2.

Besides the plasmonic-thermoelectric tweezers based on the metallic nano-film, we also introduce graphene to the field of optical-tweezer technology and demonstrate the graphene-based opto-thermoelectric tweezers (GOTT) [3]. The GOTT technology not only reduces the incident light energy required by two orders of magnitude (compared with traditional optical tweezers), it also brings new advantages such as a much broader working bandwidth and a larger working area compared to those of widely researched gold-film-based opto-thermoelectric tweezers. Compared with gold film, graphene exhibits higher thermal conductivity and higher uniformity and is easier to process. Thus, we have found that even monolayer graphene provides stable trapping for particles in a broad bandwidth and that performance is enhanced as the number of graphene layers increases. Furthermore, parallel trap multiple particles as desired shapes can be easily generated with structured graphene patterns. This work demonstrates the enormous application potential of graphene in optical-tweezer technology and will promote their application to the trapping or concentration of cells and biomolecules as well as to microfluidics and biosensors.

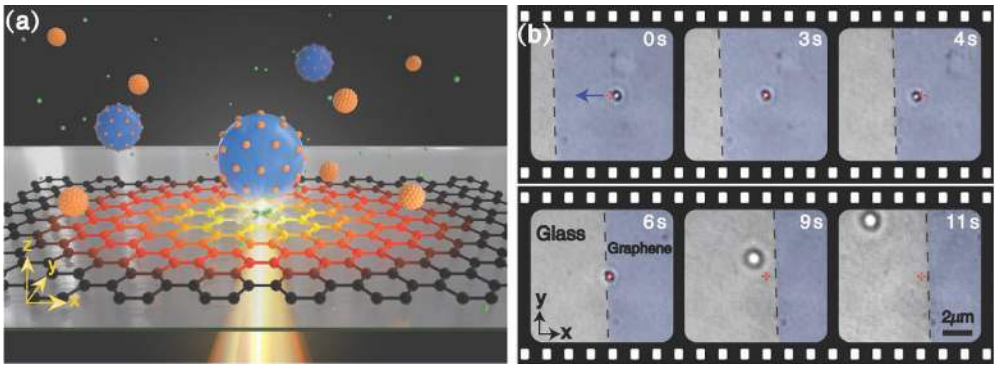

Figure 2. (a) A schematic of the GOTT featuring a graphene substrate. (b) Successive images showing a 500-nm-diameter PS particle stably trapped and dragged to the left.

Moreover, we demonstrate that the GOTT system can be used for in situ intracellular Raman spectral detection [4]. Because of the excellent photothermal conversion effect of the graphene substrate, a potent thermoelectric effect is generated to not only strengthen the trap for biological cells, but also accelerate metallic nanoparticles to permeate into these cells for intracellular Raman enhancement. An in situ intracellular Raman spectrum is thus acquired that offers the opportunity to distinguish the intracellular elements. This work provides a promising approach for use in cytobiology research and is expected to enable exciting new applications in the detection of complex intracellular life processes.

Abstract: Organic materials exhibit excitonic resonances capable of showing strong light-matter coupling at room temperature. We present a review of our recent results on organic microcavities with 3 different materials (perylene, DPAVBi, and TTPSB polymers). We demonstrate emergent optical activity (equivalent to Rashba-Dresselhaus spin-orbit coupling) leading to the formation of topological valleys capable of helical lasing, and selective strong coupling creating exceptional points. We also demonstrate ultrafast switching between bands, enhancing the polariton interactions by an applied electric field.

Topological photonics is a very active research field [1]. It exploits various types of spin-orbit coupling and symmetry-breaking terms giving rise to topological bands or valleys, often responsible for the formation of protected interface states which can have one-way propagation properties.

Combining topology with interactions is crucial for the fabrication of future devices. Strong interactions even allow reaching the quantum regime. Optical non-linearities can be obtained by different means, including the so-called strong light-matter coupling, generating optical eigenstates with a significant "material" fraction, for example, due to the coupling of the light modes with excitonic resonances. This coupling is characterized by the Rabi splitting between the mixed eigenstates. Room-temperature operation requires excitons with large binding energies and high oscillator strengths giving rise to Rabi splittings $\hbar\Omega_R > k_B T$. This is why organic semiconductors are particularly interesting for the studies of non-linear topological photonics with applied purposes. Apart from the strong light-matter coupling, organic semiconductors possess other interesting optical properties, including strong anisotropy of the excitonic resonances. One can even achieve polarization-dependent strong light-matter coupling. This can be interpreted as a strong linear birefringence.

In a recent paper [2], we have demonstrated experimentally and theoretically that a microcavity with an active region exhibiting a sufficiently strong birefringence capable of putting in resonance the cavity modes of opposite parity gives rise to an emergent optical activity. This phenomenon was originally discovered in liquid crystal microcavity [3], where it has been interpreted as a Rashba-Dresselhaus spin-orbit coupling with equal strength. This emergent optical activity is a key ingredient allowing to achieve topological valleys in cavity modes, with other ingredients universally present in many cavity systems: the TE-TM splitting (ubiquitous in all inhomogeneous systems) and the residual linear birefringence. The two latter ingredients provide valleys with tilted Dirac cones, whereas the optical activity opens topological gaps at these Dirac points. This first work, where the topology of these valleys was measured directly from the optical eigenstates, was based on the use of

an organic crystal polymer called perylene, which is often used as a dye.

In the following work, we have demonstrated the possibility to achieve helical lasing from such valleys formed in microcavities with another organic polymer, TTPSB [4]. Polariton relaxation is assisted by the vibron resonance. The circular polarization degree at the band extrema of the valleys is protected by their topological invariants, the valley Chern numbers. The device can be used as a source of directional circular-polarized laser beams.

In parallel, we have studied a different organic polymer, DPAVBi, which manifests selective strong coupling. With one polarization coupled to excitons and another uncoupled, the mass of the cavity modes is very different. This allows a single weakly coupled photonic mode to cross several strongly coupled polaritonic modes of the opposite polarization, with half of them of opposite parity, allowing the observation of emergent optical activity. Moreover, selective strong coupling gives rise to a very different linewidth of strongly and weakly coupled modes (x2 difference), thus creating conditions for the formation and observation of exceptional points [5]. Thanks to these unique properties, we have managed to demonstrate experimentally the hyperbolic divergence of the quantum metric in the vicinity of exceptional points, which is important for the beam dynamics.

Finally, using the same organic polymer DPAVBi embedded in a cavity, we have demonstrated polariton lasing assisted by an electric field [6], which improves the polariton-polariton interactions by inducing an excitonic dipolar moment and changing their radius, while at the same time increasing the exciton lifetime. The electric field thus strongly changes the properties of polaritons and controls their relaxation, allowing us to fabricate an ultrafast electric switch.

A multi-modal nonlinear optical technique to study *in-situ* polymer nanostructure formation

T. Verbiest[1,*], K. Aerts[1], and Y. de Coene[1]

[1]KU Leuven, department of chemistry, Belgium

Abstract: We describe a new multi-modal optical technique to study the formation of (polymer) nanostructures in solution. The technique is based on linear and nonlinear light scattering combined with multi-photon fluorescence and optical transmission.

Conjugated polymers in solution are extremely attractive materials for various optical and opto-electronic applications, because of their semiconducting and fluorescent properties. They have been investigated for their applications in spintronics, metamaterials and photovoltaic applications.[1,2,3] Unfortunately, predicting and reproducing their (optical) properties has proven to be extremely difficult.[4] One possible explanation is polymorphism that is commonly found in their nanostructures.[5,6] Indeed, different nanostructures can be formed depending on the processing or preparation conditions, but little is known about steering the formation process of the nanostructures towards one particular polymorph. The key in understanding lies in the mechanism of nanostructure formation, but this requires powerful *in-situ* techniques that are sensitive to aggregation and self-organization.

We have recently developed a new analytical technique to study such processes based on the simultaneous measurement of second-and third-harmonic scattering (harmonic scattering), and multi-photon fluorescence.[7] Here we describe an in-situ multi-modal optical detection scheme that combines static linear light scattering, harmonic light scattering, multi-photon fluorescence and optical transmission. We will show that it can serve as a powerful benchtop technique for studying nanostructure formation in conjugated polymers. A schematic of the technique is shown in Figure 1.

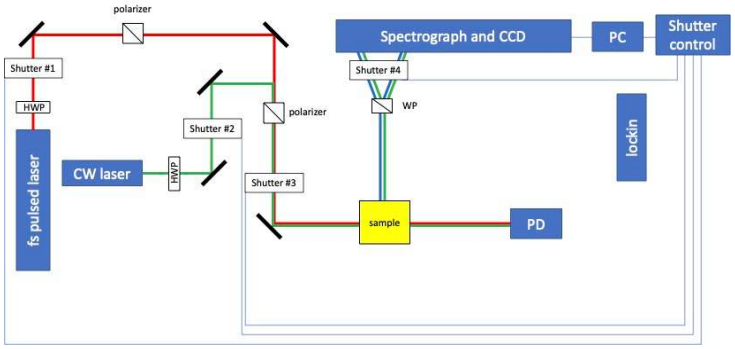

Figure 1: schematic representation of the multi-modal set-up. HWP = half-waveplate, WP = Wollaston prism, PD= photodiode. When shutter#1 and #4 are open, light from the fs laser is focused into the sample cuvette. Harmonic light scattering and multi-photon fluorescence are detected by a lens system, send through a Wollaston prism and detected by a spectrograph coupled to a CCD camera. When shutters#2 and #3 are open, light from the CW laser (532 nm) is focused on the sample and the (linearly) scattered light is collected in the same way as the harmonic scattering signals. The transmitted light through the sample is detected by a photodiode.

A typical measurement is performed as follows: a conjugated polymer is dissolved in a good solvent, and slowly a non-solvent is added to induce nanostructure formation while simultaneously recording 5 different observables (three light scattering signals, multi-photon fluorescence and optical transmission). The three light scattering signals give complementary information: linear light scattering reveals size while second- and third-harmonic scattering are sensitive to size, symmetry, and molecular conjugation. Multi-photon fluorescence and optical transmission give molecular information. Combining all these signals yields a complete view of the dynamics of the nanostructure formation. While demonstrated for conjugated polymers, the technique is suitable to apply to any type of material, either metallic, inorganic, or organic.

Lithium niobate metasurfaces—A bright nonlinear light source

Mengxin Ren[*], Lun Qu, Lu Bai, Wei Wu, and Jingjun Xu[†]
The Key Laboratory of Weak-Light Nonlinear Photonics, Ministry of Education, School of Physics and TEDA Applied Physics Institute, Nankai University, Tianjin, China

Abstract: Metasurfaces have demonstrated themselves as a promising platform for enhanced second harmonic generation (SHG) to achieve ultracompact nonlinear light sources. Lithium niobate (LN), particularly the crystalline LN thin film on insulators (LNOI) has emerged recently as a promising platform to manufacture metasurfaces. In this talk, we will present our recent work about nonlinear LN metasurfaces with high SHG conversion efficiencies.

Second harmonic generation (SHG), which converts the frequency of a laser ω to twice its frequency 2ω, plays a key role in extending spectral coverage of laser sources to wavelengths that are difficult to access by standard laser gain media. As we enter the Nano-era, the SHG at nanoscales with controllable performance is highly desired. Nonlinear metasurfaces have provided us with a revolutionary concept to engineer nonlinear responses from nanoscale. In addition, it also acts as a new platform to realize novel nanoscale SHG light sources. However, the current nonlinear metasurfaces made of noble metals or semiconductors suffer problems of either high loss or narrow transparent band, which imposes strict constraints on their applications. Recently, crystalline lithium niobate thin film on insulators (LNOI) has emerged as an excellent solution for the novel SHG metasurfaces and nonlinear light sources. However, their SHG conversion efficiencies are still limited, which seriously limits their applications. How to further enhance the SHG efficiency has become an urgent problem to address. In this talk, we will present our recent results on the topic of nonlinear LN metasurfaces [1,2,3], which show a strong nonlinear conversion efficiency larger than 10^{-4}. Our work paves an effective way for enhancing nonlinear optical processes within the framework of metasurfaces, which can be used to develop ultracompact nonlinear light sources for photonics and optoelectronics.

ABSTRACT

Optical beam steerers have been widely employed for information acquisitions. Numerous beam steering schemes have been developed and each of them can satisfy practical requirements for certain scenarios. However, there is still a lack of a comprehensive approach able to balance all the critical technical parameters for wide range of applications. In this talk, we will present a semi-solid micro-mechanical beam steering system based on micro-meta-lens arrays (MMLAs). It is operated by manipulating the probe beam over two sets of decentered MMLAs potentially driven by high-speed piezo-electric motors. Small *f*-numbers, well-corrected aberration and easy lateral reproduction of micro-meta-lenses in optimizing the overall technical parameters. As a proof-of-concept, we implement such a device exhibiting diffraction-limited resolution within a large field of view of 30°×30°. A three-dimensional depth sensing is also performed to demonstrate its potential in light detection and ranging (LiDAR) applications. In this talk, we will exhibit that this MMLAs could be employed to design a two-dimensional optical ruler with nanometric resolution.

Hierarchical Micro/Nanostructures for Light Harvesting and Photovoltaic Device Applications

Jae Su Yu[1*]

[1]Department of Electronic Engineering, Institute for Wearable Convergence Electronics, Kyung Hee University, 1732 Deogyeong-daero, Gihung-gu, Yongin-si, Gyeonggi-do 17104, Republic of Korea
[*]corresponding author: jsyu@khu.ac.kr

Abstract: Hierarchical micro and nanostructures based on inorganic and organic materials for the manipulation of light behaviors such as reflection, transmission, scattering, etc. are demonstrated. The fabrication of the micro and nanostructures on material surfaces is performed via various manufacturing techniques, together with the design by numerical modelling and simulations. Optical properties of the fabricated micro and nanostructures are theoretically and experimentally evaluated. Eventually, the hierarchical micro and nanostructures are applied to light harvesting and photovoltaic devices to enhance their performances.

Over the past years, antireflective structures including subwavelength grating structures instead of conventional antireflection multilayers and high hazed structures have been developed, based on micro and nanoarchitectured structures. For fabrication, electron-beam/photo lithography, laser interference, nanoimprint, thermal-wetted particles, and nano/microspheres for patterning, followed by dry etching processes, were traditionally employed. Bioinspired micro or nanoarchitectures which can enable efficient antireflection in the wide ranges of incident wavelengths and angles have been widely studied. These structures have been fabricated on the silicon, III-V semiconductors, metal oxides, glass, etc. In case of polymers, antireflective micro/nanostructures could be easily fabricated by a soft imprint lithography method which takes advantage of simple, cost-effective, and fast manufacturing.

On the other hand, in photovoltaic devices, both subwavelength structures and micrograting architectures can efficiently increase the light absorption by reducing the surface reflection owing to the linearly gradient refractive-index profile. Furthermore, micrograting extend light path lengths as well as promote diffuse lights and induce strong electromagnetic fields, which leads to a high haze factor. Additionally, micro/nanostructured polymer films can be used as the antireflection and protection layer of coverglasses to enhance the conversion efficiency of photovoltaic systems. In this presentation, I would like to report hierarchical micro and nanostructures for light harvesting and photovoltaic device applications, together with finite-difference time-domain and rigorous coupled-wave analysis simulations. For various photovoltaic devices based on hierarchical micro and nanostructures, light incident angle-dependent characteristics are also investigated in a broad angle range.

PT-symmetric non-Hermitian plasmonic systems for switchable radiation control

Yuto Moritake[1,2,*]

[1]Department of Physics, Tokyo Institute of Technology, Japan
[2]PRESTO, Japan Science and Technology Agency, Japan
[*]corresponding author: moritake@phys.titech.ac.jp

Abstract: Non-Hermitian photonics is research fields utilizing phenomena induced by non-Hermiticity. Especially, systems with *PT* symmetry is important due to *PT*-phase transition across an exceptional point (EP) where the eigenvalues and eigenmodes coalesce. In this presentation, we introduce our recent results on switchable radiation control with *PT*-symmetric non-Hermitian plasmonic systems. Coupled split ring resonators and coupled plasmonic wires were proposed for switching of unidirectional radiation and polarization states, respectively. The studies provide exotic photonic functionalities based on non-Hermiticity in the systems.

Recently, non-Hermitian (NH) physics has attracted a great deal of attention from researchers. Especially, the NH systems with *PT* symmetry exhibit *PT* phase transition across an exceptional point (EP). The eigenvalues and eigenmodes coalesce at the EP, which is very unique property of NH systems with *PT* symmetry and cannot be found in Hermitian systems. Since photonic systems naturally have non-Hermiticity due to radiation and material gain and loss, many photonic systems involving NH photonics have been reported and shown variety of intriguing phenomena [1].

In this paper, we introduce our recent studies on switchable radiation control with NH plasmonic systems. In the studies, we take advantage of the singular eigenstates at EPs, in which the resonators oscillate in $\pm\pi/2$ phase difference. First, we explain switchable unidirectional radiation from artificial Huygens dipoles in coupled split ring resonators (SRRs) [2]. And the second, switching of circular polarization eigenstates in coupled plasmonic dipoles at EPs is presented [3]. The studies would provide new root to realize novel photonic functionalities based on the singular eigenstates at EPs in NH systems.

Figure 1(a) shows a unit structure of coupled SRRs to realize artificial Huygens dipoles. Huygens dipole is formed by orthogonal arrangement of electric and magnetic dipoles which oscillate in- or anti-phase [4]. A Huygens dipole radiates unidirectionally due to interference between electric and magnetic dipoles. Here, LC resonance in SRRs are used for mimicking the electric and magnetic dipoles. *PT* symmetry was achieved by difference in radiation losses between the SRR1 and SRR2, which manifests the existence of EPs in a parameter space. Here, we sweep the geometrical parameters α (arc angle of SRR1) and d_x (displacement between SRRs along x-axis). Importantly, induced electric and magnetic dipoles in SRRs has initial phase difference of $\pi/2$ so that the Huygens dipole conditions, in- or anti-phase, are satisfied by the singular EP eigen states. Therefore, unidirectional radiation originating from Huygens dipole formation is observed (Fig. 1(b)). Moreover, by appropriate control of coupling between SRRs, we can realize the other EP, which has different sign of phase difference, giving rise to radiation to he opposite direction. We can switch the direction by choosing these EPs through the geometric parameters.

Figure 1(c) shows a unit structure of coupled plasmonic dipole resonators to realize single circular eigen states for normal incidence. The structures are composed of x- and y-dipole resonators in which GST (lossy materials) is added only y-resonator to realize a *PT*-symmetric system. At an EP, two resonators oscillate in $\pi/2$

phase difference which means polarization eigen state becomes a single circular polarization [5]. This strong chirality for normal incidence is originate from non-Hermiticity while generally optical chirality requires three dimensional structures. When the GST film is in crystal phase, the loss of GST induces non-Hermiticity and *PT*-phase transition in a polarization space as shown in Fig. 1(d). Here, polarization eigen states approach the circular polarization, which is EP eigen states, in the way of *PT* phase transition. On the other hand, once the GST is changed into an amorphous phase, its material loss becomes negligible, giving rise to disappearance of non-Hermiticity and only linear polarizations are allowed (Fig. 1(e)). These results demonstrated switching of polarization state, non-Hermitian to Hermitian transition, by material phase transition.

In summary, we introduced two studies on switching of photonic states based on non-Hermiticity using coupled plasmonic systems. Taking advantage of the singular eigenstates at EPs, unique photonic functionality can be achieved, which would be applicable to realize reconfigurable NH photonic devices.

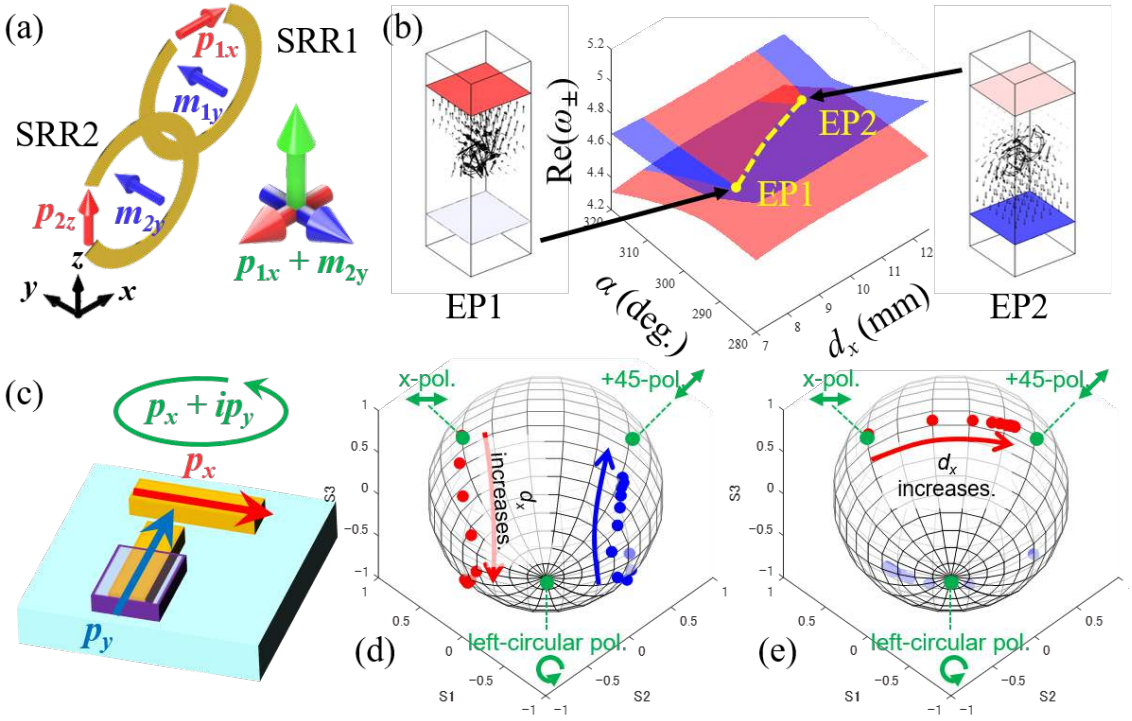

Fig. 1 (a) Coupled SRRs exhibiting artificial Huygens dipole at EPs. (b) Riemann surface structure in a parameter space and switchable unidirectional radiation from Huygens dipoles at EPs. (c) Coupled plasmonic dipole resonators for single circular eigen polarization. Change in polarization eigen states on Poincare sphire when the GST film is in (d) crystal and (e) amorphous phases.

Electromagnetic Signal Propagation Through Lossy Media

I. I. Smolyaninov[1*]

[1]Saltenna LLC, 1751 Pinnacle Drive, Suite 600 McLean VA 22102, USA
[*]corresponding author: igor.smolyaninov@saltenna.com

Abstract: It is commonly believed that electromagnetic waves cannot propagate in lossy conductive media and that they quickly decay inside such media over short length scales of the order of skin depth. I will demonstrate that contrary to this belief, surface electromagnetic waves in stratified lossy conductive media may have propagating character, and their propagation length may be considerably larger than the skin depth. This result has important consequences across the electromagnetic spectrum from radio signals propagation underwater to UV nanophotonics.

It was recently demonstrated that surface electromagnetic waves in stratified lossy conductive media may have propagating character, and the propagation length of such waves may be considerably larger than the skin depth [1,2]. The comparison of these novel surface wave solutions with the properties of the more well-known surface waves, such as surface plasmons [3] and Zenneck waves [4], is summarized in Table 1. Similar to surface plasmons, the wavelength of this wave may be considerably shorter than the light wavelength in free space, which may enable its applications in super-resolution microscopy and nanolithography techniques. However, unlike plasmonics-based nanophotonic devices, which are typically built using a very limited number of low loss optical materials, the newly found class of surface waves may be supported by a much broader range of lossy media.

Utilization of the newly discovered class of surface electromagnetic waves, which propagate along gradual interfaces of lossy optical media, should bring about quite a few developments in linear and nonlinear nanophotonics. These novel surface waves may bring the spatial resolution of 2D microscopes down to 10 nm scale and beyond [2]. Unlike plasmonics-based nanophotonic devices, which are typically built using a very limited number of low loss optical materials, the newly found class of surface waves may be supported by a much broader range of lossy media. Such materials as graphite and silicon seems to be ideal in UV nanophotonics applications where the classical plasmonic materials are not operational [2].

Indeed, such a classic CMOS material as silicon appears to be highly suitable for gradient-index nanophotonics applications. Similar to graphite, silicon exhibits very large and purely imaginary dielectric permittivity in the UV range, which strongly depends on the doping level. Therefore, silicon-based gradient index nano waveguides may potentially be fabricated using CMOS technology, which would greatly extend various silicon photonics applications. Deeply subwavelength UV nanoresonators may become possible, leading to numerous applications in sensing and UV nanolasers. In addition, such applications as deep UV high harmonic generation in these nanostructures may also become possible. Such developments have a potential to completely revolutionize UV nanophotonics.

Based on the same ideas, we also demonstrated several underwater portable radio communication systems operating in the 30-50 MHz band and capable of transmitting voice and high-definition live video images underwater. The system operation is based on launching surface electromagnetic waves propagating along the water-air and water-seafloor interfaces using specially designed surface wave antennas. Since the propagation

surface wave type	interface type	bounding media	wavelength range
Surface plasmon	abrupt	low loss metal-dielectric	from free space to deep subwavelength
Zenneck wave	abrupt	lossy conductor-dielectric	similar to free space
Interfacial wave	continuous	lossy conductor-lossy conductor	deep subwavelength

Table 1. Comparison of the basic properties of different kinds of surface electromagnetic waves.

length of the surface electromagnetic waves far exceeds the classical skin depth of conventional radio waves at the same frequency, this technique is useful for radio and video communication and object detection underwater. For example, in the experiments performed in a freshwater lake (Lake Phoenix, VA), a 50 MHz underwater radio operated at 5 W transmit power in combination with SEW antennas achieved clear voice communication underwater over distances up to 85 m and depth up to 8 m. The described system also appears to be efficient at communicating through the water-air interface, which is traditionally believed to be a very difficult problem.

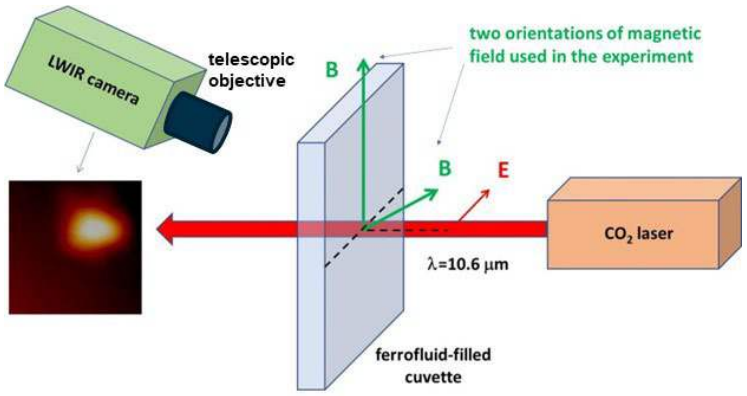
Abstract: Recent theoretical and experimental work demonstrated that nonlinear optics of ferrofluid-based hyperbolic metamaterials exhibits very unusual 2+2-dimensional spatiotemporal dynamics. Here we report a detailed microscopic study of mutual interactions of individual self-focused optical filaments inside this metamaterial. In agreement with theoretical expectations, the observed mutual interactions of individual filaments exhibit strong similarities with general relativity in 2+1 dimensions.

Optical space is the central concept of the transformation optics paradigm. A metric of optical space inside an electromagnetic metamaterial differs from the metric of physical space, and in such unusual cases as hyperbolic metamaterials, the optical space may behave like an "optical spacetime" [1]. It was reported that the nonlinear optical dynamics of this system should have very unusual character [2], and it may have strong resemblance with gravitational physics. In particular, in several experimental situations the nonlinear optics of hyperbolic metamaterials may be reduced to effective general relativity (GR) in 2+1 dimensions, which is very interesting since such a theory may be solved exactly, even in the quantum mechanical limit.

One of such situations involves using a monochromatic CW laser light illuminating a hyperbolic metamaterial, so that at high enough power laser light passing through the metamaterial develops filamentation. The nonlinear dynamics of such light filaments looks similar to gravity in 2+1 dimensions. Initial experimental evidence of such a filamentation inside a ferrofluid-based hyperbolic metamaterial has been communicated in [2]. Here we report a detailed microscopic study of this effect. We substantially improved the spatial resolution of our experimental setup, so that the properties of individual filaments and details of their mutual interaction have been revealed in fine detail. The schematic diagram of our experimental setup is shown in Fig. 1. Compared to the original setup described in detail in [2], we have implemented a high-resolution telescopic objective mounted on the LWIR camera. An example of high-resolution image of the extraordinary laser beam propagated through the metamaterial sample is shown in Fig. 2. This 6.48 mm x 6.48 mm image frame was taken from a recorded video of the extraordinary beam evolution as a function of time. This image was recorded at 960 mW CO_2 laser power. The average (approximately Gaussian) laser beam profile was subtracted from the image. This background subtraction allowed to reveal the optical filaments formed within the beam and study the temporal dynamics of their mutual interactions. The filaments appeared to be quite stable, having an average lifetime of about 10 s. At higher laser powers, when the filaments appeared to be well-defined, their width to intensity ratio was approximately constant (Fig.2b). The increase of laser power passing through the metamaterial led to increase of the number of filaments (Fig.2c), while their relative sizes remained mostly similar. This initial increase was followed by eventual near saturation of the number of filaments at higher powers.



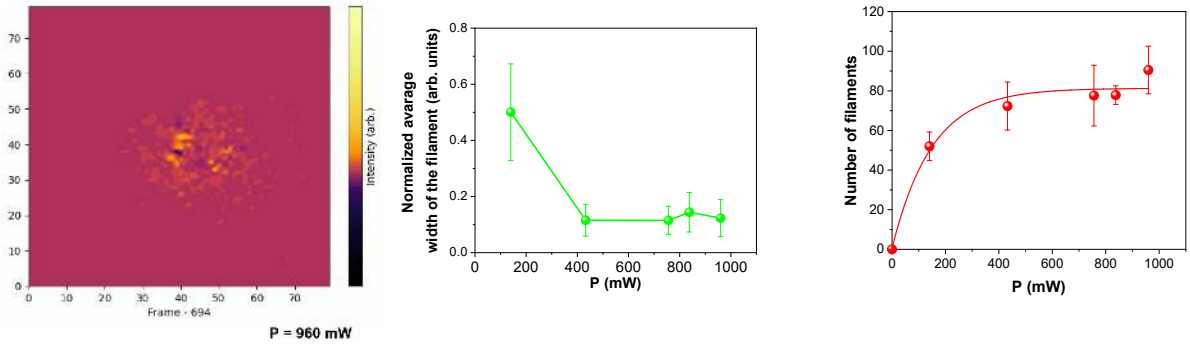


Fig. 1. Schematic diagram of the experimental setup. A LWIR camera with an attached telescopic objective is used to study propagation of CO_2 laser beam through the ferrofluid-based hyperbolic metamaterial, which is subjected to external DC magnetic field. The inset shows the measured beam shape of the CO_2 laser in the absence of the metamaterial sample. Two orientations of the external magnetic field B used in our experiments are shown by green arrows. The red arrow shows polarization of laser light.

(a) (b) (c)

Fig. 2. (a) A 6.48 mm x 6.48 mm image of the extraordinary CO_2 beam. This image was recorded at 960 mW laser power. The average (approximately Gaussian) laser beam profile was subtracted from the image to reveal optical filaments within the beam. (b) At higher laser powers, when the filaments appeared to be well-defined, their width to intensity ratio is approximately constant. (c) The increase of laser power passing through the metamaterial leads to increase of the number of filaments. The line is a guide to the eye.

In agreement with theoretical expectations, the analysis of mutual interactions of individual filaments exhibit strong similarities with general relativity in 2+1 dimensions.

Plasmonic high entropy alloy materials for midinfrared metasurfaces towards efficient photo-thermal energy conversion

Yoshiaki Nishijima[1*]

[1] Department of Electrical and Computer Engineering, Graduate School of Engineering, Yokohama National University, 79-5 Tokiwadai, Hodogaya-ku, Yokohama, 240-8501, Japan

[*]corresponding author: nishijima-yoshiaki-sp@ynu.ac.jp

Abstract: We have realized High entropy alloy, (HEA) materials for plasmon applications, especially midinfrared absorption metasurfaces. Optical obtained permittivity realized FDTD simulations that can well reproduce the experimental data. Also FDTD results indicate that HEA metasurface became true perfect absorption condition.

Conventional plasmon resonance materials have been studied using simple metals such as gold (Au), silver (Ag), copper (Cu), and aluminum (Al). And some rare earth, alkaline metals were not used for plasmonic research, but they show plasmon resonance from considering the permittivity. The limitation of materials comes from the richness of free electrons (free carrier density) and relaxation time or dumping of oscillation during resonances. These properties has appeared in the permittivity that can be described using Drude-Lorenz model. To overcome this limitation, alloying metals is one of the promising ways. We have studied the alloying metals such as Au-Ag-Cu, and Au-Pd for plasmon resonance and hydrogen sensing applications, beyond the material limitation. We have primarily focusing experimentally determined optical permittivity of such alloy materials for quantitative evaluation of plasmon resonances [1].

In recent years, high-entropy alloys (HEA) composed of more than five metals have attracted attention. This is because they can realize the highest configuration entropy in their crystal. In particular, HEA forms homogeneous phases without phase separation, exhibiting stronger physical properties than components. In addition, HEA also focused on new catalytic materials. For example, when HEA was composed with Au, Ag, Cu, Pt, Pd, HEA can improve catalytic activity [2].

The aim of this study is to apply such HEAs for plasmonic metasurfaces, which consists of metal-insulator-metal nanostructures. Especially in mid infrared wavelength region, metasurfaces have important roles of efficient photo-thermal energy conversion materials [3-6]. To evaluate the optical properties of metasurfaces quantitatively, it is essential to obtain the complex optical permittivity ($\varepsilon = \varepsilon_1 + \imath\varepsilon_2$). We have experimentally determined the optical permittivity of HEA materials from visible to mid-infrared wavelength and evaluated their plasmon resonances.

An alloy system consisting of gold, silver, copper, platinum, and palladium was selected as a HEA. HEA film on a glass substrate was prepared by a sputtering method. Their optical permittivity was measured using spectrometric ellipsometer UV-VIS (250 to 1000 nm) and MIR (1700 nm to 20000 nm), respectively. Also, Metal-insulator metal (MIM) metasurfaces were fabricated using electron beam lithography. Their optical responses were analyzed with FTIR and FDTD simulations.

Figure 1 shows the experimentally obtained optical permittivity of Au, Ag, Cu, Pd, Pt, and HEA. The optical permittivity of HEA located between Pd and Pt. When we apply them to mid-infrared metasurfaces, the absorption band of the MIM metasurface can be obtained only in a limited range concerning the film thickness of SiO_2. In contrast, the HEA has good absorption properties over the range of 2-7 μm in the mid-infrared wavelength region. This suggests that HEA is the better material for MIM metasurfaces for optical light absorbers and thermal radiators.

In the presentation, we will discuss the detail experiments, numerical simulation results, and future application of HEA for efficient midinfrared photonic materials.

Color Selective 3D Polarization Profiles

Xianzhong Chen*

School of Engineering and Physical Sciences, Heriot-Watt University, Edinburgh, UK
*corresponding author: x.chen@hw.ac.uk

Abstract: We propose and experimentally demonstrated a single metasurface device that can realize color selective 3D polarization structures. The device design includes multi-foci design, polarization rotation, and color multiplexing in 3D space. The efficacy of this approach was exemplified through the demonstration of multiple 3D knots with controlled local polarization states. The unprecedented design degree of freedom of optical metasurfaces has provided a compact platform to develop ultrathin optical devices with engineered 3D polarization profiles and color selective functionality.

Vector beams have been recognized as a promising future technology in quantum memories, particle trapping, and high-resolution lithography. However, the real-life applications remain limited, mainly because of complexity of the experimental system and the inability to arbitrarily manipulate polarization state of light at subwavelength scale. It has found many applications ranging from quantum to classical optics (e.g., polarized sunglasses and 3D cinema). Polarization control has been used to record, process and store information. Light beams with spatially inhomogeneous polarization distributions have received great attention owing to their peculiar optical features and practical applications such as higher resolution lithography and patterning of lyotropic chromonic liquid crystals by photoalignment.

Driven by device miniaturization and system integration, there is huge interest in developing ultrathin (light wavelength scale) and lightweight planar optical devices with novel functionalities that cannot be obtained with conventional optical elements. Optical metasurfaces are planar nanostructured interfaces and have recently attracted tremendous interests due to their unprecedented capability in the manipulation of the amplitude, phase and polarization at subwavelength scale. The emergent optical metasurface based flat optics has revolutionized design concepts in photonics, providing a new platform to develop unusual ultrathin optical devices (e.g., dual-polarity lenses, polarization sensitive holograms). Optical metasurfaces have shown much promise for polarization manipulation [1]. We have experimentally demonstrated 2D polarization profiles with uniform intensity to hide high-resolution images in a light beam based on optical metasufaces [3, 4]. The target images are encoded in the spatially variant polarization states in 2D space. We designed and demonstrated metalenses that can achieve arbitrary 3D focal curves with customized polarization profiles without the aid of additional optical elements [5]. A number of focal curves ranging from a simple ring to a more complicated 3D knot are observed in the focal region of metalenses. The proposed approach is very flexible and robust to generate various polarization profiles of the focal curves, including linear and nonlinear relations between polarization rotation angles and positions along the curves.

Multispectral polarization manipulation will add more degrees of freedom. Furthermore, multifunctional optical devices have profound implications for the research fields where light weight and integrated optical systems are highly desirable. There is an urgent need to develop multifunctional ultrathin devices that can simultaneously encode color and intensity information into 3D polarization profiles. However, how to realize color selective 3D polarization structures has not been reported. Here we propose and experimentally demonstrate color selective

three-dimensional (3D) polarization structures with a single metasurface. The geometric metasurfaces are designed based on color and phase multiplexing and polarization rotation, creating various 3D polarization knots. Remarkably, different 3D polarization knots in the same observation region can be achieved by controlling the incident wavelengths, providing unprecedented polarization control with color information in 3D space. Our research findings may be of interest to many practical applications such as vector beam generation, virtual reality, volumetric displays, security and anti-counterfeiting.

Metasurface enabled arbitrary polarization manipulation is a new research field. The precise control over the polarization state of light in 3D space can be faithfully mapped onto the intensity profile for each color. By combining multiple 3D polarization structures and dispersion effect of a metalens, this work provides a compact platform to realize different 3D polarization structures. Multispectral polarization manipulation will add more degrees of freedom. The small volume, light weight, and color selective functionality bring 3D polarization engineering capabilities closer to being feasible on integrated polarization optics system and wearable devices with smaller footprints. The flexible and controllable generation of 3D polarization distributions with customized intensity profiles of different colors (wavelengths) may be of interest to many practical applications such as vector beam generation, virtual reality, color displays, information security, anti-counterfeiting, and high-density information storage.

Abstract: We report a polariton laser in a GaN ridge waveguide, switching from mono to multi-mode laser operation as temperature is increased. The free spectral range's study between the modes first leads to the unambiguous proof that the polaritons are in strong coupling regime; and above 150K, during the transition to multi-mode lasing, a flattening of the FSR demonstrates a synchronization of the modes. These results therefore pave the way to the investigation of harmonic mode-locking in polariton waveguide lasers.

Polaritons in microcavities are a rich playground that has led to numerous researches for more than thirty years. The polariton laser has a specificity compared to a more conventional ridge laser: the absence of reciprocity between the processes leading to gains and losses. A new trend in polaritonics is developing, based on the waveguide geometry. By studying the operation of a CW polariton laser in a GaN waveguide geometry with distributed Bragg reflectors (DBR) forming the cavity, we have shown that the lasing effect is achieved even for a pump length of only 15% of the cavity length with only a threefold increase in overall threshold in stark contrast to conventional ridge lasers [1]. Waveguide polaritons form a new platform of choice for integrated photonics relying on both laser pumping specificity, potential nonlinearities, low losses and long propagation distances. The small footprint of the cavities studied, the choice of base materials, namely gallium nitrides, outline this promising future in terms of a device operating at room temperature [5].

Half-light and half-matter, polaritons exhibit a large nonlinearity which eclipses the values of the photonic nonlinearities in semiconductors by several orders of magnitude. Thus, an experimental observation of nonlinear self-modulation of UV pulses in an AlInGaN-based waveguide has been reported [2]. Other waveguide geometries are investigated such as polaritonic micro-rings, where mode-locking and soliton formation was predicted [3] and cw lasing was experimentally demonstrated [4].

For this presentation we will focus on the extension of the study we conducted previously. We perform spatially- and spectrally-resolved power-dependent microphotoluminescence experiments on GaN/(AL,Ga)N planar waveguide with DBR. We evidence at 70K, the laser operation which above

threshold happens to be CW and mono-mode. The increase in the temperature of the structure above 150K makes a switch towards a laser which is, at threshold, directly multi-mode.

Below the threshold, for all investigated temperatures, our photoluminescence spectra exhibit, over a large part of the measured energy range, so-called Fabry-Perot modes. A detailed study of the experimental free spectral range (FSR) of these modes compared to that calculated from the dispersion of the LPB will, assesses the strong coupling regime in our polaritonic device. We will see that the change in laser regime with temperature causes two phenomena. Just before the threshold, the FSR decreases near the exciton resonance and just above the threshold, a flattening of the FSR. This last point is important, because it happens to be the signature of mode synchronization arising from the nonlinearity recently evidenced under resonant excitation [2]. These results therefore opens interesting prospects regarding harmonic mode-locking in polariton waveguide lasers.

Image processing with metaoptics: phase imaging and asymmetric optical transfer functions

N. Priscilla[1], S. B. Sulejman[1], W. S. Lee[1], L. Wesemann[1], T. J. Davis[1], and A. Roberts[1*]

Abstract: The capacity to modify images in the Fourier domain using all-optical methods in real-time is well-known but there is an emerging interest in manipulating images using metasurfaces in the object or image plane leading to an orders-of-magnitude reduction in size and weight. Many applications, however, require the introduction of a transverse asymmetry in the optical transfer function. Here approaches to introducing the required asymmetry will be discussed and their application to phase contrast imaging of transparent objects will be highlighted.

Although the use of optical systems to perform image processing in the Fourier plane has been well-known since the 1940s, most commonly used modifications (such as edge enhancement) are more widely performed digitally. Furthermore, information carried in an optical wavefield introduced by, for example, propagation through transparent objects or turbulence, is lost on acquisition with a camera. Although sophisticated computational strategies for extracting phase from intensity images exist, these can be relatively slow. Conventional all-optical approaches for image processing and phase contrast imaging, however, typically require relatively bulky, and sometimes expensive, optics. The increasing amount of data being generated, the drive for miniaturization of optical components, and advances in nanoscience have underpinned a renewed interest in all-optical image processing.

When considering the propagation of an optical wavefield carrying an image we typically consider the decomposition of the field into a superposition of plane waves each with a characteristic amplitude and phase. Conventional spatial filtering involves introducing an amplitude and/or phase mask into the focal plane of a lens taking advantage of the Fourier transforming property. This places constraints on the positioning of the filter as well as requiring bulky lenses and the inclusion of propagation distances from the object to Fourier plane. Another approach that we are currently investigating involves directly manipulating the spatial frequencies via a device that has a reflection or transmission that depends on the angle of incidence of a plane wave. In 1979 it was shown that the introduction of a suitably tailored phase grating into the object plane of an optical system generated an edge-enhanced output [1]. It was highlighted that there was considerable flexibility in the positioning of the device since spatial filtering was no longer required a the angular spectrum was manipulated directly. The emergence of metaoptics has reignited interest in this approach since concepts from nanophotonics can produce compact devices with a tailored angular dispersion and, hence, expanded capacity to manipulate images and, more generally, perform analogue computing [2,3].

We have considered both reflective and transmissive geometries. One system with a well-known angular sensitivity is a simple, commercially available notch filter that can be used to perform edge detection in

transmission at the design wavelength [4]. A planar metal-insulator-metal also can be used to enhance edges in reflection at the resonant wavelength [5] as can a resonant waveguide grating in transmission [6]. Many mathematical operations, however, require an inherent asymmetry in the optical transfer function that is used to describe the way that spatial frequencies propagate through the metasurface. Although some devices have been demonstrated that can generate the derivative of the device after interaction with the metaoptic, detection with a camera results in a loss of phase information that precludes determining the sign of the gradient which is particularly important when imaging phase objects. The introduction of a simple tilt of the device introduces a phase ramp that shifts the effective transfer function so that is no longer symmetric about normal incidence [4,6,7]. This generates a pseudo-3D phase contrast images of transparent objects similar to those seen in Differential Interference Contrast microscopy but with a simple thin device. Furthermore, through appropriate device design and choice of polarization, it is possible to create an asymmetric transfer function about normal incidence removing the requirement to tilt the device. In this talk two metasurfaces [8,9] that have this capacity will be discussed and recent experimental results presented.

This research was funded by the Australian Government through the Australian Research Council Centre of Excellence grant (CE200100010). S.B.S also gratefully acknowledges the support of the Ernst & Grace Matthaei Scholarship and the Australian Government Research Training Program Scholarship.

Flat Band Induced Metal-Insulator Transitions With Weak Disorder and Many Body Interactions

Certain lattice wave systems in translationally invariant settings have one or more spectral bands that are strictly *flat* or independent of momentum in the tight binding approximation, arising from either internal symmetries or fine-tuned coupling [1]. Originally considered as a theoretical convenience useful for obtaining exact analytical solutions of ferromagnetism, flat bands have now been observed in a variety of settings, ranging from electronic systems to ultracold atomic gases and photonic devices [1],[2]. I will review the design and implementation of flat bands, classification schemes, discuss recent results on adding many-body interactions [3] and disorder[4], and chart future directions of this exciting field.

Deep ultraviolet to visible absorbing and sensing applications by stacking film with highly lossy ultra-thin film

Abstract: Stacking films with ultra-thin highly lossy material provides unique destructive interference condition in complex phase space far from the real axis. Utilizing the interference, we demonstrated the broadband deep ultraviolet and visible perfect light absorbers with large angle tolerance and the highly sensitive refractive index sensing technique in planer structure.

Broadband perfect light absorbers with insensitive for the incident angle and the polarization states are extremely suitable for photodetectors and solar cells. Especially, perfect absorption into the ultra-thin film is highly desirable for efficient light-photocurrent conversion.

Perfect absorption can be obtained by the simultaneously vanishing reflection (R) and transmission (T). The enhancement of the absorption has been reported using quarter wavelength thin films [1, 2] and meta-materials [3] and -surfaces [4]. However, the suppression of both R and T for broad wavelength, wide angle, and both polarizations (p- and s-polarizations), is challenging.

We utilized the unique interference in the highly lossy ultra-thin film to overcome the above issue and demonstrated the attractive deep ultraviolet (DUV) to visible (VIS) applications, such as ultra-broadband perfect absorbers. The highly lossy film (namely, the real and the imaginary parts of its complex refractive index with sane order) causes a non-zero or $-\pi$ phase shift of Fresnel coefficients. The large complex valued Fresnel coefficients can provide unique destructive interference condition in the complex phase space and enhances the light-matter interaction inside deep subwavelength region [5-9]. The destructive interference of our optimized multi-stacking system with highly lossy film realized almost perfect DUV and VIS absorptions into the much thinner film than the incident wavelength. The properly designed structures also show polarization-insensitive flat-top absorption spectra with large angle tolerance. The features are very advantageous for several applications of the high-efficiency conversion between light and photocurrent.

Moreover, we applied the destructive interference of the highly lossy films to the refractive index sensing applications. The destructive interference of the optimized highly lossy film shows very high sensitivity for the refractive index of the incident medium.

Research on Intelligent Photonic Computing Chips

Xiaoyong Hu*, Kun Liao

Department of Physics, Peking University, Beijing 100871, China

*corresponding author: xiaoyonghu@pku.edu.cn

Abstract:

With the rapid development of advanced engineering computing, economic data analysis, and cloud computing, the demand for ultra-high speed and energy-efficiency computing is growing exponentially. However, for electronic processors, the scaling of computing time and power consumption is limited by data transfer between memory and processing units, RC delay associated with integrated circuits and excessive heating due to Ohmic losses. Integrated photonics adopting photons as information carriers with multiple degrees of freedom benefiting from the CMOS-compatible manufacturing with modularity and scalable fabrication technology of integrated circuits, could reach a high computational efficiency with minimal power consumption and low-latency at the speed of light.

One of the most important applications of combining machine learning and integrated photonics is Photonic Hardware for AI. As one of the artificial intelligent algorithms, neural network has strong judgment in solving inference tasks because of its superior learning ability. In addition, neural networks implemented on photonic platforms can take advantages of photonic computing, including ultralow energy consumption, ultra-fast time response, low integration crosstalk, and multidimensional degrees of freedom. In recent years, photonic neural networks have achieved superior performance in artificial intelligence tasks such as pattern recognition and image classification. So far, there are still some challenges in the field of photonic neural networks that need to be further studied, including expanding the functions of neural networks by taking full advantage of using photons for computing; improving computing efficiency by designing new configurations of neural networks adapted to photonic hardware platforms; increasing complexity of neural networks by realizing reliable all-optical nonlinear activation layers; and saving the computing power by realizing hardware on-chip training [1].

Here, we have done some corresponding research from several aspects of the challenges mentioned above. Firstly, we proposed an all-optical computing chip based on the convolutional neural network from the perspective of extending the functions of neural networks [2]. We extended the function of the optical neural network to realize logical operations and solve complex mathematical operations for the first time, providing a potential direction for a new generation of intelligent all-optical computing chips. In addition, we also proposed a matrix eigenvalue solver based on reconfigurable photonic neural network [3]. The designed principle of the network is simple and reconfigurable with the efficient and scalable implementation scheme. Secondly, starting from improving network efficiency, we proposed the concept of "photonic diffraction neuron", and designed a silicon-based optical neural network based on the proposed photonic diffraction neurons [4]. The inverse-designed photonic neurons provide higher-density optical connection, achieving efficient signal processing from low to high dimensional datasets. Afterwards, from the perspective of increasing the complexity of the network, we proposed the graphene/silicon heterojunction-based reconfigurable optical activation functions [5]. Here we used complex amplitude activations, demonstrating that the proposed activations in complex networks outperform the classical computer activations. This work realized rich and effective nonlinear activation layers, which provides a feasible way for the effective implementation of all-optical neural networks on integrated photonic platforms.

Plasmon Resonance Mode Evolution in a Semiconductor Nanodimer in the Overlapping Regime

Z. Wang and T. Wong*
Illinois Institute of Technology, USA

*corresponding author: twong@ece.iit.edu

Abstract: Field intensification and polarization enhancement are exhibited by semiconductor nanodimers (SND) in the non-overlapping regime. On the other hand, an SND in the overlapping regime exhibits unique characteristics of geometrical influence on space charge interactions, leading to secondary resonance that is strongly dependent on the amount of overlap between the constituent particles. The charge distribution, interior and exterior field, and dipole moment induced on a model SND by a terahertz electric field is studied by a charge transport formulation for carrier dynamics with a quasi-static framework for the polarizing field. Spectral components observed are interpreted by considering the evolution of charge distribution within the semiconductor material.

Being the simplest form of nanoparticle clusters, the nanodimer is of particular interest in the study of polarization coupling between particles in multiple particle systems. Nanodimers can be categorized into non-overlapping and overlapping types. The former exhibits field intensification in the gap region between the particles when they are placed in a linearly polarized electric field parallel to the axis of the dimer (1). When a semiconductor nanodimer (SND) is made up of particles with different doping levels, the enhanced field in the gap sways from one side to the other as the frequency of the applied field is varied from the surface plasmon resonance (SPR) of one particle to that of the other (2). The absence of the gap in the overlapping case implies the dimer is actually a single-body nanostructure whose shape varies from that resembling a dumbbell to that of an elongated sphere as shown in Fig. 1.

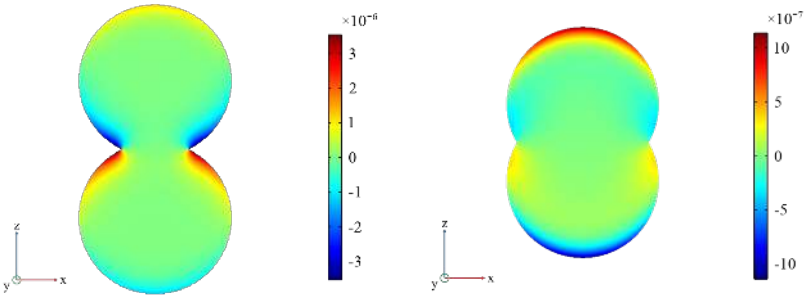

Figure 1. Charge distribution in SND with different amount of overlap at frequency of applied field close to the SPR frequency of the isolated particles making up the dimer. The SNP has radius of 50 nm and doping of 10^{18} cm^{-3}.

In this paper, an account of investigation on the polarization in an overlapping SND immersed in a terahertz electric field is presented. Numerical solution for the space-charge dynamics in an SND is obtained by a finite-element simulation tool applied on a system of equations derived from the moments of the Boltzmann

transport equation for the charge carriers coupled with the field equations (3). A general observation from the results of computation is that the SND in the overlapping regime exhibits SPR with resemblance to that of the standalone SNP with a slight red shift in the resonance frequency. When the amount of overlap between the constituent SNPs is small, an additional resonance with a smaller amplitude appears at a frequency slightly above the intrinsic SPR of the SNP. This secondary SPR can be attributed to the space charge accumulated at the waist of the SND as shown on the left of Fig. 1. This observation is in qualitative agreement with prior results obtained for metallic nanodimers (4). As the overlap increases, both resonant modes blue shift while the weaker resonant mode at higher frequency diminishes in amplitude and eventually vanishes. Results of computation for the charge density, interior field and exterior field, and the total induced dipole moment are presented.

Strong coupling between two-dimensional excitons and plasmonic nanocavities with a low exciton number

Xiulai Xu[1*]

[1]School of Physics, Peking University, Beijing, China
[*]corresponding author: xlxu@pku.edu.cn

Abstract: The interaction between two-dimensional excitons and plasmon nano-cavities has a potential to realize exciton-polaritons in quantum regime. Here, we report on a robust strong exciton-plasmon coupling with MoS_2 layers and bowtie nanocavities. With a proper exciton transition dipole moment, we estimated that the exciton number contributing to the coupling is reduced to 40, which is the lowest for this type of work so far. The interacting between 2D excitons and chiral nanocavities will be also discussed.

Atomically thin transition-metal dichalcogenides (TMDs) have been exploited widely for numerous photonic applications. One of the intriguing properties is the large exciton binding energy, providing the opportunity to realize exciton-polariton at room temperature when embedded in a microcavity. Plasmonic nanocavities with mode volumes beyond the diffraction limit make it possible to demonstrate strong coupling with a small number of excitons, which has rich applications in the research of quantum many-body phenomena, photon blockade with many emitters, cavity cooling and so on. However, achieving a robust plasmon−exciton coupling with nanocavities is still very challenging, such as the layer area is usually small in the conventional approaches and the two-dimensional excitons are hard to couple with the cavity modes effectively.

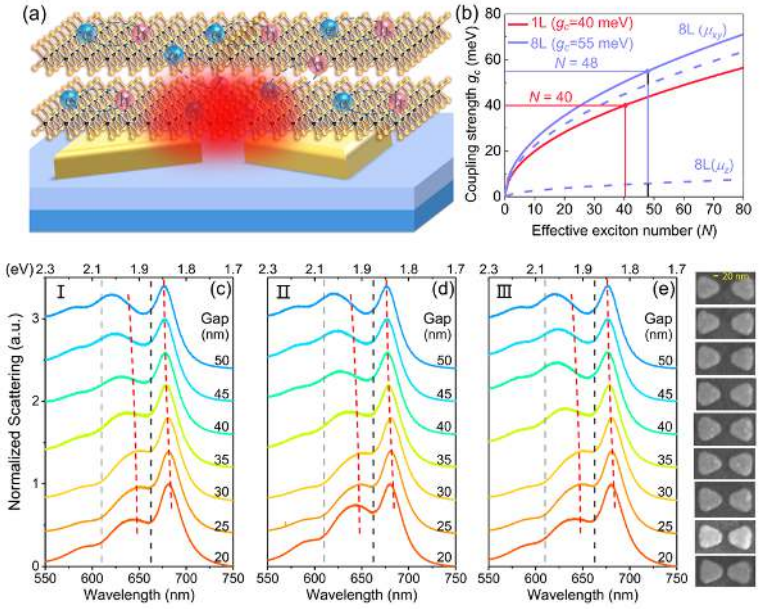

Figure 1. Strong coupling of individual bowtie resonators with layered MoS_2. (a) Schematic of the system with layered MoS_2 on a single gold bowtie resonator. (b) Coupling strength g_c as a function of the effective exciton number (N) for single-layer and eight-layer systems. (c)-(e) The dark-field scattering spectra of coupled hybrid systems of three groups with the same parameters. The image on the right shows the bowties with different gaps.

In our work, we obtained a robust strong exciton−plasmon coupling between the gap mode of a bowtie and the excitons in MoS_2 layers utilizing gold-assisted mechanical exfoliation and nondestructive wet transfer techniques. Due to the ultrasmall mode volume and strong in-plane field, the estimated effective exciton number contributing to the coupling is largely reduced. For estimating the exciton number contributing to the coupling, we corrected the value of exciton transition dipole moment in two-dimensional layer by quantum well method and absorbance measurements. With a corrected exciton transition dipole moment, the exciton numbers are extracted as being 40 for the case of a single layer and 48 for eight layers, which is the lowest for this type of work so far. Our work paves the way to realize strong exciton-plasmon coupling in quantum regime at room temperature.

Abstract: Incorporating subwavelength grating metamaterials in nanophotonic waveguides has opened new degrees of freedom to control light propagation on a photonic chip. In this invited contribution, we will present our recent advances in development of subwavelength-engineered metamaterial devices for silicon photonics.

Subwavelength grating (SWG) waveguides and components comprising nanophotonic structures with dimensions on a scale below the wavelength of light, have enabled development of integrated photonic devices with unprecedented performance. Since their first demonstration in the early 2000's by NRC Canada [1,2], SWG metamaterial waveguides have attracted a strong research interest and are being extensively used as a powerful engineering tool for overcoming performance limitations of conventional integrated photonic devices [3,4,5]. Here we present an overview of our recent advances in this surging field and discuss how on-chip optical metamaterials improve the performance of state-of-the-art silicon photonics devices, including fiber-chip couplers, nanophotonic waveguides with controlled anisotropy, complex spectral filers and nanoantennas for Optical Phased Arrays (OPAs).

Color centers in ZnO nanowires

Carsten Ronning*

Institute of Solid State Physics, Friedrich Schiller University Jena, Helmholtzweg 3, 07743 Jena, Germany

*corresponding author: carsten.ronning@uni-jena.de

Abstract: Even though intrinsic semiconductor nanowires have already extraordinary optical properties, doping them with optically active impurities significantly expands the potpourri of photonic applications. This talk therefore supplies a snapshot of the most recent progress on the structural and optical properties of transition metal and rare earth element doped ZnO nanowires using ion beam implantation. Here, ion implantation is advantageous, as concurrent defect generation and diffusion upon subsequent annealing allows the formation of defect complexes. This scenario is in many cases even inevitable for the optical activation of the intra-shell luminescence of the implanted impurities, as density functional theory calculations demonstrate. Analysis of the prepared systems was partly performed by a new experimental setup installed at the synchrotron ESRF in Grenoble, which will be presented in detail and allows the detection of the carrier dynamics and the luminescence in respect to the elemental composition and the local environment of the color centers in single zinc oxide nanowires.

The author acknowledges the ESRF for the beamtime allocated on the beamline ID16B (experiment: MA-4444), and the financially supported by the German Federal Ministry of Education and Research under the streakXEOL project (Contact No. 05K19SJ2).

Extremely Localized Optical Modes and Direct Electro-optical Modulation

Xue-Wen Chen[*1,2]

[1]School of Physics and Wuhan National Laboratory for Optoelectronics, Huazhong University of Science and Technology, Wuhan, China.
[2]Wuhan Institute of Quantum Technology, Wuhan, China.
[*]corresponding author: xuewen_chen@hust.edu.cn

Abstract: Recent developments of nanoscience and nanofabrication techniques have enabled optical confinement into deep nanoscale or even atomic scale in space, offering exciting new opportunities. Here we discuss the physics to devise extremely localized optical modes that feature quantum-optical mode volumes down to one cubic nanometer. In particular, we present the approaches to overcome Landau damping to make the modes far-field accessible. Moreover, we introduce the concept of nanoscopic electron reservoir for direct electro-optical coupling that potentially allows energy-efficient ultrafast modulation.

In the past decade, the dramatic advents of nanomaterial science and precision nanofabrication techniques have been pushing the optical confinement from micro/nano scale down to deep nanoscale or even sub-nanoscale. These developments lead to a new frontier of nanophotonics, *i.e.*, extreme nanophotonics, that lies at the nexus of photonics, electronics, and nanoscience. It provides opportunities to simultaneously have extreme optical confinement and nanoscopic electronics as well as their interaction.

Firstly, we report the discovery and the rationale to devise bright single optical eigenmodes with mode volumes about 1 nm^3 and the lowest down to 0.5 nm^3[1]. Our discovery originates from a fundamentally new understanding of electromagnetic modes associated with extreme field localization. The discovery is possible because we develop an advanced theoretical platform capable of describing microscopic details of a macroscopic system. Moreover, we provide a strategy to resolve the longtime difficulty of huge loss occurring with extreme localization. The finding will enable to venture into a new regime of optical physics as the optical modes could now approach the scale of electron wave functions in an atom or a molecule.

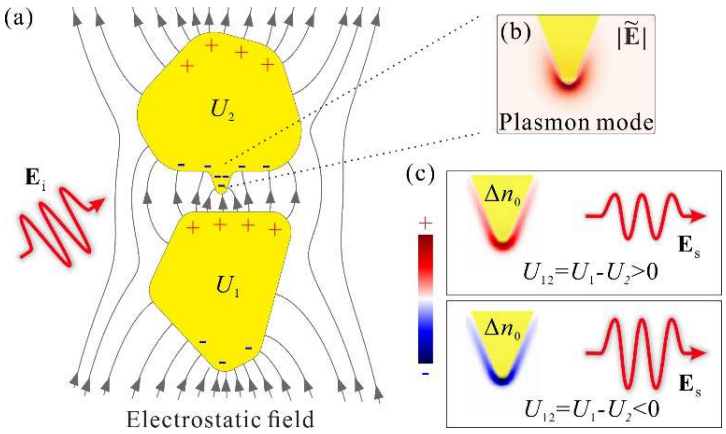

Fig. 1 Schematic illustration of an electro-optic modulation via a nanoscopic electron reservoir (NER) situated on a metal host. The details can be found in Ref. [2].

Secondly, we discuss the interaction of the extremely localized optical modes with the static electric field, which, as shown in Fig. 1, will lead to the direct electrical tuning of the localized modes and its far-field response [2]. Direct electrical tuning of localized plasmons at optical frequencies boasts the fascinating prospects of being ultrafast and energy efficient and having an ultrasmall footprint. However, the prospects are obscured by the grand challenge of effectively modulating the very large number of conduction electrons in three dimensional metallic structures. Here we propose the concept of nanoscopic electron reservoir (NER) for direct electro plasmonic and electro-optic modulation. A NER is a few-to-ten-nanometer size metal feature on a metal host and supports a localized plasmon mode. We provide a general guideline to construct highly electrically susceptible NERs and theoretically demonstrate pronounced direct electrical tuning of the plasmon mode by exploiting the nonclassical effects of conduction electrons with the help of quasinormal mode analysis [3]. Moreover, we show the electro-plasmonic tuning can be efficiently translated into modulation of optical scattering by utilizing the antenna effect of the metal host for the NER. Our calculations show it is possible to have electro-optic modulation at a speed of 20 fs/bit and with an energy consumption rate of 100 atto-joule/bit. Our work extends the landscape of electro plasmonic modulation and opens appealing new opportunities for quantum plasmonics.

Abstract: The potential application of guided-mode resonance devices as an external laser mirror with oscillation wavelength stabilization and waveguide input coupling functions that is a key component for constructing a future ultra-compact multi-wavelength light source is discussed.

A guided-mode resonance (GMR) filter consists of a subwavelength surface grating integrated in a thin-film optical waveguide on a transparent substrate, and shows a narrowband reflection spectrum for an incident free-space wave [1]. GMR filters have much attention for use as external mirrors of fiber or waveguide lasers due to their advantages of fabrication convenience, design flexibility, polarization selectivity, and so on. However, a normal GMR filter needs a sub-millimeter-size aperture for nanometer-order reflection bandwidth. We proposed a cavity-resonator-integrated GMR filter (CRIGF) for aperture miniaturization [2]. Figure 1(a) shows the basic configuration of the CRIGF. It has a micro-aperture grating coupler (GC) in a waveguide cavity resonator composed of two distributed Bragg reflectors (DBRs). Only at the resonance wavelength of the waveguide resonator, a vertically incident wave is coupled by the GC to the resonant guided wave, and the substrate radiation from the guided wave cancels out the transmission, resulting in a strong reflection. In addition, by shortening the coupling length of one of the DBRs and thereby reducing its reflectance, the excited guided wave can be extracted from the CRIGF through the shortened DBR (S-DBR).

(a) (b)

Figure 1. (a) Schematic cross-sectional view of CRIGF. (b) Concept image of ultra-compact multi-wavelength light source based on CRIGFs and stripe LD array.

Because of this multifunctionality of narrowband reflection and guided wave extraction, CRIGF is expected to serve as an external laser mirror which stabilizes oscillation wavelength to the reflection wavelength and couples the laser light to the waveguide. In addition, since the resonance wavelength of CRIGF is determined by the cavity length, integration of CRIGFs of different wavelengths will enable wavelength multiplexing. The authors have proposed and investigated an ultra-compact multi-wavelength light source without separate multiplexers, such as an arrayed waveguide grating or a multimode interference coupler by combining a stripe laser diodes (LDs) array and different CRIGFs integrated on a bus waveguide as shown in Figure 1(b). The

lasing wavelength is determined by a reflection peak of the CRIGF because antireflection coating is made on the facing end of the LD. However, there are several issues to the practical application of this multi-wavelength light source. In this presentation, our results on fundamental study to solve them are introduced.

One of key issues is the optimization of CRIGF reflectance for giving the highest electrical-optical power conversion efficiency. Lower reflectance of S-DBR for higher efficiency of a guided-wave extraction gives lower vertical reflection of the CRIGF, resulting in higher threshold current and lower differential efficiency of the stripe LD. The S-DBR reflectance needs to be optimized to maximize the conversion efficiency from the input electrical power to the multiplexed optical power. Another issue is DBR bandwidth limiting the wavelength spacing. The guided wave should pass through other CRIGFs to reach an output waveguide. The bandwidth of the DBR reflection is set to be narrower than the wavelength spacing in order to avoid undesirable reflection of other multiplexed signals. Four CRIGFs with a wavelength spacing of 15 nm on the same waveguide were designed and fabricated. Simultaneous guided wave extraction with vertical reflection and the possibility of four-wavelength multiplexing were experimentally confirmed [3].

The diameter of an incident beam to the CRIGF must coincide with the aperture size to obtain high reflectance. The aperture size will be several microns at least even though it is much smaller than normal GMR filters. Meanwhile, a field diameter of the guided mode of an LD waveguide is submicron. We cannot expect high-efficiency direct butt coupling of the LD to the CRIGF and need some beam-size conversion. We proposed a focusing CRIGF (F-CRIGF) for reflecting and focusing a diverging wave back to the divergence point. [4]. A focusing GC (FGC) and a high-reflection substrate are used in an F-CRIGF instead of the GC and a transparent substrate, respectively. An F-CRIGF can retroreflect the emitted light from the LD. As a result, we can avoid the unpreferable integration of additional lens. An F-CRIGF was designed and fabricated not only for narrowband retroreflection but also for guided wave extraction. An external cavity laser was constructed by combining this F-CRIGF and a gain chip, and the simultaneous realization of wavelength stabilized laser oscillation and input coupling was demonstrated [5].

Discovering new high-refractive-index dielectric materials

Søren Raza
Department of Physics, Technical University of Denmark, Fysikvej, DK-2800 Kongens Lyngby, Denmark

E-mail: sraz@dtu.dk

Abstract: Dielectric materials with a high refractive index are key in the design of optical nanoantennas and metasurfaces. Here, we use a high-throughput screening method combined with optical Mie theory to evaluate the performance of more than 2000 materials and discover a new promising material, boron phosphide, which has so far been elusive. We prepare boron phosphide nanoparticles and experimentally demonstrate that they support Mie resonances across the visible and the near ultraviolet using both optical measurements and electron energy-loss spectroscopy.

Optical metasurfaces and nanoantennas based on high-refractive-index materials offer efficient manipulation of light on the nanoscale due to low optical losses and their ability to support both magnetic- and electric-type Mie resonances.[1] The development of all-dielectric nanophotonics has been largely driven by the availability of just a few high-index materials, such as silicon, gallium phosphide, and titanium dioxide, which offer low-loss operation in most of the visible spectral range and where lithographic processing has been well established.[2] For applications in the important ultraviolet spectral range, the availability of high-index materials is even more scarce. Identifying new optical materials that may outperform the ones currently available, offer new functionalities or give access to other spectral regions is critical for many applications.

In this work,[3] we discover new high-index materials using high-throughput screening based on density functional theory (DFT). Starting from a library of more than 2000 thermodynamically stable binary materials, we develop a workflow to identify isotropic high-index dielectric materials across a spectral range spanning from mid infrared to the deep ultraviolet. The wavelength-dependent complex refractive indices of these materials are calculated within the random phase approximation and used as input for Mie scattering calculations to evaluate their optical performance. Our methodology identifies all of the known high-index materials as well as other materials, which have been less investigated. In particular, we identify boron phosphide (BP), which offers a refractive index above 3 with very low absorption losses in a spectral range spanning from the infrared to the near ultraviolet.

To support our computational discovery, we prepare BP nanoparticles and experimentally demonstrate that they support Mie resonances across the visible and ultraviolet spectral ranges using dark-field optical measurements and electron energy-loss spectroscopy. The Mie resonance energies can be tuned with particle size. We also demonstrate a laser reshaping method to realize spherical BP nanoparticles, which host multiple Mie resonances in quantitative agreement with full-field optical simulations. Our experimental measurements of Mie resonances in BP nanoparticles demonstrate the potential of high-index BP across a broad spectral range as well as validate the refractive index obtained from DFT calculations. Besides the discovery of BP, we believe that our high-throughput screening results provide an overview of existing materials as well as a pathway for realizing new high-index materials.

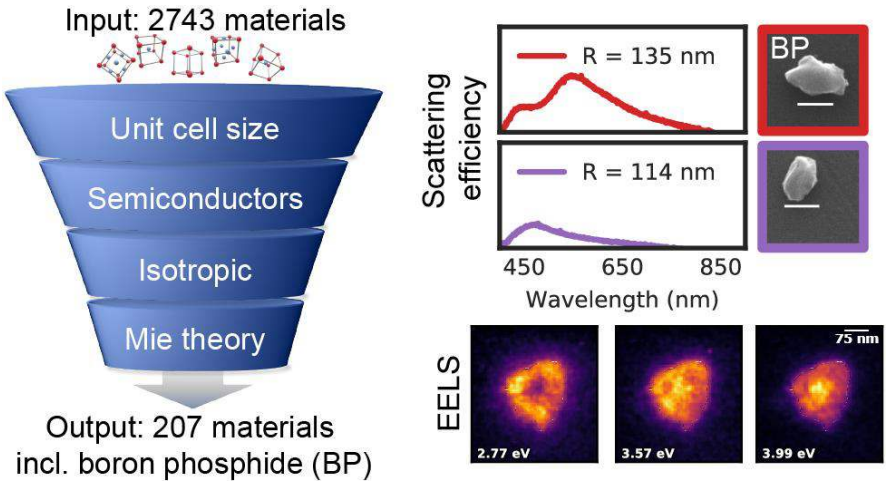

Fig. 1. High-throughput screening of a large library of materials identifies many high-refractive-index materials across a broad spectral range. Boron phosphide (BP) appears particularly promising due to its refractive index above 3 in a spectral range covering the visible and reaching the near ultraviolet. BP nanoparticles are prepared and their scattering properties are measured using far-field dark-field spectroscopy and near-field electron energy-loss spectroscopy (EELS). Combined with full-field optical simulations, these measurements demonstrate that BP nanoparticles support Mie resonances at visible and ultraviolet energies.

Abstract: In this talk we numerically investigate heavily doped semiconductors as a platform for integrated nonlinear plasmonics at mid-infrared frequencies. We study free-electron nonlinearities and use surface charge density modulation to control and enhance the nonlinear response.

The control and the concentration of light at subwavelength scales are of extreme importance for the realization of integrated optical technologies, especially to reach operational efficiencies in devices based on nonlinear optical effects. In this context, the study of light interaction with free electrons (FEs), i.e. plasmonics, in materials characterized by a high carriers density has a central role. Notoriously, noble metals have been the main material choice for plasmonic devices in the visible spectrum for many years. Heavily doped semiconductors (i.e. with charge densities $n_0 \sim 10^{19}$ - 10^{20} cm^{-3}), on the other hand, have recently emerged as alternative materials for plasmonics in the near-infrared (NIR), i.e. $0.8 < \lambda < 2$ μm, and in the mid-infrared (MIR), i.e. $2 < \lambda < 20$ μm [1]. Being low-loss high-quality materials that can be compatible with standard microelectronics fabrication processes, and being their optical response tunable through electrical or optical doping, heavily doped semiconductors offer a unique perspective for integrated optical devices in the NIR and in the MIR. [2].

In this talk we show that FE nonlinearities could be up to two orders of magnitude larger than conventional semiconductor lattice nonlinearities [3,4]. We use a hydrodynamic description that includes terms up to the third order, usually negligible for noble metals. Within the hydrodynamic formalism, the third-order response, expressed through the third-order polarization vector is inversely proportional to the squared equilibrium charge density, i.e. $\mathbf{P}_{\mathrm{NL}}^{(3)} \propto \frac{1}{n_0^2}$. Indeed, doped semiconductors with a plasma wavelength in the MIR have a charge density ($n_0 \sim 10^{19}$ cm^{-3}) much lower than noble metals, such as gold ($n_0 \sim 10^{22}$ cm^{-3}). Hence, FE nonlinearites may grow as much as six orders of magnitude, overcoming by far the contributions originating in the crystal lattice nonlinear susceptibility $\chi^{(3)}$, which instead represents the dominant third-order nonlinear source in gold due to the high concentration of charge carriers. Moreover, the nonlinear active volumes are expected to increase in semiconductors due to their smaller effective masses [3].

Finally, we consider modifications of the charge density at the semiconductor surface obtained through the application of an external bias, i.e. by means of field-effect modulation (Fig. 1). We present a model for describing the influence of surface charge depletion on FE nonlinearities and make quantitative predictions about the role of field-effect modulation for the control of the optical nonlinear response of heavily doped semiconductors [5]. This technique may provide the unique ability to externally and dynamically modulate the nonlinear coefficients of heavily doped semiconductors by a simple setting of DC electric potential levels.

Symmetry, connectivity, and topology in photonic crystals

Thomas Christensen[1]

[1] Department of Electrical and Photonics Engineering, Technical University of Denmark, Denmark
[*] thomas@dtu.dk

Abstract: Symmetry imposes strong constraints on the frequency dispersion and topology of photonic crystal bands. I will describe several interesting consequences of these constraints, highlighting implications for the connectivity of photonic bands, the prevalence of photonic topology, and the outlook for having frequency-isolated topological degeneracies at high-symmetry points in the Brillouin zone.

The transverse nature of photons produces a polarization singularity at zero frequency which distinguishes the lowest bands of photonic crystals from those of other quasiparticles. I will discuss our recent work [1] on how symmetry, topology, and this polarization singularity lead to constraints on where the first photonic band gap can be opened. These constraints can be solved by a symmetry-based framework that allows determining the minimum connectivity of bands below the first photonic gap as well as the any associated symmetry-identifiable topology. By systematically examining the topology of all possible minimal configurations, we find a new, uniquely photonic topological effect which obstructs symmetry-allowed gap-openings by requiring the presence of topological nodal lines.

The framework developed to answer these questions allows the whole-sale application of recent methods from electronic topology – known as symmetry indicators or topological quantum chemistry – to the photonic context; I will highlight a few interesting examples of the opportunities that this brings, including an assessment of the prevalence of topology in two-dimensional photonic crystals and whether frequency-isolated Weyl points can exist at high-symmetry points of the Brillouin zone.

Chemical interface damping by electrochemical oxidation of gold

M. Pfeiffer[1], **M. Eich**[1,2], **A. Yu. Petrov**[1,2*]

[1]Institute of Optical and Electronic Materials, Hamburg University of Technology, Germany
[2]Institute of Photoelectrochemistry, Helmholtz-Zentrum Hereon, Geesthacht, Germany
[*]corresponding author: a.petrov@tuhh.de

Abstract: Chemical interface damping (CID) is a change of the effective collision frequency of electrons in metal due to chemical change of the metal interface. We show that electrochemical oxidation of gold leads to CID effect. The increase in collision frequency is determined by in-situ ellipsometric measurements during oxidation of flat single crystal and polycrystalline gold films.

Chemistry at the surface of metals can change the effective collision frequency of electrons in a free electron model determining the dielectric properties of metals. This effect is widely discussed. The increase in effective collision frequency was observed in plasmonic nanostructures due to thiol [1] and metal-oxide [2] coatings. Different explanations for the underlining physical effect exist, such as additional roughness seen by electrons at the surface or temporal electron transfer into states at the surface [3].

Here we investigate the CID effect on flat single crystal gold films due to electrochemical surface oxidation. We conduct in-situ measurement of ellipsometric data of the sample inside an electrochemical cell. The Ψ and Δ measured by ellipsometric method correspond to the ratio of s and p polarized light reflection and the phase shift between them and are used to fit a layer stack of gold and gold oxide with varying collision frequency as well as oxide thickness. Previously similar investigations were done disregarding the increase in collision frequency of gold; the change of reflection was attributed solely to oxide coating [4]. Including the change in collision frequency in the consideration we can clearly demonstrate both increase in the oxide thickness and increase in collision frequency. Important is also the fact, that at some point further oxide growth does not lead to further increase of collision frequency as the structure of the interface between gold and oxide does not change any more. This is an additional confirmation for the ellipsometric model that we use.

The collision frequency increase in the order of 10 meV observed for bulk gold can be recalculated in terms of electron mean free path, which allows the comparison to the results obtained with thiols and other oxides on gold nanoparticles. We show that electrochemical gold oxidation provides a stronger effect on collision frequency than coatings. The results of these ellipsometric study can be used to design electrochemically tunable gold nanostructures.

Reconfiguring electric and magnetic resonances of individual meta-atoms using phase-change materials

Lukas Conrads[1], Andreas Heßler[1]

and Thomas Taubner[1,*]

[1] I. Institute of Physics (IA), RWTH Aachen University, Germany
[*]corresponding author: taubner@physik.rwth-aachen.de

Abstract: We employ Phase-Change Materials (PCMs) for local addressing of individual meta-atoms in both metallic and low-loss dielectric metasurfaces, with special emphasis on tuning electric dipole (ED) and magnetic dipole (MD) resonances simultaneously or individually. Individual control of the electric and magnetic dipole resonances of split-ring resonators (SRRs) is demonstrated by locally changing the refractive index of aluminum SRRs in the corresponding hotspots of the antenna resonances and by direct writing and reconfiguration of SRRs in the new plasmonic PCM In_3SbTe_2.

For miniaturized active nanophotonic components, resonance tuning of nanoantennas is a key ingredient. Phase-change materials (PCMs) provide a switchable dielectric environment for resonant nanostructures, altering their resonance wavelengths in a non-volatile, reversible way. While PCMs usually exhibit a high optical contrast between their amorphous and crystalline phases [1], the "plasmonic" PCM In_3SbTe_2 (IST) has optical properties which change from dielectric to metallic upon crystallization in the whole infrared spectral range [2]. Resonant metallic and dielectric nanostructures (meta-atoms) can host a variety of different modes, ranging from electric dipole (ED) over electric quadrupole to even magnetic dipole (MD) modes etc. The full control over each resonance mode individually was not yet been obtained, although this could dramatically improve the design freedom of individually addressable meta-atoms and allow for post-fabrication fine-tuning.

Here, I will present our recent progress on the local optical addressing of individual meta-atoms in metallic [3] and low-loss dielectric [4] metasurfaces, with special emphasis on tuning ED and MD resonances either simultaneously or individually. While a homogeneous change of the refractive index around a meta-atom shifts both ED and MD in a similar way [4], the controlled optical addressing or modification within each meta-atom unit cell allows to specifically tune ED and MD separately.
For example, PCM-covered aluminum split-ring resonators (SRRs) are switched locally to tune both the electric dipole resonances as well as the magnetic dipole resonances. By selectively switching the PCM at different hotspots of the SRRs, both resonances can be tuned individually. The field enhancement in the magnetic resonance allows continuous tuning of surface-enhanced infrared absorption (SEIRA) of native SiO_2 [5]. Exploiting the "plasmonic" PCM IST, split-ring resonators (SRRs) are directly optically written and reconfigured in their arm size to continuously tune their magnetic dipole resonances over a range of 2.4 µm without changing their electric dipole resonances [6].

Our concepts are well-suited for rapid prototyping of ultrathin, tunable, plasmonic devices for infrared nanophotonics, telecommunications or (bio)sensing, and fine-tuning functionalities of metasurfaces on a meta-atom level by locally changing the refractive index at the hotspots of the selected antennas.

Abstract:

Multiphoton Lithography is a laser-based additive manufacturing technique which allows fabrication with resolution down to a few tens of nanometres. Based on nonlinear absorption, Multiphoton Lithography has unique capabilities that no-other technique can provide. It has been implemented with a variety of materials and several components and devices have been fabricated such as metamaterials, biomedical devices, photocatalytic systems and mechanical models

The unique capability of Multiphoton Lithography lies in that it allows the fabrication of computer-designed, fully functional 3D devices. In this talk, I summarize the principles of microfabrication, and present recent research in materials processing and functionalization of 3D structures. Finally, I discuss future applications and prospects for the technology.

Plasmon-enhanced nano-spectroscopies for highly sensitive biomolecular detection

T. Yano[1, 2*], R. Kato[1, 2], and T. Tanaka[1, 2]

[1]Institute of Post-LED Photonics, Tokushima University, Tokushima, Japan
[2]Innovative Photon Manipulation Research Team & Metamaterials Laboratory, RIKEN, Saitama, Japan

Optical biosensing has attracted considerable attention due to its capability of highly sensitive molecular detection and analysis. We have been developing a variety of nanostructure-enhanced biomolecular spectroscopies in combination with plasmonics and metamaterials where optical nanostructures play a crucial role in enhancing various optical signals (visible absorption/reflection, Raman scattering, fluorescence, and infrared absorption) from targeting biomolecules. Here in this talk, we focus on our recent works on high-sensitivity and super-resolution optical sensing and imaging for biomedical analysis [1-7].

The first topic is plasmonic detection of single biomolecules. A nanometric gap between a silver tip and gold substrate enabled us to enhance and detect Raman scattering from a single gold-binding peptides (GBP) which exhibited specific binding affinity to gold surface, resulting in spectroscopic elucidation of the binding sites and mechanisms. The second topic is nanoparticle-enhanced surface plasmon resonance (SPR) sensing of coronavirus (SARS-CoV-2). A crucial plasmonic role in significantly enhancing the limit of detection (LOD) is revealed for exceptionally large gold nanoparticles with diameters of hundreds of nm. SPR enhanced by these large nanoparticles lowered the LOD of SARS-CoV-2 N protein to 85 fM, resulting in the highest SPR detection sensitivity ever obtained for SARS-CoV-2 N protein. We also developed a digital SPR biosensing technique based on plasmon hybridization, which improved the SPR sensitivity down to sub-fM level. The last topic is plasmon-enhanced fluorescence spectroscopy using polymer-coated silver nanoparticles. The polymer layer coated was adequately thin to efficiently achieve plasmonic enhancement of fluorescence and also thick enough to effectively suppress quenching of fluorescence, achieving a huge net enhancement of fluorescence. The polymer-coated plasmonic nanoparticles are a promising platform for demonstrating highly sensitive biosensing for medical diagnostics.

Abstract: Single-photon sources that form the basis for various quantum applications have seen fast development. The deterministic generation of single photons can amongst others be realized by semiconductor quantum dots. To achieve efficient sources, parameters such as the brightness, photon rates, directionality, room-temperature stability, etc. need to be optimized. To modify the emission properties of individual quantum dots, they can be coupled to nano-antennas. Here a design that enables bright room-temperature quantum light sources is demonstrated.

The authors independently developed techniques for enhancing the directionality of quantum dot-based single photon sources by positioning single nanocrystals at the center of concentric Bragg antennas [1.-3.] and for enhancing emission rates via coupling to a nanocone antenna [4., 5.]. In the presented configuration, both approaches are combined, see Figure 1 [6.]. The Bragg antennas are numerically optimized for their collimation effect and narrow emission angles, which allow for high collection efficiencies even in systems with low numerical apertures. The attachment to the apex of a nanotip leads to a reduction of the lifetime and consequently to a brightness enhancement.

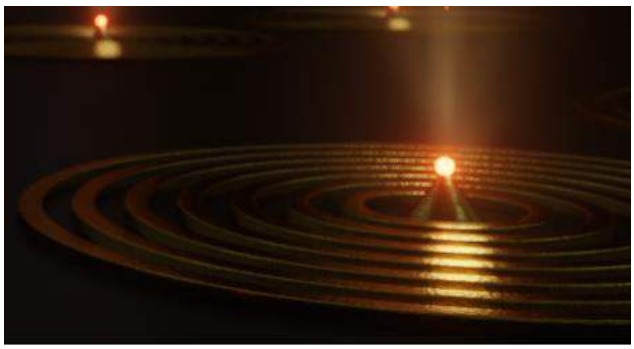

Figure 1: Schematic illustration of a bullseye antenna with a central nanocone to which a single quantum dot is attached, resulting in directional emission [courtesy of L. Lüder].

In the presentation, the design considerations for the overall hybrid bullseye-nanocone-nanoemitter device will be outlined. The geometry is illustrated by scanning electron microscopy images, and the optical performance is evaluated in terms of the projected photon rates.

Support by COST (European Cooperation in Science and Technology) Action MP1302, the German Excellence Initiative, the Israeli Innovation Authority: Quantum Communication Consortium, and the Center for Nanoscience and Nanotechnology at the Hebrew University of Jerusalem is gratefully acknowledged.

Proximity Induced Chiral Quantum Light Generation in Strain Engineered WSe_2/MPX_3 Heterostructures

Han Htoon
Center for Integrated Nanotechnologies, Materials Physics and Applications Division, Los Alamos National Laboratory, Los Alamos, NM 87545
*htoon@lanl.gov

Abstract: We report free-space generation of highly chiral single photons from QEs created via nanoindentation of monolayer WSe2 - NiPS3 heterostructures at zero external magnetic field. These QEs emit with a degree of circular polarization and single photon purity as high as 0.89 and 80% respectively, independent of pump laser polarization. The chiral quantum light emission arises from magnetic proximity interactions between localized excitons in the WSe_2 monolayer and the out-of-plane magnetization of defects in antiferromagnetic (AFM) order of NiPS.

Generation of chiral quantum light is critically needed for realization of non-reciprocal single photon devices, deterministic spin-photon interfaces, and complex quantum networks.[1] To date however, emission of such chiral quantum light has only been achieved through the application of intense external magnetic fields,[2] by electrical/optical injection of spin-polarized carriers/excitons,[3] or by coupling with complex photonic/meta-structures.[1] We exploit *magnetic proximity interactions* for the first time to realize free-space, zero-field generation of chiral quantum light.

"Proximity effects" – the class of phenomena by which an atomically-thin material borrows properties of an adjacent material (such as magnetism) via quantum mechanical interactions – has recently been explored by coupling transition metal dichalcogenides (TMD) with various bulk and 2D magnetic materials.[4] However, chiral light emission without spin polarized carrier/exciton injection at zero magnetic field remains elusive to date. A van der Waals antiferromagnetic (AFM) material, $NiPS_3$, has recently been identified as fertile ground for exploring emergent phenomena of 2D magnetism.[5] Because this material displays in-plane AFM order, it is not conventionally expected to induce ferromagnetic proximity interactions necessary for chiral light emission. Surprisingly, however, our work shows that chiral quantum light sources with a high degree of circular polarization and 80% single-photon purity *can* be realized by strain-engineering the $WSe_2/NiPS_3$ heterostructure with nanoscale indentations. Through state of art scanning diamond NV microscopy experiment and temperature dependent magneto-photoluminescence studies, we show that the chiral quantum light emission arises from magnetic proximity interactions between localized excitons in the WSe_2 monolayer and out-of-plane magnetization of AFM defects in $NiPS_3$, both of which are co-localized by the strain field arising from the nanoscale indentations. Interestingly, a similar chiral localized excitonic emission is also observed in our more recent experiment performed on $WSe_2/MnPS_3$ and $WSe_2/FePS_3$ heterostructure with nano-indents (See Extended Data Fig. 10).

Our work establishes TMD/$TMPX_3$ (TM = Mn, Ni, Fe, Co; X = S, Se) heterostructures as a novel material platform for not only exploring proximity-induced emergent phenomena but also for the development of spin-photon interfaces, magnon based quantum transduction, and sensing schemes. Our observations also reveal that local strain

engineering can be utilized not only to create QEs, but also to localize ferromagnetic proximity effects required for creation of chiral single photon emitters in $WSe_2/NiPS_3$ heterostructures.

Abstract: We discuss about ultra-sensitive infrared spectroscopic techniques enhanced by 3D metasurfaces. To suppress unwanted background and noises in IR spectroscopy, metasurface absorber with three-dimensional vertical-oriented metal-insulator-metal (v-MIM) structure was introduced. Owing to small footprint of v-MIM, the density of hot spots was dramatically increased resulting in strong signal enhancement and efficient suppression of background light. Using this device, 20 ppm concentration of carbon dioxide and butane molecule detection was demonstrated.

Metasurfaces have attracted considerable attention due to their capabilities to manipulate light. Recently we applied metasurface light absorber for improving the sensitivity of IR spectroscopy. Owing to its plasmonic interaction with incident light wave, and molecules, unwanted background and noises in IR spectroscopy were suppressed and molecular signals are enhanced. This technique has already been applied for self-assembled monolayer of 16-mercaptohexadecanoic acid molecules on the device surface and atto-molar (10^{-18} mol) level molecular sensitivity was realized [1]. For liquid samples, to introduce target molecules into the hot spot region of the metamaterial, we proposed a metamaterial absorptive device that incorporates with nanofluidics, and demonstrated an ultra-high sensitivity of IR absorption detection [2]. In this paper, we introduced metasurface absorber with three-dimensional vertical-oriented metal-insulator-metal (v-MIM) structure for ultra-sensitive infrared spectroscopic techniques for gas sensing [3]. We designed and fabricated the v-MIM structure with a nano-gap of 25 nm channel which enabled the delivery of small molecules into hot-spot region. Figure 1 shows the electron micrographs of the fabricated v-MIM array structure. Owing to small footprint of v-MIM comparing conventional lateral MIM structure, the density of hot spots was dramatically increased resulting in strong signal enhancement and efficient suppression of background light.

This metamaterial was applied to carbon dioxide and butane detection designing to exhibit a resonance at 4033 cm^{-1} and 2945cm^{-1} which spectral overlap with the C=O and $–CH_2$ vibration mode, respectively. The mutual coupling of these two resonant modes creates a Fano resonance, and their distinct peaks are clearly observed in the corresponding transmission dips. In addition, owing to its small footprint, v-MIM structure allows the detection of a 20 ppm concentration with suppressed background and high selectivity in the mid-infrared region.

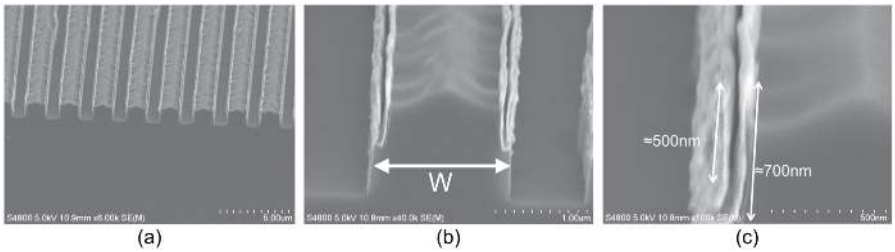

Figure 1 Fabricated vertically-oriented metal-insulator-metal (v-MIM) metasurface absorber.

Abstract: The interest in flexible and integrated photonics requires new strategies for device manufacturing on arbitrary complex surfaces. THz technology can particularly benefit from this approach to implement compact systems for generation, detection, and manipulation of THz radiation. Here we present a novel fabrication method to realize conformable metasurfaces. The flexible and versatile character of polymeric nanomembranes is combined with direct laser writing and metal deposition to develop freestanding ultra-thin THz devices with an unprecedentedly high level of conformability.

Optical metasurfaces are a very promising platform to go beyond traditional metamaterials in terms of both compactness and functionality. Here, we propose a novel fabrication method for ultra-sub-wavelength free-standing plasmonic THz metasurfaces with high degree of conformability. The developed technique merges direct laser writing via two-photon polymerization (2PP) and transfer printing using ultra-thin polymeric membranes. As proof of concept, we focused on developing a highly absorbing structure using a suspended membrane consisting of a dielectric thin film encapsulated by two metallic layers. By inscribing in the top metallization a terahertz metasurface, an absorption resonance is introduced, whose depth is strongly enhanced by the presence of a homogeneous bottom metallization. Regulating the thickness of the dielectric material, high levels of absorption are demonstrated in an ultra-subwavelength thickness (even < λ/100).

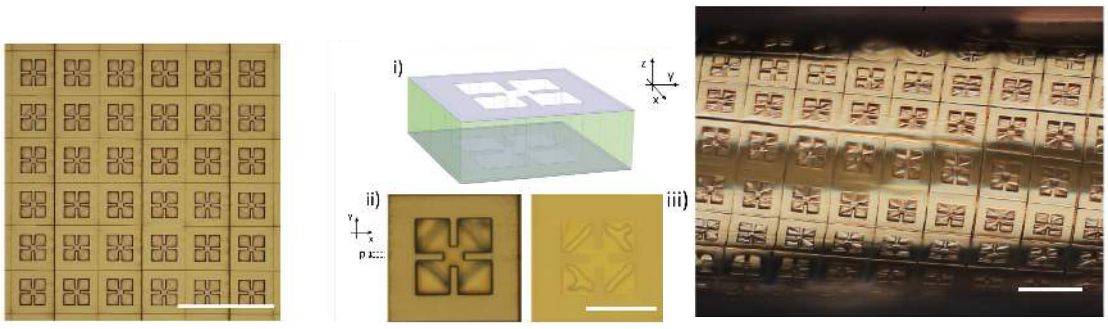

Figure 1: Optical images of a representative 2 μm-thick conformable THz metasurface absorber showing the square array of split ring resonators. (i): 3D sketch highligthing the two metal surfaces displaced by the resist thickness. Front (ii) and back (iii) view of the metasurface unit-cell of 45 μm size. Scale bars are 100 and 30 μm, respectively. Image showing the all-round conformability of the metasurface around a 100 μm-radius wire. Scale bar is 50 μm.

A fabricated sample 2 µm-thick is shown in the optical image of Figure 1. It shows the metasurface pattern where it is possible to observe the square array arrangement and geometry of the unit-cell with size a = 43 µm. The realized resonator shape belongs to the most widely used class of sub-wavelength optical resonators at microwave, THz and FIR frequencies known as split-ring resonators (SRRs), which can present electric and/or magnetic response by design.

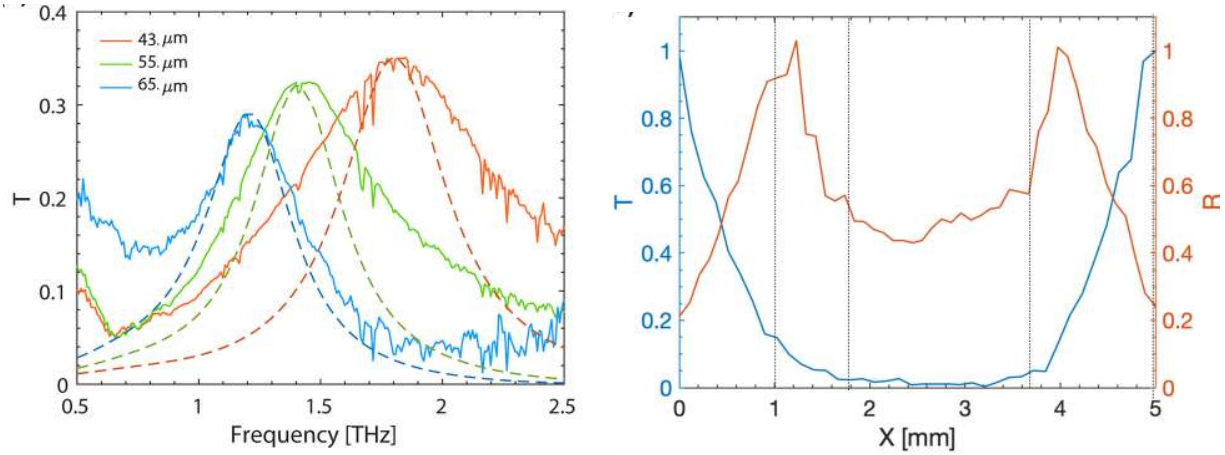

Figure 2: Left: transmission spectra for three metasurfaces having only the top metallization with 43, 55 and 65 µm unit-cell represented by the orange, green and blue solid curves, respectively. Dashed lines with same darker colors report the corresponding calculated results obtained via full-wave finite-element simulations. Right: transmission and reflection profiles for the double-metal metasurface.

THz transmission measurements were first performed on single-metal membranes using time-domain spectroscopy (TDS) in the frequency range from 0.5 to 3.5 THz to check the SRR resonances. The measured transmittance of three devices with a = 43 µm, 55 µm and 65 µm is shown in Figure 2 (left). A clear resonance is observed for each sample, with a linear blueshift of the frequency peak according to the downscaling of the metasurface unit-cell.

In order to investigate the absorption of the dual-metal devices fabricated with one continuous metal ground plane, a single-mode quantum cascade laser, nominally emitting at the 3.5 THz of the chosen metasurface resonance peak, is used. Figure 2 (right) shows the acquired transmission and reflection profiles. They highlight the absorbing character of the metasurface placed in the middle of the scan. Even if a considerable (>40 %) absorption is observed, the deviation from a quasi-perfect absorption can be ascribed to a possible frequency resonance detuning of the laser emission frequency due to a discrepancy between nominal and real geometrical parameters of the structure.

Abstract: We show that ellipsometry is an ultrasensitive tool for spatiotemporal probing of surface plasmon-generated hot electrons.

The strong localization of plasmon-assisted photon absorption facilitates the emergence of so-called hot electrons with energy levels deviating from Fermi-Dirac distribution. We demonstrated that spectroscopic ellipsometry is capable of grabbing the in-depth distribution and the temporal evolution of surface plasmon polariton (SPP) mediated hot electron populations [1].

For the excitation of SPPs, a Kretschmann-geometry involving a glass right angle prism coated with 50 nm gold was applied. SPPs were excited from the backside of the film using either an 808 nm cw diode laser or the 35 fs pump pulses of an amplified Ti:sapphire laser under resonance angle. Spectroscopic ellipsometry was applied at the top side of the films (Fig. 1. left panel), illuminating the samples with a broadband cw light source or white light continuum probe.

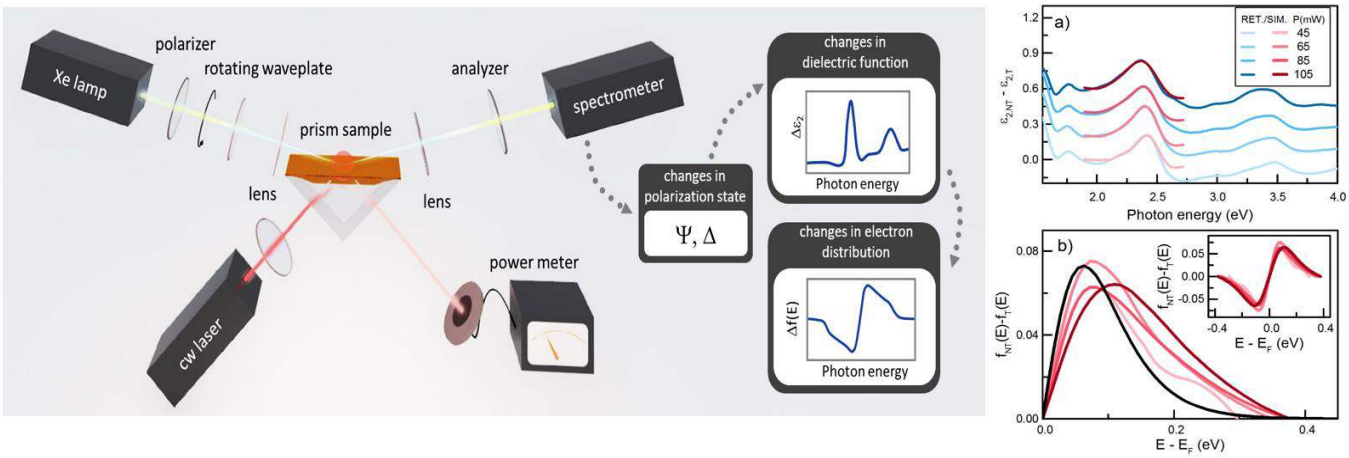

Fig. 1 Left) Experimental setup for ultrasensitive probing of plasmonic hot electrons with spectroscopic ellipsometry. SPPs are excited by a cw laser at the resonant angle of incidence from the backside, while ellipsometric data is recorded on the gold-air interface with white-light probing from the top. These measurements are capable of accessing the dielectric function of the investigated system, the changes of which are in close correlation with the electron distribution function. Right a) retrieved and simulated differences between the dielectric function of the non-thermalized top layer (NT) and the thermalized part (T) of the gold film and b) the corresponding electron occupancies for cw excitation.

In the case of cw excitation of SPPs, ellipsometry revealed - besides the temperature raise of the gold layer -

the presence of a surface layer accounting for the appearance of SPPs and the associated hot electron generation. The spatial extent of this non-thermalized layer (1.5-4 nm) and its dielectric function became also visible. We retrieved the changes in the electron occupancies based on the proportionality of ε_2 with the electron distribution and the band structure. The observed changes provide a clear indication of the existence of a hot-electron population with moderately increased energies close to the film surface where plasmon excitation takes place (Fig. 1 right panel a) and b)).

For the pump-probe experiments, the pseudo dielectric function of the gold layer was deduced. These dielectric functions were modelled by assuming different electron distributions describing the different mechanisms following the SPP excitation. The very good accordance between the measured and calculated curves supports the applicability of our method.

Abstract: Traditional deep ultraviolet (DUV) light sources using nonlinear optical crystals exhibit limitations such as bulky size, inadequate efficiency, and requirement of phase-matching conditions. We proposed a crystalline silicon metasurface with symmetry breaking, which can excite bound states in the continuum (BIC) resonance to enhance third harmonic generation (THG) at the DUV regime. We experimentally realized a high Q-factor of ~ 180 and the measured THG power is around 200 pW at a pump power of 200 mW.

1. Introduction

Traditional coherent light sources in the DUV regime (200 nm – 300 nm) have been widely adopted in applications such as optical lithography,[1] bioimaging,[2] and medical inspection.[3] Although conventional nonlinear crystals exhibit high conversion efficiency, the optical loss in the DUV regime limits their operating ranges to visible and longer wavelength only. In addition, nonlinear optical crystals suffer from their bulky size, low efficiency and stringent requirement of phase-matching conditions, which hinders their applications where miniaturized and compact light sources are needed. In recent years, optical bound states in the continuum (BIC) have emerged as a new paradigm for trapping and confining resonant modes for numerous applications.[4] BIC metasurfaces have been manifested to be able to confine the incident light efficiently with very high Q-factors. Metasurfaces consisting of high-quality nonlinear materials, such as silicon (Si) would enhance the nonlinear conversion efficiency.[5] In this work, we have theoretically proposed a BIC resonant structure inside c-Si metasurface and experimentally obtained a high Q-factor BIC. Our finding shows that c-Si is a good candidate for THG in the DUV regime due to its high nonlinearity. In addition, exciting the BIC resonance via the c-Si metasurface can significantly boosted the THG efficiency.

2. Results and discussion

The concept of the proposed BIC resonance inside the c-Si metasurface and its unit cell consisting of two resonators are sketched in Fig. 1a. The key design parameters include the width of top and bottom sides denoted by L_1 and L_2, respectively. The shape of the two resonators is a right-angle trapezoid. In the case of L_1=L_2, the BIC resonance is confined so that it cannot be coupled to the radiation spectrum. The BIC resonance is observed only after inducing a lattice symmetry breaking, i.e., creating a difference of ΔL between L_1 and L_2, as shown in Fig 1b. A maximal theoretical Q-factor of up to 900 is calculated upon for ΔL =20 nm.

The BIC metasurfaces was fabricated via electron beam lithography followed by dry etching to transfer the nanopattern from the hydrogen silsesquioxane (HSQ) to the c-Si and the SEM image of the unit cell of the fabricates BIC metasurfaces is shown in the inset of Fig. 2a. We pumped the fabricated c-Si metasurface using a linearly polarized fs-laser with the polarization in the horizontal direction. The measured THG power as a function of the pump power is plotted in Fig. 2a, showing a third order dependence between the pump and the THG signals.

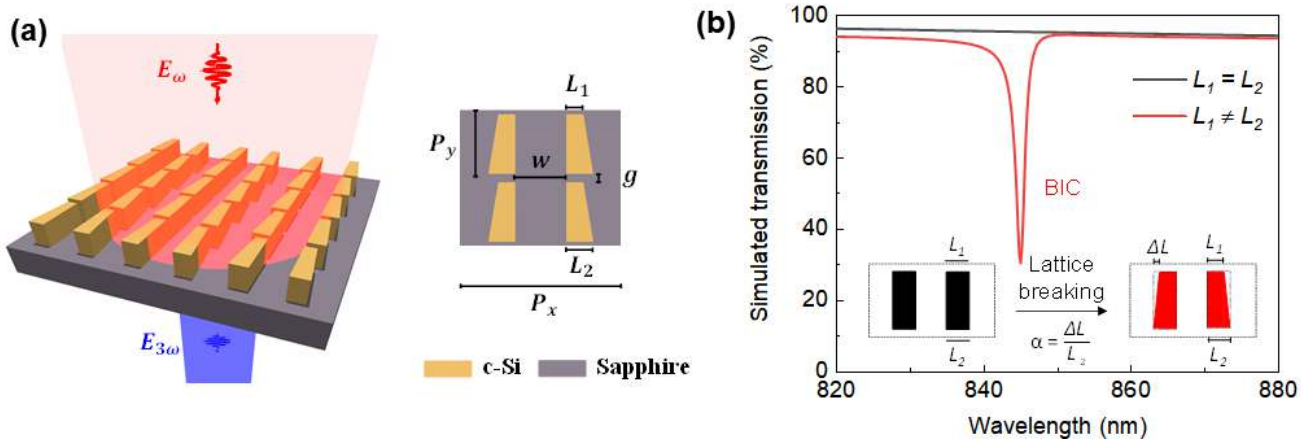

Figure 1. Metasurface design and parameters of c-Si metasurface supporting BIC resonance. (a) The schematic of c-Si metasurface on sapphire under an incidence of a pump fs-laser at the wavelength of 840 nm denoted by E_ω, and the collected THG at the wavelength of 280 nm denoted by $E_{3\omega}$. (inset): the dimensions of unit cell of c-Si metasurface: periods P_x = 550 nm, P_y = 320 nm, horizontal gap g_x = 155 nm. The width of pillars L_1 varies while L_2 is fixed to break lattice symmetry. (b) Simulated transmission before and after the lattice symmetry breaking showing the BIC near 840 nm.

The maximum THG power was up to 200 pW at a pump power of 200 mW. In addition, we measured the THG spectrum, and the results are plotted in Fig. 2b. The experimental Q-factor was more than 120. Our results indicate that c-Si metasurfaces have great potential to develop highly efficient ultracompact DUV light sources.

Abstract: We successfully reconstruct the spectrum of a multi-wavelength input by using the inverse matrix method for data obtained with a random chirped photonic crystal waveguide.

With conventional spectrometers, there is a tradeoff between device compactness and high spectral resolution. Although integrated photonic devices are expected to overcome this issue, they suffer from fabrication errors that degrade the resolution. We have already reported spectrometer operation based on photonic crystal waveguides with randomness [1, 2] that can overcome this problem. The process is based on capturing the wavelength-dependent light localization pattern of a photonic crystal waveguide with a camera and reconstructing the spectrum. Since the localizations usually exhibit a Q of 10^5 or higher, corresponding to a ~ 0.01 nm spectrum width, we expect a wavelength resolution of the same order. We used simulated annealing [1] and deep learning [2] to reconstruct the spectra, but these approaches were slow and could not provide a high resolution.

Here, we report our significant process as regards wavelength resolution, where we show that a value of 0.07 nm is possible by improving the reconstruction method, employing low-rank approximation, and regularizing least squares for the algorithm while realizing real-time operation, which was not possible with the previous method [1]. We should note that a device that has such a high resolution (0.07 nm) and a footprint as small as mm^2 outperforms other spectrometer devices.

The chirped waveguide structure is shown in Fig. 1(a), where the cut-off frequency is shifted up in each section by reducing the waveguide width by 2 nm. Since Anderson localization occurs close to the mode gap, usually exhibiting Qs of 10^5, we can use them to reconstruct the spectrum information. Localization patterns were captured from the top of the chip while scanning the wavelength of the incident laser (Fig. 1(b)).

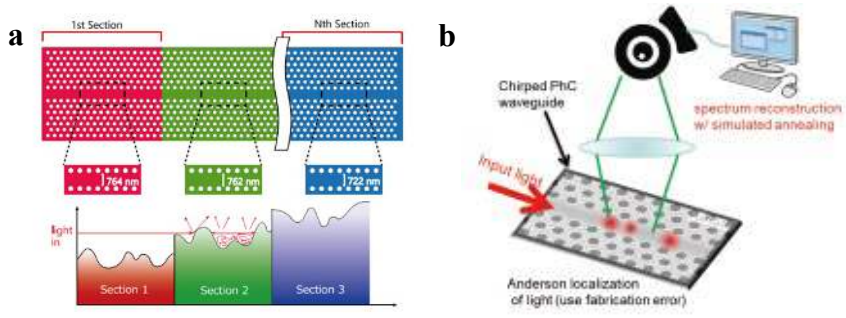

Fig. 1: (a) PhC waveguide and conceptual diagram of the waveguide mode gaps. (b) Schematic diagram of the experimental system.

The captured images are processed by cropping, deforming, and averaging, and then converted to one-dimensional data. By arranging them in wavelength order, a matrix T is obtained. Therefore, the localization

pattern $\vec{I}$ when an unknown spectrum $\vec{S}$ is injected satisfies the following,

$$\vec{I} = T\vec{S}. \tag{1}$$

Therefore, ideally, the spectrum is reconstructed using the inverse matrix of *T*. We must also take account of the noise during processing. Hence, we consider a singular value decomposition of *T* given as [3],

$$T = USV^T. \tag{2}$$

Since lower singular values are more strongly affected by noise, a threshold value is set, and singular values below the threshold are truncated. This is called low-rank approximation. Using S_{tr} consisting only of singular values above a threshold, we correct the *T* matrix to

$$T_{tr} = US_{tr}V^T. \tag{3}$$

Furthermore, a regularized inverse matrix is obtained by introducing a constant λ that compensates for the sensitivity to noise. The reconstructed spectrum is then given as,

$$S = [(\lambda I - T_{tr}^T T_{tr})^{-1} T_{tr}]I. \tag{4}$$

We obtained the *T* matrix based on this algorithm, as shown in Fig. 2(a). The wavelength step is 0.1 nm, which will give the resolution. Figure 2(b) shows the localized pattern for two different wavelength inputs simultaneously. We assume that the localization pattern is the superposition of the two patterns at different wavelengths. Indeed, the blue line of the numerically multiplied pattern agrees well with the red line, which is the experimentally obtained localized pattern. Figure 2(c) is the spectrum reconstructed using our algorithm. It demonstrates that our approach can reconstruct a multi-wavelength input at a wavelength separation of 0.8 nm, which is beyond the designed wavelength resolution of the chirped photonic crystal waveguide. The calculation time was only 0.097 sec.

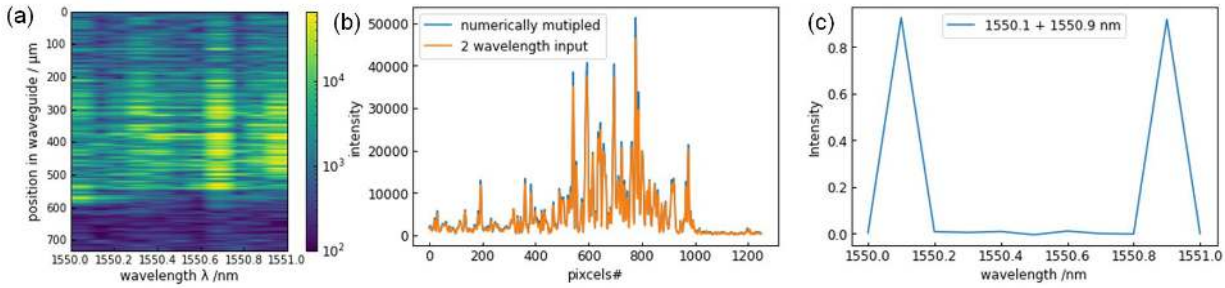

Fig. 2 (a) Obtained *T* matrix. (b) Localization patterns at two wavelength inputs. The blue line is the numerically calculated (as the superposition of two different inputs) pattern. The red line is the obtained pattern. (c) A reconstructed spectrum of a multi-wavelength input from the obtained localization pattern.

In conclusion, we show that we can distinguish the peak of an input light of the order of sub-seconds with a resolution of 0.07 nm by using a chirped photonic crystal waveguide where randomness is inherent.

Abstract:
Surface-enhanced infrared absorption (SEIRA) spectroscopy is a powerful technique for a label-free identification of molecular species. The low infrared absorption cross sections of molecules are made up for the electromagnetic field enhancement provided by the excitation of surface and/or localized plasmons of metallic structures [1]. The design of actual plasmonics detectors is a trade-off between the detection of very small volumes of molecules and the signal to noise ratio level. We demonstrate that an epsilon-near-zero (ENZ) material combined with nano-slits lifts this constraint and provides both extreme enhancement factor up to 10^7 and highly contrasted SEIRA signal for an extremely low amount of material of interest [2]. These results are explained by the modification of the electromagnetic field of the gap plasmon mode sustained by the slits in the presence of the ENZ material, Fig. 1. We propose to implement this concept with a semiconductor whose doping level engineering provides a versatile way to scan the whole molecules' fingerprint frequency range.

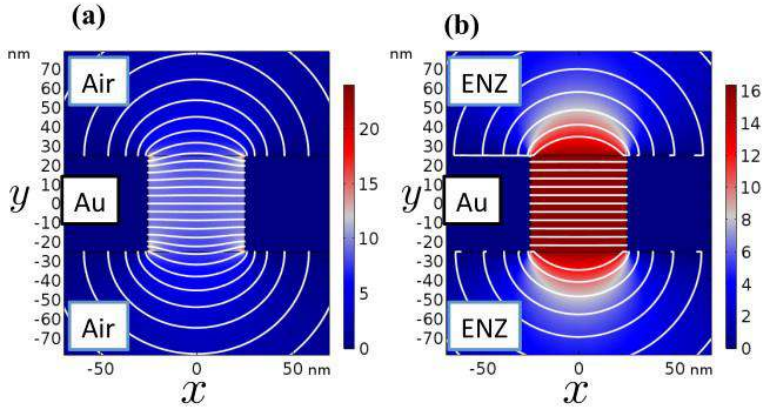

Figure 1: Modulus of the x-component of the normalized electric field for 50 nm silts filled with air, when the slit is, respectively, surrounded by air (a) and by an ENZ medium (b). The permittivity of the ENZ medium is equal to -0.01. The electric field lines are represented in white.

Advances in multiphysics modeling of phase change materials based metasurfaces

Dmitry N. Chigrin[1,2]

[1]I. Physikalisches Institut (1A), RWTH Aachen University, Aachen, Germany
[2] DWI Leibniz Institute for Interactive Materials, Aachen, Germany
*corresponding author: chigrin@physik.rwth-aachen.de

Abstract: Phase change materials are substances that can undergo rapid and reversible phase transitions, leading to significant changes in their physical properties. By incorporating these materials into metasurface design, it is possible to create programmable photonics components that can be reconfigured. This is particularly important in the fields of artificial materials, neuromorphic computing, and integrated photonics, where there is a growing demand for adaptivity and reconfigurability. In this presentation, we report on recent developments of the multiphysics description of complex composite active metasurfaces that incorporate phase change materials as building blocks. We provide a detailed discussion of the method and examples of its application.

Photo-Induced Sources within Multilayer Optics: from Light Scattering to Micro-cavities and Thermal Radiation

C. Amra, P. Rouquette, M. Zerrad, G. Soriano, M. Lequime

Aix Marseille Univ, CNRS, Centrale Marseille, Institut Fresnel, Marseille, France
*corresponding author: claude.amra@fresnel.fr

Abstract: We use the same formalism to analyze light scattering, luminescence, and photo-induced thermal radiation in optical interference filters. The 4D spatio-temporal regime is considered. Analytical techniques are presented to design strong inhibition (case of scattering) or huge enhancement (luminescence, thermal radiation) of the pattern emitted from these multi-dielectric coatings.

Optical interferential filters [1,2] are currently used to modify the spectral properties of substrates. This has led to numerous multilayer designs of varying complexity, such as broadband antireflection coatings and beam splitters, dichroic filters with steep edges, multi-cavity narrowband filters, notch filters, chirped mirrors and others. In the field of manufacturing (dual ion beam sputtering, magnetron sputtering, ion assisted deposition...), the know-how is very advanced so that these amorphous coatings can be produced up to 1000 thin films with sub-micron thicknesses.

In addition to the mechanical properties of these components, their energy balance remains a key issue in high precision optics (space optics, gyro-laser mirrors, gravitational wave detection). This balance requires that the total losses due to absorption and scattering be less than 10^{-6} of the incident flux (1ppm), a barrier to be overcome in the coming years. For this reason, light scattering is still the subject of extensive research [3], including the role of interface roughness, bulk inhomogeneities, and local defects. We first show how to analyze these phenomena using electromagnetic theory and high-end laboratory equipment. Scattering sources are described with fictitious currents at all interfaces and bulks, which interfere to produce the scattering pattern of multilayers in free space. Thanks to a mutual coherence factor close to unity, these interferences can be destructive, opening the door to anti-scattering effects with great advantages.

Multilayer optics can also be used in the form of microcavities [4,5], where the illumination beam is replaced by one or more luminescent layers in the stack. The deposition techniques are different (epitaxial growth on crystalline substrates), but the formalism is similar, since physical bulk sources take account of the luminescence processes. A key difference with light scattering is the lack of coherence between these currents. In this context, we present an analytical technique to design huge pattern enhancements of these micro-cavities, which finds applications in the field of sensors and micro-sources. Huge enhancements can be designed for arbitrary polarizations, wavelengths, or angles, which can also occur simultaneously [6].

Photo-induced thermal radiation [7,8,9] is also predicted and designed with the same formalism [10]. In fact, thermal radiation originates from stochastic bulk currents, both magnetic and electric, with no mutual coherence. The main difference is that these currents are temperature dependent, which requires first calculating the absorption heat source in the multilayer and then solving the 4D spatio-temporal heat equation in the stack [11]. The results allow to predict the photo-induced thermal radiation in the most general case, versus time, direction and wavelength, and versus illumination parameters (incident energy, pulse duration and repetition rate,

polarization and incidence). Finally, we show how multi-dielectrics allow to design narrow-band huge emissivity [10] of controlled amplitude at predetermined frequencies and polarizations.

To be complete, for all processes (scattering, luminescence and thermal radiation) we quantify both the amount of light that merges outside the coating in free space, and the amount of trapped light that is transferred to the guided modes of the multilayer. Depending on the coating design, one (free space) or the other (guided modes) process may dominate the energy balance [12].

We acknowledge the French Space Agency (CNES), the French Research Agency (ANR) and Cilas ArianeGroup for their support.

Purcell factor for plasmon-enhanced metal photoluminescence

Tigran V. Shahbazyan

Department of Physics, Jackson State University, Jackson, MS 39217 USA
shahbazyan@jsums.edu

Abstract: We present an analytical model for plasmonic enhancement of metal photoluminescence (MPL) in metal nanostructures. We obtain a universal expression for MPL Purcell factor in terms of metal dielectric function, plasmon frequency, and the system volume. We find that the lineshape of MPL spectrum is affected by the interference between direct carrier recombination processes and those mediated by plasmonic antenna which leads to a blueshift of MPL spectral band relative to scattering spectra observed in the experiment.

The origin of bright MPL from plasmonic nanostructures was suggested [1] to be due to excitation of the localized surface plasmon (LSP) by a recombining electron-hole pair [2] followed by the LSP radiative decay. This plasmonic antenna scenario has been confirmed by MPL measurements from single gold nanorods which revealed strong similarities between the MPL spectra and scattering spectra measured from the same structures [3-5]. At the same time, a persistent blueshift of MPL peak positions relative to LSP resonance in scattering spectra has been reported, which has not so far been explained.

We present an analytical model for MPL from plasmonic structures of arbitrary geometry with characteristic size is below the diffraction limit. For such systems, we derive an explicit expression for the MPL Purcell factor, which describes the plasmonic antenna effect, and trace the observed blueshift of MPL spectral band to destructive interference between the direct and antenna-assisted recombination processes. For frequencies w close to the LSP frequency w_n, we obtain the MPL Purcell:

$$\mathrm{F}(\omega) = \frac{2\pi \mathrm{c}^3}{\omega^3 V_\mathrm{m}} \frac{\varepsilon''(\omega)}{|\varepsilon(\omega) - \varepsilon'(\omega_n)|^2} \tag{1}$$

where $\varepsilon(\omega) = \varepsilon'(\omega) + i\varepsilon''(\omega)$ is metal dielectric function, c is speed of light, and V_m is metal volume. With such Purcell factor, we obtain the MPL enhancement factor relative to bulk MPL background as

$$M(\omega) = A_n \left| \frac{\varepsilon'(\omega_n) - 1}{\varepsilon(\omega) - \varepsilon'(\omega_n) - (2i\omega^3/3c^3)[\varepsilon(\omega) - 1]V_n} \right|^2 \tag{2}$$

where V_n is the effective system volume and the coefficient A_n depends on system geometry. The enhancement factor (2) can be used to describe the MPL spectra for systems of various shapes and sizes.

To illustrate our results, we present the MPL spectra for several gold nanostructures immersed in water by plotting Eq. (2) for a single LSP mode. In all calculations, we use the experimental gold dielectric function and, accordingly, the LSP wavelength range extends above 530 nm, which corresponds to the interband transitions onset in gold. Specifically, we choose the LSP peak positions at the wavelengths 620 nm, 670 nm, 710 nm and 750 nm, which are close to those measured in the MPL experiments [3-5]. We assume no particular shape but specify the overall nanostructure volume as $V_\mathrm{m} = L^3$, where L is the characteristic linear size. For gold structures, the optimal L lies in the interval between 20 nm and 60 nm, in which the MPL quenching is relatively weak while the LSP radiative damping is not too strong.

In Fig. 1, we plot the MPL enhancement factor (2) for general-shape gold nanostructures with L = 20 nm, in which the LSP resonance position can be tuned by varying the structure shape (e.g., by varying the aspect ratio of nanorods). The MPL enhancement factor exhibits nearly-Lorenzian resonances, whose amplitude increases with the wavelength, consistent with MPL quantum yield measurements [3-5].

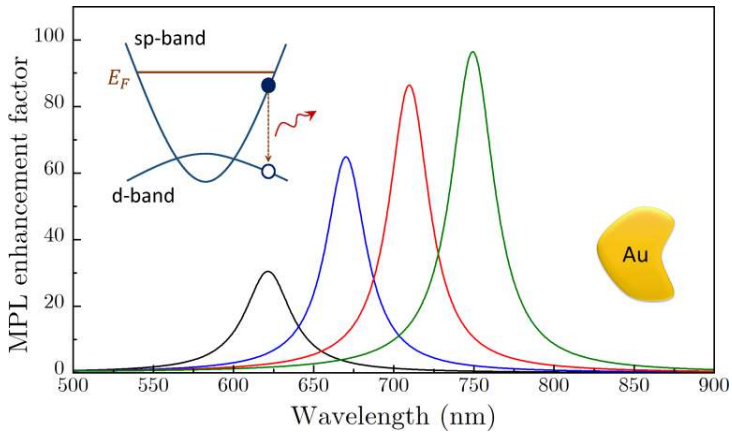

Figure 1. MPL enhancement factor for gold nanostructures with characteristic size 20 nm at various LSP wavelengths 620 nm, 670 nm, 710 nm and 750 nm. Inset: Schematics of interband transitions in gold.

In Fig. 2, we compare the MPL spectra for L = 40 nm gold nanostructures at same LSP wavelength values and the scattering spectra, which are both normalized to their maxima. A clear blueshift of the MPL spectral band relative to the LSP resonance in scattering spectra persists for all structures but is more pronounced for shorter wavelengths, consistent with the experiment [3-5]. This blueshift and the change in the resonance lineshape originate from the interference between the direct and LSP-mediated recombination processes, which is incorporated in the MPL enhancement factor (2).

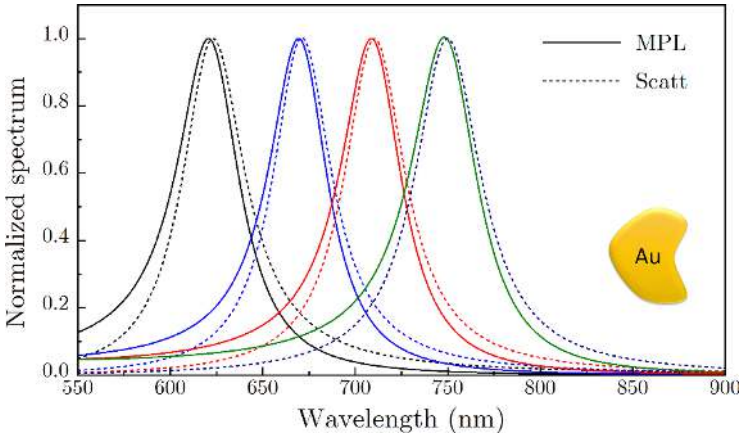

Figure 2. Normalized MPL and scattering spectra for gold nanostructures with characteristic size 40 nm at the same LSP wavelengths as in Fig. 1.

Abstract: This paper reviews recent advances in the research and development of graphene-based 2D plasmonic metamaterials for terahertz (THz) laser transistors.

The authors' theoretical discovery of THz laser transistors in 2007 [1-4] was realized in 2018 [5] as a distributed-feedback dual-gate graphene-channel field-effect transistor (DFB-DG-GFET). However it had small output power (single-mode emission at 5.2 THz with ~0.1 μW output intensity) and operated at a low lasing threshold temperature (100K). Various approaches have been introduced and discussed to realize room temperature, dry-cell battery operating, and intense THz lasing with fast direct modulation, based on graphene plasmonic metamaterials The proposed designs include (i) replacement of the laser photonic cavity with a plasmonic cavity enormously improving the THz photon field confinement with larger gain overlapping [6], (ii) introduction of THz amplification of stimulated emission via current-driven instability of graphene Dirac plasmons (GDPs) [7-12], and (iii) controlling the parity and time-reversal symmetry of GDPs enabling ultrafast direct gain-switch modulation [13-15]. Possible device structures and design constraints were discussed as a promising pathway towards coherent light sources for future 6G- and 7G-class THz wireless communication systems. The graphene plasmonic metamaterial solutions offer new ways for designing efficient devices for future robust far-infrared and THz plasmonic device technology. New physical models should meet new important challenges for theoretical physics and provide a full quantitative description of current-driven plasma phenomena in graphene and other 2D systems with Dirac-like energy band structure.

All-optical Control of Nonlinear Light Interaction with Topological Photonic Structures

Yupei Wang[1], Jitong Wang[1], and Nicolae C. Panoiu[1*]

[1]Department of Electronic and Electrical Engineering, University College London, Torrington Place, London WC1E 7JE, UK

[*]corresponding author: n.panoiu@ucl.ac.uk

Abstract: In this talk I will review some recent results regarding nonlinear interactions and all-optical control of one-way edge-modes of topological photonic crystals (PhCs) and graphene metasurfaces. Thus, I will show that the Kerr effect in graphene can be used to effectively control the valley-Hall topological transport in certain waveguides implemented in graphene metasurfaces. I will also demonstrate that pairs of bound states in the continuum of certain PhC slabs can be employed to achieve a remarkable enhancement of second-harmonic generation.

Topological photonics aims to utilize topological photonic bands and corresponding edge modes to implement robust light manipulation, which can be readily achieved in the linear regime of light-matter interaction. In this talk, I will review some recent results regarding nonlinear optical interactions and all-optical control of one-way edge-modes in frequency mixing processes in topological photonic crystals (PhCs) and graphene metasurfaces. Thus, I demonstrate that the influence of Kerr effect on valley-Hall topological transport in graphene metasurfaces can be used to implement an all-optical switch. To this end, by taking advantage of the large Kerr coefficient of graphene, the index of refraction of a topologically protected graphene metasurface can be tuned *via* a pump beam, which results in an optically controllable frequency shift of the photonic bands of the metasurface. This spectral shift can in turn be employed to control the propagation of an optical signal in certain domain-interface waveguide modes of the graphene metasurface. Our theoretical and computational analysis reveals that the threshold pump power needed to optically switch ON/OFF the signal is strongly dependent on the group velocity of the pump, especially when the device is operated in the slow-light regime. Certain methods for coupling light into the domain-interface waveguide modes of the graphene metasurface are also discussed.

In the second part of my talk, I will illustrate how bound states in the continuum (BICs) of certain silicon nitride (SiN) PhC slabs, engineered to possess sharp resonances with high quality factors at both the fundamental frequency (FF) and second-harmonic (SH) can be used to achieve an orders-of-magnitude enhancement of the SHG. By investigating the angle-resolved reflection spectra and corresponding modal analysis, we demonstrate that two PhC slabs with different configurations but same lattice constant, operating at telecommunication wavelengths, support a pair of at-Γ and a pair of off-Γ resonances. In both cases, BIC-type resonances are observed at the FF while BIC-like resonances are found at the SH. This double-resonance phenomenon is subsequently used to significantly enhance the SH generation (SHG) from the PhC slabs. The electric field patterns corresponding to the optical resonances reveal that there is a strong spatial overlap between the optical field of the modes for both at-Γ and off-Γ resonances. To quantify the efficiency of the nonlinear optical processes, we explore the dependence of SHG intensity on the angle of incidence. The existence of peaks in SHG spectra reveals the strong light-matter interaction facilitated by the double-resonance effect. The corresponding peak values of the SHG signal are several orders of magnitude larger than those corresponding to homogeneous SiN slabs with the same thickness.

Abstract:

Fluid-coupled Lamb waves (LWs) were proposed to facilitate the self-assembling of three-dimensional (3D) photonic crystals (PCs) in this work. Numerical models were constructed for proof-of-concept, and a fabrication set-up was developed for experimental demonstration. LWs were initially generated by a piezoelectric substrate. A couplant altered the propagating direction of these LWs to form the fluid-coupled LWs at a superstrate. The coffee-ring effect (CRE) of a suspension droplet on the superstrate was thus suppressed. The suspended nanospheres formed 3D PCs after the droplet dried out. Diversified PCs were fabricated using the developed set-up. Their transmittance spectra demonstrated the corresponding bandgap clearly. Advantages of utilizing fluid-coupled LWs for self-assembling 3D PCs include flexibility in excitation frequency, fabrication cost-effectiveness, acceptance for a passively oscillating substrate, and enlargement of sample area.

Abstract: We study topological Tamm states at the interface between two comb-like photonic or phononic crystals based on a new mechanism of band inversion symmetry due to the existence of flat bands. Several arguments such as the Zak phase or the phase of the reflection coefficients support the topological nature of the interface states. The analytical results are well reproduced by experiments using coaxial cables.

1. Introduction and methodology

The interface between two photonic or phononic crystals (PCs) can support localized states called optical or acoustic Tamm states[1]. In this work, we are interested by topological Tamm states at the interface between two one-dimensional PCs, each consisting of a periodic array of stubs attached along a waveguide (Fig. 1 (a)). Several works have addressed such Tamm states in comb-like PCs[2] in the framework of the well-known Su-Schrieffer-Heeger (SSH) model[3], a dimerized chain based on two resonators per unit cell. This PC exhibits a Dirac cone at the boundaries of the Brillouin zone. By changing the parameters of the PC, a gap opens at the Dirac cone and a common gap between two topologically different PCs (characterized by a symmetry inversion of their bulk edge modes) supports an interface state of topological nature. In this work[4-5], we propose a new concept for the existence of topological interface states which results from band edge symmetry inversion around a flat band, namely the mechanism is based on the vanishing of the width of a passband instead of the closing of a bandgap. The flat bands originate from the local resonances of the stubs constituting the PC.

We start from the geometrical parameters and a frequency where the flat band occurs. Then, by changing the periods of the PCs from the initial value, we realize two crystals with different topological properties around the initial flat band and demonstrate the existence of Tamm states in the common gaps of the two PCs. Different arguments and approaches are used to discuss the Tamm states and their topological character, namely the topology of the passband from the determination of their Zak phases and the symmetry of their edge modes, or a condition on the phases of the reflection coefficients when each PC is attached to a waveguide at its extremity. These interface states manifest themselves as peaks in the local density of states. They also appear as peaks or dips in the transmission and reflection spectra when a finite structure constituted by two combined PCs is inserted in a waveguide or is vertically attached to a waveguide. For some specific geometrical parameters, the interface state becomes a bound state in the continuum (BIC) which is characterized by an infinite lifetime. All the theoretical demonstrations are based on semi-analytical calculations using a Green's function method. They are supported by simple experiments using coaxial cables in the radiofrequency range.

2. Theoretical and experimental illustrations

The comb-like PC (Fig. 1(a)) is defined by the length of the stubs $\mathbf{d'_1}$, chosen as the unit of length, and the period $\mathbf{d_1}$. Figure 1(b) shows the successive passbands of an infinite PC as a function of the period $\mathbf{d_1}$. The points labeled 1 to 4 represent the position of the flat bands where the bands close and reopen. The edge modes of two

bands in the vicinity of a flat band are characterized by the same symmetry. The lines with pink and cyan colors indicate the symmetric and antisymmetric band edge states and the Zak phase of each band is respectively zero or π depending on whether the symmetry of its edge states is the same or different (area respectively colored in gray and dark cyan). From the band diagram of Fig. 1(b), one can easily select two PCs with different periods exhibiting a common band gap such that the edges of their lower passbands have two different symmetries. Such a gap necessarily supports a topological interface state. As an example, for the pair of PCs called PC1 and PC4 (with d_1=0.5 and 1.7 respectively), there is an interface mode in their common gap around the dimensionless frequency Ω = 0.6 and not in their other common bandgaps around Ω = 0.5 and Ω = 1.5. This result is confirmed by a dip indicated T (Fig. 1(c)) in the reflection spectrum of a finite structure constituted by an association of PC1 and PC4 and embedded inside a waveguide (Fig. 1(a)). The theoretical results in presence of loss (blue lines) are confirmed by an experimental validation (open circles). Another example with an association PC2-PC3 is shown in Fig. 1(d), where two interface states appear in two consecutive gaps separated by a flat band in their middle around Ω = 1.5. Finally, let us mention that the above results can be easily transposed to acoustic waves in slender tubes[5] and plasmonic metal-insulator-metal waveguides operating in the telecommunication domain[6].

Ultrafast nanophotonics: from all-optical control of exciton dynamics towards plasmon-tailored nano-chemistry and information processing based on cavity-electrodynamics

N. Maccaferri[1,2*]

[1]Department of Physics, Umeå University, 901 87 Umeå, Sweden

[*]corresponding author: nicolo.maccaferri@umu.se

Abstract: Light as information career can revolutionize how we store and process information. At the same time, nanoscale confinement of electromagnetic fields can change the way we approach photo-chemical reactions and electronic energy landscapes. This rich potential can pave the way to develop new hardware enabling faster and more energy-efficient computing schemes, thus contributing to the raise of photonic quantum nanotechnologies.

Ultrafast control of light-matter interactions is fundamental in view of new technological frontiers, for instance in light-driven information processing and nanoscale photochemistry [1]. In this framework, we explore metal-dielectric nanocavities to achieve all-optical modulation of the light reflectance at a specific wavelength. Without the need of driving higher order effects, our system is based on linear absorption, provides large relative modulation exceeding 100% and switching bandwidths of few hundred GHz at moderate excitation fluence [2]. This archetypical system becomes even more interesting if the "gain medium" is an inorganic van der Waals bonded semiconductor, like a transition metal dichalcogenide (TMD). TMDs are subject of intense research due to their electronic and optical properties which are promising for next-generation optoelectronic devices. In this context, understanding the ultrafast carrier dynamics, as well as charge and energy transfer at the interface between metals and semiconductors is crucial and yet quite unexplored. By employing a pump-push-probe scheme, we experimentally study how thermally induced ultrafast charge carrier injection affects the exciton formation dynamics in bulk WS2 [3], opening up excellent opportunities also in nano-chemistry. In fact, if an electronic transition strongly interacts with the light modes of a resonator, we can tailor the energetics and the morphology of a molecular state. By combining quantum mechanical modelling and pump-probe spectroscopy, we shed light on the ultrafast dynamics of a hybrid system composed of photo-switchable dye molecules coupled with optically anisotropic plasmonic nanoantennas, which allow us to selectively switch between two regimes where the light-matter interaction is either weak or strong [4]. Our synergistic approach is instrumental to devise new strategies for tailoring electronic states by using plasmons for applications in polaritonic chemistry on femtosecond timescales.

Abstract: This work shows a review of our last works in the design of dielectric nanostructures and dielectric metamaterials to improve the performance of photonics devices and/or development new ones.

It is well known that dielectric nanostructures with a refractive index such that there is a high contrast respect to the surrounding medium are able to support Mie resonances with a myriad of interesting properties. In this sense, this kind of nanostructures are able to present an effective magnetic behavior, produce light scattering directionality or enhance non-linear effects [1-4]. In the last years, the main efforts are focused on the exploration of using these nanostructures and their unique properties in the improvement and/or development of new photonic devices. In this sense, several research groups are currently working on the integration of all-dielectric nanostructures to improve the performance of optical biosensors or functional communications devices, among others.

In this work, we review our last works in the numerical design of dielectric nanostructures and dielectric metamaterials for different applications. In particular, we are mainly focused on the development of novel designs for optical emitters, such as LEDs, and detectors, such as solar cells.

This work was funded by the Spanish Research Agency (AEI) through the grants PID2019-109072RB-C31/AEI/10.13039/501100011033 and PDC2021-121370-C22 and Comunidad de Madrid by SINFOTON2-CM (grant number S2018/NMT-4326). These grants are also co-founded by the European Fund for Regional Development.

Enhanced electric field and emission directionality of gap mode

D. Zhang,* P. Miao, F. Schneider, Y. Zhao, T. Parker, A. Meixner

Institute of Physical and Theoretical Chemistry,

Eberhard Karls Universität Tübingen, Tübingen, Germany

*e-mail of corresponding author: dai.zhang@uni-tuebingen.de

Abstract: The localized plasmonic resonance and electric field in small gaps will be discussed. To evaluate the enhanced excitation electric field, the intensities and energies of the photoluminescence, and Raman signals are compared by varying the gap sizes systematically. Further insights into the gap-mode emission properties in the k-space are obtained by combining the back focal plane technique with parabolic mirror assisted optical microscopy.

High-resolution optical technique combining scanning probe microscopy and optical microscopy has shown its distinct capability in characterizing materials with high chemical and spatial resolution. In the past years this technique has witnessed an extremely active development, which has shown to be operated at low temperature, ultra-high vacuum or electrochemical environment [1].

In this talk, our work about applying tip-enhanced Raman and fluorescence microscopy to study the nanometer scale structural properties of optoelectronic materials will be reported. [2] Further, back focal plane imaging of gap mode that is formed either by single nanoparticle-on-ultrasmooth gold film or gold tip/gold crystal, will be presented. The influences of nanoparticles and tips of different geometries on the directionalities of the emission signals from the narrow gap will be discussed. [3]

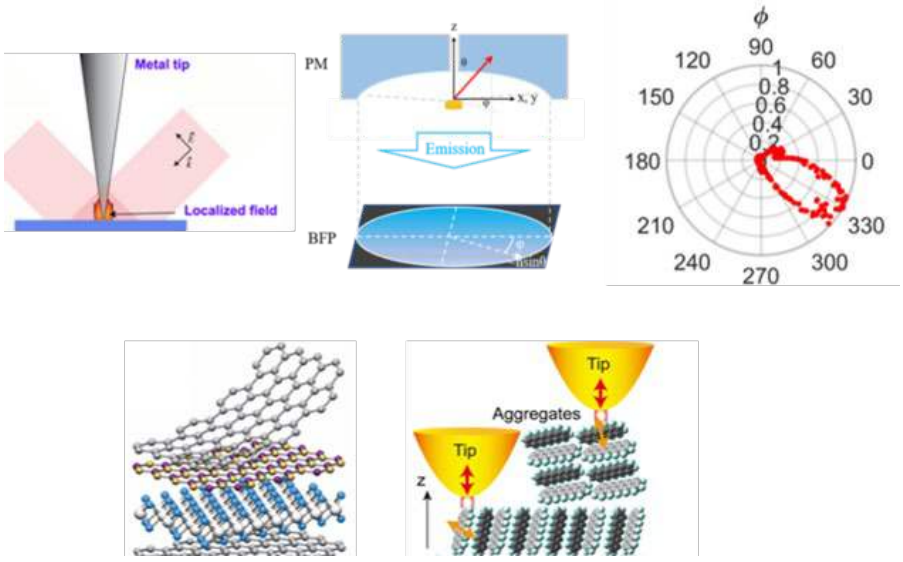

Figure 1. Plasmonic enhanced optical microscopy and k-space imaging visualize the local structural properties of semiconductive molecules at the nanometer scale.

Chiral Phase Change Nanomaterials: A nanoscale path to microscopic optics

Imad Agha[1,2,*]

[1]Department of Physics, University of Dayton, Dayton, OH, USA
[2]Department of Electro-Optics and Photonics, University of Dayton, Dayton, OH, USA
[*]corresponding author: iagha1@udayton.edu

Abstract: In this talk, we present our most recent results on phase change nanomaterials, based on bottom-up self-assembly fabrication techniques, as well as their use in phase, amplitude, and polarization control.

Due to their optical and electrical tunability aspect, there has been a renewed and strong interest in Phase change materials (PCMs) in1many fields beyond traditional memories. Given their unique characteristic of changing phase on-demand from amorphous to crystalline1 and vice versa, they can be applied in many applications ranging from optical filters to rewritable metasurfaces. The ultimate limitation, however, has been the thickness at which these materials can be switched. Due to the thermal distribution in the thin film, PCMs have been limited to switching at sub-100nm thicknesses. In our work[1], we found that through a self-assembly technique, commonly referred to as Glancing Angle Deposition (GLAD) (Fig. 1), it is possible to beat the limit of thickness on Chiral Phase Change Nanomaterials (PCNMs), and produce devices for phase, amplitude, and polarization control.

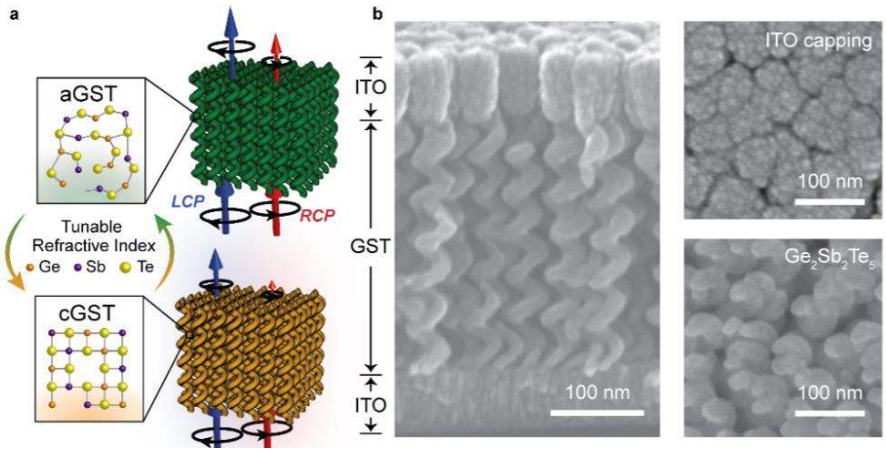

Fig 1: Growth of Chiral PCNMs (a) and SEM of structures (b)

The PCNMs are grown using glancing angle deposition, whereby a substrate is placed at a sharp angle and rotated during electron beam evaporation. Two targets were used here: Germanium Antimony Telluride (GST) and Antimoney Selenide (SbSe). While GST is highly opaque in the visible regime, it produces sharp resonances due to absorption, that can be exploited in highly resonant processes, such as optical chirality, in which selective absorption between left and right handed polarizations can be amplified through the left or right-handed geometry. In the case of SbSe nanorods, the effect is less pronounced, however these structures are useful as

they allow for the growth of very thick films well beyond the growth methods for bulk thin films. Additionally, due to the low packing density, it is possible to optically (and potentially electrically) cycle much thicker films than the earlier reported limit of ~ 100 nm between the amorphous and crystalline phases. This method will open the door to a variety of future devices that hitherto have been impossible to implement due to fundamental limitations of PCMs in their bulk thin film structure.

Strong light matter interaction in plexcitonic crystals

M. Ferrera[1], J. S. Pelli Cresi[1], V. Aglieri[1], E. Ghidorsi[1] and A. Toma[1*]

[1]Istituto Italiano di Tecnologia, via Morego 30, 16163 Genova, Italy
[*]corresponding author: andrea.toma@iit.it

Abstract: Nanohybrid platforms featuring strong light-matter interactions were fabricated and spectroscopically investigated. Both steady-state and ultrafast pump-probe spectroscopies were exploited to investigate the radiative properties of the hybrid systems and to assess the strong-coupling regime achievement.

The interaction of electromagnetic radiation with matter plays an instrumental role in our everyday life and typically involves an energy exchange between an external electromagnetic field and a photon emitter (dye molecules, low-dimensional semiconductors, etc.). The possibility of controlling/engineering the interplay between the electromagnetic field and quantum states of matter -through *ad-hoc* designed optical resonators- provides a key to reshape the energy landscapes of the nanomaterial elementary excitations [1]. In particular, if the exchange rate of energy is faster than any other competing relaxation process, the system can enter the so-called "strong coupling" regime. New hybrid light/matter states, called polaritons, are formed [2], which in turn offer huge potential for a wider class of technological applications, including quantum computing [3], non-linear photonics and polariton chemistry [4].

Here, the focus is on hybrid platforms, where quantum emitters are combined with nanopatterned metallic surfaces in order to obtain strongly coupled states. The radiative properties of the plasmonic-excitonic heterostructures has been characterized by both steady-state and ultrafast pump-probe spectroscopies. The presence of the anti-crossing behavior has been assessed, and results in terms of Rabi splitting energy and polariton relaxation dynamics reported. Experiments of time-resolved spectroscopies can indeed shed light on the intrinsic photophysics of such heterostructures by revealing the dynamics of the hybrid states. Among the various architectures, the attention has been addressed to long-range ordered plasmonic crystals. The present systems, with their open architecture, offers an appropriate platform where the excitonic material can be easily placed, thus concurrently allowing for the proper excitation and investigation of the newly formed plexcitonic states [5,6]. This work sets the base for further studies on the design, fabrication and investigation of novel nanohybrid architectures featuring strong light-matters interactions, and their exploitation towards functional devices.

Characterization of Nano-grating Profiles using Standard Ellipsometry and Deep Neural Networks

Zijie Jiang[1] and Wen-Di Li[1*]

[1]Department of Mechanical Engineering, Univ. of Hong Kong, Hong Kong, China
[*]corresponding author: liwd@hku.hk

Abstract: In-situ measurement of nano-grating profiles is of great importance in the semiconductor industry. We propose a new method based on deep neural networks and gradient descent method to fully reconstruct the profile of nano-gratings using standard ellipsometry data (i.e., ψ and Δ) rather than commonly used Muller matrix ellipsometry. A wide range of samples of fabricated by wafer-scale interference lithography were used to train and test our model with promising performance for fast, non-destructive, and in-situ characterization of nanostructure profiles.

In-situ measurement of nano-grating profiles is of great importance in the semiconductor industry. Recently, as a popular and powerful tool, deep learning is applied to infer key parameters of gratings from measured spectral and ellipsometry information. Compared with conventional characterization techniques, such as scanning electron microscopy (SEM) and atomic force microscopy, deep-learning-based methods possess the advantages of high efficiency and high throughput. However, most reported methods of this type rely on Muller matrix ellipsometry [1] or some special optical measurement systems [2], which is typically expensive and not commonly available. Moreover, geometric models used in these methods are over-simplified and usually limited to a single patterning method or material, hindering their adoption in practical applications.

In this research, we propose a new method based on deep neural networks and gradient descent method to fully reconstruct the profile of nano-gratings using standard ellipsometry data (i.e., ψ and Δ). As shown in Figure 1(a), twelve parameters are adopted to describe the grating. The application of round corners, waist width, and refractive index makes the model compatible with various kinds of patterning techniques and different resists. Figure 1(b) illustrates the architecture of the algorithm. To relieve the problem of multiple solutions, seven sets of spectra from different azimuthal angles are fitted simultaneously as an additional constraint, which can improve the accuracy and stability of our method. Notably, these azimuthal angles can be arbitrarily selected within a predefined range. The candidate solution is updated by the gradient descent algorithm to minimize the mean square error (MSE) between predicted and measured spectra. As a demonstration, samples made by interference lithography are tested. To emulate measurement data, simulated ellipsometry spectra are added with Gaussian noise. Yellow dashed lines shown in Figure 2 display the inferred profile, which is consistent with SEM images. The mean absolute errors (MAE) of profiles for three gratings are 7, 9, and 9 nm respectively. MSEs of fitted and target spectra are only 15.4, 1.8, and 0.5.

Colloidal Metal Nanoparticles under Ultrafast Laser Pulses

A. Guerrero-Martínez

Departamento de Química Física, Universidad Complutense de Madrid, Avda. Complutense s/n, 28040 Madrid, Spain
aguerrero@quim.ucm.es

Abstract: The control of the excitation of the localized surface plasmon resonances of colloidal metal nanoparticles with ultrafast laser pulses, from the nanosecond to the femtosecond timescales, can be used to prepare highly monodisperse metal nanoparticles, hollow metal nanoparticle morphologies, alloyed metal nanoparticles, or assembled and welded nanostructures.

The vast majority of the applications of metal nanoparticles developed during the last two decades have arisen from their unique optical properties. Within this context, rational synthesis and assembly of metal nanoparticles have been the main research focus, aiming at the design of nanoplasmonic devices with tailored optical functionalities. The progress made in this field is thus to be ascribed to the understanding of the origin of the interaction between light and such nanostructures, the dynamics of which have been thoroughly investigated with significant contributions from short and ultrashort pulse laser technologies.[1] This presentation focuses on the potential of pulse lasers to provide new fundamental insights into the electron dynamics involved in the interaction of light with the free conduction electrons of metal nanoparticles, that is, localized surface plasmon resonances (LSPRs). The excitation of LSPRs with a femtosecond pulse laser is followed by thermalization of the metal nanoparticle electrons and the subsequent relaxation of the nanocrystal lattice and the surrounding environment, which generally results in surface melting.[2] By contrast, nanosecond irradiation usually induces metal nanoparticle fragmentation and uncontrolled melting due to overlapping excitation and relaxation phenomena. These concepts have been exploited toward the preparation of highly monodisperse metal nanoparticles via femtosecond pulse laser irradiation of polydisperse colloids, or in the fabrication of hollow metal nanoparticles.[3] In addition, pulse laser irradiation has been proven a unique tool for the controlled assembly and welding of colloidal metal nanoparticles by electromagnetic field enhancement at the hot spots of assembled metal nanoparticles. The combination of different nanometals with pulse lasers promises significant chemical advances, including the preparation of alloyed nanostructures with potential applications in sensing and catalysis.

Self-powered Flexible Devices: Piezo-sensor and microLED

Keon Jae Lee[1*]

[1]Department of Materials Science and Engineering, KAIST, South Korea

[*]corresponding author: keonlee@kaist.ac.kr

Abstract: This seminar introduces recent progresses of self-powered flexible devices; piezo-sensors and microLED. The first part, we reported a machine learning-based acoustic sensor by mimicking the basilar membrane of human cochlear. Highly sensitive self-powered flexible piezoelectric acoustic sensor (f-PAS) with a multi-resonant frequency band was employed for voice recognition. The second part will discuss the highly efficient flexible vertical micro LED (f-VLED) for full color displays and biomedical applications. We introduces the flexible vertical GaAs/GaN microLED on plastic substrates using micro-vacuum transfer and anisotropic conductive film. The superb properties of the flexible inorganic LED enable the dramatic extension of flexible displays toward not only full color displays and wearable phototherapy patches for skin research like hair growth and melanogenesis inhibition.

Abstract: We present silicon photonic devices designed for the generation of frequency bin entangled qubits and qudits. We show through quantum tomography experiments that bin spacing, qudit dimension, and bipartite quantum state can be directly controlled using on-chip devices. We discuss further developments and the possible applications in several key quantum technologies.

Encoding quantum information in systems with dimensionality of the Hilbert space larger than 2 (qudits) is important in the development of large scale architectures for many quantum technologies. This strategy is particularly suitable when using photons as carriers of quantum information, due to the variety of degrees of freedom they possess. For example, frequency bin encoding, i.e., the use of different frequency bands to encode logical states, has been shown to be very effective in creating qudits by means of integrated quantum optical microcombs [1]. In these experiments spontaneous four wave mixing (SFWM) in a microresonator with a comb spacing (FSR) of the order of few tens of GHz is used to generate photon pairs, while coherent manipulation is achieved through off-the-shelf fiber optic components such as electro-optic modulators (EOM) and waveshapers [2].

The use of single rings and commercial EOMs generally compromises the source brightness, which scales with the inverse square of the FSR. Recently, it has been shown that this trade-off can be removed by the use of multiple resonators, each associated with the generation of a pair of non-degenerate frequency bins [3], and this paradigm has been experimentally demonstrated for a two qubit system [4,5]. In this work we exploit this concept to demonstrate the generation of entangled frequency bin qudits up to a dimension of four fully controllable via the use of photonic devices integrated on the same chip.

Our source is realized on a silicon photonic chip and is shown in Fig. 1 a). Three Mach-Zehnder interferometers are used to divide the pump power into four paths with adjustable amplitudes, to excite four identical ring resonators (R0-R3) of radius 22 microns. The comb lines of each pair of rings are offset by an amount tunable using thermal phase shifters. We use four mutually coherent pumps at different frequencies to trigger pair generation by SFWM, each pump associated with a resonance of a different ring, and we operate at a pump

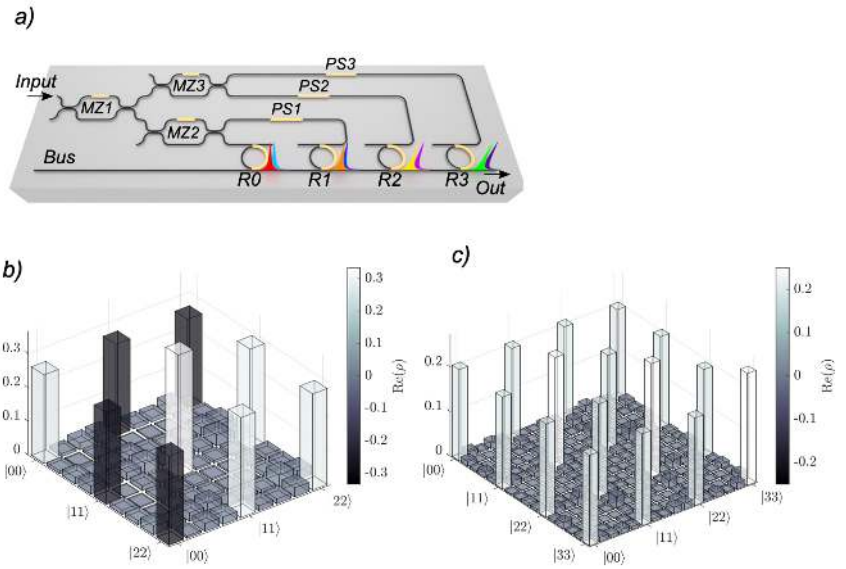

Figure 1: a) Scheme of the device. b) and c) Reconstructed density matrices of the target states as described in the text for b) a pair of qutrits and c) a pair of ququarts. The bar height indicates the modulus of the matrix element, while the color indicates the real part.

power level such that multiple-pair events are negligible.

The average brightness of the four rings is about 0.15 MHz per square mW. To show the capability to generate qudit states, we set the bin spacing to 15 GHz, and reconfigure the device to generate the target states $|\Phi_3\rangle = \frac{1}{\sqrt{3}}(|00\rangle - |11\rangle - |22\rangle)$ and $|\Phi_4\rangle = \frac{1}{\sqrt{4}}(|00\rangle + |11\rangle + |22\rangle + |33\rangle)$, for a three level qudit (qutrit) and four level qudit (ququart) respectively. Note that the former state can not be directly generated from a single resonator without external manipulation of the state, for example by using a waveshaper. The target states are confirmed through quantum state tomography, and their reconstructed density matrices are shown in Fig. 1 b) and c) respectively. In the case of the qutrit state, we obtained a fidelity of 86.2 ± 0.3 % with the target state, and a purity of 78.3 ± 0.5 %. In the case of the ququart state, we get 84.5 ± 0.2 % for the fidelity and 74.4 ± 0.4 % for purity.

To certify entanglement, we also computed the high-dimensional CGLMP inequalities [6] from the reconstructed density matrices, proving their violations by tens of standard deviations in both cases.

In summary, we experimentally demonstrated a bright and reconfigurable source of entangled frequency bin qudits. Our approach allows to simultaneously achieve high brightness and small bin spacing, which are key requirements for the efficient generation and manipulation of high dimensional, frequency-bin-encoded multipartite states.

Abstract: Photonic systems with complementary gain and loss profiles have recently been studied using non-Hermitian system with parity-time reversal symmetry. Indirect coupling via near-fields between two or more identical photonic components has been used in these systems because photons are non-interactive. In this talk, we present direct coupling via exciton nature of polaritons within a single hexagonal microcavity on a loss-modulated substrate. This polariton-based PT symmetric system provides opportunities for the investigation of non-Hermitian physics and the development of practical applications.

Exciton-polaritons are quasi-particles that have a combination of excitonic and photonic properties. They can be created and condensed into a coherent ground state within a strongly coupled microcavity and have the ability to directly interact with each other. Microcavities based on group III-nitride semiconductors are an ideal platform for studying polaritonics even at room temperature, due to their high oscillator strength and large exciton binding energy. Recently, there has been a lot of interest in non-Hermitian systems with parity-time symmetry (PT symmetry), which involves photonic systems with complementary gain and loss profiles. In most non-Hermitian photonic systems, indirect coupling via near-fields has been used to mediate interaction between two or more identical photonic components. In this talk, we present direct coupling via the excitonic nature of polaritons within a single hexagonal microcavity on a loss-modulated substrate. By using a high-quality GaN hexagonal microrod, we were able to observe the whispering gallery polariton condensate at room temperature and ballistic transport phenomenon depending on the excitation size-related potential gradient.[1] The naturally formed sixfold symmetry of the hexagonal GaN microrod provides degenerate modes between two quasi-whispering gallery polariton modes, each with upwards (equilateral) and downwards (inverted) triangular paths. By combining the coupled polariton pair with a loss-controlled substrate having gradual loss variation, we were able to realize a phase transition from an unbroken to a broken phase, creating a polariton-based PT symmetric system with only a single microcavity at room temperature.[2] This polaritonic PT-symmetric platform can be utilized to study non-Hermitian physics and to develop versatile practical applications.

Abstract: We present our progress towards scalable quantum-technology solutions on a silicon nitride platform. Using a pick-and-place technique, we demonstrate hybrid integration of single InAs quantum dots on a Si_3N_4 optical waveguide and show that the hybrid-integrated process does not ruin the single emitter properties, and may even enhance them.

Independent electrical control of phase and magnitude of second harmonic generation using intersubband polaritonic metasurfaces

Jaeyeon Yu[1], Gerhard Boehm[2], Mikhail A. Belkin[2], and Jongwon Lee[1*]

[1]Department of Electrical Engineering, Ulsan National Institute of Science and Technology, Republic of Korea

Abstract: We present electrically tunable intersubband nonlinear polaritonic metasurfaces for second harmonic generation. The phase and magnitude of effective nonlinear susceptibility of these metasurfaces can be controlled independently, with a range of 0 to 160 nm/V in magnitude and 0 to 2π in phase.

Metasurfaces made up of two-dimensional arrays of subwavelength unit structures have demonstrated new methods for producing efficient frequency mixings with relaxed phase matching constraints, opening up new avenues for innovative applications such as nonlinear holography, optical encryption, and quantum optics [1]. However, most of these metasurfaces have been passive devices with fixed nonlinear optical responses. Recently, nonlinear intersubband polaritonic metasurfaces have been developed, which leverage the giant nonlinear response of intersubband transitions (IST) in multiple quantum well (MQW) structures, coupled with electromagnetic modes of plasmonic resonators [2]. To address the static limitation in nonlinear response, an electrically reconfigurable nonlinear polaritonic metasurface has been reported by integrating electrically tunable giant nonlinear response from Stark tunable ISTs in a semiconductor heterostructure with plamonic nanocavity structures, demonstraing unprecedentedly high intensity modulation and local phase tuning of the second harmonic generation (SHG) response, reaching up to 135° [3].

To maximize the utility of electrically tunable nonlinear metasurfaces, the phase and magnitude of the second harmonic signal need to be independently controllable from 0 to its maximum value. To enable ultimate electrical control of the nonlinear response, we propose the use of electrically tunable intersubband polaritonic metasurfaces with new unit cell design. These metasurfaces can cover a full phase tuning range from 0 to 2π while maintaining a constant magnitude or cover a large range of magnitude of the nonlinear response while maintaining a constant phase.

For the experimental demonstration of these novel features, we first optimized the MQW structure by analyzing the main factors that affect the perturbation of IST energies, dipole elements, and spectral tunability. The MQW structure used in this study was made up of a three-quantum-well system in which the centers of the first three electron subbands were spatially separated [3], as shown in Fig. 1(a). The ISTs provide a giant second order nonlinear response, $\chi_{zzz}^{(2)}$, and a broadband spectral tuning of $\chi_{zzz}^{(2)}$ can be induced through the quantum confined Stark effect (QCSE). The magnitude and phase spectra of $\chi_{zzz}^{(2)}$ for different bias voltages are plotted in Fig. 1(b) and 1(c), respectively. While the theoretical coverage of $\chi_{zzz}^{(2)}$ is almost 2π phase, its magnitude rapidly decreases as the phase difference from 0V increases. To overcome this limitation, a unit cell structure with two meta-atoms was designed, as illustrated in Fig. 1(d). The two meta-atoms, which are geometrically inverted, generate effective second order nonlinear responses that are π phase shifted from each other, as depicted in Fig.

1(e). By selecting the appropriate bias voltages for the two meta-atoms, it is possible to attain complete phase control of the SHG signal from 0 to 2π with a constant amplitude in this configuration.

To achieve 2π tuning of SHG with nearly constant conversion efficiency (represented by a circle in a complex plane), we combined the two effective second-order susceptibilities of the two meta-atoms with the same phase by applying external bias voltages V_a and V_b to the two meta-atoms, as depicted in Fig. 1(d). We were able to find two bias voltages that generate an SHG signal at any location within the circle on the complex plane. Similarly, we also obtained to bias voltages that produces a particular SHG intensity with any phase within the circle, as demonstrated in points A-F in Fig. 1(f). Our calculations showed a maximum SH power conversion efficiency of 0.01% for an input pump power of 200 mW at a wavelength of 10 μm. Additionally, the proposed device can operate in a broadband range. For the input pump wavelength range from 9 to 10.6 μm, the device can cover most of the complex plane for various combinations of the two bias voltages, and the calculation results at the pump wavelength of 9 and 10.6 μm are plotted in Fig. 1(g) and 1(h), respectively.

Abstract:

Using the localized surface plasmon resonance (LSPR) to enhance the electromagnetic field in optical near field, a new simple, fast and versatile method for the functionalization of gold nanoparticles (AuNPs) by a nanoscale layer of molecularly imprinted polymers (MIPs) was developed[1,2]. The key step is based on near-field radical photopolymerization of a MIP pre-polymerization mixture. This allows the preparation of hybrid AuNPs@MIPs nanoparticles which are used as substrates for LSPR and surface enhanced Raman spectrometry (SERS) analyses with excellent sensitivity and specificity. To demonstrate the performance of AuNPs@MIPs, MIPs specific to methylene blue (MB) were prepared. The sensitivity of spectroscopic detection is in the range of 10 nM3. Specificity is demonstrated by comparing the response with a control non-imprinted polymer (NIP) and by interference tests with two analogues (Rhodamine 6G and Rhodamine 110)[3]. This fabrication method allowed us to obtain robust and recyclable sensing surfaces with high sensitivity and selectivity. The nanometric thickness of MIP allows a short analysis time (10 min), which improves the performance of MIP-based sensors and opens new perspectives to detect molecules at very low concentrations.

Abstract: We develop a microscopic theory of interacting dipolar polaritons. Numerical results in a wire geometry together with a Born-Oppenheimer type approach showcase three emerging regimes, including a polariton blockade regime that should be reachable in realistic systems. We extend our theory to higher dimensions and compare dipolar polaritons to non-dipolar ones, highlighting the roles of light-matter coupling and interaction range. Dipolar polaritons in TMDs and/or with multiple quantum wells are promising candidates for realizing strongly correlated fluids of light.

Recent advances in experiments with quantum particles formed by a superposition of light and matter excitations promise an era of realizing entirely new hybrid light-matter quantum systems with far reaching perspectives both for fundamental science and for future opto-electronic technologies [1]. To reach these goals, an outstanding challenge is to make these hybrid light-matter particles, called polaritons, interact strongly with each other.

We address this by developing a theory for the collisional properties of polaritons whose matter component carries a static electric dipole moment [2]. The repulsion between these dipolar light-matter particles is shown to make them promising candidates for realizing strong photon-photon interactions. The theoretical model is based on microscopic numerical calculations for one-dimensional geometries and on a Born-Oppenheimer type approach. We identify three different interaction regimes from impenetrable polaritons in long wires to a polariton blockade regime for smaller but still realistic wire lengths. The results are then analytically continued to two-dimensional polariton systems and highlight the light-matter coupling as a crucial ingredient to realize strong polariton interactions. In contrast to expectations, such dipolar polaritons turn out to be even more favorable in materials with tightly bound excitons and multiple quantum wells.

Our predictions suggest dipolar polaritons as a most promising solid-state platform for realizing strongly correlated fluids of light and harness them as a quantum light source for quantum technology applications.

Optical fiber is a well-established and efficient light-guiding medium. Although optical fiber is efficient for transmitting light, its functionality is limited by the dielectric material of the core, which has poor optoelectronic, magneto-optical, and nonlinear-optical responses and has a dielectric diffraction limit. Therefore, the optical properties of the optical fiber such as phase, amplitude, polarization, and mode profile, cannot be altered after the fiber drawing fabrication, thus limiting the development of novel in-fiber devices. Integration of new materials and nanostructures into fiber will enhance processing/transmission capabilities and novel functionalities.

In this talk, I will present our recent development of “Meta”-optical fiber, an advanced optical fiber integrated with emerging nanophotonic concepts such as optical metasurfaces, plasmonic nanowires, and zero-index photonics. I will present the development of ultrathin optical metalens which is cascaded on the facet of a photonic crystal fiber that enables light focusing. I will also discuss the first experimental demonstration of zero-index resonance excitation in an optical fiber coated with AZO nanolayer and excitation of plasmonic resonances on holey optical fiber for advanced optical sensing and tip-enhanced Raman spectroscopy. These advanced “meta”-optical fibers open a pathway to revolutionary in-fiber lasers/spectroscopies, optical imaging/sensing, and optical communication devices.

Abstract: We present direct and inverse-design strategies to achieve 'on demand' management of light by scattering cancellation in non-Hermitian media. The direct approach is based on our recently proposed generalized Hilbert Transform as a recipe to design complex potentials to tailor the flow of light following any arbitrary direction. Beyond this fundamental approach, we present supervised and unsupervised learning techniques for knowledge acquisition in non-Hermitian systems which accelerate the inverse the "on demand" design process. The different proposals may have direct applications to control the wave dynamics in semiconductor lasers or other linear and nonlinear physical systems including cloaking sensors and arbitrary shaped objects.

Non-Hermitian Physics has emerged as a fertile ground for a smart control of waves [1]. In turn, the pursuit of artificial materials to control and shape light is possibly one of the most attracting research areas in photonics in the last decades. In this context, we recently proposed a strategy to achieve 'on demand' dynamical manipulation of light by non-Hermitian potentials that mimics the time symmetry breaking at the basis of causality. In fact, the cancellation of the response before the arrival of the signal is warranted by a Hilbert Transform relating the spectral dependence of the real and imaginary components of the response function of the system, see Fig. 1a. Therefore, a Hilbert Transform (HT) relating the real and imaginary distributions of the complex permittivity allows to control the flow of light by scattering cancellation, Fig. 1b. A recipe that can be extended to 2D, widening the concept Kramers Kronig relations in space [2], to design complex potentials to tailor the propagation of light following any vector field [3], or to generate invisible potentials where light propagates as in free space [4], Fig. 1c. The approach allows restricting the dimensionality of the complex susceptibility within practical limits for a feasible realization or even avoiding the use of gain [5].

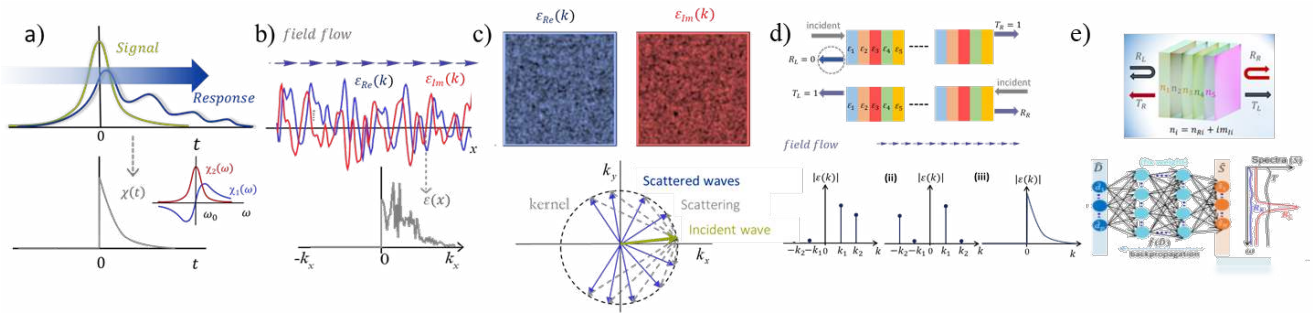

Figure 1. a) Causality imposes the cancellation of the response before the arrival of the signal; the spectral dependence of the real and imaginary components of the response function are related by a HT. b) Backward scattering cancellation in a 1D system is warranted by any complex random potential which real and imaginary parts are rated by a HT, ensuring $\varepsilon(k_x)=0$ for $k_x<0$. c) Generalization to a random potential in 2D, where the kernel of the HT uncouples incident radiation from particular backward scattering

directions. d) Algorithm assisted inverse design for a 1D structure for frequency-selective operation or broadband unidirectionality. e) Machine learning approach from ref. [7].

Beyond this fundamental approach, we also we also present supervised and unsupervised learning techniques for knowledge acquisition in non-Hermitian systems which accelerate the inverse the “on demand” design process. As a first step, proposed a general inverse-design strategy based on genetic algorithm optimization to achieve ‘on demand’ manipulation of light in 1D and 2D non-Hermitian systems [6], see Fig. 1d. Moreover, just recently, supervised and unsupervised learning techniques for knowledge acquisition in non-Hermitian systems have shown to accelerate the inverse design process while may trigger a trigger a route for intelligent inverse design and contribute to the understanding of physical mechanism in general non-Hermitian systems [7], see Fig. 1e.

These different proposals may have direct applications to control the wave dynamics in semiconductor lasers or other linear and nonlinear physical systems, including cloaking sensors and arbitrary shaped objects. Both the direct and inverse design approaches are not restricted to optical systems, and it can be applied directly to find accurate solutions to other kind of waves.

Abstract: We review our work on mimicking the dispersion relation of rotons in liquid helium in different systems (acoustic, elastic, and electromagnetic waves) and using three different strategies (nonlocal metamaterials, chiral metamaterials, and monomode metamaterials).

The roton dispersion relation in liquid helium starts with frequency being proportional to wavenumber, followed by a maximum, a region of backward waves, a minimum, and a further increase of frequency versus wavenumber. We start by briefly reviewing our work towards mimicking this dispersion relation in elastic and acoustic metamaterials [1,2] by using nonlocal interactions.

We emphasize more recent work on electromagnetic waves and nonlocal interactions [3], elastic waves and chirality in 3D cubic-symmetry metamaterials [4], and elastic waves in monomode metamaterial beams [5].

Abstract: We discuss new approaches to the synthesis, design, and exploitation of two-dimensional materials for nanophotonics, including plasmonics in ultrathin crystalline metals, a disruptive class of quantum-phase materials, recent advances in the solution to the problem of coupling between free-space light and ultra-confined optical excitations, and the application of these developments to the study of ultrafast nonlinear phenomena and quantum optics at the atomic scale.

Atomically thin materials have emerged as a robust platform for manipulating and exploiting light at the nanoscale thanks to a wide variety of polaritonic modes, ranging from plasmons in thin metals and doped graphene to excitons in transition metal dichalcogenides and phonons in ionic insulators. The electromagnetic behavior of these modes can be well understood in terms of effective surface conductivities, which capture their strong dependence on temperature and external static electric and magnetic fields. Recent advances have also been produced in the synthesis of thin noble-metal films,[1,2] which open a new regime in plasmonics. In this talk, we overview the general characteristics of the optical response of these materials, which can be understood in terms of simple theoretical models. We also discuss more sophisticated models, aiming at the exploration of genuinely quantum-mechanical effects. We further review recent advances in the control of ultrafast and nonlinear optical processes,[3,4] as well as potential applications in light modulation[5,6] and quantum optics.[7] The in/out coupling problem between external light and strongly confined polaritons remains a major challenge, for which we propose innovative solutions.[8,9] We conclude with emerging directions in the design of polaritonic materials relying on quantum phase effects.[10]

High-Q Photonics

Kerry Vahala

California Institute of Technology
*corresponding author: vahala@caltech.edu

Abstract: High-Q microresonators in the form of rings or disks provide access to nonlinear optical phenomena at milli-Watt power levels. Their resulting functionality is paving the way to integrated optical systems for sensing, metrology, spectroscopy, microwave generation, time keeping, and data transmission. Once discrete and reliant upon specialized processing techniques for optical loss reduction, high-Q microresonators are today planar, capable of integration, and in some cases fabricated on CMOS foundry lines. After a brief overview of their history, I will review recent applications. These include Sagnac gyroscopes, microwave signal sources, clocks, and high-coherent sources. The current and possible future limits of microresonator performance, and untapped application areas, will also be discussed.

META 2023, PARIS - FRANCE, JULY 19, 2023

The Challenge of Photonic Crystals (and Meta-Materials) is Inverse Electromagnetic Design (Aperiodic)

Eli Yablonovitch

Electrical Engineering and Computer Sciences Dept.,
UCLA/University of California, Berkeley, USA
eliy@eecs.berkeley.edu

Abstract: Inevitably, in electromagnetics, there is a goal, and it may be that the goal is best achieved by an aperiodic rather than a periodic design. Then there is a universal question: What is the best design to achieve a specific goal?

The problem is exacerbated by the reality that any geometrical design could have millions of design parameters that define a desirable shape. With a particular goal in mind, the adjustment of any one design parameter, requires a revision of all the other parameters, making it hard, or impossible to converge on a good design. Essentially this is a problem in multi-variable calculus: How to co-optimize the millions of parameters that are implicit in any geometrical shape? It might be called "Shape Calculus".

Fortunately there are elegant mathematical methods that have emerged in recent years that permit the co-optimization of millions of variables, but requiring only two solutions of Maxwell's Equations [1]. The mathematical approach is called the "Adjoint Method", and it is a merger the chain rule of calculus, with linear algebra [2]. Indeed this method has been rediscovered numerous times in the past 70 years, within numerous fields, wherever some optimization over many variables is needed. This has many names. For example, in neural networks this is called "Back-Propagation", in photolithography it's called Inverse Lithography Technology, (ILT), but it is also used in Control Theory, mechanical design, etc.

One of the first electromagnetic applications of the "Adjoint Method" was toward the design of lithographic masks for the photographic process by which electronic chips are manufactured. These masks consist of thin-film Chromium on glass, intricately patterned, to photographically project out the sub-wavelength shapes of transistors, wires, and other components on an integrated circuit. These metal film masks, so heavily used in electronics manufacturing, can be regarded as the original "meta-surface" [3].

Sub-wavelength transistor images were desired, but it was not at all clear what the mask pattern should be, that would produce those desired sub-wavelength images. The first company founded to employ the "Adjoint Method" for photo-lithography was Luminescent Inc., (2002). Luminescent introduced the slogan ILT "Inverse Lithography Technology" to be understood as a sub-category of Inverse Electromagnetic Design. Today, almost all memory chips and micro-processors use thin-film chromium masks and ILT software in their design and manufacture, meta-surfaces indeed [4].

Whether it's a meta-lens or any other type of electromagnetic function, there is no need to slavishly follow a

periodicity constraint. Mathematical methods have been developed, to efficiently optimize any type of electromagnetic function. I will provide some examples: “Silicon Photonics” couplers, optical antennas, solar cell surface textures, etc

Micro- and Nano-lasers: From One to Many, Unleashing Endless Possibilities

Mercedeh Khajavikhan

University of Southern California, USA

Abstract: Micro- and nano-lasers form a crucial category of optical components with significant scientific and technological implications. In this presentation, I will discuss the utilization of non-Hermiticity, supersymmetry, and topology principles to design arrays of these devices, resulting in intriguing and unexpected lasing phenomena. By considering the interaction between cavity modes, array geometry, and both short- and long-range coupling among the array elements, we can achieve novel laser phase locking regimes, high radiance emission, rapid beam steering, photonic spin machines, and unidirectional lasing.

Retrieving optical parameters of emerging van der Waals microcrystals

M. Sarkar, M.S. Saremi, M.T. Enders and G. T. Papadakis*

ICFO-Institut de Ciencies Fotoniques, The Barcelona Institute of Science and Technology, Spain
*corresponding author: georgia.papadakis@icfo.eu

Abstract: To achieve high-quality in low-dimensional layered van der Waals materials, microcrystals are typically exfoliated. The small size of exfoliated flakes makes their optical characterization with conventional far-field optics challenging. Thus, flake-characterization has typically required delicate spatial scanning via a near-field tip. We present a simple method for determining the optical properties of optically small flakes. Our method is based on far-field spectroscopy and requires minimal numerical fitting. We demonstrate the robustness of our method using hexagonal boron nitride and α-MoO_3.

The mid-long infrared (MLIR) spectral range is highly relevant for energy applications, thermal radiation control, molecular sensing and IR spectroscopy[1]. In recent years, emerging discovered low-dimensional layered and van der Waals materials (LDM) have become relevant to LMIR photonics; in particular, they often support phonon polariton resonances arising from lattice vibrations, with strong dielectric permittivity resonances within the Reststrahlen band. As exemplary LDMs, we mention classes of metal oxides (like α-MoO_3)[2] as well as dielectrics, such as hexagonal Boron Nitride (hBN), which are being explored in the MLIR range[3].

Despite significant interest in such low-dimensional composites, standard approaches for the experimental retrieval of their dielectric properties cannot be easily applied. In particular, standard Fourier Transform Infrared Spectroscopy (FTIR) and Spectroscopic Ellipsometry (SE) have characteristic beam sizes on the order of millimeters, whereas sample sizes of exfoliated flakes are typically on the order of tens to hundreds of micrometers, yielding a beam-sample size mismatch. Furthermore, a highly relevant property of LDMs is their strong optical anisotropy, often in-plane (such as in α-MoO_3)[2] . For this anisotropy to be experimentally detectable, sample sizes on the order of hundreds of micrometers to millimeters are necessary to eliminate the effect of random orientation of sub-crystals. Hence, experimental determination of the complex refractive index for LDM and van der Waals microcrystals is not trivial[4]. In this work, we present a method to retrieve the in-plane complex dielectric permittivity of microcrystals of hBN (isotropic) and α-MoO_3 (in-plane anisotropic), based on reflectivity measurements on exfoliated flakes on a gold substrate. The method applies to *any* other material.

Fig.1a shows a 1μm-thick microcrystal of α-MoO_3 on a gold substrate of cross-sectional area close to ~100μm×50μm. In Fig. 1b, the corresponding FTIR reflectivity spectra are shown, taken on two different locations of the flake. By comparing the two measurements, there exists a strong mismatch in the amplitude of the reflectance (ΔR), owing to the non-uniformity of the flake, and such a discrepancy is typical in such flakes. On the other hand, the spectral position of the dips in reflectivity ($\Delta\omega_d$) shows statistically much less variation with sample location, as also seen in Fig. 1b. The frequencies (ω_d) are related to the real part of the material refractive index (Re{n}) as[5]:

$$\omega_d = \frac{1}{2d}\left[\frac{2m+1}{2Re\{n(\omega_d)\}} - \frac{1}{2\pi Re\{n(\omega_d)\}} tan^{-1}\left\{\frac{-2Re\{n(\omega_d)\}k_s}{Re\{n(\omega_d)\}^2 - n_s^2 - k_s^2}\right\}\right] \quad (1)$$

where *d* is the flake's thickness and n_s and k_s are the real and imaginary parts of the refractive index of the metal substrate respectively.

The flake thicknesses (*d*) were measured with Atomic Force Microscopy (AFM). From Eq.1, Re{n} of the microcrystal was deterministically evaluated at each ω_d. This is shown with the black points in Figs. 1c,d for multiple microcrystals with different thicknesses, along the two optical crystal axes of a-MoO3. For values of Re{n} within the Reststrahlen band, the reflectivity spectra were measured with incident light polarized at 45° with respect to the crystal axes. Hence, from predetermined values of n_x we can derive the values of n_y. To obtain the complex refractive index of the material, the obtained Re{n} was fitted to the Lorentz oscillator model:

$$Re\{n(\omega)\} = Re\left\{\sqrt{\epsilon_{inf}\left(1+\frac{\omega_{LO}^2-\omega_{TO}^2}{\omega_{TO}^2-i\gamma\omega-\omega^2}\right)}\right\} \quad (2)$$

The fit (Fig. 1c,d) is used to retrieve the parameters of the complex permittivity namely ω_{TO}, ω_{LO}, γ and ε_{inf}.

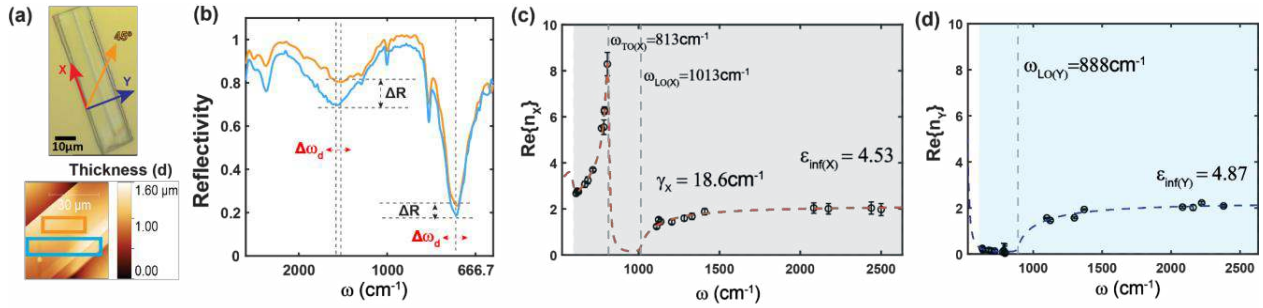

Figure 1 a) Microscope image of a MoO_3 microcrystal (d=1μm) on gold. The thickness measured by AFM is shown below. b) The reflectivity spectrum obtained by FTIR microscope on two different locations of the microcrystal. (c) Retrieval of complex refractive index along the crystal axis X. (d) The same along Y.

This work presents a method to retrieve accurately the in-plane complex refractive index of optically small flakes, without needing elaborate fitting algorithms or near-field tip-based measurements. The method was applied to retrieve complex refractive indices of two van der Waals materials in exfoliated flakes, namely hBN and α-MoO_3:

The project that gave rise to these results received the support of a fellowship from "la Caixa" Foundation (ID 100010434) and from the European Union's Horizon 2020 research and innovation programme under the Marie Skłodowska-Curie grant agreement No 847648.

[2]LG. Display Co, Ltd, Korea
[*]corresponding author: bdchin@dankook.ac.kr

Abstract: There exist a lot of technologies for a light extraction of organic light emitting diodes (OLEDs). However, for the successful commercial application, the restriction on the cost of manufacturing, directionality of color, and the requirement to maintain a high-quality image are severe. In this work, some of the simple fabrication process for the microscale light-extraction pattern formation are introduced. However, for a top-emitting OLED (TOLED), a useful platform of display for high-resolution mobile and non-transparent substrates, colors and spectra are significantly sensitive to those light extraction structures and intrinsic micro-cavity effects [1]. Here, a quasi-periodic, controllable buckling patterns [1] with broad size distribution for outcoupling-enhancing structures of top-emitting OLED are described in detail [2-3]. The formation of buckling patterns is spontaneously driven by the mismatch of thermal expansion coefficient of the organic and polymeric layers, which are easily deposited by simple deposition process. Further experimental studies on the effect of molecular weight, segmental softness/rigidity, and phase separation behavior of material combination will be investigated.

As for OLED performance, luminous efficiency of device with buckling patterns was increased without change of the spectral characteristics and color stability. Such a result, observed in case of optimum buckling structure on the transparent electrode of device, can be explained by the suppression of light loss by the surface plasmon polariton (SPP) mode at metal/air interface. Experimental data for different scale of buckling patterns at top emitting OLED were analyzed with the wavelength-dependent grating pitch and scattering order, indicating that efficiency is increased with larger periodic patterns.

Abstract:
Focused Electron Beam Induced Deposition (FEBID) is a mask-less nano-printing technique that allows for the reliable fabrication of planar and even complex, free-standing 3D nanostructures. Herein, we demonstrate its suitability for creating flexible plasmonic nanostructures, which are not producible with standard lithography techniques. We start with printing simple 2-3D Au nanostructures and evaluate their plasmonic activity via STEM-EELS further corroborated by simulations with the aim to generate an upfront design tool.

Alternative Plasmonic Metamaterials based on Titanium Nitrides and Oxynitrides with Tunable Properties

Abstract: the established potentialities of plasmonic effects in boosting light-matter interactions are at the basis for next-generation metamaterials merging multifunctionality, tunability of properties and broader spectral responses. The archetypal plasmonic materials, i.e. noble metals, show limited modulation outside the visible spectrum. Here, original meta-structures (e.g. hyperbolic metamaterials) based on non-metal plasmonic materials (titanium nitrides, oxynitrides) has been experimentally developed to finally pursue tailorable plasmonic features from VIS to IR towards extreme light manipulation in energy or nanophotonic applications.

At present, plasmonic excitations (e.g. Localised Surface Plasmon Resonances LSPRs) are at the forefront of research because they allow an ultra-fine tailoring and intensification of light-matter interactions at the nanoscale, to be exploited for example in solar-driven energy conversion devices [1]. Noble metals are the most widespread plasmonic materials (e.g. Au) due to high-quality LSPR in the visible (VIS) range. However, the impossibility to modulate plasmons outside the VIS (fixed carrier density) justifies the spreading interest for alternatives [2].

Conducting transition metal nitrides (e.g. TiN) are nowadays appointed as ideal substitutes to traditional plasmonic materials because of low-cost, CMOS compatibility and the tailored plasmonic responses in the VIS-near IR through stoichiometry [3]. Besides, thermal, chemical and mechanical stability are added advantages for operation in extreme environments. Oxynitrides (e.g. TiO_xN_y) are rising interest as well, due to the unique capability to cross twice the zero value of the real permittivity ε_1 in a wide spectral range (double epsilon-near-zero property, D-ENZ) at which new exotic phenomena arise, such as enhanced non-linear optical responses, super-intensification of light or improved photocatalysis [4]. Conversely, transparent conductors possess tunable carrier density, thus are promising for shifting the plasmonic features in the infrared (IR) [2].

In this framework, the interest is now focusing on meta-structures based on alternative materials, possessing intrinsic multifunctionalities and vast tunability of properties to fulfill at once multiple needs, spanning different applications (energy, optoelectronics, biosensing, nano-photonics). Specifically, peculiar multilayer structures, namely Hyperbolic Metamaterials (HMMs) show an anisotropic permittivity ε (parallel $\varepsilon_{//}$ and perpendicular $\varepsilon_{\perp}$ to the multilayer surface) resulting from the periodic alternation of conductors ($\varepsilon_1<0$) and dielectrics ($\varepsilon_1>0$) [5]. At the hyperbolic regime, unconventional electromagnetic phenomena are enabled (e.g. high-k modes) resulting, for instance, in unprecedented light confinement and manipulation. However, by investigating and merging alternative materials (transition metal nitrides or oxynitrides) with innovative design routes, metamaterial research can be further advanced by exploiting potentialities coming from unusual combinations of materials and properties (material stability, conductivity, broadband VIS-IR plasmonics, tunability).

In this work, single films and multilayers based on titanium nitrides TiN and oxynitrides TiO_xN_y (**Fig. 1a**),

have been developed at room temperature, on cheap substrates (Si, glass). Pulsed Laser Deposition (PLD) has been consciously selected for the one-step and manageable deposition procedure of 1-dimensional layered nanostructures. Besides, stoichiometry, composition and morphology in the growing films can be modified directly at the synthesis stage, by acting on deposition parameters (e.g. background gas pressure, laser fluence etc.) or through post-processing (e.g. thermal annealing). Great efforts have been devoted to materials characterization, understanding the physics behind while keeping a material science outlook.

First, TiN have been implemented as metal element in conducting TiN/TiO_2 multilayers, where this material couple for HMMs is a novelty and intriguing due to the good knowledge and versatility of TiO_2 as a wide-band gap semiconductor, high thermal stability of TiN and easiness in production. Material properties of the metasystem can be tailored with geometry (structural, electrical, optical/plasmonic properties). The existence of the hyperbolic character has been found by first evaluating the permittivities of single constituents through ellipsometry, then performing simulations of the anisotropic components ($\varepsilon_{\parallel}$ and $\varepsilon_{\perp}$) and final assessing the wavelength window at which $\varepsilon_{\parallel} \cdot \varepsilon_{\perp} < 0$ (HMM behaviour). Notably, a very wide HMM character in VIS-near IR (600-2100 nm) is present (**Fig. 1b**), although open to improvements by increasing the quality of the single layer materials (avoiding oxidation and internal stresses). Then, single films of oxynitrides have been synthetized from TiN by finely engineering the level of oxygen through deposition parameters (base vacuum, H_2-N_2 pressure). The not-trivial challenge is increasing the oxygen incorporation while maintaining the structure of TiN, i.e. preventing transition to TiO_2. Relationship between synthesis and structural/optical characteristics is complex and not straightforward to investigate. However, the approach is successful in obtaining D-ENZ character, since ε_1 has two zero-crossing points strongly tunable with deposition conditions at 400– 1700 nm (**Fig. 1c**). The next obligatory step is the integration in designed multilayers for broadband and multi-resonant D-ENZ HMMs.

Concluding, nitride-based alternative plasmonic nanomaterials merging multifunctional, tunable and broader plasmonic responses are starting guidelines to design real devices where the enhancement of light-matter interactions is at the core for technologically-relevant applications (thermal management in photovoltaics, plasmon-mediated broadband solar absorption/manipulation and photocatalysis).

Abstract: Vibrational coupling to quasi-bound states in the continuum (qBICs) in silicon-based dielectric metasurfaces is experimentally demonstrated. The judicious selection of the asymmetry parameter of qBICs offers tailored coupling between the resonance mode and polymethyl methacrylate (PMMA) molecules from weak to strong coupling regimes. We also show the existence of the asymmetry parameter at which the enhanced molecular signal is maximized. We believe that these findings serve as a bases for highly sensitive surface-enhanced infrared spectroscopy based on all-dielectric materials.

Identifying a small number of molecules based on surface-enhanced infrared spectroscopy is conventionally realized by utilizing the interactions between the molecular vibrations and the strongly localized electric fields in plasmonic platforms [1]. Recently, loss engineering strategies for maximizing the molecular absorptions at the vibrational modes have been reported as another strategy [2]. The ratio of the radiative to the nonradiative intrinsic loss rates originating from the metallic nanostructures can be controlled by changing the structural parameters, giving a large vibrational signal at an optimum condition [3]. This method provides significant enhancement effects without a precise nanofabrication such as a few nanometer gaps [4]. Nevertheless, it still requires elaborate structural design, and the loss tunability is limited by metal absorptions. In this respect, dielectric nanostructures have advantages in terms of their low material losses and tunability of radiative quality (Q) factors [5]. Especially, dielectric metasurfaces at quasi-BICs have great potential for the significant surface enhancement effects in vibrational coupling to the resonance modes as the radiative losses can be controlled simply by changing their asymmetry parameters.

In this work, we report on the tunability of the coupling conditions between silicon metasurfaces and molecular vibrations. Figure 1(a) shows the proposed metasurface structure on a silicon-on-insulator (SOI) wafer with a 400-nm silicon layer and a 2000-nm buried oxide layer. The period of the array P is 3900 nm, the primitive silicon rod length L is 2625 nm, the rod height w is 985 nm, and the distance between the centers of the upper and lower rods is 1825 nm. Here, the asymmetry parameter is defined as $\alpha = 2\Delta L/L$. The electric field intensity in the xy-plane ($\alpha = 0.2$) is strongly localized at the sidewalls of the silicon rods (Fig. 1(b)), which induces a strong interaction with the coupled molecules. For the field intensity in the yz-plane, the field strengths in the upper and lower rods are asymmetric (Fig. 1(c)), giving rise to the net electric component in the x-direction. Figure 1(d) shows experimental transmission spectra obtained using Fourier transform infrared spectroscopy. Both the resonance peak amplitudes and the linewidths increased with the parameter α. Notably, only the linewidths could be tuned while the resonance peak wavelengths remained nearly constant when changing α. Next, a 111-nm PMMA layer was spin-coated onto the bare metasurfaces. As can be seen in Fig. 1(e), the two split peaks appeared at the shorter and longer wavelengths of the PMMA absorption peak (C=O stretching mode) when α is large. The amplitudes of the split modes increased with increasing α. The Rabi splitting Ω was evaluated by observing the anti-crossing behavior in structures with varied detuning, indicating that strong coupling conditions were satisfied when α was smaller or equal to

0.27, where the Ω exceeded the linewidths of both the C=O absorption and qBIC modes. When α was larger than 0.27, the coupled systems were in weak coupling conditions. The enhanced molecular signal, which was calculated by subtracting transmission amplitude of the coupled qBIC-PMMA modes from the qBIC modes, was maximized at a specific α. The molecular signal can be explained by the temporal coupled mode theory [6], indicating that the surface enhancement effect originated from the radiative loss engineering based on the qBIC modes. The wide tunability of the loss in dielectric metasurfaces favors the optimization of the coupling conditions of the vibrational mode, opening potential applications for highly sensitive surface-enhanced infrared spectroscopy without using metals.

This work was financially supported by JSPS KAKENHI Grant Number JP22K20496.

Optical Metafluids Composed of Colloidal Mie-Resonant Silicon Nanospheres

H. Sugimoto[1*], and M. Fujii[1]

[1]Department of Electrical and Electronic Engineering, Graduate School of Engineering at Kobe University, Japan
[*]corresponding author: sugimoto@eedept.kobe-u.ac.jp

Abstract: Colloidal suspension of resonant nanostructures exhibiting optical magnetism may have very high and low effective index un-achievable in natural liquids, which can be exploited for the applications different from solid-state optical metamaterials. Here, dual nanoparticles with electric and magnetic resonances dispersed in solution dubbed as "dual metafluids" were developed based on Mie-resonant silicon nanospheres. In addition to the strong magnetic response in optical regime, the helicity preserved light scattering from size-purified silicon nanoparticles dispersed in solution were demonstrated.

Dielectric nanoparticles that exhibit both electric and magnetic responses provide rich functionalities for manipulating light waves in the field of metasurfaces, by enabling 2π phase control, Kerker-type directionality, enhanced chirality, negative refractive index, etc. The dielectric nanoantennas have been mostly lithographically fabricated on the substrate and used as building blocks of solid photonics devices. When the dielectric nanoantennas are synthesized in solution, they can also be a constituent of a liquid-phase metamaterial or a "metafluid". Such metafluid may be promising for applications in chemical and biology. The nanoantennas with electric and magnetic responses satisfy duality symmetry condition and they preserve the helicity of the incident light (*i.e.*, "dual"). In the helicity-preserving nanoantennas, the chirality of the local fields around the constituent nanospheres are strongly enhanced, which improves the sensitivity of enantiomer-selective chiral molecular sensing. However, experimental demonstration of the "dual" behaviors of nanoantennas in solution is not successful yet.

Figure 1. Dual nanoantennas. Helicity of incident light is preserved at Kerker condition of dielectric nanoantennas.

Over the past decades, plasmonic nanoparticles and nanoclusters have been explored as constituents of a metafluid. However, magnetic response of plasmonic nanoparticles is usually much weaker than the electric responses, i.e., the optical response is "non-dual". Here, we propose an all-dielectric metafluid composed of crystalline silicon nanospheres having the electric dipole (ED) and magnetic dipole (MD) Mie resonances at the optical frequencies At the Kerker condition, where the ED and MD resonances have the same amplitude and are in-phase, a silicon nanoparticle is "dual". We first experimentally demonstrate that a silicon nanosphere metafluid exhibits strong electric and magnetic dipolar Mie responses across the visible to near-infrared spectral range. The intensity ratio of the magnetic-to-electric responses reaches unity. We show that a solution of size-purified silicon nanospheres can be "dual" and "anti-dual" metafluids. This is the first experimental demonstration of a

liquid that can control the helicity of scattered light. The helicity-preserving metafluids with large enhancement of chiral near-fields may have applications in the fields of chiral molecular sensing.

Some 2D Magnetic Topological Photonic Crystals

Baile Zhang[1, 2‡]

corresponding authors: ‡blzhang@ntu.edu.sg

Abstract: Over a decade ago, topological photonics came into existence with the discovery of the first photonic topological insulator, which comprised a two-dimensional (2D) periodic lattice of gyromagnetic rods or a magnetic photonic crystal. Despite the significant progress made in the field of topological photonics in recent years, the potential of 2D magnetic photonic crystals remains largely unexplored. In this talk, we present some of our recent research on 2D magnetic topological photonic crystals.

The field of topological photonics [1] emerged a decade ago with the discovery of the first photonic topological insulator, a periodic lattice of gyromagnetic rods or a magnetic photonic crystal [2] that supports chiral edge states propagating in a unidirectional way. This groundbreaking achievement marked the first demonstration of the Chern insulator phase, known as the quantum Hall effect without Landau levels [3], characterized by the topological invariant of Chern number.

In this talk, I will present some of our recent studies on two-dimensional (2D) magnetic topological photonic crystals. The first study is focused on the localization of chiral edge states. According to the topological bulk-boundary correspondence, the chiral edge states should be "topologically protected" against any disorder or defect, without the possibility of being localized as long as the Chern number is valid in a non-closed band gap. However, we will discuss the possibility of localizing chiral edge states even when the Chern number is intact.

We will start by considering the non-Hermitian skin effect [4], which is the result of a non-Hermitian band topology that applies to the chiral edge states. By introducing non-Hermiticity (loss/gain) into a magnetic topological photonic crystal, we can construct the coexistence of a point band gap (for the non-Hermitian skin effect) and a line band gap (for the Chern number-protected chiral edge states), leading to skin effect of chiral edge states and causes their localization.

The second study focuses on the topological phase transition to a quadrupole topological insulator phase [5]. The quadrupole topological insulator is the first higher-order topological phase that has sparked the rise of higher-order topological physics in recent years. The typical construction of a quadrupole topological insulator requires the negative coupling and time-reversal symmetry, as required in the Benalcazar-Bernevig-Hughes (BBH) model [6]. We will show that a magnetic topological photonic crystal can exhibit a phase transition from the Chern insulator phase to a quadrupole topological insulator phase.

Abstract: The visible-light energy conversion is one of the important challenges for the sustainable society. Recently, various photocatalytic systems, such as molecular catalysts, semiconductors, or plasmonic systems, have been established. In this study, we have focused on the plasmonic photoenergy conversion system and established the new plasmonic cathode electrode system. Through the examination of photoelectrochemical measurements, we have successfully clarified the detail information about charge transfer processes on plasmonic cathode electrodes.

The establishment of high efficient visible light energy conversion system is an attractive challenge in the field of photoelectrochemical region. In order to achieve it, the wide-band gap semiconductor electrodes are often recognized as the promising candidates. However, the available wavelength region is often limited to the ultraviolet region because of their wide band gap energy. Recently, as the breakthrough for it, the introduction of the plasmonic metal nanostructures into the semiconductor electrode surfaces has been received much attention. In that system, the excited electrons or holes are injected into the semiconductor while remained holes or electrons trigger the chemical reactions at metal-semiconductor interfaces. Until now, various anodic systems which are the combination of plasmonic metal nanostructures with n-type semiconductor electrodes have been proposed. And also, the detail information and absolute electrochemical potential of excited holes were also investigated [1]. Recent study also proposes the plasmonic cathode by using the p-type semiconductor to control the reduction reactions at electrode surfaces. In our previous study, we have also proposed the plasmonic cathodic system which consists of p-type GaP and Ag nanostructures to control the visible light driven hydrogen evolution reactions [2]. In that report, the unique pH dependence of the reaction characteristic was observed, indicating unique molecular selectivity of plasmon-driven reactions. Although we have clarified unique reaction characteristics, the detail information about the charge transfer process on it was still under discussion. In this study, we have investigated its information through various photoelectrochemical measurements. At the present system, the chemically synthesized Au nanorod structures were supported on various types of p-type semiconductors to achieve the multi-color response ability. Through the photoelectrochemical measurements, we have found that the absolute electrochemical potential of excited electrons was dependent on not only the incident wavelength but also the flat band potential of substrates. As the results, we have confirmed the unique isotope effects which cannot be observed the conventional cathode system. Our current research would provide the novel insight for the accurate design of the high efficient light conversion device.

Advanced passive and active metasurfaces and zero-index materials

Harnessing the properties of emerging low-dimensional and phase-change materials for mid-IR photonics

Mitradeep Sarkar[1], Maxime Giteau[1], Michael Enders[1], Aleksandra Deeva[1], and Georgia T. Papadakis[1*]

[1]ICFO-Institut de Ciencies Fotoniques, The Barcelona Institute of Science and Technology, Spain

[*] georgia.papadakis@icfo.eu

Abstract: In this talk I will discuss the properties of several emerging low-dimensional materials that are typically exfoliated in the laboratory, rather than grown in large scale. First, I will introduce a method for retrieving the mid-IR dielectric properties of exfoliated flakes, which are typically too small to be characterized via the standard spectroscopic ellipsometry. Second, several low-dimensional materials exhibit significant anisotropy in the mid-IR range. I will discuss approaches to leverage this property for deep-subwavelength control of optical chirality and polarization control of a mid-IR beam. Finally, I will present simple design rules that can be applied in lithography-free mid-IR absorbers and emitters for active tunability via temperature-controlled phase-change materials.

The mid-infrared (IR) spectral range is of particular importance for applications in thermal energy harvesting, spectroscopy, molecular sensing and detection, and thermal camouflage. There has recently been significant interest in harvesting relevant properties of emerging materials for mid-IR photonics. Of particular interest are materials that support strong dielectric resonant features in the mid-IR range, with most prominent the case of surface phonon polaritons (SPhPs) that span the whole range from mid-IR to THz. These excitations can be found in various low-dimensional materials, such as hexagonal boron nitride (hBN) and molybdenum trioxide (MoO_3). Other than their strong dielectric resonances due to SPhPs, these materials also exhibit strong optical anisotropies, often behaving like a metal in one coordinate direction and like a dielectric in another coordinate direction. These properties have been considered by the mid-IR photonics community in the last decade as ways to control thermal radiation.

Nonetheless, these materials are not yet widely reproducible in the large-scale. Most experimental demonstrations, to ensure high material quality, utilize exfoliation to isolate thin flakes. Exfoliated flakes are typically very small as compared to a mid-IR beam, yielding a beam-sample mismatch for standard far-field mid-IR spectroscopy. This challenge also pertains to spectroscopic ellipsometry: the approach used traditionally to experimentally retrieve the optical properties of materials. Thus, exfoliated flakes with interesting mid-IR excitations are typically characterized insufficiently with near-field methods such as near-field optical microscopy (NSOM) and others. These methods are typically too delicate and sensitive to mechanical vibrations, and the reported dielectric properties deriving from them are the result of significant numerical fitting. In contrast, in this talk I will present a method to characterize small flakes of low-dimensional materials with a standard Fourier Transform Infrared Spectroscopy (FTIR) with minimal a priori knowledge of the dielectric properties of the samples. This method extends to strongly anisotropic materials, and I will present results for hBN and a-MoO_3 flakes that are close to literature values.

The SPhP resonances of several low-dimensional materials are highly relevant for directional control of mid-IR light. I will present a numerical study of how the interplay between real and imaginary part of their

dielectric permittivity dictate the degree of directional control that one may achieve. Furthermore, the strong anisotropies of low-dimensional materials can be a useful property for controlling different features of light propagation. I will present experimental results for a deep-subwavelength a-MoO_3 half waveplate operating both in transmission and reflection, and being at least two orders of magnitude thinner than standard mid-IR materials that serve as quarter waveplates. I will also discuss ways to control the chirality of mid-IR beams by leveraging this in-plane anisotropy of several low-dimensional materials.

In the final part of my talk, I will introduce design rules, compatible with any planar heterostructure, for achieving maximal dynamic tunability via temperature-control. In particular, I will discuss an approach to yield arbitrarily large shifts in mid-IR absorptivity or emissivity, as well as an approach to obtain maximal ON/OFF contrast ratio on-resonance.

Plasmonic metasurfaces and waveguide devices based on epsilon-near-zero materials

Pierre Berini

School of Electrical Engineering and Computer Science, University of Ottawa, Ottawa, Canada
Department of Physics, University of Ottawa, Ottawa, Canada
*corresponding author: berini@eecs.uottawa.ca

Abstract: We report work on tunable plasmonic metasurfaces and on polarization-independent broadband plasmonic modulators (>200 GHz), exploiting epsilon-near-zero effects in metal-oxide-semiconductor structures fabricated using conductive oxides. The tunable metasurfaces comprise subwavelength pixels that produce no grating diffraction and are used in reflection to control the magnitude and phase of the reflected beam. The broadband modulators share the same material set but are fabricated on embedded Si waveguides and designed to operate with TE or TM light.

Results

Resonant nanometallic structures, such as plasmonic nanoantennas, are essential to the conversion of light to surface plasmon-polaritons (SPPs) localized to ultra-small volumes. Such structures can provide highly enhanced fields, strong confinement, high surface sensitivity, and can double as a device electrode for applying voltages or passing currents to active regions in optoelectronic devices. In optoelectronics, plasmon enhancement can be exploited for high-performance electro-optic modulators and beam-steering devices [1-6].

Fig. 1 shows an electrically-tunable plasmonic metasurface on fused silica. The metasurface consists of an array of Au dipole nanoantennas contacted perpendicularly by electrical contact lines (Fig. 1(b)). The contact lines are centred on the nanoantennas (dipoles), which ensures that they are minimally invasive optically, due to their orthogonal alignment relative to the incident polarisation (along the nanoantenna axes). The nanoantennas are connected to an electrical fan-out structure (Fig. 1(a)) and coated with a HfO_2 layer then an ITO layer (Fig. 1c)), and finally by a metal mirror structure (Fig. 1(d)). Electrically the structure operates as a MOS capacitor (Au-HfO_2-ITO) with the top Au mirror structure also acting as the Ohmic contact to the ITO. When driven into strong accumulation, the ITO enters the epsilon-near-zero regime [6] resulting in large changes in the resonant behaviour of the nanoantennas. The structure produces a reflection coefficient at telecom wavelengths ($\lambda_0 \sim$ 1550 nm) that varies significantly (magnitude and phase) with applied voltage. The individual pixels (meta-atoms) in this structure are subwavelength such that grating diffraction upon reflection is completely avoided. The structure forms the basis of a solid-state optical phased array or a spatial light modulator.

Using the same material set (Au-HfO_2-ITO) a broadband plasmonic electro-optic modulator operating at telecom wavelengths and based on free carrier dispersion in ITO is enabled [5]. MOS structures are integrated into a pair of coupled metal-insulator-metal (MIM) waveguides aligned on a planarized silicon waveguide. The coupled MIM waveguides support symmetric and asymmetric plasmonic supermodes, excited adiabatically using mode transformation sections, by the fundamental TM and TE modes of the underlying silicon waveguide, respectively, such that the modulator can operate in either mode. The modulators are 1.5 to 2 μm long, due to the strong interaction of the plasmonic modes with the perturbed ITO layer, and an electrical bandwidth exceeding 200 GHz. The modulators produce an extinction ratio in the range of up to 6 dB and an insertion loss in the range of 4 to 7.5 dB including input/output mode conversion losses. The AC drive voltage is ±1.75 V.

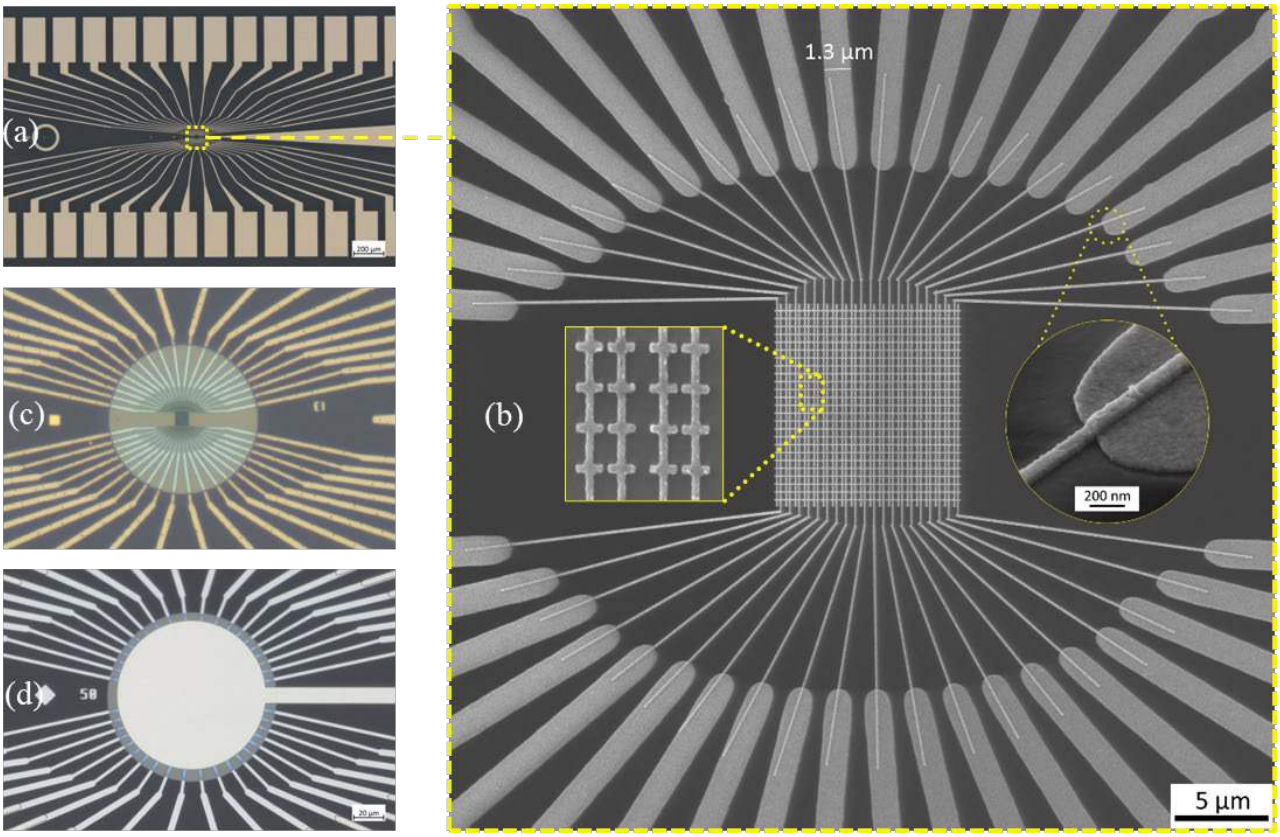

Fig. 1. Electrically-tunable plasmonic metasurface on fused silica: (a) First layer metal (Au contacts, alignment marks), (b) Au nanoantennas (He+ litho), (c) HfO_2 and ITO deposition followed by etching, (d) backside metal (Ohmic contacts, mirror).

Magnetic Nearfield Reshaping Metasurfaces

Hanwei Wang[1], Xiaodong Ye[1], Joshua Yu[1], Yun-Sheng Chen[1], Yang Zhao[1*]

[1]Department of Electrical and Computer Engineering, University of Illinois Urbana Champaign, USA
[*]corresponding author: yzhaoui@illinois.edu

Abstract In this talk, I will discuss a wearable metasurface that can actively reshape the magnetic nearfield to form a desired mode. The active tuning of the metasurface enables an on-demand magnetic field distribution that can be used for efficiently wirelessly charging embedded medical devices. We show that our metasurface can be worn on hands and enhances the delivered power by 10 fold.

Summary

Over 2 million patients in the United States benefit from electrically powered, implanted medical devices, such as cardiac pacemakers, implanted insulin pumps, and cochlear implants. The implants significantly prolong the patients' lifetime and improve their living quality. For example, cardiac pacemakers yield an average life increase of 9.5 to 20 years. In 1988, among the 1152 elderly patients over 65 years old who took surgical implantations of cardiac pacemakers due to chronic heart failure, 73% survived over five years after the surgery.4 Most medical implants use batteries as their power supply. The battery level needs to be checked frequently and replaced through a surgical procedure when they are out of charge. To enable an easier replacement, the batteries are usually placed in a pocket site underneath the skin and connected through a wire to the executing device inside the body. The leading wire can cause infection, blood vessel damage, and allergic reactions. Most patients report discomfort caused by the wire and the battery pocket. To overcome these problems, researchers have developed integrated devices without wires, i.e., leadless micro-implants. In 2009, Medtronic developed the first leadless pacemaker that can be implanted into the ventricle through minimally invasive surgery. The power consumption is optimized so that the battery can last 12 years, longer than the average lifetime of its patients. However, in the cases that the battery is running low, the devices have to be replaced with open-heart surgery.

Self-powering implants have been a research hotspot for decades. Researchers have utilized power from percutaneous light, blood flow, and body motion. However, these approaches require a complicated energy harvesting device that either needs to be installed invasively or has relatively low efficiency or reliability. To date, none of these approaches have been clinically approved. Radiofrequency (RF) electromagnetic waves, on the other hand, have high penetration depth in tissues and can be easily received by a resonant antenna.[1] Ubiquitous RF power from radio and television stations has proved to be capable of powering battery-free sensors and cameras, where milliwatt-level power can be harvested from a 6-inch antenna at the frequency of 915 MHz.[2, 3] However, medical devices, especially those deeply implanted, such as in the ventricle or cochlea, do not have the space for a 6-inch antenna. Therefore, techniques, such as adaptive phase-tuning have been developed to efficiently capture the energy for charging deeply implanted medical devices. Regardless of the energy harvesting efficiency, the maximum power is limited by the RF field intensity; therefore, power transducers are still required.

Metasurfaces, as a promising man-made material that can manipulate electromagnetic fields and waves, open a new path to overcome the challenges of self-powering the implants with ubiquitous RF fields. Metasurface uses an array of phase-tunable resonators to reshape the wavefront of the radiative wave and,

theoretically, can focus the electromagnetic field into any desired beam form. Different from the applications of the conventional metasurfaces,[4] the physical scale of the medical devices is much smaller compared to the wavelength (~30 cm for 915 MHz RF wave). In our recent work, we pioneered the theory and a design of a highly subwavelength metasurface that is capable of manipulating electromagnetic field in the nearfield range with an arbitrary target field distribution and orientation.[5] We have demonstrated its ability to enhance the signal-to-noise ratio for magnetic resonance imaging.[6]

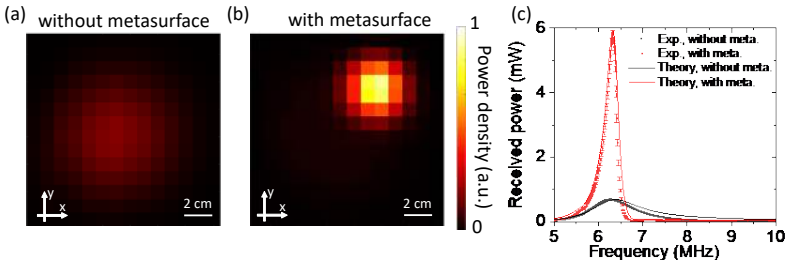

Figure 1. Experimental demonstration of the magnetic nearfield reshaping capability using metasurface. (a) Magnetic field from a coil without metasurfaces. (b) The reshaped magnetic field using the metasurface that 'refocus' the magnetic beam and re-directs the beam to an off-center location. (c) Experimentally demonstration of the enhanced power delivery using the metasurface by more than 10 fold compared to that without the metasurface. The experimental demonstration matches well with our theory.

In this talk, I will discuss recent advances in wearable metasurfaces for enhancing efficiency and delivered power by actively reshaping the magnetic nearfield distribution.[7] We inversely design the metasurface impedance based on the targeted mode distribution using coupled mode theory; we then configure the reactance distribution of the metasurface so that the resulting mode of the metasurface resembles the targeted mode due to strong coupling among the metasurface unit cells and with the transmitting and receiving coils. We have demonstrated two sets of metasurfaces. One operates at 6.8 MHz, compatible with AirFuel Alliance standard, and another one operates at 190 KHz, compatible with the Qi standard. In both devices, we show enhanced power delivery by more than 10 times.

Leveraging Thermo-optical Effects in Nanoantennas and Metasurfaces

G. Tagliabue[1]

[1]Laboratory of Nanoscience for Energy Technologies (LNET), Ecole Polytechnique Federale de Lausanne (EPFL), CH

corresponding author: giulia.tagliabue@epfl.ch

Abstract: Thermo-optical effects in dielectric nanoresonators open new opportunities for contactless manipulation of metasurfaces.

In the last decade, optical nanoantennas have revolutionized light manipulation and control at the nanoscale. Light absorption was initially considered a purely detrimental process, reducing the efficiency of optoelectronic devices. Recently, however, it has attracted growing interest, enabling novel light-energy conversion pathways and offering intriguing opportunities for reconfigurable systems.

In this talk, I will discuss self-induced optical heating effects in highly absorbing Silicon (Si) and Germanium (Ge) nanoresonators. In particular, I will show recent calculations demonstrating that, due to thermo-optical effects, self-heating can give rise to a complex, non-linear relationship between illumination intensity and temperature, even for moderate illumination intensities relevant for applications such as Raman scattering [1]. Subsequently, I will discuss how self-induced optical heating could be employed for thermally reconfigurable optical devices and metasurfaces [2]. Finally, I will discuss our recent effort in controlling the temperature field in multi-dimensional arrays of nanoantennas, highlighting the importance and opportunities offered by thermo-optical effects [3].

Abstract: We report the development of angle-sensitive photodetectors based on specially designed metasurfaces that can map the phase distribution of the incident light and visualize transparent phase objects without any external spatial-filtering elements. Pixel arrays of these devices can provide quantitative phase reconstruction in a single shot with state-of-the-art sensitivity.

Traditional image sensors detect light incident from all directions with equal responsivity, and as a result can only measure the intensity distribution of a visual scene. At the same time, all information associated with the phase profile and local directions of light propagation is lost in the image acquisition process. The ability to capture such information, however, would allow for more advanced image sensing and processing functionalities, such as image differentiation by optical spatial filtering and the visualization of transparent phase objects, which normally require rather bulky and complex setups. In turn, these functionalities have important applications ranging from computer vision to biomedical microscopy.

Here we report the development of angle-sensitive image sensors that can measure the phase profile of the incident optical field directly, without the need for any external optical elements other than standard imaging lenses. These devices consist of photodetectors stacked with a composite plasmonic metasurface that introduces a strong dependence of responsivity on illumination angle. Specifically, the metasurface is designed to couple light incident at the desired detection angles into surface plasmon polaritons supported by an underlying metal film, which are then scattered into the photodetector active layer by a set of subwavelength slits perforated through the metal film [Figs. 1(a) and 1(b)]. Light incident along all other directions is instead simply reflected back or diffracted away from the device.

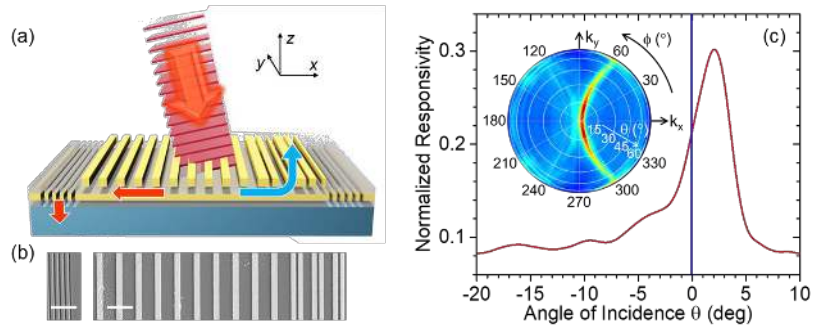

Fig. 1. Angle-sensitive metasurface photodetectors. (a) Schematic device structure. (b) Top-view SEM images of an experimental sample, showing the slits (left image) and nanostripes (right). The scale bars are 2 μm. (c) Inset: measured responsivity of this device at $\lambda = 1550$ nm versus polar θ and azimuthal ϕ illumination angles, normalized to the responsivity of an identical photodetector without any metasurface. Main plot: horizontal line cut of the color map. The vertical blue line indicates normal incidence.

In prior work, similar devices have been developed to demonstrate a planar lensless camera with ultrawide field of view, based on the compound-eye vision modality [1]. The same devices can also be used as optical

spatial filters, based on the notion that different spatial-frequency components of an illuminated object correspond to optical plane waves propagating from the object along different directions [2]. Here we focus on the ability of angle-sensitive photodetectors to visualized transparent phase objects, where light transmission generally involves a deflection in the direction of light propagation proportional to the local phase gradient. To maximize the device sensitivity to small deflection angles, the metasurface is designed to produce an asymmetric dependence of responsivity on angle of incidence around the surface normal. The measured angular response of this device (i.e., responsivity versus polar and azimuthal angles of incidence) is shown in Fig. 1(c).

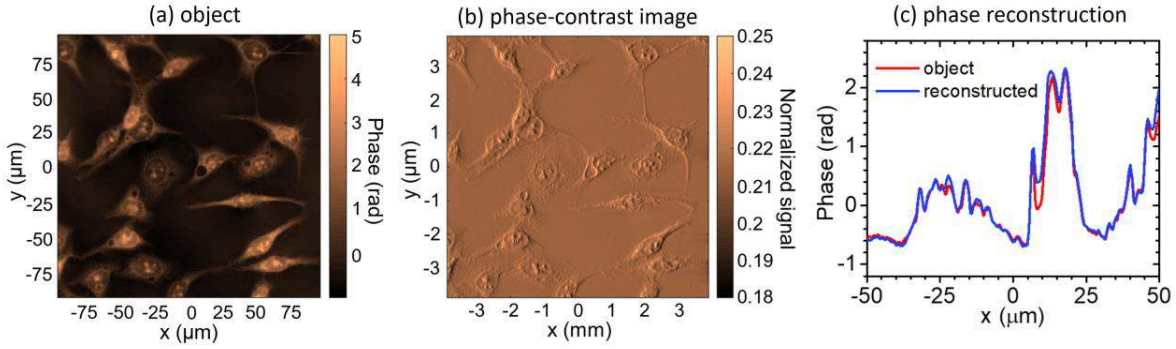

Fig. 2. Phase imaging results. (a) Representative phase object. (b) Corresponding image detected by an array of identical angle-sensitive pixels. (c) Red trace: phase distribution along the horizontal line at y = 0 in the object of (a). Blue trace: reconstructed phase profile from an array partitioned into blocks of four adjacent pixels, each coated with the metasurface of Fig. 1 oriented along one of four orthogonal directions.

These measurement results, combined with computational imaging simulations, indicate that a standard camera or microscope based on such devices can directly map the phase gradient of the incident light and therefore visualize any phase object in its field of view. As an illustration, Figs. 2(a) and 2(b) show, respectively, a phase object of practical interest (HeLa cancer cells) and its phase-contrast image recorded with this approach. A detailed analysis based on the noise properties of high-performance image sensors also show that the minimum detectable phase contrast is smaller than 10 mrad, which is comparable with state-of-the-art phase imaging systems involving significantly more complex and bulky setups [3].

Furthermore, the combination of sensors with equal and opposite angular response on the same pixel array can be used to perform quantitative phase reconstruction in a single shot with a straightforward computational protocol [Fig. 2(c)]. At the same time, with this approach the overall imaging system can be significantly simplified and miniaturized compared to traditional setups for quantitative phase imaging, e.g., based on optical spatial filtering, interferometry, or structured illumination. As a result, this approach is particularly promising for applications where space is highly constrained, such as point-of-care and in vivo microscopy and measurements involving freely moving objects.

Abstract: We present a miniaturized pulse shaping device that creates an arbitrary dispersion through the interaction of multiple metasurfaces on less than 2 mm^3 volume. For this, a metalens and a grating-metasurface between two silver mirrors are fabricated. The grating contains further phase information to achieve the device's pulse shaping functionality.

Ultrashort laser pulses are an important part for nonlinear applications; however, inherent dispersion in optical components tends to distort these pulses. To compensate the dispersion, pulse shaping devices usually utilize bulky prisms or gratings. Furthermore, prism-based pulse shapers are limited to correcting second order dispersion only, whereas newer applications involving metasurfaces promise a more compact design and allow for an arbitrary phase control [1]. Still, these metasurface based devices often rely on free space propagation to generate angular dispersion which leads to extended setups [2,3]. In this work, we report a compact pulse shaping device on a single glass substrate. We demonstrate the application of arbitrary dispersion to an input laser pulse, and analyze the experimental data by second-harmonic generation frequency-resolved optical gating (SHG-FROG) measurements.

The fabricated sample consists of an off-axis focusing metalens (MS1) and a grating metasurface (MS2) embedded in a spacer layer, on one side of a single 2 mm thick BK7 glass-substrate (Fig. 1). Both sides of the substrate are covered with a silver mirror. MS1 focuses the laser beam on MS2 while also introducing angular dispersion, which spreads the laser pulse's bandwidth over the second metasurface. MS2 acts as a grating with half the grating period of MS1 in order to redirect the beam back to MS1. Furthermore, additional wavelength dependent phase information is encoded onto MS2, which is used to alter the laser pulse dispersion.

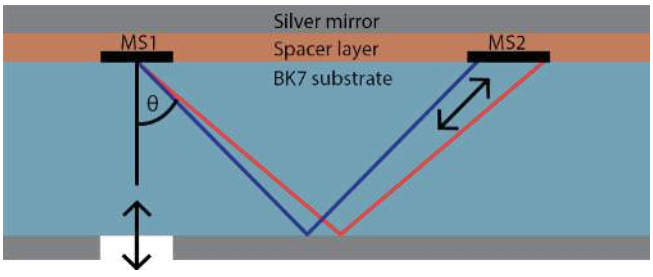

Fig. 1: Schematic image of the pulse-shaping device. A laser beam can pass the aperture in the silver mirror and hit the off-axis metalens (MS1) which redirects the beam under the angle θ towards MS2 while also causing angular dispersion. MS2 contains further phase information which can introduce wavelength dependent arbitrary dispersion.

Multiple MS1 and MS2 pairs with different functionality are fabricated, such as the compensation of the device's inherent dispersion caused by the material and angular dispersion, third order dispersion and phase information which leads to the generation of two laser pulses. The signal from the pulse shaping device is evaluated in an SHG-FROG measurement, consisting of an autocorrelator and a spectrometer, from which the existing pulse dispersion can be retrieved. To illustrate the device's ability of creating a complex pulse shape, Figure 2 compares the reference measurement with an SHG-FROG trace for an MS1-MS2 configuration that is designed to generate a double pulse. In order to achieve this double pulse, a periodic π phase shift encoded on MS2 is applied to the spectrum with a modulation that corresponds to the desired temporal separation of 200 fs between the two laser pulses.

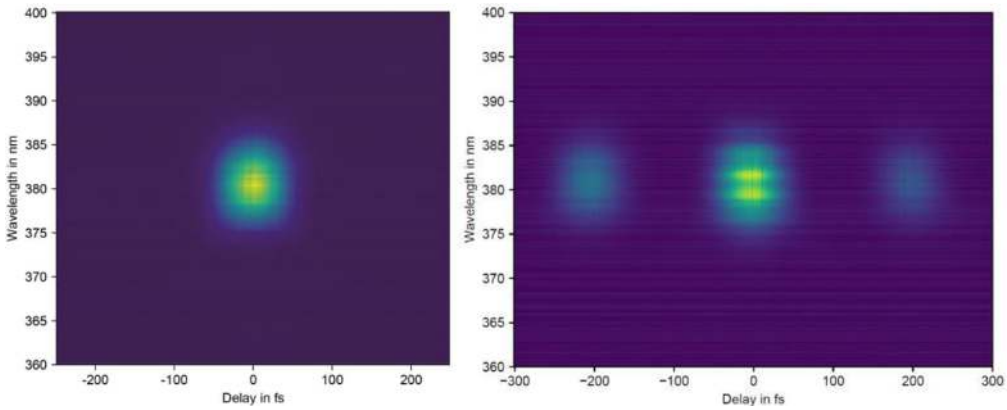

Fig. 2: Left) Measured SHG-FROG trace for a 45 fs laser pulse as second harmonic wavelength over the delay time τ (reference measurement). Right) Measured SHG-FROG trace for a generated double pulse with 200 fs temporal separation.

Our work presents a pulse shaping meta device that can apply arbitrary dispersion which is verified by our measurements. We show that by adding a well-defined phase information, a double pulse with a desired temporal separation can be generated as expected. Further pulse shaping such as the control of second- and third-order dispersion are also demonstrated. The device manages such functionality on a volume of less than 2 mm^3 and on a single substrate, making it compact and easy to use in space limited applications.

Title: Building Uncooled Infrared Camera based on One Atom Thick Graphene

Abstract: The talk will outline a novel strategy for uncooled, tunable, multispectral infrared detection. Due to the low photon energy, detection of infrared photons is challenging at room temperature. One atom thick graphene offers an alternative mechanism bypassing material bandgap restriction. Further, the ability of carrier concentration modulation on graphene via external voltage offers dynamic spectral selectivity for "color" night vision/sensing. The performance of preliminary demonstration compares favorably even with present cryogenically cooled detection schemes paving the path for commercial development of many applications from space exploration to healthcare.

Prof. Debashis Chanda is a Professor, jointly appointed with NanoScience Technology Center, Dept. of Physics and College of Optics and Photonics (CREOL), University of Central Florida (UCF). Dr. Chanda received his PhD from University of Toronto. His PhD work was recognized in the form of several awards, including prestigious National Sciences and Engineering Research Council (NSERC) fellowship. Dr. Chanda completed his post-doctoral research with Prof. John A. Rogers at Beckman Institute, University of Illinois at Urbana-Champaign. Quite a few of this research works were extensively covered by National Science Foundation news, BBC, Daily Mail, NBC, Fox, Science Radio and other national/international media outlets. His research has appeared on American Scientist magazine as focused article where it was outlined how companies like Intel, Toshiba etc are trying to adopt some of the printing techniques which were developed in his group. Dr. Chanda is a recipient of the 2012 DOE Energy Frontier Research Center (EFRC) Solar Energy Future Direction Innovation Proposal Award, 2013 NSF Summer Institute Fellowship and International Displaying Future Award-2016 by Merck Germany, UCF Reach of the Stars Award (2018), Samsung Global Research Outreach (GRO) Award (2022), Sony Research Award 2022. Dr. Chanda's research has been supported by NSF, DoD, DARPA, Florida Space Institute/NASA, Northrop Grumman, Lockheed Martin etc. Apart from that Dr. Chanda is the founder of start-up, E-Skin Displays Inc., out of his research in California.

Conductive Nitrides for Plasmonics in the Visible Region: Properties and Applications

Yu-Jung Lu*[1,2]

[1]*Research Center for Applied Sciences, Academia Sinica, Taipei 11529, Taiwan*

[2]*Department of Physics, National Taiwan University, Taipei 10617, Taiwan*

Abstract: In this presentation, I will discuss emerging plasmonic platforms based on transition metal nitrides. We demonstrated that the refractory hafnium nitride (HfN) plasmonic crystals could generate full-visible color with a high image resolution of ~63,500 dpi while withstanding a high temperature (900 °C). In addition, I will present an overview of my research works over the past five years on the plasmon-enhanced light-matter interactions in visible regions and their applications.

Plasmonic nanostructure based on silver and gold that produces LSPR to withstand ultrahigh temperatures without damage remains a great challenge for future ultra-compact integrated circuits, and high-power enabled photonic devices. In principle, the shapes of plasmonic nanostructures containing noble metals would change after the heat treatment that altered the plasmonic resonance. Thus, discovering refractory plasmonic materials that can exhibit plasmonic resonance in the visible range is essential. A challenge in refractory plasmonic materials is the bulk plasmon frequency is usually in the near-infrared range, making it difficult to generate plasmonic colors in the visible. We first reported a new refractory plasmonic material HfN, one of the conductive nitrides, that has a relatively high bulk plasmon frequency ($\lambda = 400$ nm) with a high melting point ($T \sim 3583$ K) and a relatively large magnitude of the real part of the permittivity, which enables intense local electromagnetic field confinement to form LSPR in the visible region. We use this unique property to develop full-color plasmonic pixels with sub-diffraction resolution through tailoring HfN plasmonic crystals and demonstrate that HfN refractory plasmonic crystals can withstand high-temperature annealing (900 °C) without damage. The novel HfN refractory plasmonic materials unlock new opportunities for ultra-compact integrated functional plasmonic devices. Especially the unique property of HfN, implying a bright future for emerging plasmonic materials at visible wavelengths [1]. In addition, I will present an overview of my research works over the past five years on the plasmon-enhanced light-matter interactions in the visible regions and their applications [1-6], including the plasmonic nanolasers [2-3], tunable plasmonic modulators [4], plasmonic phototransistors [5], plasmon-enhanced solar energy harvesting [6], and the refractory plasmonic colors for back-light free displays [1]. My group discovered several unique working mechanisms that utilize plasmonic nanocavities to improve optoelectronic device performance. By engineering the local electromagnetic field confinement, the light-matter interaction strength can be enhanced, which results in efficient energy conversion in the designed nanosystem. Moreover, I will discuss the detailed mechanisms and possible applications. These results have broad implications for the use of alternative plasmonic nanocavities in high-performance optoelectronic devices.

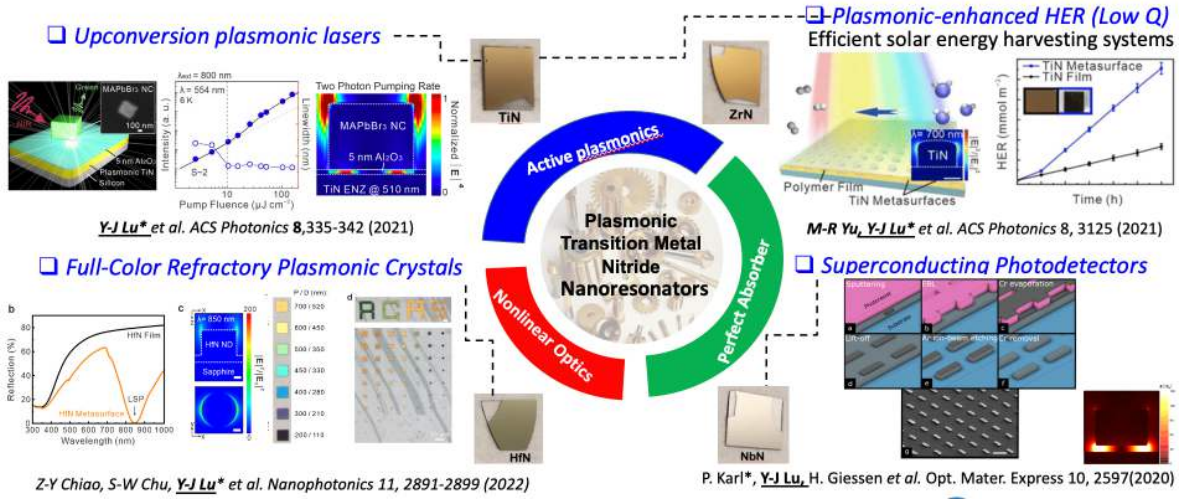

Figure 1. Research works based on plasmonic transition metal nitrides (TiN, HfN, NbN) as plasmonic platforms that reported by our Lab. By engineering the local electromagnetic field confinement, the light-matter interaction strength can be enhanced, which results in efficient energy conversion in the designed nanosystem for various applications.

Abstract: Active tunable metasurfaces have been demonstrated by various methods including mechanical actuation and phase change materials. Metasurfaces can be easily infiltrated with liquids through microfluidics. The change in refractive index will tune the resonance of meta-atoms and therefore can be used to modulate the optical properties and functions of the given metasurface. Here we demonstrate a series of integrated optofluidic metasurface devices, with wide applications including transparent displays, tunable color filters based on structural color, switchable meta-holograms and biosensors.

Comprised of a planar thin layer of nanostructures, optical metasurfaces enable the engineering of optical resonance and wavefront within sub-wavelength thickness, which will promote a new generation of ultra-compact optical systems [1]. Conventional metasurfaces have static optical functions, because the sub-wavelength meta-atoms are static and fixed after fabrication. Active tunable metasurfaces have been drawing increasing attention, and demonstrated by various methods including mechanical actuation and phase change materials. Among all the different approaches, we are particularly interested in the interactions between metasurfaces and their surrounding media. Metasurfaces can be easily infiltrated with liquid crystals [2-4], or liquids [5] by adding superstrates or microfluidic chambers, respectively. The change in refractive index (RI) of the infiltration medium will tune the resonance of meta-atoms and therefore can be used to modulate the optical properties and functions of the given metasurface.

The integrated optofluidic metasurface device is schematically shown in Fig. 1a. Titanium oxide (TiO_2) was selected due to the excellent optical properties in the visible spectrum. TiO_2 nanostructures of different geometries (i.e., nanodisk radius and disk-to-disk gap) were fabricated on glass substrates using electron beam lithography, as shown in the scanning electron microscope images (Fig. 1b). A polydimethylsiloxane (PDMS) chamber was formed in a mold, and then bonded on top of the metasurface after Oxygen plasma treatment. Microfluidic tubes were inserted to the PDMS chamber, forming inlet and outlet channels. Liquids with different RI can be injected and exchanged. For example, the metasurface surrounding medium can be switched between water (n = 1.33), and a medium with a higher n = 1.40 (e.g., 40% glucose or 50% glycerine solutions by weight).

Huygens metasurfaces based on Mie resonance are used in this work. From the finite-difference time-domain (FDTD) simulation, the metasurface resonance spectrum shifts in response to the medium RI change (Fig. 1c). Based on the resonance tuning, the integrated optofluidic devices provide a simple implementation of active tunable metasurfaces. The change in transmission amplitude could switch on/off a single-wavelength light, with potential applications in tunable transparent displays [6]. Furthermore, TiO_2 metasurfaces form structural colors in the visible region [7], so the device can be used as a tunable color filter, which changes the transmitted color under white light (Fig. 1d). More importantly, in addition to amplitude modulation, the phase modulation enables wavefront engineering. For example, tunable holographic

metasurfaces can be achieved by the microfluidic medium change (Fig. 1e) [5]. The dynamic tunable meta-holograms are useful in holographic display, optical information processing and encryption. Finally, medium-induced resonance change can be used not only for medium-switchable metasurfaces, but also for refractometric sensing (Fig. 1c). Using the same optofluidic devices, we demonstrated a sensitive detection of RI change down to 0.001 RIU. The devices can be further bio-functionalized for biosensing applications.

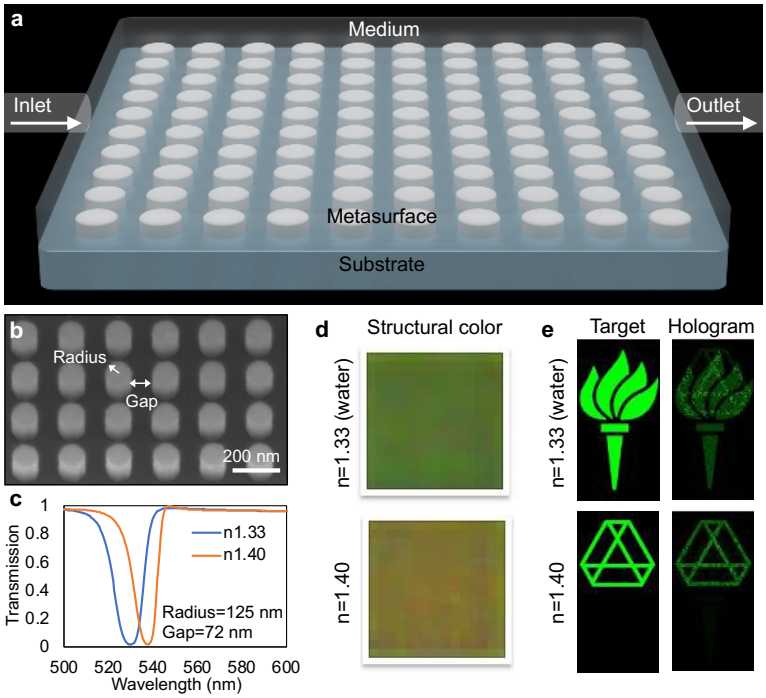

Figure 1. (a) Schematic diagram of the integrated optofluidic metasurface device. (b) SEM images of the fabricated TiO_2 metasurfaces. (c) Spectral shift of resonance, (d) structural color change, and (e) meta-hologram switching in response to the medium refractive index change between water (n = 1.33) and n = 1.40.

Exciton resonances in two-dimensional materials for dynamic wavefront manipulation

Melissa Li, Claudio Hail, Souvik Biswas, Harry Atwater

Thomas J. Watson Laboratory of Applied Physics, California Institute of Technology,
Pasadena, California 91125, United States

Dynamic control of the scattering properties of resonant nanophotonic structures is central to the realization of active metasurfaces. However, concepts thus far primarily employ geometrical resonances, e.g. plasmonic or Mie resonances, in three-dimensional nanostructures and show very weak electro-optic effects. As structures for light manipulation become increasingly complex and compact, the demand for novel materials that exhibit strong tunable light-matter interactions in the ultra-thin regime is rapidly growing.

Exciton resonances in two-dimensional (2D) van der Waals materials have gained widespread attention for opto-electronics based multifunctional devices due to their large binding energies, strong oscillator strengths, and high tunability through electrostatic gating. In this talk, we discuss how excitons in these layered materials can be engineered to achieve a wide range of optical wavefront manipulation. We demonstrate how in a field-effect heterostructure, the radiative and nonradiative rates of excitons in monolayer molybdenum diselenide ($MoSe_2$) can be actively tuned, thereby strongly modulating the light-scattering properties. By applying spatially-varying amplitude and phase gradients across the monolayer $MoSe_2$ with electrostatic gates, we observe large tuning of the complex refractive index at various excitonic frequencies and demonstrate dynamic beam steering. We show how optical cavities, otherwise needed to enhance light-matter interactions, can be eliminated by using a high quantum yield 2D semiconductor that serves both as the resonant scatterer and the tunable material. Our results uncover conceptually new metasurface design principles by engineering material resonances and have broad implications for the use of low-dimensional excitonic materials for atomically-thin, active nanophotonic devices.

Quasi-Bound State in the Continuum in Intra-Coupled Si Dielectric Metasurface

Wen-Hui (Sophia) Cheng*
National Cheng Kung University, Taiwan
*corresponding author: wcheng@gs.ncku.edu.tw

Abstract: A structure of all-dielectric metasurface with the concept of q-BIC is introduced and studied. Magnetic quadrupole being induced by asymmetry and near field coupling contribute to the high Q resonance. The effect of pitch, size, and scaling factor will be discussed for better understanding of the system.

Metasurfaces present a viable prospect for the alteration of electromagnetic wave properties, including amplitude, phase, and polarization, through the customization of meta-atom geometry. Notably, dielectric metasurfaces have garnered significant interest in recent times owing to their minimal radiative loss. In this work, we incorporate the concept of quasi-bound state in the continuum (q-BIC) with the dielectric metasurface. By introducing the asymmetry factor and parameter optimization in our metasurface, we theoretically obtain a resonance with a quality factor (Q-factor) of 650 with a bi-radius four-unit structure. We performed a multipole decomposition analysis of the resonance, revealing that the resonance is resulted from addition of the magnetic quadrupole to the electric dipole. In addition, we explore the pitch effect and find that the resonances are influenced not only by pitch in x-direction but also y-direction. We attribute this result to magnetic quadrupole being induced by asymmetry and near field coupling. Therefore, the pitch size should not be too large for the maintain of the q-BIC resonance. For practical application, we also examine the tunability of the q-BIC resonance with scaling factor. A broadband tunability from 600nm to 1200nm without sacrificing much the Q-factor can be realized. Our studies with fundamental understanding of the q-BIC in the proposed structure support the potential application of the all-dielectric metasurface including sensing, emission control, and nonlinear optics.

Physics-informed reinforcement learning for nanophotonic device design

M. S. Jang[1 *]

[1]School of Electrical Engineering, Korea Advanced Institute of Science and Technology (KAIST), Korea
[*]corresponding author: jang.minseok@kaist.ac.kr

Abstract: The increasing demand on a high-performance metasurface requires a freeform design method that can handle a huge design space. Accordingly, various nanophotonic device design schemes have been investigated including the ones based on machine learning. In this presentation, I discuss design approaches based on deep reinforcement learning, which have achieved great success in many different fields spanning video games, the game of Go, protein folding problems, to matrix multiplication algorithms. Reinforcement learning has not yet been actively explored in the field of nanophotonics compared to other machine learning methods such as generative or discriminative models. I will introduce how to apply deep reinforcement learning to design a metasurface beam deflector with large degrees of freedom, and discuss how to increase the sample efficiency by informing the agent of the reinforcement learning using physical constraints that govern the electromagnetic system.

Active metamaterials and devices: from rapidly-tunable lenses to emergent polaritonic materials

Gennady Shvets

Cornell University, USA

Abstract: One of the attractions of resonant metamaterials is the possibility of tuning their resonant frequencies in real time by integrating them with actively-controlled materials. In this talk, I will describe how metasurfaces can be combined with liquid crystals to develop a new class of electrically-controlled varifocal metalenses operating at multiple wavelengths. Experimental demonstrations of imaging using actively controlled varifocal and bifocal metalenses will be presented, and new approaches to making widefield electrically-tunable metalenses will be described. I will also describe how electrically-biased plasmonic metasurfaces – also known as metagates – can be integrated with 2D materials to simultaneously modify the band structure of free carriers and plasmons. The resulting active material possesses emergent polaritonic properties that are absent without the metagate.

Dielectric and Transient Optical Properties of Ultrathin TiN and $Ti_{1-x}Al_xN$

I-H. Ho and H. Ahn*

Department of Photonics, College of Electrical and Computer Engineering, National Yang Ming Chiao Tung University, Hsinchu 30010, Taiwan.
*corresponding author: hyahn@nycu.edu.tw

Abstract: Titanium nitride (TiN) with excellent optical and thermal properties has recently attracted attention in the fields of plasmonics and photothermal applications. We report the dielectric as well as the transient optical responses of ultrathin TiN and $Ti_{1-x}Al_xN$ ($0 \leq x \leq 0.67$) films grown by molecular-beam-epitaxy method. With increasing Al compositions, drastic increase of VIS-NIR absorption and the redshift of the epsilon-near-zero wavelength is observed for $Ti_{1-x}Al_xN$. Strong sub-picosecond electron-phonon coupling and nanosecond-long heat-preservation is observed for $Ti_{1-x}Al_xN$ in the whole visible spectral range.

Along with hafnium nitride (HfN) and zirconium nitride (ZrN), titanium nitride (TiN) is a refractory transition metal nitride with high melting temperature (~3000 °C) and many excellent optical and plasmonic properties comparable or superior to gold (Au), making it a good candidate for robust and low cost metallic material with compatibility to complementary metal–oxide–semiconductor (CMOS) fabrication technologies. TiN possesses the epsilon-near-zero wavelength (λ_{ENZ}) at ~2.47 eV, emerging as an alternative plasmonic and ENZ material to gold operating in the visible range. Typically, wide tunability in λ_{ENZ} has been realized by using metamaterials requiring complicated structural engineering. In our work, we prepared the high crystalline quality ultrathin TiN and $Ti_{1-x}Al_xN$ epitaxial layers by using the molecular-beam epitaxy (MBE) method. We have achieved the tunable λ_{ENZ} from 470 nm to 530 nm in the ultrathin TiN films by reducing the thickness from 30 to 2.4 nm. Moreover, even wider tunability from visible to near-infrared range could be achieved by alloying with Al in $Ti_{1-x}Al_xN$. This talk would be divided into two topics; Dielectric, optical, and electrical properties of ultrathin TiN and the Al composition dependence of transient behavior for TiN and $Ti_{1-x}Al_xN$.

Ultrathin metal film is a promising transparent and conductive electrode (TCE) material, but noble metal films grown by evaporation or sputtering methods exhibit poor morphology at the initial stage and its percolation thickness is in the range of 6 – 10 nm. While TiN films grown via sputtering, PLD, or ALD techniques show relatively low quality films, the influence of oxygen-related defects is greatly reduced for MBE-grown TiN films owing to ultrahigh vacuum growth. Our ultrathin (<6 nm) TiN epilayers have high optical transparency (≥75%) over the whole visible spectra regime and λ_{ENZ} could tuned with different film thickness, as shown in Figure 1a.[1]

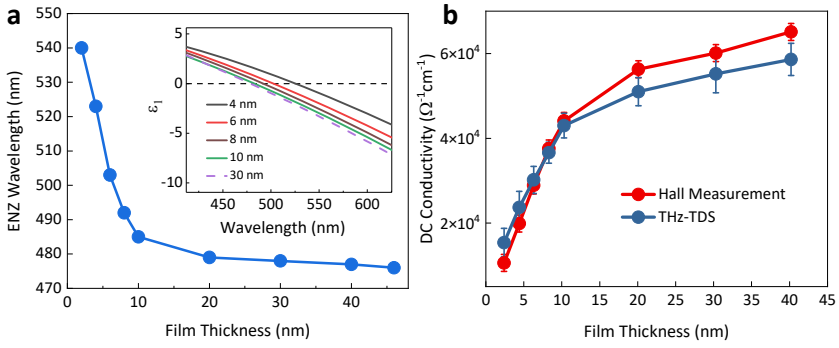

Figure1. (a) Film thickness dependence of ENZ wavelength. Inset; Real dielectric functions (ε_1) measured by spectroscopic ellipsometry. (b) Thickness dependence of DC conductivity measured by THz spectroscopy and Hall-effect techniques.

The electrical properties of ultrathin films are explored by the terahertz time-domain spectroscopy (THz-TDS) and the Hall effect techniques which are the optical and direct contact measurement method, respectively. In Figure 1b, we found an excellent agreement between optically and electrically measured results.

Recently, several contradictory results have been reported in electron-phonon (*e-ph*) coupling time of TiN, namely, either strong and ultrafast (sub-ps)[2] or weak and slow (a few tens of ps). From the comprehensive study of broadband transient reflectivity spectroscopy, we found that these two distinct *e-ph* coupling processes are concurrently occurring in TiN, but critically depending on the probe wavelength. In particular, the one with sub-picosecond coupling time occurs only within a narrow ENZ region. As shown in Figure 2a, the visible light absorption for Ti-rich (x<0.5) $Ti_{1-x}Al_xN$ is enhanced by doping with Al and more importantly, the ultrafast *e-ph* coupling is observed in the whole visible spectral range, demonstrating that $Ti_{1-x}Al_xN$ can play an important role in development of a new family of plasmonic and ENZ-based opto-electronic devices. Figure 2b also shows that following the e-ph coupling process, the magnitude of transient reflectivity is high and decay to equilibrium in a nanosecond, indicating the great potentials of TiN and TiAlN films as highly efficient materials in photothermal and photochemical applications.

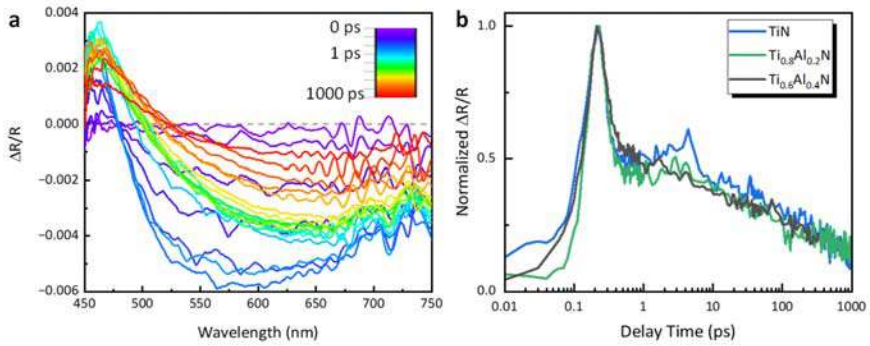

Figure2. (a) Spectral cuts of transient reflectivity of $Ti_{0.6}Al_{0.4}N$ at different delay times from 0 ps to 1000 ps, indicated by the color bar. (b) Temporal evolution of transient reflectivity for TiN, $Ti_{0.8}Al_{0.2}N$, and $Ti_{0.6}Al_{0.4}N$.

Metallic quantum well based extreme nonlinear materials and metasurfaces

Zhaowei Liu*
Department of Electrical and Computer Engineering, University of California, San Diego

Abstract: Optical power dependent nonlinear metasurface has attracted much attention recently due to its great potential in ultrafast meta-optics, optical image and signal processing. Here, we review our recent studies about the development of various metallic quantum well systems with extremely high Kerr nonlinear coefficients and a few examples of applying those materials to nonlinear metasurfaces. We think nonlinear metasurface with exceptionally high nonlinear effect is becoming a promising candidate in real time image processing and parallel analog computing.

Exceptionally large Kerr nonlinearity has been demonstrated in various quantum well heterostructures due to the inter-sub-band (ISB) transitions. In order to achieve the operational frequency to visible and near infrared range, we developed metallic quantum well with film thickness around 3nm or less. Specifically, TiN/Al_2O_3 multiple layers show not only high nonlinearity ($\chi^{(2)}$ ~1500 pm/V, and $\chi^{(3)}$ ~2×10^{-15} m^2/V^2 in the VIS/NIR), but also ultra-high damage threshold, rendering them compatible for nonlinear optical studies. However, TiN is a lossy metal with relatively high linear optical loss. There is a desire to further improve performance through different material platforms that offer additional resonant characteristics with lower linear material losses.

Materials that can be characterized as possessing free charge carrier, such as metallic films and highly doped semiconductor films have a special regime where the real permittivity of the material approaches zero, denoted as the Epsilon-Near-Zero (ENZ) regime. There is significant interest in this class of material, as they display a variety of exotic nonlinear effects, such as near-unity refractive index change, and harmonic generation enhancement. Stemming from the continuity of the normal E-field through a medium, when the permittivity for a medium approach zero, the normal E-field component within the ENZ film is greatly enhanced. In addition, ultrathin ENZ films support leaky modes that further enhance the E-field enhancement by an order of magnitude than its bulk counterparts.

We will discuss our new strategy to combine the extreme nonlinearity in metallic quantum wells and the ENZ to achieve much stronger nonlinear effects and the applications in nonlinear metasurfaces.

Generation and Control of Ultrafast Directional Photocurrents at Nanoscale Using Symmetry-Broken Hybrid Graphene Nanoplasmonic Metasurfaces

Jacob Pettine[1] and H.-T. Chen[1*]

[1]Center for Integrated Nanotechnologies, Los Alamos National Laboratory, Los Alamos, NM 87545, USA
[*]Corresponding author: chenht@lanl.gov

Abstract: The generation of directional photocurrents via a variety of mechanisms is essentially linked to the breaking of spatial inverse and/or time-reversal symmetries. Here we introduce a class of optoelectronic metasurfaces, more specifically hybrid graphene nanoplasmonic metasurfaces with broken inversion symmetry, for the generation of arbitrarily and spatially varying ultrafast directional photocurrents at nanoscales. We further apply this concept for efficient emission of pulsed THz radiation and direct generation of THz vector beams.

The generation of directional electrical currents is ubiquitous, with obvious examples including applying a voltage bias using a battery and illuminating a photodiode with light. The directionality is essentially linked to symmetry breaking associated with applying extrinsic stimuli (voltage bias), device structural designs (p-n junction), and/or intrinsic material properties (noncentrosymmetric crystal structures). This enables a variety of device applications for microelectronics, energy harvesting, and sensing, to name a few. The generation of directional currents can be also exploited to investigate material and structural properties due to the broken spatial inversion and/or time-reversal symmetries, e.g., circular photogalvanic effects in topological insulators, two-dimensional van der Waals heterostructures, Weyl semimetals, and other emerging quantum materials [1]. However, the generation of directional photocurrents so far are mostly at the macroscopic and mesoscopic scales; the ability to generate arbitrarily and spatially varying directional currents at nanoscale remains a considerable challenge, although it may find important applications in microelectronics and signal transductions.

Here, we introduce a class of optoelectronic metasurfaces for light-driven vectorial charge flow at ultrafast timescales and nanometer spatial scales. The hybrid graphene nanoplasmonic metasurfaces (Fig. 1(a)) consist of an array of teardrop-shaped gold nanoantennas on top of a CVD-grown graphene monolayer. The inversion symmetry breaking of gold teardrop nanoantennas makes them act as lightning rods; strong plasmonic hot spots at the sharp (< 15 nm radius) tips occur under resonant photoexcitation. Directional photocurrents will emerge

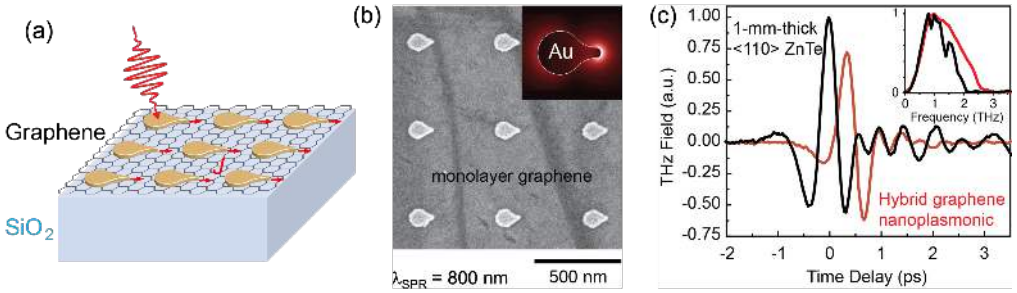

Figure 1. (a) Schematic of the hybrid graphene nanoplasmonic metasurface. (b) SEM image of a fabricated sample, with inset showing the plasmonic resonance. (c) Radiated THz pulses from the metasurface and from a 1-mm-thick ZnTe crystal.

within the underlying graphene monolayer due to the strong asymmetry in the plasmonic field mode and the corresponding hot carrier excitation, acceleration, and/or injection. The direction of the generated photocurrents is locally determined by the orientation of the gold teardrop nanoantennas, and the ultrafast timescales are enabled by the femtosecond laser excitation as well as the picosecond hot carrier relaxation within the graphene. Such hybrid graphene nanoplasmonic optoelectronic metasurfaces can be scaled to operate at arbitrary excitation wavelengths ranging from near-infrared to terahertz (THz) regimes. This provides a versatile and adaptive light-based control over ultrafast, nanoscale vectorial currents with designer spatially varying magnitude and direction.

We validate the optoelectronic metasurfaces by fabricating millimeter-scale devices through a wet transfer process of graphene and electron-beam lithography process for the gold teardrop nanoantenna array (Fig. 1(b)), along with a suite of electrical and optical measurements. We first investigated the metasurfaces with gold teardrop nanoantennas all aligned to form a uniform square array. The resonant properties of the fabricated metasurfaces were first verified via white light transmission spectroscopy, revealing excellent agreement with the designs. Under optical excitation using wavelength-tunable femtosecond lasers with linear polarization along the principal axis of the gold teardrop nanoantennas, we observed directional photocurrents by directly reading out the time-averaged photocurrents, the magnitude of which also revealed strong dependence on the excitation wavelength, with highest photocurrents right at the resonance wavelength. The ultrafast characteristic of the generated photocurrents was verified by successful probing of emission of picosecond pulses (i.e., broadband THz radiation) to free space, measured in the time domain (Fig. 1(c)). The radiated THz pulses provide indications of the light-matter interactions and hot carrier dynamics, limited here only by the bandwidth of the THz detector. Our experiments showed that this THz emission is highly efficient, approaching that of a widely used THz emitter (1-mm-thick ZnTe nonlinear crystal) under the same experimental conditions. With this result, we continued to investigate optoelectronic metasurfaces with designer spatial profiles of gold teardrop nanoantenna orientation, and successfully generated high-quality radial and azimuthal THz vector beams when the nanoantenna orientation is aligned at the radial and azimuthal directions, respectively.

By judicious considerations of symmetry-breaking in structural designs and integration of materials with desirable properties, hybrid nanoplasmonic metasurfaces can provide a pathway for the generation and control of nanoscale ultrafast directional currents. Such optoelectronic metasurfaces can also inspire the discovery of new efficient THz sources [2] and the direct generation of arbitrary THz (vector) beams, thus manifesting the importance of metasurfaces for advancing THz science and technology [3].

Piezoelectric Shifter for Wideband Tunability in Chalcogenide Metamaterials

Abstract: A large-area thin film, with position carefully controlled by a piezoelectric transducer, can be used as a "shifter," a mechanism that provides a large shift in the resonance of a metasurface. Designs for such devices, based on chalcogenide glasses (ChGs) and operating in the midwave infrared (MWIR) are presented, demonstrating resonance shifts of >400 nm for a shifter translation of only several hundred nanometers.

Tunability has been long sought after in photonic metamaterial devices. A variety of approaches to achieving tuning have been explored including mechanical tuning, i.e. physically changing the geometry of a device; incorporating a material with tunable optical properties such as a phase change material or liquid crystal; applying electromagnetic fields; or by incorporating a material with optical nonlinearity [1,2]. Each of these methods has distinct advantages for different types of devices, yet it remains challenging to provide optical tuning over large bandwidths, on the order of hundreds of nanometers.

One promising approach is to provide tuning with a piezoelectric transducer. Some recent work has taken advantage of piezoelectric transducers to alter the near-field environment of a metamaterial and thus produce tuning [3,4]. To date, most work has shown small changes in optical properties and provided tuning over a small physical area. For many applications, tuning over large bandwidths and large areas is required. To do so, a piezoelectric shifter configuration is evaluated. In the proposed configuration, illustrated in Fig. 1 where (a) shows the top view of a metasurface (MS) and (b) shows the device in cross section, a piezoelectric actuator is used to operate a shifter—an optically transparent thin film that changes the near-field environment of the MS. The shifter is displaced above the waveguide by *d,* the shifter spacing, and a piezoelectric actuator is employed to vary *d*. When the shifter assembly is sufficiently close to the waveguide, it alters the position optical response of the MS. Fig. 1(c) shows simulation results for these devices indicating that, for the design illustrated, varying *d* from 0-600 nm changes the position of a resonance of the structure from approximately 4.1 to 3.65 μm, a change of >400 nm.

To experimentally demonstrate this effect, we designed and fabricated several devices based on arsenic sulfide (As_2S_3) glass, a ChG with high MWIR transparency. Bulk As_2S_3 samples were batched from purified precursors in an N_2 purged glovebox, melted, and quenched to obtain a glass boule. Small pieces of the boule were used as deposition sources. Films of As_2S_3 were deposited via thermal evaporation while maintaining the substrate at approximately 25 °C.

Prior to testing the shifting approach with a MS, experiments were first carried out with a waveguide device, where the shifter is applied to tune the effective index, n_e, of the waveguide, in order to ensure that the mechanism works over a large area. For these experiments, we used a MWIR nonmechanical beam steering (NMBS) chip [5] that consists of a silicon substrate and a planar waveguide with an As_2S_3 subcladding, and an

As_2Se_3 core. A shifter, consisting of 500 nm of As_2S_3 on a CaF_2 substrate is brought into near-contact with the waveguide. A quantum cascade laser with a wavelength of 4.7 μm is coupled into the waveguide. A piezoelectric transducer is used to control *d* by moving the shifter position. Steering is achieved by varying n_e in the output coupling region. In this experiment, steering angles of up to ~8 mrad were observed, showing that modulation of n_e has been achieved. Experiments to apply this same approach to a MS in order to shift its resonance are ongoing.

Ultrathin Titanium Nitride Epitaxial Structures for Tunable Infrared Plasmonics

Shangjr Gwo

National Tsing-Hua University, Taiwan
shangjr@hotmail.com

Abstract: Titanium nitride (TiN) is an excellent material for infrared plasmonics due to unique optical properties (comparable to gold), refractory material nature, mechanical and chemical stabilities, as well as bio- and CMOS compatibilities. In this work, we demonstrate that ultrathin and scalable TiN epitaxial structures can be applied for tunable infrared plasmonics, extending from near- (NIR) to mid-infrared (MIR) spectral region.

Nanophotonics-based chiroptical sensing of drug solutions

R. Adhikary[1], A. Sahoo[1], M. Aschi[1], I. Daidone[1], M. Silvestri[1], M. Venturi[1], C. Ferrante[2], A. Mecozzi[1] and A. Marini[1*]

Abstract: We theoretically model the bi-anisotropic linear response of reparixin, ladarixin and levodropropizine solutions, discussing the potential of photonic crystal fibers, metasurfaces and photonic nanostructures for chiroptical sensing of drug solutions.

Chirality plays a central role in fundamental and applied physics, chemistry, biology and pharmaceutics, where the specific enantiomeric form of drugs affects their functionality, as in particular pharmacodynamics, pharmacokinetics and toxicity [1]. In turn, chiral sensing plays a central role in pharmaceutics, drug discovery and particularly in nanomedicine to optimise biological tissue penetration and to gain enhanced control of contrast agents, detection markers and biosensors. Currently, the enantiomeric excess of chiral molecular mixtures is assessed by nuclear magnetic resonance, X-ray crystallography, gas chromatography, capillary electrophoresis and high performance liquid chromatography. However, such techniques are not suitable for real-time analysis, lab-on-a-chip integration and wider nanomedicine applications.

Here we discuss the potential of nanophotonics-based devices for chiroptical sensing of drug solutions. Specifically, we focus on isotropic assemblies of reparixin (an inhibitor of the CXCR2 function attenuating inflammatory responses [2,3] that has been adopted in clinical trials for the treatment of hospitalized patients with COVID-19 pneumonia [4]) dissolved in water with dilute number molecular density of the order $n_{mol}=n^{(R)}_{mol}+n^{(S)}_{mol} \approx 10^{-2}$ nm^{-3} (corresponding to a concentration of 5 mg/ml), where $n^{(R,S)}_{mol}$ indicate the number densities of R and S enantiomers, respectively. We further focus on ladarixin dissolved in water and levodropropizine dissolved in a mixture of ethanol and hexane (40:60 volume ratio). Our results are based on molecular dynamics (MD), time-dependent density functional theory (TD-DFT) and Perturbed Matrix Method (PMM) simulations for the calculation of the drugs electronic structure and of their static and transition electric/magnetic dipole moments. All macroscopic optical parameters (including the dielectric permittivity ε_r, the magnetic permeability μ_r and the chiral parameter κ of the isotropic chiral mixtures, see Fig. 1) are calculated from first principles by perturbatively solving the density matrix equations accounting for the leading electronic absorption peaks and by averaging the obtained first/second-order hyper-polarizability tensors over the random molecular orientation through the Euler rotation matrix approach.

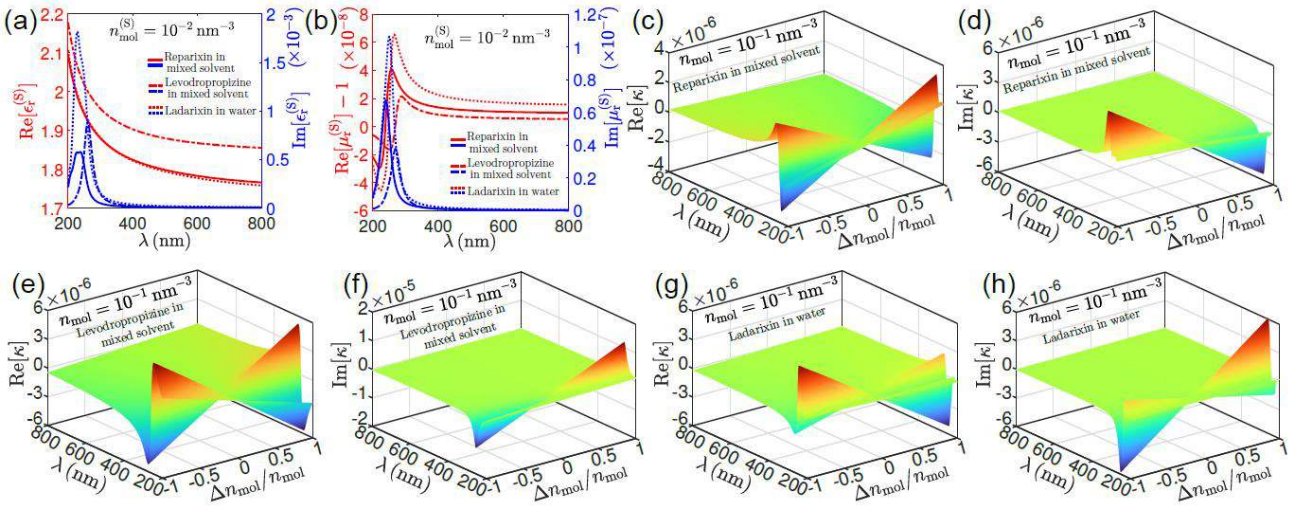

Fig. 1 Real (red curves) and imaginary (blue curves) parts of the **(a)** relative permittivity ϵ_r and **(b)** permeability μ_r of the S-type chiral enantiomer of the three pharmaceutical molecules (with concentration $n_{mol} = 10^{-2}$ nm^{-3}) in different solvents. Here, the left (red) and right (blue) axes represent the real and imaginary parts of ϵ_r and μ_r. The solid curves correspond to reparixin dissolved in $CH_3CN + H_2O$ (50:50 volume ratio), the dashed curves indicate levodropropizine dissolved in $C_6H_{14} + C_2H_5OH$ (40:60 volume ratio), and the dotted curves correspond to ladarixin dissolved in water. **(c,e,g)** Real and **(d,f,h)** imaginary parts of κ as a function of wavelength (λ) for relative concentration ($\Delta n_{mol}/n_{mol} = [n^{(S)}_{mol} - n^{(R)}_{mol}]/n_{mol}$) of an enantiomeric mixture of R and S enantiomers.

Abstract: Here, we will demonstrate how the fusion of optical fibers with nanostructures creates a new category of fiber-integrated devices – hybrid optical fibers - that unlocks novel applications. We achieve this by leveraging 3D nanoprinting, which is highly compatible with the fiber geometry, to integrate high-NA holographic meta-lenses, achromatic metasurface-based lenses, and dielectric ring-like gratings onto the end faces of single-mode fibers, allowing to trap biological relevant objects, to focus light across the telecommunication range, and to boost incoupling efficiencies.

The development of nanostructures on the end faces of commercially available optical fibers offers a promising approach for unlocking new functionalities across various fields, such as biophotonics, quantum technologies, and optical sensing. However, conventional top-down fabrication methods are challenging to apply to optical fibers due to their unique geometry that differs from commonly used wafers [1,2]. In this presentation, we show our recent findings on 3D nanoprinting using direct laser writing, which circumvents this bottleneck. With this approach, we can implement intricate nanostructures on the end face of optical fibers, resulting in significant performance enhancements compared to fibers with unstructured end faces, as demonstrated in the following examples.

Optical trapping with single fiber (Figs. 1(a) and (b)): Effective focussing of light is crucial for various applications, such as optical imaging and microscopy, biophotonics, quantum technology, and materials processing. However, optical fibers have limitations in that respect due to the divergence of light emitted from the fiber facet. Note that to achieve single-focus optical trapping, a numerical aperture of greater than 0.8 is necessary. In this study, we used 3D nanoprinting to integrate ultra-high numerical aperture holographic meta-lenses onto functionalized single-mode fibers [3]. By considering the fiber environment, we achieved a record-high numerical aperture of up to 0.9 with diffraction-limited spots. This breakthrough allowed us to optically trap microspheres and biologically relevant bacteria, such as E. coli, with individual single-mode fibers, overcoming a significant limitation in fiber optic research.

Achromatic light focusing (Figs. 1(c) and (d)): The efficient and tailored focusing of light is crucial for future applications of optical fibers. An open issue in the field of telecommunications is achromatic light focusing, for which no satisfactory solution exists so far. By integrating a nano-printed metasurface-based lens onto a fiber, we have been able to achromatically and efficiently focus the output light of a SMF-28 over the entire telecommunications range [4]. Crucial here is the possibility of realizing nanopillars of different heights within one single metasurface, which is a unique feature provided by the nanoprinting process and has actually enabled the wavelength independent focussing of the light. With the conducted study we could thus show that metasurfaces can be very relevant for fiber optic applications with respect to telecommunication.

Boosting in-coupling efficiency (Figs. 1(e) and (f)): Conventional commercial fibers suffer from the limitation of low numerical aperture, which restricts light coupling to small angles. To address this problem, we have integrated axial-symmetric nanogratings consisting of nanoprinted concentric rings onto the core of single-mode fibers (SMF-28) [5]. This integration has already resulted in an impressive improvement of coupling efficiency at near-grazing incidence by more than four orders of magnitude compared to fibers with unstructured end faces. This improvement is based on an additional wave vector provided by the grating, which suppresses the electric field oscillation on the fiber surface at a certain angle, thereby allowing for exciting specific fiber modes. Additionally, we were able to achieve incoupling at preselected angles and across large angular intervals by employing an optimization procedure and 3D nanoprinting. This approach has helped to overcome the low numerical aperture limitation of commercial fibers and can lead to advancements in the field of fiber optics.

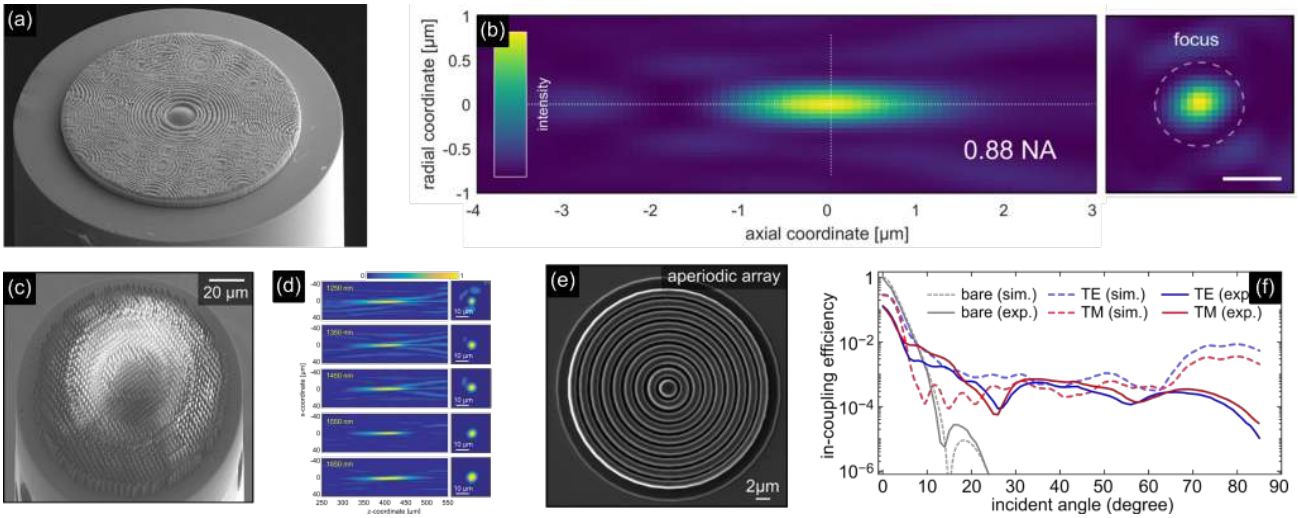

Fig. 1: Examples of printed nanostructures on optical fibers. (a) High-NA holographic metalens located on the end face of an optical fiber [3]. (b) Corresponding measured beam profile in water (632 nm). (c) Nanopillar-based metasurface located on an optical fiber and used for achromatic light focusing [4]. (d) Measured profile of the focus at different telecommunication wavelengths. (e) An aperiodic nano-grating on SMF-28 [5]. (f) Measured coupling efficiency vs. angle of incidence for a bare fiber (gray) and a nanostructured-interfaced fiber (1.55 µm).

We have demonstrated that the integration of optical fibers with nanostructures results in a new category of fiber-integrated devices that offer unprecedented applications in fiber optics. With the implementation of versatile application strategies, we anticipate broader use of nanostructured fibers in various fields, including quantum technology, bioanalytics, and nanophotonics.

Modulating and Spinning thermal radiation with incandescent metasurfaces

B. Vest[1]

[1]Université Paris-Saclay, Institut d'Optique Graduate School, CNRS, Laboratoire Charles Fabry, 91127, Palaiseau, France.

[*]email: benjamin.vest@institutoptique.fr

Abstract: Blackbody radiation is intrinsically isotropic, broadband and unpolarized. However, these properties can be strongly modified using appropriate nanostructures. Here we report about the design, fabrication and characterization of incandescent metasurfaces based on subwavelength metallic gratings. When heated by Joule effect, the grating acts as a thermal emitter that can be modulated at frequencies higher than the MHz. The system geometry can also be engineered to provide circularly polarized light with a polarization degree around 35%.

Thermal emission is an intrinsically incoherent process, delivering broadband, isotropic and unpolarized radiation. Therefore, generation of a circularly polarized beam from an incandescent source generally requires the use of several components, such as filters and waveplates, in order to provide the adequate retardance at chosen frequencies. This limits the compactness of the whole device. In this presentation, we report about the design, fabrication and characterization of thermal metasurfaces, designed to provide light at fast modulation regimes, and that can be designed to provide either linearly or circularly polarized light in the mid-wave infrared domain. We follow a design method based on a generalized Kirchhoff's law approach : we engineer the absorptivity features of the metasurfaces in order to shape the properties of light emitted by the structure by reciprocity [1].

In the first part of the presentation, we report the performances of a device designed to achieve fast modulation of IR emission (see Fig. 1). In our work, the emission modulation relies on fast temperature modulation of thin emitters placed on a cold substrate [2]. Thanks to heat conduction, the emitters can cool down within a characteristic time which varies as the square of its thickness. In the proposed structure, we use a sub-wavelength metallic grating as the emitting source, thus demonstrating a MWIR source linearly polarized with the emission modulation up to 10 MHz.

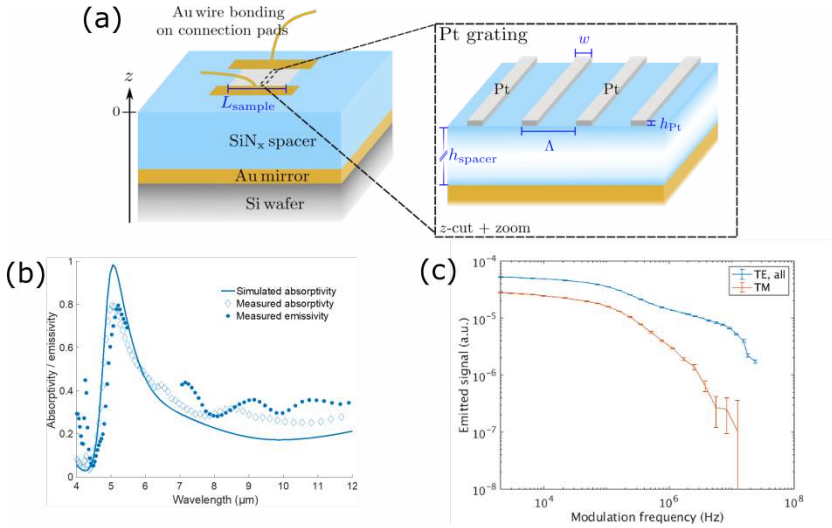

Fig. 1 Experiments on fast modulation of incandescence. (a) Design of the structure. The platinum grating lays the role of the emitting source (b) Simulated and experimentally measured absorptivities and emissivities showing peak emission at 5.5 µm. (c) Evolution of the average emitted power as a function of modulation frequency in both polarizations.

In the second part, we present a similar where the top surface is paved with a subwavelength metallic grating following a chiral pattern [3] (See Fig 2.). The dimensions of the system are chosen in order to make the grating a good chiral absorber : we maximize the contrast in absorption of the system when illuminated respectively by right-handed circularly polarized light (RCP) and left-handed circularly polarized light (LCP). The top metallic grating is then heated by Joule effect. It acts a thermal emitter with a contrast in emissivity between LCP and RCP.

We designed a specific protocol to accurately measure the different Stokes vector components of the highly polychromatic emission over a broad range of wavelengths between 3 and 5 microns, thus evaluating with precision the polarization state of the infrared light as a function of the emission wavelength. Our devices emits light with a degree of circular polarization (DCP) up to 35% at 4.7 microns, to be compared to simulations predicting a maximum of 50% for our design.

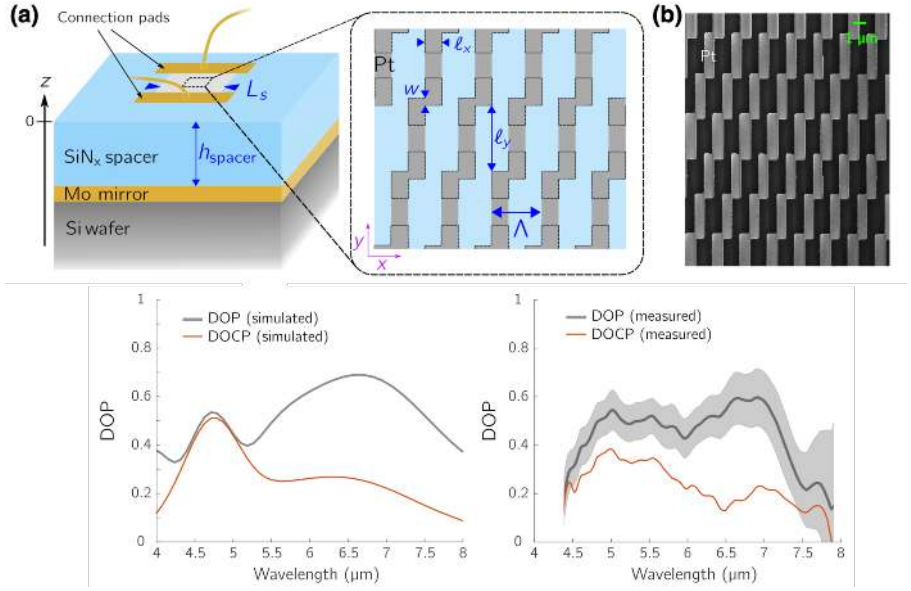

Fig. 2 Experiments on circularly polarized light emission of incandescence. (a) Design of the structure. The platinum grating follows a chiral pattern (b) SEM picture of the fabricated device. (c) Simulated and measured degree of polarization (DOP) and degree of circular polarization (DOCP). Shaded areas represent one-sigma error bars.

Our system paves the way towards cheap and compact devices to generate infrared light with a decent DCP using only one single component, for applications in communication, sensing, security and counterfeiting.

Full color Imaging with Large-Aperture Meta-Optics

Abstract: By exploiting computational backend, coupled with a designer meta-optics we demonstrate high-quality imaging using a single meta-optics with an aperture of 1cm.

The miniaturization of image sensors in recent decades has made today's cameras ubiquitous across many application domains, including medical imaging, smartphones, security, robotics, and autonomous transportation. However, only imagers that are an order of magnitude smaller could enable novel applications in nano-robotics, in vivo imaging, mixed reality, and health monitoring. While sensors with sub-micron pixels exist now, further miniaturization has been primarily prohibited by fundamental limitations of conventional optics. Traditional imaging systems consist of a cascade of refractive elements that correct for aberrations, and these bulky lenses impose a lower limit on camera footprint. A further fundamental barrier is the difficulty of reducing focal length, as this induces greater chromatic aberrations.

We employ computationally designed meta-optics to close this gap and enable ultra-compact cameras that could allow for unprecedented capabilities in bio-imaging or mixed reality systems. Ultrathin meta-optics utilize subwavelength scatterers to modulate incident light with greater design freedom and space-bandwidth product over conventional diffractive optics. Existing meta-optics, however, achieve an order of magnitude higher reconstruction error than achievable with refractive compound lenses due to severe, wavelength-dependent aberrations that arise from discontinuities in their imparted phase. Dispersion-engineered meta-optics aim to mitigate this by exploiting group delay and group delay dispersion to focus broadband light, but this technique is fundamentally limited, constraining designs to apertures of only ~10's of micron with low f-number (high numerical aperture). As such, existing approaches have not been able to increase the achievable aperture sizes without significantly reducing the numerical aperture or supported wavelength range. Other attempted solutions only suffice for discrete wavelengths or narrowband illumination, which cannot be used for broadband imaging under ambient light.

Figure 1: 1cm meta-optics integrated camera.

Our solution is to design the meta-optics such that the modulation transfer function (MTF) of all the wavelength across the desired optical bandwidth are same at the sensor plane. Additionally, the area under the MTF curve needs to be large, such that enough information is captured and the orginal image can be reconstructed. Same intuition can be employed for different angles to mitigate the geometric aberrations as well. However, designing such meta-optics is not trivial.

We have developed essentially three different methods to solve this problem. In the first approach we used well-known designs of extended depth of focus (EDOF) meta-lenses, such as cubic [1] or log-asphere lenses [2]. Such EDOF property allows light at different wavelengths to reach the sensor in identical way. The computational backend involves either Wiener filtering or Total-Variation (TV) regularization. In the second approach, we employ inverse design to create the meta-optics, but the computational post-processing remains same [3,4]. Finally, we can co-design the meta-optics and computational algorithm. Such an "end-to-end" designed optics and computational algorithm [5] can provide high quality imaging. Specifically we obtained photographic-quality imaging with a single meta-optics,

rendering the total volume of the sensor at least four orders of magnitude smaller. The image quality improves from the first to last approach, while the design becomes more complex. By exploiting rotational symmetry and different field propagators, we recently extend the designs to upto 1cm diameter, which for the first time allows comparing imaging between a refractive and a meta-optics. Figure 1 shows the fabricated metalens and direct integration with a camera. We then compare the imaging between different versions of the 1cm meta-optics and refractive for an OLED screen in lab (Figure 2). Finally, we performed imaging under ambient light (Figure 3).

Flat Optics for Dynamic Wavefront Manipulation

Mark Brongersma

Stanford University, United States
*corresponding author: brongersma@stanford.edu

Abstract: Since the development of diffractive optical elements in the 1970s, major research efforts have focused on replacing bulky optical components by thinner, planar counterparts. The more recent advent of metasurfaces, i.e. nanostructured optical coatings, has further accelerated the development of flat optics through the realization that nanoscale antenna elements can be utilized to facilitate local and nonlocal control over the light scattering amplitude and phase.

In this presentation, I will highlight our recent efforts to realize electrically-tunable metasurfaces employing nanomechanics, microfluidics, phase change materials, and atomically-thin semiconductors. Such elements are capable of dynamic wavefront manipulation for optical beam steering and holography. I will also discuss how the nanostructured, planar optical elements can be fabricated by scalable fabrication technologies, opening the door to a wide range of commercial applications.

Tailoring the visual appearance with disordered arrays of resonant metaatoms

Abstract: Metasurfaces have flourished in the last few years thanks to their extraordinary capabilities in the manipulation of light. In this work, we propose a theoretical tool that can effectively and intuitively predict the visual appearance of disordered resonant metasurfaces.

In a recent work, some of the authors succeeded in designing the very first simulation tool to predict the appearance of disordered metasurfaces made of array of resonant meta-atoms [1]. The modelling platform may find use in several branches of visual arts, to predict the appearance of augmented reality devices using metasurfaces, design unusual effects for counterfeiting applications or luxury goods …

Importantly, the tool predicts the possibility to create fancy appearances, unseen so far with the nanostructures available in nature,

see also the Supplementary Videos 1 & 2 in [1] for a rapid glance.

The tool in [1] relies on an approximate model that predicts the Bidirectional Reflection Distribution Function (BRDF) of disordered metasurfaces. Because the BRDF is a huge multidimensional function, the tool relies on repeating many full-wave electromagnetic simulations for all wavelengths, incidence angles and polarizations of the incident light. However, such a brute force approach is inefficient and, more importantly, completely hides the physics. It clearly lacks from intuition and does not provide any feedback on how the nanoscale morphology affects the BRDF first, and subsequently the visual appearance.

We need a tool not only for calculating but also for understanding the processes and for conceptualizing the problem before we even begin to calculate. In this work, such a tool is proposed, implemented and tested for disordered metasurfaces made by silver nanoparticles deposited on a reflective substrate coated with a submicrometric SiO_2 spacer [2]. The tool is

based on recent advances [3] on the analysis of electromagnetic nanoresonators in the basis of their natural resonance modes, also known as quasinormal modes (QNMs). We stress that the modal tool not only result in a considerable reduction of the computational loads, but also provides an advanced conceptualization of the form factor which unveils the physics and the control knobs at play to harness the appearance. The tool quantitatively predicts and intuitively explains a remarkable iridescence phenomenon, in which the diffuse light exhibits only two **very distinct** colors, irrespective of the viewing and illumination directions [2]. The modal tool also explains why, despite the renowned strong sensitivities of the resonance wavelength of nanoresonators to shape and size variations that are present in our samples, the observed colors remain vivid and accurately predicted with simulations assuming monodispersity. This resilience to fabrication imperfections is crucial for genuine applications because it considerably lowers fabrication costs and enables large-scale fabrication.

Lithography-free control of thermal emission.

M. Sarkar, M. Giteau, M.T. Enders and G. T. Papadakis*

Abstract: Blackbody thermal emission is spatially diffuse. Achieving highly directional thermal emission typically requires nanostructuring the surface of the thermally emissive medium. Here, we revisit the simple motif of a planar Salisbury screen and show that hexagonal Boron Nitride thin films can enable grating-like thermal emission lobes in a lithography-free platform.

Gaining control over the spatial and spectral characteristics of mid-infrared (IR) thermal emission is central to various applications like thermophotovoltaic systems, radiative cooling, IR sources, thermal camouflage and molecular sensing[1]. Blackbody thermal emission is spectrally broad and spatially diffuse, however with photonic design, one can narrow the spectral range and control the directionality of thermal emission[2]. Previously, this was achieved by coupling light into the phonon polaritons in polar materials[3]. To couple into these modes and to achieve strong directionality, typically, one requires a grating structure [4]. Other than being lithographically complex, this approach is also limited to p-polarization.

In contrast, here we introduce an approach that allows omni-polarization directional control of thermal emission without *any* lithography. To achieve this, we leverage the strong dielectric permittivity resonances of polar materials. We introduce design rules for achieving both narrowband diffuse and narrowband directional thermal emission in a three-layer heterostructure.

Our meta-structure is shown in Fig 1a. It is based on the Salisbury screen configuration[5]: a dielectric spacer layer is sandwiched between a thin lossy emitter and a perfect electric conductor (PEC). For maximum emissivity at a given incidence angle θ, it is necessary for light to experience constructive interference in the spacer. Considering an acquired phase of π and Ψ for reflections at the PEC and lossy material respectively, we derive the condition for constructive interference:

$$2k_0 h_m \aleph_m + \pi + \Psi = 2l\pi \quad (1)$$

where l is an integer denoting the interference order and $k_0 = 2\pi/\lambda$, with λ the wavelength of light. The emitter (with subscript e) and the spacer (with subscript m) can be considered anisotropic, having a diagonal permittivity tensor with elements ϵ, ϵ/α_Y^2 and ϵ/α_Z^2 along x, y and z axes respectively. The terms $\aleph_Z^2 = \epsilon - \alpha_Z^2 sin^2\theta$ and $\aleph_Y^2 = (\epsilon - \alpha_Y^2 sin^2\theta)/\alpha_Y^2$ are the effective index of the anisotropic medium. It can be shown that for maximum directional control, we need $\Psi = \pi$ while, for minimum angular dependence, (diffuse thermal emission), we need $\Psi = 0, 2\pi$. We have derived the acquired phase on reflection from the lossy material as

$$\Psi_P = \pi - 2tan^{-1}\frac{\aleph_{Ze}\,\epsilon_m}{\epsilon_e \aleph_m}\frac{\epsilon_e cos\theta + i\aleph_{Ze}T_e}{\epsilon_e cos\theta\, T_e - i\aleph_{Ze}} \quad (2)$$

for P polarization with $T_e = tan(h_e k_0 \aleph_{Ze/Ye})$. A similar equation can be derived for the S polarization.

By optimizing the geometrical parameters of the metastructure and using Eq.1 and Eq.2, complete directional control can be achieved. We demonstrate this concept with hexagonal Boron Nitride (hBN) as the emitter[6]. The

high permittivity near the phonon resonances (Reststrahlen band) of hBN allows for strong directional control while the narrow bandwidth of these resonances also yields spectral control. This is shown in Fig 1c and d for the metastructure and the directional control achieved is comparable to lithographically complex nanostructures (grating) shown in Fig.1b.

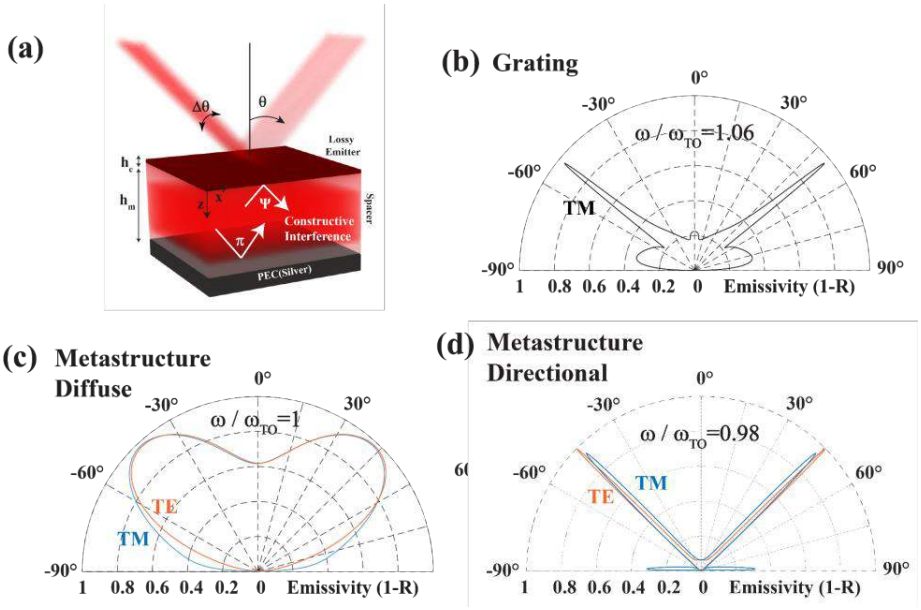

Figure 1 a) The schematic of the meta-structure in the Salisbury screen configuration. b) The polar plot for P polarized emission from a grating structure[2] for a frequency in the center of the Reststrahlen band of hBN. (c) The polar plot for the meta-structure for diffuse emission for both P and S polarizations. (c) The same for a frequency where the emission is directional for both polarizations.

In this work, we present a method to bypass the inherent difficulty in achieving strong spatial and spectral control of thermal emission. We present a standard geometry involving a Salisbury screen and, via optimizing the emitter and spacer thicknesses, we have shown that one can strongly confine light emitted due to the volume polaritons of polar materials in the lossless spacer.

Abstract: The plasmonic phase-change material In_3SbTe_2 can be reversibly switched from an amorphous dielectric to a crystalline metallic state. Infrared emissivity control by patterning a grating absorber metasurface for different polarizations, which can be only seen in the long-wave infrared regime, is demonstrated. Additionally, a 1x1 cm² metasurface is fabricated with enhanced emissivity to display an apparent local temperature pattern.

Metasurfaces with perfect infrared absorption promise integrated filters and compact detector elements with narrowband thermal emission. Phase-change materials (PCMs) are prime candidates for active, non-volatile absorption tuning [1]. Commonly, the response of the entire metasurface is tuned, while local adaptions remain elusive. Currently, a novel material class of switchable infrared plasmonic PCMs, like In3SbTe2 (IST), is emerging. Since IST can be locally optically switched between dielectric (amorphous phase) and metallic (crystalline phase) states in the whole infrared range, it becomes possible to directly change the geometry and size of nanoantennas to tune their infrared resonances [2,3]. In this work, we show flexible encoding of different absorption/emission properties within a metasurface. We employ the plasmonic PCM IST to obtain control over the emissivity by patterning an adaptable grating absorber metasurface. Using a commercial direct laser writing setup, we locally switch the IST from an amorphous dielectric into a crystalline metallic state and write cm-sized stripe gratings above a reflecting mirror. We demonstrate modification of already written patterns by changing the laser power and thus the IST stripe width to encode different polarization-sensitive patterns with nearly perfect absorption into the same metasurface. Finally, we measure an apparent local temperature pattern due to our large-area emissivity shaping metasurface with a conventional thermal camera [4]. Our results pave the way towards low-cost, large-area and adaptable patterning of metasurfaces with wavelength and polarization-selective perfect absorption, enabling applications like enhanced thermal detection, infrared camouflage or encoding anti-counterfeiting symbols.

Shape-multiplexed conformable holographic metasurfaces

Sebastian A. Schulz[1], Jianling Xiao[1], Robert. I. Hunter[1], Duncan A. Robertson[1], Graham M. Smith[1], Simon Horsley[2], Andrea Di Falco[1]

[1]SUPA, School of Physics and Astronomy, University of St Andrews, St Andrews, UK

Abstract: Conformal metasurfaces hold great potential for retro-fitting optical functionality and decoupling the complexity of the final shape from the constraints of nanofabrication. Here we demonstrate a reflective conformable metasurface that shows one of two independent holographic images, where we can switch between two independent holographic images, by changing from a concave to a convex shape and vice versa.

Metasurfaces - two-dimensional distributions of meta-atoms – allow control over the phase, polarization and amplitude of scattered light [1]. Within metasurfaces two developments are of particular interest, flexible and conformable metasurfaces, and multiplexed metasurfaces. In multiplexed metasurfaces different, independent information is encoded into different states (e.g. polarization or wavelength) of light [2], enabling applications such as encryption, sensing or displays [3-5]. Flexible and conformable metasurfaces on the other hand can be used to encode and retrieve information [6] or decouple the optical response from an object's shape [7] when applied to non-flat surfaces. Here we combine these two fields and present a conformal metasurface that displays two independent holographic images, dependent on the curvature of the object that it is applied to [8].

Fig. 1(a) and (b) show a schematic of the metasurface and its operation. When in a convex shape the displayed hologram features two focal spots, in the top left and bottom right corner of the image plane respectively. However, when in a concave shape the metasurface displays a holographic image featuring three focal spots

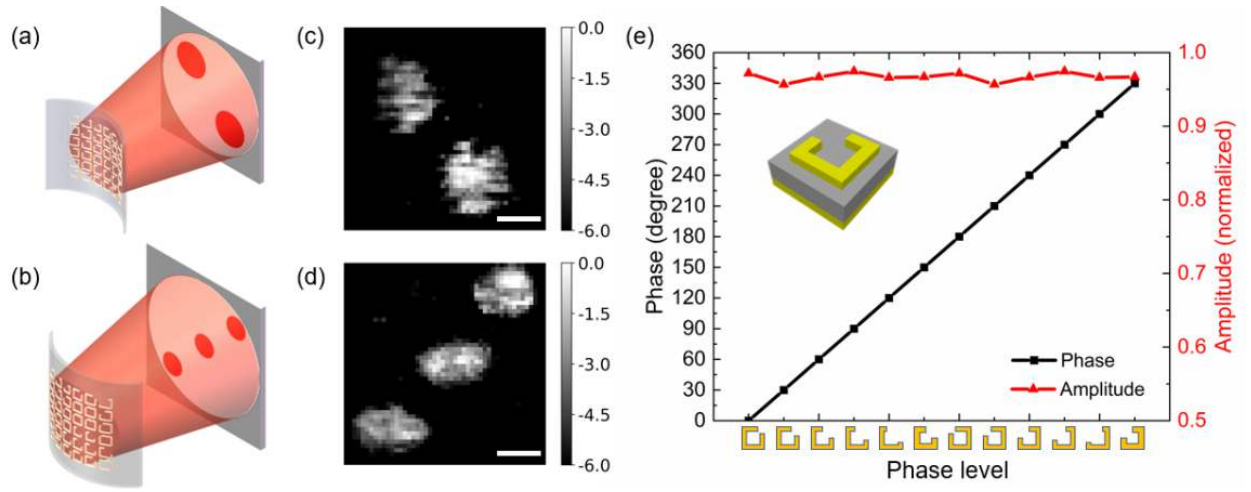

Figure 1: Schematic of the (a) convex and (b) concave operation of the metasurface. (c) and (d) experimental observation of the expected holographic image, obtained at 94 GHz. The scalebar corresponds to 20 mm. (e) Phase and amplitude response of the underlying c-ring resonators that form the meta-atoms.

along the opposite diagonal, i.e. from the bottom left to the top right corner of the image plane.
For our experimental realization of these images (see fig. 1(c) and (d)), we implement a radius of curvature of 35 mm and -100 mm for the convex and concave shape respectively. These images are obtained using a reflective metasurface operated in the mm-wave regime (illuminated with 94 GHz mm-waves). The metasurface consists of an array of copper c-ring resonators with varying gap positions and sizes, giving us a uniform amplitude response and 12-level full 2π-phase coverage, as shown in Fig.1(e). The c-ring resonators have a thickness of 200 nm and are on a 380 μm PMMA layer, followed by a 200 nm copper back reflector. This is a mm-wave band implementation of the popular, high-reflectance metal-dielectric-metal metasurface geometry [7].
To achieve the shape multiplexing we interleave two independent holograms, each designed for the relevant radius of curvature of the metasurface, using the Gerchberg-Saxton algorithm, with the Rayleigh-Sommerfeld integral as a propagator.
We believe that the demonstration of shape-multiplexed metasurfaces paves the way towards novel applications in reconfigurable antennas, optomechanical sensors, and actuators across a wide range of wavelengths and operating bands.

Rotary metaswimmers powered by linearly polarized light

M. Shanei[1*], E. Engay[1], V. Mylnikov[1], and M. Käll[1]

[1] Department of Physics, Chalmers University of Technology, Gothenburg, Sweden

[*]corresponding author: mahdi.shanei@chalmers.se

Abstract: Metasurfaces offer great possibilities to manipulate the momentum of light. Changes in linear optical momentum can result in forces and torques acting on a movable metaswimmer. Here, we demonstrate that by spatially distributing the changes in the linear momentum of light across the metasurface, these optomechanical effects can be utilized to generate optical torques able to rotate metaswimmers that are tens of micrometers wide in aqueous environments. We delineate the counterintuitive dynamics resulting from physical and hydrodynamic interactions between metaswimmers.

Metasurfaces are flat structures with engineered subwavelength building blocks that provide various possibilities for tailoring optical forces and momentum exchange. In the process of shaping a light beam, a metasurface is itself subject to momentum exchange and optical forces. This effect can be observed if a metasurface is incorporated into a micro-scale object allowed to move freely across a surface [1,2]. In this work, metaparticles are designed based on defining silicon-based deflectors that mimics conventional blazed gratings. The deflection of light from the propagation axis by the grating adds an in-plane linear momentum onto the outgoing beam. Conservation of the system's total momentum generates a reaction force that results in the translation of the particle as shown in Fig 1.

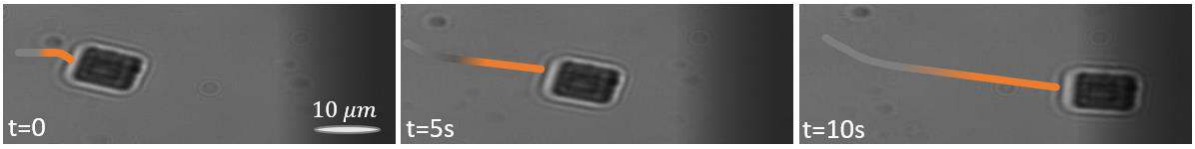

Figure 1. Translation of a metaswimmer due to the reaction force resulting from high-angle deflection of an incident plane wave.

The exchange of linear momentum between light and matter can also be exploited to rotate particles and micro-swimmers. Different approaches have been used to rotate an object with a linearly polarized plane wave [3], such as using chiral or birefringent structures, breaking the symmetry of objects, or utilizing unbalanced light-matter interactions in different sections of a particle. Figure 2 illustrates that when a spatial dependency is added by placing different grating orientations on the body of a metaswimmer, the interaction of the incident light and the meta-swimmer can generate an optical torque. In this presentation, we will discuss the fabrication, optical properties, dynamics and mutual interactions of rotary metaswimmers that range in lateral size from a few microns to several tens of microns, while still being essentially flat. We envisage that these kinds of structures could find use in microfluidics and bionanotechnology, and may serve as testbeds for probing the dynamics of physically diverse systems, such as microorganisms or other biological entities.

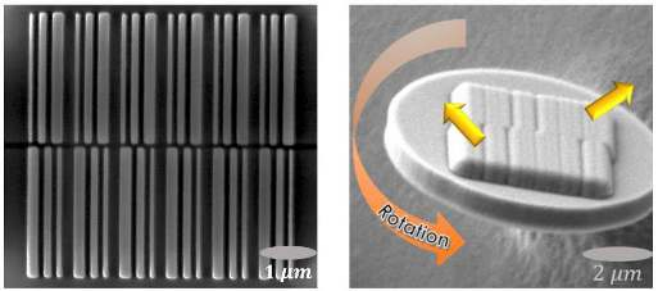

Figure 2. SEM images of a rotary metaswimmer propelled by the deflection of incident light in opposite directions.

Abstract: Active metasurfaces provide unique advantages for on-demand light manipulation at a subwavelength scale for emerging applications of 3D displays, augmented/virtual reality (AR/VR) and light detection and ranging (LiDAR). Here, we introduce an electrically active Huygens' metasurface based on in-situ grown conductive polymer with holistic switching performance. Our active metasurface design can be readily incorporated into other metasurface concepts to deliver high-reliability electrical control over optical response, paving the way for compact and robust electro-optic metadevices.

Active metasurfaces, often alternatively termed as tunable or reconfigurable metasurfaces, are rapidly emerging as a major frontier in photonic research and have launched tremendous breakthroughs in modern optics[1]. Compared with their passive counterparts, active metasurfaces consist of ultrathin planar arrays of subwavelength active nanoantennas, whose optical responses can be dynamically modulated on-demand. The active tuning schemes mainly rely on varying optical properties of the nanoantennas or their surrounding materials through chemical reactions[2], mechanical displacements[3], electrical switching[4], thermal modulation[5] and all-optical switching[6]. Among these modulation schemes, electrical switching is of particular interest because it promises compact integration of meta-optics with miniaturized on-chip electro-optic systems, which can be readily incorporated into electronic smart devices for practical applications[1], such as 3D displays, augmented/virtual reality (AR/VR) glasses, dynamic holograms, beam steering and light detection and ranging (LiDAR).

To this end, a number of active metasurfaces have been implemented by using different electro-active materials. Previous active metasurfaces exhibit only distinct subsets of key performance metrics[1], including switching speed, cycling duration, controllability over intermediate states, modulation contrast, optical efficiency and operation voltages. However, these performance attributes are hardly met simultaneously, making them almost impossible for any practical use. For instance, even though phase-change-materials metasurfaces can provide a switching speed of up to 2 MHz[7], they require high operation voltage and large cell manipulation. Recently, conductive polymers have shown many desired properties for electrically active metasurfaces, such as large variation of refractive index, fast switching speed, superior cycling stability and low operation voltages[8]. However, previous active metasurfaces purely based on conductive polymers are disadvantaged by low diffractive efficiency, due to the geometric phase design and the weak resonant nature of the nanostructured polymer[4]. Moreover, the fabrication of the conductive polymer relying on spin-coating prevents long-term switching durability since the contact issue between the polymer and the substrate.

In this work, we introduce an electrically active Huygens' metasurface based on the in-situ grown conductive polymer, polyaniline (PANI), and experimentally demonstrate its holistic active switching performance. We combine the superior electro-optical response of PANI with the accurate and continuous phase modulation of the Huygens' nanoantennas, and achieve an unprecedented switching performance covering all key requirements for display applications. Our active Huygens' metasurface exhibits a high modulation contrast of 1400% and a diffraction efficiency up to 28%, which is 25 times higher than the previous polymer-based metasurface6,14 and comparable to liquid crystal-based metadevices[9]. The manufacture of the active PANI layer is realized by in-situ polymer growth on the pre-fabricated metasurface. The solid contact between the nanoantennas and the grown PANI facilitates mechanical and electrical durability, enabling a superior cycling duration of over 2000 switching cycles without noticeable degradations. The intrinsic dynamic properties of PANI endow the active metasurface with fast switching speed of 60 fps and virtually hysteresis-free controllability over continuous intermediate states within a low operation voltage range from -0.2 V to +0.6 V. Unlike previous active metasurfaces performing well only in subsets of performance metrics, our electrically active metasurface with holistic switching performance holds great promise towards practical display applications.

Abstract: Ultra-thin artificially engineered nanoscale scatterers, known as metasurfaces, have gained immense attention in recent years to realize dynamic nanophotonic components by engineering meta-atoms. In this study, we propose an electrically tunable metasurface for optical intensity modulation by leveraging gap-plasmon resonance effect. The presented metasurface exhibits ~15 dB modulation depth at 1550 nm for both TE- and TM-polarized incident wave with an energy-consumption as low as 213 fJ/bit.

Introduction: The metasurfaces can provide enormous degrees-of-freedom to dynamically control the light–matter interactions at the nanoscale [1]. Recently, metasurface-assisted optical modulators find potential candidature to realize active nanophotonic components [2]. Various design strategies have been demonstrated to achieve large modulation depth by incorporating numerous active materials *viz.* ITO (indium-tin-oxide), VO_2 (vanadium dioxide) and graphene [3]. Among these, ITO has gained huge attention due to its astonishing electro-optical properties by external applied bias induced free-carrier accumulation [4]. By leveraging this technique, numerous metasurface based modulators have been proposed *via* exploiting gap-plasmon resonance (GPR) and guided-mode resonance [5]–[7]. However, realization of a polarization-independent modulator that can exhibit a low energy consumption remains a great challenge. In this regard, our design of energy-efficient electro-tunable polarization-insensitive metasurface is crucial to find prospective applications in future nanophotonic systems.

Structural Overview: Our presented metasurface comprises a 2D Ag-nanodisk array (with radius, r = 300 nm and height, h = 100 nm) on cascaded layers of ITO, HfO_2 (Hafnium oxide), and Ag-ground layer, as presented in Fig. 1(a). We leverage GPR-effect combined with free-electron accumulation in ITO under applied bias-voltage, to realize the modulation of light reflected from the metasurface. A side-view of the meta-atom is shown in Fig. 1(b). To study the optical response, a 3D finite-difference-time-domain simulation model has been considered.

Results and Discussion: The permittivity of ITO can be defined by the Drude model, given as [8]:

$$\varepsilon_{\mathrm{ITO}} = \varepsilon'_{\mathrm{ITO}} + j\varepsilon''_{\mathrm{ITO}} = \varepsilon_\infty - \frac{\omega_\mathrm{p}^2}{\omega^2 + \mathrm{j}\Gamma\omega}, \qquad \omega_\mathrm{p} = \sqrt{N\mathrm{e}^2/\varepsilon_0 m_\mathrm{e}^*} \qquad (1)$$

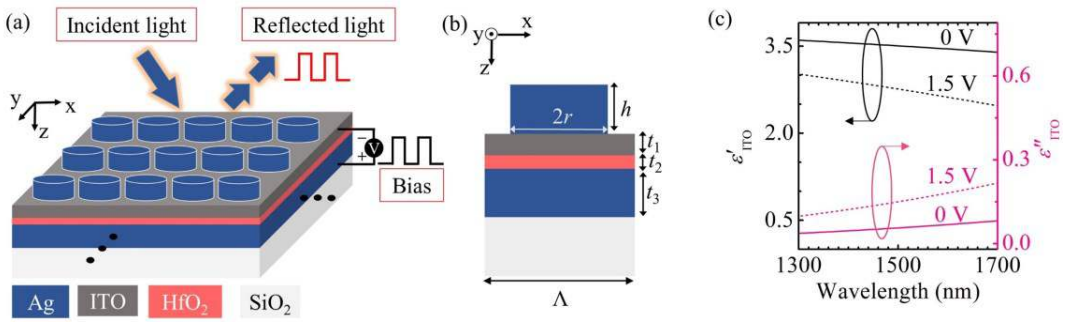

Fig. 1. Schematics of the metasurface presenting (a) perspective view and (b) a unit-cell side view with 700 nm periodicity (Λ) along x- and y axis. Note: t_1 =10 nm, t_2 = 5 nm, and t_3 = 100 nm. Here, the direction of propagation light is along z-axis. (c) The deviation of complex permittivity of ITO inside the accumulation layer for two different biasing conditions.

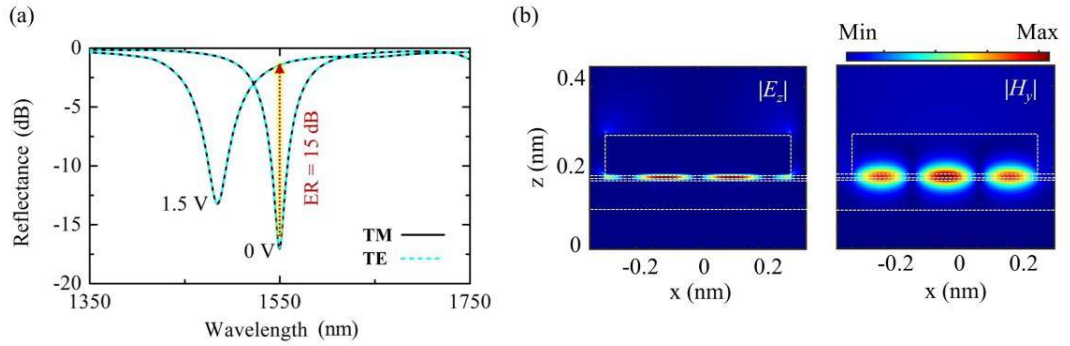

Fig.2. (a) Variation of the resonance dip in reflectance spectrum as a function of bias-voltage for both TM- and TE-polarized light. The arrowed-dotted line denotes the achieved ER = 15 dB at 1550 nm. (b) electric- (E_z) and magnetic-field (H_y) distributions for 0 V bias at 1550 nm.

where high-frequency permittivity, plasma frequency, oscillation frequency, and damping constant are represented by ε_∞, ω_p, ω, and Γ, respectively [1]. Note that ω_p varies with carrier concentration (N) and effective electron mass m_e*. We have considered $N = 6 \times 10^{19}$ cm^{-3} for 0 V bias. With an increase in bias-voltage, the free-electrons of ITO start accumulating at the ITO–HfO_2 interface, leading to a formation of ultra-thin (~3 nm) accumulation region. This leads to a modulation of the complex ITO permittivity, as shown in Fig. 1(c).

With 0 V bias, we observe excitation of third-order GPR-mode at 1550 nm, as shown in Fig. 2, which leads to a dip in the reflectance (R) spectrum. On the contrary, with 1.5 V biasing, the resonance dip gets blue-shifted due to the deviation in the permittivity of the accumulation layer. Thus, we realize an amplitude modulation of reflected beam with an extinction ratio (ER [dB]= $R_{1.5\,V} - R_{0\,V}$) as high as 15 dB while operating between 0 V and 1.5 V biasing states, as presented by the vertical dotted-arrow in Fig.2(a) for both TM and TE polarized plane wave. The electric (E_z) and magnetic (H_y) field distributions at resonance wavelength for 0 V bias are shown in Fig. 2 (b) and 2(c), respectively, where we can clearly observe the excitation of third-order GPR-mode [9].

The per bit energy-consumption of the device can be calculated as, E_b (= $CV^2/4$), where C denotes the total capacitance of the device. Based on electrostatic simulations, we can estimate the unit-cell capacitance (C_{unit}) as ~15 fF/μm^2. Hence, with a total device footprint around 5 × 5 μm^2 (containing 50 meta-atoms), the estimated $C \approx$ 376 fF. Therefore, the estimated energy requirement per bit is $E_b \approx$ 213 fJ/bit for 1.5 V applied bias.

Conclusion: In summary, we have presented an electro-tunable polarization-insensitive metasurface for optical intensity modulation by utilizing the astonishing electro-optic behavior of ITO. For both TM- and TE-modes, the device exhibits an ER of ~15 dB at 1550 nm while marinating a low energy-consumption of 213 fJ/bit.

Magnetoelectric coupling of topological magnets for spintronic and quantum information applications

T. Hirosawa

Aoyama Gakuin University, Japan
*corresponding author: hirosawa@phys.aoyama.ac.jp

Abstract: In multiferroic materials, the magnetic and electric dipole moments are strongly coupled with each other. Here, we propose a novel method to control multiferroic skyrmions via magnetoelectric coupling, which have swirling spin textures characterized by an integer topological charge. Firstly, we consider skyrmions under high-frequency laser irradiation. We find the laser-driven skyrmion motion and laser-controlled magnon band topology. Secondly, we introduce the magnetoelectric magnon-photon coupling by placing skyrmion crystals inside a microwave cavity and discuss potential applications in quantum information.

Magnetic skyrmions are microscopic magnetic vortices with an integer topological charge. They attract much attention as future information carriers in the field of spintronics [1]. Furthermore, they are recently proposed as a qubit, a fundamental building block of quantum computers [2]. In this work, we show that the magnetoelectric effect of multiferroic materials could broaden and enhance the functionality of magnetic skyrmions in spintronics and quantum information science [3,4].

Firstly, we consider the classical spin dynamics of skyrmions under circularly polarized lasers at terahertz frequencies [3]. In multiferroic systems, the coupling between electromagnetic fields and magnets is written as

$$H_{EM}(t) = -\sum_{i}^{N} [\boldsymbol{p}_i(t) \cdot \boldsymbol{E}(\boldsymbol{r}_i, t) + \boldsymbol{m}_i(t) \cdot \boldsymbol{B}(\boldsymbol{r}_i, t)] , \quad (1)$$

where $\boldsymbol{p}_i(t)$ are $\boldsymbol{m}_i(t)$ denote electric and magnetic dipole moments at *i*th site, respectively. The spin-driven electric moment is assumed to arise from the d-p hybridization mechanism as observed in a skyrmion-hosting insulator Cu_2OSeO_3 [5]. Our method combines the numerical simulation of Landau–Lifshitz–Gilbert equation and Floquet-magnus expansion for classical spin systems. We demonstrate that via a delicate balance between the energy injection from a high-frequency laser and dissipation processes, single skyrmions can be driven with a velocity and propagation direction that can be tuned by the laser field amplitude and polarization, respectively. Moreover, we uncover an ultrafast Floquet magnonic topological phase transition in a laser-driven skyrmion crystal.

Secondly, we introduce a theory of magnetoelectric magnon-photon coupling in cavities hosting noncentrosymmetric magnets [4]. Analogously to nonreciprocal phenomena in multiferroics, the magnetoelectric coupling is time-reversal and inversion asymmetric. This asymmetry establishes a means for exceptional tunability of magnon-photon coupling, which can be switched on and off by reversing the magnetization direction. We reveal the electrical activity of skyrmion eigenmodes and propose it for magnon-photon splitting of ``magnetically dark'' elliptic modes. Furthermore, we predict a cavity-induced magnon-magnon coupling between magnetoelectrically active skyrmion excitations. We discuss applications in quantum information processing by proposing protocols for all-electrical magnon-mediated photon quantum gates, and a photon-mediated SPLIT operation of magnons.

Observation of bulk chiral anomaly in photonic crystal systems

H.W. Jia[1], M.D. Wang[1], and C.T. Chan [1*]

[1]Physics Department, Hong Kong University of Science and Technology, Hong Kong, China
[*]corresponding author: phchan@ust.hk

Abstract: We show that chiral anomaly can be induced in the bulk of 2D photonic crystal systems using the inhomogeneous effective mass or by imposing special boundary conditions. We experimentally characterized the associated transport properties.

We observed chiral Landau levels in 2D Dirac cone systems which carries inhomogeneous effective mass. Chiral zeroth Landau levels are topologically protected bulk states that give rise to chiral anomaly. It is known that 3D Weyl degeneracies can give rise to such chiral Landau levels. We show that such chiral anomaly can be realized using 2D photonic crystal systems that have Dirac point. We introduce an inhomogeneous effective mass in the photonic crystal through breaking local parity inversion symmetries. Zeroth-order chiral Landau levels with one-way propagation characteristics emerged and they are experimentally observed. In addition, the chiral zeroth mode are shown to demonstrate robust transport of the against defects in the system.

We also observed boundary condition induced chiral anomaly bulk states. The most useful property of topological materials is perhaps the robust transport of topological edge modes, whose existence depends on bulk topological invariants. We suggest here that instead of designing the bulk to create topological transport on the edges, we can create topological transport in some bulk modes by imposing certain boundary conditions on the edge. The idea is demonstrated by showing that a topologically trivial 2D hexagonal phononic crystal waveguide bounded by some specific boundaries guarantees the existence of bulk modes with chiral anomaly inside a pseudogap due to finite size effect. We experimentally observed robust valley-selected transport, complete valley state conversion, and valley focusing of the chiral anomaly bulk states. The same concept applies to phononics and electromagnetics.

If time permits, we will discuss some topological transport properties of disordered magnetic photonic crystals.

Abstract: We present several approaches that allows exciting non-reciprocal spin wave beams in thin magnetic films. Using primarily the spin wave spectroscopy techniques performed in both in- and out-of-plane geometries, we show that the spin wave beamforming can be tailored using concepts inspired from optics. We also developed a near-field diffraction model that benchmarks spin wave diffraction in thin films for any geometry, and is readily applicable for future designs of magnon interferometric devices.

Magnonic devices, which take advantage of the versatility of spin waves, are anticipated to be a propitious alternative for efficient signal processing. Spin waves constitute the building blocks of novel wave computing methods such as spectral analysis [1], and neuromorphic computing [2], which are all interference based techniques. Recently, basics concepts of optics applied to spin waves demonstrated the possibility to shape and stir spin wave beams, suggesting prominent performance in particular tasks such as image processing and speech recognition [3]. Along these ideas, we demonstrated that the beamforming in ferromagnetic thin films follows directly the near-field interference pattern of the excitation geometry [4-6].

In this communication, we focus on the beam shaping of spin wave using different methods such as curvilinear antennas, grating of nanomagnets, and sharp constrictions. Firstly, we will introduce our near-field diffraction model, which is applicable for all spin wave modes in thin magnetic films, and serves as a decisive tool to identify proper designs of spin wave beam antennas. Secondly, we will present measurements done via spin wave spectroscopy on various pairs of antenna whose designs allows characterizing the propagation properties in the 2D plane as shown in Fig. 1. Thirdly, using spatially resolved micro-focused Brillouin light spectroscopy, we will show how a sharp constriction in an antenna can directly excite caustic beams in an extended film when the suitable conditions of field and frequency meets an inflection point in the dispersion relation. These findings have important implications for the development of switchable spin wave splitters, passive spin-wave frequency-division demultiplexers, and magnonic interferometry.

Abstract: We studied the factors affecting the giant magnetoimpedance, GMI, effect value and magnetic field dependence in magnetic microwires. Generally, excellent magnetic softness and high GMI effect have been observed in as-prepared Co-rich microwires. Specially designed postprocessing allows also to improve substantially the GMI effect in less expensive Fe-rich microwires. There is a relationship between the optimal frequency for the GMI performance and the wire diameter: to achieve the maximum GMI effect a trade-off between wire dimensions and frequency is required. Considerable GMI effect in thin microwires is observed up to GHz frequency range. A new sensing method involving free space microwave spectroscopy using inclusions of ferromagnetic microwires presenting the GMI effect at GHz frequencies is proposed for the stress, temperature and magnetic field monitoring in carbon fiber containing composites.

Studies of Giant magnetoimpedance, GMI, effect have attracted considerable attention in the last few years owing to it suitability for sensor applications [1,2]. The GMI effect was interpreted in terms of the classical skin effect in a magnetic conductor assuming the dependence of the penetration depth of the AC current flowing through the magnetically soft conductor on the DC applied magnetic field [1-3].

Commonly, the GMI effect is described as the magnetoimpedance ratio, ΔZ/Z, defined as:

$$\Delta Z/Z = [Z(H) - Z(H_{max})] / Z(H_{max}), \quad (1)$$

where H_{max} is the axial DC-field with maximum value up to few kA/m.

Extremely high sensitivity of the GMI effect to applied magnetic field attracted great interest for magnetic sensors applications. Cylindrical shape and high circumferential permeability observed in amorphous wires are quite favorable for achievement of high GMI effect [1-3]. At low frequency range (roughly up to 10 MHz depending on sample diameter/thickness) the GMI effect originates basically from variations of the magnetic penetration depth due to strong changes of the effective magnetic permeability caused by a DC magnetic field [3,4]. However, for GHz frequencies, the magnetization rotation is strongly influenced by the gyromagnetic effect. With increasing the frequency, the GMI peaks are shifted to larger fields where sample is magnetically saturated. At this frequency range strong changes of the sample's impedance have been attributed to the ferromagnetic resonance (FMR)[4,5].

Recently major attention is focused on high frequencies (GHz range) GMI applications owing to the development of thinner magnetically soft materials and recent tendency in miniaturization of magnetic field sensors [4]. Another promising application of GMI effect at GHZ frequencies is use of soft magnetic wire inclusions presenting the GMI effect at GHZ frequency in composites, enabling wireless stresses, temperature and magnetic field monitoring [1,5].

The purpose of this paper is present last results on the GMI effect in soft magnetic wires at high frequencies and explore the application of such microwires in carbon containing tunable composites with thin microwires inclusions.

We measured magnetic field dependences of impedance, Z, and GMI ratio, ΔZ/Z, of

magnetic microwires prepared by the Taylor-Ulitovsky method using specially designed micro-strip sample holder. The sample holder was placed inside a sufficiently long solenoid that creates a homogeneous magnetic field, H. The sample impedance Z was measured using vector network analyzer from reflection coefficient S11, using the expression:

$$Z=Z_0(1+S_{11})/(1-S_{11}), \qquad (2)$$

where Z_0=50 Ohm is the characteristic impedance of the coaxial line [1]. Described technique allows measuring of the GMI effect in extended frequency, *f*, ranges up to GHz frequencies.

As discussed elsewhere [1], for amorphous materials characterized by the absence of magneto-crystalline anisotropy the main sources of magnetic anisotropy are the shape and magnetoelastic anisotropy, K_{me}. The latter is determined by the magnetostriction coefficient, λ_s, and the internal stresses, σ_i, by the relation [1]:

$$K_{me} = 3/2\ \lambda_s\sigma_i, \qquad (3)$$

Nearly-zero λ_s – values can be achieved in the Co_xFe_{1-x} ($0 \leqslant x \leqslant 1$) or Co_xMn_{1-x} ($0 \leqslant x \leqslant 1$) systems at x about 0,03 – 0,08 [1]. Such compositions present better magnetic softness [1]. From ΔZ/Z(H) dependencies measured in Co-rich microwires with vanishing λ_s – values with but with different diameters, d (d=25.6 μm and d=10.8μm) was observed that thicker microwires present higher ΔZ/Z ratio at f=100 MHz. However, at 700 MHz the opposite tendency is observed: higher ΔZ/Z ratio is observed for thinner microwire. Accordingly, the diameter of ferromagnetic metallic nucleus must be mentioned among the other factors relevant for the GMI ratio optimization at a given frequency. The observed behaviour confirms the relationship between the optimal frequency for the GMI performance and the wire diameter: to achieve the maximum GMI effect a trade-off between wire dimensions and frequency is required [1,4]. The diameter reduction must be associated with the increasing of the optimal GMI frequency range [1].

Magnetic softness and GMI of Fe-rich microwires with high and positive λ_s – values can be substantially improved, when Fe-rich microwires were subjected to stress-annealing allowing induction of transverse magnetic anisotropy [1].

The integration of such ferromagnetic microwires into composite materials significantly modify the effective microwave response, making it possible to obtain a new tunable and self-sensing composite material [5]. In the case of the composites containing carbon fibers, the surrounding conductive carbon fibers interfere in the microwave signal generated by ferromagnetic microwires, making it difficult to be measured. However, low frequency magnetic field modulation allows to extract the microwave signal from ferromagnetic microwires inclusions. These results demonstrate the capability for the integration of ferromagnetic microwire inclusions into structural carbon composite parts for wireless monitoring of external stimuli, such as applied stress, temperature or magnetic field.

Extreme time modulation of material properties and Hawking radiation

J. B. Pendry

The Blackett Laboratory, Department of Physics, Imperial College London, London SW7 2AZ, UK

Abstract:

Experiments demonstrating extremely rapid modulation of the permittivity have been performed by exploiting the enhanced non-linear effects possible in the presence of plasmonic resonances. These experiments measure an extreme rise time by exploiting the analogy between Young's slits which produce diffraction in momentum space, and closely spaced time windows which produce diffraction in frequency space.

I go on to discuss some theoretical consequences of space-time modulated structures. Diffraction gratings moving at trans-luminal velocities contain points where wave and grating velocity are equal. We show these points can be understood as a series of optical event horizons where wave energy can be trapped and amplified, leading to radiation from the quantum vacuum state. We calculate the spectrum of this emitted radiation, finding a quasi-thermal spectrum with features that depend on the grating profile, and an effective temperature that scales exponentially with the length of the grating, emitting a measurable flux even for very small grating contrast. Stimulated emission also takes place under the influence of incident photons, but in contrast to emission from excited atoms, transluminal systems radiate correlated photon pairs.

Electric-field Control of Magnetism and Topological Spin Textures

Masahiro Sato[1*] and Shunsuke C. Furuya[2]

[1]Department of Physics Chiba University, Chiba, Japan
[2]Department of Basic Science, University of Tokyo, Tokyo, Japan
[*]corresponding author: sato.phys@chiba-u.jp

Abstract: Effects of dc electric fields on nano materials have been investigated, especially, in the fields of multiferroics and spintronics. However, their microscopic theories have not been developed enough. We have theoretically tackled this issue, focusing on Mott insulators in Hubbard-like models under a strong electric field. As a result, we predict that a strong enough electric field can generate spin textures (magnetic skyrmion, soliton, hedgehog, etc.) and phase transitions in thin films of chiral magnets and other magnetic systems.

A dc electric field (or an electric voltage) is one of the few things that human beings can quantitatively apply to materials in order to control their properties. In the last decades, effects of this external field have been actively studied from the viewpoints of both pure and applied physics. Particularly, studies of such effects in spintronics [1] and multiferroics [2] have been largely developed. However, even now it is not easy to quantitatively explain experimental results driven by an electric field in quantum, microscopic level. It means that solid theories for electric-field effects have not been established enough and there are several open issues there.

In recent years, we have developed theories for several effects of dc electric fields applied to nano systems (thin films, one-dimensional systems, etc.) of magnetic Mott insulators, by analyzing Hubbard like models [3,4,5]. Using the second- and fourth-order strong coupling expansion (large-U expansion), we have computed direct- and super-exchange couplings and some magnetic anisotropies like Dzyaloshinskii-Moriya (DM) interaction as a function of the electric field and microscopic parameters (strengths of electron hopping, on-site Coulomb repulsion, Hund coupling, spin-orbit coupling, etc.). From these results, we can predict several magnetic phenomena driven by an electric field in magnets in a quantitative manner.

If our result is used in nano-scale systems with a magnetic order, we conclude that a sufficiently strong electric field can generate several spin textures such as magnetic skyrmions, magnetic soliton lattices, and magnetic hedgehogs (see Fig.1) when we add the field to nano materials in a proper setup. For instance, if we apply both electric and magnetic fields to a thin film of a chiral ferromagnet in a proper way, we can create or annihilate the skyrmion lattice phase as shown in Fig. 2. For quantum spin systems, we predict electric-field induced quantum phase transitions and field-induced spin gaps in several models. Particularly, we show that when we apply a strong electric field to Kitaev honeycomb model [6] (see Fig. 3), the field-induced DM interaction or Gamma anisotropy can create new quantum spin liquid states such as a sort of Chern insulators.

In the conference, we will report these theoretical results of the electric-field effects.

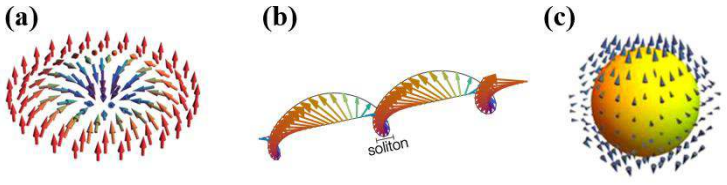

Fig.1: (a) Magnetic skyrmion, (b) magnetic soliton lattice, and (c) magnetic hedgehog. If we apply a strong electric field in proper magnetic systems, we can create these topological spin textures.

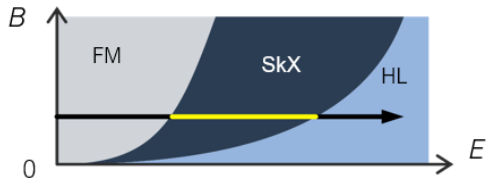

Fig.2: Phase diagram of a film of chiral ferromagnet in the space of an electric field (E) and a magnetic field (B). FM, SkX and HL are respectively forced ferromagnetic, skyrmion lattice, and helical ordered phases.

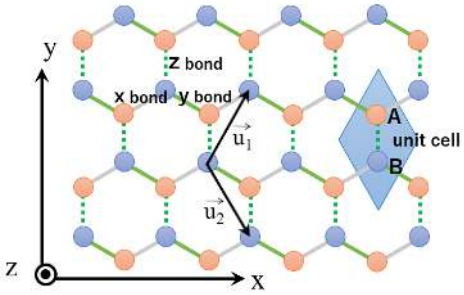

Fig.3: Kitaev honeycomb model [6] whose ground state is a quantum spin liquid state with fermion excitations. This model is exactly solved and regarded as an effective low-energy model for a class of spin-orbit coupled Mott insulators.

Hyperbolic Anisotropic and Bianisotropic Media

M. Durach[1*]

[1]Georgia Southern University, USA
[*]corresponding author: mdurach@georgiasouthern.edu

Abstract: We report on the work of Durach et al. at Georgia Southern University demonstrating that anisotropic and bianisotropic media can be classified as belonging to one of the five classes: non-hyperbolic, hyperbolic, bi-hyperbolic, tri-hyperbolic, and tetra-hyperbolic according to the high-k plane waves in the media. This determines the topology of the Fresnel iso-frequency surfaces, the reflection and transmission properties, resonances, and surface electromagnetic waves in both anisotropic and bianisotropic media.

Bianisotropics, as the electromagnetic research of bianisotropic media is known [1-4], was started in 1888 by investigations of magnetoelectric effects in moving media first observed by Roentgen and Wilson [4,5]. Magnetoelectric crystals were first studied by Landau, Lifshitz, and Dzyaloshinskii [7,8]. To unify the research on moving media and on magnetoelectric crystals, the concept of a bianisotropic medium was coined in 1968 by Cheng and Kong [9] describing the most general case of linear local media. Today, the metamaterial research is central to electromagnetics in all frequency bands [10-13]. Metamaterials feature many properties important for applications, such as superresolution imaging and sensing, optical cloaking, subwavelength optical confinement, guiding, emission rate and directivity control, optical magnetism etc. These properties are mostly due to metamaterials being anisotropic and bianisotropic.

Metamaterials with extreme anisotropy can exhibit both plasmonic and dielectric properties depending on the excitation direction and polarization. Such metamaterials are known as hyperbolic due to formation of high-k states in momentum space where transition between metal and dielectric properties occur, which leads to open Fresnel iso-frequency k-surfaces [14]. Hyperbolic metamaterials find numerous applications [15,16]. In 2016 Kruk et al. [17] experimentally observed magnetic hyperbolic metamaterials, with hyperbolicity due to the extreme anisotropy in the magnetic permeability tensor. In 2017 Tuz, Fedorin and Fesenko [18] predicted that simultaneous extreme anisotropy in dielectric permittivity and magnetic permeability tensors can be observed in non-reciprocal gyrooptic magnetic-semiconductor superlattice resulting in bi-hyperbolic optical phase.

Here we report on the work conducted by Durach et al. at Georgia Southern University [19-24] in relation to the taxonomy of bianisotropic media. In a bianisotropic medium with effective medium parameters tensors $\hat{\epsilon},\hat{\mu},\hat{X},\hat{Y}$ for the dielectric permittivity, magnetic permeability, and magnetoelectric couplings the equation describing the direction of propagation of the high-k modes is given by the *high-k characteristic function*:

$$(\boldsymbol{k}^T\hat{\epsilon}\boldsymbol{k})(\boldsymbol{k}^T\hat{\mu}\boldsymbol{k}) - \left(\boldsymbol{k}^T\hat{X}\boldsymbol{k}\right)\left(\boldsymbol{k}^T\hat{Y}\boldsymbol{k}\right) = 0 \qquad (1)$$

The complete Fresnel wave surface of bianisotropic media can be characterized using the *index of refraction operator method* [22,23,24], follows a quartic dispersion equation, and, therefore, should follow a topological classification into the 5 hyperbolic classes, which include the following topological classes: non-, mono-, bi-, tri-, and tetra-hyperbolic materials. The prefix in the name of each topological class indicates the number of the double cones that the iso-frequency k-surface has in the high-k limit.

In principle, the tri- and tetra-hyperbolic phases require magnetoelectric coupling and in the purely anisotropic regime (i.e. without magnetoelectric coupling) only non-, mono-, and bi-hyperbolic phases can be achieved [22]. However, the formation of tri- and tetra-hyperbolic-like topological phases in media without

magnetoelectric coupling by hybridization of plasmonic and magnetic high-k waves is possible when the double cones due to plasmonic and magnetic anisotropies intersect [23]. This leads to the separation of the 2 double cones of the bi-hyperbolic dispersion into 3 or 4 double cones via anti-crossing whose width is inversely proportional to the magnitude of the k-vector as k tends to infinity.

The properties of the high-k waves topologically determine the parameters of the Fabry-Perot resonances and surface electromagnetic waves (SEWs) in bianisotropic objects [24]. For example, thin subwavelength bianisotropic layers support high-k Fabry-Perot resonances if the bianisotropic material is oriented such that the high-k directions, given by the zeros of high-k characteristic function [Eq. (1)], are close to perpendicular to the interfaces of the layer. As the thickness of the layer increases, the resonance spectrum becomes more populated with lower-k modes of the bulk bianisotropic media. The SEWs appear as arcs in the regions where evanescent waves are supported between the regions with propagating waves [20,21,24], which are topologically separated by the high-k characteristic function [Eq. (1)]. This is in line with the statement that the high-k states separate the parameter space into regions where metal-like and dielectric-like properties of bianisotropic media occur.

Mimicking TMDs by Plasmonic Topological Metasurface with a broken time-reversal symmetry

Abstract

In this paper we present a topological plasmonic metasurface exhibiting spin-dependent distribution in the k-space analogical to the behaviour of the K and K' valleys in 2D materials. We intentionally break the lattice inversion-symmetry by local rotation of the lattice features and analyze the helicity dependence in the isofrequency plane. We attribute the characterisic valleytronic behavior to the local geometric Berry phase induced between the structure sublattices.

Two dimensional (2D) materials have been a subject of great interest for many years, since the discovery of graphene. In recent years the field has developed rapidly with the discovery of many more types of 2D materials such as transition metal dichalcogenide (TMD) monolayers [1]. Due to their unique physical properties and potential applications in a wide range of technologies, much research has been devoted to fabrication methods, together with theoretical and experimental studies of their underlying physics. TMDs are semiconductors of the form MX_2 where M is a transition metal atom such as Mo or W and X is a chalcogen atom such as S, Se or Te. It has been shown that these materials, when cleaved to a monolayer, have a direct band-gap and strong spin-orbit coupling, together with favourable electrical and mechanical properties. With these properties, TMDs such as MoS_2 have a valley degree of freedom, enabling the development of valleytronic devices [2]. They also posses topological phases due to their symmetry giving rise to a non-trivial Berry phase and many TMDs behave as topological insulators (TIs) hosting topologically protected conducting edge states [3]. Because of the great promise of these materials, further understanding of the physical processes is needed. The Berry phase [4] is a phase which is being added

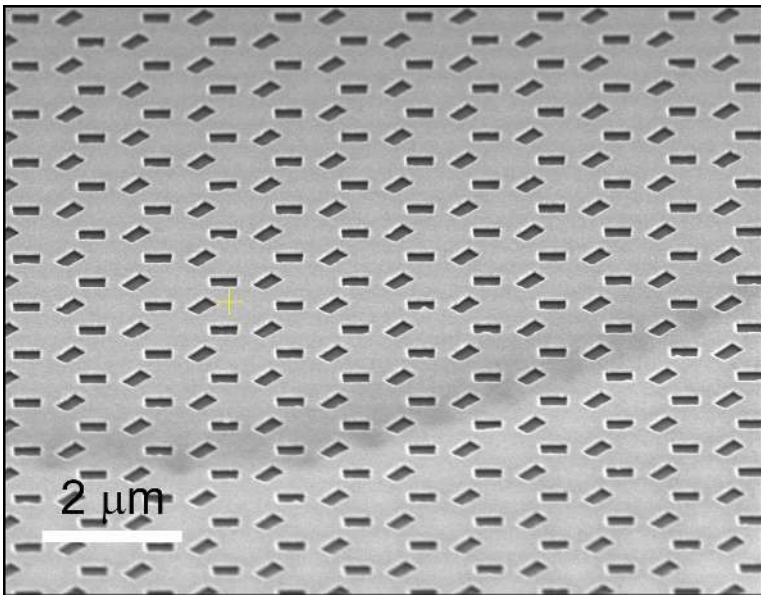

Fig. 1. Scanning electron micrograph of the graphene-like topological structure with broken inversion symmetry.

to an eigenstate after completing a closed loop in the parametric state defining it. It is caused by non trivial topology of the state-space, therefore it is often called a "geometric phase". In points of level degeneracy in the parameter space, topological monopoles appear giving rise to the Berry curvature resulting in parallel transport of the particle's state [5]. In crystals with

Corresponding author: Y. Gorodetski (email: yurig@ariel.ac.il).

broken time-reversal or inversion symmetry the level degeneracy of the chiral eigenstates (quasi-spins) is lifted giving rise to so called Berry curvature which can be compared to appearance of magnetic monopoles. Apparently, a strong magnetic field can be used to break a time-reversal symmetry in originally symmetric structures such as graphene. TMDs such as MoS_2 and WSe_2 also have a hexagonal graphene-like structure, but unlike the latter, the different atoms in the honeycomb unit cell, break inversion symmetry. Therefore, the Berry phase accumulated by Bloch electrons at their Dirac points, which are degenerate in graphene, are of opposite sign making the K and K' valleys distinguishable. The parameter space that defines a state of a polarized light is the Poincaré sphere. A gradual cyclic change of the polarization state induces a measurable and helicity-dependent Pancharatnam-Berry (PB) phase [6]. This phase is equal to the half of the solid angle enclosed by the loop. The PB phase is responsible for the spin-Hall effect of light [5] and has played an important role in numerous applications in optics [7] and plasmonics [8], [9].

Here we consider plasmonic PB phase metasurfaces with a graphene-like structures but with broken inversion symmetry. Plasmonic metasurfaces with subwavelength space-variant anisotropic scatterers have previously been shown to produce the PB phase [10]. By measuring the plasmonic response upon illumination with different spin states in momentum space, we show that the excited plasmonic modes strongly depend on the helicity of the incident light. Explicitly we observe a spin-degeneracy lifting analogical to the behavior of TMD lattices in K and K' valleys while the inversion symmetry is broken here by varying the angle between adjacent apertures in the metasurface. This angle leads to opposite PB phases in K and K' directions resulting in different contrast between the two circular polarizations in both the near and far field. These results are consistent with numerical calculations that we performed.

It seems that an analogy can be drawn between our structures and 2D materials and we believe that this could open many doors to further understanding of TMDs and other topological materials.

Creation, Manipulation and Switching of Topological Magnetisms in Spin-Charge Coupled Magnets

Masahito Mochizuki

Department of Applied Physics, Waseda University, Japan
email: masa_mochizuki@waseda.jp

Abstract: We discuss our recent theoretical studies on the dynamical creation, manipulation and switching phenomena of topological magnetisms in a spin-charge coupled magnet described by the Kondo-lattice model.

Dynamical switching, creation, and manipulation of topological magneism, e.g., skyrmions, merons, hedgehogs and Z2 vortices, by application of electromagneic waves (i.e., light and microwave) are subject of intensive study in recent research of condensed-matter physics. In this talk, we discuss our recent theoretical studies on dynamical phenomena and dynamical manipulation of such topological magnetic textures in spin-charge coupled magnets via light or microwave irradiation.

We start with the Kondo-lattice model which describes metallic magnets with localized spins coupled to itinerant electrons via exchange interactions called Kondo coupling. The localized spins are mutually coupled through effective interactions mediated by the conduction electrons. These effective interactions result in emergence of rich magnetically ordered phases including various types of skyrmion crystals as superpositions of multiple magnetic helices. Taking this model, we theoretically demonstrate the microwave-induced skyrmion creations [1], the microwave-induced switching of magnetic topology [2], and the photoinduced 120-degree spin order with topological Z2 vortices [3].

Flat optical devices for 4D light manipulation through orbital angular momentum

A. Ambrosio[1]

[1]Istituto Italiano di Tecnologia, Via Raffaele Rubattino 81, 20134 -Milano Italy
*corresponding author: antonio.ambrosio@iit.it

Abstract: By controlling amplitude, phase and polarization of light, optical metasurfaces have recently allowed spin-to-orbital angular momentum transformations with a single device that are not possible with standard optical components. We will present our most recent results in developing flat optical components for orbital angular momentum manipulation.

In our research activity, we developed a structured light laser capable of producing vortex laser arrays with actively tunable topologies and non-local coupling dictated by the array's topology. The gain medium of our laser has a large transverse cross-section supporting many transverse modes that we forced to organize and form a lattice of a hundred laser beams by inserting a metasurface mask that modulates the phase and amplitude of the field. More specifically, the phase profile was designed to produce vortex beams with an annular intensity profile, useful for communication, microscopy and lithography applications. In our scheme, the optical cavity resulted to be effectively partitioned into two sections—one on either side of the mask— each emitting a laser array imbued with a different topological charge (Orbital Angular Momentum). We achieved spatial coupling of the lasers in the array exploiting dissipative losses in the cavity, making the system stable and coherent. Importantly, in our new laser arrays, the coupling network is not limited to the nearest neighbours as for arrays of Gaussian lasers with no topological charge, but instead can be tailored to mix vortices that are widely separated in the lattice. Although different schemes for generating a single vortex inside a resonator have been demonstrated, we demonstrated the conditions for generating vortex laser arrays in a single cavity, realizing a platform to explore complex topological transformations and collective vortex effects at the source. Furthermore, we demonstrated the robustness of the designed complex light distribution to defects in the metasurface mask. This opens up the possibility of iteratively manipulating structured light parameters and could be used to develop photonic simulators.

Identifying topology directly from Maxwell's equations: Band structures and Bloch eigenstates not required

A. Cerjan[1*], and T. A. Loring[2]

[1]Center for Integrated Nanotechnologies, Sandia National Laboratories, Albuquerque, New Mexico 87185, USA
[2]Department of Mathematics and Statistics, University of New Mexico, Albuquerque, New Mexico 87131, USA
[*]corresponding author: awcerja@sandia.gov

Abstract: We develop the mathematical framework for determining a photonic structure's topology directly from its real-space description (i.e., Maxwell's equations), without the need to calculate its band structure or Bloch eigenstates. We illustrate the generality of this approach in three different systems, a standard 2D photonic crystal topological insulator, a novel class of gapless topological photonic crystals, and photonic topological crystalline insulators.

Recently, the study of topological structures in photonics has generated significant excitement, due to these systems' ability to realize robust, non-reciprocal chiral edge states and cavity-like confined states that may have applications in both linear and non-linear devices. However, traditional band theoretic approaches can present some challenges for identifying the topology of photonic crystals and metasurfaces due to both fundamental and numerical difficulties. In this talk, I will develop a mathematical framework for determining a photonic structure's topology directly from its real-space description (i.e., Maxwell's equations), without the need to calculate its band structure or Bloch eigenstates [1]. Instead, this framework is based on the photonic system's spectral localizer, which yields a set of local invariants, protected by local gaps, for every symmetry class [2,3]. Using this framework, I will show that non-trivial topology, and associated boundary-localized resonances, can appear in photonic crystals that lack complete band gaps. Finally, I will show how to develop local invariants for topology stemming from a system's crystalline symmetries, which allows for the prediction of spatially localized topological states without the construction of Wannier centers or the calculation symmetry indicator invariants.

Photocurrent induced by the momentum-space Berry phase in magnetic materials at a microwave frequency

Hiroaki Ishizuka and Akira Harada

[1]Department of Physics, Tokyo Institute of Technology, Japan

*corresponding author: ishizuka@phys.titech.ac.jp

Abstract: The low symmetry of chiral materials realizes electromagnetic phenomena prohibited by symmetry in most materials. For instance, recent studies on Weyl semimetals discovered the photovoltaic effect and magnetoresistance reflecting the Berry phase. Drawing inspiration from the adiabatic charge pump, we discuss that another kind of Berry phase, the Berry phase arising from the magnetic dynamics, induces a photocurrent through a mechanism similar to the adiabatic pump, a topological effect known in driven systems.

Materials with low crystal symmetries, such as a chiral crystal structure, host rich electronic states such as chiral topological semimetal. The optical properties of such topological electrons have attracted attention in recent years as they give rise to unique features reflecting the topological properties, such as unique properties in the circular photogalvanic effect and Fermi arcs. These phenomena are related to the unique distribution of the Berry phase in the momentum space, which characterizes the topological state. The recent discovery of magnetic topological semimetals further enlarged the possibility of realizing novel phenomena arising from the interplay of magnetism and topological electronic state.

To explore the novel photovoltaic response in magnetic semiconductors, we focus on a Weyl semimetal, a topologically nontrivial electronic state often realized in chiral materials. The effective Hamiltonian reads

$$H(t) = \sum_{\boldsymbol{k},\alpha,\beta} c^{\dagger}_{\boldsymbol{k}\alpha} \left[v\boldsymbol{k}\cdot\boldsymbol{\sigma} - \{v_0 k_z + \mu(t)\}\delta_{\alpha\beta} - J_K \boldsymbol{m}(t)\cdot\boldsymbol{\sigma} \right]_{\alpha\beta} c_{\boldsymbol{k}\beta} \qquad (1)$$

where $\sigma = (\sigma_x, \sigma_y, \sigma_z)$ ($\sigma_{x,y,z}$ are the Pauli matrices), $\mu(t)$ is the chemical potential, v is the velocity of the Weyl electron, v_0 ($|v_0| < |v|$) is the velocity of the tilting term, J_K is the Kondo coupling, $c_{k\alpha}$ ($c^{\dagger}_{k\alpha}$) is the annihilation (creation) operator of an electron with momentum $k = (k_x, k_y, k_z)$, and $m(t) = [m_x(t), m_y(t), m_z(t)]$ ($|m(t)| = 1$) is a unit vector parallel to the ferromagnetic moment. The response of magnetic moment to the microwave is calculated using the Landau-Lifshitz-Gilbert equation, and the electronic response to the magnetic dynamics is calculated using a Boltzmann theory taking account of the Berry phase effect [1].

As a demonstration of how magnetic dynamics affects electron transport, we particularly focus on a setup similar to the ferromagnetic resonance, namely, illuminating a ferromagnet using an electromagnetic wave in the microwave to the terahertz regime [Fig. 1(a)]. We show that the precession of the ferromagnetic moment modifies the electronic band, moving the Weyl cone in a circular motion in the momentum space. A similar effect was previously proposed in non-magnetic Weyl semimetals [2,3]. However, the radius of the circular motion is orders of magnitude larger than the non-magnetic semimetals. As a consequence, the circular motion of the Weyl nodes by magnetic precession induces a larger Berry curvature. The Berry phase effect results in a macroscopic current, resulting in a photocurrent by a microwave or the terahertz wave.

From the viewpoint of the Berry phase, this phenomenon is similar to the adiabatic pump proposed by D. J. Thouless [4]. The induction of Berry phase by the circular motion of Weyl cone resembles Faraday's law of electromagnetism, in which the circular electric current induces a magnetic field. Similarly, the circular motion of the Weyl node, a magnetic charge in the momentum space, induces a momentum-space electric field that appears in the adiabatic pump [3].

In a different view, this phenomenon is a spin motive force, an electric current induced by magnetic dynamics. Unlike the conventional spin motive force, however, this phenomenon produces a finite current without a magnetic gradient. The result shed light on a novel material property arising from the Berry phase effect and its potential for spintronics application.

Circular Polarization in absorption and emission of light by molecules and molecular assemblies

S.C.J. Meskers[1*]

[1]Molecular Material and Nanosystems, Technische Universiteit Eindhoven, The Netherlands
[*]corresponding author: s.c.j.meskers@tue.nl

Abstract: Chiral molecules and materials preferentially absorb and emit one of the circular polarizations of light. Yet the reverse statement is not necessarily true. Recent developments in circular polarization in topologically chiral molecules, supramolecular assemblies and materials with strong light-matter coupling are discussed.

Chiral molecules preferentially absorb and emit one of the two circular polarizations of light. The degree of circular polarization, or dissymmetry factor, g for isotropically oriented molecules

$$g = \frac{4\,\mathrm{Im}(\vec{\mu}\cdot\vec{m})}{|\vec{\mu}|^2 + |\vec{m}|^2} \qquad (1)$$

is determined by the relative magnitude and orientation of the electric (μ) and magnetic (m) transition dipole moments of the transition. The electric dipole represents the translational motion of the electron during the spectroscopic transition while the magnetic dipole cover the rotational, circular aspect of the electron oscillation.[1] An electron oscillating along a helical polymer chain, executes linear and circular oscillatory motion resulting in selective absorption/emission of light.[2] As a recent example we mention helical ladder polymers, where g can be used to gauge the delocalization of the excited state responsible for light emission. The circular differential absorption of light by chiral molecules can be used to make compact detectors for the circular polarization of light.[3]

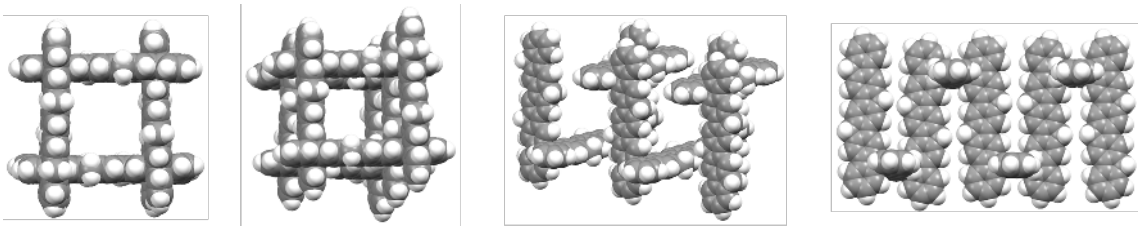

Figure 1. A helical ladder polymer seen from different angles

Interestingly, g reaches its extremal values (±2) for molecules whose electric and magnetic dipoles are equally large and parallel, thus extending the electric-magnetic duality symmetry of the free field to the transition dipoles describing the molecule-light interaction. In general, g is a tensorial property, i.e. it varies with the direction in which the photon is absorbed/emitted. Recent experiments on individual polymer nanoparticles indeed confirmed this anisotropy.[4]

Selective absorption and emission of circular polarized light is not an exclusive property of chiral molecules. Also achiral molecules may show a difference in the interaction with left and right polarized light for a particular

orientation of the molecules with respect to the light beam. In the isotropic limit i.e., when averaging over all orientations this circular selectivity should vanish for achiral systems. Also, molecules that have been magnetized via excitation with circularly polarized light can show circular polarization of their photoluminescence in one direction. For these magnetized systems, the circular polarization should average out when measuring over photon emission directions. A distinguishing feature of these magneto-optical systems is that the time inversion symmetry operation, the sign of the circular polarization should change whereas for truly chiral molecules the circular preference is invariant.

The spectroscopic properties of supramolecular assemblies and materials are obviously more complex than those for isolated small molecules because of the many possible intermolecular interactions. Interestingly, for some systems it is now possible to program the circular polarization in absorption and emission by irradiation with circularly polarized light.[5,6] Understanding the complex electrodynamic couplings within the aggregates can be guided by the notion that the interaction between distant molecules may be described in terms of optics. As an example, the circular polarization of light emitted by an achiral dye in a chiral nematic host material does not originate directly at the site of photon emission but arises gradually as the photon travels out through the chiral matrix. A key challenge are systems with strong coupling the light and matter, where electromagnetic waves acquire mass and molecular electronic excited states wave character.

Nonreciprocal Magneto-optical Metasurfaces

W. Yang[1], S. Xia[1], J. Qin[1], L. Deng[1] and L. Bi[1*]

[1]University of Electronic Science and Technology of China, China
[*]corresponding author: bilei@uestc.edu.cn

Abstract: Unconstrained by Lorentz reciprocity, nonreciprocal metasurfaces may provide unique functionalities with distinctive characteristics for forward and backward electromagnetic wave propagation. In this work, we report our recent progress on nonreciprocal metasurfaces based on magnetic meta-atoms, demonstrating nonreciprocal phase gradient, magnetic bias free properties and anomalous magneto-optical effects.

Metasurfaces have attracted great research interest recently. Most metasurfaces reported to date follow the Lorentz reciprocity theorem, where the wave propagation characteristics is the same between forward and backward directions. Nonreciprocal metasurfaces unconstrained by Lorentz reciprocity may provide distinctive characteristics between forward and backward propagating waves, which is important for applications in antennas, radomes and full-duplex communications. Magnetic materials are naturally nonreciprocal. However, limited by the weak magneto-optical effect and large biasing magnet, nonreciprocal metasurfaces have rarely been demonstrated using magnetic nanostructures. In addition, the biasing magnetic field make all materials magnetized along the same orientation, causing significant challenge to achieve nonreciprocal phase gradient.

In this work, we report our recent progress on nonreciprocal magneto-optical metasurfaces. We first report Mie resonance enhanced magneto-optical effect in magnetic meta-atoms, showing several new magneto-optical effects such as optical gyromagnetic properties. Then we report a magnetic bias-free, phase-gradient nonreciprocal magneto-optical metasurface in the Ku band. Finally, we discuss the possibility to achieve strong nonreciprocal light propagation in optical frequencies based on high quality factor metasurface designs

First, we report the observation of optical gyromagnetic properties, where the effective permeability, rather than permittivity tensor of the metamaterial is gyrotropic in a Si/Ce:YIG/YIG/SiO_2 all-dielectric magneto-optical metasurface. As shown in Fig. 1, we observe giant transverse TMOKE up to 7 % under s-polarized incidence in the infrared. The effective gyrotropic permeability and permittivity were both retrieved using 4 x 4 transfer matrix methods, demonstrating the bi-gyrotropic nature of the device.

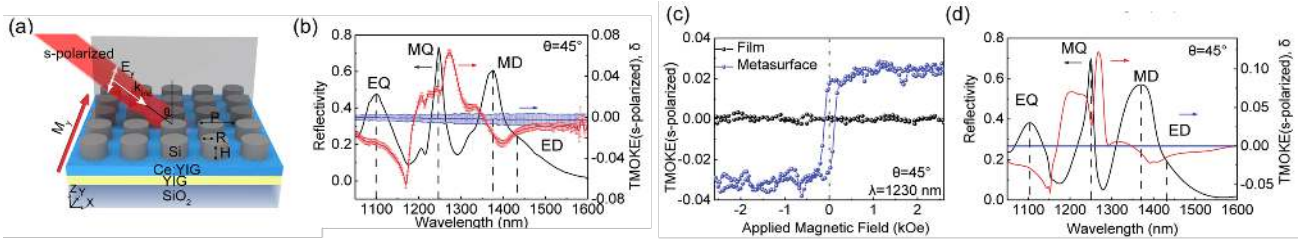

Fig. 1. Reflection spectrum and giant TMOKE for s-polarized incident light. (a) Schematic diagram of the s-polarized TMOKE characterization set-up. (b) Measured s-polarized TMOKE and reflection spectra of the metasurface compared with bare Ce:YIG/YIG thin films. (c) Measured TMOKE hysteresis for the metasurface and the bare MO films at 1230 nm wavelength. (d) Simulated reflection spectra and TMOKE responses of the metasurface for s-polarized light and θ=45° incidence angle.

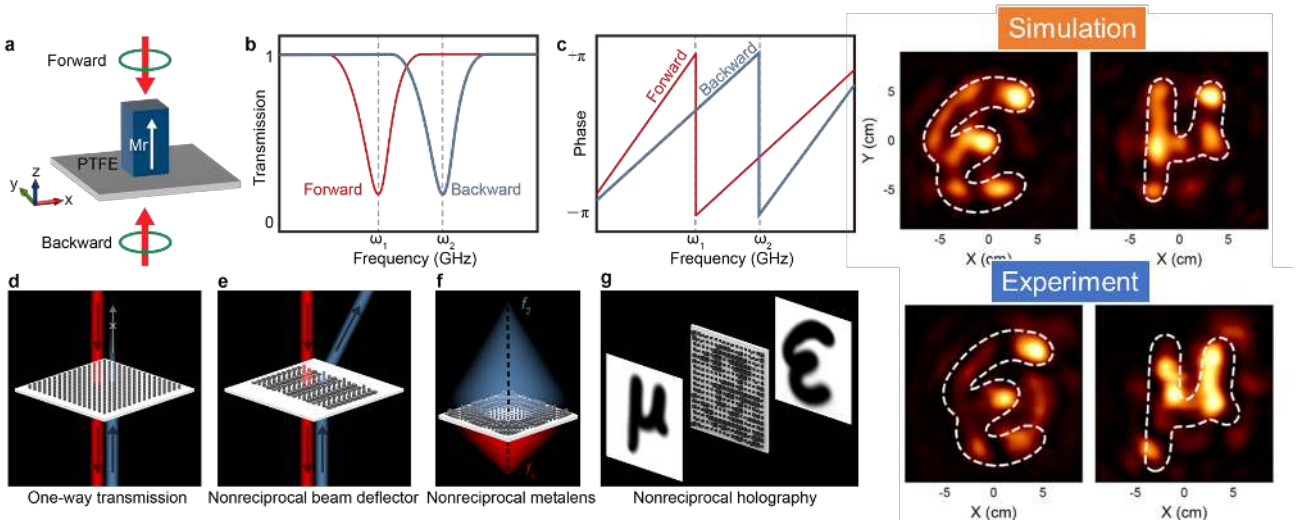

Fig. 2. Self-biased nonreciprocal MO metasurfaces. (a) Operation mechanism of the a self-biased magnetic metaatom. (b) Illustration of nonreciprocal transmission near Mie resonance modes, leading to nonreciprocity in transmission amplitude. (c) Illustration of nonreciprocal transmission and phase near Mie resonance modes. Metasurfaces functions: (d) one-way transmission (e) nonreciprocal beam deflector (f) nonreciprocal metalens and (g) nonreciprocal holography metasurfaces. Also shown are the simulation and experiment results of the nonreciprocal metasurface.

Second, we report a self-biased MO metasurface with nonreciprocal phase gradients, as shown in Fig. 2. Thanks to the large remanent magnetization and coercivity of hexaferrite materials, the biasing magnetic field is not required. Moreover, the magnetization of each meta-atom can be directed along independent directions, facilitation the realization of phase gradient metasurfaces. At ~15 GHz frequency, we experimentally demonstrated unidirectional transmission with an isolation of 9.18 dB and insertion loss of 1.35 dB. We demonstrate a non-reciprocal deflector reaching 0°/29° forward/backward deflection angles. We also demonstrate a nonreciprocal lens with forward focal length of 110 mm and backward focal length of 54 mm. Finally, we showed nonreciprocal holograms with ε and μ patterns in the far-field for forward and backward propagations, respectively.

Rational Design and Fabrication of UV-Resonant Plasmonic Nanoantennas for Enhanced CD Spectroscopy

B. M. Reinhard[1]

[1]Department of Chemistry and The Photonics Center, Boston University, United States
*corresponding author: bmr@bu.edu

Abstract: Rational electromagnetic optimization strategies for plasmonic aluminum antennas in the ultraviolet range of the electromagnetic spectrum are presented, evaluated, and discussed. Scalable fabrication strategies for UV resonant plasmonic antennas for applications in CD spectroscopy are experimentally evaluated.

Circular dichroism (CD) spectroscopy provides important structural information about biomolecules in solution, but the method suffers from low sensitivity, which makes high sample concentrations necessary. Especially for valuable biomolecules, the need for high concentrations is a significant impediment. One potential strategy to overcome this challenge is in the development of adequate antenna structures that can enhance the CD signal. Electronic CD arises from differential absorption of left and right circularly polarized light. Since molecular electronic transitions lie in the ultraviolet (UV), there is an urgent need for antennas that can enhance electromagnetic fields in this wavelength range. Aluminum supports localized plasmon resonances in the UV which make it an interesting material for UV-resonant plasmon resonances. In this presentation, we will review our recent work in the design, fabrication, and characterization of UV-resonant aluminum nanoantennas.

Although electromagnetic simulations can provide reliable predictions of the performance of a nanoantenna with defined geometry, by themselves they cannot predict the best antenna design. In order to optimize the structure of an antenna design they need to integrated in a rational optimization algorithm. Genetic optimization strategies have shown promise for the rational design of plasmonic nanoantennas.[1–3] Inspired by these studies, we have investigated genetic optimization algorithms to achieve a rational design of aluminum nanoclusters that optimize the performance at a desired wavelength in the UV. The implemented algorithm, the resulting structural predictions, and some general implications for designing UV-resonant nanoclusters will be discussed.

In addition to the optimization of the antenna design through electromagnetic simulations, scalable fabrication strategies for aluminum nanoantennas are necessary for CD application. In this presentation, we will review our strategy for large scale fabrication of defined aluminum nanostructures. At the end of the presentation, we will provide an outlook about how the performance of the current generation of aluminum antennas can be further enhanced.

Nonlocal response of magnons in photonic structures

H. Ishihara*, K. Kato, and T. Yokoyama

Department of Materials Engineering Science, Osaka University, Japan
*corresponding author: ishi@mp.es.osaka-u.ac.jp

Abstract: We develop a nonlocal response theory of magnons and discuss the spatial correlation between microwaves and magnon waves that leads to unconventional effects of magnon-polaritons (MPs). Based on this framework, we theoretically demonstrate anomalous selective coupling of MPs in layered magnetic thin films in the absence and presence of one-dimensional photonic structures. Further, we show the magnonic antenna effect that transcribes the functionality of the thick-layer MPs to the nanoscale thin-layer MPs.

The design of the interaction between fields and matter elementary excitations is crucial for probing quantum properties of materials and field control. The important degree of freedom for controlling the interaction is their spatial structures. However, although both of them have wave characters, the correlation of each spatial structure has not been fully exploited. In the presence of the spatial correlation between both waves, the nonlocal response occurs, namely, the response appears at sites remote from the excited sites through the spatial extension of matter wavefunctions. For example, the excitonic nonlocal response has been extensively studied and unconventional optical effects have been revealed [1][2].

The present study develops the nonlocal theory of magnons, which is an elementary excitation of magnetic materials and demonstrates functional microwave responses of magnetic thin films. A coupled system of magnons and microwaves is known as magnon-polariton (MP) which is drawing attention recently because of its potential applications. In particular, the coupling between microwave cavities and magnons is one of the representative targets of study these days [3]. However, no study has been conducted for designing the coupling of magnons and fields as waves. In our theory, we solve the constitutive equations and Maxwell equations of the magnetic field H and the magnetization M self-consistently. We should note that the induced polarization P appears for photonic structures in the coupled equations of H and M. Since P affects H in the magnetic optical response, we should treat all of E, P, H, and M self-consistently.

One of the theoretical demonstrations is the microwave response of Yttrium-Iron-Garnet (YIG) film with mm thickness (see, Fig. 1(a)). In this case, the single-mode magnon exhibits both level repulsion and level attraction-like effects. The interference between the incident field and radiative field plays an important role, and these spectral behaviors are the intrinsic response of the magnon. On the other hand, all the magnon modes (along the film axis) with different numbers of nodes energetically degenerate. However, the degeneracy is lifted by the coupling between the magnon mode and the same parity Fabry-Perot mode, which enables a selective excitation of MPs. It can be applied to control the spin texture by the spatial structure of the microwave. For the micrometer-scale YIG layer in the one-dimensional photonic crystals (see, Fig. 1(b)), where a single cavity mode couples to the separated magnon modes, the spatial correlation between the magnon and microwave appears even in a μm thin magnetic film by controlling the parity of field mode in the cavity. When the cavity mode has a node at the thin YIG layer, the coupling component to the "traveling" wave can be larger than that of the "standing" wave. By selecting the parameters of dielectric layers and the number of layers, such a situation is achieved, and the level attraction-like behavior is obtained although the MPs do not show the level attraction. Note that the level attraction-like and repulsion-like spectra are controllable by the external magnetic field.

Another demonstration is an antenna effect of magnon [4]. We have proposed a multilayered magnetic structure to demonstrate a large and switchable magnon current in the integrable thin magnetic layer (see, Fig. 2). We consider the nanoscale YIG film and macroscopic YIG substrate separated by a μm dielectric layer. Although nm films are favorable for the fabrication of MP circuit, magnons in such a thin film cannot couple with the field. On the other hand, the process of the circuit with nanoscale depth fabricated only on the surface of the thick film does not work because of MP motion is dominated by the whole thick film. Our proposed structure overcome such difficulties by the mechanisms: "waveguide modes" and a "magnonic antenna effect". The formation of the waveguide mode is attributed to the spatial structure of the dielectric constant, which considerably enhances the light–magnon coupling caused by the spatial interplay between the magnons and microwaves. The magnonic antenna effect, originating from the thickness of YIG and the magnon–magnon interaction (longitudinal field), increases the excited magnon densities in the thin layer and transcribes the functionality of the thick layer MPs to the nanoscale thin layer MPs. By analyzing the dispersion relations of the MPs in this system based on nonlocal response theory, we exhibited an enlarged and switchable magnon current in the nanometer-scale thin film. Moreover, from the radiative damping of MPs, we evaluated the coherence length for the MP transport and the figure of merit for the magnonic antenna effect. The evaluations indicate high efficiency of our proposed structure as magnonic devices.

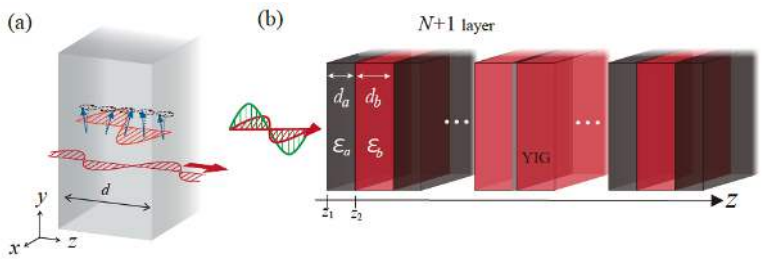

Fig. 1: Schematic figures of our system. (a)The YIG film confines the microwave and becomes the microwave cavity when the incident energy has the Fabry-Perot resonance. The microwave has standing and traveling mode and both of these modes couple with the spin waves. (b) Photonic crystal consisted of periodic N-layer.

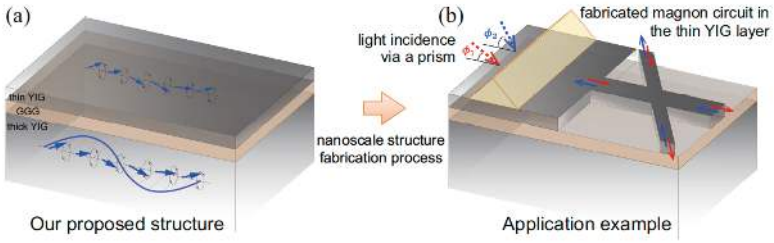

Fig. 2: Schematic of the proposed multi-layer structure for magnonic devices. (a) Proposed structure comprising thin YIG, thin gadolinium gallium garnet (GGG), and thick YIG layers. (b) Imaginary processed structure. [4]

As seen above, the nonlocal description of magnon has revealed novel coupling schemes of magnon-polaritons and their potential applications. We hope this study will stimulate future experimental studies to demonstrate our proposed effects of MPs.

Spin Relaxation, Diffusion and Edelstein Effect in Chiral Metal Surface

Y. Suzuki[1*] and Y. Kato[1, 2]

[1]Department of Physics, The University of Tokyo, Japan
[2]Department of Basic Science, The University of Tokyo, Japan
[*]corresponding author: suzuki@vortex.c.u-tokyo.ac.jp

Abstract: Motivated by recent experiments on spin polarization in chiral-crystalline metals, we investigate spin transport at the surface/interface of the chiral metals. Through eigenmode analysis of the Boltzmann equation, we first define spin relaxation time and diffusion length for the spin-splitting surface. We then describe charge–spin interconversion via the Edelstein effect at the interface between the chiral metal and a nonmagnetic metal with finite thickness. We finally show the Onsager's reciprocal relationship at that composite system.

There has been much interest in electron spin generation, detection and transport in surfaces, interfaces, and non-centrosymmetric crystals over the last three decades. Recent observations of current-induced magnetization in chiral-crystalline metals $CrNb_3S_6$, $TaSi_2$ and $NbSi_2$ [1–4] bring a new perspective to these fields of spin transport. The chiral metals display parallel coupling of current and spin, in contrast to the Rashba system where spin and momentum are coupled perpendicularly. Furthermore, two remarkable features of spin transport have been found in the chiral metals: nonlocal spin polarization in the absence of net charge current [3,4], which is recently of theoretical interest [5,6], and highly efficient charge–spin interconversion at the interface [1,3,4]. To describe these two features, it is a fundamental issue to examine spin diffusion length in the chiral metals, as well as to formulate the conversion process between charge current and spin current across the interface.

In this study [7], we describe spin relaxation and diffusion in a two-dimensional metal with anisotropic spin–orbit coupling, as a prototypical model of the chiral metals (Fig. 1 (a)). We also discuss the Edelstein effect and associated charge–spin interconversion at the interface between the two-dimensional system and a nonmagnetic metal with finite thickness (Fig. 1 (b), (c)). Our calculation is based on the Boltzmann transport equation beyond the relaxation time approximation, with which we take account of impurity scattering at the two-dimensional metal.

Our contributions are three-fold: (i) We have defined spin diffusion length for each spin component and for each diffusion direction in the chiral metal surface. Our definition does not rely on spin-dependent chemical

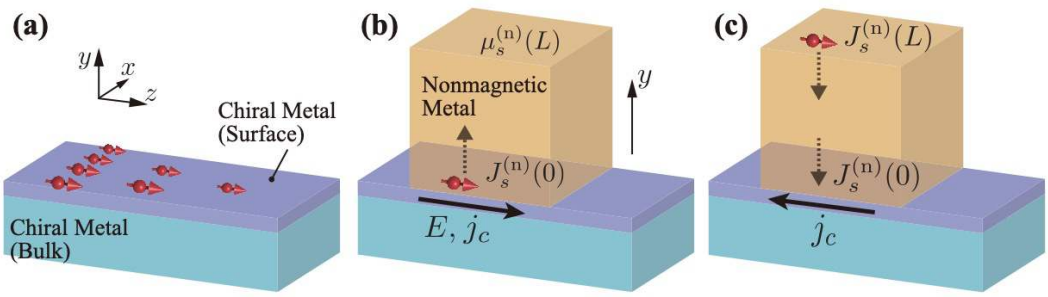

Figure 1. (a) Spin relaxation and diffusion, (b) direct Edelstein effect, (c) inverse Edelstein effect

potential, which is conventionally employed but is ill-defined under strong spin–orbit coupling of the chiral metals. (ii) We have obtained analytical expressions for the conversion efficiencies at the chiral metal interface, from charge current to spin current, and vice versa. Here in accordance with the spin-current-injection experiment, we take account of a finite thickness of the nonmagnetic metal attached on the chiral metal. Such a realistic description has been done for the first time by this study, in contrast to previous theoretical studies on the Edelstein effect [8–11]. (iii) We have developed the Onsager's reciprocity for the Edelstein effect, originally given by Ref. [8] at a surface, to the interface system. Our findings (i)–(iii) will pave the way for the future analysis of the spin transport properties in the bulk chiral metals.

Emergent inductance by dynamical ferromagnetic nanostructures

J. Ieda[1*]

[1] Advanced Science Research Center, Japan Atomic Energy Agency, Japan
[*]corresponding author: ieda.junichi@jaea.go.jp

Abstract: Emergent inductance appears universally when magnetization dynamics is coupled with conduction electrons based on a sequential action of spin torque and spinmotive force effects under ac currents. An original version of the emergent inductor using a spiral magnet can be extended to include the spin-orbit coupling effects. A striking common feature among emergent inductors is their size dependence of the effect; the inductance is inversely proportional to the sample cross-sectional area, opening a way for integrating an inductor element.

The interaction of spin current and magnetization dynamics has been a central interest in spintronics for a long time, and it is continuously being developed for better and lower power consumption device applications in the nano-scale size. S-d exchange coupling is a key factor that controls spin-dependent transport and magnetization dynamics in ferromagnetic conductors and ferromagnetic/nonmagnetic interfaces. This is due to the transfer of angular momentum and energy between conduction spin and magnetization texture. These characteristic properties are the basis for spin-transfer torque (STT), and spinmotive force (SMF) [1].

Because the SMF is the spin version of Faraday's law of induction, one can envisage the spin-extension of inductor operation in magnetic nanostructures. This was actually invented by a theoretical proposal of the so-called "emergent inductor" using a spiral magnet [2]. When an electric current flows in a spiral magnet, it stores the energy in the spiral structure formed by the local magnetization via its exchange coupling with conduction electrons. In terms of the Berry phase formalism, where the spin Berry phase is given by the solid angle sustained by magnetization dynamics, the emergent inductance can be thought of as an extension of the dynamical Aharonov–Bohm effect to a spiral magnet where the electromagnetic potential is replaced by a spin-dependent Berry connection generated by the spatial variation of the magnetization. In this presentation, we discuss the basic notion of the emergent inductance based on the well-studied theories of spin torques and spinmotive forces in ferromagnetic nanostructures.

Focusing on the adiabatic processes of STT and SMF, the inductance originating from spiral dynamics can be expressed as the following simple formula [2]:

$$L = \left(\frac{p\hbar q}{2e\sqrt{K}} \right) \frac{l}{A} \tag{1}$$

where p is the spin polarization, $\hbar$ is the Dirac constant, q is the spiral wave number, e is the elementary charge, K is the magnetic hard axis anisotropy constant, l is the spiral magnet length, and A is the spiral magnet cross-sectional area. A prominent feature of emergent inductors is their inductance magnitude dependence on physical size. Contrary to the coil inductance that is proportional to the coil cross sectional area, A ($L \propto A$), the emergent inductance is inversely proportional to the area that the current passes through ($L \propto A^{-1}$). This property opens an innovative avenue for downsizing inductor elements. Soon after the theoretical proposal, the concept was experimentally demonstrated in a centrosymmetric helical magnet, $Gd_3Ru_4Al_{12}$ in low temperatures

(T < 20 K) [3] where the inductance was reported comparable to that of a commercial one (~ 400 nH), but in a volume about a million times smaller. Theoretical studies have shown that two excitation modes of a spiral magnetic texture, namely, its translational displacement and rotation of the spiral plane, contribute to emergent inductance with opposite signs [4,5]. This may explain the negative inductance observed in the experiment [3]. Another observation of emergent inductance has been achieved in YMn_6Sn_6 at room temperature [6]. The discovery of emergent inductance has arisen a revision of electronics theories, and we are at the beginning of a new chapter exploring inductance by quantum mechanical mechanisms.

The concept of the emergent inductor is not limited to original spiral magnetization dynamics. In fact, a novel inductance of a spin-orbit coupling (SOC) origin was proposed [7] where an SOC stores the energy in itself and mediates the energy conversion with the electric energy. The spin–orbit inductance results from the time derivative of the Aharonov–Casher phase in magnetic materials, where the Berry connection originating from SOCs depends on the electron's momentum and spin. The spin–orbit inductance can be formulated based on a dynamical spin Berry phase acquired by an electron moving in arbitrary magnetic textures in the presence of SOCs. Exploring spin–orbit inductance with spatially uniform magnetization is of particular interest, where the other inductance mechanisms are ruled out, and it provides nearly frequency independent inductance, except in the vicinity of the ferromagnetic resonance frequency ~1–10 GHz. This can resolve the issue related to a limitation in the operating frequency in the previous experiments [3,6] reflecting the dynamics of spiral magnets.

A next issue to be addressed is the quality (Q-) factor of emergent inductors, defined as $Q = |\omega L/R|$, where R denotes the sample resistance leading to the energy dissipation. Because both L and R scale with the sample size in the same way, miniaturization does not improve the Q-factor. To tackle this problem, new material combinations including topological and ferromagnetic insulators are currently under investigation [8].

Topological textures and CP^2 Skyrmion crystals in quantum spin-nematics

Yutaka Akagi*

The University of Tokyo, Japan
*corresponding author: yutaka-akagi@g.ecc.u-tokyo.ac.jp

Abstract: Recently, topological spin textures such as Skyrmions have attracted scientific and technological interest. However, in most studies on topological spin textures, magnetic moments are approximated as O(3) vectors. This simplification neglects key features of quantum magnets. Thus, we develop the theoretical methods in models with spin–1 moments for quantum spin-nematics. Using the methods, we have found that CP^2 Skyrmion crystals and their relatives are realized in a new type of model for quantum spin-nematics, having a generalized Dzyaloshinskii-Moriya interaction.

Topological excitations (textures) play an important role in both conventional liquid crystals, i.e., nematic phase, and in spin systems. However, little is known about their role in quantum spin nematic phases (quadrupolar phases) [1,2] which are invisible to conventional probing techniques due to the absence of dipole long-range order. Thus, we consider the topological excitations in these nontrivial phases. The model is the spin-1 bilinear biquadratic (BBQ) model on the triangular lattice [3,4]. Using homotopy analysis and a numerical optimization technique, we identify a new family of Skyrmions with dipole moment at a particular point in parameter space, in which the system has global SU(3) symmetry. The Skyrmion with higher topological charges spontaneously decays into “elementary” Skyrmions with emergent interactions [5]. We have also found nontrivial fine structures of point-like defects in spin-nematics, which induce dipole moments as well [6]. In addition, we have examined the thermodynamic properties and dynamics of $\mathbf{Z}_2$ point-like defects in ferro-nematic order by using a molecular dynamics technique based on the framework of a u(3) algebra which we have developed [7].

Recently, through interdisciplinary collaboration (see Collaborators below), we have numerically found that CP^2 Skyrmion crystals (spin nematic Skyrmion crystals) possessing both dipole and quadrupole moments are stabilized as the ground state in SU(3) chiral magnets [8], which are SU(3) magnets endowed with a generalized Dzyaloshinskii-Moriya interaction [9]. The new type of model for quantum spin-nematics could be implemented using spin-1 spinor Bose-Einstein condensates (BECs) with an artificial spin-orbit coupling [10] in an optical lattice. We have investigated the ground state structure of SU(3) chiral magnets for wide parameter regions and found various exotic phases, for example, CP^2 Skyrmion crystal, CP^2 Skyrmionium crystal, and CP^2 Helical phase [11]. We have clarified the properties of these nontrivial phases using several physical quantities like energy, topological charge, and structure factors, mapping out the phase diagram.

Nonreciprocal charge transport and phase transitions in noncentrosymmetric superconductors

A. Daido[1] * and Y. Yanase[1]

[1]Departrment of Physics, Kyoto University, Japan
*corresponding author: daido@scphys.kyoto-u.ac.jp

Abstract: Nonreciprocal phenomena are attracting attention as the novel functionality and probes of noncentrosymmetric materials. In this talk, we discuss nonreciprocal charge transport and phase transitions in noncentrosymmetric superconductors under magnetic fields. We reveal the close connection of nonreciprocal phenomena and finite-momentum superconductivity. The obtained results show that nonreciprocal charge transport offers a versatile probe of the finite-momentum superconductivity.

Recent studies have revealed that noncentrosymmetric materials show various nonreciprocal phenomena such as the directional resistance (magnetochiral anisotropy), nonlinear Hall effect, and superconducting diode effect. They are appealing not only for engineering purposes but also as novel probes of noncentrosymmetric systems and are among the hallmarks of modern condensed matter physics. Further study of nonreciprocal phenomena would shed light on unprecedented phenomena in noncentrosymmetric materials. In particular, noncentrosymmetric superconductors offer a fertile ground to explore exotic physical phenomena arising from the interplay of nonreciprocity and macroscopic quantum coherence of Cooper pairs.

In this talk, we theoretically study the intrinsic nonreciprocity in the charge transport and phase diagrams of noncentrosymmetric superconductors under magnetic fields. In such systems, it is known that Cooper pairs spontaneously acquire a finite center-of-mass momentum in equilibrium because of the magnetoelectric coupling of electrons due to the Rashba spin-orbit coupling. We discuss the fingerprint of finite-momentum Cooper pairs in nonreciprocal charge transport such as the directional resistance, nonlinear Hall effect, and superconducting diode effect as well as the phase diagrams under the supercurrent injection [1,2,3]. The obtained results uncover the novel aspect of finite-momentum superconductors and show that nonreciprocal charge transport offers a versatile probe of the finite-momentum superconductivity.

This work was supported by JSPS KAKENHI (Grant Nos. JP18H01178, JP18H05227, JP20H05159, JP21K13880, JP21K18145, JP22H01181, JP22H04476, JP22H04933) and SPIRITS 2020 of Kyoto University.

2. Akito Daido and Youichi Yanase, to be submitted.

While SDE is a powerful probe of the finite-momentum superconductivity, it works only in small-width samples to capture the intrinsic contribution. Unfortunately, this condition is not satisfied in general thin-film samples, including the candidate finite-momentum superconductors known so far.

Considering the great interest of the research community in finite-momentum superconductivity, versatile smoking-gun probes is highly desired. To resolve this issue, we pay renewed attention to the nonreciprocal paraconductivity, the nonreciprocal transport of Cooper pairs thermally excited above the superconducting transition temperature. The focus of the pioneering works has been on the magnetochiral anisotropy at low magnetic fields, to explain the experiment in MoS_2 [R. Wakatsuki, *et al*., Sci. Adv. **3**, e1602390 (2017)]. Therefore, the previous formulation is not applicable to moderate and high magnetic fields, and finite-momentum superconductors are out of its scope.

the connection of nonreciprocal phenomena and intrinsic properties of superconducting states has not been fully uncovered, offering

Indeed, it has been pointed out that SDE can detect finite-momentum superconductivity[1] , which has been sought after for a long time.

predict the colossal nonreciprocal charge transport of finite-momentum superconductors, by developing a generalized formulation of the nonreciprocal paraconductivity. The formulation is applicable to general finite-momentum superconductors, while we mainly study the finite-momentum superconductivity in noncentrosymmetric superconductors (called the helical superconductivity). By studying the Rashba-Zeeman superconductors in two dimensions, we elucidate that both the longitudinal and Hall nonlinear conductivity are enhanced by several orders of magnitude under the moderate- and high-magnetic fields compared to the low-magnetic-field region which has been studied in previous works. The enhancement of nonreciprocal charge transport is attributed to the development of the finite-momentum Cooper pairs. It naturally follows from the obtained results that finite-momentum superconductors in centrosymmetric materials also show huge nonreciprocal transport once the symmetry-protected degeneracy of Cooper-pair momenta is lifted by external fields. We also study the case of quasi-two-dimensional superconductors by deriving a Kubo-type formula of the nonreciprocal paraconductivity. The formula can describe general situations including the system under orbital magnetic fields as well as with multiple pairing channels. It turns out that the huge nonreciprocal charge transport is also obtained in the presence of the cyclotron motion of Cooper pairs. Thus, nonreciprocal charge transport is established as powerful probes of finite-momentum superconductivity regardless of the sample dimensionality.

The enhanced nonreciprocity is accompanied by the development of finite-momentum Cooper pairs and gives strong evidence of finite-momentum superconductivity when observed in experiments. Thus, we believe that this work meets the criteria for publication in Physical Review Letters based on the promising impacts on a broad readership.

Ultrathin magneto-optical devices based on all-dielectric metasurfaces

Y. Ota[1*], S. Gao[2] and S. Iwamoto[2]

[1]Department of Applied Physics and Physico-Informatics, Keio University, Japan
[2]Research Center for Advanced Science and Technology, The University of Tokyo, Japan
[*]corresponding author: ota@appi.keio.ac.jp

Abstract: Magneto-optical (MO) devices play a key role in introducing nonreciprocity in optical systems, but tend to be bulky due to weak MO effects available in the optical regime. In this talk, we discuss our recent efforts to design of all-dielectric MO metasurfaces toward ultrathin MO devices. We found that large Faraday rotations and high light transmittance can be realized in MO metasurfaces that are much thinner than the operating wavelength.

Free-space magneto-optical (MO) devices, such as polarization-based Faraday isolators, are indispensable for regulating the flow of light beams in optical systems. They tend to be bulky to gain long-enough interaction lengths to compensate for the weak MO effects in transparent MO materials in the optical domain. For example, Faraday rotators based on yttrium iron garnets (YIG) or their derivatives, which are the materials of the first choice at the telecommunication wavelengths, typically require a few hundred micrometers or longer to attain the required 45° non-reciprocal polarization rotation.

Downsizing MO devices has been of great interest for the last few decades. Early trials employed optical resonances in one-dimensional photonic crystals[1] and plasmonic structures[2]. However, the measured Faraday rotation angles (θ_f) and transmittance (T) were insufficient for practical use. Recently, all-dielectric metasurfaces have emerged as an alternative route to realize ultrathin Faraday rotators[3-5]. The numerical simulation in the report[3] demonstrated a large θ_f of 7° at a telecom wavelength with a 260-nm-thick metasurface based on bismuth iron garnet (BIG). However, this study did not consider the influence of fabrication imperfections, which could be inevitable in this material system considering the notorious difficulty of nanopatterning of iron garnets[6]. More recently, a novel design of an ultrathin Faraday rotator based on a silicon metasurface place on a plane cerium-substituted YIG film has been proposed and experimentally demonstrated[7]. This approach allows for avoiding the direct nanopatterning of the iron garnet layer. However, the reported value of θ_f was less than 1° even in the design, which will limit the application of the device.

In this talk, we will discuss our recent efforts to design ultrathin Faraday rotators based on all-dielectric MO metasurfaces. First, we examined the influence of fabrication imperfections on the MO metasurface design reported previously[3] (see Fig. 1(a)). We found rapid degradation of θ_f and light transmittance when introducing tilted sidewalls in the constituent BIG microresonators (Figs. 1(b) and (c)). As a result, a figure of merit of the device, defined as $\theta_f T^{1/2}$, also exhibits significant reduction by reclining the sidewall just by 10°. Interestingly, we found that asymmetric cladding of the metasurface can significantly recover the performance of the Faraday rotator[8] (not shown). As another approach, we also investigated a Faraday rotator structure based on a Si photonic crystal slab on a plane YIG thin film[9] (not shown). By employing guided mode resonance in the 500-nm-thick YIG layer, we achieved high Q factor resonances, which largely enhance Faraday rotation available in the thin-film device. We numerically observed a θ_f of 45° with a transmittance of ~ 70% in an optimized design.

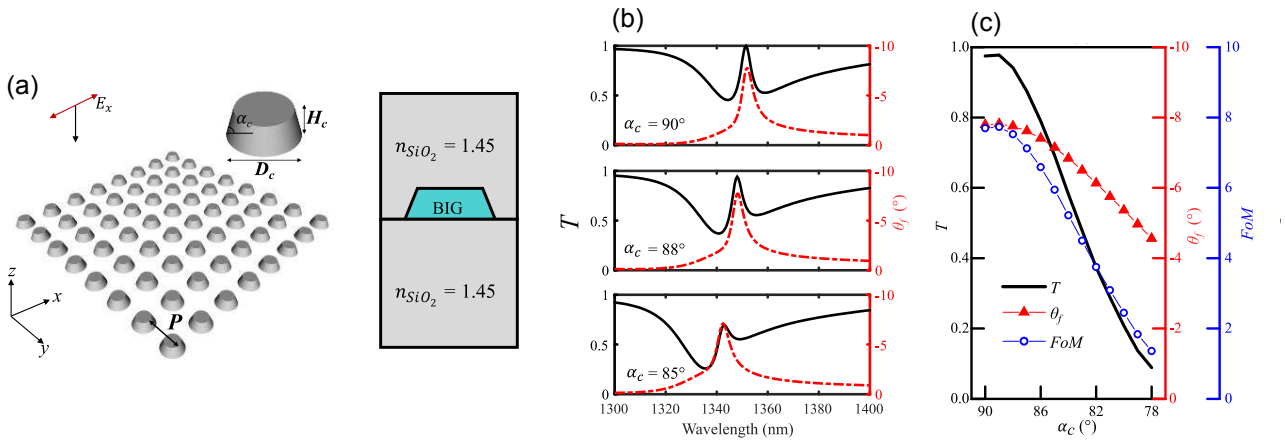

Figure 1 (a) Investigated metasurface composed of BIG microdisks with tilted side walls. (b) Faraday rotation (red dash lines) and transmission (black solid) spectra when varying the sidewall angle (α_c). (c) Faraday rotation angles, light transmittance and figures of merit as a function of sidewall angle.

Bose–Einstein condensation of freely evolving overpopulated magnon gas to the uniform precession state

A. A. Serga[1*]

[1]Fachbereich Physik and Landesforschungszentrum OPTIMAS,
Rheinland-Pfälzische Technische Universität Kaiserslautern-Landau, 67663 Kaiserslautern, Germany
[*]corresponding author: serha@rptu.de

Abstract: Bose–Einstein condensate (BEC), which magnons can form even at room temperature, is now a promising object for developing new computational concepts. Most studies employ Brillouin light scattering spectroscopy to observe a short-wavelength BEC in planarly magnetized ferrimagnetic films. However, electrical detection is essential for the implementation of magnon BEC devices. Using parametric electromagnetic pumping of magnons in perpendicularly magnetized films, we achieved a new long-wavelength type of BEC and investigated its behavior by inductive detection.

Coherent spin-wave states, such as Bose–Einstein condensates (BECs), which spontaneously form in an overpopulated magnon gas even at room temperature [1], have considerable potential for wave-based computing and information processing at microwave frequencies [2, 3].

The magnon condensate is usually created in the low-damping yttrium iron garnet (YIG) films by the parametric pumping of magnons by a microwave electromagnetic field. In this process, external microwave photons split into magnon pairs with half of the pumping frequency and opposite wavevectors. They populate a gaseous magnon distribution with internal interactions provided by the four-magnon scattering processes. Eventually, the magnon gas thermalizes to the bottom of the frequency spectrum, and if the applied pumping power exceeds a certain threshold, a BEC forms there. In in-plane magnetized YIG films, magnons condense at two frequency-degenerated minima with opposite wavevectors along the magnetization direction. Since the wavelength of such magnon condensate is only a few microns, its observation is quite challenging and is usually performed using Brillouin light scattering spectroscopy. Only recently, by exploiting the magnon wavelength transformation in a bulk YIG sample's inhomogeneous internal magnetic field, we have observed such a condensate using an inductive antenna [4].

Here, I present the formation of a new long-wavelength type of magnon BEC in perpendicularly magnetized YIG films. Under such magnetization conditions, the magnon spectrum has only one energy minimum at zero wavenumber. This state corresponds to the so-called magnon Kittel mode and represents a homogeneous precession of the magnetic moment of the sample at the ferromagnetic resonance frequency. The signal of such a precession is easily detected by a conventional inductive microstrip antenna, and its temporal evolution and spectral characteristics can be measured with high accuracy.

In our experiment, parametric magnons are generated 800 MHz above the spectral minimum at 3090 MHz and are broadly distributed around half of the pumping frequency. The intense pumping leads to a significant perturbation of the magnon distribution and often prevents BEC formation during its action [4, 5]. The same behavior of the spin system is observed in our case; only after the parametric pumping is terminated the spectrally-narrow BEC state with a linewidth of about 1 MHz is formed in the freely evolving magnon gas.

This research was funded by the European Research Council within the Advanced Grant No. 694709 “SuperMagnonics” and by the Deutsche Forschungsgemeinschaft (DFG, German Research Foundation) within the Transregional Collaborative Research Center – TRR 173/2 – 268565370 “Spin+X” (project B04).

Non-linear ferrite dynamics for microwave thin film technologies

Feodor Y. Ogrin

School of Physics and Astronomy, University of Exeter, Exeter, UK

Electromagnetic (EM) shock waves are normally associated with nuclear explosions, and as such a rare phenomenon. Analogous to a sonic boom, it is an interference effect, resulting in a surge of EM power, propagating with a speed of light. Since early 60s there was an interest to harness the effect to make it more technologically practical. One possible way to do that is within the configuration of a magnetically loaded transmission line (e.g. coaxial line). While the coaxial design has been proven to be viable for generating high power microwaves [1], its practicality in consumer technology is less so obvious due to high voltages (typically 10-100th kV) needed in order to obtain the effect. Theoretically, this problem can be resolved by scaling down the dimensions of the transmission line. Reducing down to microscopic dimensions, it is possible to obtain the effect at voltages as low as 1-10 Volts. At this level the effect can be usefully utilised in a range of electronic devices, and particularly the high frequency communications, which are of great demand in the development of modern IC technologies. Modelling extremely non-linear EM dynamics is however a challenging problem, that can not be done by the available conventional solvers. Here we approach the problem by using a unique modelling technique allowing to solve Maxwell equations in parallel to Landau-Lifshits-Gilbert's (LLG) [2]. The unique nature of our 3D FDTD-LLG code, is in the fact that LLG equation is solved exactly, accounting for the given geometry with the presence of any type of conducting or non-conducting materials [3]. This means that all non-linear effects can be calculated precisely without any linearization or imposed constraints.

In this contribution I will demonstrate the main characteristics and parameters of the shock wave propagation in microstrip transmission line. In particular, I will show the dispersion characteristics of the wave, its dependence on the geometric and material parameters of the device and those of the source of actuation. As well as the typical effects, such as applied field dependence and anisotropy, I will demonstrate some unique features, such as tuneability with the electric field pulse, allowing to manipulate the response in a broad GHz frequency range. I will also demonstrate the possibility of guiding the waves in microstripes with non-linear geometric designs, and discuss the potential for application in communication technologies.

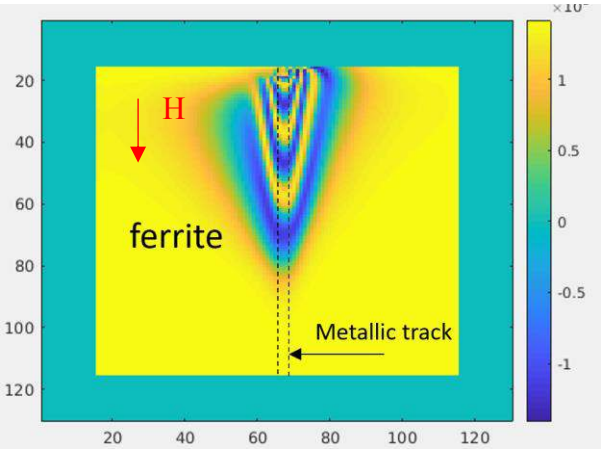

Figure 1. **Electromagnetic shock-wave propagation in a thin-film microstrip transmission line**. The wave is actuated with a short electric pulse between the microstrip (shown with dashed lines) and the base plane. Ferrite thin film (10micron) extended over the base line. Shock wave propagates below the strip, but deviates also into the whole slab. Intensity map: out-of-plane magnetisation. Initial orientation of the magnetisation is parallel to the field.

Wavelength-Independent Bragg-Like Effect

M. W. McCall* **and S. F. Koufidis**

Blackett Laboratory, Department of Physics, Imperial College London, London, United Kingdom
*corresponding author: m.mccall@imperial.ac.uk

Abstract: We have recently established that a uniform birefringent medium can exhibit an arbitrarily broadband Bragg-like response, based solely on matching the chirality parameter to the medium's average refractive index rather than on the usual Bragg condition. Here, we demonstrate that such a response can also be achieved in a broader family of optically active media, which relaxes the previously identified hard-to-achieve resonance condition while offering control over the resonance bandwidth via an externally applied static magnetic field.

The Drude-Born-Fedorov model for circular birefringence may be phenomenologically generalised, as in **[1]**, to include the effect of gyrotropy induced by an externally applied magnetic field. The constitutive relations read

$$\mathbf{D} = \epsilon_0[\boldsymbol{\epsilon} \cdot \mathbf{E} + (\chi - i\alpha)\eta_0\mathbf{H}] \quad \text{and} \quad \mathbf{B} = \mu_0[(\chi + i\alpha)\eta_0^{-1}\mathbf{E} + \mu\mathbf{H}], \tag{1}$$

where all the symbols have their usual meaning, α, χ are the chirality parameter and Tellegen coefficient, respectively, and for the static magnetic field $\mathbf{B}_0$ being aligned along the positive z-axis, the permittivity tensor is

$$\boldsymbol{\epsilon} = \begin{pmatrix} \epsilon & -ig & 0 \\ ig & \epsilon & 0 \\ 0 & 0 & \epsilon_z \end{pmatrix}. \tag{2}$$

Although the constitutive relations in Eq. (1) are oversimplified, since gyrotropy will in principle affect both the chirality and the permeability (see **[2]**), such an approximation is indeed widely-adopted as it leads to more insightful dispersion relations. Aligning the direction of propagation in a suitable z'-axis, so that the angle between the wavevector $\mathbf{k}$ and $\mathbf{B}_0$ is θ, the supported refractive indices will then satisfy the equation

$$n^4 + \beta n^2 + \gamma n + \delta = 0, \tag{3}$$

where β, γ, δ are generally functions of the medium's parameters and, crucially, of the declination angle.

In the absence of the Faraday effect ($g = 0$), the tensor in Eq. (2) describes a uniaxial medium which combined with Eq. (1) yields that of **[3]**. Then, plane-waves propagating at an angle θ off the optical axis z, along z', experience a linear birefringence $\boldsymbol{\epsilon}_\perp = \mathrm{diag}(\epsilon_1(\theta), \epsilon_2(\theta))$. Then, the solutions to Eq. (3) are given by

$$\pm n^{(\pm)} = \pm\sqrt{\alpha^2 + \bar{\epsilon}\mu - \chi^2 \pm \sqrt{4\alpha^2(\bar{\epsilon}\mu - \chi^2) + \Delta\epsilon^2\mu^2}}, \tag{4}$$

where $\bar{\epsilon}(\theta)$ is the average dielectric constant and $\Delta\epsilon(\theta)$ measures the birefringence. In the absence of absorption, it turns out that Eq. (4) becomes purely imaginary whenever the chirality parameter α lies in the regime

$$(\bar{\epsilon} - |\Delta\epsilon|)\mu - \chi^2 < \alpha^2 < (\bar{\epsilon} + |\Delta\epsilon|)\mu - \chi^2, \tag{5}$$

which signifies that a bulk medium will then support evanescent modes. For a fixed θ, calculation of the eigenmodes demonstrates that there, the upper branch of Eq. (4) refers to circular polarisation, whereas the lower to linear polarisation, which is a combination of forward and backward propagating circular polarisations. From the chirality-domain dispersion of Fig. 1, and the chirality-domain intensity transmittances for a slab of the considered medium in Fig. 2, it is evident that we have a Bragg-like response, similar to that of structurally chiral media (SCM), without however matching the wavelength of light to a spatial period but by resonant tuning of the chirality parameter to $\alpha^2 = \bar{\epsilon}\mu - \chi^2$. Such a resonant condition signifies extreme values of chirality, leading to the negative refraction regime, that has recently been achieved in meta-media at THz frequencies **[4]**.

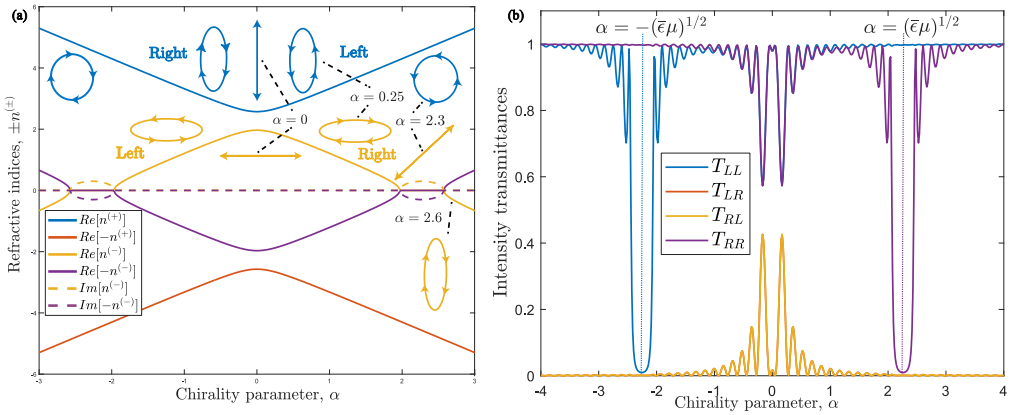

Figure 1 Bragg-like response of a linearly and circularly birefringent medium: **(a)** chirality-domain dispersion and **(b)** intensity transmittances for a slab of the considered medium. The non-reciprocity parameter $\chi = 0$, and the angle is fixed so that the slab is impedance-matched with the surrounding dielectric **[3, arXiv preprint]**.

Comparison of Fig. 1b with the well-studied case of SCM, characterised by a pitch $h\Lambda$ with $h = \pm 1$ for right/left handedness, provides a clear analogy: the chirality parameter can be mapped to the pitch $h\Lambda$, whereby $\alpha > 0$ corresponds to a right-handed SCM that back-scatters right circular polarisations, whereas $\alpha < 0$ corresponds to a left-handed SCM that reflects left circular polarisations. For $\alpha = 0$ (correspondingly, $\Lambda = 0$), the medium becomes purely linearly birefringent and an exchange between circular states ensues (cf. Fig. 1b at $\alpha \approx 0$). Unlike the case of **[3]**, here, the key-parameters $\bar{\epsilon}(\theta)$ and $\Delta\epsilon(\theta)$, which determine the centre of resonance and bandwidth, are θ-dependent offering the possibility of relaxing the hard-to-achieve tuning condition $\alpha^2 \approx \bar{\epsilon}\mu$ by manipulating the angle between the direction of wave propagation and the medium's optical axis. We note that considering material dispersion and realistic losses will not significantly alter the medium's response (see **[3]**).

In a chiroplasma medium ($g \neq 0, \chi = 0$) **[1]**, or in a so-called G-chiral medium ($g \neq 0, \chi \neq 0$) with the permeability being a scalar, the aforementioned electromagnetic response can be achieved. Indeed, for the direction of propagation being perpendicular to the static magnetic field, Eq. (3) is once again rendered bi-quadratic, like Eq. (4), but with the centre of resonance and the chirality-domain bandwidth now depending, necessarily, on the gyrotropic parameter g. Remarkably, this dependence significantly eases the resonance condition of **[3]** to $\alpha^2 = (\bar{\epsilon} - g^2/\epsilon_1)\mu$, offering at the same time a convenient platform for manipulating the reflection/transmission bandwidth $\Delta\epsilon = |\epsilon_1 - \epsilon_2| + g^2/\epsilon_1$. As the required parameters are within reach of current meta-media technology, applications in optoelectronics, waveguiding, or fibre Bragg grating sensors are expected.

Symmetry control of strong chiral light–matter interactions in photonic nanocavities for efficient circularly polarised emission

Abstract: We demonstrate a novel concept for creating chiral excited states which does not rely on molecular structure. Instead, it depends on hybridising a non-chiral molecule with a chiral electromagnetic field, producing a hybrid light-matter chiral polariton state. This is achieved by a symmetry-controlled strong chiral-light–matter interaction between an electromagnetic mode of a chiral nanocavity and an achiral molecule. This electromagnetic mechanism simplifies the creation of chiral electronic states since it is far less demanding in terms of materials design.

Chirality, the property of asymmetry, is generally perceived as a geometric concept, with chiral materials existing in otherwise identical mirror forms known as enantiomers. Thus, creating chiral molecules, which have applications spanning pharmaceuticals to next generation photonic technologies[1-3], requires precise control of 3-D structure, is a challenging chemical problem. In contrast, if chirality could be conveyed on to an achiral molecule without the need for specific stereostructural control, then it would simplify the synthesis and broaden potential applications. Therefore, in this work, we show such an effect, where chirality is induced in achiral molecules by virtue of the chiral electromagnetic (EM) environment they occupies, a concept referred to as the electromagnetic-enantiomer, shown in Figure 1(a). We have synthesised and spin coated fluorescence achiral molecules -in various concentration with respect to PMMA- on Chiral Metamaterial (CM) of two periodicity i.e., 1000 nm and 1500 nm to realise ≈200 nm thick film. The molecular structure of the synthesized achiral molecules and schematic & SEM image of CM used is shown in figure 1(b) and 1(c) respectively. The chiral photoluminescence (CP) emissions from for Left-handed (LH) CM structure for both periodicity is shown in Figure 1(d). It can be seen from the figure that, in the case of 1000 nm metafilms, the luminescence showed two distinct regions of structure centered at λ≈ 560 nm and 620 nm. The structure observed around λ≈ 560 nm for mis-matched combinations of metafilm handedness and emitted light helicity (LH/RCP and RH/LCP) is a single peak, which appear to split into two less intense components for matched combinations, with the splitting being equivalent to ~ 107 meV (Δλ~ 28 nm). This splitting in PL peak is a definitive fingerprint of strong coupling[4]. Relatively weaker structure occurs in the region around λ≈ 620 nm, with a single peak observed for the mis-matched combinations and weaker, less defined features observed for the matched combinations. For the 1500 nm metafilms, the structure is less pronounced and the most noticeable feature, a single peak, occurs close to λ≈ 594 nm. The absence of strong coupling in the 1500 nm cavity indicates relatively weak electric fields compared to those for the 1000 nm. The EM simulations do show this effect where the maximum enhancement in the Electric field was observed for 1000 nm matched combinations of metafilm handedness and light helicity. The molecule displays distinctly different luminescence behaviour i.e., peak splitting under strong coupling, and

enhanced emission under weak coupling. This provides a simple route to create efficient (≈30%) circularly polarised emission. Such a level of efficiency has previously required structurally complex and multicomponent chemical systems. A potential application of the phenomenon is in making the manufacture of OLED sources of CP light a less challenging chemical problem, since current strategies rely on the challenging synthesis and isolation of chiral geometric molecular structures in high enantiomeric excess.

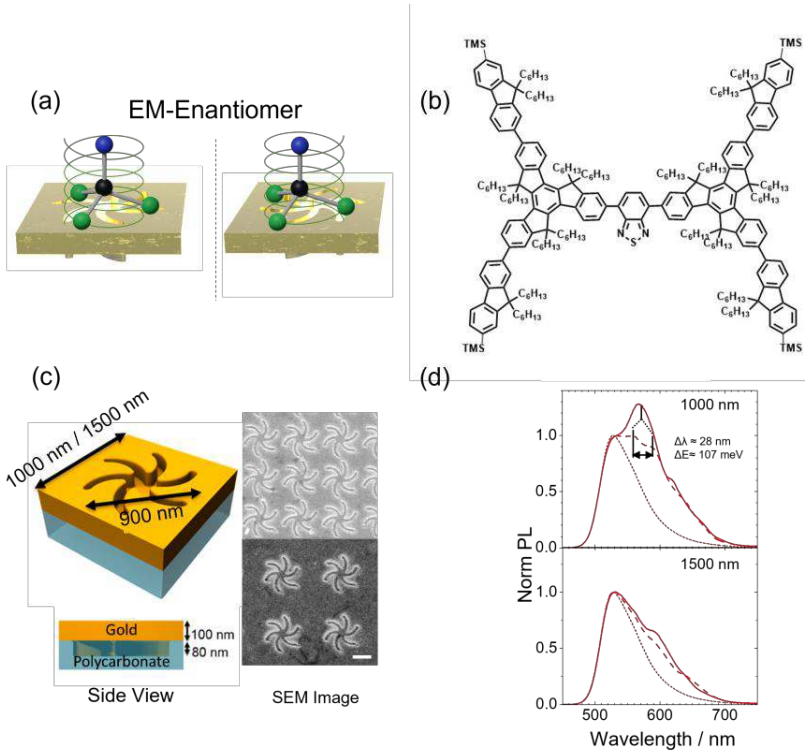

Figure 1 *(a) The interaction of chiral nearfields with achiral molecules results in EM-enantiomers, through the symmetry dependent creation of polariton states. (b) Molecular structure of MHeB14 dye. (c) SEM images and schematic showing orthographic (top) and side view (bottom) of LH nanocavity. (d) Normalised PL for both structures. The black vertical lines are guidance for eyes, highlighting the presence or absence of peak splitting. The dashed line and solid line respectively show the RCP and LCP PL emission from the structures. The overlapping dotted lines show LCP and RCP PL emission of dye when present on the flat gold. All spectra have been self-normalised to value at λ=533 nm*

Optical response of magnetic metals from first principles

M.K. Pogodaeva[1*], S.V. Levchenko[1], V.P.Drachev[1]

[1]Skolkovo Institute of Science and Technology, Russia
[*]corresponding author: mariia.pogodaeva@skoltech.ru

Abstract: We present a first-principle methodology to calculate spin-resolved dielectric function of magnetic metals applying Drude model. Interband and intraband contributions to the dielectric function are calculated using density functional theory in an all-electron full-potential framework. The results are compared to the experiments. We find a significant difference between the contribution of the spin-up and spin-down electrons. Our results allow to explain the existence of unexpected plasmon resonance in cobalt nanoparticles.

There is no clear understanding of the effects of magnetization on plasma frequency so far. Our recent research in plasmonics has shown an inconsistency between theoretical predictions and experimental measurements of optical properties of cobalt nanoparticles [1]. Specifically, a plasmon resonance was observed at 280 nm for cobalt nanoparticles that could not be reproduced by permittivity measurements for large-area films (see fig. 1).

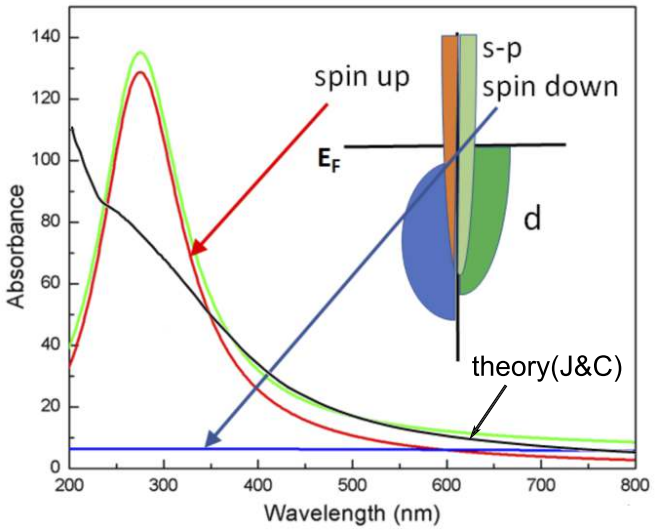

Fig. 1. Two-plasmon model for absorbance in cobalt nanoparticles. Red line shows the contribution from spin-majority electrons, while blue line shows the contribution from spin-minority electron. Green line shows experimentally observed spectrum from [1]. Black line shows theoretical prediction for spectrum of cobalt nanoparticles using data from [2].

The Mott model suggests that in magnetic metals there are two largely independent spin channels of conductivity. The probability of spin-flip scattering is low, and scattering rates for spin-up and spin-down channels are sufficiently different. The position of the absorption peak in the nanoparticles depends of the plasmon frequency, which is proportional to bulk plasma frequency where is the dielectric permittivity of the host medium, and is the interband contribution to the metal permittivity. Thus, separate consideration of spin channels for bulk optical properties will allow us to understand the unexpected plasmon resonances in magnetic nanoparticles, which the plasmonics currently fails to predict.

In our work [3] we have presented a methodolody to calculate spin-resolved plasma frequency of magnetic metals. We have applied the methodolody to calculate spin-up and spin-down plasma frequencies for cobalt and have shown that they are sufficiently different. We have shown, that the inclusion of spin-orbit coupling mixes spin channels and does not allow to fully resolve between spin-up and spin-down electrons, however, approximate resolution is still possible. The plasmon frequency in nanoparticles depends on the above described plasma frequency as follows:

$$\omega_p^2 = \frac{\omega_{pl}^2}{\varepsilon_{ib} + 2\varepsilon_h} \tag{1}$$

Here ε_{ib} is the interband contribution of bulk metal and ε_h is host permittivity. Calculated plasma frequency tensors for spin-up and spin-down channels in hexagonal cobalt have the following values: 5.03 eV and 3.44 eV for *xx* and *yy* components of the tensor and 4.89 eV and 4.63 eV for *zz* component of the tensor. Generally, the interband contribution is a frequency-dependent dielectric function, but for transition metals it is frequently considered as approximately constant small value ~1.

The dielectric function tensor of bulk metals can be separated to the vacuum, interband and intraband contributions:

$$\varepsilon_{i,j}(\omega) = \delta_{i,j} + \varepsilon_{i,j}^{inter}(\omega) + \varepsilon_{i,j}^{intra}(\omega) \tag{2}$$

In this work we are focusing on interband contribution to the dielectric function:

$$\varepsilon_{i,j}^{inter}(\omega) = \lim_{\mathbf{q}\to 0}\left\{\frac{4\pi e^2}{|\mathbf{G}+\mathbf{q}||\mathbf{G}'+\mathbf{q}|}\chi_{\mathbf{G},\mathbf{G}'}^{KS}(\mathbf{q},\omega)\right\}_{\mathbf{G},\mathbf{G}'=0} \tag{3}$$

Within the random-phase approximation (RPA), the Kohn-Sham dielectric permittivity χ^{KS} at **G**,**G**′=0 depends on wavevector **q**, difference between Fermi functions Δf_{mn} at states m and n, and difference between Kohn-Sham eigenenergies $\Delta\varepsilon_{mn}$ a of the given system:

$$\chi_{\mathbf{G},\mathbf{G}'=\mathbf{0}}^{KS}(\mathbf{q},\omega) = \sum_{m\neq n\mathbf{k}} \langle n|\mathbf{qr}|m\rangle\langle m|\mathbf{qr}|n\rangle \frac{\Delta f_{mn}}{\Delta\varepsilon_{mn}-\omega} \tag{4}$$

Abstract: We find that the known formula for the orbital magnetic moment misses a term in its diagonal elements. In this work, by considering a response to the magnetic fields including a monopole, we derive a modified formula for the magnetic quadrupole moment. We show that the trace of the magnetic quadrupole moment now has the Chern-Simons axion term, as expected from the relationship between the orbital magnetic quadrupole moment and the orbital magnetoelectric tensor.

Recently, the quantum formula of orbital magnetic quadrupole moment Q_{ij} was derived, which is defined as a response to the spatial modulation of magnetic fields[1,2]. Nonetheless, this result needs to amendments, because it does not satisfy the thermodynamic property that the derivative of the magnetic quadrupole moment Q_{ij} with respect to the chemical potential is equal to the orbital magnetoelectric tensor α_{ij}. In this work, by considering a response to the spatial modulation of magnetic fields including a monopole field, we derive a modified formula for the magnetic quadrupole moment, whose derivative correctly reproduces the orbital magnetoelectric tensor α_{ij} including the Chern-Simons term in its diagonal elements[3]. We show that the trace of the magnetic quadrupole moment comes from the correction of density of states due to the monopole field. We note that the magnetic quadrupole moment derived as such is not equal to the classically defined quadrupole moment, but it has additional terms[3]. We also discuss axion insulators, which have a quantized orbital magnetoeletric tensor. This class of systems is equivalent to higher-order topological insulators with chiral hinge states, and we explain that these hinge states are not primarily related with magnetoelectric response or orbital magnetic quadrupole moment.

Novel materials with magnetic skyrmions and their three-dimensional dynamics

S. Seki[1*]

[1]Department of Applied Physics & Institute of Engineering Innovation, University of Tokyo, Japan
[*]corresponding author: seki@ap.t.u-tokyo.ac.jp

Abstract: Topological swirling spin textures, such as skyrmions and merons, have attracted much attention as a unique building block for high-density magnetic information devices. In this talk, I overview recent discovery of novel materials and mechanisms to realize a rich variety of nanometric magnetic quasi-particles with nontrivial symmetry and topology.

Magnetic skyrmion, i.e., a topologically stable swirling spin configuration, has recently attracted attention as a particle-like object potentially suitable for the design of high-density information bits. Previous observations of skyrmions have mostly focused on noncentrosymmetric systems, where Dzyaloshinskii-Moriya interaction plays an important role[1,2]. On the other hand, recent theoretical studies suggest that skyrmions can be stabilized even in centrosymmetric systems by considering different microscopic mechanisms. For example, geometrical frustration of short-range exchange interactions on triangular lattice is predicted to stabilize a hexagonal lattice of skyrmions[3]. Another potential mechanism is the RKKY and four-spin interactions mediated by itinerant electrons, which is expected to favor a skyrmion lattice state for highly-symmetric (such as hexagonal or tetragonal) crystal lattice systems[4].

In this talk, I overview the recent experimental discovery of skyrmions in centrosymmetric systems[5-9]. In particular, we focus on the case of centrosymmetric tetragonal magnets, where the square lattice of skyrmions with extremely small diameter (1.9 nm for $GdRu_2Si_2$, i.e. the smallest value ever reported for single-component bulk materials) has been observed[7-9]. These compounds also host various non-trivial topological spin textures, and the present findings demonstrate that even a simple centrosymmetric magnet with competing interactions can be a promising material platform to realize a rich variety of nanometric magnetic quasi-particles with distinctive symmetry and topology.

If time allows, I will also discuss the recent experimental observation of skyrmion strings in three-dimensional systems and their excitation dynamics[10,11].

Magnetoelectric fields for chirality discrimination

E. O. Kamenetskii

School of Electrical and Computer Engineering, Ben Gurion University of the Negev, Israel

corresponding author: kmntsk@bgu.ac.il

Chirality is fundamentally related to a magnetoelectric response. But the magnetoelectric response is characterized by the violation of both spatial and temporal symmetry. It is claimed that time-even pseudoscalar optical chirality gives enantioselective fields. Are only time-even pseudoscalars required to describe local properties of chiral light-matter interactions? We argue that near fields with both spatial and temporal symmetry breaking, called magnetoelectric near fields, are true enantioselective fields for describing local properties of chiral light-matter interactions.

*corresponding author: hc.schneider@rptu.de

Abstract: We analyze the contributions of electron-magnon scattering and Elliott-Yafet spin-flip scattering to ultrafast magnetization dynamics in a model metallic ferromagnet. We find that far-from-equilibrium magnon distributions are created after ultrashort-pulse excitation and play an important role in the demagnetization process. We compare these findings to earlier calculations using the Elliott-Yafet mechanism alone.

Ever since its experimental discovery mor than 20 years ago, the demagnetization dynamics in ferromagnets has mostly been described in terms of effective temperature models for electrons, spins and lattice. Also, the spin-lattice coupling was mostly envisaged as being due to electron-phonon spin-flip scattering, similar to the Elliott-Yafet spin-relaxation mechanism in semiconductors and normal metals. Recently, there have also been suggestions that the angular momentum of phonons may be of importance. In order to compare the different contributions to the demagnetization process and how they affect the conservation/flow of angular momentum, one needs to understand them in microscopic detail.

In the past, we have used a microscopic description of electron-phonon scattering to study the spin-dependent electron dynamics of ferromagnetic metals [1] and ferromagnetic model systems [3] after ultrashort-pulse excitation. In this way, the electron-lattice coupling and its effect on the electronic spin polarization can be studied directly on ultrashort, i.e., sub picosecond, time scales, where the system is far from equilibrium and also far from any quasi-equilibrium as assumed in the 3-temperature mode..

More recently, we have investigated the coupling of electrons to magnons on the same ultrashort timescales. We introduce magnons as separate degrees of freedom by adapting the approach of Ref. [3]. We then compute the dynamics of momentum resolved electron and magnon distributions due to electron-magnon and statically screened Coulomb electron-electron scattering, which are treated at the level of Boltzmann scattering integrals, and electron-phonon scattering. The coupled equations for the spin and momentum dependent distribution function thus have the general form

$$\frac{\partial}{\partial t} n_{\boldsymbol{k},\sigma} = \frac{\partial}{\partial t} n_{\boldsymbol{k},\sigma}\Big|_{e-m} + \frac{\partial}{\partial t} n_{\boldsymbol{k},\sigma}\Big|_{e-e} \frac{\partial}{\partial t} n_{\boldsymbol{k},\sigma}\Big|_{e-pn}$$

We find that the electron-magnon scattering leads to a pronounced non-equilibrium for magnon modes that couple directly to spin-flip transitions in the spin-split ferromagnetic band structure. For reasonable parameters for iron, the electronic spin-flip scattering with magnons results in a transient electron spin polarization on a timescale of a few ten femtoseconds. We find that the transient electronic spin polarization and magnon distributions are similar for excitations either within the minority or the majority band. The connection of the calculated results to experimental findings and other models will be discussed.

We acknowledge funding by the Deutsche Forschungsgemeinschaft (DFG, German Research Foundation) through No. TRR 173–268565370 (project B03).

Chirality is a fundamental asymmetry phenomenon, with chiral optical elements exhibiting asymmetric response in reflection or absorption of circularly polarized light. Recent realizations of such elements include nanoplasmonic systems with broken mirror symmetry and polarization-contrasting optical absorption known as circular dichroism. An alternative route to circular dichroism is provided by spin-valley polarized excitons in atomically thin semiconductors. In the presence of magnetic fields, they exhibit an imbalanced coupling to circularly polarized photons and thus circular dichroism. Here, we demonstrate that polarization-contrasting optical transitions associated with excitons in monolayer WSe_2 can be transferred to proximal plasmonic nanodisks by coherent coupling. The coupled exciton-plasmon system exhibits magneto-induced circular dichroism in a spectrally narrow window of Fano interference, which we model in a master equation framework. Our work motivates exciton-plasmon interfaces as building blocks of chiral metasurfaces for applications in information processing, non-linear optics and sensing.

Chiral quantum phase shifters

N. Rotenberg[1*]

[1] Centre for Nanophotonics, Department of Physics, Engineering Physics & Astronomy, Queen's University, Kingston, Canada

[*]corresponding author: nir.rotenberg@queensu.ca

Abstract: Phase-shifters are a key component of photonic circuits, including those that process quantum information. This talk introduces such a phase-shifter based on a single, solid-state quantum emitter chirally coupled to a nanophotonic waveguide, covering both the basics of such a device and its performance in the presence of realistic imperfections. Finally, the fidelity of simple quantum photonic circuits based on these phase-shifters is considered.

The basic element of a reconfigurable quantum photonic circuit are phase shifters integrated within a Mach-Zehnder-Interferometer (MZI), with meshes of these devices enabling universal quantum information processing [1]. The phase-shifters must provide a phase shift spanning 2π in a controllable and accurate manner, and to date this is overwhelmingly accomplished by thermal shifters where a change of temperature by an applied current changes the optical properties of a section of the waveguide through which photons travel. Although highly accurate, such thermo-optical phase-shifters are slow, bulky and in general incompatible with cryogenic temperatures at which single-photon detectors (another critical component of integrated circuits) operate.

Here, we suggest a different type of phase-shifter, one based on a single quantum-emitter chirally-coupled to a nanophotonic waveguide [2]. We show how such an emitter-waveguide system can be used to shift the phase of passing photons by the requisite 2π range, and how this performance is altered by the presence of imperfections. Specifically, we consider imperfect emitter-waveguide coupling (leading to losses), directionality (i.e. sub-optimal chiral coupling, leading to reflections), pure-dephasing (a fast, scrambling of the quantum coherence) and spectral diffusion (a slow drift of the system response). We identify regions within this rich phase-space where high fidelity operation is possible, and show that it is compatible with current experimental chiral quantum systems, providing an additional route towards phase-shifters that meet the stringent requirements of quantum photonic technologies.

Gain-enhanced chiral sensing with achiral metasurfaces

S. Droulias[1*]

[1]Department of Digital Systems, University of Piraeus, Piraeus 18534, Greece

[*]corresponding author: sdroulias@unipi.gr

Abstract: Metasurfaces are ideal platforms for enhancing the inherently weak chiroptical signals of natural optically active molecules. Intuitively, the introduction of gain could provide the desired enhancement, however requires gain media that can couple directly to the chiral medium. In this work, it is shown that metasurfaces can mediate the coupling between the gain and chiral medium, enabling enhanced chiral sensing. The coupling mechanisms are analyzed and, through numerical simulations, the regimes and conditions for enhanced chiral sensing are demonstrated.

Among the most widely used techniques for chiral sensing are the polarimetric techniques of optical rotatory dispersion (ORD) and circular dichroism (CD), both routinely applied in industrial applications [1]. However, for measurements of dilute samples, and, particularly, of nanometer-scale thin films (e.g., protein monolayers), these signals become extremely weak, close to or even below the detection limits of modern instrumentation, practically rendering the chiral medium undetectable. To overcome this limitation, modern nanophotonic-based schemes rely on the utilization of resonant near fields, rather than propagating waves [2-5]. Alternatively, one could attempt to achieve the desired enhancement in the chiroptical signals, simply by introducing gain in the vicinity of a thin chiral film, for example, thus circumventing the need for the fabrication of sophisticated nanophotonic platforms. However, this would require gain media that can couple directly to the chiral medium.

In this work it is shown that metasurfaces that generate collinear electric and magnetic dipole moments can mediate the coupling between the chiral medium and gain, leading to signals stronger than those achieved from the chiral medium alone or when combined with the same metasurface without gain [6]. It is found that the indirect coupling between the chiral medium and the gain medium depends on how strongly gain couples with the metamaterial. For weak coupling, incident waves can be amplified without the metamaterial resonance being undamped (regime of background amplification), however for strong coupling the resonance becomes undamped (sharpened), i.e. loss compensated (regime of loss compensation) [7]. In this context, it is shown that the chiroptical signal enhancement occurs within the regime of loss compensation, as background amplification may as well result in amplified transmitted fields, but does not guarantee the enhancement of their chiral far-field signatures.

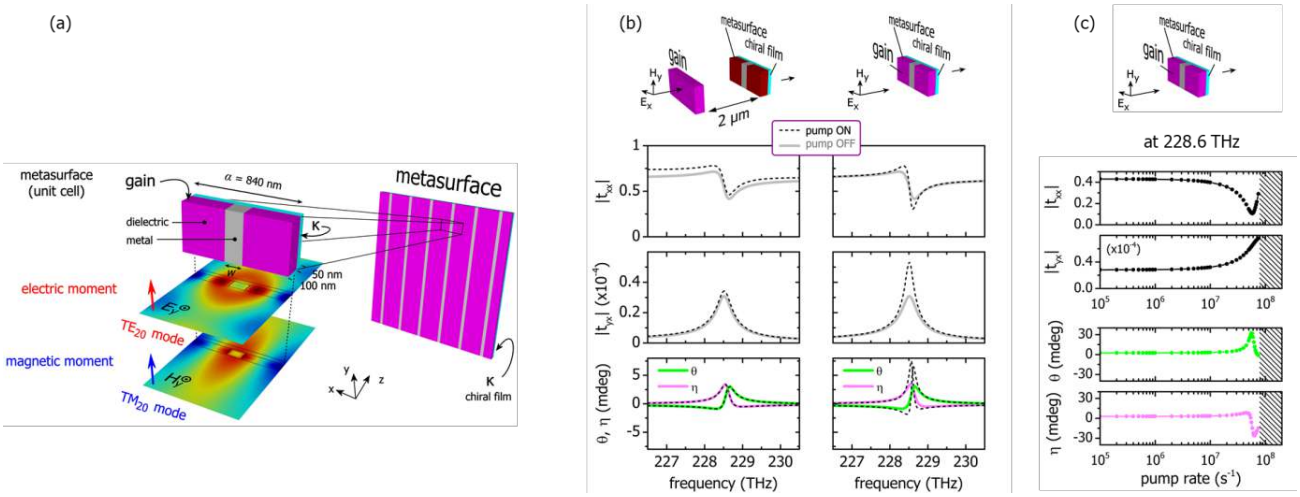

Figure 1. Achiral metasurface for gain-enhanced chiral sensing. (a) Implementation of gain-enhanced chiral sensing in the infrared, illustrating a single unit cell and a schematic of the metasurface containing 6 unit cells. The spatial field distribution of TE_{20}, the electric-type mode (that provides the electric dipole moment), and TM_{20}, the magnetic-type mode (that provides the magnetic dipole moment) are also shown. (b) Chiroptical signal enhancement for constant pump rate $R_p = 3\times10^7$ s^{-1}. *Left panel*: Gain coupled weakly to the metasurface leads to background amplification (enhanced t_{xx}, t_{yx} signals), however no chiroptical signal enhancement (optical rotation θ, ellipticity η). *Right panel*: Gain coupled strongly to the metasurface leads to loss compensation and enhanced chiroptical signals. (c) Pump-dependent study of the gain-assisted metasurface with chiral inclusions. Measurements of co-polarization (t_{xx}), cross-polarization (t_{yx}) transmission amplitudes and chiroptical signals θ, η as a function of the pump rate R_p at 228.6 THz, the resonant frequency of the metasurface's electric and magnetic modes, TE_{20} and TM_{20}, respectively.

The optical Dirac equation and confined modes at chiral, magnetoelectric, and non-Hermitian interfaces

S. A. R. Horsley[1*]

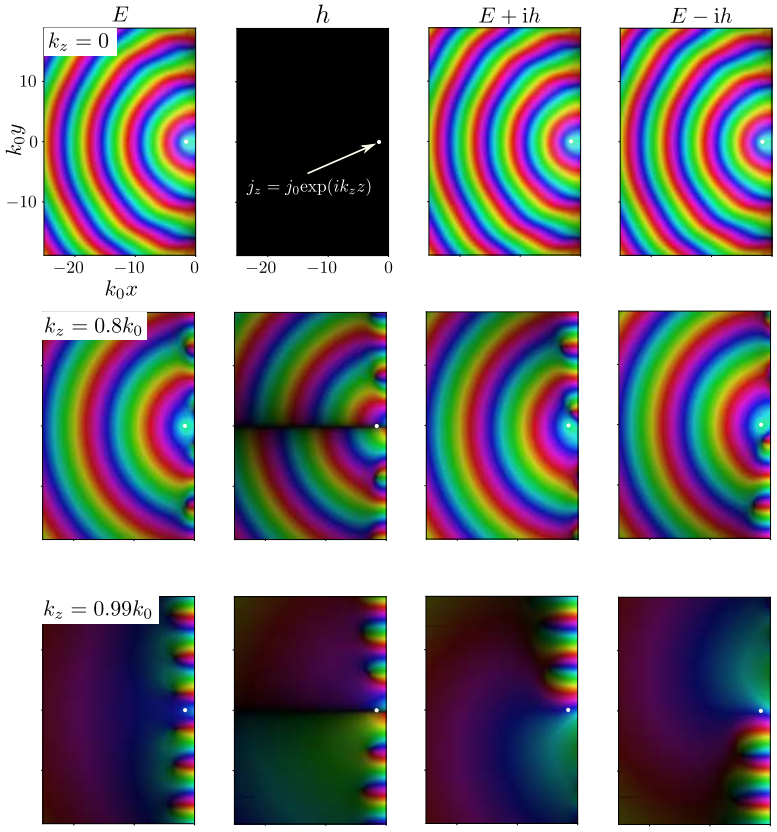
[1]School of Physics and Astronomy, University of Exeter, Stocker Road, Exeter, EX4 4QL UK
[*]corresponding author: s.horsley@exeter.ac.uk

Abstract: Despite describing particles of different spin, the structure of the classical Maxwell equations and the Dirac equation is almost identical. I will show this is useful for navigating the space materials, where in differing cases we can understand magneto-electric materials as an effective mass, or gauge field for light. I shall show how this analogy enables us to find new interface modes without ever solving Maxwell's equations, in addition to finding one-way propagating optical edge modes, and perfect absorbers.

The Dirac equation was developed to describe high energy electrons, but describes any spin ½ particle. For massless particles it reduces to simply the differential equation $c\,\boldsymbol{\alpha}.\nabla\,\psi+\partial_t\,\psi=0$,where $\boldsymbol{\alpha}$ is a 4x4 matrix. Interestingly, Maxwell's equations take exactly the same form as the Dirac equation when the curl equations are grouped together

$$c\begin{pmatrix}0 & -\nabla\times\\ \nabla\times & 0\end{pmatrix}\begin{pmatrix}\boldsymbol{E}\\ \eta_0\boldsymbol{H}\end{pmatrix}+\frac{\partial}{\partial t}\begin{pmatrix}\boldsymbol{E}\\ \eta_0\boldsymbol{H}\end{pmatrix}=0 \qquad (1)$$

The only modification is that the matrix $\boldsymbol{\alpha}$ is now a 6x6 matrix, consistent with the EM field being spin 1. In this form ("the optical Dirac equation") Barnett [1], and more recently Dennis et al. [2] have explored the connection between free space optics and spin half fields.



Here we use the same connection to design materials. Working at a single frequency, and introducing a set of linear material parameters (permittivity $\boldsymbol{\epsilon}$, permeability $\boldsymbol{\mu}$, and bi-anisotropy $\boldsymbol{\xi}$) , Maxwell's equations becomes

$$c\begin{pmatrix}0 & \nabla\times\\ -\nabla\times & 0\end{pmatrix}\begin{pmatrix}\boldsymbol{E}\\ \eta_0\boldsymbol{H}\end{pmatrix}=-i\,\omega\begin{pmatrix}\boldsymbol{\epsilon} & \boldsymbol{\xi}\\ \boldsymbol{\xi}^{\dagger} & \boldsymbol{\mu}\end{pmatrix}\begin{pmatrix}\boldsymbol{E}\\ \eta_0\boldsymbol{H}\end{pmatrix} \qquad (2)$$

Comparing Eq. (2) with the Dirac equation, the bianisotropy can play the role of a gauge field $\boldsymbol{\xi}$ for the EM field, a "mass" can be associated with $\boldsymbol{\epsilon}-\boldsymbol{\mu}$, and an "energy" with $\boldsymbol{\epsilon}+\boldsymbol{\mu}$ (for details see [3-4]). Using known analytical results for the Dirac equation in one and two dimensions we can use this equivalence between electromagnetic material parameters and gauge fields, mass, and energy to design materials with a given effect on the EM field.

In this talk I will review three applications of this analogy. Firstly I shall demonstrate cases of interface states between electromagnetic materials, showing that analogues of the Jackiw-Rebbi mode of the two dimensional Dirac equation occur in many chiral and non-chiral electromagnetic materials. These modes are unusual in that they are insensitive to the details of the interface, depending only on the asymptotic material

parameters. Secondly I shall explore an unusual aspect of the Dirac equation, where at zero energy the wave becomes an analytic function of position $\psi = \psi(x + i\,y)$. This analyticity indicates that the wave is only able to circulate in one sense, and is thus forced to propagate in only one direction at a boundary. Through using our Dirac-Maxwell equivalence and imposing this same condition on the material parameters in Maxwell's equations, we thus find a general condition for materials supporting unidirectional propagation, without every using topological arguments [5]. An interesting special case of this is free space, when one component of the wave-vector is fixed equal to ω/c (see Fig. 1).

Finally I will discuss the application of the Dirac-Maxwell analogy to design non-Hermitian media with controlled reflection and transmission properties, using known properties of the Dirac equation to design perfectly reflectionless index profiles [6].

Figure 1: *The Dirac equation, free space propagation, and chiral modes:* Taken from [7]. Shows the electric and magnetic fields from a line source (out of the page) along which the current is modulated with propagation constant k_z. When $k_z = k_0$ the Dirac-Maxwell analogy tells us that the wave is forced to circulate in one sense, and thus interface modes can propagate in only one direction (bottom right).

Abstract: Taking advantage of a fundamental laws of geometrical optics, i.e., Fresnel equations, allows for coupling polarization and spatial phase degrees of freedom. We show that this conversion of spin to orbital angular momentum can be accomplished by a simple planar, homogeneous, and isotropic layer of an epsilon-near-zero material.

Epsilon-near-zero (ENZ) materials give rise to extraordinary linear and nonlinear optical effects [1]. Here we show that an unstructured circularly polarized beam incident on a planar and isotropic ENZ layer is converted into a beam carrying orbital angular momentum and, hence, a structured phase front [2,3]. While this effect can be realized for almost any interface, the vanishing permittivity of an epsilon-near-zero material environment leads to a special set of Fresnel coefficients, which greatly enhance the spin-orbit-coupling between the incident field and the converted light mode.

Spin-orbit Coupling and Topology of Optical Fields in Metamaterials

Vittorio Aita[1], Diane J. Roth[1], Alexey V. Krasavin[1], Anatoly V. Zayats[1*]

[1]Department of Physics and London Centre for Nanotechnology, King's College London, Strand, London WC2R 2LS, United Kingdom

Abstract: We will discuss spin-orbit coupling manifestations in interaction of complex vector beams with plasmonic metamaterials. Spin-orbit coupling and topology of evanescent waves and vector beams propagating in epsilon near-zero metamaterials will be considered.

The ability to engineer and manipulate the properties of optical wavefronts and pulses, such as phase, polarisation and amplitude, and dispersion is very important in various applications including imaging, metrology, optical communications as well as biomedical and quantum technologies [1]. As light waves carry both spin and angular optical momenta, their interactions are important in controlling the flow of light, especially on the nanoscale. Optical spin-orbit coupling describes how spin angular momentum of light (associated with circular polarisation of an electromagnetic wave) influences its extrinsic and intrinsic orbital angular momenta, associated with the propagation direction and energy flow. This effect provides interesting applications in polarisation-enabled control of optical signals, or in reverse, controlling light polarisation, sensing applications, optical forces and quantum optical processes [2–14].

In this talk, we will discuss spin-orbit coupling in guided waves and complex vector beams, both carrying longitudinal fields, their topological manifestations, interaction with anisotropic and epsilon-near-zero metamaterials, and applications. Topologically protected states in guided and propagating beams, and polarisation structure stability and transformations will be considered. Strongly anisotropic metamaterials provide a flexible platform for tailoring complex vector beams and pulses for harvesting functionalities and applications of complex light beams with complex polarisation and phase distributions in numerous photonic and quantum technologies, imaging and metrology.

Chiro-optical characterization of self-assembled plasmonic nanostructures

E. Petronijevic[1], H. P. Ram Kumar[1], G. Leahu[1], R. Li Voti[1], C. Sibilia[1], and A. Belardini[1]*

Abstract: In order to control the circular polarization of light at nanoscale, complex structures can be realized. Among different fabrication techniques, self-assembled approach can produce high reproducible, low cost, large area asymmetric metasurfaces that present different optical functionalities, and in particular can exhibit chiral optical response both in the near field and in the far field. Here we show the optical chiral properties of different self-assembled metasurfaces measured by different characterization techniques, both in linear and nonlinear regime.

.

Symmetry breaking in plasmonic nanostructures can lead to strong manipulation of the circular polarization at the nanoscale. Among different complicated fabrication techniques, self-assembled procedure can be a suitable way for low-cost, time-reduced, large area, chiral-effective metasurfaces production. In this talk, after summarizing the relationship between chirality and symmetry breaking that leads to the concept of pseudo-chirality or extrinsic chirality [1], we show that this concept, together with real chirality gives rise to effective chiro-optical signal in different self-assembled plasmonic nanostructures. We apply different measurement techniques, based on transmission/reflection of light, absorption measured by photoacoustic technique (PA), second harmonic generation (SHG) on nanostructures, showing that managing the symmetry of the investigated system can lead to a tuning of the spatial localization of the circular polarized components of the electromagnetic radiation in proximity of the plasmonic nanoantennas. This fact open the possibility to fine tune the chiro-optic properties of the different nanostructures under study.

We start showing results on very simple geometries like nanowires and nanopillars. First example is a metasurface formed by tilted gold nanowires: by depositing gold at grazing incidence on a silicon substrate maintained at a temperature of ~300 K (Glancing Angle Deposition-GLAD) were realized a self-ordered forest of tilt Au 300nm long nanowires (NWs). The asymmetric orientation of the gold wires with respect to the pumping light orientation (Fig.2a) leads to the excitation of extrinsic chiral response in reflection, PA and SHG response that can be evaluated by using circular polarized pump light [2]. Second example is a sample formed by Au partially covered GaAs nanowires 5 microns long fabricated on Si substrate by a by a self-catalyzed approach. Also in this case we present reflection, PA and SHG measurements [3]. Comparison with the same sample without asymmetric gold covering gives rise to a dramatic circular dichroism enhancement.

The last set of samples that we show present a planar arrangement of polystyrene nanospheres (PNS) covered by asymmetric metallic shell. From that sample, by removing the polystyrene spheres is obtained a elliptical nanohole array (NHA) that exhibit chiral properties in a broad near-infrared range [4].

Here, we demonstrate the broadband chiral properties of such nanostructures exhibit interesting resonant features which are widely tunable by means of the incident angle.

Chiral optical properties namely the circular dichroism (CD) of the NHA are governed by the incident angle-dependent coupling of the light with Rayleigh anomalies and surface plasmon polaritons (see figure 1). On

this samples we performed chiral transmission measurements, photoacoustic absorption (PA) and photothermal deflection (PD) experiments [5-8].

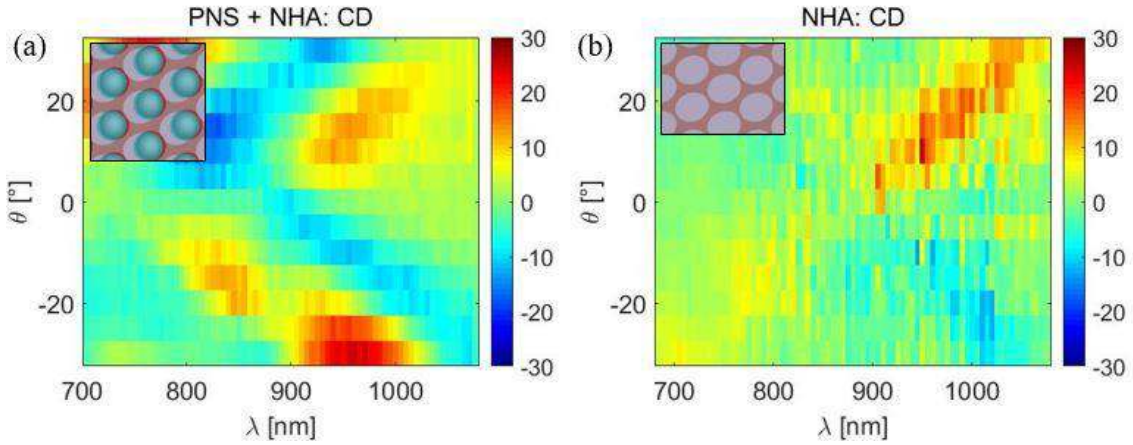

Figure 1. Map of circular dichroism as a function of the wavelength and the incident angle θ, for the sample with (a) PNS and NHA, and (b) with NHA only (after PSN removal).

Chirality sensing employing parity-time symmetric and general gain-loss media

I. Katsantonis[1,2], M. Kafesaki[1,2]

Abstract: We demonstrate the potential of gain materials and parity-time symmetric systems to enhance the circular dichroism response and the dissymmetry factor of molecular chiral systems, highly facilitating thus the sensing of such systems and the discrimination of the different enantiomers, issue critical in biology and pharmaceutics.

Molecular chirality sensing and enantiomer discrimination is an issue of particularly high importance for biology, medicine and pharmaceutical industry. This is due to the fact that the two different enantiomers of a chiral substance (e.g. a medicine), although they share the same physical properties, they can have completely different biological activity. To detect chirality, a common approach to date is based on the exploitation of another difference of the two enantiomers: their different interaction with circularly polarized light, and in particular the different absorption of left- and right-handed circularly polarized waves, known as circular dichroism (CD=A_+-A_-; $A_{+/-}$ is the absorption of right/left-handed circularly polarized waves; denoted by +/- respectively). Circular dichroism (CD) response signal though of chiral molecules is usually extremely weak, making difficult the detection of small quantities of a chiral substance. Recently it was shown that a very promising way to enhance the CD signal is through the interaction of a chiral substance with super-chiral local fields, i.e. fields with optical chirality, C, larger than that of circularly polarized light ($C \propto \mathrm{Im}(\boldsymbol{E}\cdot\boldsymbol{H}^*)$, with $\boldsymbol{E}$, $\boldsymbol{H}$, electric and magnetic field, respectively; Im denotes the imaginary part and * complex conjugation). Such local fields can be produced in the vicinity of properly designed nanophotonic or metamaterial structures. The realization of the C-mediated CD enhancement stimulated an intense research effort to devise design rules for super-chiral field generation and to design appropriate structures and strategies.

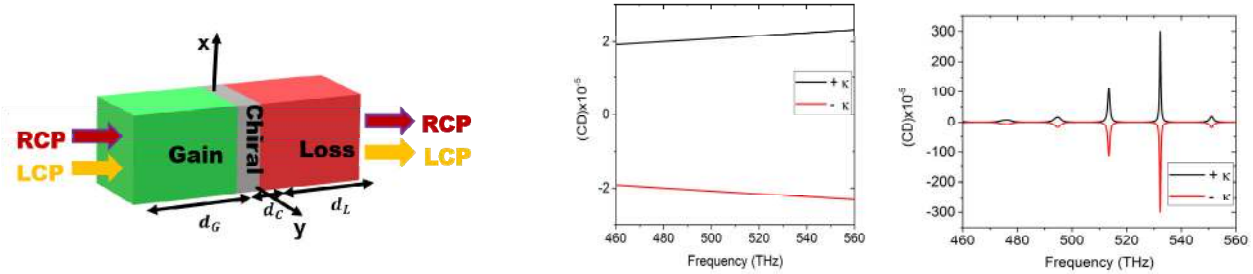

Fig. 1: Left panel: A PT-symmetric bilayer with a thin (10 nm) chiral layer in between the gain and loss layers (of μm thickness); RCP and LCP denote the right and left-handed circular polarization respectively. The gain and loss here are considered constant (frequency independent). For details see [1]. Middle panel: Circular dichroism of the chiral layer alone. Black and red lines show the CD for layers made of the two different enantiomers of the chiral substance.

Right panel: Circular dichroism for the chiral layer in the middle of the gain-loss bilayer. An up to x1500 CD enhancement compared to the chiral layer alone can be observed. The maximum enhancement is achieved at the lasing threshold of the PT-symmetric system.

Here we propose an approach that is able to be combined with nanophotonics-based structures and strategies and enhance not only the CD response of a chiral substance but also the dissymmetry factor, *g*. (*g* is crucial not only for chirality sensing but also for enantio-specific synthesis; it is defined as the ratio of the circular dichroism to the average absorption, $(A_+ + A_-)/2$). This is by employing gain media. Gain media, by providing "negative" absorption, can highly extend the absorption-related properties and capabilities of any structure and device that they are involved. To test the potential of gain materials in chirality sensing we examined the simplest possible gain-loss system, i.e. a gain-loss bilayer (see Fig. 1), empowering it though with Parity-Time-symmetry, which gives the possibility of zero total absorption and advanced tailoring of the optical modes of a system. The chiral medium was placed initially in the middle of the PT-bilayer, as shown in Fig. 1 [1]. Even in this simple geometry we achieved an enormous circular dichroism enhancement (see Fig. 1), with the CD reaching values up to 1500 times larger than the ones achieved for chiral layer alone. The largest CD enhancement was achieved at the lasing threshold of the PT-bilayer, close to the exceptional point of the system. Besides, we overserved in the system an up to 15 times dissymmetry factor enhancement compared to the chiral layer alone, with the *g*-peaks to coincide with the anisotropic transmission resonances of the PT-bilayer.

Similar to the above results were obtained also when the chiral layer was placed next to the gain layer of the bi-layer (at the left side of the structure of Fig. 1), while placing it next to the loss layer led to significant deterioration of the observed response. Moreover, in all cases we examined the CD enhancement was always associated with enhancement of the field chirality in the position of the chiral structure.

To test the impact of gain and PT-symmetry in structures more favorable for super-chiral near fields than the PT-bilayer (which is actually a Fabry-Perot resonator), we examined also metasurfaces based on dielectric cylindrical pillars with incorporated gain material. In all the cases the gain-involving structure led to significant enhancement of both circular dichroism and dissymmetry factor response, verifying that the employment of gain media can lead to a novel path in the molecular chirality sensing research and applications.

Abstract: Non-collinear antiferromagnets (NC-AFM) have attracted much attention recently due to the observation of the anomalous Hall effect (AHE) in these materials despite the small magnetic moments present in their unconventional spin structures, in addition to the giant piezomagnetism and a strain-induced anomalous Nernst effect. These fascinating qualities have hints of multiple competing orders that could be harnessed to enable chirality switching and bring these materials ever closer to realistic antiferromagnetic spintronic devices.

Modern spintronics must adapt to meet the challenges of the new era. Computer processors can no longer follow Moore's law yet the demand for greater computational power is ever increasing. Inventive solutions are therefore required to achieve the desired processing power whilst also being more energy efficient to combat the increasing effects of climate change. Chiral magnetic textures have emerged as a promising avenue for addressing these challenges, as they have already shown to exhibit a wide range of exotic phenomena such as skyrmionic textures [1], large anomalous [2], spin [3] and chiral hall [4] effects and even long-range triplet supercurrents have been generated when interfaced with superconductors [5,6].

Furthermore, the new and upcoming field of orbitronics [7] has established itself as a possible successor to spintronics due its prolific orbital current generation and efficient orbital-to-spin conversion [8,9]. The materials which exhibit large orbital currents do not correlate with the spin-orbit interaction and some are very light such as 3d elements [7], paving the way for extremely efficient devices which do not require expensive materials to manufacture. Whilst recently the potential for a 'chiral' spin current and subsequent chirality switching has been addressed [4], the addition of the orbital degree of freedom presents a new channel which, when coupled to the chiral degree of freedom, could allow for more flexibility when designing realistic antiferromagnetic spintronic devices.

In this talk, I will discuss our recent work unpacking the competing orders present in chiral magnetic textures in noncollinear antiferromagnets using a combination of first principles and model techniques to introduce the orbital degree of freedom. We construct an efficient basis set of maximally localized Wannier functions to describe the orbital textures complete with spin orbit coupling, and introduce the noncollinear magnetic textures with a combination of fully noncollinear first principles spin relaxation calculations and exchange fields in the Wannier functions. Such a technique represents the first ever attempt to combine both noncollinear magnetism with orbital currents in a first principles-based approach. This work aims to shed light on the complex interplay of competing magnetic orders present in the latest experiments on noncollinear antiferromagnets, whose response to current, strain and temperature go beyond the current understanding of the state-of-the-art.

Mixed Quantum/Classical Approach to Surface-Enhanced Spectroscopies

T. Giovannini[1*], and C. Cappelli[1]

[1]Scuola Normale Superiore, Piazza dei Cavalieri 7, 56126, Pisa, Italy

[*]corresponding author: tommaso.giovannini@sns.it

Abstract: We present a novel theoretical approach to calculate the optical response of molecular systems interacting with plasmonic substrates, either metallic or graphene-based.

Peculiar electromagnetic responses arise when a molecular system is adsorbed on plasmonic substrates under the effect of an external radiation. As an example, surface enhanced Raman scattering (SERS) has become a widely used analytical technique, taking advantage of the huge enhancement of the Raman signal when a target molecule is adsorbed on metal nanoaggregates [1]. This phenomenon can allow single molecule detection, thanks to enhancement factors as much as 10^{10} [1]. In this contribution, we present a novel theoretical approach to treat surface-enhanced spectroscopies, including SERS. The plasmonic structure is described by means of fully atomistic classical electromagnetic models, which have recently been developed by the present authors [2-5]. The adsorbed molecular system is treated at the quantum mechanical (QM) level. The approach can treat nanostructures of complex shape, and are general enough to describe both metal nanoparticles [2,3,5] and graphene-based materials [4,6] at the same level of accuracy. The approach has huge potential for large scale nanoplasmonic simulations (more than 1 million atoms), also for systems dominated by quantum effects, such as subnanometer junctions [2,5], or geometrical defects [6,7].

The robustness and reliability of the developed method is demonstrated for selected test cases and by the comparison with experimental spectra [8].

Creating, Reading, and Switching Skyrmions in a Magnetic Tunnel Junction

Shaohai Chen[1]

[1] Institute of Materials Research & Engineering, Agency for Science, Technology &

Research (A*STAR), 138634 Singapore

Abstract: Magnetic skyrmions – nanometre-scale topological spin textures – are promising active elements for scalable, energy-efficient bio-inspired and unconventional computing electronic devices. A key technological roadblock to unleashing their potential is achieving deterministic electrical readout and manipulation. Here we present wafer-scale realization of a nanoscale skyrmionic magnetic tunnel junction (SK-MTJ) shown to host a single skyrmion in addition to uniform states, and systemically investigate its electrical and magnetic properties.

Besides the parallel and antiparallel MR states possessed by conventional MTJ, the SK-MTJ exhibits an additional skyrmion state with sizeable MR (20-70%), whose magnitude scales proportionally with skyrmion size. A suite of electrical and imaging techniques demonstrates that the nanoscale SK-MTJ consistently nucleates skyrmion with a fixed polarity, albeit via two distinct, asymmetric mechanisms. The distinguishing feature in turn facilitates the zero-field stability of distinctly sized skyrmions, with established promise towards multi-state functionality. Crucially, it is found that such SK-MTJs can be electrically switched by using a low current density of about ~10^7 A/m^2, ~1000 times lower than achievable via conventional spin torques. The possible originations are attributed to the voltage control of magnetic anisotropy (VCMA) and spin transfer torque (STT) effects, which collaboratively drive skyrmion nucleation and deletion in our SK-MTJs. Together, our findings provide a platform to incorporate electrical readout, writing and erasing within skyrmionic devices, and provide a springboard for their use in unconventional computing applications.

Parity-broken vacuum as a chiral catalyst

Yanzhe Ke[1], Zhigang Song[2], and Qing-Dong Jiang[1*]

[1]Shanghai Jiao Tong University, China
[2]Harvard University, America
[*]corresponding author: qingdong.jiang@sjtu.edu.cn

Abstract: A material with symmetry breaking inside can transmit the symmetry breaking to its vicinity by vacuum fluctuations. The vacuum in proximate to a symmetry-broken material is referred as its quantum atmosphere[1]. Here, we show that a parity-symmetry-broken quantum atmosphere can induce a chirality-dependent shift of the ground-state energy of a chiral molecule, resulting in a chemical reaction process that favors producing one chirality over the other[2]. We evaluate the chirality production rate for concrete examples, showing the promise of quantum atmospheric selectivity.

Summary: Chemical and physical systems can occur in two forms distinguished solely by being images of each other. This phenomenon, known as chirality, interlocks the physical and biochemical sciences and attracts continuous interest. Two related research directions are of great importance: i) What is the origin of molecular handedness? ii) How to find a universal and efficient way to select chirality?

In this paper[4], we propose an entirely new route to select chirality by using quantum fluctuations near parity-symmetry-broken materials. The vacuum in proximate to a symmetry-broken material is referred as its quantum atmosphere[1,2,3]. Using quantum atmosphere to select chirality is efficient yet dramatically different from previous proposals where real fields are needed. We show that parity-symmetry breaking and quantum fluctuations can induce a chirality-dependent shift of the molecular ground-state energy, leading to a chemical reaction process that favors producing one chirality over the other. Besides analytical analysis, we further perform the first-principle calculation to find specific examples, showing that our proposal gives significant chirality selectivity.

Abstract: An electrically controllable multilayer structure for discerning and confining chiral electromagnetic fields is demonstrated. Upon scattering, the chiral nature of the noncollinear spin texture in multiferroic layers is imprinted on the electromagnetic fields resulting in well-defined and electrically controlled chirality density of the standing waves within the resonator. Analytical and full-numerical, material-specific simulations endorse the feasibility and flexibility of the proposed scheme.

Schemes for generating externally tunable chiral photonic fields and resonators are of key importance to studying and functionalizing chiral matter (1). Considering dielectric stacks of oxide helical multiferroic (2) layers, we propose a setup for electrically-controllable resonator that efficiently traps purely chiral photonic fields (Fig.1).

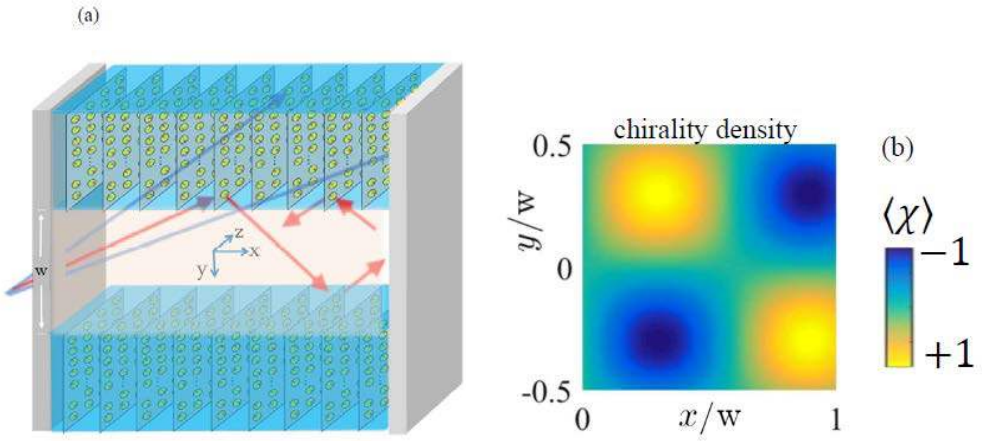

Figure 1: (a) Proposal for an electrically controlled generation of purely chiral light between chiral multiferroic multilayers. The modes are bounded by perfect mirrors attached to the left and right sides of the resonator. *w* is the thickness of the confining region. Radiative modes (blue arrows) leak out from the guiding region. Standing wave modes (red arrows) are purely chiral due to the spin-dependent scattering of electromagnetic waves from the non-collinear spin texture (small red arrows in the yellow circles) in the multiferroic layers. (b) The calculated, time-averaged chiral density of the standing waves within the resonator. The spin texture is tunable by a DC voltage.

Using analytical and the rigorous coupled wave methods (3) we performed simulations and analysis that expose the dispersion and scattering properties of electromagnetic waves in multiferroic (2) multilayers. The results evidence that due to scattering from the non-collinear spin texture in the multiferroic layers, only modes with a particular transverse wavenumber leads to the formation of standing chiral waves in the resonator. All other modes leak out from the cavity. An external static electric field leads to a change in the spin texture in the multiferroic layers. Therefore, also the enclosed modes in the cavity and their chirality are affected and can be tuned to a certain extent.

Abstract: Metallic nanostructures support localized surface plasmon resonances (LSPR) resulting from the collective motion of the electrons excited by electromagnetic fields. At the LSPR, the intensity of the electromagnetic near-field is also strongly enhanced, which find applications in many domains of Physics, Chemistry, Biology… Lately, there has also been a strong interest in the vectorial properties of the electromagnetic nearfield, in particular for generating strong chiral fields which may be used for biodetection applications.

The chirality of the interaction of light with resonant nanostructures is generally characterized through the measurement of Circular Dichroism (CD) which measures the difference in the absorption rates of the nanostructures for light of opposite helicities. However, in the case of supported and/or oriented nanostructures, the measured CD does not necessarily mean chirality. Secondly, the farfield measured CD does not give all the information about the nearfield polarimetric properties of the electromagnetic field.

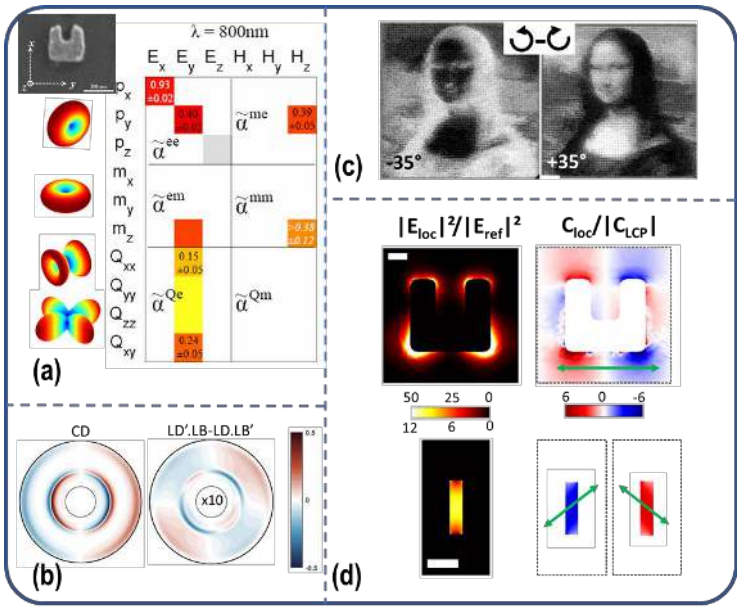

Figure 1: (a) polarizability tensor of achiral resonators exhibiting chiral optical response. (b) True CD and contribution of linear retardance and diattenuation to the CD of U-shaped resonators as a function of wavelength and azimuthal angle. (c) Image showing contrast reversal in CD based on achiral resonators. (d) Calculated chiral near field intensity and chirality density for incident linear polarization for U-shaped resonators and nanoslits in gold. The white scale bar is 50 nm.

Nanostructures obtained through top-down techniques (lithography, ion etching…) are very useful for the precise control of the shape and the organization they offer. Even achiral nanostructures supporting multipolar modes can exhibit chiral electromagnetic fields which chirality can be reversed upon changes in the illumination conditions (Figure 1(a) and (b)). [1] Farfield polarimetric properties can then been used to generate contrast in CD that is controllable spatially [2]. The link with the nearfield is more difficult to establish and relies on extensive numerical simulations. Numerical simulations show the generation of unexpected effects like asymmetric or uniform and reversible chiral fields (Figure 1(d)) for illumination conditions that do not yield any farfield CD. [3] These effects are very promising effects for the detection of chiral biomolecules because they offer additional degrees of freedom and increased sensitivity.

This work was realized partly thanks to the support of the ANR (n◦ ANR-18-CE09-0010). LC and XY acknowledge support from the Chinese Science Council.

Microwave-to-Optical Quantum Transduction Utilizing the Topological Magnetoelectric Effect

Akihiko Sekine[1*], Mari Ohfuchi[1], and Yoshiyasu Doi[1]

[1]Fujitsu Research, Fujitsu Limited, Japan
[*]corresponding author: akihiko.sekine@fujitsu.com

Abstract: The quantum transduction between microwave and optical photons is essential for realizing scalable quantum computers with superconducting qubits. Due to the large frequency difference between microwave and optical ranges, the transduction needs to be done via intermediate bosonic modes or nonlinear processes. In this study, we focus on the transduction via the magneto-optic Faraday effect (i.e., the magnon-photon interaction) and propose that the transduction efficiency can be greatly improved by utilizing magnetically doped topological insulator thin films.

The quantum transduction, or equivalently quantum frequency conversion, is an important quantum technology which enables the interconnects between quantum devices. Especially, the quantum transduction between microwave and optical photons has so far gathered attention in pursuit of large-scale quantum computers with superconducting qubits [1]. Due to the large frequency difference between microwave and optical ranges, the transduction needs to be done via the interaction between photons and intermediate bosonic modes or via the nonlinear interaction between photons, such as optomechanical effect, electro-optic effect, and magneto-optic effect. To date, the transduction efficiency, whose maximum value is 1 by definition, has recorded the highest value $\sim 10^{-1}$ with optomechanical effect.

In this study, we focus on the microwave-to-optical quantum transduction via the magneto-optic Faraday effect (i.e., the magnon-photon interaction). A previous experimental study has observed the transduction efficiency $\sim 10^{-10}$ by using a ferromagnet YIG [2]. We take advantage of the fact that three-dimensional topological insulators exhibit a universal Faraday rotation angle from the topological magnetoelectric effect, leading to a large value of the Verdet constant in the thin-film geometry. We show theoretically that the transduction efficiency can be greatly improved to $\sim 10^{-4}$ by utilizing magnetically doped topological insulator thin films [3]. The transduction efficiency can be further improved to $\sim 10^{-3}$ in a heterostructure of a few dozen of layers consisting of magnetically doped topological insulator thin films and nonmagnetic substrates. We also expect that the transduction efficiency can be further improved by incorporating an optical cavity. Our study paves the way for a possible application of topological materials in achieving an efficient quantum transduction.

We would like to thank Shintaro Sato for his advice, encouragement, and support on this project.

Dynamic magnetoelectric effects at dielectric/ferromagnetic metal interface: generation of spin currents and modulation of spin wave amplitude

Piotr Graczyk[1*] and Maciej Krawczyk[2]

[1]Institute of Molecular Physics, Polish Academy of Sciences, Poznań, Poland
[2]Institute of Spintronics and Quantum Information, Adam Mickiewicz University, Poznań, Poland
[*]corresponding author: graczyk@ifmpan.poznan.pl

Abstract: We present the operation of the device which non-resonantly modulates the spin-wave amplitude by the ac electric field. The spin accumulation is generated by the charge-mediated magnetoelectric effect at the dielectric/ferromagnetic metal interface and interacts with magnetization through the spin transfer torque.
We show the criteria for the effective amplification and dependences of the obtained gain on the applied voltage amplitude and spin-wave frequency.

Spin waves are potential candidates to replace electrons in logical systems to operate faster, with ultralow energy consumption and operating at sub-micrometer scale. Much effort has been devoted to develop methods of spin-wave generation, steering and conversion which led to the first laboratory realization of the spin-wave-based logic units [1]. However, the main challenge for the magnon computing, which is relatively high attenuation, remains unresolved. In our proposition [2], the modulation of spin-wave attenuation/amplitude takes place in the magnetoelectric cell (MEC, Fig. 1) which consists of two high-permittivity dielectric (D)

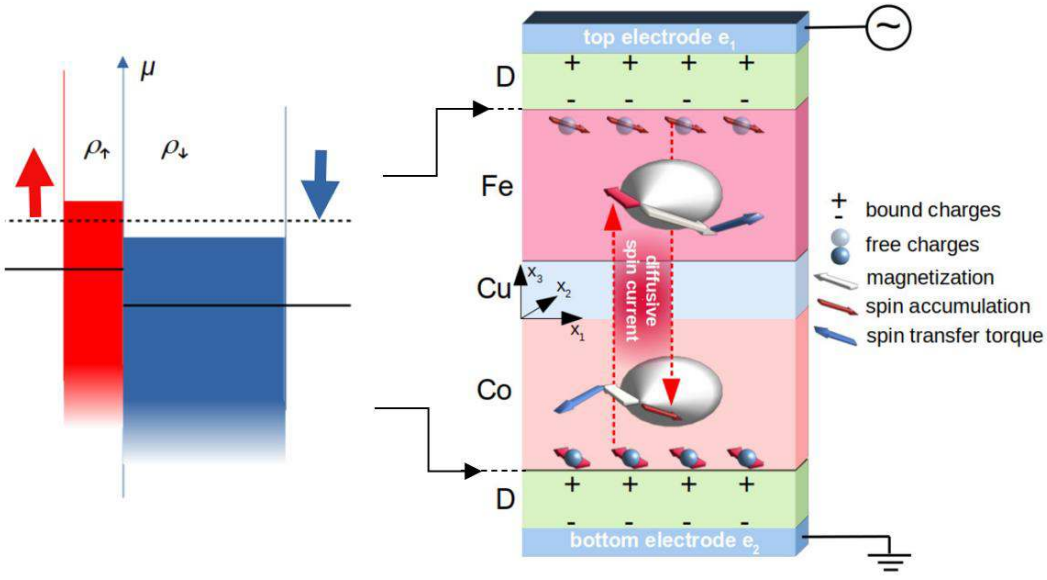

Fig. 1. The principle of operation of magnetoelectric cell subjected to the ac voltage. The dynamic splitting of the spin-up and spin-down subbands (i.e. spin-dependent surface screening, left part of the figure) at the Fe/dielectric and Co/dielectric interfaces generates the spin accumulation which diffuses through the Fe/Cu/Co layers and exerts the spin-transfer torque on the local magnetization.

nanocapacitors in series connected through a conductive ferromagnetic bilayer. The thin ferromagnetic layers, made from Fe and Co are separated by a nonmagnetic metal (Cu).

The principle of operation is as follows (see, Fig. 1). The ac voltage applied to the MEC generates time-varying screening charges at the ferromagnetic interfaces with dielectrics. Because the density of the screening charge is spin-dependent [3]–[5], the dynamic spin-dependent potential produces nonequilibrium spin density at the interfaces, as we have demonstrated in Ref. [6]. Importantly, the strength of the effect depends on the magnetoelectric constant. The spin accumulation is polarized along the local, precessing magnetic moment at the interface with the dielectric, and it diffuses between the layers. If the magnetization of the second layer is non-collinear to that spin accumulation (i.e., to the magnetic moment at the surface of the first layer), it exerts a spin-transfer torque.

To describe the coupled charge-spin-magnetization dynamics of the system and demonstrate usefulness of the MEC we solve numerically the set of coupled differential equations for magnetization dynamics and charge/spin transport. We show that the spin accumulation driven by the spin-dependent surface screening in ultrathin magnetoelectric cell effectively modulates coherent spin wave modes of specific symmetry and group velocity. The signal is periodically modulated: amplified and suppressed with the frequency of the ac voltage applied to MEC. We discuss in detail the spin-wave amplitude gain in dependence on the ac voltage amplitude, spin-wave mode and frequency.

The presented mechanism is non-resonant and may be useful e.g., for the modulation of the spin-wave amplitude, amplification of short impulses or when the effect is used for two parallel spin-wave conduits operating on the split signal with respective microwave fields delayed by π.

The study has received financial support from the National Science Centre of Poland under grant 2018/28/C/ST3/00052.

Optical interface for a hybrid magnon-photon resonator

E. Buks[1*]

[1]Andrew and Erna Viterbi Department of Electrical Engineering, Technion, Haifa 32000 Israel
[*]Corresponding author: eyal@ee.technion.ac.il

Abstract: We study magneto-optical coupling in a ferrimagnetic sphere resonator made of Yttrium iron garnet. Methods to manipulate quantum entanglement induced by light-matter interaction are explored.

We study optical detection of magnetic resonance of a ferrimagnetic sphere resonator (FSR), which is strongly coupled to a microwave loop gap resonator [1, 2]. Optical fibers are employed for coupling the FSR with light in the telecom band. We find that magnetic resonance can be optically detected in the region of anti-crossing between the loop gap and the ferrimagnetic resonances. By measuring the response time of the optical detection, we rule out the possibility that microwave induced heating is responsible for the optical detectability.

We study a device composed of an FSR integrated with an optical interferometer. Magneto-optic coupling can be employed in such a device to manipulate entanglement between optical pulses that are injected into the interferometer and the FSR [3]. The device is designed to allow measuring the lifetime of such macroscopic entangled states in the region where environmental decoherence is negligibly small. This is achieved by recycling the photons interacting with the FSR in order to eliminate the entanglement before a pulse exits the interferometer. The proposed experiment may provide some insight on the quantum to classical transition associated with a measurement process.

Pushing the limits of magnetoplasmonics by (meta)material design

F. Pineider[1,2]

[1]Department of Chemistry and Industrial Chemistry, University of Pisa, Italy

[2] Department of Physics and Astronomy, University of Florence, Italy
*francesco.pineider@unipi.it

Abstract: The field of magnetoplasmonics has reached a relatively mature state and is currently striving to take the step toward technological application. In this talk, I will show some interesting approaches to increase the magnetoplasmonic modulation, based on rational material design and structuration into metasurfaces. Finally, I will discuss a (failed) attempt to observe magnetochiral behaviour in a nickel-silver metasurface.

In its simplest form, the interaction between charge carriers of a plasmonic unit with a static magnetic field can be rationalized as a Lorentz force component that alters carriers' trajectories in the conductor. [1,2,3] In recent years, several approaches have been proposed to capitalize on this interaction and boost it up to a usable magnitude. [4,5]

In this contribution, I will give a general description of the factors that must be balanced to improve magnetoplasmonic performance and describe the critical rules to design efficient materials. As an application of these rules, I will present the case of plasmonic degenerately doped semiconductors, [6] which have recently shown outstanding magnetic field response, even if completely non-magnetic (Figure 1). [7,8] Further discussion on the possibilities offered by magnetic co-doping of the semiconductor matrices will follow.

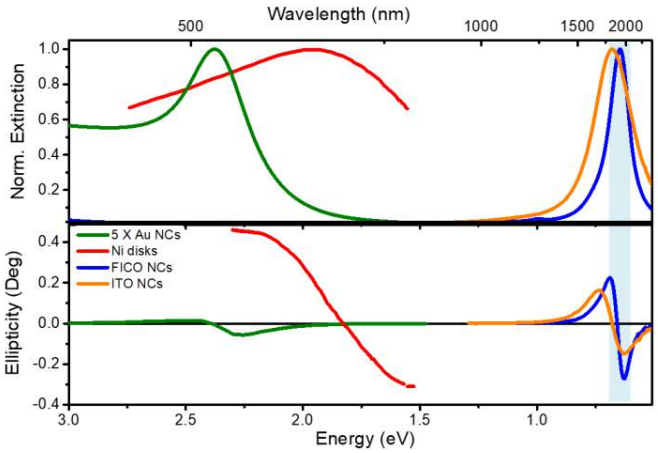

Figure 1. Optical and magneto-optical response of doped semiconductors compared to noble metal and ferromagnetic metal plasmonic structures.

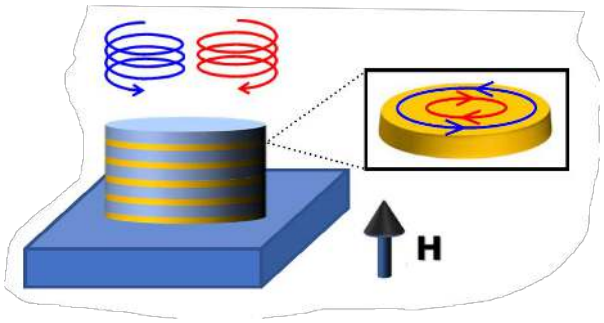

Figure 2. Sketch of a hyperbolic metamaterial unit and of its interaction with circularly polarized light in the presence of a static magnetic field.

Besides the features of the plasmonic material, which should maximise the effect of magnetic field on their optical properties, I will also give a preliminary account on ways in which the organization of plasmonic resonators in metasurfaces can give rise to novel types of magneto-optical response (Figure 2) [9] and increase the general magnetoplasmonic performance. [10]

Finally, I will describe a brief venture in the fascinating yet still partly elusive field of magnetochirality, i.e. one of the manifestations of simultaneous spatial and temporal non-reciprocity. [11] In our attempt, we prepared a plasmonic chiral and magnetic metasurface, and looked for signs of magnetochiral effects. [12] Although no effects were observed, we were able to derive important design guidelines for plasmonic magnetochiral candidates.

Interfaces of B20 compounds with exotic spin currents

G. Pantano[1], C. Gibson[1], S. Tkacik[1] and J. Gayles[1*]

[1]Department of Physics, University of South Florida, Tampa, FL 33620, USA
[*]corresponding author: gayles@usf.edu

Abstract: We use first principal calculations to investigate 2D planar twinning interfaces in B20 compounds. We employ supercell calculations where the area of the interface is restricted to the primitive cell interface. The calculations are carried out for the Weyl semimetal CoGe. Our results show that the spin and anomalous Hall effect can be significantly increased due to the increase in spin-orbit coupling with the change in atomic potential at the interface.

Modern electronics have reached their full maturity due to the unprecedented increase in the demand for computation and data management. However, the inability to miniaturize electronic components to the atomic scale and eliminate crystal imperfections severely limits the performance and efficiency of devices. Crystal imperfections are near unavoidable during the growth of materials and often reduce their physical properties, such as the ability to conduct electricity. Furthermore, removing crystal imperfections is costly and detrimental to the environment. The challenge is overcoming these technological constraints; we must classify and understand the symmetries of crystal imperfections, discover new materials whose electronic properties are enhanced by crystal imperfections, and develop new mechanisms to carry and manipulate information [1-7]. The research will contribute to substantial breakthroughs in the design of energy-efficient low-power devices and help mitigate the toxic purification process of materials. Materials in modern devices are nominally restricted by various impurities and defects, reducing desired transport phenomena and increasing waste heat. This leads to a substantial investment in creating high-quality single crystals. However, 2D planar defects can potentially increase select transport phenomena such as the spin and anomalous Hall effect in systems that break inversion symmetry [7-9]. Intuitive tight-binding Hamiltonians are used to understand the role of symmetry and to reduce the complexity of the interface band structure.

Here we use first principle calculations on crystal domain boundaries of CoGe [10] with distinct symmetries on either side of the boundary interface. Figure a), b), and c) show the effect of spin-orbit coupling (SOC) strength on bulk CoGe on the bandstructure and Fermi arcs. Figure d) shows a schematic of the opposite chirality interfaces with a sharp interface highlighted in green. We compare the total energies to find stable interface boundaries that are predictable to form under finite temperatures in experimental conditions. In figure e), we show the total energy comparisons for a few boundary interfaces compared to the vacuum state in orange and the bulk in black. A strain analysis of the systems is also considered, based on symmetries, which allows for selecting distinct interface boundaries with topological electronic structure. Depending on the interface, the SOC strength can be varied by two orders of magnitude compared to that of the bulk CoGe [10].

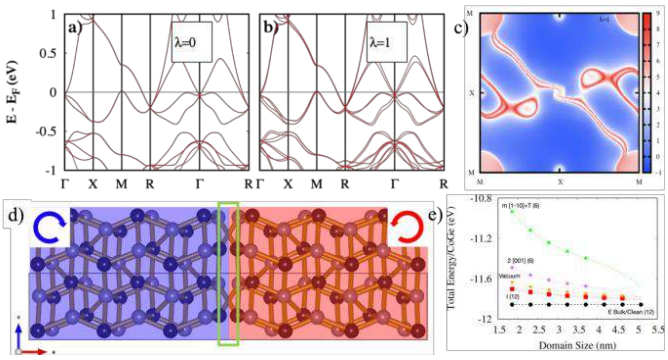

Figure showing band structure calculations, schematic of an interface boundary with opposite chiralities and the total energy comparison of interfaces.

Additionally, a finite magnetic moment is stabilized close to the boundary interface, which allows for Dzyaloshinkii-Moryia interaction. We calculate the spin and anomalous Hall effect, which show a

considerable variation for the boundaries distinct from the bulk and related to the topological surface states that survive on specific boundary systems. We develop tight-binding models, motivated by first principle calculations, to intuitively understand the effect of symmetry and the interface on transport. Unique combinations of boundaries suggest novel topological states not present in bulk can be stabilized due to the interface [5,7,10].

Hot-electron generation in chiral plasmonic nanocrystals as a mechanism for chiral photo-growth and photochemistry

Alexander O. Govorov[1]

[1]**Department of Physics and Astronomy, Ohio University, Athens, USA**
govorov@ohio.edu

The generation of energetic (hot) electrons and the photoheating are intrinsic properties of any optically excited plasmonic nanocrystal [1,2]. In addition, high-energy hot electrons and phototemperature contribute to the kinetic processes observed in colloidal nanocrystals, metal-semiconductor hybrids, plasmonic Schottky photodetectors, and metastructures [1,2]. In this talk, we will focus on the theory of hot electron injection and present related applications for chiral photo-growth, plasmonic photochemistry and plasmonic photocatalysis [3,4,5,6].

Orbital angular momentum of light creates exotic chiral structures

T. Omatsu[1,2]

[1]Graudate School of Engineering, Chiba University, Japan
[2]Molecular Chirality Research Center, Chiba University, Japan
[*]corresponding author: omatsu@faculty.chiba-u.jp

Abstract: We herein report on the demonstration of chiral engineered optical materials, including chiral crystallization of $NaClO_3$, galaxy-shaped reliefs of azopolymers with spiral arms, and self-written helical fibers, by the illumination of light fields possessing orbital angular momentum.

Light field possessing an orbital angular momentum (OAM), that is optical vortex, exhibits an annular spatial form originated from its helical wavefront with an on-axis phase singularity [1,2]. In recent years, optical chirality and optical activity of optical vortex have been widely studied [3]. In fact, it has been discovered that the optical vortex with OAM twists the irradiated materials, including metals, semiconductors, polymers, and even crystals, towards clockwise (right-handed) or counter-clockwise (left-handed) direction to form nano/microscale helical structures [4,5]. This phenomenon never happens with only the spin angular momentum (SAM) associated with a circular polarized light field with a planar wavefront.

Such chiral structures under optical vortex illumination will offer new avenues to develop chiral engineered optical materials with exotic physical properties beyond natural materials.

In this work, we review the formation of chiral structures under optical vortex illumination, including chiral crystallization of $NaClO_3$ [6], galaxy-shaped reliefs of azopolymers with spiral arms, and self-written helical fibers [7] by employing optical vortex and its hybrid mode. Surprisingly, we discover that the chirality of $NaClO_3$ crystals is selectively controlled (crystal enantiomeric excess (CEE)>55%) by altering the helicity of an irradiating optical vortex. This demonstration will provide us new fundamental insights into the origin of homochirality.

Also, galaxy-shaped reliefs of azopolymers reflect full physical parameters (not only handedness and but also topological charge) of the irradiated optical vortices, and they allow the development of advanced photo-induced chiral engineered optical materials with the freedom of chirality and topological charge.

Abstract: We show how to imprint chirality into achiral matter using tailored light, and how to monitor such achiral-to-chiral phase transitions in an all-optical setup. Our proof-of-principle simulations reveal that the hydrogen atom undergoes ultrafast and nonlinear chiral electron dynamics when exposed to a locally chiral laser pulse, giving rise to chiral high harmonic generation. Furthermore, the atom remains in a chiral superposition of stationary states after the pulse is gone, emitting chiral free-induction decay radiation which reveals the imprinted handedness.

Chiral molecules owe their handedness to the spatial arrangements of their *nuclei*, which form chemical structures which are not superimposable with their mirror images. However, chirality can also be related to *electronic* degrees of freedom. Indeed, as shown by Ordoñez and Smirnova, even the hydrogen atom can have chiral superpositions of electronic excited states [1].

Synthetic chiral light [2] enables ultrafast and highly efficient imaging of molecular chirality. Such light is locally chiral: the tip of the electric-field vector draws a chiral (3D) Lissajous figure in time, at each point in space. Interestingly, such tailored light can also be used to create chiral electronic states in atoms [3,4], which emit chiral photoelectron currents and exhibit photoelectron circular dichroism [3].

Here we show how to apply synthetic chiral light which is both locally and globally chiral [2] to drive ultrafast chiral electron motion in systems which are initially achiral, such as atoms, thus driving ultrafast achiral-to-chiral phase transitions. This tailored light can be created with the two-colour noncollinear setup introduced in [2].

We solved the time-dependent Schrödinger equation for the hydrogen atom exposed to an ultrashort, intense, locally chiral field. The induced polarization, proportional to $\langle\Psi(t)|\mathbf{r}|\Psi(t)\rangle$, is depicted in Fig. 1. As shown in Fig. 1a, the laser drives ultrafast chiral electron motion at its fundamental frequencies (800 and 400nm), although nonlinear effects are also evident. Indeed, the high-frequency components, shown in Fig. 1b, also create a chiral structure in time, and give rise to chiral high harmonic generation (HHG).

Chiral HHG is suppressed after the pulse is gone, but chiral electron motion does not stop. Indeed, the atom remains in a chiral coherent superposition of stationary states, and thus the electron continues to undergo ultrafast chiral dynamics, see Fig. 1c. This chiral electron motion results from having populated excited stationary states of the atom with different energy and angular momentum. The ultrafast chiral current shown in Fig. 1c gives rise to chiral free-induction decay radiation with elliptical polarization. As we will show in this conference, the imprinted handedness is recorded in the polarization of the emitted light.

We believe that this work creates exciting opportunities for driving and monitoring achiral-to-chiral phase transitions in all-optical setups, also in complex systems, as well as for driving chiral photo-chemical reactions using achiral reagents.

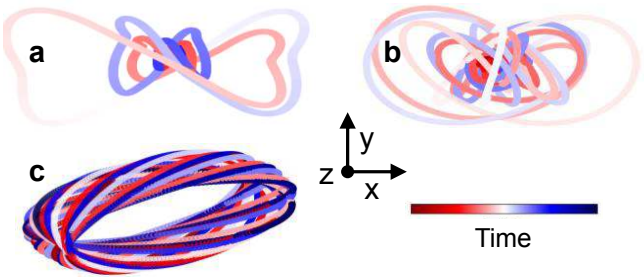

Fig. 1. Ultrafast polarization induced in the hydrogen atom by our locally chiral field [2]. **a**, total polarization the presence of the field. **b**, high-order components, resulting from filtering out the linear response in **a**. **c**, induced polarization after the pulse is gone. Laser parameters: wavelengths 800 and 400nm, intensity 10^{14} Wcm^{-2}, pulse duration 7fs (FWHM).

Microbundle array of Magnetoplasmonic Nanorods for reconfigurable chiral Metasurface

Juyong Gwak[1], Hyojin Kang[1] and Jaebeom Lee[1,2*]

[1]Department of Chemical Engineering and Applied Chemistry, Chungnam National University, Republic of Korea[2] Department of Chemistry, Chungnam National University, Republic of Korea
[*]corresponding author: nanoleelab@gmail.com

Abstract: Flexible devices are a fascinating application for wearable electronics, life & healthcare, and stealth technology. In this study, a metasurface film was fabricated by arranging core-shell magnetoplasmonic nanowires in microbundles on a flexible polymer substrate. Its chirality is manipulated by the tilt angle (θ), i.e. the angle between the applied magnetic field vector (B) and the tangent vector (T) of the curved metasurface. These flexible chiral metasurface platform could be useful for fabricating integrated enantiomeric sensing and AR devices.

Chirality is a property that appears everywhere from simple molecular structures to galaxies in the universe.[1] To study the chirality of nanomaterials and amplify their signals, inducing chirality in three-dimensional nanostructures has been well researched and developed over the past decade.[2] In particular, 2D planar metasurface has obtained a novel field of research.[3] They reported the smart metasurface, which has a uniform nanopattern, can control the chirality by inducing external curvature at the microscale. Active planar chiral metamaterials and reconfigurable metasurfaces have drawn intense interest thanks to both their unique ability to manipulate CPL and the lower complexity required in fabrication. Herein, a reconfigurable metasurface decorated with planar magnetoplasmonic microbundle arrays of Au@Fe_xO_y core-shell nanowires (NWs) on polydimethylsiloxane film is fabricated.

Ag@Fe_3O_4 NPs and Au@Fe_xO_y (NWs) were aligned using a magnetic field to create linear nanochains and microbundles depending on the concentration of NWs. Chiroptical properties are not well recognized in NP linear arrays, whereas NW linear and microarrays exhibit remarkable CD spectra due to the external tilt angle (θ_{ex}) at the microscale, where the CD was modulated by controlling the bending curvature of the film. Also, the computational simulation demonstrates an asymmetric interaction mechanism derived from the optically anisotropic nature of the NW array. The electric field strength of the linear array of NPs, that is the thickness of the line in which the NPs are aligned, does not exhibit high asymmetric interactions from mineral interactions. However, that the both NW linear and microbundle array induced highly recognizable asymmetric distribution by LCP and RCP light, that is, symmetric disrupted metasurface, which is considered the main cause of the chirality of the experimental condition. Particularly, microbundle arrays exhibit inherent symmetry breaking at certain curvatures due to the internal skew angle (θ_{in}) from the NW skew alignment inside the microbundle at the nanoscale. Although both NP and NW appear to be 1D arrays, the magnetically induced NW assembly differs from the NP array in that it induces chirality and increases the specific CD signal. The chiroptical properties of the microbundles themselves were confirmed by MCD and simulations. These results suggest a strategy to realize spectacle lenses with circular polarizer function, and the fabricated metafilms can be a novel universal means to specifically tune the absorption of circularly polarized light and produce flexible devices for further signal enhancement in nanoantennas and biosensors.

Abstract: We studied Giant magnetoimpedance (GMI) effect and magnetic properties of various Co-rich amorphous microwires. We measured magnetic field dependences of the GMI ratio up to GHz frequency range and observed quite high GMI ratio in studied thin magnetic microwires even at GHz frequencies. We observed different values of the magnetic anisotropy field obtained from the hysteresis loops and the impedance curves. Observed dependences can be explained considering different magnetic anisotropy in the surface layers and in the inner part of metallic nucleus and skin depth effect. Features of high frequency GMI effect have been analyzed using FMR-like approximation.

Applications of Giant magnetoimpedance, GMI, typically observed in soft magnetic materials, have attracted considerable attention owing to extremely high sensitivity of the GMI effect to low magnetic field. Among soft magnetic materials, thin ferromagnetic amorphous microwires (typically of about 10 μm in diameter) are considered as the most promising materials owing to outstanding soft magnetic properties, highest GMI effect and reduced dimensions suitable for microsensor applications [1,2]. Comparison of various magnetic field sensors shows that magnetic sensors using GMI effect of amorphous microwires present a number of advantages such as cheap technology, excellent magnetic field resolution and low sensor dimensions [2].

Recently, much attention has been paid to the studies of the GMI effect at GHZ frequencies owing to the recent tendency in miniaturization of magnetic field sensors [2,3]. The thinnest soft magnetic microwires can be produced by so-called Tailor-Ulitovsky method allowing fabrication of glass-coated microwires with metallic nucleus diameter, d, from 0.05 to 100 μm and total diameter, D, from 5 to 120 μm.

We present our last results on the GMI effect of thin amorphous magnetically soft Co-rich microwires suitable for creation of microsensors based on high frequency GMI effect.

We studied magneto impedance effect in Co- rich microwires at frequencies up to 4 GHz using specially designed micro-strip sample holder and S_{11} reflection coefficient obtained using the vector network analyzer.

Experimentally measured dependencies of impedance, Z on magnetic field H for several Co-rich microwires with vanishing magnetostriction coefficient: $Co_{67.7}Fe_{4.3}Ni_{1.6}Si_{11.2}B_{12.4}Mo_{1.25}C_{1.55}$(d $\approx$10μm, D=13.8 μm), $Co_{69.2}Fe_{3.6}Ni_1B_{12.5}Si_{11}Mo_{1.5}C_{1.2}$ (d=22.8μm; D=23.2μm) present considerable influence of magnetic field on sample impedance up at GHz frequency. Additionally, the magnetic field of maximum shifts to the higher field region with increasing of the frequency, f. But, at GHz frequencies the magnetic fields corresponding to the impedance maximum, H_m, are much higher than the magnetic anisotropy field. Therefore we must assume that studied samples are magnetically saturated when exhibit an impedance maximum at GHz frequency range. Such discrepancy between the H_m -values and magnetic anisotropy field can be explained considering different magnetic anisotropy in the surface layers and in the inner part of metallic nucleus and skin depth effect.

For interpretation of observed frequency dependence of impedance this behavior we paid attention on the fundamental link between ferromagnetic resonance, FMR and GMI [2,3].

Thus the saturation magnetization, M_s, can be estimated from this approach using the equation:

$$M_s = 0.805x10^{-9}\, df_0^2/dH \qquad (1)$$

where f_0 is the resonant frequency and H is the applied magnetic field. Previously we already got quite reasonable M_s values for lower frequencies considering this link between the GMI effect and FMR [4].

For studied samples and for GHz range we obtained linear fit of the square of the resonance frequency, f_0, on applied field. Some deviation has been observed only in low-field region. The origin of this deviation is unclear and can be related with low field magnetization process.

Concluding, studies of magnetic properties and GMI effect of amorphous Co-Fe rich microwires reveals that they present considerable GMI effect at GHz frequencies. Magnetic field dependences of GMI effect are affected by the microwires composition and geometry. We discussed observed experimental dependences considering both different magnetic structure, saturation magnetization and magnetic anisotropy in the bulk and near the surface and close analogy between giant magnetoimpedance and ferromagnetic resonance. Features of high frequency GMI effect can be described using FMR-like approximation.

Casimir Force Between Pasteur Materials

Zixuan Dai[1], Qingdong Jiang[1]

[1] *Tsung-Dao Lee Institute and School of Physics and Astronomy, Shanghai Jiao Tong University, Shanghai 200240, China*

Abstract Both theoretical and experimental interest in achieving repulsive Casimir force increases in recent years. A well-known paper demonstrated that the Casimir force between two objects is always attractive if the parity symmetry is preserved. In this paper, we calculate the Casimir force between two parallel Pasteur materials and show that the sign of the Casimir force can be modified by breaking parity symmetry.

Casimir effect is one of the famous manifestations of quantum fluctuation. In 1948, Casimir proposed that attractive forces exists between two uncharged, parallel perfect metal plates [1], which is given by

$$F_c = -\frac{\pi^2 \hbar c A}{240 d^3} \tag{1}$$

Here d is the distance between the two plates, A is the area of the plates, c is the speed of light and $\hbar$ is the Planck constant. To achieve the repulsive Casimir force, materials with different optical properties [2–6] and different geometries [7–10] have been investigated. Specifically, Oded Kenneth and Israel Klich proved that "the Casimir force between two bodies related by reflection is always attractive" [11], which suggests that chiral materials may lead to repulsive Casimir force [12, 13].

In our paper, we calculate the Casimir force between two uncharged, parallel Pasteur materials. Pasteur materials are linear isotropic chiral materials with constitutive relations

$$\begin{aligned} \mathbf{D} &= \epsilon \mathbf{E} - i\kappa\sqrt{\epsilon_0 \mu_0}\mathbf{H} \\ \mathbf{B} &= \mu \mathbf{H} + i\kappa\sqrt{\epsilon_0 \mu_0}\mathbf{E} \end{aligned} \tag{2}$$

Here κ is the chirality parameter which characterizes how strong the material breaks the parity symmetry. Our results show that the sign of the Casimir force can be modified by tuning κ.

Our work shows how Casimir force changes with the chirality parameter. The results would be very useful for designing nano-devices and give a hint on understanding how parity symmetry would affect the sign of the Casimir force, which has both theoretical value and promising application potential.

Tailoring MIMO transfer of sound using reflective reconfigurable intelligent surfaces

Hongkuan Zhang[1], Qiyuan Wang[1], Guancong Ma[1*]

[1]Department of Physics, Hong Kong Baptist University, Hong Kong
[*]Corresponding author: phgcma@hkbu.edu.hk

Abstract: Acoustic signals emitted by multiple sources in a room are mixed together due to reverberation, resulting in a loss of intelligibility of speech. Here, we demonstrate that the acoustic channel matrix among multiple inputs and outputs can be controlled with reflective reconfigurable intelligent surfaces by the mean of wavefield shaping. We show how 2×2 and 4×2 channels can be customized almost at will. This research has many potential applications, including scenarios such as enhanced indoor speech communications and recognition.

In recent years, wavefield shaping in disordered systems has garnered considerable attention[1–3]. Reverberant environments are typical wave-disorder systems. Acoustic signals from different sources interfere and mix, eventually becoming indistinguishable. Here, we experimentally demonstrate a method based on a channel matrix and wavefield shaping to tame the effect of disorder for achieving multiple-input and multiple-output (MIMO) acoustic communications.

In our experiments, a loudspeaker array represents the speakers, and a microphone array represents the listeners, as shown in Fig.1(a). A channel matrix is used to describe how the signals travel from the loudspeakers to the microphones. In the Fourier domain, this can be written as $\boldsymbol{R}(f) = \boldsymbol{H}(f) \cdot \boldsymbol{S}(f)$, where $\boldsymbol{R}$ and $\boldsymbol{S}$ denote receiving signals and transmitting signals at frequency f, respectively. The channel matrix $\boldsymbol{H}$ has complex-valued entries h_{ij} that describe the channel gain from the loudspeaker to the microphone. A 2×2 channel matrix corresponds to the situation with two speakers (loudspeakers) and two listeners (microphones). Our target is to eliminate cross-talks between speakers and listeners so that listener 1(2) only hears speaker 1(2). Mathematically, this means the reduction of the off-diagonal components of the channel matrix while maintaining the effective rank of $\boldsymbol{H}$. The objective function can be expressed as

$$F(f) = w[\boldsymbol{H}(f)] + |\mathrm{rank}[\boldsymbol{H}(f)] - \mathrm{erank}[\boldsymbol{H}(f)]| \quad (1)$$

where $w = \sum_{i\neq j}|h_{ij}(f)| \,/\, \sum_{i=j}|h_{ij}(f)|$ is the ratio between the off-diagonal part and the diagonal part of the channel matrix, which is called as the weight factor of channel matrix in this paper. The symbols $\mathrm{rank}[\cdot]$ and $\mathrm{erank}[\cdot]$ denote the rank and the effective rank of a matrix, respectively. The effective rank[4,5] acts as a measure of the transmission among different channels and can be defined as $\mathrm{erank}[\boldsymbol{H}] = \exp\left(-\sum_{k=0}^{n} p_k \ln p_k\right)$, where $p_k = \sigma_k/(\sum_i \sigma_i)$ is the normalized singular values of the channel matrix $\boldsymbol{H}$. Normally, if the energy is concentrated only in one channel, the effective rank is smaller (close to 1). Conversely, if and only if the energy is evenly distributed among all channels, the effective rank takes the maximum value which is equal to $\mathrm{rank}[\boldsymbol{H}]$.

We use a 200-unit reflective reconfigurable intelligent surface to control the disordered sound field, as shown in Fig.1(a). Each unit is an electrically tunable Helmholtz resonator capable of changing the reflected phase over a wide frequency range of 1050-1750 Hz. We obtain each entry in the channel matrix by measuring the complex transfer function between the loudspeakers and the microphones. Then we calculate the objective function with Eq. (1) and use it as feedback to guide the optimization. Figure 2(b) shows the result of the 2×2 channels, wherein the off-diagonal entries are indeed suppressed. Figures 2(c, d) show the effect of optimization on acoustic

communications. Two loudspeakers independently and simultaneously emit two different pulses, signal 1 and 2. Before the optimization, it is seen that both microphones can pick up the two signals, whereas after the optimization, microphone 1(2) can only pick up the signal emitted by speaker 1(2). In other words, the two channels are completely independent and cross-talks are completely eliminated.

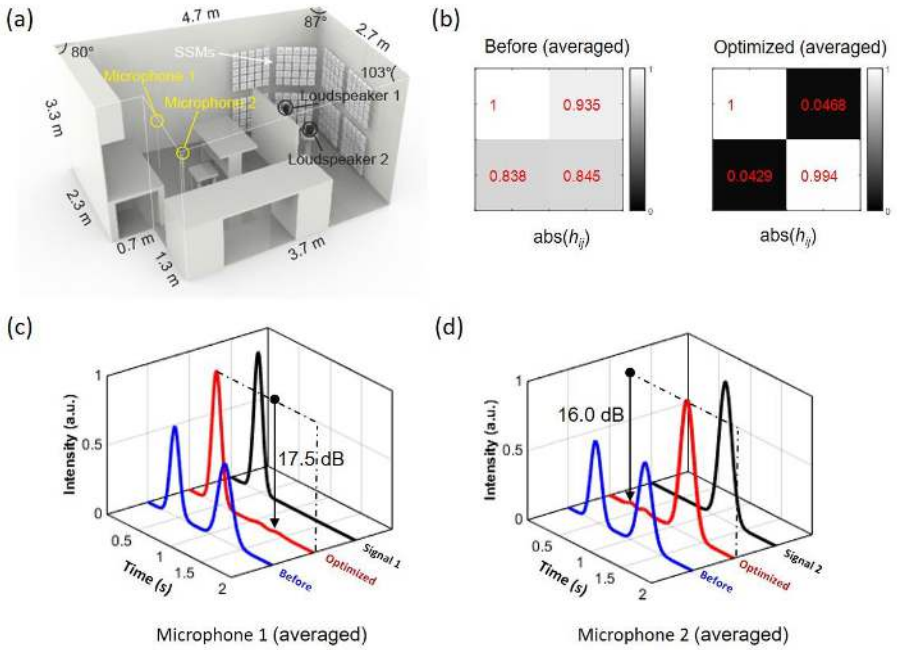

Fig. 1. (a) The room and experimental setup. (b) The channel matrices of 40 independent realizations at 1300 Hz before (left) and after (right) optimization. (c) and (d) show the averaged time-domain signal envelopes of 40 realizations received by microphones 1 and 2, respectively. The blue, red, and black lines represent the envelope of the received signal before optimization, the received signal after optimization, and the signals sent by the loudspeakers, respectively.

Abstract: This work presents a general design methodology of metamaterial absorbers made of arrays of Helmholtz resonators for open-duct problems, which is encountered in broad practical applications. By using a single point scatterer, it is insufficient to attenuate both the reflected and radiated waves; a frequency-dependent maximum absorption exists and is derived analytically. To go beyond this absorption bound and achieve perfect absorption, at least two point scatterers are necessary. Specific designs are provided and validated both numerically and experimentally.

The absorption of both reflected and radiated acoustic waves by using monopolar point scatterers in the unidimensional (1D) open-duct problem is studied in this work. The absorption coefficient is defined as

$$\alpha = 1 - E_{\mathrm{Ref}} - E_{\mathrm{Rad}}\,. \tag{1}$$

where E_{Ref} and E_{Rad} are the reflection and radiation energies normalized by the incidence energy, respectively.

(a) (b)

Figure 1: Schematic illustrations of metamaterials made of point scatterers in the 1D open-duct problem: (a) Single point scatterer. (b) Two coupled point scatterers.

In the case that a single point scatterer is used, which is illustrated in Figure 1(a), the maximum absorption coefficient is derived as

$$\alpha_{\max} = \frac{1}{2}\left[1 + \sqrt{\frac{\left(\theta_{\mathrm{Rad}} - 1\right)^2 + \chi_{\mathrm{Rad}}^2}{\left(\theta_{\mathrm{Rad}} + 1\right)^2 + \chi_{\mathrm{Rad}}^2}}\right]. \tag{2}$$

which is in general frequency dependent and less than unity. Note that in the 1D problem, the acoustic response of the open end can be modelled by the specific radiation impedance [1] $\zeta_{\mathrm{Rad}} = \theta_{\mathrm{Rad}} + \mathrm{i}\chi_{\mathrm{Rad}}$ under the $\mathrm{e}^{\mathrm{i}\omega t}$ convention. To achieve $\alpha_{\max}$ at a single frequency, two conditions are necessary: (1) the scatterer provides the optimal impedance ζ_{opt} and (2) the distance between the scatterer and the open end is the optimal value L_{opt}. In contrast, to achieve perfect absorption ($\alpha = 1$), at least two point scatterers are needed as illustrated in Figure 1(b). Moreover, it is required that the scatterers should achieve the optimal impedance values:

$$\begin{cases} \zeta_{\mathrm{HR1}} = 0 \\ \zeta_{\mathrm{HR2}} = -\mathrm{i}\sin\left(k_0 L_2\right)\mathrm{e}^{\mathrm{i}k_0 L_2} \end{cases}. \tag{3}$$

The above definition (Eq. (1)) and results (Eqs. (2) and (3)) in the open-duct problem are direct generalizations of the 1D reflection [2] and transmission [3,4] problems. The reflection or transmission problem corresponds to the special case when the boundary impedance ζ_{Rad} approaches to infinity or 1+0i, respectively.

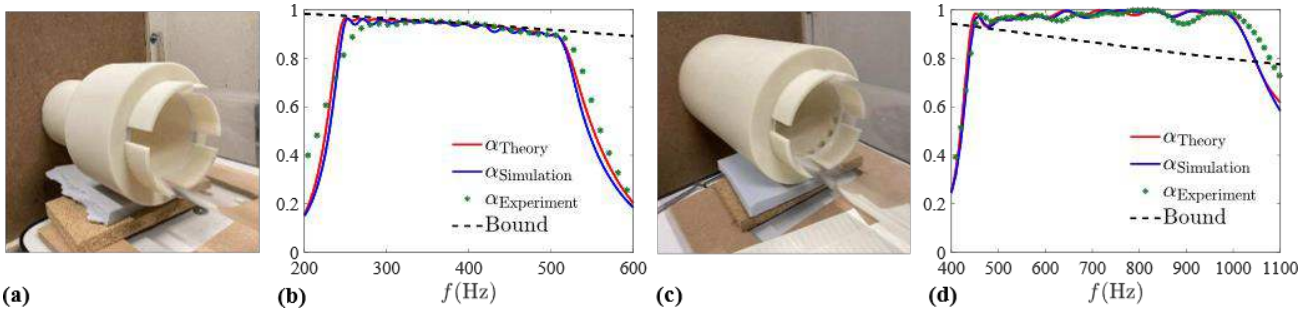

Figure 2: Single-point-scatterer metamaterial for broadband maximum absorption: (a) Sample working from 250 Hz to 500 Hz. (b) Absorption coefficient of the sample: comparison of the theory, simulation, and measurement. Coupled-point-scatterer metamaterial for broadband perfect absorption: (c) Sample working from 450 Hz to 1000 Hz. (d) Absorption coefficient of the sample: comparison of the theory, simulation, and measurement.

To realize $\alpha_{\max}$ and perfect absorption as well, we propose a general design strategy, in which monopolar point scatterers are employed. A circular waveguide (whose radius is 5 cm) with an open end in the baffled wall is considered. Arrays of Helmholtz resonators in parallel with the waveguide, i.e., in both the circumferential and the wave directions, are used to play the roles of the point scatterers. As predicted by Eq. (2), the maximum absorption is close to perfect in the low frequency range. Specifically, for this circular waveguide, $\alpha_{\max} \geq 0.9$ when $f \leq 500$ Hz. Thus, a compact and efficient absorber is realized by utilizing this property with a single point scatterer made of detuned Helmholtz resonators, which possesses deep subwavelength size and achieves broadband (250 Hz to 500 Hz) maximum absorption as shown in Figures 2(a) and 2(b). In contrast, coupled point scatterers are necessary to break the absorption bound and thus to achieve perfect absorption. A specific design is provided with numerical and experimental validations over the frequency band 450 Hz to 1000 Hz as shown in Figures 2(c) and 2(d).

Strain-gradient-driven and magnetoelectric operation with order parameters in Cr_2O_3

O. V. Pylypovskyi[1,2*]

[1]Helmholtz-Zentrum Dresden-Rossendorf e.V. 01328 Dresden, Germany
[2]Kyiv Academic University, 03142 Kyiv, Ukraine
[*]corresponding author: o.pylypovskyi@hzdr.de

Abstract: Progress in computing technologies enforces an active search for novel materials, assuring low-power and high-speed operations. One of prospective materials for such needs is Cr_2O_3. Here, we discuss access to the order parameters and properties of antiferromagnetic domain walls related to the possibility of electric operations on them, as well as fundamental and technological perspectives of the recently accessed flexomagnetism in thin Cr_2O_3 films.

Strong technological need in low-power and high-speed solid-state elements of electronic devices brings attention to antiferromagnets. Being usually used as a supplementary parts of ferromagnet-based devices, this class of materials offers a wide range of phenomena related to the crystal symmetry and spin-orbit torques. Among them, Cr_2O_3 is of special interest because of easy-axis anisotropy and room-temperature magnetoelectric effect [1]. The latter gives a possibility to manipulate the primary magnetic order parameter $\boldsymbol{L}$ by electric field. In this way, magnetoelectric cooling through the Neel temperature T_N with spatially varying magnetic field allows to set the domain wall in a Cr_2O_3 single crystal. It was demonstrated, that this domain wall can be moved by the laser spot and can be pinned or deflected by the surface topography of the sample. Stable geometric bends of the domain wall mimicking an elastic ribbon enable a possibility to design a memory unit cell [2].

While distinguishing of the oppositely ordered domains separated by 180º domain walls by imaging could be complicated, anomalous Hall effect in Pt capping layer of a Cr_2O_3 sample is a powerful tool to access the net sublattice magnetization. Combining with the linear magnetoelectric effect, this gives a possibility for the completely electric operation with direction of $\boldsymbol{L}$, where the hysteresis behavior necessary for the memory storage appears due to bias of the gate voltage associated with the defect-induced magnetic moment [3]. Thin Cr_2O_3 films typically have a complex grain structure whose landscape has a correlation with antiferromagnetic domains in equilibrium because of domain wall pinning on defects. However, defect structure can be effectively controlled by the deposition and annealing temperatures, while the magnetoelectric effect is preserved even for the random orientation of single grains [4].

Low bulk T_N of about 35ºC is the key limiting factor for direct technological use of Cr_2O_3. There are theoretical predictions and experimental observations that the internal strain can rise T_N giving wider operational temperature range [5]. In addition to the average strain of order of 3% enhancing T_N, up to 100 ºC, epitaxially grown thin Cr_2O_3 films can also possess sizeable strain gradient of order up to 0.1%/nm. This enables flexomagnetic response of the film, resulting in the additional net magnetization consisting of two terms. The ordinary flexomagnetic moment is directly produced by the strain and is uniform within the film plane. The observed strain gradient also induces gradient of T_N along the film thickness z and respective scaling of $\boldsymbol{L}$ with z. The latter produces an uncompensated magnetization aligned with $\boldsymbol{L}$ and therefore accessible via stray fields measurements [6].

Magnetoelectric Cr_2O_3 is a prospective material platform for energy-consuming devices, where access to the primary antiferromagnetic order parameter can be done via electric fields. Furthermore, despite weak ferromagnetism by itself is forbidden in this material, inhomogeneous strain enables non-zero magnetization and graded Neel temperature in film interior, which provides additional degrees of freedom in design of antiferromagnetic racetracks and sub-THz magnonic waveguides.

Abstract: We study experimentally and numerically how to reduce the backscattering of water waves in a channel with multiple turns. We show that it is possible to achieve enhanced transmission in such geometries, in agreement with a recent theoretical prediction. In order to avoid the reflection that naturally arises at each turn of the waveguide, we used an anisotropic metamaterial made of closely-spaced thin vertical plates.

In the last decade, there has been a theoretical effort [1-3] as well as an experimental one [4, 5] on using gratings with a subwavelength structure to obtain a broadband wave shifting. Recently, it has been shown [6] that the exact solution to the problem of an array of inclined infinitely thin parallel plates occupying a region of finite width yields total transmission for all wavenumbers when the inclination of the plates is opposed to the incident wave direction.

In the present study, we show experimentally a broadband backscattering reduction through an array of vertical surface piercing thin plates with a perpendicular angle with respect to the incident wave. We performed experiments in a waveguide that undergoes a twist at 90° and then continues in a direction parallel to the first section, as shown in Figure 1. In an empty channel (i.e. without the plate-array metamaterial), the transmission coefficient decreases with the frequency; it only reaches high values at the resonances. However, the addition of an anisotropic metamaterial not only reduces the backscattering but also allows for an enhanced transmission. It is important to emphasize that this effect occurs for all frequencies below the cut-off frequency, without relying on resonant phenomena.

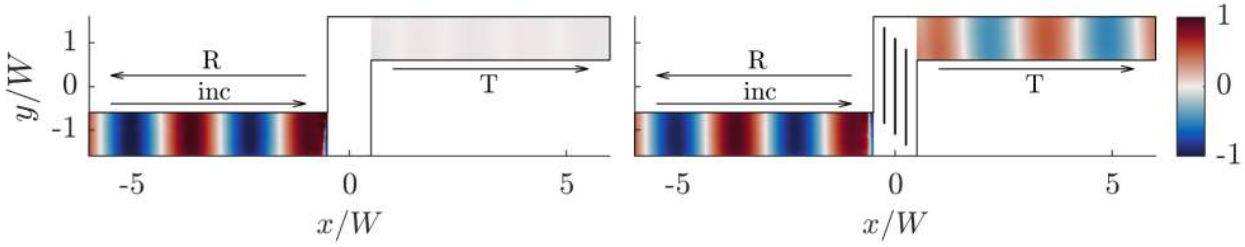

Figure 1. Experimental result: real part of the measured free surface deformation filtered at the forcing frequency for $kW = 9\pi/10$ (normalized), for a configuration without (left) and with (right) the plate array metamaterial, showing the directions of the incident, reflected and transmitted waves.

We first studied numerically the effect of the ratio between the length of the twist and the width W of the channel, proposing a 1D model analogous to a Fabry-Perot interferometer. Based on this study, we chose to work with a twist of length $3.2W$, because it is the largest ratio where we only see one

resonance (it should be reminded that we are looking for a broadband effect, regardless of resonant phenomena). Since the plates that form the metamaterial have a finite thickness, we addressed its influence on the reflection and transmission coefficients. We then decided to fix the thickness at $0.02W$ in order to have a small reflection and at the same time be large enough to perform experiments.

Experiments were performed in a 3 m long channel of width $W = 0.10$ m, with a water depth of 0.05 m, using the Fourier Transform Profilometry method [7] to measure the free surface deformation. We took measurements in a wide range of frequencies below the cut-off frequency, changing the number of plates that constitute the metamaterial, always maintaining the space between the plates smaller than the wavelength. We observed a significant backscattering reduction, providing empirical evidence to the theoretical predictions made by [6] and exploring its capabilities in terms of an experimental realization.

How to steer acoustic waves in a random medium in a programmable way?

Abstract: Recently emerged aperiodic textured metamaterials have opened up routes to multi-functional and programmable functionalities. Such possibilities have, however, been explored mainly in quasi-static regimes. Here, we show that the "tuning-by-pruning" strategy enables realizing multi-frequency steering in random elastic networks thus showing a way to the rational design of a new class of programmable acoustic metamaterials.

Metamaterials open exciting venues for unprecedented manipulation of mechanical characteristics and control of acoustic waves. Recently, discrete pruning of random nearly-isostatic networks has enabled the simultaneous optimize two static mechanical properties – the shear and bulk modulus [1] and evolving networks with an "allosteric" response, where static forcing at location A yields a response localized at a distant location B without a traceable load path [2]. Disordered networks constitute an attractive design space for exploring programmable functionality [3]. Here, we apply the discrete pruning strategy to control the wave dynamics of random mass-spring networks and aim at achieving multichannel wave steering. For this, we choose wave frequency as a canonical control parameter that naturally leads to intricate design questions and opportunities.

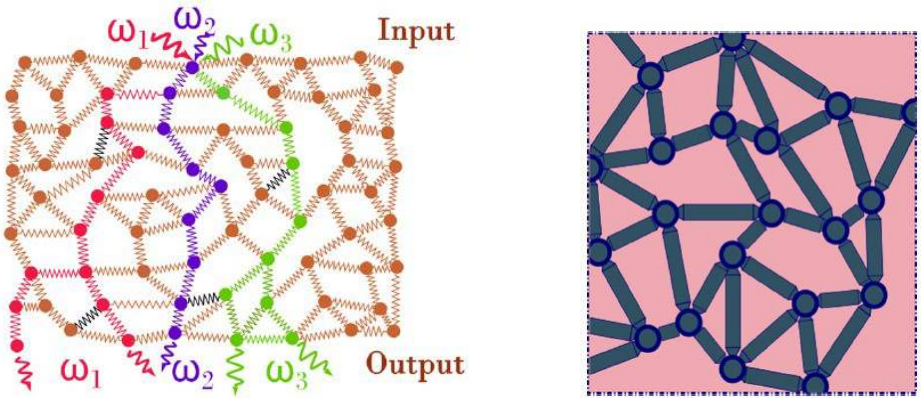

Fig.1 (left) Schematics of the expected functionality: exciting the input node of a rationally pruned network directs the vibration energy toward the output nodes depending on the excitation frequency. (right) Sketch of possible practical realization.

We consider mass-spring systems. Given n output channels and m harmonic excitations of unit amplitude and frequency $\{\omega_m\}$, how close can we approach target amplitudes $\{A_n^m\}$ with a network consisting of k springs (Fig. 1, left)? How many independent patterns ("capacity of the network") as functions of k, m or n are possible to create the foundation for the computer design of pluripotent networks?

Here, we analyze cases when m preselected frequencies (m=1,2,3) yield l on/off (1/0) normalized target amplitude patterns at n outputs for two-dimensional networks with 5x5, 7x7, … 27x27 masses. We use a greedy

pruning algorithm that removes one spring at each step which yields a minimal value to a cost function. The cost function is defined as the sum of squares of differences between the actual and target amplitudes at the outputs. Note that in the dynamic regime, such pruning is more computationally expensive as compared to previously analyzed strategies for static properties [1, 2]. In the latter case, the target function can be expressed as a sum over springs so that springs can be removed independently reducing computational costs. In our systems, the removal of a spring modifies the eigenmodes that require recalculating the cost function at each step.

We have shown that rational pruning allows controlling vibration properties of disordered networks by pruning a small number of springs (less than 10%). The pruned configurations do not show discernible paths but enable steering acoustic energy to targeted nodes at pre-defined frequencies. We observe that the number of springs that are required to be pruned increases with more stringent design objectives such as larger contrast of amplitudes at outputs or more outputs, as can be expected. For a given target functionality, the number of pruned springs increases linearly with the number of masses, so the fraction of pruned springs diminishes with this number. This suggests that larger systems allow for even more functionalities to be integrated.

Our results demonstrate that pruning is a viable strategy to realize multi-objective optimization in disordered spring-based metamaterials. Further studies are required to verify the obtained results experimentally, e.g., by testing systems as shown in Fig. 1 (right) and to extend the pruning strategy to three-dimensional network configurations.

Control of wave propagation in networks of gyro-elastic discrete strips

G. Carta[1*], M. J. Nieves[2], and M. Brun[1]

[1]Department of Mechanical, Chemical and Materials Engineering, University of Cagliari, Italy

Abstract: We present a novel mechanical network, which can guide the elastic waves generated by an external loading towards any of its endpoints, that can be selected *a priori*. The proposed *Mechanical Switching Network* (*MSN*) is made of an arrangement of intersecting strips, possessing a lattice structure where the nodes are connected to gyroscopic spinners. This innovative system can be useful in engineering applications, where the control of energy propagation plays a crucial role.

The system under investigation, named *Mechanical Switching Network* (*MSN*), is a network of lattice strips with different orientations. The micro-structure, shown in Figure 1(a), consists of a triangular array of point masses connected by elastic links and attached to gyroscopic spinners, which couple the in-plane displacement components of the masses. The gyroscopic spinners are characterised by a quantity, denoted by Ω^* and referred to as "effective gyricity", that is given by the sum of the spinner's initial precession and spin rates and that remains constant during the motion.

In the time-harmonic regime, the vector problem is solved analytically by writing the governing equations of the particles inside the bulk and at the upper and lower free boundaries, as described in [1] for the case without gyroscopic spinners. The dispersion curves for the periodic strip exhibit a semi-infinite band-gap at higher frequencies and their number is equal to twice the number of the lattice rows. In the transient regime, the formulation is based on the use of Laplace transform and discrete Fourier transform [2]; in this case, the presence of an applied load has been taken into account.

The response in the time-harmonic and transient regimes of the MSN to an external source is determined numerically, by constructing a finite element model in *Comsol Multiphysics* (version 5.6). An example is shown in Figure 1(b), where the total displacement field is plotted. The external loading is represented by a time-harmonic horizontal force, indicated by an arrow and labelled as "S", while the four endpoints are denoted by "A" to "D". Adaptive Absorbing Layers are introduced near the ends of the MSN branches, in order to avoid reflections at the boundaries.

In Figure 1(b), the effective gyricity in each strip is selected such that waves are forced to propagate to the endpoint C. It is found that more than 96% of the energy coming from the external source is channelled towards the chosen endpoint. We point out that wave propagation can be diverted to any of the other endpoints by tuning the effective gyricity in each branch (see [2] for further results). The preferential directionality of the MSN is due to the non-reciprocal behaviour induced by gyroscopic spinners, which was formally proved in [3] and demonstrated with numerical simulations in [4] in relation to Rayleigh waves.

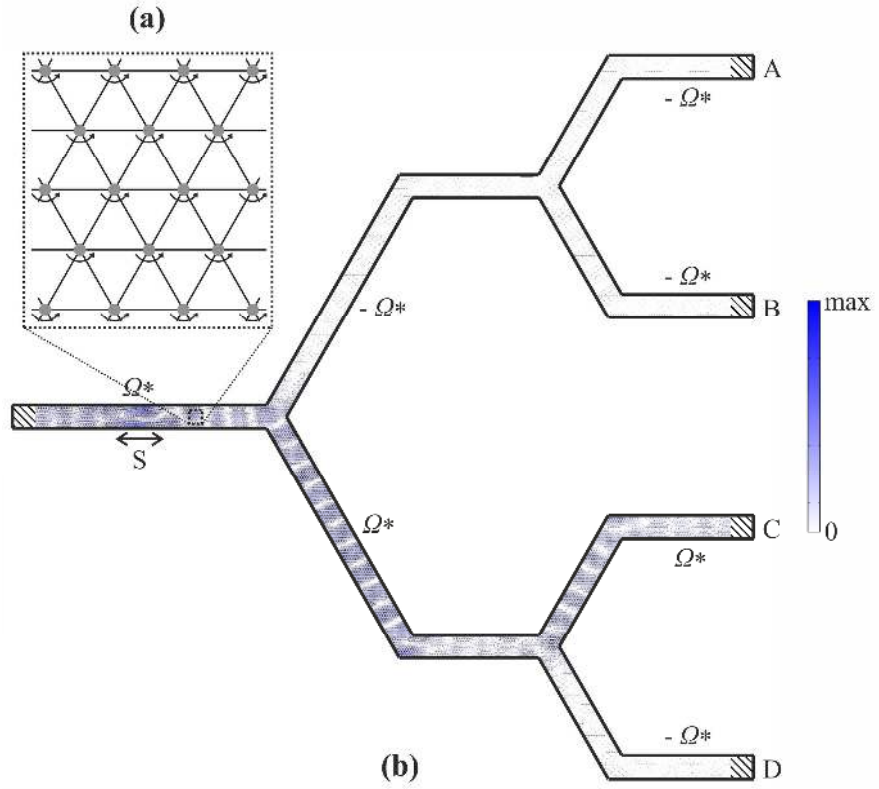

Figure 1. *Mechanical Switching Network* (*MSN*): (a) detail of a branch of the system, characterised by a lattice structure whose nodes are connected to gyroscopic spinners (circular arrows); (b) wave propagation induced by an external source S (arrow) and channelled to endpoint C by properly choosing the effective gyricity Ω^* in each branch (the dashed regions near the ends of the network indicate Adaptive Absorbing Layers).

We envisage that his work can lead to innovative engineering applications in Micro-mechanical and Signal Processing Systems, where control and tunability of wave propagation play an important role.

Abstract: Here by actively controlling electroacoustic resonators, we implement a one-dimensional nonlinear topological system. We demonstrated theoretically, numerically, and experimentally that by adding nonlinearity, the edge state can be preserved at the same frequency as the linear case, provided that the chiral symmetry is satisfied. A good agreement has been found between theoretical, numerical, and experimental results. Our active control approach shows great potential for exploring different types of systems at the intersection of non-linear physics and other fields.

Active control is an efficient means to tailor the physical properties of the materials. By assignment of a specified electrical current sent to a loudspeaker, one can modify its impedance in a prescribed manner [1]. In our work, we use such a feedback control loop to design active unit cells, and then build a one-dimensional topological lattice. We first apply linear control to generate linear edge states, then we combine it with nonlinear control to study the evolution of the edge state generated. Our exploration starts from theoretical work on the nonlinear Su–Schrieffer–Heeger model, then we demonstrate with simulation and experiments that in the nonlinear cases, by satisfying the chiral symmetry, the edge state can be preserved at the same frequency as the linear case, which in agreement with the conclusions of the theoretical topology work of L. Jezequel and P. Delplace [2].

Abstract: We develop deep learning models based on discriminative and generative networks to solve the forward and inverse acoustic scattering problems and show how these models benefit solving the inverse design process by eliminating the non-unique solution space. We demonstrate examples of using the developed deep learning models for designing broadband acoustic cloaks and arbitrarily-shape acoustic object recognition for underwater applications

The conventional modeling of wave-media interactions is based on analytical and numerical schemes, which often rely on hit and trial modeling of physical variables or physics-informed optimization for 'on demand' scattering properties. In general, these schemes are computationally expensive, and are slow especially for complex systems involving a design space with large degrees of freedom. On the other hand, with the blossoms of artificial intelligence, models that can capture the underlying correlation between various physical quantities and streamline the inverse design process provide completely different tools for the study of wave-media interaction. Recently, data driven approaches were on the main stream of research due to their ability to solve a wide range of physical problems with unprecedented speed and accuracy[1]. Despite of this progress, there have been limited efforts to using deep learning techniques to learn input-output mappings with diverse designs and inverse design insights. In this work, novel deep learning models are developed for the design of broadband acoustic cloak and arbitrary object recognition in water. As a surrogate physical model, discriminative neural networks are designed for forward process of one-to-one mapping. However, generative neural networks based on variational inference and adversarial learning are designed for the inverse process of one-to-many mapping, where the fundamental issue of nonuniqueness is addressed by learning the latent distribution of data structures.

In the first example, we demonstrate deterministic and probabilistic deep learning models for inverse design of broadband acoustic cloak. Acoustic cloaks, making an object invisible for sound waves, are usually build from artificially structured acoustic metamaterials. The realization of metamaterial-based cloak faces multiple challenges, such as stringent requirements on the material parameters and narrow operating bandwidth. To address these issues, we propose a design of acoustic cloak with a four-layer core-shell configuration driven by machine learning. The performance of the system is quantified by the ratio of total scattering cross-section (TSCS) spectra for the cloaked object and the bare object, computed using transfer matrix method (TMM). To achieve broadband invisibility, we first train a forward neural network (FNN) to model the relation between the design and response space using a set of training data. Once trained, the pretrained FNN is cascaded behind the inverse network forming a probabilistic encoder-decoder-like structure to capture the underlying physics to generate a variety of design parameters for one desired spectral response and uncovering the sensitivity of the design parameters on the cloaking effect [2].

In the second example, we show a generative deep learning approach for shape recognition of arbitrary objects from phaseless acoustic scattering data. Shape recognition, which relies on inverse scattering, has a wide range of applications, such as sonar detection, remote sensing, underwater imaging, and nondestructive testing. For underwater objects, however, accurate shape recognition is challenging because of high nonlinearity, large background index contrast, and one-to-many mapping in the solution space. Here, we consider a 2D arbitrarily-shaped steel scatterer submerged in water and propose a latent space to learn the nonlinear mapping between acoustic objects and its far-field scattering patterns once illuminated. The non-unique solution space is eliminated by training the probalistic networks with multi-frequency phaseless far-field amplitudes. The scatterer is discretized as a pixel-based binary image, which different indices representing different materials. A commercial software based on finite-element, COMSOL Multiphysics, is used to simulate the far-field patterns of random geometries at five different frequencies across the full angular range. The proposed deep-learning model employs an adversarial autoencoder as a training method for Generator, which generates geometric patterns from the latent distribution of arbitrary-shaped objects. The inverse neural network predicts the 2D object with the matrix of 64 × 64 for the given multi-frequency far-field scattering amplitudes [3]. The approach is generic and readily extended to design complex and random geometries of three-dimensional space structures and other physical systems.

Abstract: We demonstrate wave reflections at temporal boundaries, at which physical constants change suddenly, by use of a one-dimensional mechanical metamaterial in the form of a Shive wave machine. We also demonstrate a temporal antireflection layer by temporal impedance matching, that makes use of an appropriate intermediate temporal layer.

Wave can reflect and transmit at spatial boundaries between two homogeneous media. Waves also reflect and transmit at temporal boundaries. To make temporal boundaries, the physical parameters of the whole medium should be changed suddenly, on a scale much faster than the time for propagation through the region of study. Because of the difficulty of making such clear temporal boundaries, there are few experiments to directly investigate reflected waves at temporal boundaries. An experiment with temporal boundaries on a water surface using a change in the effective gravitational constant has been reported [1]. Recently, an experiment for the temporal reflections at temporal boundaries on a transmission-line metamaterial is reported [2].

Here we follow the reflection and transmission at temporal boundaries for the case of a simple and readily visible one-dimensional (1D) system. The key idea is, by use of a Shive wave machine [3,4], to make the wave speed of the whole medium change suddenly. This allows the investigation of the wave propagation with the naked eye or by use of a video camera, using a system constructed with inexpensive mechanical parts.

To realize wave reflection phenomena at a temporal boundary, we construct a Shive wave machine that uses 5 wires and 95 rods (Figure 1). The central wire goes through the center of gravity of each rod and supports the rods. Two inside wires are arranged symmetrically about the center, which allows torsional motion to be transferred from rod to rod as the wave propagates. Two outside wires, with a similar function, are also arranged symmetrically and can be pulled by a stepping motor, controlled by a computer, in order to change the wire tension and hence the wave phase velocity. The rods are square cross-section brass bars ($320 \times 6 \times 6$ mm) arranged with a 20-mm lattice constant. The motion of the wave machine is recorded by four cameras with a commercial motion-capture system (OptiTrack). We have thereby recorded reflected waves at a temporal boundary, and also realized a temporal antireflection layer by adding an

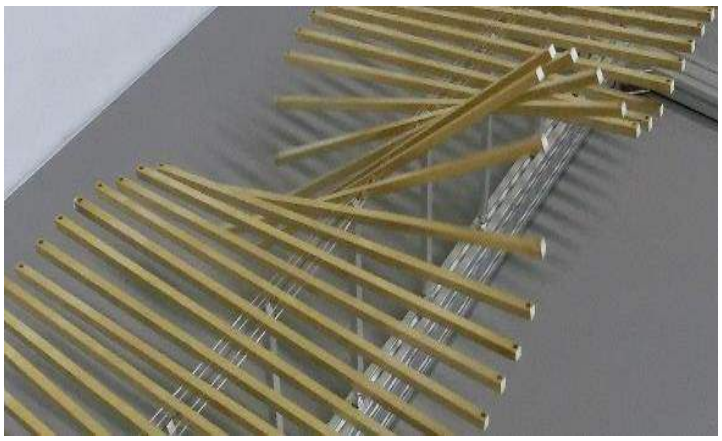

Figure 1. Photograph of the wave machine.

appropriate intermediate temporal layer [5].

In future, it should be possible to demonstrate the wave physics of time-dependent media and space-time metamaterials, for example by involving phenomena such as amplification, wave shaping or frequency transformation [6,7].

Abstract: We study the localization of flexural and acoustic waves in metasurfaces by means of clusters of scatterers. We show that when the scatterers are placed regularly in the perimeter of a circumference the structure forms a resonator which quality factor grows up exponentially with the number of scatterers. This allows the realization of high-quality resonant cavities whose quality factor can be easily tailored and, consequently, its interaction with the continuum. These modes, also named quasi-bound states in the continuum or QBICs, are robust against small perturbations in the geometry of the cluster, being therefore an excellent platform for the design of efficient structures for wave-trapping devices. Numerical experiments are performed for elastic waves in thin elastic plates and acoustic waves trapped atop a metasurface, and an experimental validation of the latter is also presented.

Acoustic and elastic resonators are indispensable structures for all type of devices devoted to the control of the energy carried out of these waves. Bound states in the continuum (BICs) offer a route for the realization of high-quality resonant cavities, since although in principle these modes cannot couple to free propagating waves, structures based on them can be used for the design of excellent resonators presenting finite lifetimes which interact weakly with the continuum.

In this work we study the realization of mechanical resonators for acoustic and elastic waves. First, we consider the propagation of flexural waves in thin elastic plates, latter we study acoustic waves trapped atop a structured metasurface. The geometry analyzed for both systems consists in clusters of scatterers regularly placed along the perimeter of a polygon. We show that in the limit of an infinite number of scatterers this structure forms a cavity with a set of resonances with an infinite quality factor, obtaining therefore a perfect BIC. However, having a finite number of scatterers allows for a finite quality factor which grows up exponentially with the number of scatterers in the cluster. The robustness of these modes is analyzed numerically performing perturbations to the geometry of the cluster, showing that while the peak of the resonance remains unchanged the quality factor can be reduced significantly.

Numerical simulations and experimental realizations support our findings, showing that this work opens a path towards the design of easy-to-tailor acoustic cavities.

Abstract: A central characteristic of a reflection-symmetric wave system is the definite parity of its eigenmodes. In this talk, we will show that such parity of all eigenmodes, however, can also occur in asymmetric systems. To this end, we equip acoustic waveguide networks with so-called latent symmetries, that is, symmetries that become apparent only after a dimensional reduction of the underlying setup. Besides providing a systematic construction principle for such latently symmetric networks, we also explore their scattering properties.

Meso-scale analysis of non-periodic and periodic discrete flexural waveguides

M. J. Nieves[1] **and A.B. Movchan**[2]

[1]School of Computing and Mathematics, Keele University, UK
[2]Department of Mathematical Sciences, University of Liverpool, UK
[*]corresponding author: m.nieves@keele.ac.uk

Abstract: The dynamic behavior of asymmetric flexural systems, involving a master beam attached to a non-periodic collection of flexural resonators, is discussed. The resonators couple longitudinal and flexural responses of the master beam. Its response is described via Green's functions, with intensities determined from an algebraic system embedding interactions of individual resonators. For infinite periodic waveguides, we derive an effective model called the generalized Rayleigh beam that supports flexural-longitudinal wave coupling and is efficient in regimes not typically encountered in homogenisation.

A pathway to lossless non-reciprocal scattering based on synchronization

N. Noiray
CAPS Laboratory, Department of Mechanical and Process Engineering, ETH Zürich, 8092 Zürich, Switzerland
noirayn@ethz.ch

Abstract: Non-reciprocal transmission of information across large periodic networks of resonators is often hindered by their intrinsic dissipation. As a remedy to these irreversible losses, we propose to equip the resonators of these metamaterials with negative resistance elements and with suitable damping nonlinearities, such that they exhibit self-sustained oscillations. Lossless or amplified non-reciprocal scattering at each of these resonators can then be achieved, thanks to the synchronization between the natural radiation of the self-oscillating mode and the incident waves. A theoretical framework is derived in analogy to the temporal coupled-mode theory, and aero-acoustic realizations of this tunable concept are achieved by using flow-induced whistling of cavities, such as in [1].

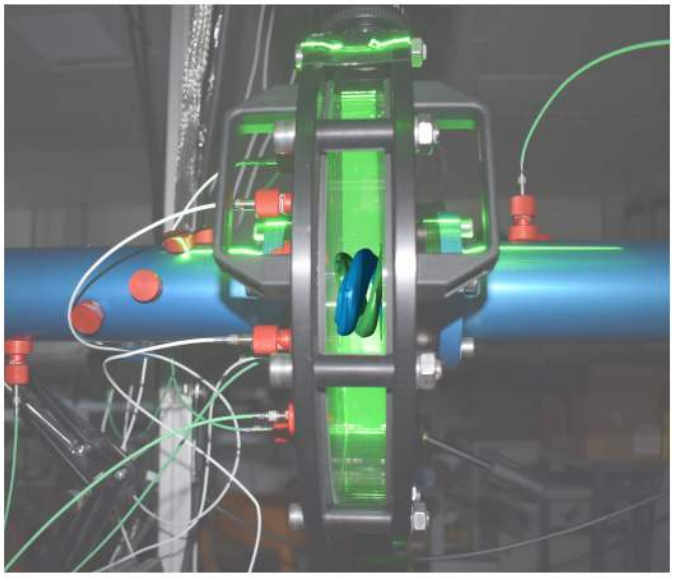

Figure 1: Experiment for the aeroacoustic realization of lossless non-reciprocal scattering based on the synchronization of incident waves with a limit cycle. The coherent flow structures at the cavity opening, obtained with stereoscopic particle image velocimetry, have been superimposed to the picture of the setup.

Abstract: The hallmark of topological phases in periodic materials is the existence of localized modes on the edges that are immune to backscattering. However, in the context of classical waves such as in photonics or acoustics, total immunity to backscattering has never been achieved so far. In this work, we show how to obtain perfect transmission and invisibility of topological edge waves over defects or disorder by exploiting a combination of chiral and mirror symmetry.

The main result of this work [1] is the following. Let us consider a periodic system that possesses commuting chiral and mirror symmetries, and such that there is a single pair of propagating modes at zero energy ($E = 0$). Then, the transmission across any defect or disorder that preserves both symmetries is either zero or unity. Moreover, it is possible to define topological indices of the defect such that if the indices are zero, then the (complex) transmission coefficient is 1.

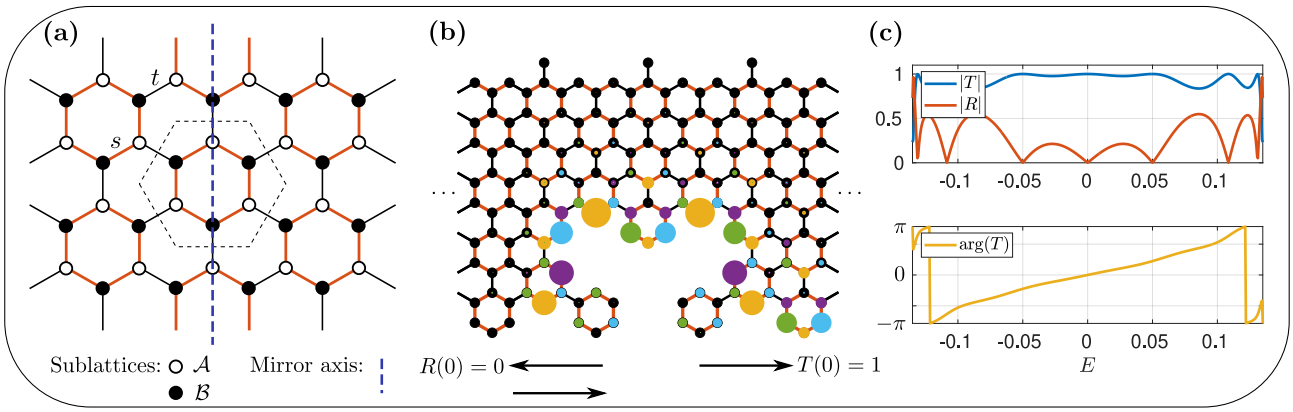

Figure 1: Topological invisibility across defects in Kekulé lattices. (a) Kekule model. (b) Scattering solutions at $\varepsilon = 0$ on the different defects. Circle radii give the field absolute value, and colors show the phase: due to the symmetries of the problem, the phase is either 0 (yellow), $\pi/2$ (green), π (purple) or $-\pi/2$ (cyan). We took $s = 0.25$, $t = 0.5$ and work with the complex energy $\varepsilon + i\nu$. (c) Illustration of perfect transmission in a chiral and mirror symmetric ribbon.

We illustrate this result in the context of the Kekule model. It is a lattice model governed by the Hamiltonian $H = \sum_{i,j} t_{ij} \hat{a}_i^\dagger a_j$ on a honeycomb lattice. The t_{ij} are the hopping coefficients and $\hat{a}_j$ the annihilation operator on site j. The hopping coefficient are modulated so as to preserve the hexagonal symmetry of the system: unit cells (molecules) are made of six sites on a hexagon, and intracell hoppings s differ from extracell hoppings t, as shown in Fig. 1-(a). This model is chiral symmetric: the lattice can be split into two sublattices $\mathcal{A}$ and $\mathcal{B}$ such that by defining the chiral operation $\Gamma = \mathrm{diag}(-\mathbf{1}_\mathcal{A}, \mathbf{1}_\mathcal{B})$, we have $\Gamma H + H\Gamma = 0$. Moreover, it also has

*Electronic address: coutant@lma.cnrs-mrs.fr

several mirror symmetries, that is, there is a mirror operation M such that: $MH - HM = 0$. Those whose axis pass through lattice sites commute with Γ.

Along an edge invariant by mirror symmetry, topological edge waves can be generated. These edge waves are protected by a pair of mirror winding numbers, a topological invariant protecting not only the existence of edge waves but also a Dirac point at $E = 0$ [2]. For instance, for molecular zigzag edges (lower edge in Fig. 1-(b)), the system is topological when $s < t$. Usually, when going from edge waves of a semi-infinite (half-plane) configuration, a mini-gap opens in their dispersion relation, due to the evanescent coupling between the upper and lower edges. Our first result [1] is that by building a lower molecular zigzag edge and an upper partially bearded edge, the Dirac point at $E = 0$ is maintained exactly (it is symmetry protected). Considering such a ribbon with a defect, for E such that only edge waves are propagating (including $E = 0$ and its vicinity), a scattering solution is asymptotically a superposition of an incident wave, a reflected wave, and a transmitted one. This defines the (complex) reflection $R(E)$ and transmission $T(E)$ coefficients (see Fig. 1-(b)). Now, using the symmetries Γ, M and energy conservation, we showed that either $T(0) = 0$ or $T(0) = \pm 1$. Moreover, any defect made of missing or added molecules and/or modified hopping (this includes a slab of chiral mirror disorder) has trivial topological indices. As a result, they are completely invisible:

$$T(0) = 1. \tag{1}$$

This means that not only the energy is fully transmitted, but also that no phase shift is induced by the defect. To confirm this, we solve the ribbon scattering problem numerically using a transfer matrix formalism [1]. The scattering solution and scattering coefficients are shown in Fig. 1-(b-c) for a defect satisfying the previous conditions.

We also propose an acoustic setup to implement this effect with high accuracy. It consists in a network of acoustic waveguides (e.g. hollow tubes) connected on a honeycomb lattice. The waveguide all have the same length L and are much longer than wide. The system is then described by an effective Hamiltonian with hoppings directly proportional to the cross-section of the corresponding tube, and an effective energy $E = \cos(kL)$ with k the natural acoustic wavenumber. The topological invisibility is shown numerically by solving the Helmholtz equation with COMSOL, see Fig. 2.

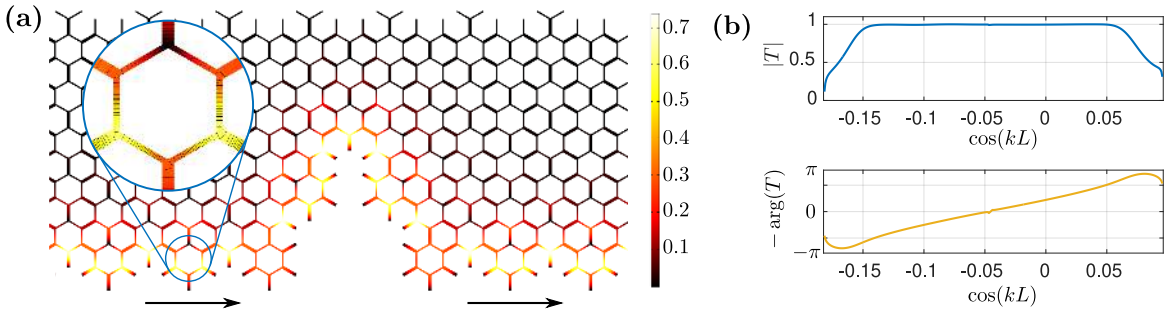

Figure 2: Finite element simulations of the 2D Helmholtz equation in a Kekulé network. We took tubes with $L = 40$, $\sigma_s = 4$ and $\sigma_t = 8$ (hence $s = 0.25$, $t = 0.5$). (a) Scattering solution. (b) Transmission coefficient (modulus and phase).

A solution to cloaking with Willis materials

P. Brucks, H. Nassar *

[1]Department of Mechanical & Aerospace Engineering, University of Missouri, U.S.
*corresponding author: nassarh@missouri.edu

Abstract: Willis elasticity is shown to be a particular microcontinuum field theory where the kinematic enrichment has been eliminated in favor of the macroscopic displacement field. The result is somewhat disappointing: it means that Willis elasticity encompasses no wave phenomena that are not already within the reach of generalized elasticity. That said, the gained insight allows to solve the longstanding problem of elastodynamic cloaking with Willis materials. In particular, the Willis materials useful for cloaking are resolved into mechanical lattices.

"Willis elasticity" is an elasticity theory where stress is coupled to velocity and momentum is coupled to strain through a typically weak "Willis coupling" tensor. The original application of Willis elasticity, by J. R. Willis, was to the effective dynamic modeling of random composites.[1] Interest in the theory was renewed when it was discovered by Milton, Briane and Willis that Willis-elastic materials can be used for elastodynamic cloaking purposes.[2] In that setup, the transformation method provides the constitutive properties needed to achieve cloaking. The difficulty resides in architecting the underlying microstructure, often a gradient of metamaterials, whose effective behavior matches the properties of the cloak. This problem of inverse design remained unsolved due to a poor understanding of the microstructure-property relationships of the Willis coupling. Here, the main contribution is to propose a solution to this problem, i.e., to provide the first architectures that produce a strong passive Willis coupling with a clear and rational set of microstructure-property relationships. The main insight that enabled this discovery is the realization that Willis elasticity is equivalent to a particular microcontinuum field theory (i) with a kinematic enrichment such that (ii) the micro-velocities are inertially coupled to the macro-velocity. Upon elimination of the kinematic enrichment in favor of the macro-displacement, the inertial coupling re-emerges as a Willis coupling (as if by Schur completion). The insight provides a clear view of the architectures that are suitable for cloaking applications: (i) the kinematic enrichment is achieved in architectures with soft deformation modes, e.g., in isostatic lattices with uninterrupted fibers running through the whole lattice;[3] (ii) the inertial coupling is achieved by offsetting the center of mass of a unit cell. Numerical simulations and proofs based on leading-order asymptotics are presented.

Abstract: We will demonstrate how to utilize the crystal growth methods for manufacturing of novel composite materials for various applications, especially photonics (metamaterials, plasmonic materials), topological insulators, energy conversion. We will focus on two novel bottom-up manufacturing methods: (i) method based on directionally-grown self-organized eutectic structures; and (ii) NanoParticles Direct Doping meth-od (NPDD) based on directional solidification of dielectric matrices doped with various nanoparticles.

Recently, we proposed the idea of utilizing directional solidification as a method for manufacturing metamaterials [1] and plasmonic materials [2]. We develop two methods: (i) method based on directionally-grown self-organized eutectic structures [3-5]; and (ii) NanoParticles Direct Doping method (NPDD) based on directional solidification of dielectric matrices doped with various nanoparticles [6-8]. In both of these methods we can easily use all available resonant phenomena to develop materials with unusual electromagnetic properties. Utilizing described above methods we demonstrated: (i) volumetric eutectic-based material with localized surface plasmon resonance at visible wavelengths [9-10]; (ii) enhanced luminescence and up-conversion processes in the eutectic material exhibiting LSPR and co-doped with erbium ions [6]; (iii) volumetric matrix-nanoparticles-based materials with plasmonic resonances at visible [6, 11] and IR wavelengths based on silver (Ag), antimony-tin-oxide (ATO) and titanium nitride nanoparticles (TiN); (iv) matrix-nanoparticles-based composite with enhanced photoluminescence at the telecommunication frequency of 1.5 μm; (v) material with subwavelength transmission at IR frequencies [12]; (vi) narrow band filter and polarizer [13-14]; (vii) surface enhanced Raman scattering in a bulk eutectic material enabling enhancement of selected Raman modes [15], (viii) materials with enhanced Faraday effect; (ix) materials for photoanodes in photoelectrochemical cells for generation of hydrogen [16-17], (x) topological insulator heterostructures.

State of the art on the recovery of mechanical energy in the city: The role of seismic metamaterials

S. Brûlé[1*], S. Enoch[1], and S. Guenneau[3]

[1] Aix-Marseille Université, CNRS, Centrale Marseille, Institut Fresnel, 13013 Marseille, France
[2] The Blackett Laboratory, Imperial College, SW7 2AZ, London, United Kingdom
[*]corresponding author: stephan.brule@yahoo.com

Abstract: Studies on structured soils, including seismic metamaterials, have shown the existence of complex wave phenomena within and around the structured zone. Seismic protection in conjunction with invisibility cloak has led to the emerging research area of seismic energy harvesting with seismic metamaterials. In this fast-developing niche, it is a question of evaluating the zones of energy concentration and deciding on the interest of valuing them by placing piezoelectric energy sensors. The article presents what is already being done and shows the interest of seismic metamaterials in this context.

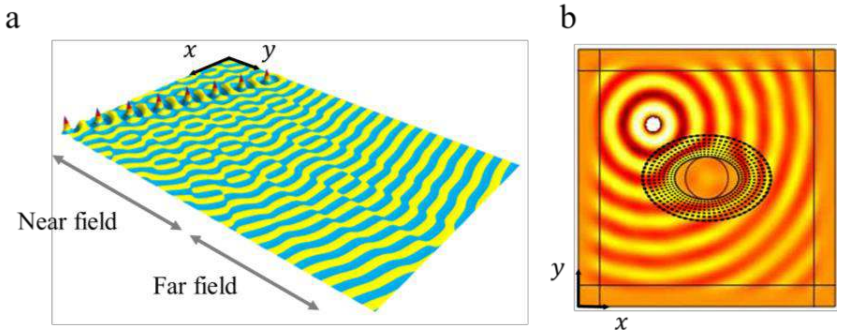

Figure 1: The zone of interest in seismicity of structured soils is the near field around the device (a) and inside the device itself, for instance an arena reminiscent of an invisibility cloak (b).

Soil dynamics as well as science of seismic metamaterials have led to the identification of materials or assemblies of materials with contrasting mechanical properties and local modes. The coupling of buildings such as surface resonators with structured soils constitutes an opportunity for development in the trapping of mechanical energy. In the era of energy transition, any source of free energy represents an interest [1-3]. The measurements show that the near field is the area of interest (Figure 1). Questions remain and technical obstacles have to be overcome. Nevertheless, applications such as podo-electric sidewalks using the kinetic energy of passers-by to produce local lighting is an encouraging avenue.

We return to the results obtained on structured soils under ambient seismic noise and under urban noise and we qualify the energy emitted by different civil engineering structures. In Figure 2 we present the case of a building which generates vibrations in its immediate environment [4].

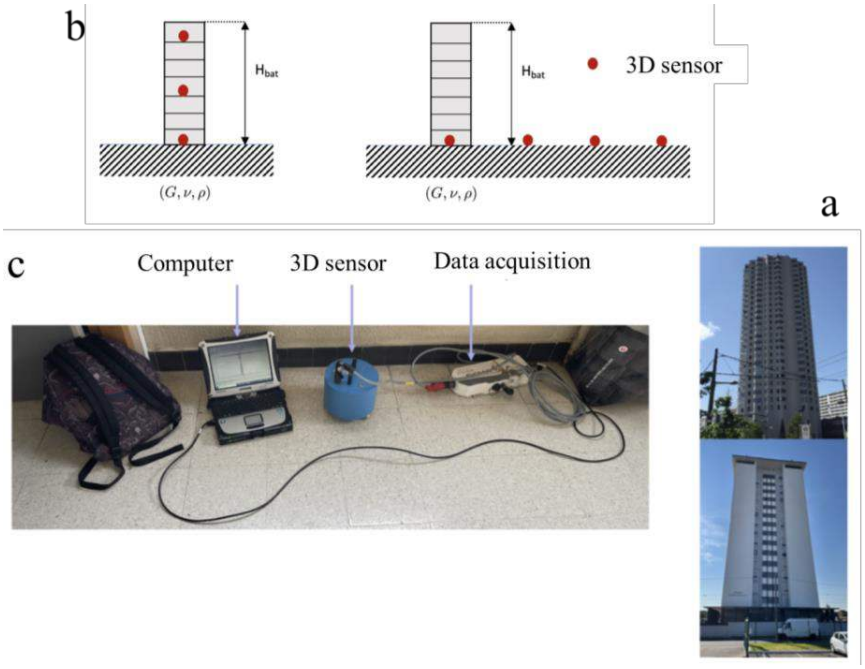

Figure 2: Instrumented buildings (a). Principle of measurement with location of 3D sensors (red dots) inside the building and on the ground surface away from the structure (b). The device for the acquisition of seismic ambient noise measurements (c).

Abstract: the dynamic response of an elastic porous material with a periodic distribution of elongated holes is considered[1]. The presence of the cuts makes the effective behavior auxetic and guarantees the presence of multiple Dirac points in the dispersion diagram.

By perturbing the length of half of the cuts and mirroring the structure on the opposite side of an interface, topologically protected edge modes have been showed numerically (see Figure 1). Such modes are associated with a Chern number close to 0.5. Auxeticity plays a fundamental role on the presence of such topologically protected modes, which are not present when the internal morphology is such that the effective Poisson's ratio is positive.

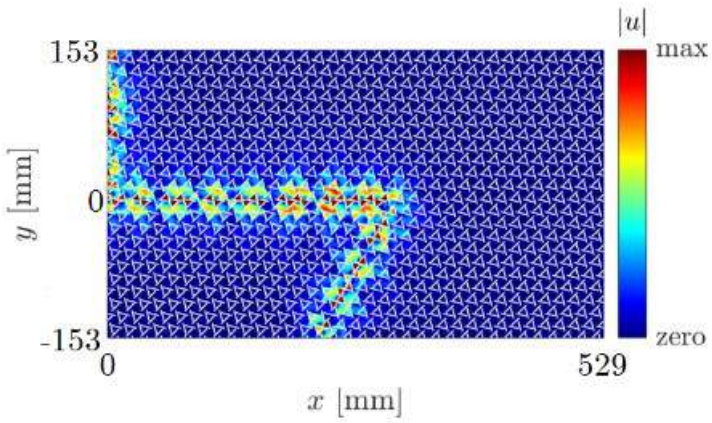

Figure 1. Topologically protected mode propagating along an interface with a sharp angle.

The dynamic response can be tuned by applying a large deformation. In such a case, the lower edge mode can be annihilated, while the upper mode can be moved at different frequencies. In addition, the possibility to activate edge modes in disjointed portion of the interface is shown.

Design, fabrication and performance assessment of an acoustic focusing metamaterial lens

Feng Qin[1*], Jie Zhang[1] and Bruce W. Drinkwater[1]
[1]Department of Mechanical Engineering, University of Bristol, Bristol BS8 1TR, United Kingdom
[*]corresponding author: feng.qin@bristol.ac.uk

Abstract: we describe a procedure to design and assess an acoustic focusing metamaterial lens operating at 40kHz. The lens is based on a square unit cell containing a cross-shaped feature. The design procedure involves using the retrieval method to calculate the unit cell size and lay out, and a time delay approach to focus an acoustic wave. The designed lens was manufactured from ABS using a 3D printer and this paper carefully considers the fabrication limitations. The performance of the lens was assessed experimentally on artificial flaws, and this shows the potential for application in the non-destructive testing field.

Metamaterials are artificial components composed of subwavelength sized units which have inhomogeneous material properties. These unconventional material properties can be achieved by, for example, changing the geometry and layout of metamaterial units. In this paper, we manufacture a metamaterial lens using a cross-shape unit cell[1] and a number of layers. We first use the retrieval method[2] to evaluate the effective refractive index and impedance for a range of unit cells geometries in a finite element model. The lens is then designed using well-known ray theories, the required phase delay found and the unit cells selected to achieve a specified focused acoustic beam.

The contribution of this paper is to explore how to optimize the manufacture of this lens. Key objectives here are to reduce the cost of manufacture and this means using rapid manufacturing techniques such as 3D printing. This in turn leads us to select the largest possible unit cell size which means that the metamaterial is not truly homogenous and so has some unusual properties, for example the unit cell performance is affected by it neighbors which can no longer be considered identical. We explore how lenses can be built in this regime. We also explore how to design a unit cell that is relatively insensitive to manufacturing errors, as this enables us to manufacture the lens at low cost with a medium-quality 3D printer. Finally, the optimally designed lens was manufactured, and the experimental validation performed as shown in Figure 1. The focusing ability of this lens was such that it was capable of detecting flaws in plate-like structures with high resolution.

Acoustic metagratings: From principle to applications

Jun Mei

South China University of Technology, China
*corresponding author: phjunmei@scut.edu.cn

Abstract: Wavelength-thick metagratings for airborne and waterborne sound are highly desirable in various application scenarios. In this talk, we present a class of metagratings with which distinct and switchable wave manipulation functionalities, such as extraordinary transmission, total reflection, and abnormal reflection can be achieved through a single acoustic grating. Simultaneous and high-efficiency control over both reflected and transmitted waves is achieved through a systematic design approach in which wave diffraction theory and intelligent optimization algorithms are concurrently utilized.

For many industrial applications related with airborne and waterborne sound, steerable and controllable transport of acoustic signals along preferred directions is highly demanded. It is also desired that the wave front can be manipulated by a planar acoustic device, and it would be even better if such a device has a structure as simple as possible and a steering efficiency as high as possible. To meet these demands, we construct the metagratings with iron cylinders only, which are probably the simplest element of structure in two-dimensions (2D), not only making them considerably simpler to synthesize than conventional metasurfaces, but also significantly lowering fabrication demands.

Furthermore, we want to design customized metagratings that can fulfill the desired wave-front manipulation requirement, aiming to solve the inverse-design problem that scientists and engineers are constantly encountering in practical applications. Through diffraction analysis and a genetic-algorithm-assisted optimization process, we propose a powerful inverse-design approach that can faithfully and promptly produce desired wave-front manipulation effects. Various wave-diffraction functionalities, including perfect beam splitting, anomalous reflection and transmission, retroreflection, and highly asymmetric transmission response are unambiguously demonstrated with unitary efficiency.

Abstract: Exceptional points and skin effect are two hallmarks of non-Hermitian systems combining gain and loss. We demonstrate these phenomena for flexural waves in phononic beams based on applied forces with feedback control. The non-Hermiticity is realized either by means of applying piezoelectric patches on top of the beam or by using a periodic beam made of piezoelectric materials operating as sensor and actuator. We highlight the applications of exceptional points for enhanced sensitivity and of skin modes for energy harvesting.

Non-Hermitian systems containing loss and gain elements have attracted a great deal of interest due to the discovery of several new phenomena such as invisibility, cloaking, enhanced sensing associated with exceptional points or skin effect. In this work, we are interested by the last two aspects that we shall demonstrate for elastic flexural waves propagating in a finite or a periodic beam.

Non-Hermitian systems satisfying the parity-time (PT) symmetry by a balance between gain and loss exhibit real eigenvalues with a transition at the exceptional point where the eigenvalues and eigenfunctions coalesce before a change of the spectrum from pure real to complex conjugate. We show this phenomenon[1] for flexural waves on the geometry shown in Fig. 1(a) constituted by a finite beam supporting two pillars. The gain and loss are respectively achieved by the application of appropriate forces with feedbacks at the points 1-2 and 3-4 by means of small piezoelectric patches. Figure 1(b) and (c) illustrate the evolution of the real and imaginary parts of the eigenfrequencies as a function of a parameter γ representing the strength of the feedback forces[1]. When this parameter is fixed at the position of the exceptional point, the introduction of a small perturbation, such as the addition of a mass m on the beam, gives rise to a splitting of the degenerated eigenfrequency. This is revealed by the appearance of two peaks in the frequency response as shown in Fig. 1(d). The splitting between the two peaks behaves as the square root of the perturbation which corresponds to an enhanced sensitivity and makes the exceptional point attractive for the purpose of sensing in presence of very small perturbations.

In another configuration of the applied forces with feedback control, this structure can exhibit the skin effect[1]. The latter reflects the localization of all bulk modes in a specific frequency region at a given boundary of the structure with an unconventional bulk-boundary correspondence. We have shown the localization of an incident wave towards one end of the beam whatever the position of the source in the beam. Such a skin mode is very efficient for energy harvesting[1] by attaching a piezoelectric patch at the location of the mode.

We have also studied the skin effect in a periodic phononic beam[2] containing piezoelectric elements which play the role of sensor and actuator in each unit cell to achieve the feedback control (Fig. 2(a)). By implementing effective gain and loss in the infinite beam, the band structure exhibits complex dispersion curves. For a given

wavevector, a positive or negative value of the imaginary part of the frequency means a wave attenuation or amplification, which is at the origin of the skin effect. Also, for two opposite wavevectors, the real and imaginary parts of the frequencies (Re(f) and Im(f)) are respectively equal and opposite which means a non-reciprocity in the attenuation/amplification. In Fig. (3(b), we illustrate the winding of the complex eigenfrequencies when the wavevector sweeps the one-dimensional Brillouin zone. Then, Fig. 3(c) illustrates the skin effect for selected frequencies in the consecutive bands of the infinite crystal. The sign of Im(f) defines the side of the structure (left or right) where the mode is localized whereas the magnitude of Im(f) indicates the degree of confinement.

Currently, our work is being extended to a two-dimensional lattice where the control of feedback forces allows not only to demonstrate the skin effect but also to realize a reconfigurable localization by appropriately distributing the applied forces.

Long-time dynamics of one-dimensional topological lattice models

B. Many Manda[1*] **and G. Theocharis**[1]

Abstract: We consider a Su-Schrieffer-Heeger chain of oscillators. In the periodic and nonlinear regimes, we show that the dynamics of unstable nonlinear topological edge states leads to the thermalization of the entire lattice due mode interactions and chaos. Furthermore in the linear and disordered limit, the long-time dynamics of localized wave-packets is able to characterize the transition between two different topological phases. The latter feature is lost in the presence of nonlinearity once again due to mode interactions and chaos.

We consider a mechanical lattice analog of the Su-Shrieffer-Heeger (SSH) tight-binding lattice [1] with Klein-Gordon-type nonlinearity. We perform the nonlinear continuations of the linear topological edge mode and obtain a family of topological nonlinear states localized at the edge of the chain. These objects can be stable or unstable depending on the sign and strength of the nonlinearity and seem to radiate a portion of their energy (mass) in short-time scales, whenever they are unstable. Nevertheless, because a strong component of their shapes is derived from the linear topological edge mode, their long-time dynamics remains unclear. By performing long-time and high accuracy numerical simulations, computing observables such as the entropy, participation ratio and maximal Lyapunov exponent of the system, we show that the delocalization of unstable nonlinear topological edge states results in the thermalization of the entire lattice due to chaos and mode interactions. In addition, stable nonlinear topological edge states also reach the same fate, but pass a critical strength of perturbation [2].

We also study a disordered variant of the standard SSH model. We look at the connection between the system's topological phases and long-time dynamics of initially localized wave-packets in the bulk of the chain. We demonstrate using theory and numerical simulations that the transition between two different topological phases is characterized by an anomalous subdiffusion of the bulk wave-packet, in contrast to its (Anderson) localization within these topological phases. This anomalous spreading is characterized by a growth of the wave-packet's moments pass a critical order, following logarithmic laws in time. Nevertheless, in the presence of nonlinearity this feature is lost once again due to chaos and mode interactions. Since the two latter processes constitute the leading mechanisms of wave-packet dynamics, we find at all strengths of nonlinearity a wave-packet spreading characterized by moments following power laws of time in all orders, in the whole system's parameter space [3].

Since several works are carried out in the static regime of topological systems, our work emphasizes the importance of modes interactions and chaos in the dynamics of nonlinear topological lattices which must be studied in order to define reliable topological indicators.

Airborne Transverse Sound: from Spin-Orbit Interactions to Circular Dichroism

Shubo Wang[1,2*], **Qing Tong**[1], **and Guancong Ma**[3†]

Abstract: In this talk, I will report our study about a new type of sound wave—airborne transverse sound. The transverse sound carries both spin and orbital angular momentum, and the spin-orbit interactions can give rise to novel phenomena that cannot be found in conventional acoustic systems, such as the negative refraction induced by acoustic activity and the spin-dependent vortex generation in sound scattering. We also demonstrate the acoustic circular dichroism associated with the interaction of circularly polarized transverse sound with chiral structures.

It is commonly believed that airborne sound is a longitudinal wave carrying no spin. Thus, many intriguing phenomena associated with spin, such as spin-orbit interactions, cannot be found in acoustic systems. We demonstrate that airborne sound can become a transverse wave when artificial transversality is introduced by using a micropolar metamaterial composed of acoustic dipolar resonators [1]. We show that the transverse sound carries spin-1 and possesses totally 6 degrees of freedom same as a three-dimensional transverse vector wave. This allows the realization of acoustic spin-orbit interactions in both momentum space and real space, leading to counter-intuitive phenomena such as chirality-dependent negative refraction and spin-dependent acoustic vortex generation. Our study deepens the fundamental understanding of sound waves and opens a new avenue to sound manipulations beyond the conventional scalar degree of freedom.

We further demonstrate a novel phenomenon of acoustic Circular dichroism (CD) associated with the interaction of circularly polarized transverse sound with a chiral metamaterial [2]. We find that the effect is negligible in the lossy metamaterial with C_4 rotational symmetry but is strongly enhanced in the C_2-symmetric system with inhomogeneous loss. The CD phenomenon can be well understood by analyzing the metamaterial's complex band structure and the quality factors of its eigenmodes. The enhanced CD in the C2-symmetric system is attributed to the polarization bandgaps and the non-Hermitian exceptional points appearing near the Brillouin-zone center and boundaries. The results provide new mechanisms for chiral sound-matter interactions with potential applications in the manipulations of acoustic angular momentum and acoustic sensing of chiral structures.

Study on acoustic metasurface controlling phase of transmitted waves

Jia-Hong Sun* and Ching-Yun Chang

Department of Mechanical Engineering, Chang Gung University, Taiwan
* jhsun@mail.cgu.edu.tw

Abstract: This paper studied the acoustic metasurface with microstructures that can control the phase of sound waves passing through it. The microstructures were designed to have a proper phase delay and a high transmission coefficient. After designing the structure properly, acoustic metasurfaces that control refraction angles, focus sounds, and diffuse waves were constructed. The work included design, fabrication of specimens, and experiments. This study is valuable for the development of acoustic metasurface applications.

Metamaterials are materials consisting of some special artificial microstructures, and the ones with microstructures arranged only on the surface are called the metasurface. Acoustic metasurface was currently studied to control the reflection, transmission, and absorption of sound[1-4]. In these applications, controlling the phase shift of sound by using metasurfaces is a potential topic. Controlling phase shift can realize deflecting the directions of the reflected wave or the transmitting wave; thus, the corresponding sound field characteristics can be altered. For example, a Schroeder diffuser is defined by wells with different depths to have the non-uniform phases of the reflected wave[4]. Some metasurfaces that control transmitted waves' phase were reported[1,3], but further applications wait. Thus in this paper, we studied the microstructure for controlling the phase shift of sound that passes through the microstructure and further applications.

A channel is the fundamental part of the microstructure that allows sounds to pass through a metasurface. This study used coiling channels introduced in reference 4 to control the phase delay. The coil channels defined paths with different lengths, thus delaying the incident wave and shifting the output's relative phase. The open channels are embedded in a rectangular cuboid with a square cross-section area. Considering the fabrication of specimens, the microstructures were designed for 40 kHz sound. The finite-element method (COMSOL Multiphysics) was used to calculate the sound pressure fields of waves passing the coiling channel, and the channel topology was designed to have a phase delay of 0, $\pi/8$, ..., $15\pi/8$, respectively. Meanwhile, with a square side of a half wavelength (λ), transmitted wave amplitudes are over 97%. These cuboids with a channel were defined as the basic units.

The functional metasurfaces were then constructed by combining the units with different phase delays in space. An array of linear increasing phase delay units can steer the direction of the incident wave when it passes the metasurface, as shown in Fig. 1(a). A focusing acoustic lens was also simulated, as shown in Fig. 1(b). By setting the basic units in the proper location, the plane wave passing the lens reaches the focal point (the focal length is 5λ in this case) in phase. Further, we also designed a diffuser for transmitting waves according to the principle of Schroeder diffusers. The units were redefined for 7- and 11-step phase delay in 2π, and the calculated pressure fields behind the lens showed no more synchronous.

These results showed that the coiling channels are feasible to control phase delay and keep a high transmission coefficient. Metasurfaces consisting of the units showed the potential applications of beam steering control, energy focusing, and noise diffusion. The study is expected to be valuable in building acoustics and sound control.

Abstract: We investigate both analytically and numerically the two-dimensional propagation of shallow water waves over a time-varying medium, which switches from isotropic to anisotropic at a given time. The anisotropy is established with the abrupt appearance of a plate array at the fluid bottom, which changes the effective water depth in each direction in the long-wavelength limit. Depending on the wavenumber angle incident on the plate array, the angle of the energy flow will change, allowing us to deflect the wave.

Time-varying metamaterials is a rapidly growing research field which provides the perfect playground for controlling wave propagation. Motivated by the study of Pacheco-Peña et al. [1], where temporal waveguides were designed for electromagnetic waves, we propose here a water-wave analog. By changing the water depth everywhere in space at a given time, the water wave velocity is modified in time. In addition, when the medium is switched from isotropic (homogeneous depth) to anisotropic (different effective depth in the x and y direction), one can deflect the wave since the angle of the energy flow θ_S is different than the angle of the wave vector θ. A schematic representation of such a deviation is depicted in Figure 1a). Note that isotropic time variation of the water wave speed has been already explored in [2] and [3].

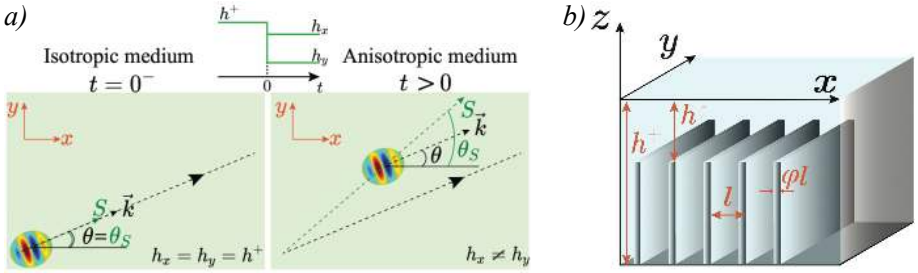

Figure 1:a) Wave packet deviation from its initial trajectory due to the anisotropy introduced at t=0. b) Representation of the plate array at the fluid depth.

As was demonstrated in [4], a structured bathymetry can create an anisotropic medium for water waves in the long wavelength approximation. In that case, an effective two-dimensional wave equation has been derived (see ref. [4],[5]):

$$\eta_{tt} = g\nabla\cdot(\mathrm{h}\nabla\eta), \quad \mathrm{h} = \begin{pmatrix} h_x & 0 \\ 0 & h_y \end{pmatrix}, \qquad (1)$$

where $h_x < \langle h^{-1}\rangle^{-1}, h_y = \langle h\rangle^{-1}, \langle h\rangle = \varphi h^- + (1-\varphi)h^+$, with h^+, h^-, φ defined in Figure 1b). When the medium is modified in time, rather than in space, and the switch occurs much faster than the wave period, the wave "sees" a time interface from which it is partly reflected and partly transmitted. One can easily demonstrate that the reflection R and transmission T coefficients are given from the expressions (see ref. [1]),

$$R = \frac{\omega_1-\omega_0}{2\omega_1}, \quad T = \frac{\omega_1+\omega_0}{2\omega_1}, \qquad (2)$$

with $\omega_0 = k\sqrt{gh^+}, \omega_1 = k\sqrt{g(h_x\cos^2\theta + h_y\sin^2\theta)}$, while the angle of energy flow θ_S is found to be

$$\theta_S = \tan^{-1}\left(\tan(\theta)\frac{h_y}{h_x}\right). \qquad (3)$$

By allowing h to depend on time, Eq. (1) can be solved numerically, where at t=0 we pass from h^+ to (h_x, h_y). Thus, numerical results are obtained for the scattering coefficients as a function of the incident angle, which show good agreement with our theoretical predictions (see Figure 2a). In Figure 2b we illustrate the maximum wave packet deviation, for the case where l=0.8cm, φ=0.0625, h^+=2cm, h^-=0.5cm, f_0=6Hz, $\theta=\theta m$.

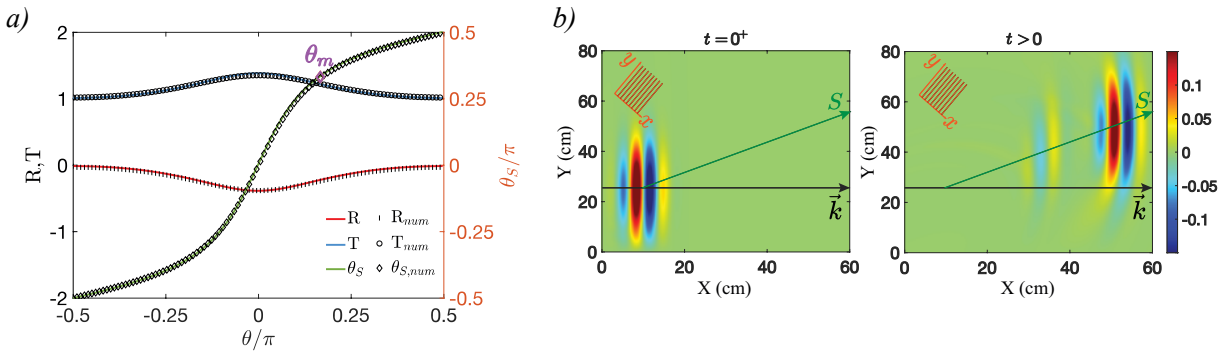

Figure 2:a) R, T and θ_S as a function of θ along with their analytical expressions (2) and (3). b) Wave packet deviation for the case where $\theta=\theta m=\pi/6$.

Finally, the ongoing part of this study is to experimentally verify our proposed theory. For this purpose, we have designed an experimental setup which allows the plate array to be suddenly lifted at the fluid bottom. Figure 3 shows the plate array right before and right after the switch. This set-up is currently under test.

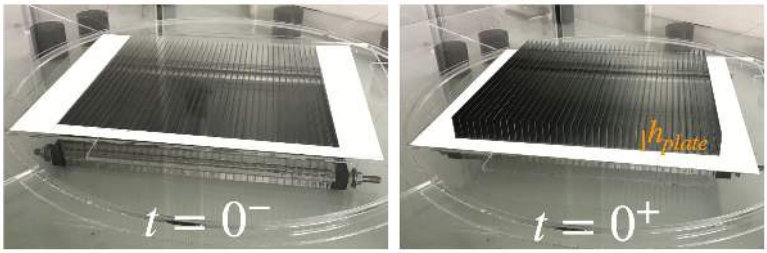

Figure 3: Fluid bottom inside the water tank before and after lifting the plate array.

Invariance of the transmitted field in a periodic waveguide

E. Salemeh*, S. Félix and V. Pagneux

Laboratoire d'Acoustique de l'Université du Mans LAUM – UMR CNRS 6613, France
elie.salemeh@univ-lemans.fr*

Abstract: A characteristic of the localized regime in a disordered medium is the insensitivity of the transmitted speckle pattern to the incident wave. We show that a similar phenomenon is possible in an ordered, periodic medium, when the wave is mainly carried by a dominant Bloch mode. The work presented aims to characterize this phenomenon in the case of propagation in a periodic acoustic waveguide.

Among the many striking wave phenomena that arise in disordered media and explain undiminished interest in this field of wave physics over decades [1, 2] the single channel regime is quite remarkable. Since the ratio between successive transmission eigenvalues (TEVs) is large in the localized regime, the first (largest) one dominates all others, hence the corresponding eigenchannel in the transmission problem. A consequence is that "*the speckle pattern of the transmitted intensity is literally frozen*", that is, at a given frequency, the speckle pattern is independent of the incidence conditions. Note that it was experimentally evidenced (as well as the crystallization of the TEVs) by Shi and Genack with microwaves [3] and later numerically investigated in optics in a two-dimensional medium, and used to probe Anderson localization in a single configuration of this medium [4]. Although this phenomenon is understood as being characteristic of the localized transport, the medium-induced reduction of the transmission problem to a rank-1 matrix is not intrinsically related to disorder and can be observed in other contexts, in particular in regular media. In this work, we show that the transmitted pattern through a periodic medium, though complex, can be *frozen* under proper conditions. The first condition corresponds to a frequency located in a bang gap in the periodic medium: no Bloch-Floquet mode is propagating. This case is similar to the case of localized transport: a single channel dominates the transmission. An example of such an evanescent transmission is shown in [Figure 1(a)].

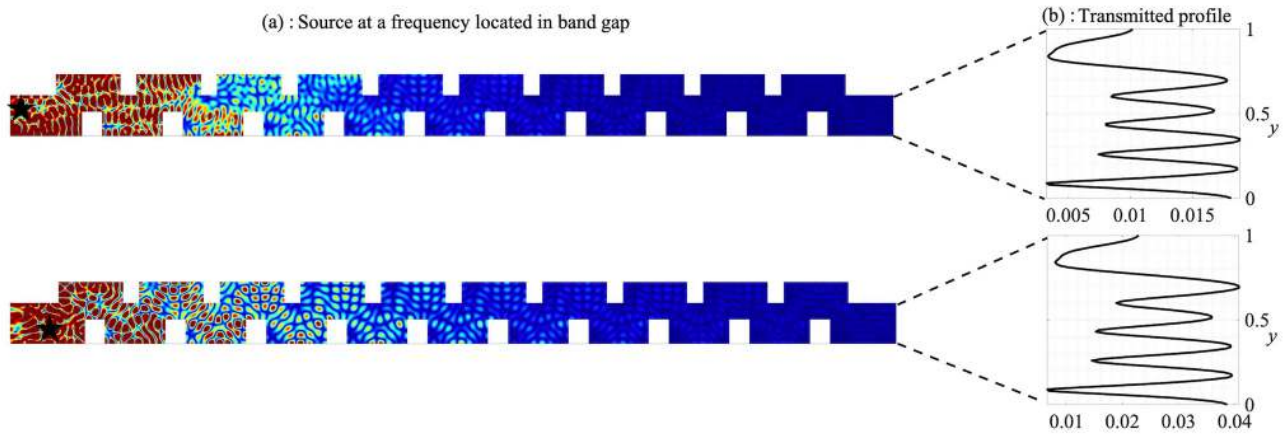

Figure 1 (a) Normalized absolute value of the field in a periodic wave guide which is excited by a source at two different positions at a frequency located in a band gap. (b) Comparison of the absolute value of the transmitted profile.

A point source (★) at a frequency located in a band gap is located in the left lead at two different positions. While the excitation, hence the incident wave, is modified from one case to the other, the pattern of the transmitted field is almost the same [Figure 1(b)].
Computing the wavefield (solution of the Helmholtz equation) in the whole waveguide allows us to go further than the only analysis of

the transmitted pattern. We can already observe the strong decrease of the amplitude but, above all, the progressive freezing of the wave pattern as we move away from the source. Thus, the transmission in a band gap of a periodic waveguide displays characteristics which, although resulting from different mechanisms, are similar to those of a Anderson-localized medium, and therefore lead to the freezing of the wave pattern.

However, the periodic system makes possible another regime of single channel transport, which cannot be observed in the disordered case. This is the case where the first TEV dominate all others without being itself small, this case corresponds to a frequency located in a region when a single Bloch-Floquet mode is propagating. It is then possible to freeze the transmitted pattern, without the counterpart of having a very low energy transmission. An example of freezing of a propagating field is shown in [Figure 2].

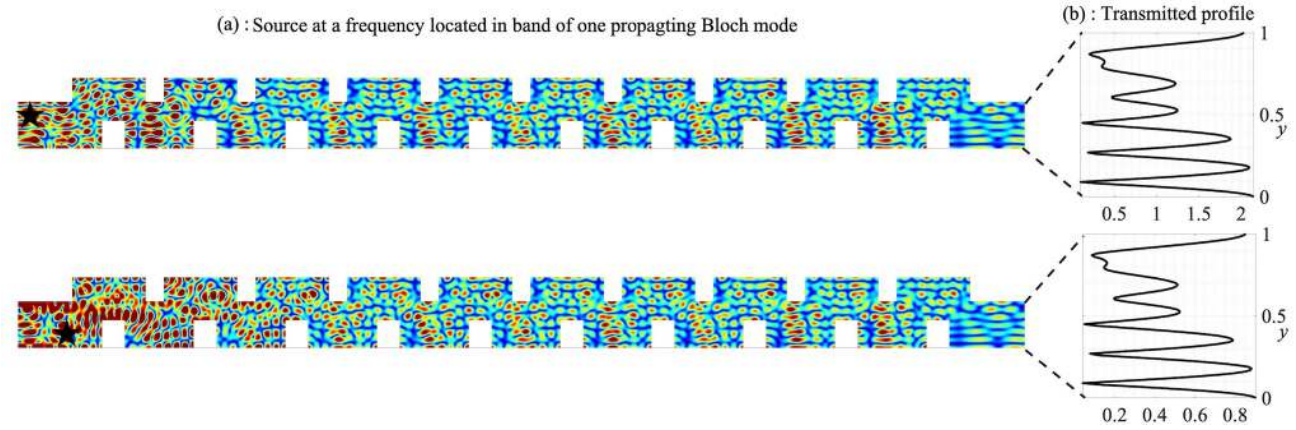

Figure 2 (a) Normalized absolute value of the field in a periodic wave guide which is excited by a source at two different positions at a frequency located in a band of one propagating Bloch mode. (b) Comparison of the absolute value of the transmitted profile.

Abstract: Orientation of anisotropic nanoparticles in macroscopic materials have a great potential for the generation and maximization of optical properties such as polarization. Here, we demonstrate an approach for the generation of circularly polarized (CP) light with high purity and high light intensity by luminescence-based CP convertors composed of one-dimensionally aligned quantum rods composite films and retardation film.

Circularly polarized (CP) light is recently attracting worldwide interest because of its irradiation effect on the promotion of plant growth[1] and on the enhancement of photovoltaic energy conversion efficiency[2,3]. However, despite remarkable recent progress in CP light generation, the trade-off relationship between light intensity and polarization degree of CP light remains an important issue. In this presentation, we introduce a new approach for creating CP light with high purity and high light intensity by converting linearly polarized luminescence (LPL) using luminescence-based CP convertor[4].

In our approach, LPL material play an important role to determine the performance such as light intensity, polarization degree, and spectral pattern. In this study, we selected CdSe/CdS core/shell quantum rods (QRs) as highly emissive LPL source. When the QRs was incorporated into transparent elastic polymer such as poly(ethylene-*co*-vinyl acetate) (EVA), the QRs were easily aligned in one-direction by uniaxial stretching of the QR/EVA composite film. The degree of linear polarization in the emission process ($P_{\text{LP-lum}}$) showed maximum value (0.68) when the stretching ratio of QR/EVA composite film was over 6. On the other hands, the degree of linear polarization in the absorption process ($P_{\text{LP-Abs}} = 0.28$) was clearly smaller than that in the emission process ($P_{\text{LP-lum}} = 0.68$). These phenomena could be explained by the different origin of linear polarization. Namely, linear polarization in absorption process mainly originates from dielectric effect based on the morphological anisotropy of QRs (aspect ratio: 5.1), whereas linear polarization in emission process is mainly derived from quantum confinement effect based on the QRs width (ave. 4.9 nm) of being smaller than the exciton size (10.6-10.8 nm)[5,6].

When the obtained LPL film was laminated on the quarter-wave film, with the angles between polarization plane of LPL and fast-axis of quarter-wave film were -45˚ and +45˚, left-handed (LH-) and right-handed (RH-) CP light were produced, respectively. No significant difference was observed in the light intensity and spectral pattern even after lamination. The degree of circular polarization (P_{CP}) of both LH- and RH- CP light (0.66) was similar to the $P_{\text{LP-lum}}$ value (0.68), indicating that the polarization degree of LPL was directly converted to the polarization degree of CP light. Such a large P_{CP} value with keeping the original emission intensity and the spectral pattern was also provided from other-colored CP convertors.

In this presentation, we will also discuss about multiplexing of optical information by multilayer-type luminescence-based CP light convertor consisting of various LPL films composed of different color-emissive QRs.

Abstract: The DNA biosensors are powerful tools in the gene mutation or pathogens detection. That is why there are a lot of DNA detection strategies and methods. Here we present the insight on a slightly overlooked DNA detection technique, surface-enhanced Raman scattering (SERS) spectroscopy. We analyse how to construct more efficient sandwich-type SERS biosensor for DNA identification. A new SERS strategy for the gene mutation identification based on rearrangement of alkanethiols linker and blocking chains is also presented.

The deoxyribonucleic acid (DNA) is the carrier of genetic information for all living organisms. Even a small mutation in its structure can lead to the development of a serious disease. Therefore, many scientists are working on developing fast, sensitive and precise methods for detecting specific DNA fragments. A very promising method for detecting and identifying many compounds, including DNA,[1-3] is surface-enhanced Raman scattering (SERS). The essence of SERS phenomenon is very large increase in the efficiency of the Raman signal generation (in some cases by 7-8 orders of magnitude on average, and locally even by 10-12 orders of magnitude) for molecules located at or near the surface of certain nano-plasmonic structures.

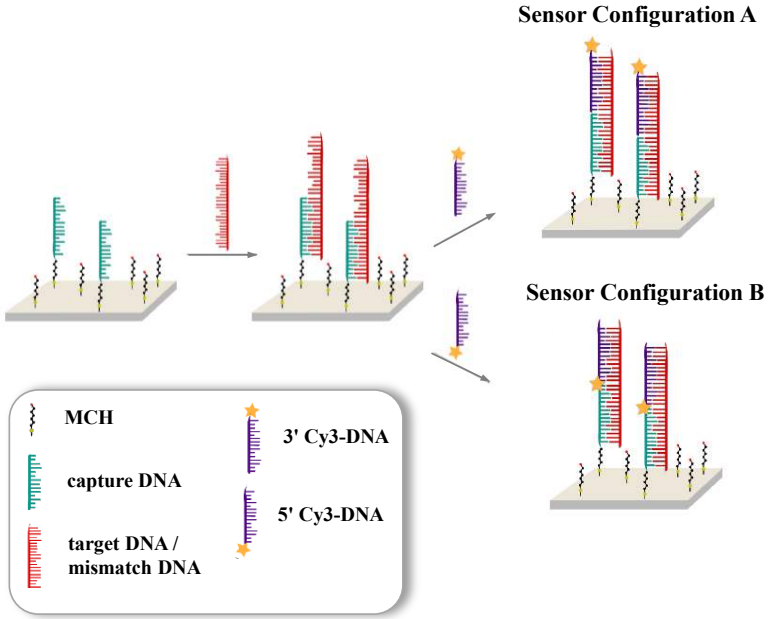

Figure 1. Scheme of the construction of sandwich-type SERS sensors for DNA detection: in configuration with Raman reporter "outside" the double-stranded DNA and with Raman reporter "inside" the double-stranded DNA.

In this work, we decided to determine how various modifications of one of the most frequently used SERS DNA sensors (so-called sandwich-type sensors - see Figure 1)[1,2] can affect the intensity of the SERS signal generated. We tested: attaching a Raman reporter moiety (chromophore) at various places of the reporter DNA chain; SERS substrates from various plasmonic metals, and the use of DNA chains with some mismatches. We hope that our results will help in the construction of more sensitive and effective sandwich-type SERS DNA sensors.

Moreover, we also developed a new SERS method of DNA detection based on the hybridization-induced (in the presence of target DNA) conformation change (*gauche* → *trans*) of alkanethiols adsorbed on the metal surface between the attached DNA strands and on the conformation change of the alkanethiol linker chain modifying the capture DNA (see Figure 2). The new DNA SERS (bio)sensor has been tested on 17 clinical samples and is characterized by the low detection limit at the level of pg μL^{-1}, wide analytical range from ca 7 pg μL^{-1} to ca. 70 ng μL^{-1} and high selectivity.

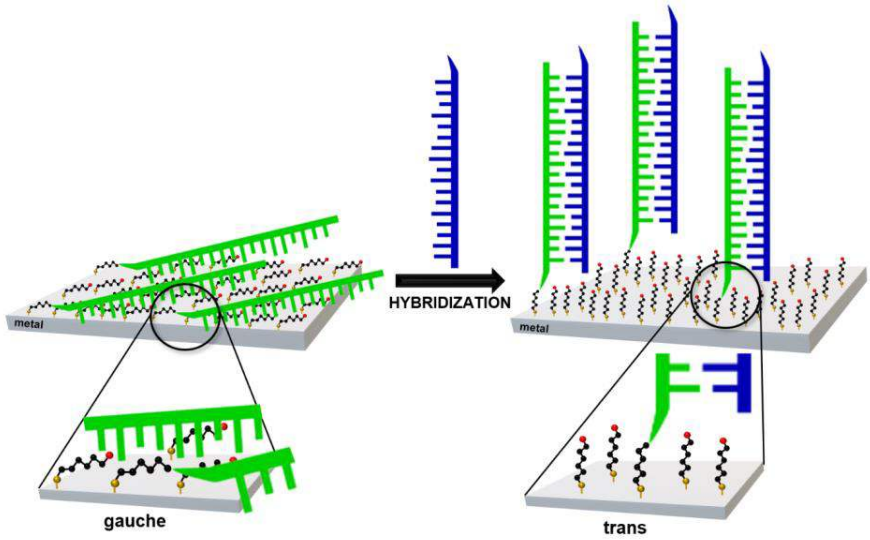

Figure 2. Scheme of the procedure of the modification of SERS substrates by DNA fragments and induced by the DNA hybridization change of the average structure of the metal–S–C–C chain.

Review of Remote Epitaxy and Blue Spectral Intensity Enhancement Using Surface Plasmon Resonance

Jun Hee Choi*, Kiho Kong, Eunsung Lee, Joo Hun Han, Jung Hun Park, Nakhyun Kim, Jinjoo Park, Joosung Kim, Dong Chul Shin, Sunil Kim

Abstract: We review remote epitaxy potentially coupled with pixelated InGaN LEDs via ion implantation for micro displays for augmented reality. Next, we discuss the degree of blue light enhancement in low-efficiency CdS/ZnS core/shell quantum dot (QD) light emitters using Ag/dielectric surface plasmon resonator.

First, we briefly review remote epitaxy for reduction of defect density for developing red InGaN LEDs as shown in Figure 1 [1]. The remote epitaxy can be coupled into tailored ion implantation pixelation (TIIP) for pixelating InGaN based micro-LEDs (μLEDs). Owing to the planar geometry, TIIP pixelation is readily incorporated into high-resolution pixel-driving circuits in high-ppi μLED displays for AR glasses [2-4].

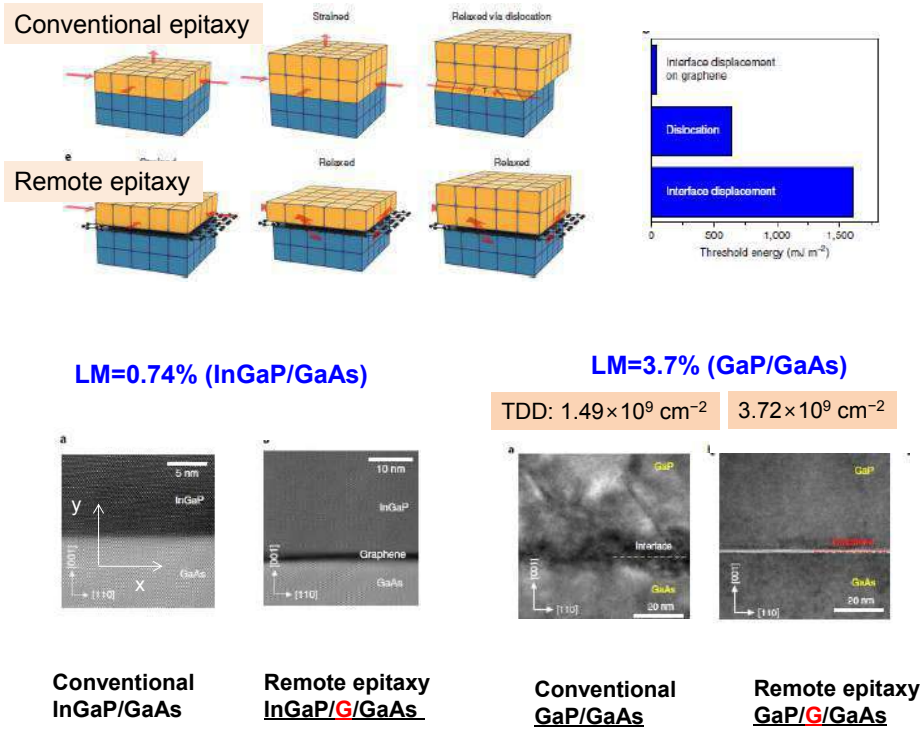

Figure 1. Schematic of remote epitaxy for reducing dislocation density [1].

Next, we discuss the light enhancement by surface plasmon resonance (SPR), a kind of energy recycling, i.e., the useless energy (the energy in the non-radiative recombination process normally wasted away in the form of heat) can be relevantly transferred to SPR with minimized charge transfer, then transferred by SPR propagation,

and finally out-coupled to light through nano-sized protrusions [5]. Therefore, in case of light emitter with quantum efficiency of unity, SPR rather acts as a loss mechanism [6]. The frequency (ω) or wavelength (λ) for SPR is determined by the equation;

$\varepsilon_{m,\,real}(\omega) + \varepsilon_d(\omega) = 0$

By selecting different combinations of metal/dielectric, the resonance frequency can be modulated: $\lambda(Ag/Si_3N_4) \sim 470$ nm, $\lambda(Ag/Al_2O_3) \sim 540$ nm, $\lambda(Au/SiO_2) \sim 520$ nm, $\lambda(Au/Al_2O_3) \sim 630$ nm, and $\lambda(Au/HfO_2) \sim 800$ nm. Finally, we investigate SPR in core/shell CdS/ZnS blue QDs on Ag/Si_3N_4 which is suitable for blue-light enhancement ($\lambda(Ag/Si_3N_4) \sim 470$ nm). The charge and energy transfer mechanism between QDs and QD and Ag is illustrated in left panel of Figure 2 [7]. From multi-layer-QD experiment, the effective distance of light enhancement by SPR is about 5 layers of QDs (30-40 nm). We suggest the optimum structure of light enhancement by SPR in right panel of Figure 1.

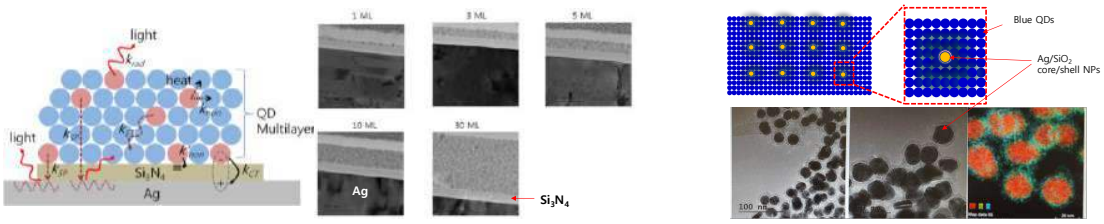

Figure 2. Diagram showing energy and charge transfer between QDs or to plasmonic structure in multi-layer QD and Optimized SPR structure for PL emission

In situ growth: Bottom-up wet-chemical preparation of plasmonic gold nanostructures on substrates

G. A. Vinnacombe-Willson[1,*]

[1]BioNanoPlasmonics Laboratory, CIC biomaGUNE, Basque Research and Technology Alliance (BRTA), 20014 Donostia-San Sebastián, Spain
[*]corresponding author: gvinnacombe@cicbiomagune.es

Abstract: We present an unconventional *in situ* growth approach where bottom-up wet-chemical synthesis is used to synthesize plasmonic gold nanoparticles (AuNPs) directly on substrates, rather than in colloidal suspension. This *in situ* growth technique was implemented to prepare anisotropic AuNPs on various materials. Furthermore, we show that combining *in situ* growth and soft lithography opens the doors for the preparation of plasmonic arrays with collective plasmonic responses and tuneable optical properties.

Over the last few decades, developments in bottom-up colloidal nanofabrication have enabled the preparation of colloidal gold nanoparticles (AuNPs) with precisely tailored chemical and physical properties.[1] In this work, rather than forming AuNPs in colloidal suspension, we adapt bottom-up wet chemical synthesis to instead form plasmonic nanostructures directly on substrates for straightforward fabrication of plasmonic materials (**Figure 1**).[1-2] While the *in situ* growth approach appears intuitive, further improvement of the fundamental synthetic understanding of this class of techniques is required to elevate it to the same robustness and versatility as conventional colloidal synthesis.

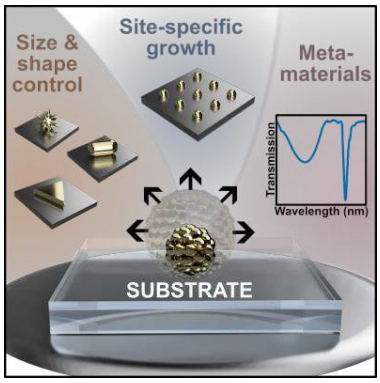

Figure 1. Schematic showing substrate bottom-up formation of gold nanoparticles.

In this work, we utilize *in situ* growth to form nanospheres and nanostars, demonstrating that the size and shape of the particles can be controlled by modulating the chemical composition of the growth solution.[2] We then combined *in situ* growth with a soft-lithographic method based on thermal nanoimprint lithography, which does not require specialized equipment nor clean-room sample preparation, to fabricate plasmonic arrays. The resulting arrays can be prepared with different periodicities, therefore exhibiting tuneable lattice plasmon resonances in the visible and near-infrared with quality factors >20.

Beyond plasmonic arrays, the *in situ* growth can be a useful approach for the fabrication of hybrid plasmonic materials with biomedical applications. For instance, plasmonic nanoparticle-decorated hydrogels can be used as matrices for 3D *in vitro* tumor models, whereby the integrated nanoparticles function to monitor the microenvironment of embedded or seeded cancer cells *via* surface-enhanced Raman scattering (SERS)-based sensing.[4] Towards this goal, we performed proof of concept tests interrogating shape control *in situ* on hydrogels.

Ultimately, we show that the creation of chemical contrast *via* surface functionalization with strong reductants can assist in controlling and directing the growth of AuNPs specifically on the substrate. Moreover, changing the chemical composition of the growth solution, while paying special attention to reducing secondary colloidal nucleation, which competes with substrate growth is key for controlling nanoparticle size and shape. Overall, continued development of *in situ* growth protocols constitutes an exciting synthetic opportunity for fabricating plasmonic materials for potential application in catalysis, optoelectronics, and as biomedical platforms.[5]

Self-organization of eutectic two-phase composites: insights from phase-field simulations

M. Plapp[1*]

[1]Laboratoire de Physique de la Matière Condensée, CNRS, Ecole polytechnique, Institut Polytechnique de Paris, 91120 Palaiseau, France
[*]corresponding author: mathis.plapp@polytechnique.edu

Abstract: The crystallization of eutectic alloys yields composites in which the two solid phases are arranged in regular lamellar or rod microstructures. Those are created by a pattern-formation process at the solid-liquid interface which results from the interplay of capillary effects and diffusion. I will review several insights obtained by phase-field modeling on the effect of interphase boundary anisotropy on the emergence of lamellar patterns, the influence of transverse temperature gradients, and the transition from lamellar to rod patterns.

The crystallization of a liquid close to its eutectic composition leads to the simultaneous growth of two distinct solid phases of different compositions. The interplay between chemical diffusion in the liquid and capillary effects created by the surface energies of interfaces and interphase boundaries leads to the emergence of a characteristic length scale [1]. The most frequently observed microstructural patterns are alternating lamellar platelets of the two phases, or rods of the minority phase embedded in a matrix of the majority phase. However, many other and more complicated structures have been observed, in particular for substances with facetted solid-liquid interfaces. The idea was put forward [2] to use this capability of spontaneous structuration as a route for large-scale bottom-up fabrication of metamaterials. In this perspective, the self-organization must take place in a well-controlled manner, which requires a good fundamental understanding of the pattern-formation dynamics.

Phase-field models have emerged since three decades as the numerical method of choice for the study of microstructural pattern formation during solidification. In the phase-field approach, interfaces and boundaries are implicitly described by auxiliary scalar fields, the so-called phase-fields. The equations of motion of those fields are coupled to the relevant transport equations, such as diffusion of chemical species, and the coupled model can be derived from a free-energy functional using the thermodynamics of irreversible processes. The resulting set of partial differential equations can be solved using standard numerical methods.

Phase-field models have been used by many groups to investigate eutectic patterns. I will highlight several of our own findings that shed light on observations made in experiments. For example, we have shown that anisotropy of the solid-solid interphase boundaries is crucial for the emergence of lamellar patterns in extended systems [3]. Without anisotropy, lamellae can still be created by the presence of a transverse temperature gradient; otherwise, labyrinth-like two-phase patterns prevail [4]. Large-scale variations in concentration in the liquid can create transitions between lamellae and rods that are mediated by a propagative lamellae breakup instability [5]. Finally, the competition of this instability with a lateral temperature gradient can be used to obtain controlled transitions between lamellae and rods [6].

Abstract: Metallic nanoparticles are well know for their resonant response, usually associated with Purcell effect and losses. We show here that a very large and broadband enhancement can be reached using metallic nanoparticles far from resonance. The density of nanoparticles is critical and needs to be well controlled to maximize the efficiency.

Many devices include photoluminescent layers (for lighting or sensing typically[1]) which have to be optically excited and generate light than has then to be extracted from the layer. Metallic nanoparticles can provide such an enhancement typically because they can help couple light in, present a large Purcell effect when they resonate, and can enhance light extraction. Since such particles constitute very good absorbers at resonance, the overall efficiency at resonance can be disappointing. In addition, leveraging the Purcell effect means putting nanoparticles very close to emitters. Another path would be to use metallic nanoparticles as non-resonant scatterers only at the surface of the material and to focus on the enhancement of in-coupling, with the excitation of guided modes and out-coupling of light, but giving up on Purcell effect. However, coupling efficiently a large number of guided modes requires to be able to control the density of scatterers: too many of them and the structure is reflecting or absorbing, while a lower density is associated to a lower efficiency. Using carefully designed experiments, we have shown that unexpectedly large enhancement can be reached and provide a physical analysis of the phenomenon[2]. A rule of thumb would be to keep, between nanoparticles, distances that are close to the effective wavelength of guided modes inside the luminescent layer. Such a versatile technique is likely to be useful for many devices.

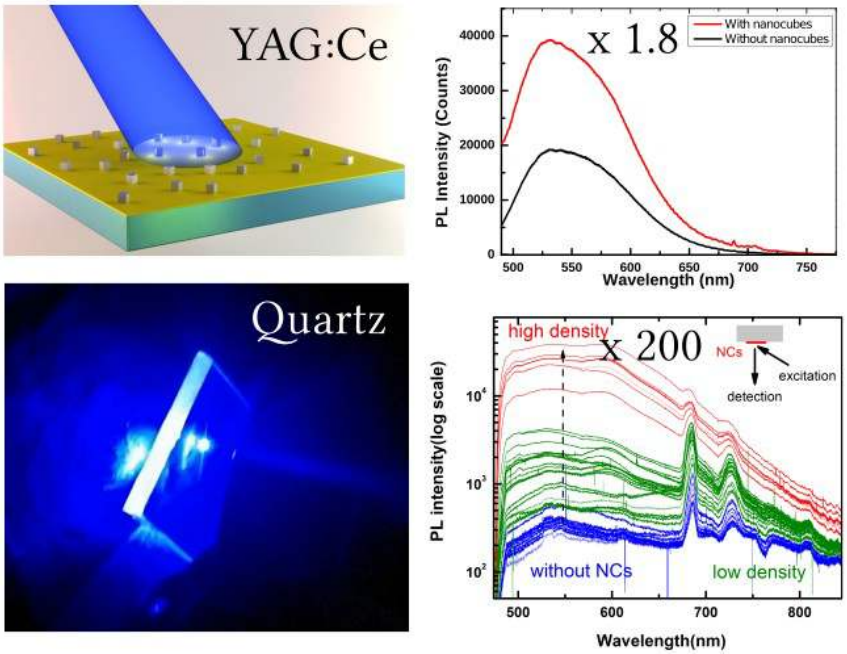

Figure 1: (top left) Artistic view of the nanocubes spread on a luminescent layer of YAG:Ce (in yellow) (top right) photoluminescence enhancement in the case of a YAG:Ce layer (bottom left) quartz slab illuminated using a blue laser showing an enhanced coupling of guided modes and (bottom right) the corresponding luminescence enhancement.

Abstract: A fabrication process of Ag/GaAs Tamm emitting devices will be described. As the maximum electric field of the Tamm mode is close to the surface, the fabrication of the devices requires a special procedure to maintain their emissive properties. For Tamm structures of 5µm diameter, mode confinement appears in the diode emission with energy discretization [1]. The observation of the electrically excited emission of a Tamm structure is an important step towards the exploitation of Tamm structures for novel optical devices.

Tamm plasmon modes appear at the interface between a metallic film and a Bragg mirror and exhibit properties of both cavity modes and plasmons [2]. Their main interest lies in the surface character of the mode, which allows the integration into sources of geometries ranging from simple disks [3] to complex metal metasurfaces [4]. As the field maximum is close to the surface, the metal micro/nano-structuration controls the properties of the source such as its directivity or polarization [5].

To exploit the advantages described above, electrically excited devices have to be fabricated. But the micro-structuration of a surface mode is a technological issue that is not present in the usual emitting devices. Indeed, the first few nanometres of the structure must be preserved and requires the development of specific processes.

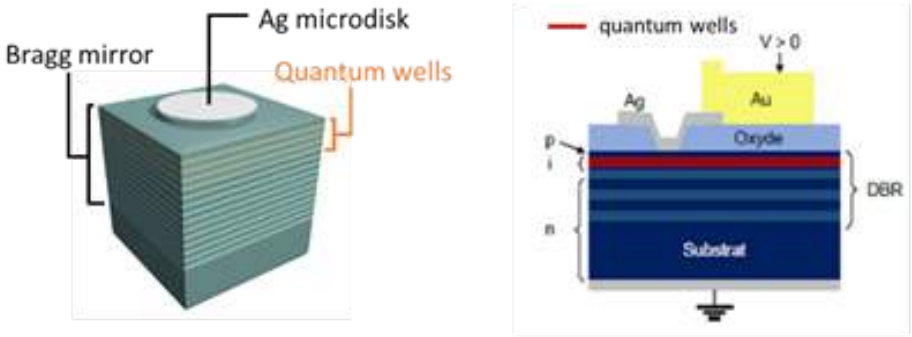

Fig. 1 a) Tamm confined principle b) Layout of the Tamm plasmon diode

The semiconductor part of the structure is constituted by a GaAs/$Ga_{0.9}Al_{0.1}As$ Distributed Bragg Reflector (DBR) grown by Molecular Beam Epitaxy. The last layer of this DBR is formed by a 3λ/4 GaAs film

comprising 6 $In_{0.15}Ga_{0.85}As$/GaAs quantum wells located at the two maxima of the electric field. To leave the thickness of the semiconductor unchanged in the emitting region, a fabrication based on pulsed laser deposition and lift off has been used.

The electroluminescence of fabricated structures follows the dispersion of the Tamm mode, showing that it occurs predominately in the Tamm mode. For a diode of 5 µm diameter, the emission dispersion shows an energy discretization characteristic of 3D confinement. The emission spatial intensity profile extracted from experiments can be superposed with the spatial profile of a HE_{11} mode.

The demonstration of the electrically excited emission of Tamm structure is a key point toward the exploitation of their versatility for confined lasers or sources with unconventional polarisation.

Abstract: This work introduces a new class of bioinspired 3D-architected metasurfaces which enable the quantitative, colorimetric visualization of tissue microstructure for a variety of fiber-affecting diseases encompassing organ fibrosis, heart disease, neurodegenerative disease or various cancers.

The origin and progression of a variety of leading health challenges, encompassing Alzheimer's disease, heart disease, fibrosis and cancer, are directly linked to changes in the presence and orientation of fibrous matter in biological tissue. Fibrous biological tissue exhibits distinct anisotropic optical properties, which can be leveraged for selective imaging. However, these naturally occurring light-matter interactions are inherently weak, posing barriers to their visualization in a clinically translatable manner. Existing imaging techniques which visualize the fibrous properties of biological matter face challenges in complexity, cost, destructiveness, or precision. Thus, innovation in imaging technology of fibrous tissue with facile clinical implementation is urgently needed.

To address this challenge, we develop a new class of anisotropic, colorimetric metasurfaces to selectively visualize disease-relevant fiber density and orientation in biological tissue. We draw inspiration from iridescent structural color which is abundant in nature, arising in the saturated blues of the Morpho butterfly wing or the greens of jeweled beetle shells. At the micrometer scale and smaller, these naturally occurring, three-dimensionally (3D)-architected photonic crystals are composed of ordered, geometrically anisotropic features which exhibit distinct interactions with light at varying angles of incidence or polarization state. Due to their 3D hierarchical architecture, these nature-derived systems are unique sources of polarization-sensitive structural color with high color purity and brightness. Here, we use two-photon lithography to fabricate multilayer grating structures which surpass the polarization-sensitive colorimetric response attainable in nature. Bringing additive manufacturing to the regime of visible light-matter interactions, we implement our colorimetric metasurfaces as a next-generation tissue microstructure imaging technology. Starting with the example of breast cancer diagnostics, we then expand our view to the rich palette of fiber-affecting diseases where metasurfaces hold great potential to achieve rapid, precise and low-cost tissue diagnostics with facile clinical implementation.

Abstract: Doped semiconductor nanocrystals represent an emerging class of materials that host localized surface plasmon resonance (LSPR). Their wide spectral range (from visible to the entire IR regions) and post-synthetic tunability through doping promise new plasmon-assisted active optical materials and devices. Recent studies discovered various semiconductor species that perform efficient LSPR. However, the nanocrystals' structural impact on their LSPR remain poorly explored.

This presentation illustrates how multiple structural factors can be synergistically tuned to promote novel LSPR properties that are unseen from metal hosts. For instance, hexagonal cesium-doped tungsten oxide (Cs_xWO_{3-y}) nanocrystals exhibit crystalline anisotropy that causes a strong LSPR band-splitting into two distinct and intense peaks [1]. We combine this property with the well-known shape anisotropy of plasmonic nanoparticles to tune the multimodal LSPR bands [2]. For this, we exquisitely control the synthesis of Cs_xWO_{3-y} and achieved their variable shape aspect ratio across a widely extended range from 0.2 (platelets) to 20 (rods) [3]. With this large structural tunability, the spectral range of LSPR peaks covers the entire near-infrared region and beyond (750~4000 nm). Moreover, the LSPR response of these highly anisotropic nanocrystals can be post-synthetically and reversibly tuned by inducing LSPR coupling effects in their self-assembled structures [4]. We demonstrate how this tunable LSPR can be used to design window NIR-shields for energy-saving applications [5].

Abstract: The integration of plasmonic effects into metamaterial architectures presents exciting opportunities to design and develop new metamaterials with desired optical properties of plasmonic metal nanostructures with different geometries, shapes and sizes. In this talk will overview fabrication and optical characterisation of large-area plasmonic metamaterials based on arrays of hybrid plasmonic nanotubes and nanorods and their applications in nonlinear optics and sensing. The structural and material degrees of freedom allow such metamaterials to find a wide range of applications in nanophotonics, opto-electronics, optical filters, sensing and photocatalysis.

Plasmonic nanostructures possess unique intrinsic optical properties including a strong resonant enhancement and confinement of the local electric field. Spectral tunability of these resonances can be achieved throughout the ultraviolet to infrared via the geometry (size and shape), surrounding media and the inherent properties of the plasmonic material from which it is made from. In this talk will be overview fabrication and optical characterisation of scalable self-assembled plasmonic metamaterials based on arrays of hybrid plasmonic nanotubes and nanorods with optical properties controlled by structural and material degrees of freedom, and their various applications.

The self-assembled fabrication approach based on the anodic aluminium oxide (AAO) template method was chosen for its ability to inexpensively create subwavelength arrays of designed plasmonic nanoparticles with large surface areas. This highly controllable, facile and inexpensive fabrication technique allows for various nanostructures of different shapes and dimensions with a high uniformity and reproducibility. This allows to control the geometrical parameters of the materials with nanometric precision and illustrate the resultant spectrally tunable plasmonic behaviour, well described by numerical simulations.

Metamaterials based on plasmonic nanorods, nanotubes, core-shell coaxials, as well as hybrid plasmonic-dielectric architectures for exquisite control of optical field localisation and strong-matter interactions were developed (Fig. 1). To harness fully functionalities of the nanorod based metamaterials, they should be illuminated at oblique incidence to access all the optical modes of the metamaterial. Plasmonic nanotubes-based metamaterials are free from this restriction and also provide the increased surface area for absorbing a large number of molecules. Advantageously, the core-shell cylindrical architecture allows the functional properties of the core to be exploited in combination with the plasmonic properties of the surrounding material and can play a role in carrier extraction for reactive plasmonic applications.

The advantages of such metamaterials have been demonstrated for bio- and gas sensing, nonlinear optics, controlling spontaneous emission, nanoscale light sources and memristors. As the examples of the emerging applications, we will discuss the metamaterials designed to maximise their potential for hot-carrier plasmonic applications, metamaterial-based spectrally selective filters and nonlinear intensity limiters. For the former applications, implementation of gold/nickel-oxide core-shell metamaterials as an optical sensor for the detection

of acetone, copper metamaterials in the plasmon enhanced photo-electrochemical reduction of CO_2 will be discussed in detail.

Large scale plasmonic and hybrid dielectric-plasmonic metamaterials provide wealth of opportunities for designing spectral position of the resonant response, tuneable spatial localisation of the electromagnetic field and the related advantages in the applications in nanophotonics, nonlinear optics, opto-electronics, sensing and photochemistry.

Abstract: While it appeared that metasurfaces offer almost unlimited functionality, volume metamaterials may provide advantages in specific applications. In this presentation I will give an overview on the limits and perspectives of the research field of volume metamaterials, which governed the meta-research in its beginning, but later was outperformed by the advances in metasurfaces. However, new nanotechnologies bring the dream of a real meta-volume in reach.

Refractive and also diffractive optical systems are designed mostly based on classical bulk optical materials. However, the dispersion properties of these materials usually restrict the optical system design quite severely. Materials being constructed from nanosized building blocks supporting resonances in the targeted wavelength range, therefore offer a viable perspective to extend the degrees of freedom in optical system design processes considerable. These so, called metamaterials have long been investigated in their 2D equivalent, the so-called metasurfaces, where just a single layer of resonant nanoscatterers, the so-called metaatoms, controls the transmission and reflection of light. While this proved to be a quite powerful concept, it naturally has its limitations, since it allows to control only the local state of light and diffraction happens in the homogeneous space surrounding the metasurfaces, following the classical rules of diffraction in homogeneous space. Extending the metasurfaces to 3D volumes or metamaterial, would offer the perspective of controlling the diffraction itself and was therefore heavily investigated for many years. However, technological limitations rendered this field quite unpractical.

Metamaterials from densely packed scatterers could be realized by top-down or bottom-up techniques. However, while top-down techniques offer unprecedented control over the achievable geometries of metaatoms, they suffer from being limited to planar and periodic structures. In contrast, materials made with bottom-up techniques do not have such disadvantages, but unfortunately, they offer little control over the geometries that can be achieved for the metaatoms. Recently, we have introduced a nanofabrication strategy that combines these both approaches and therefore brings volume metamaterials into reach. In our approach a large number of metaatoms is fabricated by a standard lithography method on the surface of a planar substrate. By detaching the metaatoms from the substrate and reassembling them into a volume form, a bulk metamaterial containing densely packed and randomly arranged metaatoms is obtained. The fabrication of an isotropic metamaterial from these scatterers with a strong electrical and magnetic response is therefore feasible and opens up new possibilities for the production of artificial materials with tailorable optical properties in bulk form, but more importantly also on arbitrarily shaped surfaces.

When such composite nanomaterials should be introduced into the design processes for optical systems, their specific material properties, which renders them differently from classical bulk materials, must be considered.

Most prominently, these materials might suffer from considerable scattering. Hence, we have investigated this aspect and showed, that despite the presence of scattering, thin elements, like diffractive optical lenses can be constructed from such materials and might offer application advantages, like full chromatic correction.

Novel surface interactions of 2D TMDs with different bacteria and virus models

Manjot Singh

University of Naples, Federico II, Italy
*corresponding author: manjot.singh@unina.it

Abstract: graphene) have attracted increasing interest and attention from the various scientific fields such as catalysis, energy storage, sensors, coatings and biomedicine, due to their unique physicochemical properties. Particularly, in biomedical applications, the high-aspect ratio sheet-like structures such as transition metal dichalcogenides (2D TMDs) have been widely studied to understand the biological and environmental interactions of these novel nanomaterials on account of their biocompatibility, stability and multifunctionality. To fulfil this aim, green fabrication routes, now-a-days have become a mainstream approach from the sustainable research point of view worldwide. In view of this, we extensively studied the surface interactions of pure water based exfoliated 2D MoS2 (belonging to the family of 2D TMDs) and graphene oxide nanosheets with a gram-negative bacterium, Escherichia coli, and a gram-positive bacterium, Staphylococcus aureus. Both the materials were also utilized to study their antiviral action towards the Herpes simplex virus type-1 (HSV-1). The obtained results showed different bactericidal impacts as well as very novel and surprising antiviral action of one nanomaterial over the other. Experimental results were also interpreted by using a simple kinetic model based on the Derjaguin-Landau-Verwey-Overbeek theory. On the other hand, among various theranostic platforms, magnetic resonance imaging (MRI)-based nanoprobes (contrast agents CA) have attracted increasing attention, with high selectivity using CAs, amplifying the T1 or T2 signal from the imaging. To this aim, we conjugated manganese oxide nanosheets with water-based iron oxide nanoparticles, based on an eco-friendly fabrication technique, to study their relaxivity properties in phantom applications.

Tailoring Surface Reflectance Using Self-Assembled Block Copolymer Nanopatterns

G.S. Doerk[1*] and C.T. Black[1]

[1]Center for Functional Nanomaterials, Brookhaven National Laboratory, U.S.A.
[*]corresponding author: gdoerk@bnl.gov

Abstract: This talk will discuss how thin film block copolymer self-assembly provides an alternative to nanolithography for engineering surface reflectance of visible light. Using existing nanofabrication infrastructure, we demonstrate near-ideal, omnidirectional, broadband antireflection in nanotextured silicon and glass. Furthermore, we use polymer blends that assemble with periodicities exceeding 200 nm to create resonant, reflective structural color. Using ultraviolet crosslinking-modified thermal reflow to locally tune pattern feature sizes, we fabricate hierarchical patterns for self-assembled metasurfaces with customizable reflectance.

By leveraging the existing infrastructure for nanofabrication, the use of metasurfaces comprising nanopattern arrays presents a potent method for engineering reflectance of visible light with a straightforward path to device integration. However, employing traditional nanolithography methods (e.g., electron beam lithography) precludes their use for applications requiring large areas, high-throughput, and low cost. Thin film block copolymer (BCP) self-assembly offers a promising alternative approach to create subwavelength, periodic nanopatterns that is compatible with common nanofabrication techniques [1]. In this talk, we summarize demonstrations by our group using BCP nanopatterning to tailor surface reflectivity.

In the first example, we show how combining hexagonal BCP nanopatterns with selective inorganic infiltration [2] and reactive ion etching can be used to fabricate wafer-scale arrays of conical nanotextures (~50 nm pitch). By acting as an effective medium with an ideal gradient refractive index, these nanotextured surfaces reduce reflectance to < 1% across the entire visible spectrum, which persists to incidence angles > 50°. This broadband, omnidirectional antireflection improves silicon photovoltaic efficiency [3] and renders glass "invisible" [4].

Second, we show how blending ultrahigh molecular weight block copolymers with very short homopolymer plasticizers can overcome sluggish ordering kinetics to assemble patterns with periodicities exceeding 200 nm [5]. Transferring these patterns into silicon yields reflective structural color based on electromagnetic resonances in the individual features (i.e., electric dipole, magnetic dipole, cavity). Furthermore, thermal reflow modulated through ultraviolet crosslinking can be used to locally tune feature sizes within large-area nanopatterns, generating hierarchical nanopatterns with customizable visible light reflection, exemplified in patternable structural color [6].

This research used the Materials Synthesis and Characterization Facility and the Nanofabrication Facility at the Center for Functional Nanomaterials (CFN), and the Soft Matter Interfaces (SMI) beamline at the National Synchrotron Light Source II (NSLS-II), which are U.S. Department of Energy Office of Science User Facilities at Brookhaven National Laboratory under contract no. DE-SC0012704. G.D. acknowledges support from the Department of Energy Early Career Research Program.

Self-assembled hexagonal array or correlated disorder plasmonic metasurfaces: optical properties comparison

Gil Cardoso[1], Frédéric Hamouda[1], Vy Yam[1], Béatrice Dagens[1,*]

[1] Université Paris-Saclay, CNRS, Centre de Nanosciences et de Nanotechnologies, 91120, Palaiseau, France

[*]corresponding author: beatrice.dagens@c2n.upsaclay.fr

Abstract: plasmonic metasurfaces have been fabricated following two different approaches in order to deliver large area devices for augmented reality systems. Their optical properties are compared at different levels: the contribution of the plasmonic nanostructures arrangement is evaluated thanks to the metasurfaces structure factors, the physical properties are assessed through optical transmission and reflection measurements, and finally the whole metasurfaces are macroscopically tested in a head-up display.

Metasurfaces based on plasmonic nanoparticles (NP) on glass substrates are of great interest for transparent displays [1] or for augmented reality (AR) applications [2]: they functionalize transparent plates to have high reflectivity at specific wavelengths (blue, green, red) by choosing the size and shape of the NPs, while preserving good transparency over the whole visible range (i.e. without scattering or diffraction effects) through an appropriate spatial arrangement of NPs [2]. However, the design of these metasurfaces must also be compatible with the fabrication of large surfaces. Self-assembly of nanoobjects is an efficient bottom-up approach to create nanostructured metasurface on large areas. Nevertheless, despite high deposition quality, arrangement defaults appear which can have a significant impact on the global optical properties of the metasurface. In order to develop transparent semi-reflective plates for AR systems, we compare here large-area metasurfaces with self-assembled patterns with those with correlated disorder patterns well controlled by electron lithography: we consider and discuss as well NPs spatial arrangement impact as plasmonic resonance effects on their global optical properties. We also propose and evaluate a combination of bottom-up and top-down approaches to better control final optical properties.

Fabrication: targeted plasmonic nanostructures constituting the metasurface are nanorods made of silver with typical dimensions of 100 to 200 nm diameter and 30 nm thickness, for operation in the visible range. We consider two samples fabricated with different approaches. The first sample, used as a reference, is made of high-quality correlated disorder nanostructuration obtained on 1 cm² thanks to electron beam lithography followed by a lift-off of silver [2]. The second sample is realized using soft UV nanoimprint lithography (soft UV-NIL), with an original process to fabricate the nanostructured PDMS (polydimethylsiloxane) stamp: in order to circumvent limitations observed with usual PDMS molding [3], we have developed a new approach which enables at the same time large area pattern definition by 200nm diameter polystyrene nanospheres (PS-NS) self-assembly, and PDMS stamp nanostructuration by RIE etching [4], as schematized in Figure 1. Thanks to arrangement breakings, the whole hexagonal compact arrangement appears as globally isotropic.

Optical transmission and reflection are performed on the both metasurfaces by using an ellipsometric setup, in order to determine their spectral filtering capabilities. Figure 2 shows that the enhanced reflection wavelength of the P polarization is near 640 nm for the ‘e-beam sample’, and near 720 nm for the ‘self-assembly sample’, when the incident angle is around 45°. Additionally the spectra of the latter are significantly broaden and attenuated, revealing the size dispersion of the plasmonic NPs.

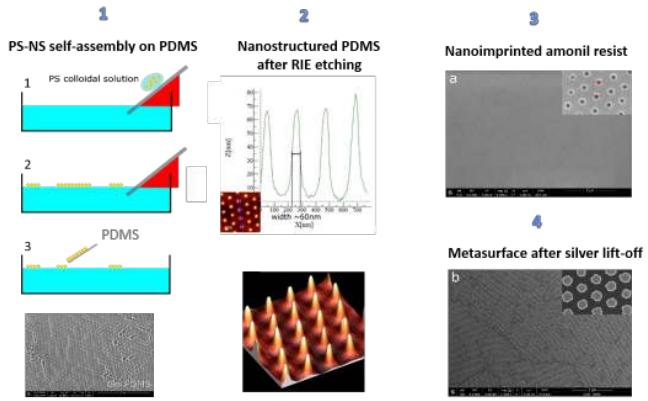

Fig. 1. Self-assembly based metasurface fabrication: (1) PDMS stamp fabricated by self-assembly and (2) RIE etching; (3) Nanoimprint process and (4) silver lift-off to generate the final metasurface.

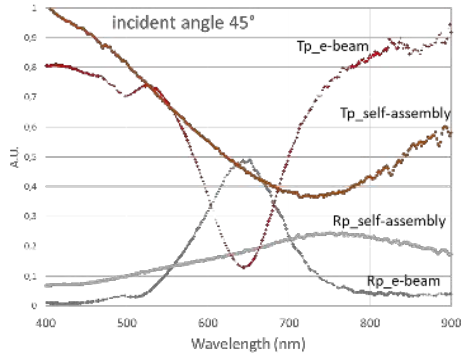

Fig. 2. Optical transmission and reflection spectra for polarization p measured on the both metasurfaces with an incident angle of 45°.

Structure factor: functionalized plate transparency quality can be numerically evaluated by the structure factor of the metasurfaces. The structure factor S(q) represents the optical response of the structure as a function of spatial frequencies q, without the influence of NPs resonance. In order to minimize diffraction and diffusion effects induced by spatial arrangement, the value of S(q) must be zero in the q range corresponding to usual observation conditions of the metasurface. In Figure 3 we calculate the structure factors using a computer vision program analyzing SEM images of the fabricated metasurfaces ((a),(b)) and of a numerically modified arrangement based on correlated disorder (c) to reduce NP density. Considering the observation range, the self-assembled metasurface with sub-wavelength period seems to be more robust in terms of transparency quality, and the spatial density reduction can be easily performed by choosing appropriate microstructuration.

These results will be presented in details, as well as the final performance of the both metasurface on a head-up display system.

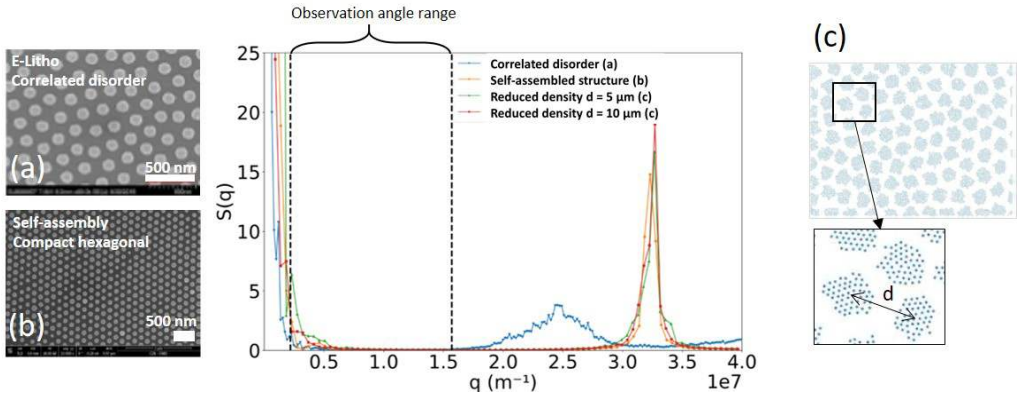

Fig. 3. Factor structure of large area metasurface made of silver nanorods, fabricated (a) by e-beam lithography with correlated disorder arrangement (average distance ~274nm) [2], (b) by self-assembly and nanoimprint (period 200nm) [4], (c) possibly followed by spatial density reduction in a correlated disorder arrangement.

This work was done with the technical support of the French cleanroom network RENATECH.

Designing Mode Coupling in Two-Phase Metamaterials made by Sequential Self-Assembly

Jelena Wohlwend[1], Georg Haberfehlner[2], Ralph Spolenak[1] and Henning Galinski[1]

[1]ETH Zürich, Switzerland
[2]TU Graz, Austria
*corresponding author: jelena.wohlwend@mat.ethz.ch

Abstract: Design and fabrication of large-area metamaterials is an on-going challenge. Here, we demonstrate how a sequence of self-assembly processes can be used to design and fabricate large-area two-phase metamaterials. These two-phase metamaterials consist of a disordered nanometric network and nanoparticles or nanosheets, which can be readily designed by chemical engineering. Using energy electron loss spectroscopy, we probe the plasmonic environment and coupling between the two phases, confirming energy exchange with the nanoparticle modes and localized "hot spots" of the network.

Self-assembled metamaterials are scalable and can, due to their often disordered structure, give rise to unique properties unattainably by ordered systems[1]. Despite their enormous potential as a platform for energy materials, disordered metamaterials are often limited to single phase systems, and complex multi-phase metamaterials have scarcely been explored. We propose a novel path to fabricate two-phase disordered network metamaterials: sequential self-assembly (phase separation during deposition followed by chemical dealloying). The resulting metamaterial consist of a disordered network[2] with embedded nanoparticles of different shapes and chemistries, shown in Figure 1.

Figures 1: Two Phase Metamaterials. (a) & (b) Schematic illustration of Cu-Sn and Cu-Ta two phase metamaterials, (c) & (d) HAADF micrographs and elemental distribution maps showing a Cu based disordered network with randomly distributed Sn NPs and a Cu-Ta based disordered network with randomly distributed Cu nanosheets respectively.

Interestingly, the different two-phase metamaterials, shown in Figure 1 a and b, can be achieved by a simple change in initial chemistry during deposition. To map the plasmonic environment of these two-phase metamaterials we take advantage of the high-spatial and high-energy resolution of electron energy loss spectroscopy (EELS). Inhomogeneous localization of light in the network is observed, concurrent with dipolar and higher-order localized surface plasmon modes in the nanoparticles. Thereby, we show that through chemical engineering during the sequential self-assembly, we are able to engineer the interaction, i. e. mode coupling between the disordered network and the nanoparticle. Since the chemistry in these metamaterials can be readily controlled, our approach can serve as a versatile platform to design materials for plasmonic catalysis and energy conversion.

Abstract: In this work, we introduce a bottom-up fabrication approach based on Electron Beam Induced Deposition to directly fabricate plasmonic nanoantennas onto the surface of tapered optical nanofibers. The structures are optically characterized by measuring the scattering from a propagating Near Infrared laser beam and a supercontinuum beam. The results, along with numerical predictions, suggest that the fabricated structures can enhance the single photon emission properties of room temperature solid-state emitters.

Quantum emitters are of great interest for various applications in quantum photonics, sensing, and information processing, as they can produce on-demand single photons with high purity and brightness and sub-nanosecond lifetimes. Different material systems have been examined as potential options for single photon sources (SPS)[1-3], including single atoms, ions, and solid-state emitters such as organic molecules, color centers in diamonds, and quantum dots. Colloidal solid-state emitters, which have simple fabrication and can operate at room temperature, have a lifetime of the order of tens of nanoseconds and face challenges in efficiently extracting their photon emissions, which hinder their practical application. Therefore, integrating SPS into photonic circuits requires specific experimental arrangements, and optical nanofibers (ONFs)[4], which have a subwavelength diameter and strong evanescent field, offer a promising input/output platform.

To further improve the performance of quantum emitters and the efficiency of single photon collection, coupling with plasmonic nanostructures has been proposed[5]. Indeed, integrating SPS with plasmonic resonances in metallic low Q cavities provides a strong enhancement of the radiative rate of the emitter while acting as a redirecting element for the radiative pattern. However, deterministic methods to fabricate single nanostructures or complex geometries directly on the ONF are not currently available, nor have been proposed. The techniques employed to realize an integrated SPS/ONF plasmonic system are based on separate or simultaneous drop-casting of the plasmonic particle and emitter, introducing a high degree of uncertainty in the positioning and orientation of the nanostructures on the ONF, as well as the reciprocal positioning with respect to the SPS. As a result, these methods fail to ensure the best coupling between the resonator and the ONF.

Here we introduce a *bottom-up* Electron Beam Induced Deposition (EBID) fabrication approach to directly pattern plasmonic nanoantennas onto ONFs, enabling sub-10 nm control over the position and the geometry of the realized structures. A specific aspect of the fabrication process is the exploitation of deliberate beam defocusing, obtained by controlled blurring of the beam during the exposure: this is needed to reduce the electron flux over the exposed area, thus reducing the mechanical pressure exerted by the beam onto the ONF, that otherwise would prevent the correct result of the nanopatterning. In general, blurring of the beam is considered a detrimental condition for nanofabrication, but instead in this work this strategy has been used to

enable the patterning on these specific substrates, that are suspended, dielectric, and nanometric samples, while maintaining practically unaltered the composition of the nanostructure.

To optically characterize the properties of the interaction between the evanescent field guided by the ONF and a single nanopillar or two nanopillars separated by a nanogap (nanoantenna, ***Figure 1.a***), we measured the degree of polarization scattered light from a Near Infrared 785 nm laser beam. Two experimental configurations were investigated to measure how the intensity of the scattered light depends on the input polarization (***Figure 1.b***) and how, by fixing the input polarization of the beam, the light scattered from the structures is polarized. Moreover, we measured the spectral differences in the scattering of a supercontinuum laser from the two geometries, highlighting a red shift of the scattered signal for the nanoantenna configuration. The experimental results were confirmed by Finite Differences Time Domain (FTDT) numerical simulations, which also showed the redirecting effect on the radiative field, which is routed towards the collection channel represented by the ONF. These results showed how our approach presents a promising alternative to top-down fabrication methods for plasmonic nanostructures, such as quantum dot SPS coupled with drop-casted gold nanorods on a ONF system. Overall, this work represents a promising way to enhance light-matter interactions and improve the performances of quantum emitters, while promoting a more efficient collection channel via the ONF.

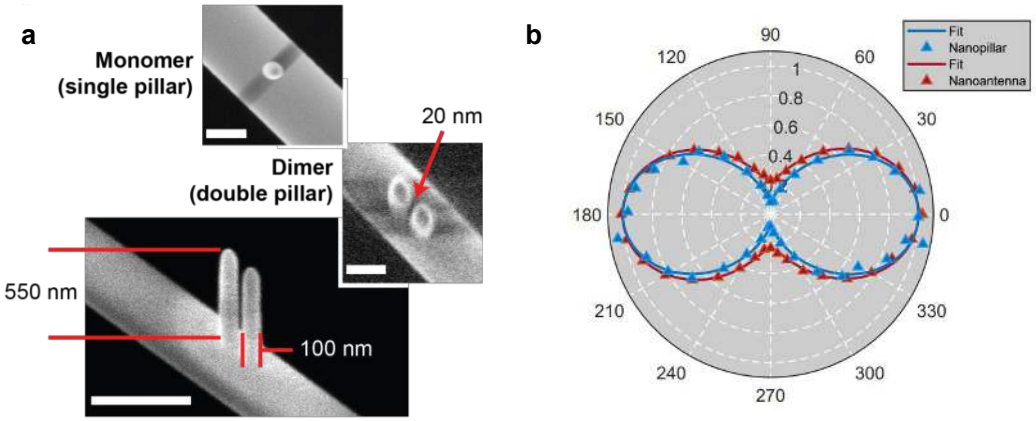

Figure 1.a) *Examples of nanostructures fabricated on a ONF using the proposed approach. The scale bar for the tilt-view SEM image is 500 nm, while for the top-view SEM image is 200 nm.* ***b)*** *Dependence of the scattered signal intensity from the EBID Nanostructures on the polarization orientation at the ONF entrance.*

Abstract: Three-dimensional topological insulators attract a great deal of interest due to their potential use of the topologically protected gapless surface states in topological spintronics and quantum computation [1]. However, challenges such as the high sensitivity of the surface states to the atmosphere, the low surface-to-volume ratio, and the need for various material heterojunctions currently limit the application of these materials [2]. Here, we report the successful fabrication of the topological insulator heterostructures by an easy, fast, and single-step process, which could meet all those challenges and pave the way for exploring other exotic phenomena shortly. Utilizing directional solidification different topological insulator-based eutectic composites were produced, where two crystalline phases are combined in a structured form with joined interfaces. The material exhibits lamellar micro/nanostructures with atomically smooth interfaces. The existence of the metallic surface states and the formation of the *p-n* junction have been confirmed through specific characterization methods.

Abstract: Plasmonics based on conventional metals are broadly used for biosensing and optoelectronic devices, but suffer from limited optical tunability. We recently demonstrated conducting polymers as a new category of plasmonic materials exhibiting excellent optical tunability. In this talk, I will briefly introduce the emergence, current status, and future prospects of using conducting polymers for dynamic plasmonics.

Metal nanostructures are key elements in nano-optics due to their intense resonant interaction with light *via* plasmonic charge oscillation. However, they suffer from limited tunability due to the fixed optical properties of metals. By contrast, conducting polymers, a new category of organic conductors, exhibit excellent tunability and were recently introduced for dynamic plasmonic antennas. We revealed that nanoantennas based on conducting polymers show clear dipolar plasmonic resonance and sustain reversible tuning *via* chemical and electrochemical approaches[1,2]. In this talk, I will present our latest progress of conducting polymer nanoantennas made through colloidal lithography and their applications for dynamic optical systems[3].

Bottom-up fabrication of 2D MoS_2: from thermochromic sensing to hyperbolic metamaterials.

Abstract: MoS_2 has been extensively researched ever since the discovery of its thickness-tunable properties. However, its applicability is still limited by fabrication constraints and its integration with other materials. We present a bottom-up fabrication route enabling large-area synthesis of bulk and 2D MoS_2. We demonstrate how a thermochromic sensor can be used to track the thickness and the mechanical, electrical and optical properties. To showcase the precise control on the fabrication conditions, we fabricate a large-area hyperbolic metamaterial containing 2D- MoS_2.

From computers to energy harvesting, the utilization of semiconductor materials and the management of their electrical and optical properties have played a critical role in the advancement of society during the past century. Silicon, in particular, has been the backbone of semiconductor technology, and our enhanced capacity to process it has led to the ongoing reduction of device feature sizes, resulting in devices with ever-increasing capabilities and speeds. However, the push for even smaller devices has hit some major obstacles as silicon technology reaches its fundamental physical limits.

In this context, MoS_2, a semiconductor transition metal dichalcogenide, has emerged as a potential next-generation semiconductor. Unlike other 2D materials, MoS_2 is a natural material formed by earth-abundant elements and is currently used in industry due to its mechanical properties, which originate in its crystal structure, in which layers are held together by weak van der Waals forces. This weak interlayer bonding allows for thickness-tunable electrical and optical properties, making MoS_2 a promising candidate for replacing silicon in the development of future semiconductor devices. Proposed applications of MoS_2 include transistors, light-emitting diodes, and catalysis [1].

However, applications of MoS_2 have been hindered by the difficulty of processing MoS_2 into high-quality thin films and device structures. Exfoliation and chemical vapor deposition, the two most prevalent processes used to generate MoS_2 films, generally result in non-uniform coverage and can only produce crystalline MoS_2. The ability to control the synthesis of large-scale MoS_2 is therefore crucial to become a widely adopted standard semiconductor material, as is the ability to combine MoS_2 with different materials to create new device architectures [2].

Here, we present a two-step fabrication method for MoS_2 thin films. By using magnetron sputtering, it is possible to produce the material on an industrial scale, deposit it over a great variety of substrates, and study both the amorphous and crystalline forms of the material. We investigate the structural and functional properties of magnetron sputtered MoS_2 using a combination of optical and electrical characterization with scanning and electron microscopy, nanoindentation, X-ray diffraction, and Rutherford back scattering.

We demonstrate that continuous amorphous MoS_2 with thicknesses as low as 1 nm can be deposited and then crystallized by thermal annealing into horizontally layered MoS_2 with optical properties comparable to those found in the literature.We exploit the change in the optical properties of MoS_2 upon crystallization to build a thermochromic sensing platform. The presence of a metallic reflector underneath the semiconductor enables the detection of small changes in the optical properties down to the order of 1% using strong interference [3]. Here, we use zirconium nitride as an inert metallic reflector that does not react with MoS_2 at annealing temperatures < 485°C. We further use this material combination to realize a multilayered hyperbolic metamaterial. Control over the ratio between the two constituents and their thickness is demonstrated by comparing the experimental results with simulations. Our results showcase how this 2-step bottom-up fabrication route opens the door to wafer-scale photonic applications incorporating 2D MoS_2.

Abstract: We developed centimeter scale metasurfaces of self-assembled monolayer gold nanoparticle (GNP) superlattices. Through ligand exchange, the interparticle gap distance was actively tuned from 2.4 to 0 nm. The *in-situ* reflectance spectra of the GNP metasurfaces showed a monotonously red-shifted bonding dipolar plasmon (BDP) mode of enhanced intensity upon diminishing interparticle gaps until 0.2 nm. The deposited GNP metasurfaces on SiO_2/Si wafer showed tunable effective refractive index, where the maximal real part exceeded 5.

Plasmonic capacitive coupling in nanogaps promotes light-matter interaction via strong electromagnetic field confinement and enhancement. However, it has been shown that quantum effects, e.g., nonlocal screening and electron tunneling, can limit the maximal achievable local field enhancement [1]. Previous studies on various binary plasmonic systems showed a threshold of 0.5-1.1 nm gap distance as onset of a weakening BDP mode [1-3], whereas investigation into the plasmonic metasurfaces remains scarce. Recent theoretical simulation suggested a substantially reduced threshold of quantum limit in the plasmonic metasurface compared to the binary systems [4]. Experimental demonstration of plasmonic metasurfaces with tunable periodic sub-nanometer gaps remains yet an untackled task.

Here, we obtained large scale (cm^2) hexagonal close-packed GNP monolayers via interfacial self-assembling method, reaching micrometer scale single domain size. In combination with a free-floating ligand exchange process, the interparticle gap distances of GNP superlattices can be precisely controlled from 2.4 to 0 nm. When substituting the native oleylamine (OAm) ligands by ethanedithiols (C2DTs), the gap distance reduced from 1.4 to 0.2 nm. The *in-situ* reflectance spectra of the GNP metasurface acquired during ligand exchange (Figure 1a) shows a monotonously red-shifted BDP mode, with increasing peak intensity and width, upon diminishing interparticle gaps. We determined the effective refractive index of deposited GNP metasurfaces on SiO_2/Si wafer from ellipsometry measurements. The effective refractive index can be actively tuned depending on the gap distance and constituent, where maximum of the real part can exceed 5 at 0.2 nm gap distance, as shown in Figure 1b. The results of reflectance and ellipsometry measurements indicate a continuously enhanced plasmonic capacitive coupling in GNP metasurfaces of hexagonally periodic nanogaps down to 0.2 nm gap distance, allowing extreme field confinement and enhancement.

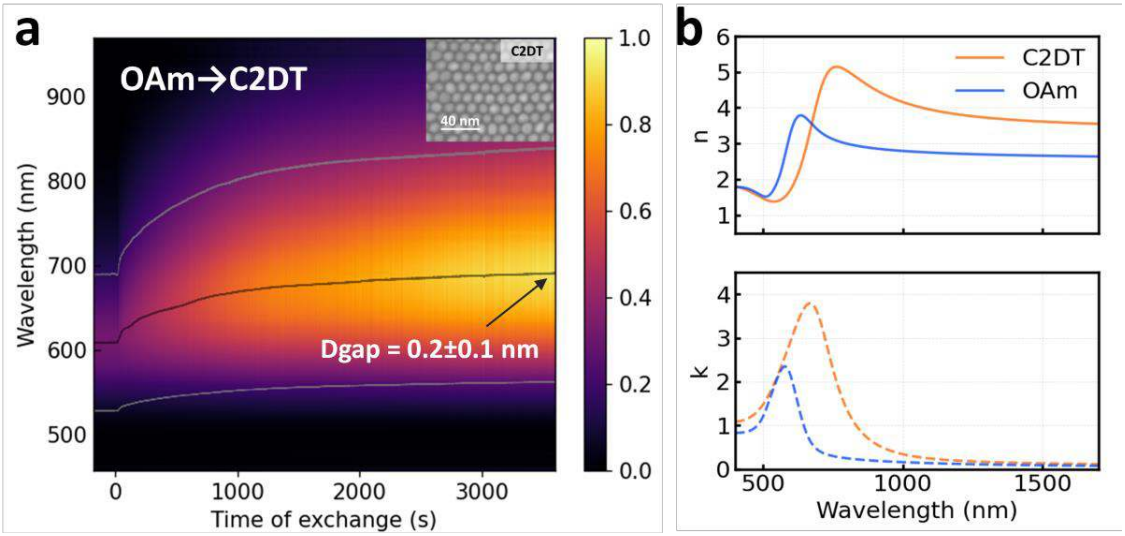

Figure 1. (a) Reflectance spectra measured *in-situ* on a GNP metasurface during ligand exchange with C2DT, launched ~0 s (insert, a high resolution SEM image of the GNP metasurface after ligand exchange). (b) The effective real, n, and imaginary, k, refractive index of the GNP metasurface with OAm and C2DT capping, respectively.

Efficient grating coupling strategies for silicon photonics

P. Petropoulos[1*], V. Vitali[1, 2], T. Domínguez Bucio[1], F.Y. Gardes[1], and C. Lacava[2]

Abstract: We discuss techniques for optimizing the coupling efficiency between optical fibers and silicon photonic waveguides through the use of back-end-of-line CMOS-compatible grating couplers.

Silicon photonics has enjoyed tremendous progress in recent years, offering exciting opportunities for miniaturizing the footprint of optical components and enabling the implementation of complete systems on chip. Its adoption has already transformed communications, sensing, nonlinear optics, as well as quantum technologies. A prevalent challenge however, remains the efficient coupling between optical fibers and silicon photonic waveguides. Among the two options available, edge coupling is admittedly the most efficient, especially when combined with suitable taper designs, which may vary in degree of sophistication. Edge coupling however, requires precise alignment, which might be an impediment when the manufacturability of a large number of devices is considered. Conversely, grating couplers that direct light off-plane offer an attractive alternative and performance that is acceptable for most applications.

A challenge associated with achieving a high coupling efficiency in grating coupler designs, relates to controlling the directionality of the gratings. To address this, several works have embedded metallic mirrors or distributed Bragg reflectors in the substrate of the wafer. By reflecting stray waves that would otherwise travel towards the bottom of the substrate and redirecting them towards the surface of the chip, these reflectors facilitate their recapture. Even though an effective solution, the implementation of back-reflectors may require the adoption of non-CMOS compatible materials in the fabrication, which can be prohibitive in certain environments. The work we discuss in this presentation, aims at maximizing the coupling efficiency of grating couplers by combining strategies that aim at: optimizing the apodization of gratings, so that the mode of the diffracted beam closely resembles that of the optical fiber [1]; adopting a dual-level grating design, which breaks the symmetry of the structure and contributes towards increasing its directionality [2]; and finally, combining two different materials to the same effect [3]. We will present the predicted performance of such designs, as well as experimental results that represent the state-of-the-art for gratings without the use of any back-reflectors. A -0.8-dB coupling efficiency for a grating written in the 220-nm silicon photonic platform is reported.

This research was funded by the UK's EPSRC through grant EP/T007303/1 "Silicon-rich silicon nitride Nonlinear Integrated Photonic ciRcuits & Systems (juNIPeRS)".

Generation of spatial rogue waves in a Q-switched Nd:YAG laser

R. Navitskaya[1,2], I. Stashkevitch[1], S. Derevyanko[2*], and A. Karabchevsky[2]

[1]Faculty of Physics, Belarusian State University, 4 Nezalezhnasti Avenue, 220030 Minsk, Belarus

Abstract: The generation of spatial rogue waves is demonstrated in a Q-switched Nd:YAG laser operating in a low-power regime under low Kerr nonlinearity. We investigate the dependence of rogue waves' statistics on the laser mode configuration. We show that spatial rogue waves can emerge when the lasing takes place at a large number of high-order transverse modes, while high Kerr or saturable absorption nonlinearity is not a necessary factor for their formation.

Spatial rogue waves are rare events that represent tightly focused spots in the transverse cross-section of the beam with extremely high intensities. They represent a particular case of general class of rogue waves (RWs) – extreme events that emerge and disappear spontaneously, and can be observed in different optical systems [1].

The exact mechanisms leading to the formation of spatial rogue waves are still under investigation. One of them concerns with the active role of nonlinearity. Typically, RWs are observed in optical systems with high medium nonlinearity, e.g. in fibers or lasers operating in a high-power regime with considerable Kerr nonlinearity or with intracavity saturable absorbers [1]. However, there are examples of purely linear optical systems that exhibit RWs generation. In such systems, RWs can be generated in the case of inhomogeneity and granularity of the beam profile [2], thus indicating the importance of spatial effects and modal dynamics. Spontaneous coupling of transverse laser modes possibly assisted by the longitudinal mode-locking can lead to the formation of complex output beam patterns with filamentary structure dynamically changing in time [3, 4]. In the extreme cases, the intensities of individual filaments can be high enough to damage the laser crystal or optical elements in the cavity [5].

Here, we demonstrate experimentally the generation of spatial RWs in a multimode Nd:YAG laser operating in the active and passive Q-switch regime [4,6]. The observed rogue wave statistics depend on the transverse mode configuration, as illustrated for example in Figure 1 for the laser generation in the active Q-switch regime. Thus, the spatial RWs were generated when a large number of high-order transverse modes were involved in the lasing (Figure 1b), while in the case of a smaller number of lasing modes with lower order the rogue wave generation was not observed (Figure 1a).

In addition, we performed a number of experiments for different pump powers to investigate the effect of Kerr nonlinearity on the properties of spatial RWs for the case of the laser operation below the self-focusing limit. In these experiments, the Nd:YAG laser was actively Q-switched without a saturable absorber in the cavity. We obtained the generation of spatial RWs under different pump powers corresponding to the output Q-switched pulse energies from 9 to 20 mJ [6]. The observed RWs had similar statistics and properties independent on the pump power. These results confirm that high Kerr nonlinearity or saturable absorption nonlinearity is not the main factor leading to the spatial rogue wave generation in a multimode solid-state laser.

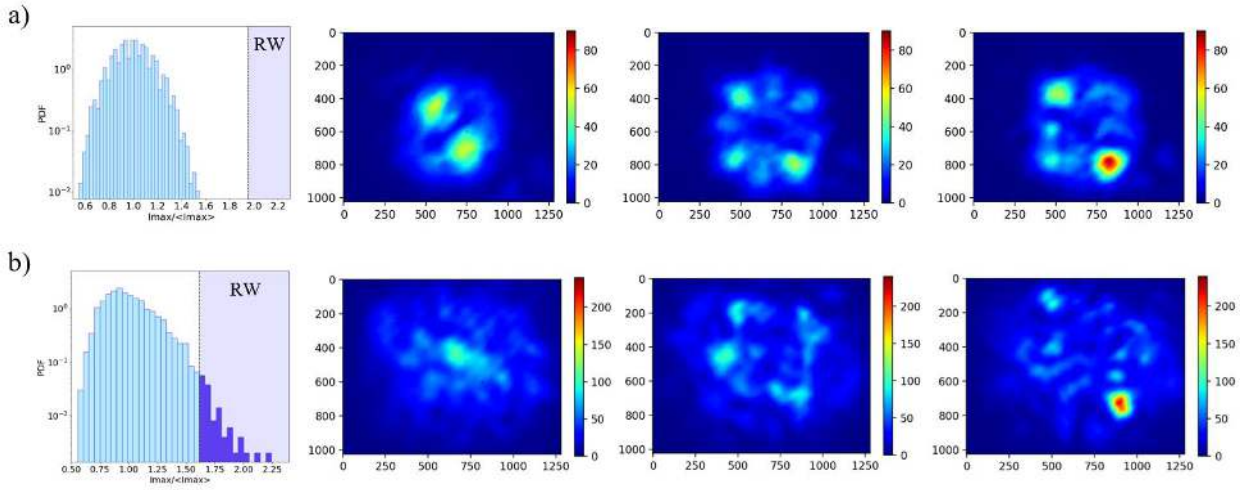

Figure 1. Statistics of pulse-to-pulse peak intensity over the transverse intensity profile and example output beam profiles for different laser mode configurations: a) small number of lasing modes with low order (spatial RWs are not observed); b) large number of high-order modes (the rightmost figure corresponds to a spatial rogue wave). The rogue wave limit is shown as a boundary of the shaded region in the statistics plots.

Integrated photonics offers unique devices and platforms for the development of cutting-edge technologies that allow for low-latency and ultra-fast signal processing, while utilizing established fabrication techniques and exploiting conventional fiber telecom networks. However, optimization of complex photonic integrated circuits is a challenging task due to their many degrees of freedom and fabrication imperfection, requiring intense design and numerical modeling. To overcome these challenges, machine learning-based smart optimization techniques can be incorporated with reconfigurable photonic circuits, thus allowing the widespread enhancement of the device functionality beyond the capabilities of traditional applications. Our group has previously demonstrated the effectiveness of this approach in both the temporal and spectral degrees of freedom by tailoring the shape of picosecond waveforms [1] and supercontinuum generation [2], respectively.

In this work, we propose the use of machine learning-based autonomous optimization techniques for the generation and arbitrary tailoring of the spectral shape, bandwidth, and repetition rate of an integrated micro-ring resonator-based optical frequency comb [3]. This technique has the potential to achieve increased comb efficiency, high repeatability, and reduced generation time. Additionally, this approach is translatable to micro-ring resonators of any geometry and composition, making it promising in telecommunication applications such as frequency synthesis and coherent parallel optical communication.

Furthermore, the small footprints (μm-nm), low power (milliwatts) consumption, and compatibility of our integrated platforms with fiber telecom infrastructures align our research with the need for new low carbon emission technologies and improvements of interconnected systems. In this regard, our research can pave the way for the advancement of artificial intelligence-assisted signal processing devices and encoding techniques for ultra-dense data transmission protocols compatible with 5G and upcoming 6G networks. Additionally, our results will strengthen the role of cross-disciplinary research between nonlinear/integrated photonics and artificial intelligence.

Abstract: We present results on the development of up to 200 mm full-wafer fabrication of mid-infrared metasurfaces for a variety of applications in energy, defence & space, including AZO and W:VO_2 thermal control metasurfaces, and silicon meta-lenses fabricated using deep-UV lithography.

Functional metasurfaces combine expertise in advanced materials, state-of-the-art nanofabrication, and sophisticated design. In recent years, our team has worked on different aspects in a variety of projects and here I will provide examples toward scalable metasurface technology using wafer-scale production level tools.

In the domain of advanced materials capabilities our work has focused on a number of tunable and switchable oxides that can be deposited reproducibly and with high accuracy using Atomic Layer Deposition. This includes transparent conducting oxides for infrared plasmonics and metasurfaces using Al-doped ZnO, where doping levels can be tuned not only by Al-doping, but importantly through oxygen plasma treatment.[1] We have demonstrated ability of precise lateral patterning of doping profiles with resolution better than 100nm, which can be used to define infrared metasurfaces through local doping in an otherwise completely planar structure. Wafer-scale fabrication of infrared metal oxide metasurface was demonstrated to achieve a dual band control over the spectral response in the mid and long-wave infrared.[2]

We have also reported the first demonstration of 200mm wafer-scale fabrication of tungsten-doped vanadium dioxide (W:VO_2) using atomic layer deposition, showing room-temperature insulator-to-metal phase transition.[3] This capability opens up a wide range of new applications in integration of non-volatile switching in metasurfaces and integrated photonics, with potential applications in communications, optical data processing and, thermal control coatings for energy applications.[4]

Parts of the presented work were done with the support from EPSRC, Dstl, and Horizon 2020.

Abstract: Anapole states are broadly investigated in nanophotonics for their ability to provide field enhancement and transparency. While low extinction has been achieved in dielectric nanoparticles due to the absence of intrinsic losses, in the case of plasmonic nanostructures this is still elusive. In this talk, we will present recent findings on anapole states in planar plasmonic nanostructures that were optimized for near-field energy enhancement using a topology optimization approach. The optimized structures exhibit an anapole state with characteristic properties in the visible regime including weak absorption, high near-field enhancement outside the structure, and strong suppression of scattering. We use our multipole analysis to explain both the near-field and the far-field features of the anapole state possessed by the nanostructures. Because of the low inter-coupling at the anapole state, the nanostructures act as individual meta-atoms that preserve their optical response even when used in highly packed metasurfaces and metamaterials. Due to their transparency while providing field enhancement, anapoles might be combined with waveguides in integrated optical platforms to unlock advanced functionalities for sensing, nonlinear optics, and optical information processing.

Abstract: We report emission enhancement of Er3+-ions across the telecommunications C-band in a single plasmonic waveguide based on the Purcell effect. Our gap waveguide uses a reverse nanofocusing approach to efficiently enhance, extract and guide emission from the nanoscale to a photonic waveguide while keeping plasmonic losses at a minimum. A large and broadband Purcell enhancement allows us to resolve Stark-split electric dipole transitions. Simultaneous enhancement of multiple quantum states is of great interest for photonic and quantum networks.

The influence of a local electromagnetic environment on light-matter interaction offers a route to realise faster and brighter light sources with associated control over the quantum states of light and matter. Mastering this control is especially important in sensing and quantum technologies [1] when working with low photon numbers and single emitters such as isolated molecules [2–4], quantum dots [5] and atoms [6], all of which inherently interact particularly weakly with light.

Optical cavities localize light in both frequency, quantified by the cavity quality factor, Q, and space, quantified by a mode volume, V_m, to accelerate luminescence by the Purcell factor, $F_p = 3\lambda^3 Q/(4\pi^2 n^3 V_m)$, where λ is the optical wavelength and n is the refractive index. This has proven to be incredibly effective; however, comes at the price of requiring innovative ways to tune and match both cavity and emitter frequency as well as the restriction of access to a single electronic transition at a time. A promising alternative is to couple luminescence into a single highly confined optical waveguide mode [7–9]. Now the mode's confinement area, A_m and group velocity, v_g, determine the Purcell factor, $F_p = 3c\lambda^2/(4\pi n^2 v_g A_m)$ [10], while the continuum of modes provides tuning-free enhancement across a broad frequency range [11]. This in principle should provide simultaneous access to multiple electronic transitions at distinct energies [12]. Although slow light propagation in photonic crystal waveguides shows excellent Purcell enhancement, their bandwidth-delay product limit prohibits broadband operation. Thus, plasmonic waveguides are especially promising as they offer large bandwidth sub-wavelength confinement without excessive dispersion.

Here we report both the enhancement and efficient guided mode extraction of dipole luminescence using reverse nanofocusing from a nanoplasmonic waveguide coupled to a buried photonic waveguide. We demonstrate this using technologically relevant Er3+ ions on a hybrid silicon plasmonic waveguide platform. Our reverse

nanofocusing device gives rise to 300-fold shorter Er3+ ion emission lifetimes accompanied by an enhancement of >338x in luminescence efficiency when compared to non-plasmonic control devices. Efficient collection of the enhanced luminescence is achieved by exploiting photonic to plasmonic nanofocusing methods, but in reverse. All plasmonic devices were found to produce more photons than photonic control devices. The extraordinary enhancements of this system are further underpinned by the observation of multiple enhanced Stark-split electric dipole transitions across the Er3+ telecommunications emission band. This demonstrates the capability to strongly dress multiple atomic transitions simultaneously using a one-dimensional mode continuum at room temperature.

Simulation of Plasmonic Absorption Interplays in Hybridized Semiconductor/Metal Nanostructures

Atefeh Habibpourmoghadam[1*], Wenyong Xie[1], Antonio Calà Lesina[1]

Abstract: In low intensity regime, the plasmonic response of hybridized nanostructures can be seen as the linear combination of each constituent's response. However, the surface plasmon resonance (SPR) at the interface between two materials, can further modify the absorption cross-section of a hybridized nanostructure. We numerically studied the optical response of hybridized nanostructures made from metal (i.e., gold) and highly doped semiconductor (i.e., copper sulfide) both in the static and transient regimes, and we will present the unconventional response of such a system.

Amongst various copper chalcogenide combinations (Cu2-xS), copper sulfide (CuS) can offer multiple advantages, such as low toxicity, and higher stability due to oxidation in air [1]. In hybridized nanostructures (see Figure. 1) made of CuS and gold (Au), charge carriers transfer can happen from Au to CuS at the interface which can change the overall optical properties of the system [2]. In addition to permittivity tensor, this mechanism can also modify electronic band gap at their interface [1]. Dual plasmonic response in Au/CuS nanostructures were experimentally investigated with transient absorption spectroscopy (TAS) [3]. Here, we provide theoretical insight to explain the optical response of these dual plasmonic hybridized nanostructures, which are not yet fully understood. Through numerical modeling, we found that Au/CuS hybrid nanostructures show unusual absorption properties due to their asymmetric geometry, which enables strong coupling between their constituents due to the excitation of plasmonic modes located at their common interface. Numerical modeling was performed both in the static and transient optical regimes. In the static regime – similarly to a conventional Mie-type calculation under linearly polarized plane wave – the total response can be understood as the linear combination of resonant modes attributed solely to the Au and CuS counterparts, with a slight spectral shift correction due to the coupling.

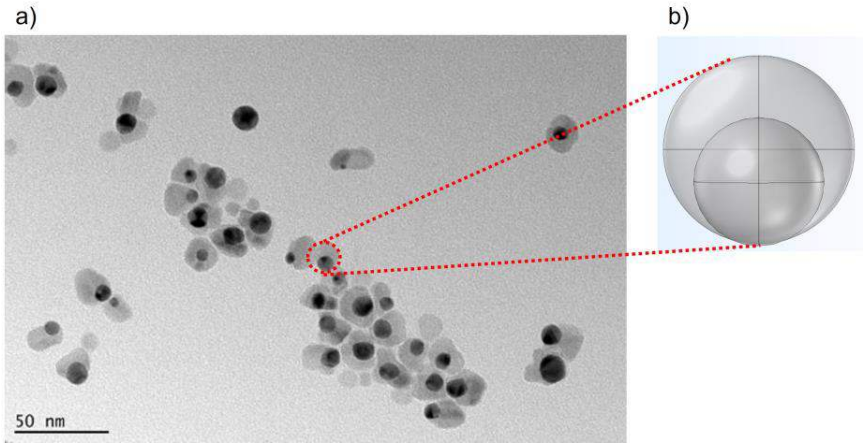

Figure 1. a) Transmission electron microscopy (TEM) image of colloidal distribution of Au/CuS nanoparticles in toluene (adapted from Ref. [3]), b) corresponding simulation configuration.

In the transient regime, a pump-probe simulation was performed as a function of delay between pump and probe signals. The experimental transient absorption results were reproduced with good accuracy, and the origin of such response identified. More details will be discussed during the talk.

Abstract: With the increasing demand for graphene, the need for a simple, fast, efficient, low-stage and environmentally safe method of its production also increases. In our work, we used physical ultrasound treatment without the addition of surfactants to extract graphene films from a mineral of shungite. From our study of the structures of the resulting graphene, we see that they have the form of films with a surface length of 200 nm with a graphene structure with a hexagonal center and a lattice pitch of 0.335 nm.

We investigated two regions of shungite, as illustrated in Figure 1a,d, and conducted EDS analysis on each region. Our results indicate that the completely dark areas in region 1 (Fig. 1b) and 21 (Fig. 1e) are composed entirely of carbon. Conversely, region 2 (Fig. 1c) and 21 (Fig. 1f) is composed of carbon containing impurities, including low concentrations of oxygen, silicon, aluminum, nickel, iron, and vanadium.

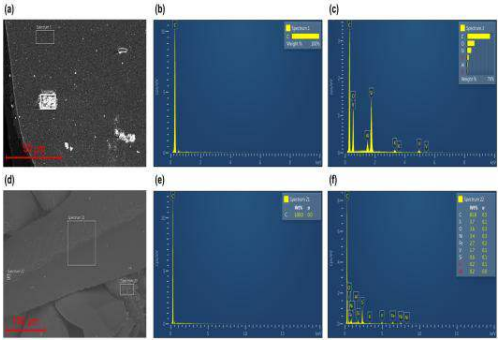

Figure 1. Scanning electron microscopy with EDS image of shungite particles: (a) first-selected sample study areas, chemical composition of area spectrum (b) 1, (c) 2, (d) second-selected sample study areas, chemical composition of area spectrum (e) 20 and (f)21.

Next, we characterized the surfaces of samples processed from shungite with a carbon concentration of 100%.

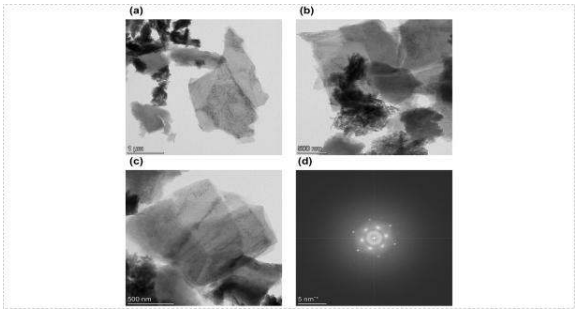

Figure 2. TEM images of sonicated shungite sample at magnifications of (a) x13,500, (b) x35,000 and (c) x22,000. (d) Fast Fourier transform pattern of sonicated shungite sample.

Transmission electron microscopy (TEM) images of a sonicated shungite sample (Fig. 2a-c) reveal the formation of thin films with a high specific surface area. For a sample with a carbon concentration of 98%, the particles have collapsed into thin monolayers. The fast Fourier transform pattern [1, 2] of the resulting films exhibits a symmetrical hexagonal pattern characteristic of primary graphene (Fig. 2d).

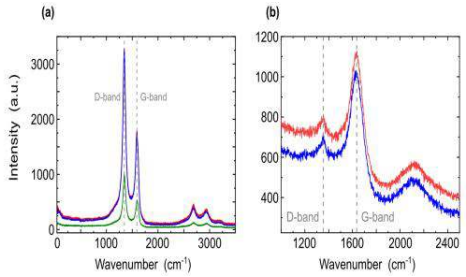

Figure 3. Raman spectra of natural shungite (a) before and (b) after sonication

Raman spectra of natural shungite from the different regions investigated (Fig. 3a) reveal the presence of a G-band at 1600 cm^{-1}, indicating the tangential stretching vibrations of sp2-bonded carbon atoms in the hexagonal graphene planes[3,4]. A D-band at 1330 cm^{-1}, indicating diamond-like sp3 bonds, corresponds to the amorphous structural state of carbon (graphite), indicating that the main allotrope of carbon in natural shungite rock is graphite. However, in Raman spectra of sonicated shungite samples (Fig. 3b), the graphene-related G-band shows increased intensity, with a corresponding decrease in the graphite-related D-band. No obvious second-order peaks appear in the spectra.

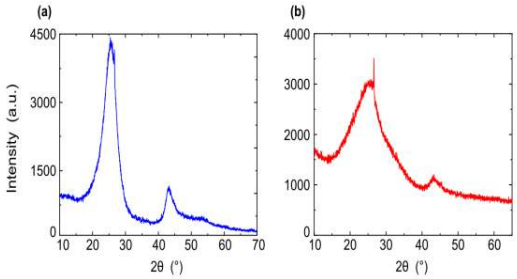

Figure 4. X-ray spectra of shungite sample (a) before, and (b) after sonication.

Figure 4 shows the X-ray spectra of shungite before and after ultrasound treatment. For the sample before sonication (Fig. 4a), wide spectra at 26.5° refer to graphite-like carbon, as well as a secondary peak at 42°, 44°, corresponding to the hexagonal structure. Here 26.5° is the angle of the base plane of centered graphene and the lattice pitch of 0.335 nm. Figure 4b shows X-ray spectra after ultrasound treatment. The positions of the peaks are located at 26.5°, 42° and 44°. The vertex is 26.5°, increased compared to the peak before processing, which means that the carbon peak can be interpreted as a decrease in the size of the coherent scattering region along the c axis in stacked graphene layers. The peak is 44° is more intense than that of shungite before ultrasound treatment, which means that the size of the hexagonal structure has been increased. Our results show that graphene films were obtained from shungite using green-extraction methods.

We acknowledged DIEGO project ERA-NET, Ministry of Energy, Grant No. 221-11-032 for funding the research.

Abstract: Surface-Enhanced InfraRed Absorption (SEIRA) spectroscopy is a powerful tool to overcome the limitation offered by the standard IR spectroscopy in the case of very small amount of analyte to be detected.
Our platform relies on a plasmonic metasurface engineered to exhibit different resonances covering the infrared region of the electromagnetic spectrum (EM). In the present work, the resonances are matched to the vibrational modes of the Amide groups, to demonstrate the ability of such device to monitor a denaturation biological process over a dehydrated monolayer of protein A, with an estimated detection limit of about 3 fmol of molecules.

SEIRA spectroscopy is a powerful method for the structural determination of molecules in biological samples in a univocal, non-destructive, and label-free way, which relies on plasmonic metasurfaces (MSs) at very low concentration and with small MW [1]. Molecular vibration frequencies essentially depend on the arrangement of the atoms, as well as the strength of the involved chemical bonds, which renders this technique a valuable tool for the investigation of proteins' structure, molecular mechanisms underlying protein reactions, as well as protein folding, unfolding and misfolding [2]. MSs are composed of two-dimensional periodic arrays of sub-wavelength metallic elements (also called nanoantennas, NAs) laid on a dielectric substrate. The optical response of an MS can be tailored across the EM spectrum by varying the shape, size, and metal film thickness of each NA, as well as the array periodicity. When MSs are resonantly coupled with the incoming EM radiation, the field can be strongly confined and enhanced around the NAs and into the gaps between them; this yields a several order of magnitude amplification of the vibrational modes of nearby molecules, which in turn enables spectroscopic characterizations with unprecedented sensitivity. Especially for low concentrations of the analyte, it is crucial that the field hotspots occur consistently and homogeneously across the MS, so that the probability of enhanced light-matter interaction is maximized.
The development of our proposed sensing platform revolves around four main lines: EM modeling and design, fabrication, biofunctionalization, and IR characterization. Our design procedure relies on a preliminary parametric study, in which we extensively explore the geometrical parameter space and identify possible resonances of interest. For the inverse design, i.e., the synthesis of a resonance with desired position and line-width, we start from a coarse initial guess from the computed codebooks, and progressively fine-tune the parameters. We adopted an innovative design based on a multiresonant MS made of different pixels (covering an area of 500 x 500 μm^2) characterized by different designs, in order to exhibit resonances covering the wavenumber range 1500 – 2100

cm^{-1} related to Amide groups I and II (i.e., 4.8 – 6.7 μm in wavelength) [3]. This requires reliable and reproducible nanofabrication approaches [4]. The proposed multiresonant MS is fabricated on a 10 x 10 mm^2 float-zone silicon chip by means of electron beam lithography and lift-off processes [4]. In the present work, we take a further step and apply SEIRA spectroscopy to probe the denaturation of a protein monolayer. All pixels are biofunctionalized with Protein A (PA) by using dithiobis(succinimidyl propionate) (DSP) taken as a sample model, following a precise protocol [5] and after the characterization of their absorption SEIRA spectra they follow a PA denaturation protocol and their SEIRA spectra are acquired. The comparison between the native state and the denatured state of the PA is showed in Figure 1 through the related SEIRA spectra. We can determine changes in the Amide I and Amide II vibration coupled modes. In the region 1665 – 1650 cm^{-1}, we estimate a red-shift of 9 cm^{-1} for the Amide I band, which is frequently interpreted in terms of structural changes of α-helical structures. Moreover, we estimate a red-shift of 10 cm^{-1} for the Amide II vibration coupled modes [5]. These red-shifts are mainly due to the breaking of hydrogen bonds, which can result in insurmountable barriers to refolding. Thanks to the large surface field enhancement and the precise methods of surface chemistry, we are able to demonstrate that SEIRA spectroscopy can provide real-time, high-sensitivity, label-free methods for monitoring the protein unfolding in a simpler and cheaper fashion, against traditional experimental methods which are expensive and complicated to use.

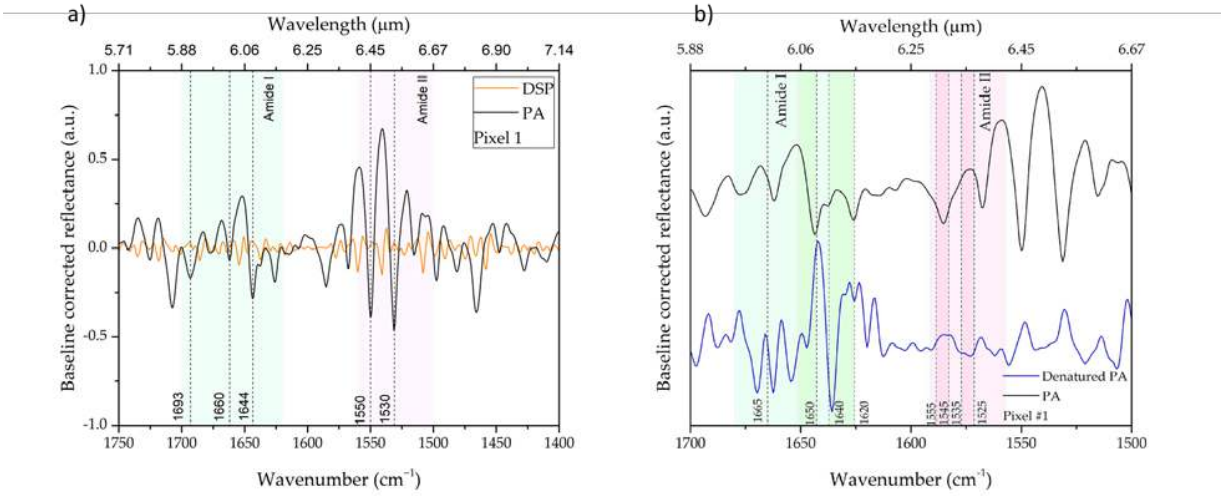

Figure 1: SEIRA reflectance spectra: a) orange curve refers to the spectrum acquired after the DSP incubation, while black curve refers to the reflectance response after the PA layer binding; b) comparison between the SEIRA spectrum of native PA (black curve) and of the denatured PA (blue curve) [5].

Abstract: Innovative goods authentication strategies are of fundamental importance considering the increasing counterfeiting levels. We propose a hybrid plasmonic/photonic multilayered structure working as a three-level strong Physical Unclonable Function. Our approach combines a functional nanostructured surface, a resonant response and a unique chromatic signature together in one single device. The proposed architectures could also be used as an irreversible and quantitative temperature exposure label in the framework of food safety. They are inexpensive, scalable and can be deposited over different substrates.

The Organization for Economic Co-operation and Development (OECD) certified that the trade in counterfeit goods is rapidly increasing. New technologies and approaches are, therefore, required. In this respect, a great promise is held by the so-called Physical Unclonable Functions (PUFs).[1] PUFs are physical signatures whose intrinsic unpredictability produces a unique and unclonable response to a specific challenge. PUFs owe their specifics to unavoidable randomness in fabrication processes, over which the manufacturer has no control. In this respect, micro- and nano-fabrication processes represent the ideal framework where to look for user-independent randomness. On the other hand, good-labeling approaches based on colors and iridescence proved their validity in countless applications. The emerging technological framework of plasmonics allows to unify these two approaches. At the nanoscale, indeed, plasmonics is synonym of "color", even though a specific tint results from an optical resonance, rather than a pigment.[2] Here, we propose a hybrid photonic/plasmonic system as a three-levels strong PUF.[3] The proposed plasmonic architecture, sketched in Fig. 1a, provides three different authentication levels: (i) chromatic (Fig. 1b), (ii) spectral (Fig. 1c), and (iii) morphological (Fig. 1d). The technological core of the idea lies in silver nano-islands (Ag-NIs) obtained by depositing Ag layers below their percolation threshold, via a DC

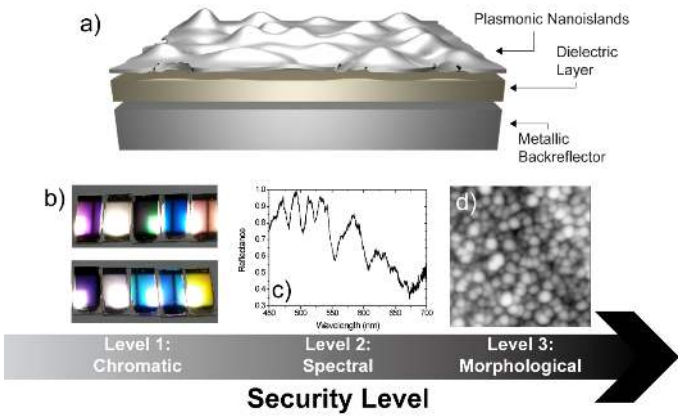

Figure 1 - a) Sketch of the Plasmonic PUF architecture. b) Chromatic and lightness effect (Level 1 - chromatic signature). c) Typical spectral response of a sample resembling the architecture shown in a). (Level 2 - spectral signature) d) Ag-NIs morphology revealed via AFM analysis (Level 3 - nanoscale morphological signature).

magnetron sputtering technique. Such a procedure allows to obtain Ag nanoclusters whose density and size depend on the sputtering deposition parameters, but whose spatial disposition and clustering is random. Ag-NIs unify a marked chromatic response with a peculiar plasmonic behavior. We demonstrate that, when used as the top layer in a multilayered configuration involving also metal/insulator/metal (MIM) resonators, the interplay between photonic cavity resonances and plasmonic modes gives rise to a glaring and distinct chromatic response. Such a property, combined with a marked iridescence, gives rise to a unique chromatic response, that cannot be reproduced by commercial paints, representing the first level of authentication of the proposed PUF. These chromatic properties stem from the spectrally rich optical response of the proposed architecture (Fig. 1c), which we characterized both by sophisticated ellipsometric measurements and by using the LED flash lamp of a smartphone in a simple spectroscopic setup. In the end, the strongest and most innovative authentication level is given by the morphological fingerprint, which is constituted by the spatial disposition of Ag-NIs (Fig. 1d). The morphology of a precise area of the patterned sample surface has been investigated through Atomic Force Microscopy (AFM) measurements and registered as a fingerprint to be compared with those of different areas by an imaging recognition algorithm. We found that the number of tags recognized by comparing two images of the same area acquired through two different AFM measurements is 2 orders of magnitude larger than the number of tags recognized by comparing AFM measurements belonging to two different areas of the patterned surface. In the end, we demonstrate that our plasmonic PUF could work as a thermal exposure label. We show, indeed, that, when the sample is exposed to temperatures higher than a certain threshold, its color and optical response change dramatically and irreversibly in a deterministic and quantitatively measurable way.

Abstract: Label-free and nondestructive mid-infrared (MIR) vibrational hyperspectral imaging is emerging as an important biomedical tissue analysis tool. However, the chemically complex and heterogeneous composition of tissue specimens limit analytical performance of conventional MIR spectral histopathology. We introduce an advanced MIR spectrochemical tissue imaging modality using plasmonic metasurfaces supporting strong surface-localized electromagnetic fields to capture quantitative molecular maps of large-area brain tissue sections. Our surface-enhanced chemical imaging method is well-suited to impact translational biomedical research and diagnostic clinical histopathology.

Developing sensitive and specific analytical tools to capture the sub-wavelength biomolecular information within the complex biological media using light is one of the main challenges of the biophotonics field. Label-free and nondestructive MIR vibrational spectroscopic imaging (MIRSI) is emerging as an ex-vivo digital tissue analysis tool that can provide spatially resolved biochemical information. Thus far, many reports have shown its prospects targeting diagnostics of a large cohort of diseases [1,2]. However, the chemically complex and spatially heterogeneous composition of tissue specimens and the inherently weak interaction of infrared light with biomolecules limit the analytical performance of MIRSI hindering its potential impacts on the biomedical sciences.

In this work [3], we present plasmonic metasurface-enhanced MIR spectral imaging (SE-MIRSI) as an advanced label-free chemical tissue-imaging method (Fig. 1). We demonstrate MIR spectroscopy of murine brain tissue sections, interrogating nanoscale thicknesses over large areas using engineered photonic substrates and a hyperspectral imaging microscope with illumination from four tunable QCLs (Fig. 1a). To satisfy the critical requirement of multiplexed molecular fingerprint analysis of SE-MIRSI, we developed polarization-tunable multi-resonant plasmonic metasurfaces that enhance light-matter interactions in sub-wavelength volumes over our target spectral range of 950–1800 cm^{-1} (Fig. 1b). We reveal how tissue morphology affects quantitative chemical analysis by comparing absorbance from numerous vibrational bands, measured from murine brain tissue sections of different thicknesses, ranging from 20 μm to 80 μm, mounted on standard CaF_2 substrates and plasmonic metasurfaces. We show that SE-MIRSI is not affected by bulk morphological properties of complex tissue samples because the absorption is constrained to the plasmonic hotspots: nanoscale volumes with strong enhancement of the electric field intensity (~1.4×10^3). We also show that SE-MIRSI can detect fine spectral details corresponding to protein backbone structures, as well as other important biomolecules, such as glycogen, nucleic acids, proteins, and lipids (Fig. 1 c). Finally, we show that SE-MIRSI enables chemical analysis of ultrathin brain tissue regions, which are not otherwise detectable on standard substrates, underscoring the high analytical sensitivity of our approach. Our method, for the first time,

addresses a well-known quantitative analysis limitation of infrared absorption spectroscopy by decoupling chemical and morphological properties and enabling highly sensitive and chemically selective analysis of complex and heterogeneous biosamples. Our chemical imaging method is versatile and can be used to study any tissue type with potential applications in fundamental research and clinical histopathology.

Abstract: We present a study of biocompatible gallium nanoparticles using STEM-EELS on a single particle level showing that they support plasmon resonances in the ultraviolet to visible spectral region. Moreover, we introduce a study of complementary plasmonic antennas designed using Babinet's principle and demonstrate spectral changes in the localized surface plasmons resonances when introducing variations in the parameters of a nearby dielectric analyte.

Localized surface plasmons (LSP) are self-sustained collective oscillations of free electrons in metal nano- and microstructures coupled to the local electromagnetic field. The mapping of LSP resonances with high spatial and energy resolution is necessary to understand their origin and properties. Scanning transmission electron microscopy (STEM) combined with electron energy loss spectroscopy (EELS) has become a standard technique to map LSP resonances in individual nanoparticles with a nanometer spatial and good energy (in our case 0.1 eV) resolution [1]. In this contribution, we will discuss LSP resonances in biocompatible gallium nanoparticles and we will explore the use of Babinet's principle in plasmonics for sensing.

Gallium is commonly known as a metal with a melting temperature of 29.7 °C. It is non-toxic and rather friendly to the environment. It has several solid-state phases which enable a variety of phase-changing systems which are under investigation. The bulk plasmon energy of gallium is 13.7 eV and it has in the liquid phase no interband transitions in a wide region from ultraviolet to infrared, which makes it an ideal plasmonic candidate. We have explored the plasmonic nature of its nanoparticles and shown that its plasmon resonances can be tuned from the ultraviolet to the visible spectral region by simply changing the size of the nanoparticle [2].

Babinet's principle originates in the wave theory of light and analysis of diffraction. Moreover, it is a classical EM theory that considers perfect electric conductions. In plasmonics, it relates the properties of a planar plasmonic antenna (particle) and a complementary aperture in a thin metal film of the same size and shape. In particular, the energies of LSP resonances in both antennas shall be identical and the corresponding near fields shall be complementary with the electric field distribution of the solid antenna corresponding to the magnetic field distribution of the complementary aperture [3–5]. This link allows studying the magnetic near field, for example, by measuring the electric near field by EELS in the complementary structure [6].

In this communication, we make use of Babinet's principle to design and demonstrate the performance of plasmonic sensors. We will explore the dimers of gold nanodiscs and the dimers of disc-shaped apertures in a gold film. Our recent efforts to understand their performance in terms of LSP resonances span from numerical to experimental demonstrations. We will also discuss the potential of these plasmonic nanostructures to be used as sensors by observing spectral variations of their LSP resonances depending on the thickness and refractive index of a dielectric analyte introduced on/into the plasmonic structure [7].

Numerical and experimental, studies of complementary plasmonic antennas designed using Babinet's principle will be presented. Spectral changes in the localized surface plasmons resonances will be demonstrated when introducing variations in the parameters of a nearby dielectric analyte.

Abstract: The study of novel plasmonic nanopatterns are of great interest for different applications including biological investigation and sensing. In this work we design, fabricate and characterize periodic arrangements of a novel metamolecular cell based on gold nanoelements. We tested their SERS performance analyzing different analytes among which a SARS-CoV-2 (COVID-19) Spike Antibody. Our results suggest that these plasmonic patterns are promising to develop nanodevices for the analysis of biological samples.

Development of nanostructures based on plasmonic functionalities is of great interest for a range of applications including optoelectronic devices, sensing and platforms to improve the performance in spectroscopic measurements [1, 2]. The ability to manipulate and control visible and infrared light using nanopatterns based on different geometries of metallic elements has been used to realize displays, filters, and anti-counterfeiting and sensing systems with unique and outstanding properties [3, 4]. In case of biological applications, many nanoscale systems based on gold nanoelements have been designed and tested in several research works for the study and detection of various kinds of biological analytes, giving appreciable results [5-7]. Plasmonic properties associated to the nanostructure can be tuned by changing the size and the shape of the nanoparticles or the periodicity or, more in general, the geometry of the nanopattern. These features are key to many applications aiming at signal enhancement and low threshold sensing. In this work we present a study of periodic arrangements of novel plasmonic metamolecular unit cells made of triangular nanoelements. Their plasmonic properties were firstly analyzed through numerical simulations using the finite element method (FEM) approach and their size were optimized appropriately, Successively, the nanostructures analyzed were fabricated using electron beam lithography technique (EBL) that allows to create patterns with high repeatability and accuracy. Morphological analysis was realized by Scanning Electron Microscopy (SEM) and their plasmonic properties were studied and compared using experimental set-up for Localized Surface Plasmon Resonance (LSPR) and Surface Enhanced Raman Spectroscopy (SERS) measurements. We finally tested the sensing performance of our nanostructures by detecting both Norovirus and a Spike Antibody SARS-CoV-2 (COVID-19) obtaining its

molecular fingerprint and developing some functionalization strategies for both of them on the surface of the nanopatterns under consideration. The experimental activities were realized in the frame of the projects "SERSCov-Advanced Nanobiosensing platforms for diagnostics and POC surveillance" funded by POR Campania FESR 2014/2020 (CUP B53C22003100002) and "H2OSafety-Design and development of environmental sensors for the research of microbiological and chemical contaminants hazardous to health" funded by the National Fund Sviluppo e Coesione (FSC) Proof of Concepts projects (POC01_00109).

Our preliminary results suggest that the considered plasmon nanopatterns are promising for the development of devices for rapid, label-free and high-sensitivity detection of biological analytes and, moreover, they can be integrated with other on-chip chemical/biological devices to realize portable points-care-tools.

Development of plasmonic platforms for sensitive and selective detection of macromolecules for food-quality assessment and environmental monitoring

G. Rusciano[1*]

[1] *Department of Physics "E.Pancini, University of Naples "Federico II"* - Naples, Italy.
[*]corresponding author: giulia.rusciano@unina.it

Abstract: Surface-Enhanced Raman Spectroscopy is a powerful analytical technique which allows high sensitivity and chemical specificity thanks to the fingerprint character of Raman spectra. Herein, we present the development of novel silver-based SERS substrates endowed with relevant plasmonic performances and their use for the detection of species of environmental interest (Polycyclic Aromatic Hydrocarbons) and relevant for food-quality monitoring (melamine and lipopolysaccharides).

Nanostructures supporting surface plasmon resonance (SPR) have been widely used for sensing and biosensing applications, being at the base of different techniques, including surface-enhanced Raman spectroscopy (SERS). In the last years, SERS has attracted a high interest for the effective detection of analytes across a wide range of scientific and technological fields. Alongside the label-free nature and molecular specificity deriving from the chemical fingerprint character of Raman spectroscopy, SERS can benefit of the great amplification of Raman signals for molecules in close proximity of proper plasmonic nanostructures, allowing even the single-molecule detection. The amplification is mainly due to the excitation of the localized surface plasmon resonances (LSPRs), which originates from the resonant collective oscillation of conduction electrons on noble metal nanostructured surfaces. Since the SERS substrate plays a key role, that explains the efforts are still underway for the development of nanostructured films that are easy to produce, reproducible and with high Enhancement Factor (EF), being the latter typically of the order of 10^4-10^8.

In this work, a novel approach has been followed to fabricate highly porous SERS substrates: the process consists of three steps, schematically depicted in Fig. 1, and described in detail in [1]. In the first step, a cleaned glass coverslip (15x15 mm^2) is sequentially coated with 3 nm Cr, 10 nm Au and 30 nm Ag by magnetron sputtering. The Cr/Au bilayer assures a high adhesion of Ag layer to the underlying layer. In a second step, the substrate is exposed to an inductively coupled plasma (ICP) in synthetic air atmosphere (power = 18W, p = 0.4Torr, exposure time = 90 s). As a matter of fact, the reactive oxygen species produced in the discharge give rise to the morphological evolution of the surface metal through complex surface physics mechanisms, which leads to a high porous nano-patter, resembling to a coral-like structure (Fig.1(b)). While oxygen is crucial for nanopattering, it gives rise to the oxidation of the material which reduces its plasmonic properties. Therefore, in a third step the substrate is exposed to a further ICP treatment but using Argon as gas process (exposure time = 50 s). This step has revealed very effective in the removal of oxide layer by preserving the pristine nanotexture. Globally, our protocol produces substrates with an excellent spatial reproducibility, EF larger than 10^7, and a broad-band optical response in the Vis-NIR spectral range, which enables Raman band amplification even at wavelengths quite far from the Raman probe wavelenght.

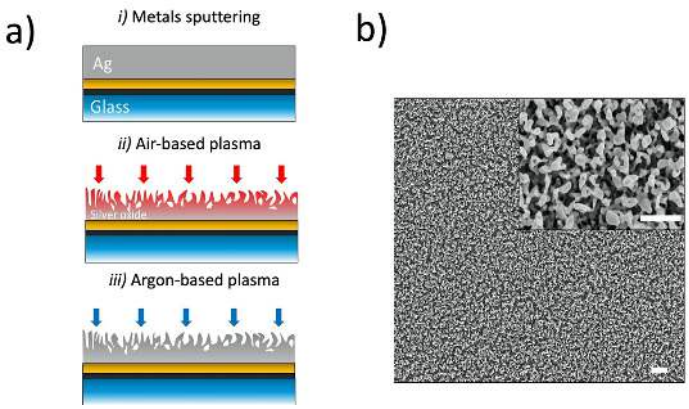

Figure 1: a) Schematic representation of the SERS substrates fabrication process. b) SEM image of SERS substrate (scale bar=1 μm). The inset shows the magnification of the SEM image (scale bar=500 nm).

These substrates have been successfully employed for the detection of chemical species relevant for the environment and food safety. Among these, of particular importance for environmental issues are Polycyclic aromatic hydrocarbons (PAHs), cancerogenesys species mainly originating from the incomplete combustion of fossil fuels. Despite the apolar nature of the PAH, our substrates are able to detect them in water without any functionalization of the surface, reaching a limit of detection (LOD) of ~ 20 nM for pyrene (PYR) [2].That because, the nanoporous nature combines a high density of hotspots with the capacity to trap PAH molecules through not covalent bonding, facilitating their adhesion to the metallic surface. In perspective, our outcomes demonstrate the high potentiality of our approach for chemical sensing and environmental control applications.

Our SERS substrates have also been used for the detection of lipopolysaccharides (LPS) in complex matrices. LPS are macromolecules consisting of lipidic and polysaccharide groups that are bacterial toxins. They are released by bacterial cells when they integrate. In order to assure a selective LPS detection in complex environment, our substrate was coated with an LPS antibody (Ab@c-SERS). LPS was revealed by the analysis of the slight modification of the antibody Raman bands. Interestingly, a detection limit of a few ng/mL was achieved.

Finally, SERS studies have been done for the detection of melamine, a toxic, nitrogen-rich chemical used for adhesives and glues but also illegally added to foodstuff (such as milk for infant) to increase apparently the protein content.

Optical metasurfaces with hybrid TE-TM collective resonances for spectroscopic applications

R. Kolkowski[1*] **and A. Shevchenko**[1]

[1]Department of Applied Physics, Aalto University, P.O.Box 13500, Aalto FI-00076, Finland
[*]corresponding author: radoslaw.kolkowski@aalto.fi

Abstract: Due to their narrow spectral bands, collective resonances of periodic metasurfaces are of growing interest in many areas of photonics. Here, we investigate collective resonances that emerge from coupling between TE and TM modes via plasmonic nanoparticles in a metasurface-based slab waveguide. We show that these hybrid resonances can provide high local field enhancement and high quality factors, which makes such plasmonic-photonic metasurfaces especially promising for applications in spectroscopic sensing and detection.

Optical resonances are essential for many photonic applications, such as spectroscopy, metrology, laser technology, nonlinear optics, etc. The quality factor Q is directly related to spectral width, $\Delta\omega$, of the resonance, or the damping rate γ ($Q = \omega/\Delta\omega = \omega/2\gamma$). Periodic metasurfaces can support high-Q resonances known as Surface Lattice Resonances (SLRs)[1] which result from multiple scattering of light by periodically arranged structural units of the metasurface (meta-atoms).[2] Of particular interest are dark SLRs, such as those that form quasi-bound states in the continuum (quasi-BICs).[3] Their coupling to external radiation can be controlled by tuning the symmetry of the structure towards a desired tradeoff between a high excitation efficiency and a low radiative loss.

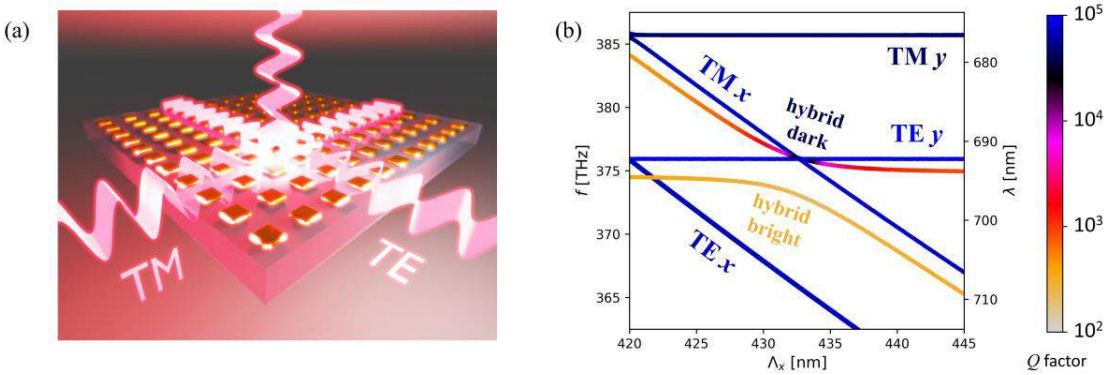

Fig. 1. (a) Illustration of a metasurface (a slab waveguide coupled to a plasmonic nanoantenna array) supporting hybrid TE-TM resonances. (b) Eigenmodes of a metasurface at normal incidence ($k_x = k_y = 0$) with varying lattice period Λ_x and fixed $\Lambda_y = 420$ nm, calculated using COMSOL Multiphysics.

In this work, we consider periodic metasurfaces on a slab waveguide in which multiple scattering is mediated by the guided modes of the waveguide.[4] In the absence of nano-scatterers, the waveguide supports mutually orthogonal TE and TM modes. These modes can be efficiently mixed by periodically arranged nano-scatterers on the waveguide surface. The nano-scatterers give rise to SLRs with band edges at the 2nd Bragg condition (resonant wavelength $\lambda_{res} = \Lambda n_{eff}$, where Λ is the lattice period and n_{eff} is the effective mode index). These SLRs can be excited by light at normal incidence. The resonance condition along a given lattice direction is different for TE and TM modes due to their different mode indices ($n_{TE} \neq n_{TM}$). However, by tuning the

periodicity Λ independently along the two orthogonal lattice directions (Λ_x and Λ_y), the resonance conditions for the TE and TM modes can be matched (e.g., $\Lambda_y n_{TE} = \Lambda_x n_{TM}$). Figure 1(b) shows the anti-crossing of TE and TM resonances in the presence of resonant nano-scatterers (gold nanoparticles) creating two hybrid TE-TM resonances: a red-shifted low-Q bright resonance and a blue-shifted high-Q dark resonance. The latter forms accidental degeneracies with completely dark modes whose field profiles "avoid" the nano-scatters. Near the degeneracies, the Q factor of the hybrid TE-TM resonance is boosted even further. At the same time, the local field enhancement at the nanoparticle surface and inside the waveguide remains relatively strong, as can be seen in Fig. 2(a). In addition, the field profile, shown in Fig. 2(b), does not resemble any of the conventional modes, but constitutes a mixture of the TE and TM modes.

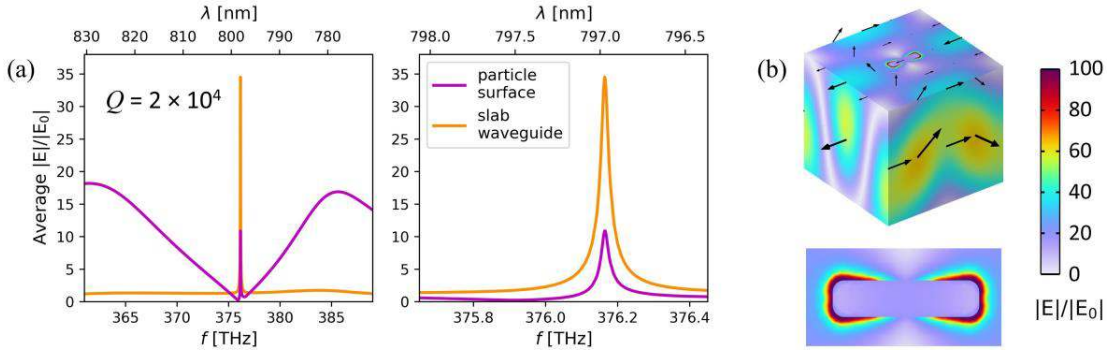

Fig. 2. (a) Spectra of the average field enhancement at the surface of a gold nanoparticle (magenta) and inside the waveguide (orange) under normal incidence illumination for $\Lambda_x = 432$ nm and $\Lambda_y = 420$ nm. The dark hybrid resonance at 376.2 THz exhibits $Q = 2\times10^4$. (b) On-resonance electric field distribution inside the waveguide and around the particle. Calculations are done using COMSOL Multiphysics.

Because of a high Q factor and strong field enhancement, the TE-TM collective resonances presented above can be used in spectroscopy, especially surface-enhanced Raman spectroscopy. Moreover, the mechanisms underlying their formation are very general, enabling one to choose a proper material platform and optimize the metasurface design for specific purposes. Experimental realization of such metasurfaces is one of the current goals of our ongoing research.

Plasmonic sensing for application in food science and eco/nanotoxicology

Duncan S. Sutherland[1]

[1]Interdisciplinary Nanoscience Center (iNANO), Aarhus University, Aarhus, Denmark

corresponding author, E-mail: duncan@inano.au.dk

Abstract:

Nanosized sensors based on the local refractive index sensitivity of plasmonic nanostructures can be applied to study interactions occurring at biointerfaces relevant for understanding proteins interactions in eco and nanotoxicology and in food science. Different functionalized plasmonic sensor designs will be described to study bio-interactions. Projects include detection of contaminants in milk via refractive index sensors and SERS, quantification of astringency in wine and the study of protein coronas in nanotoxicology.

Summary:

Metallic nanostructures supporting plasmon resonances are proposed and applied as enabling materials for bio and chemical sensors. Refractive index sensing structures at structures with appropriate functionalization can be applied for detection of molecules and bacteria through specific interactions [1,2]. For some applications such as in the food area, non-specific interactions or aggregate interactions from many different poorly specific interactions are responsible for important and measureable effects (such as sensations) requiring mimicking interfaces to provide useful sensing function. Measuring of astringency in foods and wines is complicated process typically carried out by panels of tasters and develops over the lifetime of the food. Here quantifying of specific (bio)molecules does not typically give a measure of the effect since it is an aggregate effect from many components. Plasmonic sensors can be used as multifunctional sensors allowing both refractive index measures and other spectral readouts. Here different plasmonic elements will be described as well as functionalization with biomolecules or molecular imprinted polymers to allow the study of both specific and non-specific interactions.

Examples of sensor development and designs relevant for food science and eco and nanotoxicology will be given. The first will relate to quantifying astringency in wine. Quantification of interactions of polyphenols with saliva proteins can be carried out via refractive index readout and correlated to conformational change of the proteins which are the initial steps in the sensations caused by astringency [1]. Approaches to capture biomimetic saliva coatings via MIPs allow both the classification of wines but also the study the role of individual polyphenol components from wine in causing astringency [3]. A second example will involve detection of contaminants in milk either bacteria (s. aureus) via aptamer functionalized plasmonic disk refractive index sensors [4] or disk/crescent cavity nanostructures for SERS detection of antibiotics, A last example with show quantification of protein and biotransformations relevant for nano and ecotoxicology where weak and strong interactions of proteins at different sites of silver nanocubes are studied via plasmon resonances [5] and related to biotransformations altering nanoparticle cytotoxicity [6].

Abstract: This presentation will introduce our research activities in plasmonic nanobiosensing, where we use metallic nanoparticles to develop LSPR and SERS sensors for a series of applications. This paper will highlight our latest developments for sensing off-flavors in maple syrup and neurotransmitters involved in neurochemical processes.

Our research lies in the areas of plasmonic materials, low-fouling surface chemistry and instrumental design for biosensing. This presentation will focus on applying these concepts for several classes of sensors, such as for monitoring off flavors in maple syrups and our recent development of sensors for in tissue measurement of neurotransmitters. In the first example, AuNP were optimized to aggregate in presence of maple sap or syrup presenting off flavors. The sensor was tested with more than 30,000 maple syrups in the lab and at the maple sugar shacks by producers (Figure 1). In a second embodiment of our research, we are currently exploring the concept of optophysiology using plasmonic nanopipettes for monitoring living cell secretion events. Due to the lack of analytical techniques for detecting metabolites near living cells, developing tools to monitor cell secretion events remains a challenge to overcome in chemical analysis. Plasmonic nanopipettes were developed based on the decoration of patch clamp nanocapillaries with Au nanoparticles (Figure 2). The plasmonic nanopipette is thus competent for dynamic SERS measurements in the liquid environment near cells. We combine this technique with machine learning to identify spectral differences in analytes and in different conditions. This nanobiosensor was tested with the detection of small metabolites near living cells and of neurotransmitters released by neurons.

Abstract: Optomechanical resonators have been successfully applied on a variety of sensing applications. Here we propose combining the optical and mechanical signals provided by this kind of devices, in order to increase their sensitivity and reliability. In particular, we use nano-optomechanical disks fabricated out of GaAs. They support high quality optical and mechanical modes that allow for high accuracy measurements. First, we apply the dual sensing technique for monitoring environmental changes. Then, we focus on the detection of single nanoparticles.

Over the last years, optomechanical resonators have stood out in terms of sensing since they exploit both optical and mechanical modes, combining the extraordinary sensitivity of optical resonator sensors and the reliability of mechanical ones. Here we use optomechanical resonators for two different sensing applications: environmental monitoring and nanoparticle detection. In particular, we employ semiconductor disk resonators fabricated out of GaAs. Optically, disk resonators support the so called whispering gallery modes (WGMs), which couple very efficiently with a particular family of mechanical modes, the radial breathing modes (RBMs) (Figure 1) [1].

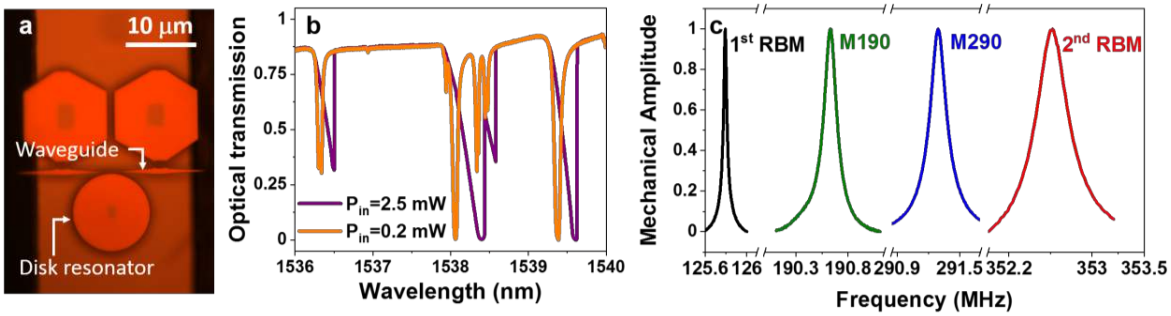

Figure 1: Optical and mechanical resonant modes. a*. Optical microscope image of a GaAs disk resonator of radius 11 μm and thickness 200 nm, together with its integrated waveguide and supporting structures.* ***b****. WGMs of the disk measured at different input powers: 2.5 mW (purple) and 0.2 mW (orange).* ***c****. Mechanical spectrum measured at 2.5 mW. Specifically, it shows the resonances associated to the 1st and 2nd RBMs (black and red) and two other in-plane modes labeled as M190 and M290 (green and blue).*

The in-plane nature of the motion associated to RBMs provides them excellent assests when operating in air, and even, in liquids [2]. For monitoring environmental changes, we employ a disk of 2.5 μm in radius and 320 nm in thickness. Figure 2 shows their optical and mechanical response to temperature and humidity changes. Taken into account the Allan variance, we demonstrate very high resolution reaching 1 mK and 0.1%, respectively. Notably, combining optical and mechanical sensing, enables disentangling temperature and humidity effects [3]. For nanoparticle (NP) detection experiments, in order to increase the capture area and, thus, the efficiency, we employed

disks having 11 μm in radius and 200 nm in thickness. Figure 3 shows the optical and mechanical response of a device, when a single polystyrene nanoparticle (70 nm in radius) is adsorbed. The dual sensing approach allows accessing the NP optical and mechanical properties [4].

Abstract: Optical forces can be used to trap, manipulate and push micro and nanoparticles. In this work we will discuss the realization of aggregates of plasmonic nanoparticles by optical pushing, aiming at the high-sensitivity sensing of biomolecules and microplastics.

High-sensitivity detection of contaminants is an important task in fields such food safety and environmental monitoring. In this work, it will be shown how optical [1] and thermophoretic forces [2] can be exploited to create aggregates of plasmonic nanoparticles directly in liquid environment on flat [3] and curved surfaces [4] of different nature [5], in short times (tens of seconds) and without special preparation. The aggregates are active sites for the Surface Enhanced Raman Spectroscopy of proteins and toxins [6], decreasing their ordinary Raman limit of detection in solution by several orders of magnitude. Moreover, thermal gradients due to the heating of the plasmonic aggregates induces thermophoretic fluxes, which concentrate the microplastics dispersed in the liquid and improve their detection [7].

Abstract: Acute myocardial infarction is the most serious cardiovascular illness; threatening human lives for decades. Its fast diagnosis can considerably improve the patient's prognosis as well as survival, thus a great amount of effort is directed to the development of biosensing technologies, which are able to efficiently and accurately detect the cardiac troponin biomarkers, the gold standard in detecting myocardial injury. Therefore, we developed a microfluidic plasmonic chip for the fast and accurate real-time detection of the cardiac troponin I biomarker.

Specifically, the fabrication of a plasmonic nanoplatform is based on immobilized gold nanobipyramids, which exhibits optical and thermoplasmonic properties that favour a multimodal localized surface plasmon resonance (LSPR) & surface enhanced Raman spectroscopy (SERS) & thermal detection of the cTnI biomarker. The plasmonic nanoplatform is characterized in terms of LSPR and SERS sensitivity and the thermoplasmonic performance is evaluated. Based on a sandwich-like immunoassay, the "proof-of-concept" LSPR-SERS-thermal detection of the cTnI in simulated conditions is evidenced. Furthermore, after the integration of the plasmonic nanoplatform in a microfluidic channel, the determination of the cTnI in real plasma samples is successfully realized and compared with a conventional high-sensitivity clinical assay proving good correlation. Thus, the proposed portable and miniaturized microfluidic plasmonic chip is validated for clinical applications supporting the further transfer to clinical settings for the early diagnosis of cardiac diseases and progress of personalized medicine.

Abstract: We discuss numerical simulation and optimization methods and their application to models of optical light scattering from plasmonic nanostructures. Agreement between experimental results and corresponding numerical results is discussed for various settings.

Modern fabrication methods allow to fabricate plasmonic nanostructures at high accuracies. This in principle allows for highly efficient plasmonic devices in which electromagnetic field energy may be concentrated to very small volumes. Results from theoretical physics provide models which accurately describe physical processes in complex setups. However, in order to reach efficient designs which optimize specific interactions, numerical simulations and optimizations are frequently used, as these can be applied to arbitrary geometrical settings, are significantly easier to realize than experimental optimization setups, and may provide additional insight.

In this contribution we will discuss numerical simulation methods and machine learning based optimization algorithms (1,2) which have recently been developed in our group. In particular, hp finite element methods and Bayesian optimization based on Gaussian processes will be discussed. We will discuss recent applications of these methods to various nanoplasmonic and nanophotonic settings. These include nanoplasmonic, chiral and achiral setups for sensing, photo-chemistry, and photovoltaics (3-8). We will in particular focus on chiral interactions in plasmonic setups assembled by DNA-origami.

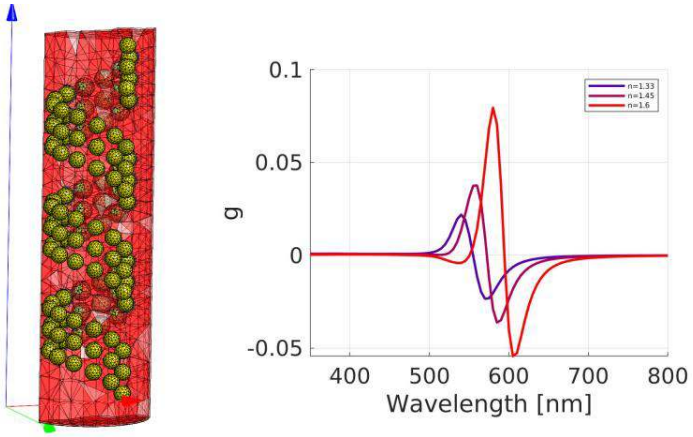

Figure: (Left) Visualization of a FEM model of a chiral arrangement of plasmonic nanoparticles. (Right) Wavelength-dependent chiral response (g-factor) for varied refractive index of the background material (blue: n=1.33, purple: n=1.45, red: n=1.6), obtained in numerical simulations.

Mass customized optical metasurfaces

A. Kristensen*

[1]DTU Health Tech, Technical University of Denmark, DK-2800 Kongens Lyngby

*corresponding author: akri@dtu.dk

Abstract: Fabrication costs may limit applications of optical metasurfaces. This may be addressed by mass customization where identical metasurfaces or meta-film templates are manufactured by low-cost replication techniques, such as nanoimprint lithography, and differentiated for specific optical functionality by post-processing. High resolution and high throughput structural color prints as well as transparent flat optical elements are demonstrated.

This paper describes up-scalable fabrication of optical metasurfaces for ink-free color decoration and flat optics by post-processing homogenous template surfaces [1].

Our optical metasurfaces are based on the concepts of both localized surface plasmon resonances (LSPR) [2,3] and high-index dielectrics [4] compatible with technologies for high volume manufactured plastic products [5]. The optical metasurfaces are formed by nanoimprinting a surface texture comprising nanoscale cylinders. By subsequent deposition of a thin film of metal or high index dielectric, isolated nano-disks are formed on top of the cylinders, while a continuous film is formed on the substrate surface in between the cylinders. The nano-scale disks and corresponding holes in the continuous film form optical resonators. The master-original for the square-centimeter nano-texture is realized by means fast e-beam writing [6]. The nanotextured plasmonic metasurface may be covered with a transparent protective coating, which can withstand the daily life handling.

Laser post-writing can modify disks and holes, and hence the optical resonances [4,7]. Laser pulses induce transient local heat generation that leads to melting and reshaping of the imprinted nanostructures. This enables flexible definition and alignment of optical components on high volume manufactured plastic products [8]. Our approach offers a printing speed of 1 ns per pixel (in raster scan), resolution up to 127,000 dots per inch (DPI) and power consumption down to 0.3 nJ per pixel.

A cost-effective and lithography-free method for printing optical meta-films was also demonstrated [9]. It is based on resonant absorption of laser light in an optical cavity formed by a multilayer structure of ultrathin metal and dielectric coatings. A nearly perfect light absorption is obtained via interferometric control of absorption and operating around a critical coupling condition. Controlled by the laser power, the surface undergoes a structural transition from random, semi-periodic, and periodic to amorphous patterns with nanoscale precision. The reliability, upscaling, and subwavelength resolution of this approach are demonstrated by realizing metasurfaces for structural colors, optical holograms, and diffractive optical elements.

This work was in part supported via the EC funded project ODYSSEY (Grant agreement ID: 951899).

Bright-field imaging of nanoscale bioparticles with Gire-Tournois photonic platform

Young Min Song

[1]Electrical Engineering and Computer Science, Gwangju Institute of Science and Technology, Gwangju 61005, Korea
[*]corresponding author: ymsong@gist.ac.kr

Abstract: we propose a novel approach to quantify nano-sized bioparticles by combining nanophotonics and deep learning (DL). We employed Gires-Tournois (GT) resonators as an immunosensor platform functionalized with antigen-specific antibodies without labelling or amplification. Based on the GT resonator, nanoscale bioparticles are dynamically detected and the number of particles is inferred from optical microscope images by a convolutional neural network as a vision-based DL model.

Biological imaging techniques have revolutionized the field of biomedical research by enabling the visualization and quantification of biological tissues. Various imaging modalities have been developed to achieve high resolution and accurate quantitation, including confocal microscopy, two-photon fluorescence, second harmonic generation, Raman spectroscopy, Fourier-transform microscopy, and electron microscopy. While these techniques have been successful in advancing biomedical research, their widespread use is limited by the need for sophisticated equipment and professional expertise. Recently, advanced nanophotonic technologies have been developed for microscale cell imaging applications such as colorimetric histology and ptychographic phase microscopy by utilizing plasmonic-based nanostructures. Moreover, nanophotonic sensors based on surface-enhanced Raman scattering (SERS) and surface plasmon resonance (SPR) have been studied by signal-based approach rather than imaging techniques. Meanwhile, recent advances in artificial intelligence have also revolutionized biomedical research, with machine learning and deep learning (DL) algorithms offering new opportunities for image classification, computer vision, and natural language processing. Specifically, the subfield of machine learning has seen significant growth in recent years, with convolutional neural networks (CNNs) demonstrating superior object categorization skills that model human vision. Although these algorithms have been successfully applied to various biomedical applications including biopotential signals and cell counting, they have not yet been properly applied to nanoscale bioparticles such as viruses and proteins.

Here, we present an intuitive method for quantifying nanoscale bioparticles by leveraging the fields of nanophotonics and DL. The Gires-Tournois (GT) resonator composed of three thin films, aimed at a 100-nm-diameter SiO_2 nanosphere, facilitates dynamic colorimetric sensing[1-2]. The DL model, which is trained with diverse structures of nanoparticle (NP) clusters with ground truth density maps from the scanning electron microscopy (SEM) images, infers the effective number of NPs in the optical microscopy (OM) images. The GT resonator was functionalized with an antigen-specific antibody, enabling utilization as an immunosensor without labeling and amplification. Therefore, viral NPs can be counted through the commercial bright-field microscope without any accessories. In addition, the DL model was trained with further hard negative samples to filter out irrelevant information and obtain only the desired data. We confirmed that our system showed the comparative limit of detection (LoD) with existing diagnostics. Also, the pre-trained model is applied to the diverse sizes of analytes in the range of zoonotic viruses using transfer learning with high transferability. We expect that this biosensing system could be deployed as a screening diagnosis in preparation for emerging viruses, saving time

and costs in clinical applications.

Abstract: The advent of optical neural interfaces in neuroscience research has boosted the scientific community to devise novel methods and systems to interrogate brain cells and neural circuits. A promising approach relies in the use of light-matter, for both sensing and triggering neural activity. In this presentation we will describe our technology to fabricate different types of plasmonic structures on an optical neural implant, for enhanced bio-sensing, beam-manipulation and opto-thermal heat delivery in the brain.

Optical methods to control and monitor neural activity represent one of the most diffused techniques in neuroscience labs to study functional connectivity in the living mouse brain. However, the brain tissue is characterized by a high scattering coefficient and a therefore a very short photons free path, making sub-cortical regions very challenging to reach for microscopy-based methods. This has boosted the development of implantable optical neural interfaces, which represent a promising paradigm to both control and monitor neural activity with high spatio-temporal specificity. In this framework, the interest of the scientific community has recently put its spotlight on the possibility to use light-matter interactions to communicate with brain cells, aiming at increasing the number of functionalities that can be integrated in a single device. Surface plasmon polaritons represent a promising candidate for this aim, since they allow to establish a peculiar interaction between light radiation and conduction electrons to implement both triggering and sensing capabilities.

We will present our approach to generate surface plasmon polaritons (SPP) on different types of implantable fiber optics. This is obtained by exploiting the peculiar features of multimode optical fibers (MMF) to control how guided modes couple to plasmonic resonances, for enhanced bio-sensing, beam-manipulation and opto-thermal heat delivery in the brain.

Firstly, we will describe the tapered optical fibers (TF) technology. A TF is a step-index MMF gently tapered for a few millimeters down to a tip smaller than 1μm in diameter [1]. This peculiar shape reduces tissue invasiveness with respect to standard optical fibers, and it has the unique features of generating a widely-extended non-planar surface on which guided modes can interact with nanometric structures conformally laying around the waveguide [2]. To fabricate plasmonic structures on the non-planar surface of the taper, we have employed both top-down and bottom-up nanomachining. Focused ion beam milling (FIB) was used to obtain sub-diffraction apertures on a metal thin film and generate extraordinary optical transmission to control the spectral and angular patterns of optical transmission [3]. Non-planar repeated dewetting was instead employed to obtain sub-10nm plasmonic hotspot and perform sensing of neurotransmitters through surface

enhanced Raman spectroscopy, down to a detection limit of 10^{-7} M for both dopamine and serotonin [4]. An alternative method to control how guided modes interact with nanostructures fabricated at the terminal end of an optical fiber, relies in using wavefront shaping. In the second part of the talk we will describe how phase-only spatial light modulators at the input of a flat-cleaved MMF can be used to control the workpoint of the coupled system in the dispersion diagram [5], paving the way toward multifunctional plasmonic neural interfaces.

Nanophotonics for biosensing: development of optical platforms for high sensitivity and specificity

G. Palermo
Department of Physics, NLHT-Lab, University of Calabria and CNR-NANOTEC Istituto di Nanotecnologia, 87036 Rende, Italy
*corresponding author: giovanna.palermo@unical.it

Abstract: Plasmonics is a branch of optics that deals with the study of surface plasmons. These plasmons can be used to manipulate light at the nanoscale, allowing for the development of novel devices for applications in sensing, imaging, and information processing. One important application of plasmonics is the development of plasmonic biosensors, which can detect and quantify the presence of molecules as biomarkers with high sensitivity and specificity.

It is well known that pathological tissues release a whole series of compounds into the vascular system, such as circulating DNA, extracellular vesicles, proteins, metabolites and so on. Going for early detection of these analytes in blood or other body fluids could allow to detect a disease when it is really in an early stage, giving the possibility to intervene promptly.

For this reason, it is necessary to develop sensing platforms capable of detecting very small concentrations of analyte, that are of the order of femtomolar or even in the attomolar range.

Plasmonic metasurfaces play a key role in the development of the next-generation nanophotonic biosensors, which can detect and quantify the presence of molecules with high sensitivity and specificity. The metal surface is typically patterned with nanoscale features, such as nanoparticles or nanoholes, that can support surface plasmons.

These sensors work by measuring the changes in the plasmon resonance of a metal surface caused by the binding of analyte molecules. The shift in plasmon resonance can be measured using various optical techniques, such as reflectance or transmission spectroscopy, and can be used to detect and quantify the presence of analyte molecules.

The highest sensitivity for a plasmonic biosensor can be achieved by optimizing the design of the sensor to maximize the interaction between the analyte molecules and the plasmonic field. Our research group addresses this challenge by developing next-generation nanophotonic biosensors based on surface plasmons and metamaterials.

In this talk, I will present some of our recent efforts in these directions [1-4]. I will show how the sensitivity of a plasmonic biosensor can be influenced by the design of the sensor surface, such as the density, the size, and shape of the metal nanostructures on the surface.

I will describe ultra-compact, rapid, and low-cost nanophotonic microarrays and their use for early disease diagnostics in real-world settings. I will also highlight chiral plasmonic metasurface that can improve the sensitivity of biosensors by using specialized CD techniques, such as resonance-enhanced CD or surface plasmon-coupled CD, which can enhance the signal-to-noise ratio and improve the detection limit.

Abstract: Organophosphate pesticides are neurotoxic chemical compounds, widespread in the environment due to agricultural and domestic use. They are a major cause of cancer and some neurological diseases such as Alzheimer's and Parkinson's. Their detection in food and in the environment requires complex and expensive equipment and highly specialized operators. This has sparked growing interest in developing multifunctional platforms that can both detect and detoxify these hazardous agents. In this work we present a Poly (dimethylsiloxane) - gold nanoparticles composite thin film for detection and degradation of organophosphorus neurotoxins.

Pesticides are widely employed in agriculture to manage pests and increase productivity to address the rising demand for food, but they are equally hazardous to species that are not their intended targets, including humans. [1] Therefore the development of highly sensitive, stable, and responsive detection technology for such toxic agents is crucial for environmental and public health protection.

Polymer composites with embedded metal nanoparticles (NPs) can offer an ideal solution for detection purposes, by converting chemical or biomolecular information into a physically readable signal. The surrounding environment sensing ability of the plasmonic NPs can be exploited, while the polymer matrix holds and stabilizes the NPs allowing the loading of small molecules. Polydimethylsiloxane (PDMS) is an appealing polymeric matrix in this context, thanks to its properties, including chemical inertness, biocompatibility, mechanical flexibility and stability, optical transparency in the VIS and UV region, and most importantly, its simplicity of processing. AuNPs can be used in optical sensors thanks to the localized surface plasmon resonance (LSPR) phenomenon, the collective oscillations of delocalized electrons in response to an external electric field, by measuring changes in the refractive index of the surrounding media with high sensitivity. [2] The fabricated nanocomposite film was suitably functionalized to maximize the adsorption and at the same time trigger the degradation of the organophosphate pesticide (OP). For this reason, the enzyme phosphotriesterase was used, which can bind and detoxify OP and toxic chemical agents from the same class of chemical compound.

The obtained PDMS-AuNPs film was fully characterized. The loading and hosting ability of the PDMS-AuNPs film was tested by using a fluorescent dye as a model system. The LSPR sensing performances of the nanocomposite films were tested by systematic monitoring the UV-Vis spectroscopic signal from the AuNPs.

The presented PDMS-AuNPs has shown promising sensing responses, and could be easily integrated in microfluidic chip to perform the accurate detection of low concentrations OP neurotoxins in environmental samples.

Abstract: In this communication, an overview of the applications of nanophotonic biosensors based on bound state in continuum is reported. Perspective exploitation of this new class of devices is also discussed.

In recent years, the use of Bound States in Continuum (BICs) in optical sensing applications is rapidly growing [1]. BICs are a type of resonant state that exists within a continuum of radiative modes, meaning that they are bound to the structure in which they exist but are not coupled to the external radiation. This unique property has made BICs a topic of significant interest in the photonics community. In particular, BIC-based sensors have shown exceptional sensitivity thanks to their high-quality factors that enhance the signal-to-noise ratio and provide a higher detection limit compared to conventional resonant sensors. Furthermore, these sensors have a great selectivity, which is due to the ability to tune the BIC wavelength to the desired sensing targets [3].

Our group has shown interesting potential application of BIC-based biosensors in detecting and quantifying various bio-molecules, including proteins, DNA [4], cancer cells [3], and toxins in food and environment [4]. An overview of such applications, developed in our laboratories, will be presented, with a particular emphasis on future perspectives, including the integration of BICs in microfluidic platforms, which can also enable the detection of multiple analytes in a single device.

Abstract: Optical biosensors hold potential for applications in numerous important areas. Herein, we discuss the main challenges in developing plasmonic biosensors for applications in biomedicine and present selected advances in biosensor research that aim to address these challenges. We cover advances in plasmonic nanostructures, sensor instrumentation, transport of target molecules in microfluidic systems, functional coatings, and detection assays. We also highlight applications of plasmonic biosensors related to the investigation of biomolecular interactions related to Alzheimer's disease and diagnosis of Myelodysplastic syndromes.

Au/Ag SERS active substrate for broader wavelength excitation.

Abstract: We present a two-stage process for developing dense Au-coated Ag nanoparticle arrays on ion-beam patterned nano-rippled Si substrates for broader range Surface Enhanced Raman Spectroscopy (SERS). These substrates show LSPR excitation in a broader wavelength range and good enhancement for 532 and 785 nm lasers. Results are qualitatively compared with FDTD simulations where the effect of interparticle gap and Au/Ag layer thickness on their SERS enhancement is explored.

The SERS enhancement strongly depends on the excitation laser and LSPR wavelength. A substrate shows maximum enhancement when excitation frequency matches the LSPR wavelength [1]. Therefore, developing a substrate that shows a broad LSPR region is important. Recent progress in nanoparticles grown on ripples produced using low-energy ion sources shows good control over the tunability of the LSPR active region [2][3]. However, a substrate with good sensitivity for all wavelengths, from visible to infrared, must be addressed. In this work, we deposited ordered Au/Ag nanoparticle (NPs) arrays on low energy-produced rippled Si substrates [4]. The produced substrates show good SERS enhancement for 532 nm and 785 nm lasers.

In particular, nanoscale ripple patterns are fabricated on Si surfaces by irradiating 300 eV Ar ion beams for a fluence of 5×10^{18} ions cm^{-2}[5]. Following this, using e-beam evaporation, Ag-NPs are deposited on rippled Si substrates at an oblique angle of 70° to produce ordered arrays of Ag-NPs. Further, a capping layer of Au is deposited on Ag-NPs using magnetron sputtering. The wavelength and amplitude of rippled Si are analyzed using atomic force microscopy (AFM), as shown in ***Figure 1***(a). The average wavelength of the ripple patterns is ~28 nm. The size of Ag-NPs and Au capping thickness is varied to optimize the SERS efficiency. SEM micrograph of optimized arrays of Au/Ag-NPs is shown in ***Figure 1***(b). It is observed that with increasing thickness of the Au capping layer, the interparticle gap of Au/Ag-NPs starts decreasing, and finally, they are merged to make bigger NPs. STEM images confirm the presence of Au as a capping layer on Ag-NPs. For instance, ***Figure 1*** (c-f) shows the elemental mapping of Si, Ag, Au, and all together, confirming the Au capping on top of Ag-NPs. Further, the effect of Au coating on the optical response of Ag-NPs is studied using FDTD simulations, and it is observed that the LSPR peak is red-shifted after Au deposition. The simulated spectral response for the maximum electric field between two NPs along the ripple direction is depicted in ***Figure 2*** (a). The spectral response of Ag-NP arrays exhibits an LSPR peak at ~540 nm suggesting their activity for 532 nm laser excitation. Similarly, Au-NP arrays are suitable for 785 nm laser excitation due to the LSPR peak appearing at ~625 nm. On the other hand, Au/Ag-NP arrays can show excellent SERS efficiency for both laser excitations due to the presence of doubly LSPR peaks at ~525 nm and ~650 nm. Moreover, the maximum *E*-field is observed to be 16 Vm^{-1} for Au/Ag-NP arrays along the ripple patterns, which is ~2.5 times higher than bare Ag- or Au-NPs. Optical reflection measurement of Au/Ag-NPs along and across the ripple patterns also exhibits LSPR[***Figure 2*** (b)]. Using crystal violet dye as a probing molecule, SERS efficiency is examined, and it is observed that Au/Ag-NP arrays show excellent SERS enhancement for a 532 nm laser, which is comparable to the SERS enhancement of Ag-NP arrays. However, for 785 nm laser excitation, SERS sensitivity is very low for Ag-NP arrays, which is significantly enhanced for Au/Ag-NPs [***Figure 2***(c)]. The optimized SERS substrate

shows good spatial uniformity (RSD below 10%) with a detection limit of 100 pM and 100 nM for 532 and 785 nm lasers, respectively. A SERS enhancement factor of the order of 10^5 is observed for the 532 nm laser and 10^4 for the 785 nm laser. Thus, this study results in an optimized Au-coated Ag-NP arrays-based SERS substrate for excellent sensitivity in a wide range of laser excitations.

Abstract: We present a general and rigorous theory of chiral light-matter interactions in arbitrary optical resonators. Our theory describes the chiral interaction as a perturbation of the resonant states, also known as quasi-normal modes. We observe two dominant contributions: A chirality-induced resonance shift and changes in the modes' excitation and emission efficiencies. Our theory brings new and deep insights for tailoring and enhancing the chiral light-matter interactions. Furthermore, it allows to predict spectra much more efficiently in comparison to conventional approaches.

Detecting the handedness of chiral molecules is of utmost importance for chemical, biological, and pharmaceutical applications, since the handedness of a molecule determines its interaction with the environment. This includes chemical interactions as well as the interaction with light. Hence, it is possible to determine the handedness of chiral molecules by optical measurements, but the chiroptical response of such molecules is usually rather weak. Therefore, conventional approaches require using large numbers of chiral molecules.

Plasmonic nanoantennas and other nanophotonic resonators can enhance the chiroptical response. We have recently shown that the electromagnetic enhancement of the circular dichroism, which is the difference in absorption of left- and right-handed circularly polarized light, can be as high as three orders of magnitude [1]. Hence, plasmon-enhanced circular dichroism spectroscopy yields a promising approach for determining the handedness of even few molecules. However, little was known about the underlying enhancement mechanisms.

We close this gap and provide a theoretical understanding of chiral light-matter interaction that is based on the expansion of the nanophotonic response in terms of resonant states [2]. More specifically, we treat the chiral interaction as a small perturbation, which yields explicit expressions for the changes of the near- and far-field properties. Our theory reveals several contributions to the resonant enhancement of that interaction. The first one is a change in the excitation and emission efficiencies of the resonant states, which requires a coplanarity of the incident field and the dominant field components at the location of the chiral medium. The second one is a chirality-induced resonance shift, which surprisingly only occurs in chiral

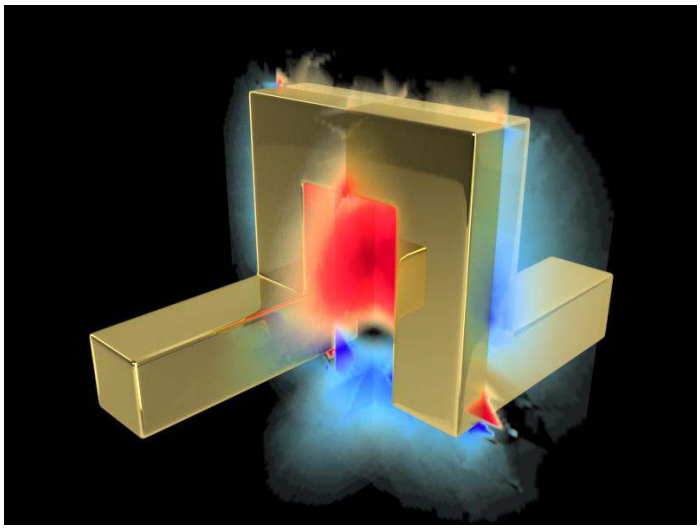

Figure 1. Local resonance shift per volume near a plasmonic nanoantenna. Positive/negative shifts (red/blue) require parallel/antiparallel electric and magnetic near fields [2].

spatial arrangements of the resonator and the chiral medium. We demonstrate that this contribution can be enhanced if we tailor the resonant electromagnetic near fields such that the electric and magnetic field components are either parallel or antiparallel, as in the case of the local optical chirality [3], see figure 1. The third contribution is based on an interplay of nearly degenerate resonant states. We find that this requires a thorough tailoring of the resonator geometry. In the perturbation regime, there is also a non-resonant contribution, which, however, is – as all higher-order contributions – usually negligible. Furthermore, only odd orders of perturbation theory allow for a handedness discrimination. Finally, we show that the coupling of quasi-degenerate modes can allow for a boost in sensitivity.

Hence, our theory allows for analyzing the different electromagnetic contributions to chiral light-matter interaction and for gaining a better understanding of resonantly enhanced chiroptical spectroscopy. Finally, it should be noted that our theory is not limited to chiroptical spectroscopy but can be applied to any sort of optical sensor that traces changes of the electromagnetic response such as the refractive index of an analyte material [4, 5].

High-Fidelity Reprogrammable Signal Processors Built Off the Anti-Laser

Philipp del Hougne

Univ Rennes, CNRS, IETR—UMR 6164, F-35000 Rennes, France
philipp.del-hougne@univ-rennes1.fr

Abstract: Achieving high-fidelity reflectionless (as opposed to merely low-reflection) excitation of complex scattering structures at specific frequencies is notoriously difficult, in particular if the frequency of operation is supposed to be reconfigured during runtime. We demonstrate that the combination of (i) overmoded systems with (ii) a massive amount of tunable degrees of freedom (provided by a programmable metasurface) enables high-fidelity reprogrammable reflectionless excitation of complex structures. Building on this technique, we demonstrate reprogrammable analog signal differentiation and reflectionless signal routing.

The reflectionless excitation of an arbitrarily complex scattering structure at a frequency ω_0 is possible if the system's scattering matrix $S(\omega_0)$, or a filtered version $R(\omega_0)$ thereof, has a zero eigenvalue [1]. If $S(\omega_0)$ has a zero eigenvalue, injecting the corresponding eigenvector yields coherent perfect absorption of the incident radiation [2]. This phenomenon is also referred to as "anti-laser" because it is the time-reverse of lasing at threshold; however, reflectionless excitation is compatible with steady-state operation in linear systems whereas lasing requires non-linear effects to respect energy conservation.

In general, neither S nor R can be expected to have any real-valued zero, let alone at the desired real frequency ω_0. Many groups have carefully designed simple scattering structures involving a single or few resonances in order to impose a real-valued zero at a desired frequency. However, such approaches are vulnerable to fabrication inaccuracies and environmental perturbations, and they lack in-situ reconfigurability. Adding one or a few tunable degrees of freedom (DoFs) to such structures allows one to tune the zero's position, however, there is in general no guarantee whatsoever that the zero remains on the real frequency axis upon tuning, and indeed it usually drifts away.

We have taken a presumably unexpected approach to overcome these difficulties that differs in two ways from the conventional approach outlined above since we work with:

1) an overmoded scattering enclosure with many modes instead of a single-mode or few-mode system.
2) a massive parametrization (100s of programmable-metasurface DoFs) instead of zero, one or few DoFs.

Thereby, we are able to achieve unprecedented fidelity (we reach reflected powers below -70 dB) and unprecedented flexibility (we can arbitrarily redefine ω_0 in situ) in imposing a reflection zero at a desired frequency [3].

After demonstrating how this technique can enable **physical-layer security in wireless backscatter communications** [3], we leverage this technique to implement challenging signal processing tasks in the analog domain:

1) First, we demonstrate high-fidelity **reprogrammable analog signal differentiation** with experimental in situ observations [4]. Moreover, thanks to the linearity of the wave equation, we can parallelize this wave-based mathematical operation by simultaneously imposing real-valued zeros at multiple distinct

frequencies [4].

2) Second, we demonstrate **reflectionless programmable signal routing** [5]. Here, in addition to suppressing the reflection, we must satisfy additional constraints such as transmission of the injected signal to specific ports and not to others. We report experimental in situ observations of reflectionless wavelength demultiplexing and other functionalities. Our reflectionless signal router can be reprogrammed both with respect to its operating frequencies and to its routing functionality [5]. Reflectionless signal routers remove the risk that reflected-power echoes pose for non-linear components like amplifiers in RF and nanophotonic networks, and thereby they remove the need for the to-date customary approach of preventing reflected-power echoes with isolators or in-line attenuators.

Quantum and thermal aspects of coherent perfect absorption

I. Liberal[1*]

Abstract: Coherent perfect absorption (CPA) is an interference phenomena that allows for linear photon-photon interactions, an abstract concept that can be implemented in multiple technological platforms including metasurfaces, photonic integrated circuits and plasmonics. In our talk, we will discuss quantum and thermal aspects of CPA including quantum states transformations, noise-management and the design of optical amplifiers with a reduced noise factor, as well as the practical implementation of those concepts within an integrated photonics setup.

Coherent perfect absorption (CPA) is an interference process where the proper combination of several input signals cancels out all output signals, leading to complete but phase dependent absorption [1-2]. Experimental demonstrations of CPA include technological platforms such as thin-films and metasurfaces [3-4], photonic integrated circuits [5-6] and plasmonic devices [7], laying a fertile ground for exploring applications in the fields of linear photon-photon interaction for all-optical data processing [8], sensing and quantum optics [9]. While the multiple aspects of CPA in linear optical devices have been actively investigated, quantum and thermal phenomena associated with CPA have received less attention.

In our talk, we will review our latest results on quantum and thermal aspects of CPA. In recent works [10-11], we reviewed quantum states transformations enabled by CPA, including single-photon CPA, two-photon nonlinear absorption, coherent absorption of N00N states, and absorption and manipulation of coherence in squeezed coherent states of light. Moreover, we demonstrated that by using an integrated photonics Wilkinson power divider (WPD), such transformations can be implemented in optical networks with a smaller footprint and a reduced number of elements. We pushed forward the design of a pure silicon-on-insulator (SOI) WPD, which harness radiative losses to provide a WPD response [10]. However, the concept could also be implemented in plasmonic CPA systems [6-7], providing even a smaller footprint and mitigating potential coupling to other elements of the network.

Finally, we have recently investigated the noise performance of active optical networks containing CPA elements [12]. Our analysis uncovered a number of noise cancellation effects that lead to an improvement of the noise performance. In particular, we found that it is possible to design optical amplifiers whose noise factor beat the conventional (G-1)/G expression, where G is the noise of the amplifier [12].

A Massively Degenerate Coherent Perfect Absorber

Abstract: In the field of non-Hermitian photonics it is a well-established concept that a time-reversed laser acts as a 'coherent perfect absorber' (CPA). However, CPAs are usually limited to a single, judiciously shaped wavefront (`mode'). Here, we demonstrate how this limitation can be overcome by time-reversing a 'degenerate cavity laser', based on a cavity that self-images any incident light-field onto itself. Placing a weak, critically-coupled absorber into this cavity, ensures that any incoming wavefront is absorbed with close to perfect efficiency.

While light is readily absorbed by thick materials that we perceive as black, thin and weakly absorbing media are inherently far less efficient in capturing incoming radiation and converting it into heat or other forms of energy. A well-known strategy to make even such weakly dissipative substances strongly absorbing is to embed them into a resonant structure. At the so-called 'critical coupling condition', where the coupling strength to such a resonator is exactly balanced with the internal dissipation, the incoming field gets perfectly absorbed with no energy being back-reflected from the resonator. The price one pays for this interferometric enhancement of absorption is a severe restriction on the properties of the incoming field for which this critical coupling condition can actually be satisfied [1, 2]. In other words, at the critical coupling condition, only a single, suitably adjusted wavefront (or spatial mode) gets 'coherently perfectly absorbed'. While this required wavefront adjustment opens up the possibility to control the absorption process interferometrically, it also comes with the severe limitation that, apart from the correctly matched input wavefront, all of the possibly many other modes are only weakly absorbed due to the different interference patterns they create.

In our paper [3], we demonstrate how to entirely eliminate the limitation of the number of perfectly absorbed modes in a CPA. Our design principle for a corresponding multi-mode CPA is based on the insight that 'coherent perfect absorption' formally corresponds to the time-reverse of laser emission at the first lasing threshold. In the aim to create a device that can perfectly absorb arbitrary combinations of incoming modes interferometrically, one thus needs to time-reverse a laser that emits all of these modes in parallel. Such a laser, indeed, exists, and is known under the name of a 'degenerate cavity laser'. The degeneracy of modes in such a cavity is based on the special feature that the field on either one of the two outer cavity mirrors is self-imaged onto itself after one cavity round-trip. This is realized in a straightforward fashion by placing two lenses in an imaging telescope configuration inside the cavity (Fig. 1), ensuring coherent perfect absorption of any combination of modes, regardless of their relative phases (Fig. 2). Such a robust absorption mechanism presents an important advantage to a large number of potential applications.

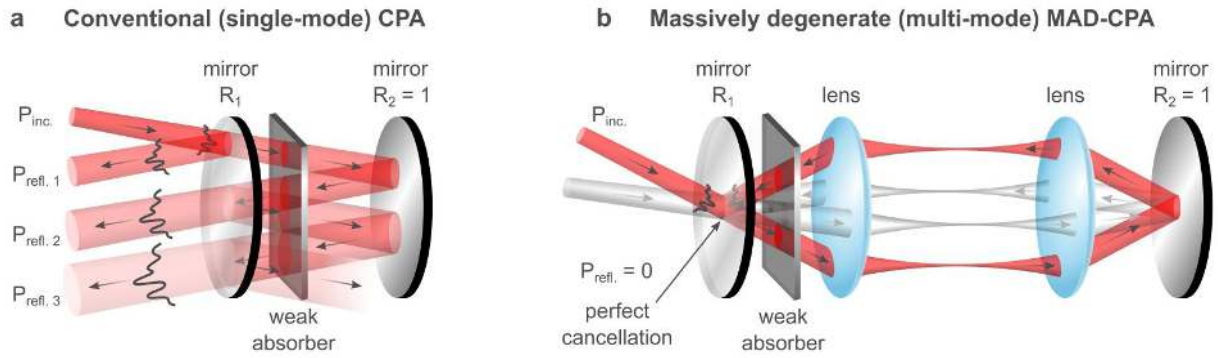

Figure 1: Concept of a massively degenerate coherent perfect absorber (MAD-CPA) for arbitrary wavefronts. ***(a)*** *A conventional (single-mode) CPA is composed of a weak absorber placed between two flat mirrors. While perfect absorption can be achieved for a normal-incident plane-wave via destructive interference of reflections, any other incoming mode, such as the simple tilted beam shown, results in multiple reflections that cannot destructively interfere.* ***(b)*** *In contrast, the massively degenerate multi-mode CPA can perfectly absorb any complex incident wavefront. This is achieved by placing the weak absorber in a degenerate (self-imaging) cavity, realized here by a conventional cavity with two lenses in a telescopic arrangement. In such a degenerate cavity, any complex input field impinging on the front cavity-mirror (R1) is self-imaged onto itself after each cavity round-trip: all reflections from the multiple cavity round-trips show perfect destructive interference with the outer reflection from the front cavity-mirror (here shown for two incoming beams at different angles), leading to perfect absorption of light in the weak absorber.*

Abstract: In this presentation we will review our recent works on using advanced interference phenomena to realize various effects in extremely thin metasurfaces.

The phenomenon of wave interference, discovered by Thomas Young, is in the core of the wave theory of light, developed by Fresnel and Huygens. Many effects due to wave interference in bulk media and in thin films are known for a long time. In recent years, coherent illumination of extremely thin lossy sheets was considered in [1], with two features highlighted: first, a possibility to absorb all incident power in a layer of negligible thickness and, second, an (obvious) possibility to change the response to one of the illuminating waves by changing the phase or amplitude of the other one. In this talk, we present a review of how coherent illuminations of purposely designed metasurfaces can bring novel, unusual, and useful properties. First, we will discuss coherent effects in non-uniform sheets and show how the incident power coming from coherent sources can be channeled towards non-specular directions in coherent retroreflectors [2]. If absorption is present, a sheet under coherent illumination can behave as a reflector or as an absorber depending on the angle of incidence, as presented in Fig. 1(a) [3]. Next, we will discuss possibilities to emulate bianisotropy effects (for example, omega coupling or chiral response) in simple isotropic metasurfaces. Such applications of coherent illuminations are illustrated in Fig. 1(b), where a single non-bianisotropic sheet can emulate asymmetric reflections under adequate coherent illuminations [4].

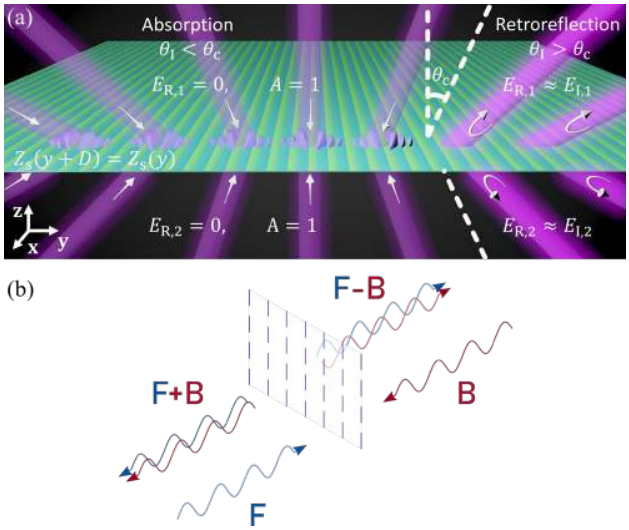

Figure 1. (a) A thin sheet can behave either as an absorber or a reflector by controlling the incidence angle of a coherent source. (b) A single non-bianisotropic sheet can replicate omega-coupling scattering under coherent illumination.

Abstract: The interference of quantum light on a thin absorber (e.g., a metasurface) leads to non-trivial phenomena such as single-photon Zeno and two-photon anti-Hong-Ou-Mandel effects with applications in light detection, communication, and metrology.

Common wisdom tells us that absorption is detrimental to the quantum properties of light and, accordingly, absorption is generally avoided as much as possible. Nevertheless, this rule has exceptions, with coherent absorption of quantum light being a bright example. The uniqueness of quantum coherent absorption relies on its selectivity: while some quantum states are effectively coupled to dissipative channels and are completely absorbed, other states are immune to absorption passing through the absorber without any changes. This mechanism provides a fruitful recipe: blend the properties of the absorber with different quantum states of light to unveil novel aspects of light absorption [1].

Here, we first consider the interference of single-photon states on a thin absorber [2]. In this experiment, the level of absorption depends not only on the relation between the absorber properties and the quantum state of the photon but also on the disclosure of which-path information. In the spirit of conventional single-photon interference on a lossless beamsplitter, which-path information destroys coherent control of absorption.

By exploiting the sensitivity of the absorber to the photon quantum state, we build a quantum state filter, a basic module of quantum experiments, and demonstrate a single-photon switching function of such a filter [3]. Discussion of quantum coherent absorption in terms of quantum states transformation opens the window for replicating this phenomenon on other quantum systems: as an example, we perform modeling of the quantum coherent absorption experiment using the transmon, a superconducting charge qubit of the IBM quantum computer [4].

One of the striking features of quantum coherent absorption is that may turn a probabilistic traveling wave absorption into a deterministic standing wave absorption. Deterministic light absorption is a must-have in numerous applications based on light-matter interaction. For instance, by treating the quantum network consisting of coherence-preserving quantum nodes as a *distributed* absorber, we show that a single photon can be deterministically absorbed within the network generating entanglement between the nodes [5]. Another application benefiting from efficient light absorption is quantum light detection. We demonstrate that distributed coherent absorption in multiple detecting layers, like superconducting nanowire single-photon detectors, allows efficient and photon-number resolving detection of quantum light, which is free of the limitations of conventional multiplexing schemes [6].

By distributing the absorption in time, rather than in space, we show that strong single-cycle coherent absorption is not equivalent to the multiple weak absorption cycles. A bizarre theoretical limit of an infinite number of absorption cycles, where the absorption of each cycle is infinitesimal suggests that absorption becomes zero despite the infinite number of absorption cycles. “Absorption is an illusion” – the ancient Greek philosopher Zeno would conclude. The proof-of-principal experiment of a few-cycle Zeno absorption experiment is presented.

Compared to single-photon states, multi-photon states of light provide even more flexibility in how light may interact with the dissipative channels of the absorber. Here, we consider the coherent absorption of entangled photons. While the conventional interference on a lossless beamsplitter – the prominent Hong-Ou-Mandel effect, results in the coalescence of bosonic particles and anti-coalescence of fermionic particles, the interference on a coherent absorber completely reverses the outcome. In the

experiment, we observe that entangled photons with symmetric spatial wavefunction (“bosonic” type) anti-coalesce and photons with anti-symmetric spatial wavefunction (“fermionic” type) exhibit coalescent-like behavior – the anti-Hong-Ou-Mandel interference takes place [7].

When one photon from the entangled pair interrogates the absorber, the absorption process can be controlled non-locally, for instance, via the geometric phase of the second remote photon from the pair. We report on the observation of such non-local control through the two-photon correlation measurements and discuss how it can be used in quantum metrology applications.

Finally, we briefly outline some general features of coherent effects in quantum light absorption, their origin, and how they would affect the absorption of other, more complex quantum states of light.

Non-Hermitian Wavefront shaping and Optical Limiting

T. Kottos

Wave Transport in Complex Systems Lab, Department of Physics, Wesleyan UniversityUSA
*corresponding author: tkottos@wesleyan.edu

Abstract: The underlying mathematical structures of non-Hermitian wave physics have inspired several recent applications. Among them are wavefront shaping protocols for efficient energy deposition at lossy targets and optical limiters based on lossy non-linear defects. An example of the first category is the coherent perfect absorption while of the second is the exceptional-point based photonic limiter. We shall explain the intimate connection between these two seemingly different concepts and present our experimental results that highlight the underlying mechanisms.

The development of non-Hermitian optics has led to new avenues for the manipulation of light transport. Examples include PT-symmetric photonics, hypersensitive sensors, unidirectional invisibility, non-reciprocal Bloch oscillations, Coherent perfect absorption, optical limiters and more.

Coherent perfect absorption (CPA) is a multichannel waveform shaping protocol which leads to a complete extinction of a monochromatic radiation when it enters a weakly lossy cavity. The scheme has been initially proposed in the framework of classical optics, as the time-reversed process of a laser. It relies on wave interference effects that entrap the incident radiation inside the lossy cavity, leading to its complete absorption. Subsequent studies nicely demonstrated the CPA implementation, beyond the original platform of optics, spanning all areas of classical wave physics ranging from microwave and RF to acoustics. In all above-mentioned cases, the CPA protocol demonstrated a narrow, resonant-based, (perfect) absorption with very sharp characteristics around the frequency of perfect absorbance. Obviously, addressing this ``deficiency" will open-up a whole new range of possibilities for the CPA scheme including solar photovoltaic or stealth applications. Importantly, the scheme was considering only linear scattering processes.

Here we analyze CPAs in two settings. The first one is associated with a CPA occurring at a chaotic cavity with one localized lossy target embedded inside. The second paradigm is involving nonlinear lossy elements. We show that in both cases CPA is still an effective protocol of targeted energy deposition despite the loss of hidden or geometrical symmetries and/or scale invariance (in the presence of nonlinear processes). In the latter case, we will show that CPA can be turned, using the incident field power as a control parameter, to a (relatively) broad-band phenomenon when the coupling of the system to the interrogating antennas is properly tuned. We have traced this broadband effect to the existence of exceptional point degeneracies (EPD) occurring in the spectrum of the zeros of the scattering matrix.

At the second part of the talk, we shall introduce a class of optical limiters based on concepts borrowed from non-Hermitian defect theory. We shall contrast this class of limiters to a novel proposal that utilizes EPDs in the spectrum of an auxiliary wave-operator (AWO) that describes a scattering process of completely transparent modes (TM). We will show that these modes can be utilized for the design of a non-resonant reflective photonic limiter in the visible range. The analysis of the AWO reveals that the formation of the TM-EPDs is a consequence of a “hidden” parity-time (PT) symmetry that characterizes this operator when the input and output channels are interpreted as effective radiative gain/loss. For low power incident radiation near the TM-EPD

frequency, the transmittance acquires a (near-)unity, flat-top lineshape. When the incident power increases, a self-induced permittivity variation enforces an explicit PT-symmetry violation of the AWO, which results in a destruction of the TM-EPD and an abrupt increase of reflectance to (near)-unity values.

Abstract: Two identical squeezed coherent states at the input ports of a 50% absorbing beam splitter do not show coherent perfect absorption (CPA). All coherence is lost, though, since at the output ports entangled squeezed vacuum states emerge. Remarkably, this output state is a pure state, although produced by a lossy device. Therefore this CPA gate could become a new tool for continuous-variable quantum state preparation. Moreover, for graphene multilayers engineered for CPA, we discuss the effects of interlayer separation.

We study coherent absorption of squeezed light by a 50% absorbing beam splitter [1]. Identical coherent states at the input ports of such a beam splitter lead to coherent perfect absorption (CPA): the output state is the vacuum state. Not so for identical pairs of squeezed coherent states, we find. We make a distinction between the loss of coherence and the loss of intensity, and show that corresponding absorption coefficients for quantum coherence and for intensity are different. This CPA gate has further intriguing properties: two identical but otherwise arbitrary incoming squeezed coherent states leave all of their coherence and half of their squeezing behind in the beam splitter, producing a pure entangled squeezed vacuum state as the output. This output state of light is not entangled with the lossy beam splitter by which it was produced. This surprising result may make the CPA gate a new tool for continuous-variable quantum state preparation.

Next we analyze absorbing beam splitters made by layers of graphene [2]. To achieve the 50% absorption needed for the CPA gate described above, we are in the "difficult" regime where we need more than a few layers of graphene on the one hand, but we are not necessarily in the bulk graphite limit either. To understand the absorption of a few layers of graphene, one typically uses the transfer matrix approach and neglects their subnanometer interlayer separation. Continuing to neglect this separation results in upper bounds to the absorption by graphene multilayers of 50%, exactly the value needed for coherent perfect absorption (CPA). This upper limit is only reached for real-valued sheet conductivities, and for pristine graphene the finite number of layers that would be required to attain this maximum is fixed by the fine structure constant. We show however that for the thicker multilayers needed to engineer 50% absorption, realistic interlayer separations need to be taken into account, in which case the upper bounds to the absorption at a finite number of layers no longer exist. More generally, more reliable predictions of the absorption by multilayer Van der Waals crystals suitable for CPA can be obtained if their subnanometer interlayer separations are carefully accounted for.

Many-body Quantum Metasurfaces with Coherent Perfect Absorption with PT Symmetry Breaking

Kyle Ballantine[1] **and Janne Ruostekoski**[1*]

[1]Department of Physics, Lancaster University, Lancaster LA1 4YB, United Kingdom
[*]corresponding author: j.ruostekoski@lancaster.ac.uk

Abstract: We theoretically show how a quantum metasurface of atoms can undergo coherent perfect absorption with an effective parity-time (PT) symmetry and non-exponential decay. The effective symmetry is achieved in delocalized collective excitation eigenmodes. These modes coalesce at exceptional points (EPs), evidenced by the emergence of coherent perfect absorption (CPA) where coherent incoming light is perfectly absorbed and scattered only incoherently. The system is versatile and can be modified for single-photon absorption and quantum storage.

Atomic physics technology provides a variety of approaches for trapping closely spaced atoms in arrays with single-site control and unit occupancy per site. For cold atoms with subwavelength spacing, the light-mediated interactions can be very strong due to resonant light undergoing multiple scattering between the atoms, when the realization of strong collective coupling in large resonator arrays of metasurfaces typically requires special arrangements. The first measurements of the transmitted light through an optical lattice of atoms have now been performed that demonstrate subradiant resonance narrowing where the entire lattice responds as a coherent collective entity.

Here we analyze a quantum-photonic surface formed by a single layer of atoms in an array with light mediating strong cooperative many-body interactions. We show how delocalized collective excitation eigenmodes can exhibit an effective PT symmetry and non-exponential decay. This effective symmetry is achieved in a passive system without gain by balancing the scattering of a bright mode with the loss from a subradiant dark mode. These modes coalesce at EPs, evidenced by the emergence of CPA where coherent incoming light is perfectly absorbed and scattered only incoherently.

By controlling atomic level shifts, a collective analogue of electromagnetically-induced transparency (EIT) can be constructed by coupling light dominantly only to two uniform collective excitation modes: a ‘bright mode’, with atomic dipoles coherently oscillating in phase in the plane of the array, and a ‘dark mode’, with the dipoles oscillating in phase perpendicular to the plane. As in a standard independent-atom EIT, the bright and dark modes couple strongly and weakly to radiation, respectively. However, here the microscopic origin of the dark mode is not single-atom interference, but collective many-body subradiance. We show that by balancing the loss of the dark mode with the scattering of the bright mode, the system becomes invariant to PT reversal. The collective eigenmodes of the system, which are linear combinations of the in-plane and out-of-plane modes, can then coalesce at the EPs, leading to spontaneous breaking of the PT symmetry of the eigenvectors, realizing CPA.

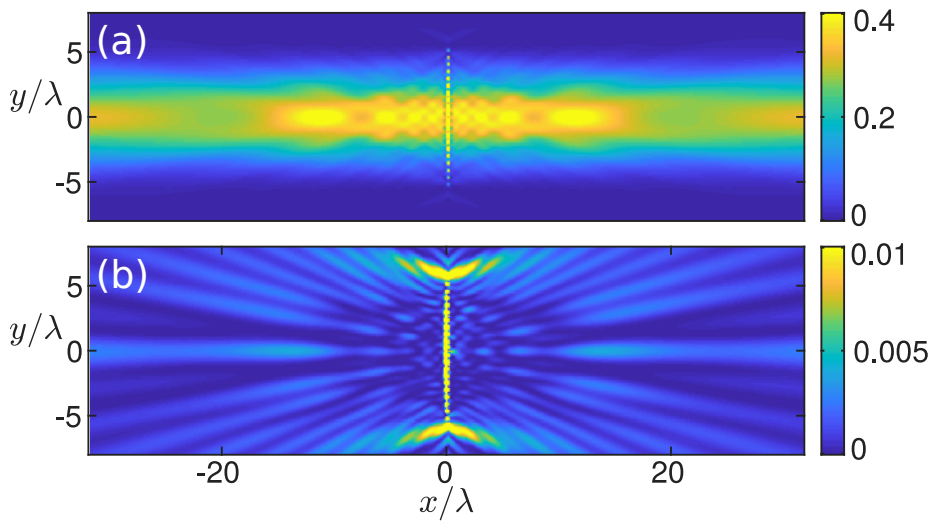

Figure 1: Spatial dependence of intensity for reflecting and CPA phases for a 20×20 atom array on the yz plane at x = 0. We show the total outgoing coherently scattered light intensity (a) in the absence of CA and (b) in the presence of CPA. The atomic arrays are illuminated by Gaussian laser beams propagating from both directions.

By generalizing the model for a bilayer lattice, we can show how the system can be used for single-photon absorption and quantum storage. The excitation can be stored in a subradiant state, transferred coherently between different subradiant states, and released, again in an arbitrary combination of highly collimated forward and backward propagating components. We explain the directionality of single and bilayer arrays by a symmetry analysis based on the scattering parities of different multipole radiation components of collective excitations.

Multipolar Coherent Amplification of Chiroptical Scattering and Absorption from a Magnetoelectric Core-shell Nanoparticle

Hsin-Yu Wu[1,2,*] **and Frank Vollmer**[1,2]

[1]Living Systems Institute, University of Exeter, United Kingdom
[2]Department of Physics and Astronomy, University of Exeter, United Kingdom
[*]corresponding author: h.wu@exeter.ac.uk

Abstract: We analytically and numerically demonstrate multipolar coherent amplification of chiroptical responses in the near-infrared wavelength regime via a magnetoelectric core-shell nanoparticle encapsulated in a monolayered optically-active substance. The proposed achiral core-shell nanoparticles can simultaneously support both multipolar electric and magnetic resonances, and thus collaboratively interact with the electric and magnetic components of the incident radiation, which enhances chiroptical signals at specific resonances in the presence of monolayered chiral substances and enables effective molecular chirality sensing at the nanoscale.

Plasmonic and dielectric nanostructures and nanoparticles are attractive in many fields of science and technology, and promising nanoscale tools for detection and analysis of the chirality (handedness) of molecules. Their optical, electronic/magnetic transition properties and resonant frequencies can be easily tuned and tailored by engineering the geometrical parameters to exhibit the desired near-field enhancement and far-field interference for achieving sensitive and reliable chirality sensing. Numerous approaches have been demonstrated, such as chiral and achiral planar nanoarrays/nanolattices, metasurfaces and nanoaggregates, for separation and identification of enantiomers at the specific resonant modes. Among them, the structurally achiral arrangements are highly preferable because each building block does not contribute to unwanted background signals so that the absolute measurement of chiral signals become feasible [1]. Although yielding decent enhancement in chiroptical signals, most of these chiral-sensing schemes only support either electric or magnetic resonances (or one is more dominant than the other). They have not taken into account the fact that the interaction of light with the chiral medium significantly relies on the coexistence of magnetic and electric, i.e. magnetoelectric, coupling implicitly implied by the bi-isotropic constitutive relations [2]. Therefore, the abovementioned chiroptical enhancements are limited since the effect of magnetoelectric coupling on the optical chirality is largely ignored and neglected. In this invited talk, we proposed a hybrid core-shell nanosphere composed of a metallic core and a dielectric shell to amplify the magnetoelectric interactions between the incident radiation and the multipolar electric and magnetic resonances of the nanosphere capped with a chiral monolayer. We derive analytically and verify numerically expressions that provide insight to the enhancement mechanism of the magnetoelectric coupling. The results of our work pave the way for use of achiral core-shell nanoparticles to efficiently boost the background-free chiroptical responses.

The authors acknowledge funding from the European Research Council under an H2020-FET open grant (ULTRACHIRAL, ID: 737071) and EPSRC (EP/T002875/1).

Beyond CPA: A General Theory of Reflectionless Scattering

A. Douglas Stone[1*], W. R. Sweeney[1], C.-W. Hsu[2], A. Alhulaymi[1] and P. Del Hougne[3]

Abstract: Coherent Perfect Absorption is one form of reflectionless scattering, involving transduction of an adapted input field. We present a general theory of reflectionless scattering, which includes CPA, based on choosing a subset of input channels and requiring no backscattering into them. We show that infinitely many such solutions exist at complex frequency, can be calculated efficiently, and can be made accessible via tuning a single structural parameter. Optimization of a parameterized structure can achieve high quality signal routing.

The discovery of Coherent Perfect Absorption (CPA) or time-reversed lasing drew attention to the existence of special non-scattering solutions of any linear wave equation, which exist in the complex frequency (ω) plane, and are the time reverse of the resonances (purely outgoing solutions of the wave equation). When gain is added to the system, a resonance can reach the real frequency axis, corresponding to the threshold for lasing in a single mode; conversely when equivalent loss is added, the incoming solution has a real frequency, corresponding to perfect trapping and absorption (or transduction). But this is true only for a specific input wavefront, adapted to the scattering structure, which is the time-reverse of the lasing mode. In the scattering matrix description, the input wavefront must be an eigenvector of the S-matrix with eigenvalue zero. The existence of such reflectionless input waves is guaranteed by the analytic structure of the scattering matrix, although they will only lead to a steady-state harmonic solution if the loss of the structure is carefully tuned. Often in wave physics, and particularly in electromagnetic systems, one is interested not in transduction of input signals, but in suppressing reflection and routing signals into chosen output channels. It is natural to ask if such solutions also exist and are robustly present as are the CPA solutions. In recent work we have shown that indeed any linear wave impedance matching problem can be framed in the a manner similar to CPA, and can also be shown to have infinitely many discrete solutions at complex ω, which can be tuned to the real axis (steady-state) with a single tuning parameter, leading to narrow-band resonant perfect impedance matching [1]. We refer to the complex reflectionless solutions as R-zeros, and the steady-state solutions as Reflectionless Scattering Modes (RSMs), in analogy to the terminology of lasing modes.

These R-zeros and RSMs exist independent of the complexity of the scattering structure (as long as it is finite) and of whether it is in free-space or accessed by guided waves. One of the insights from the theory is that reflectionless scattering is only possible if all the input channels are filled and coherently excited; similar to CPA only a special wavefront is scattered without reflection. The reflectionless scattering condition for the input modes mathematically implies that a submatrix of the scattering matrix has an eigenvector with eigenvalue equal to zero. One can show that each choice of submatrix (i.e. of input channels) leads to discrete complex solutions with spectra distinct from each other and from the resonances or zeros of the full scattering matrix. Importantly, these solutions can be

tuned to the real axis using structural or geometric parameters, without the necessity of using loss or gain, because the reflectionless condition does not inherently violate flux conservation. In the case of a single input channel with an isolated high Q resonance, this concept reduces to the familiar notion of critical coupling, but importantly it is exact and still valid when resonances overlap and the structure is relatively open, or highly damped. Finally, calculating the R-zeros of a particular structure is not significantly more difficult than calculating its resonances and in many cases can be implemented via a modification of the method of perfectly-matched layers (PML). Importantly one does not have to calculate the S-matrix and the relevant submatrix for many frequencies and search for solutions; a single computation yields the R-zeros over a wide bandwidth. In principle one doesn't need to compute the S-matrix at all, although typically this is helpful to do.

Once reflectionless states are found, it is very interesting to try to optimize or functionalize the states for routing functions. The reflectionless boundary conditions do not imply any constraint on the output field distribution, so one needs to build an optimization search on top of it to perform non-random forward scattering of the wavefront. Recently we have done exactly such a study in a massively parameterized microwave cavity with a reconfigurable metasurface [2]. We found that we could implement a demultiplexer with almost 40db of discrimination in such a system, as well as achieving other interesting routing functions which I will review in this talk. A simple example of such routing is shown in Fig. 1 below.

In addition to reviewing the structure and applications of the theory of RSMs, I will discuss the consequences of Parity-Time and other symmetries on the R-zero spectrum and the properties of exceptional points in the RSM spectrum.

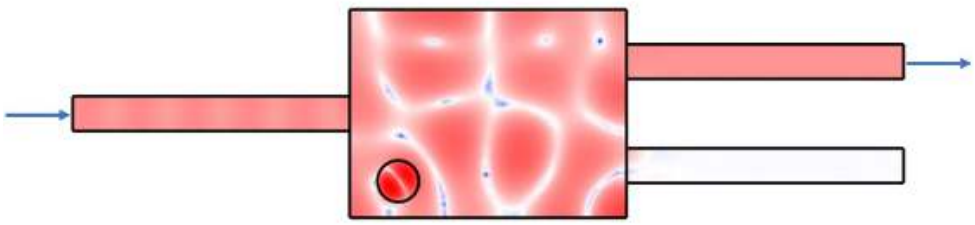

Fig. 1: Simulation of the field for reflectionless routing of a microwave signal into the upper output waveguide in a cavity with a scattering center, based on optimization of the scatterer location.

Abstract: In this contribution, we present a general methodology to manipulate the amplitude of an electromagnetic wave in a pre-defined way, without introducing any scattering. This leads to a whole class of isotropic spatially varying permittivity and permeability profiles that are invisible to incident waves. The theory is illustrated through various numerical examples, including the non-magnetic case. Also some new work on manipulating the wave phases and absorption of emission via multipole expansion is included in the hope to develop this methodology further.

Transformation optics [1, 2] is a powerful analytic tool to design impedance-matched material, which gives rise to scattering-free wave solutions up to designer's will. However, this method inevitably requires the material parameter to be anisotropic, which complicates its manufacturing process. Therefore, an isotropic material to achieve the required wave solution may solve this issue. We will demonstrate a method to design isotropic material parameters in an optical inverse problem. We will start from vectorial Helmholtz equations [3] and show how one can find some exact wave solution in a corresponding inhomogeneous medium, where light wave and medium come in pairs. After that we exploit further the idea to seek the pair of wave solution and material parameters: spatial profiles of permittivity and permeability.

We demonstrate examples of how to control wave front [4, 5]– whether maintaining it or varying it at our will. Our method is a general analytic tool to avoid unwanted scattering due to gradient-index profile of materials.

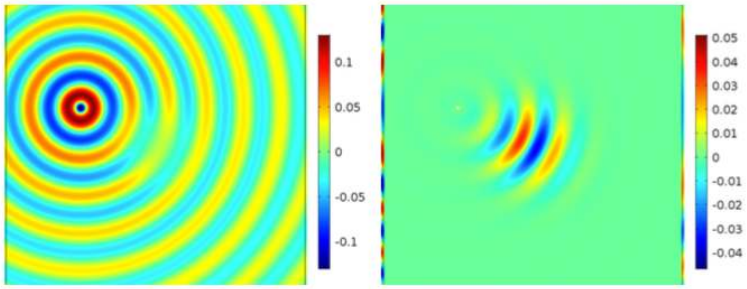

Fig. 1 An example of invisible materials for also a cylindrical wave.

Furthermore, we also demonstrate examples of how to control wave front in accurate way, and of an invisible current source which gives zero far fields at all.

Optical control of collective states in 1D ordered atomic chains beyond the linear regime

N. Fayard[1*], I. Ferrier-Barbut[1], A. Browaeys[1] and J.-J Greffet[1]

[1]Université Paris Saclay, Institut d'Optique Graduate School, France

[*]nikos.fayard@institutoptique.fr

Abstract: Driven by the need to develop new atom-photon platforms, people recently replaced cavities by large arrays of cold atoms that can support superradiant or subradiant collective states. In practice subradiant states are decoupled from radiation with constitutes a hurdle to most applications. In this work, we study a protocol that enables the deterministic coupling to subradiant modes in subwavelength atoms arrays.

Recently, a new scheme based on the local control of the transition frequency of atoms with light shifts has been proposed to store and manipulate single photon using the subradiant modes of a 2D array [1]. Motivated by the possibility to implement those idea with ongoing experiment using Sr, Yb or Dy, we study theoretically a similar protocol for 1D atomic chain [2]. More precisely, we propose a method to:

1. Excite the most superradiant singly-excited state of the chain from the far field
2. Transfer the excitation to the most subradiant state using a position varying detuning (PVD)
3. Store the excitation
4. Emit the excitation in the desired superradiant mode of the chain, thus controlling its frequency, emission rate and pattern.

In particular, we show that doubly-excited states follow a similar trajectory than singly-excited states. We thus demonstrate that they can be coherently transferred from superradiant to subradiant states, opening the way to the optical access of their entanglement.

Computational implementation of the hyper-Rayleigh scattering optical activity: theory, symmetry considerations and quantum chemistry applications

A. Bonvicini* **and B. Champagne**

Theoretical Chemistry Laboratory, Unit of Theoretical and Structural Physical Chemistry, Namur Institute of Structured Matter, University of Namur, B-5000 Namur, Belgium

Abstract: We performed the first computational implementation of the hyper-Rayleigh scattering optical activity (HRS-OA) spectroscopy, a nonlinear chiroptical method theoretically predicted by D. Andrews and T. Thirunamanchandran in 1979 [1]. Recent experiments on silver nanohelices and on molecular oligoamide foldamers confirmed this chiroptical phenomenon [2, 3]. Moreover, the measured circular differential scattering ratios make the HRS-OA a promising method for application in chiral discrimination problems due to its high sensitivity compared to other linear chiroptical methods like electronic circular dichroism.

This work reports on the first computational quantum-chemistry implementation of the hyper-Rayleigh scattering optical activity (HRS-OA) spectroscopy [1] which has been experimentally confirmed only recently [2,3]. First, from the basics of the theory, which is based on quantum electrodynamics, the equations for the simulation of the differential scattering ratios of HRS-OA are re-derived; in particular, the symmetry of the polarization and molecular tensors involved, the associated response functions of the latter, and the origin-invariance of the theory for exact wavefunctions are discussed. Then, for the first time, computations of HRS-OA quantities are presented and analyzed. They have been enacted on prototypical chiral organic molecules (methyloxirane, carvone) at the time-dependent density functional theory (TDDFT) level, using a broad range of atomic orbital basis sets. In particular, i) we analyzed the basis set convergence, demonstrating that converged results require basis sets with both diffuse and polarization functions, ii) we discussed the relative amplitudes of the 6 contributions to the differential scattering ratios, and iii) we studied the effects of origin-dependence and derived the expression of the tensor shifts. Our computations show the ability of HRS-OA as a nonlinear chiroptical method, able to distinguish between the enantiomers of the same chiral molecule.

Abstract: Resonant dielectric metastructures provide a game-changing platform for chiral optics: maximum-chiral metasurfaces are transparent to waves of a particular circular polarization and strongly interact with waves of the opposite polarization. High-quality chiral resonances enhance selectively diverse nonlinear optical transformations of circularly polarized light. Stacking chiral and achiral metasurfaces and mirrors one can build optical cavities which selectively detect/emit chiral light and open a door to chiral polaritonics and chiral electromagnetic vacuum prospectively facilitating chiral chemistry.

Chiral dielectric metasurfaces – planar subwavelength arrays of elements made of highly refracting transparent materials shaped to break the mirror symmetry – manifest unprecedentedly strong optical chirality approaching the fundamental limits [1-3]. Taking the advantage of controlled coupling of photonic bound states in the continuum (BICs) with free-space light, one can create quasi-BIC-metasurfaces with *maximum optical chirality* that are transparent to waves of one circular polarization and resonantly block their counterparts. In particular, rotationally symmetric quasi-BIC-metasurfaces, built as arrays of dimers of dielectric bars, can be maximum chiral absorbers [1]. Asymmetric arrays are capable of even better and purer maximum chirality, if their quasi-BIC eigenstate is decoupled from one circular polarization. Such quasi-BICs can be hosted by subwavelength-periodic square lattices of relatively simple unit cells containing pairs of dielectric bars of different height. Millimeter-scale ceramic bars arranged in this way fully transmit microwaves of one circular polarization and reflect the others [2]. Recent nanotechnology advances allow fabricating similarly designed arrays of silicon bars demonstrating maximum optical chirality in the near infrared range [3].

Generally, high quality factor resonances underpinned by quasi-BICs of metasurfaces amplify near electric fields and enhance numerous nonlinear-optical phenomena. For maximum-chiral metasurfaces, the circular polarization selectivity of excitation and emission of the quasi-BICs pave the way for various nonlinear-optical transformations of circularly polarized light waves. In particular, we consider how *circularly polarized high-harmonic* wave can be generated if its wavelength is matched to a chiral quasi-BIC. Alternatively, one can pump a metasurface at a chiral quasi-BIC wavelength and achieve *giant high-harmonic circular dichroism*. By comparing such processes we conclude that the best efficiency and chiral selectivity can be realized when several interacting waves are matched to chiral quasi-BICs, and, in the absence of rotational symmetry, arbitrary nonlinear co-polarized and cross-polarized chiral light transformations become possible.

All the flat-optical chiral components can be combined in *chiral cavities* supporting helical eigenmodes – standing waves with uniform chirality density. Here, apart from the geometrically chiral variants, also achiral structures, e.g., planar mirror-symmetric metasurfaces, selectively reflecting one circular polarization and transmitting the opposite while reversing its helicity, are also very useful [4]. We analyze different types of

metacavities built as stacked pairs of maximum chiral and/or mirror-symmetric metasurfaces and conclude that there are several combinations supporting helical Fabry-Perot eigenstates coupled to normally incident/outgoing circularly polarized waves. Such cavities have broad prospects for efficient generation and sensitive detection of chiral light as well as for its chiral nonlinear conversion. By expanding the set of tools for chiral light-matter interactions, they open a door to chiral polaritonics and chiral electromagnetic vacuum prospectively facilitating chiral chemistry [5].

Finally, we analyze simpler cavities consisting of a metasurface and an ordinary metal mirror. While it is unclear how they could sustain chiral cavity modes at normal incidence, there are clear advantages of such arrangements operating in oblique directions. In such a case, the metasurface may even lack intrinsic structural chirality but exhibit instead strong resonant extrinsic optical chirality. Then stacking an achiral metasurface, built as a square array of silicon triangular prisms, with an ordinary metal mirror creates a cavity selectively coupled to obliquely propagating circularly polarized free-space waves. This allows designing ultracompact chiral light sources based on thin layers of electroluminescent material confined inside such cavities [6].

Abstract: We report the use of polarization resolved hyper Rayleigh scattering to identify the chiral elements of the first hyperpolarizability tensor of small metallic nanoparticles. This operation is performed in gold nanoparticles ensemble measurements directly in liquid suspensions using an elliptically polarized fundamental beam. Several nanoparticle shapes are discussed and directions towards single nanoparticle measurements proposed.

Quantitative characterization of the physical properties of nano-objects with dimensions much smaller than the wavelength of light is still a great demand in the nanosciences, notably in view of developing probes and sensors [1]. This is routinely achieved when these nano-objects are supported onto substrates using microscopy-based methods such as Scanning or Transmission electronic microscopy (SEM or TEM). These methods indeed provide morphological parameters of nano-objects with great accuracy. A full description of a sample containing a large number of these nano-objects requires though TEM images in a large number, something that may not be easily achievable. However, in absence of substrate, the problem remains acute and challenging. This is notably the case for liquid solutions where the nano-objects are not supported and undergoing Brownian motion. Characterization of these nano-objects is on high demand due to the large variety of the physical properties that they may be shown by the nano-object ensemble as the result of bottom-up chemical syntheses. An example is the case of the nano-object size or shape that may undergo large deviations from the ensemble distribution average quantities.

Optical methods have thus been proposed to the determination of the linear properties of metallic nanoparticles, in particular the determination of their extinction cross sections, notably using UV-visible extinction spectroscopy on large ensembles. More recently, nonlinear optical methods have appeared with advantages, as the first hyperpolarizability, effectively the cross-section for second harmonic generation, namely the process whereby two photons at a fundamental energy are converted into one photon at the sum energy, scales with the

surface rather than the volume as it is the case with linear extinction for metallic gold or silver nanoparticles [2]. With nanoparticles randomly dispersed in a liquid suspension, an incoherent SHG signal can indeed be observed. This method is known as hyper Rayleigh scattering (HRS), due to the orientation fluctuations of the particles in the medium [3]. Such a technique has been extensively used to determine the first hyperpolarizability of molecules and more recently nanoparticles at the ensemble level.

In this work, the HRS method is employed using polarization analysis of both the fundamental and harmonic light to get fine details on the morphology of the nanoparticles [4]. Using elliptical light, it possible to access fine details of the nonlinear response, and in particular several tensor elements of first hyperpolarizability associated with chiral responses. This operation is performed on spherical gold nanoparticles in aqueous suspensions as it is demonstrated that these nanoparticles do not retain any specific symmetry because their shape is not perfect. Some specific shapes are then discussed in view of observing the signature of chirality with this method. Finally, some issues are discussed in order to aim to perform these measurements on single nanoparticle [5].

Transition Metal Nitride and Oxide Thin Films for Chiral Structures: Spectral and Environmental Applicability

R. Bower and P. K. Petrov*

Department of Materials, Imperial College London, Royal School of Mines, Exhibition Road, London, SW7 2AZ, U.K.
*corresponding author: p.petrov@imperial.ac.uk

Abstract: Refractory plasmonic thin film materials are of interest for the development of chiral structures due to their increased thermal stability when compared to gold and silver. Transition metal nitride and oxide thin films have been highlighted as promising alternative materials, offering both strong plasmonic and thermal performance. In this work, we analyse the stability of both the structural and optical response of various plasmonic thin films and individual nanodiscs of various diameters subjected to elevated temperature conditions in the air.

Chiral plasmonic structures combine the chiral properties of materials with the plasmonic properties of metals, leading to a wide range of potential applications in a wide range of fields, including sensing, spectroscopy, and photonics. [1]. Chiral plasmonic structures that require high operational temperatures have been of particular interest in recent years, because, at elevated temperatures, the chirality of these structures can be altered, leading to changes in their behaviour. However, typical plasmonic materials such as gold, silver and copper are unsuitable for such high-temperature applications, due to their poor thermal stability. Refractory plasmonic materials are therefore of increasing importance, presenting the potential to improve the performance and operational lifetimes of the chiral plasmonic structures at high-temperature.

In this work, the temperature stability of thin films of W, Mo, Ti, TiN, TiON, Ag, Au, and $SrRuO_3$ are investigated to assess their viability for robust refractory plasmonic applications as well as the nanostructured plasmonic materials at the level of individual nanodiscs, tracing both the shape modification and the optical response modification of the same nanostructure utilizing cathodoluminescence (CL) spectroscopy.

Films ranging in thickness from 50 - 180 nm are deposited using various deposition methods, before characterisation using AFM, XRD, spectroscopic ellipsometry, and DC resistivity. Measurements are conducted before and after annealing in air at temperatures ranging from 300 - 1000° C for one hour, to establish the maximum cycling temperature and potential longevity at the temperature for each material. It is found that SrRuO3 retains metallic behaviour after annealing at 800° C, however, importantly, the optical properties of TiN and TiON are degraded as a result of oxidation. Nevertheless, both TiN and TiON may be better suited than Au or SRO for high-temperature applications operating under vacuum conditions.

Finally, Figure 1 provides an overview of the operational limits for each of the materials under investigation. The observed maximum operating temperature in air (i.e. the annealing temperature after which metallic behaviour was lost) for each material is plotted against the plasma frequency as reported in the literature. In general, it appears oxide materials such as SRO exhibit superior stability in the air than pure metals and TiN.[2]

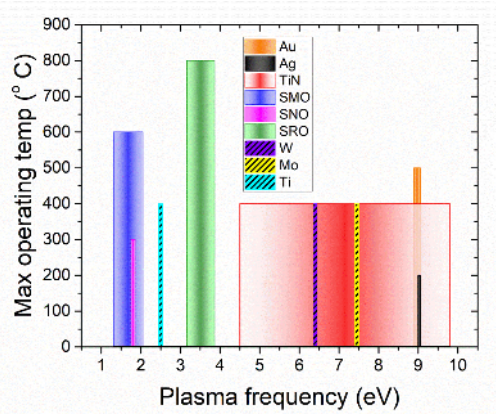

Figure 1 Spectral and temperature applicability of the investigated materials. [2]

In contrast to smooth plasmonic films, for which primarily the modification of the optical constants with annealing is important, for nanostructures, both morphology and optical constants can be modified at high temperatures. The electron beam of the CL microscope can be readily used to directly excite plasmonic modes with nanoscale resolution. Collection of the light emitted upon excitation can be used to identify plasmon resonances and hybrid modes, and also allows for the polarization and angular emission profile to be resolved [3,4]. Here, we compare the thermal stability of single nanoscale titanium nitride and gold discs, patterned on silicon substrates. Samples are annealed in the air for 30 min each at temperatures ranging from 150 °C to 325 °C. Following each annealing stage, CL spectra and SEM images are collected to assess variations in the optical response and disc morphology. Experimental spectral data for the CL response of plasmonic discs are supplemented by simulations, identifying the excited plasmonic modes and confirming the oxidation-related mechanism of the change in the optical response of TiN nanodiscs with the annealing temperature. SEM imaging and CL spectroscopy indicate that although TiN displays superior thermal stability in comparison with Au when considering morphological changes and disc deformation, deterioration in the optical properties of both materials occurs at comparable temperatures. The degradation of individual discs occurs at significantly lower temperatures than previously reported for plasmonic thin films.[5]

From these results, it is apparent that oxidation of TMNs remains a limitation to the integration of TiN components within plasmonic devices to be used in ambient conditions. However, we suggest that TiN could display improved performance compared to gold when used in inert or vacuum environments.

Abstract: Confinement of electromagnetic fields at the subwavelength scale allows engineering light-matter interactions in topological materials, providing new avenues to access nontrivial features of their electronic band structure [1]. It has been shown that nanostructures carved on the surface of topological insulator crystals deeply affect the response of their surface states, as probed by optical near-field imaging [2] and by light helicity dependent photocurrents induced by the circular photogalvanic effect [3]. Here we report deeply subwavelength nanoimaging of light helicity dependent photocurrents and their local texture in pristine and artificially nanostructured topological insulator crystals. To map the local surface photocurrents, which are typically overshadowed by the bulk electron contribution, we used $Bi_{1.5}Sb_{0.5}Te_{1.8}Se_{1.2}$ (BSTS) crystals known for their extremely high surface-to-bulk conductivity ratio [4] and developed a new differential photocurrent nanoimaging technique, built on the platform of a scattering-type scanning near-field optical microscope (s-SNOM). Deeply nanoscale resolution is achieved by higher harmonic demodulation of the polarization dependent photocurrent signal at the s-SNOM tip tapping frequency. While the helicity-dependent photocurrent distribution is found to be fairly homogeneous over the flat areas of the BSTS device far from the electrodes, patterning of the topological crystal surface with enantiomeric spirals generates local hot-spots where the photocurrent response is significantly enhanced, embedded into deeply subwavelength spatial textures. Numerical simulations accounting for the optical absorption and the spin angular momentum of the optical field suggest a link between the quantum spin Hall effect of light in the nearfield of the chiral nanostructures and the local photocurrents generated on the surface of the topological insulator. A new, direct probe of the effect of nanostructuring on the local distribution of circular photogalvanic surface currents, helicity dependent photocurrent nanoscopy unlocks the understanding and exploitation of spin-mediated light-matter interactions in in topological insulator metamaterials.

Abstract: Recently, chiral metasurfaces have been designed for numerous applications in flat optics and photonics, specifically in encrypted displays, imaging, and sensing. Here, we proposed a reflective multifunctional dielectric chiral metasurface integrated with liquid crystal modulator incorporating the ability for spin-encoded phase multiplexing based on the dynamic switching of input and output polarization of visible light. Moreover, the chiral meta-platform reproduces two distinct phase profiles with simultaneous control on its cross and co-polarized component for one-handedness of incident circularly polarized light.

Previously, numerous meta-platforms based on plasmonic and dielectric nanostructures were presented with simultaneous control on amplitude, polarization, and phase for promising applications in data encryption, quantum information processing, holographic displays, bio-imaging, etc [1]. However, dielectric metasurfaces with low losses emerged as efficient and compact solutions for integrated optical systems. Meanwhile, multiplexing and multifunctionality in the metasurfaces created more versatile meta-devices for the aforementioned applications. Metasurfaces with integrated functionality and combining multiple-phase modulation techniques have been presented for hologram multiplexing and spin-dependent wavefront shaping [2]. Although such meta-platforms provide multiplexing of multiple phase information, they cost efficiency due to the phase distortion and require additional optical components to distinguish encoded information.

In polarization optics, chiral metasurfaces have recently gained significant attention due to their unique way of interaction with light [3-5]. This work proposed a unique strategy to incorporate multiple-phase information in a single dielectric chiral structure. The proposed chiral metasurface can encode two distinct phase information using the geometric phase modulation technique compared to the conventional chiral geometries, which can embed just one phase profile. The building block of the meta-platform comprises the carefully optimized pair of hydrogenated amorphous silicon (a-Si:H) based achiral unit atoms to introduce chirality in the visible regime. Apart from chirality inclusion, the building block included extra degree of freedom to encode more than one phase information using geometric phase modulation technique. The proposed chiral meta-platform illuminated with one-handedness of circularly polarized light reproduces two distinct spin-selective phase information with output polarization control using liquid crystal (LC) modulator. The schematic art of the working principle of the designed multifunctional chiral meta-platform is depicted in Figure 1. In our opinion, such multifunctionality and multiplexing in chiral metasurfaces can pave the way for numerous applications in the healthcare sector for bio-imaging, media for polarization-encrypted displays, communication, and data encryption.

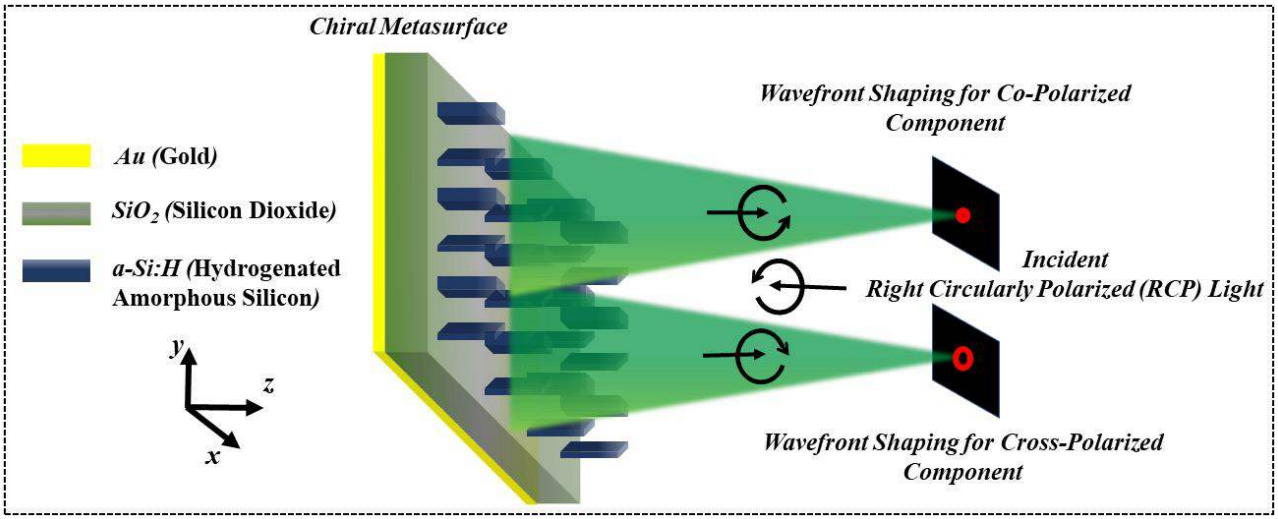

Figure 1. The artistic view of the working principle of the proposed multifunctional chiral meta-platform. The distinct wavefront shaping is depicted based on the handedness of output.

Strong broadband circular dichroism in chiral plasmonic woodpiles

B. Abdennadher[1], R. Iseli[1], U. Steiner[1], and M. Saba[1*]

[1]Adolphe Merkle Institute, Chemin des Verdiers 4, 1700 Fribourg, Switzerland

Abstract: Chiral woodpile structures are well known to boost chiro-optical effects. We here demonstrate that light scattering at a chiral plasmonic woodpile, which is structured on the order of the wavelength of the light, can be well understood by considering its fundamental evanescent Floquet states. In particular, we report a broadband circular polarization bandgap in the complex band structure between 3 and 4 μm wavelength, yielding a strong and broadband circular dichroism. Our findings could pave the way for an ultra-broadband circularly polarized thermal source.

Electromagnetic wave propagation in traditional metamaterials with a deeply sub-wavelength structure is typically well understood through homogenization and associated effective parameters [1]. On the other hand, wave propagation in lossless photonic crystals, structured on the order of the wavelength, is generally best characterized through the photonic bandstructure [2]. An extension of the classical Bloch waves to evanescent Floquet states, and an associated bandstructure with complex-valued wave number allows to fully characterize light propagation in finite material slabs (**Figure 1**) and thus provides a quantitative translation between material modes and experimentally observed scattering parameters [3]. By semi-analytically calculating the evanescent Floquet states of a layered chiral plasmonic woodpile using a standard transfer matrix method, we show that the woodpile gives rise to a large *plasmonic* bandgap for one circular polarization, with gap-to-midgap ratio of more than 2/7 [4]. This bandgap is typically found close to, but below the first Wood anomaly of the woodpile. Even considering the fundamental Floquet modes only allows surprisingly accurate predictions on the scattering parameters of a woodpile slab, which gives rise to a strong and broadband circular dichroism and thus enables circular polarized thermal emission with high enantiopurity of the emitted light.

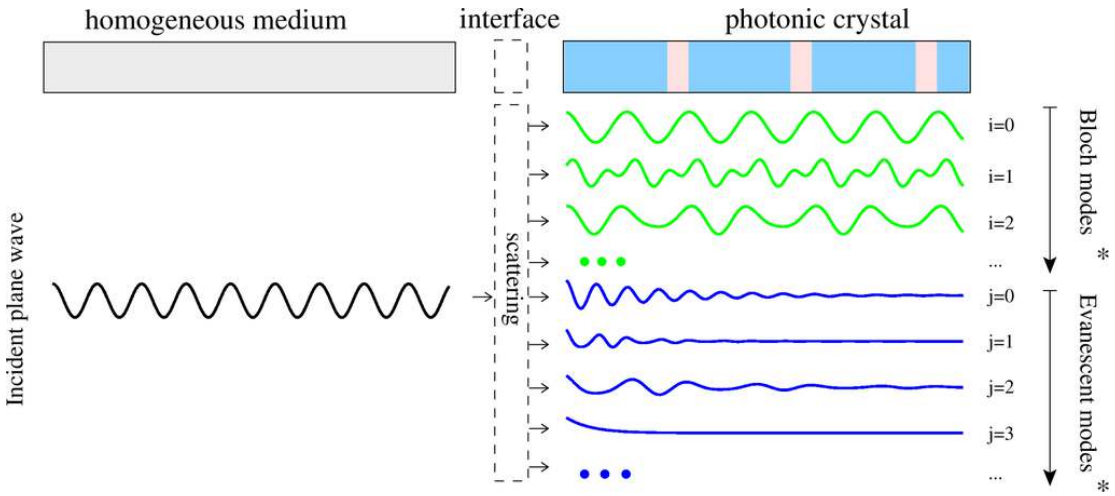

Figure 1 Mock illustration of a plane wave exciting a semi-infinite slab of a periodic material hosting a countably infinite number of evanescent Floquet modes.

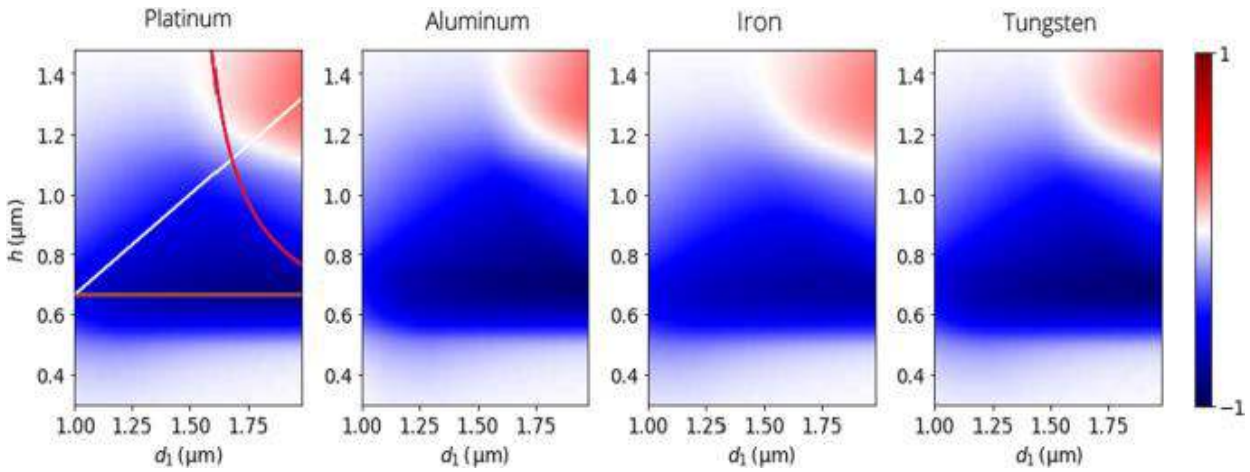

Figure 2 Heatmap of average circular dichroism (defined as absolute difference in absorptivity between right and left circularly polarized light, averaged over a spectral range between 3 and 4 μm wavelength) for a hexagonal plasmonic woodpile made of four different metals. The circular dichroism is shown to mainly depend on two geometrical parameters: the layer height h (one third of the chiral pitch), and the thickness of the air region between metallic bars in each layer d_1. The lines in the platinum figure indicate the theoretically predicted boundaries of the region of large circular dichroism.

At mid-infrared frequencies (we focus on the optical transparency window between 3 and 4 μm wavelength), due to the small size of the effective skin-depth compared to the structural lengths, the circular polarized bandgap is largely independent of the plasmonic metal and exists within a large region in the geometrical parameter space of the structure (**Figure 2**). Employing a Bouligand approximation [5] of the woodpile structure, we develop analytical expressions for the boundary of the region of large broadband circular dichroism, which agree well with the full model. The Bouligand model thus not only explains the shape and large size of the parameter space region of high circular dichroism, but further provides general design principles to optimize the latter. Our findings suggest that hexagonal plasmonic woodpiles structured on the order of the wavelength of the light are an ideal platform to build a circularly polarized thermal source. First, their performance is insensitive to structural variations and thus fabrication imperfections or high temperatures. Additionally, the frequency region of large circular dichroism is not only broadband, but close to the first Wood anomaly. The relative frequency, scaled by the lattice constant, is therefore twice a high as in comparable high-index photonic crystal structures, and thus easing the requirements of the feature size of top-down fabrication techniques, such as two-photon polymerization.

Abstract: We manufacture and evaluate the optical performance of a novel optical transducer that allows uniform surface-enhanced fields for sensing through the excitation of Bloch Surface Waves (BSWs). The aim is to attain the coherent superposition of TE and TM dispersion relations of BSWs that is essential to provide "superchiral" fields over a wide spectral range (down to the UV). The resulting BSW-based transducer paves the way to the implementation of polarization-resolved surface-enhanced techniques.

Bloch Surface waves (BSWs) can be supported at the surface of truncated one-dimensional photonic crystals (1DPCs). Thanks to the high sensitivity to the local refractive index where they propagate, BSW-based transducers are widely used for sensing analytes [1-3].

A further step in surface-enhanced spectroscopies using BSWs is the control over the polarization, which can be attained by engineering the overlap between the dispersion relations of the transverse electric (TE) and the transverse magnetic (TM) eigenmodes that can be sustained by these truncated 1DPCs. In fact, the resonant wavelength of the modes can be tuned by a proper design of the 1DPC, acting on the materials (i.e. the refractive index) and the thicknesses of the layers.

For example, the surface-enhanced study of oriented molecules anchored to the 1DPC surface could be approached via differential TE-TM reflectivity measurements, as customarily done in standard attenuated total internal reflection spectroscopy [4]. More specifically, the superposition of the TE and TM modes enables linear and circular dichroism (CD) spectroscopies. CD, in particular, is gaining more and more importance due to the wide applications in chemistry, biology, medicine and pharmacology [5]. In general, CD signals are very weak if compared to those standard absorption spectroscopies so, recently, novel "superchiral" approaches have been introduced to enhance the CD signal by engineering the optical chirality of the electromagnetic field with the use of nanostructured systems [6]. In this framework, both metallic and dielectric approaches are used [7,8]. We recently proposed a BSW-based transducer that allows for the generation of "superchiral" surface waves [2]. Here we manufacture and evaluate the optical response of alternative simplified design of the 1DPC reducing the number of layers while keeping similar polarization performance.

The BSW-based transducer is a truncated 1DPC grown by reactive magnetron sputtering and made by 2 periods of alternating layers of SiO_2 (low refractive index) and Ta_2O_5 (high refractive index) terminated with an additional low-index layer incorporating a high refractive index inclusion. The optical performance of this BSW-based transducer was monitored in water using a fluidic cell realized using a polymeric double-side tape with the fluidic chamber cut by femtosecond laser micromachining. The top layer is a fused silica slide that

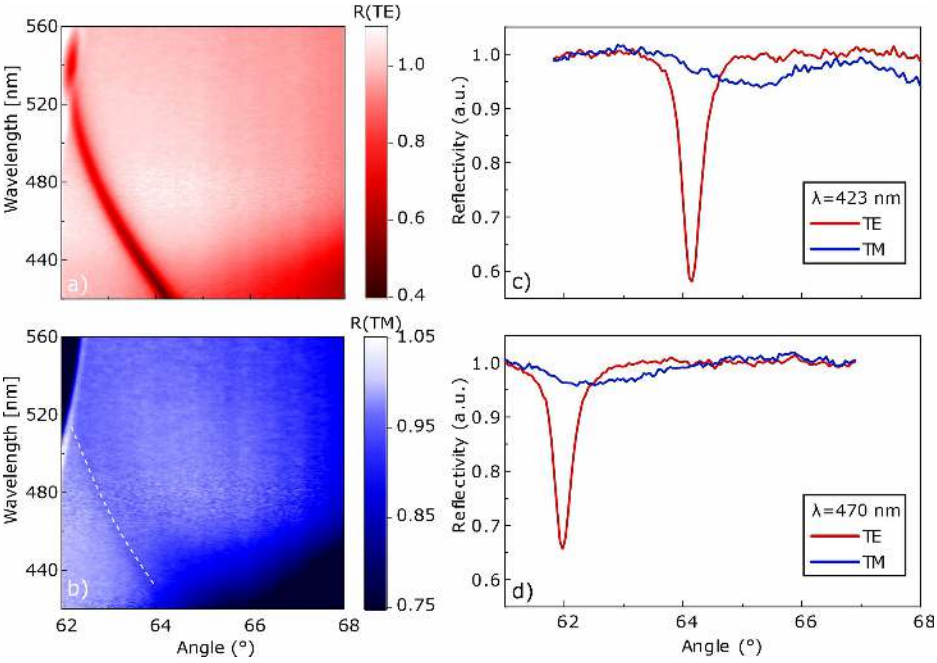

Figure 1. Experimental reflectivity (R) maps for a) TE illumination and b) TM illumination when the surface is immersed in water. The dispersive TE and TM modes are visible as dips in the reflectivity maps. Experimental angular plot for a wavelength equal to c) 423 nm and d) 470 nm.

contains the housing to plug the fluidic tubes. Experimental demonstration of the superposition in energy and momentum of the TE and TM modes can be assessed by reflectance measurements performed on the BSW-based transducer with the fluidic chamber filled with water. The modes are visible as dips in the corresponding reflectivity maps (Figure 1) evaluated for TE and TM illumination (panels a and b, respectively). Panels c) and d) include representative angular plots at specific wavelengths. It can be observed that, while the TE mode is narrow and sharp, the TM mode is broader and weaker but still recognizable, allowing experimental confirmation of the mode superposition. Upon increasing the wavelength, the excitation angle of the modes decreases, approaching the onset of total internal reflection.

The reported overlap of the TE and TM modes paves the way to the employment of such a BSW-transducer for surface-enhanced polarization-sensitive spectroscopies in the visible-UV range and more generally to the implementation of polarization-resolved surface-enhanced techniques, such as enhanced CD spectroscopy.

Abstract: We numerically studied the chiral properties of square 2D elliptic nanohole arrays in three different metallic metasurfaces (Ag, Au, and Al), from the near-infrared to the ultraviolet spectral range. Circular dichroism arises in absorption spectra at the same wavelength region of extraordinary optical transmission. We elucidate the physical origin of absorption CD and we optimize the CD as a function of the geometrical parameters of the structure. The results suggest interesting applications for chiral biomolecule sensing.

Altering the electromagnetic properties at the nanoscale can be efficiently achieved by means of specially engineered metasurfaces. Particularly, when the symmetry of the metasurface is broken, its interaction with circularly polarized light can be controlled. Different absorption of left and right circular polarization is called circular dichroism (CD). Metasurfaces able to generate large CD are very interesting for both fundamental science and applications regarding ultrasensitive chiral molecule detection. Furthermore, it was recently shown that high-quality chiral metasurface samples can be created by using low-cost nanosphere lithography combined with tilted metal deposition [1]. In this work, we theoretically study CD in square arrays of elliptical nanoholes etched in thin metallic layers (Au, Ag, Al) on a glass substrate. Fig.1 shows the metasurface structure used in our study at a normal incident on top of the surface. Transmission spectra display the well-known phenomenon of extraordinary transmission (EOT) from sub-wavelength hole arrays in a metal.

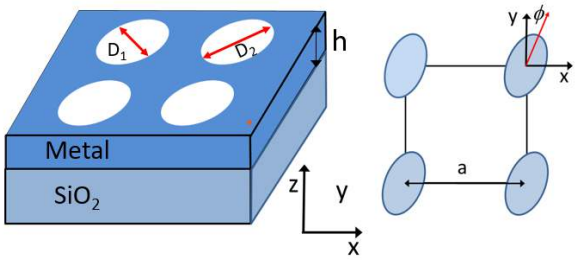

Fig.1. Scheme of the proposed structures studied in this work

The optical properties of elliptic nanoholes are numerically investigated by using two methods, 3D Finite Difference Time Domain (FDTD) simulation using Lumerical Ansys and Bloch-mode scattering matrix method in the open-source software known as Emustack [2]. To ensure convergence, we performed a comparison of the two methods. We calculate the optical spectra for circularly polarized light (RCP, LCP) to define the CD in absorption as

$$CD = (A_{LCP} - A_{RCP})/(A_{LCP} + A_{RCP}).$$

Results

We investigated chiral properties of square 2D elliptic nanohole arrays in three different metallic metasurfaces made of Ag, Au, and Al, from the near-infrared to the ultraviolet spectral range. The Elliptical NanoHole Array with tilted holes on a glass substrate is an intrinsically chiral lattice, giving rise to circular dichroism which is closely related to extraordinary optical transmission through the nanoholes, and it is resonantly enhanced at absorption peaks due to Surface Plasmon Polariton resonances at the metal/glass and metal/air interfaces. The elliptical shape of the nanoholes

splits the absorption peaks at each SPP resonance, while tilting of the nanohole axis produces an unbalance between the fields originating from linear polarizations along the long and short axes: they sum up with a phase delay of -90° (LCP) or +90° (RCP), ending up in a CD for tilted holes and explaining the strongly dispersive features of CD spectra. We then performed a full optimization on the geometry parameters, leading to substantial CD values (|CD|max > 50%) for silver and gold leading to suitable use in visible or near-IR, and (|CD|max > 40%) for aluminum leading to suitable use in the visible and ultraviolet (Fig.2). The CD resonance wavelengths have a minor dependence on the ellipse parameters, as they follow from a lattice effect, and can be effectively tuned via the lattice constant.

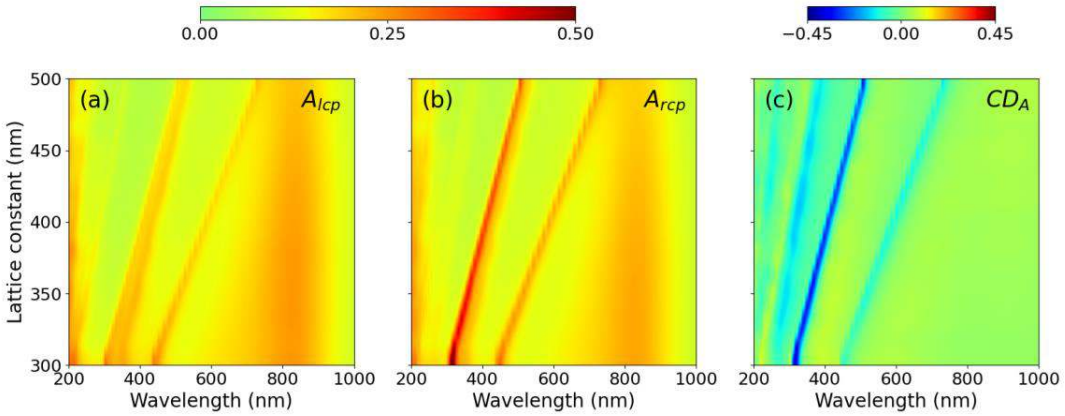

Fig. 2. (a) Absorption spectra for LCP, (b) absorption spectra for RCP, (c) CD in absorption for an Al film of thickness t=100 nm as a function of lattice constant a, keeping constant values D_1/a=0.5565, D_2/a=1, ϕ=20.95°.

The benchmark of the two computational electromagnetic tools EMUstack and FDTD leads to a good agreement of the spectra and supports the reliability of the results. Plasmonic metasurfaces made of an Al film stands up as a promising candidate to achieve large |CD| in the near-UV region, possibly with the addition of a thin oxide layer to prevent oxidation of the top surface. Absorption and CD spectra of Al films at wavelengths below the interband transition display a number of features that arise from folded SPP modes. These findings can be further pursued for deeper investigations of plasmonic light-matter coupling, as well as for applications to chiral sensing of biomolecules with resonances in the visible or near-UV spectral range.

Abstract: The interaction between chiral materials and light at the nanoscale, can be controlled and optimized by using nano-antenna. However, understanding the properties of the near field of a nano-antenna requires extensive numerical simulations where the polarization and excitation wavelength can be varied. We propose a matrix method based on the Jones decomposition of the polarization to evaluate the vectorial properties of the electromagnetic near field of an antenna.

Many physical quantities allow for characterizing the interaction between chiral materials and light at the nanoscale, including chirality density, spin density, ellipticity. By generating superchiral light, nanophotonics has brought innovative solutions to reduce the detection volume and increase the sensitivity. We have already shown numerically that an achiral plasmonic resonator based on a rectangular nanoslit could be described as a magnetic dipole and was behaving as a tunable nanosource of purely superchiral light[1] (Figure 1 (a)). Here we show that the knowledge of the nearfield for the transverse (T) and longitudinal (L) modes is enough to optimize the illumination conditions that yield the best chiral properties of the nearfield for all the polarization of excitation possible.

In order to explore systematically and efficiently the properties of chiroptical phenomena, like chirality density and ellipticity, we propose a mathematical matrix method which provides an alternative tool for the search for a specific superchiral field or circular polarization near field. In this method, the local field was related to the incident field through a generalized Jones matrix J_{GEN}. This matrix contains the information about both the electric and the magnetic field of light so that $J_{GEN} = \begin{bmatrix} J_E & 0 \\ 0 & J_H \end{bmatrix}$. The 2x2 submatrix J_E is defined by $\boldsymbol{E}_{loc} = J_E \boldsymbol{E}_{inc}$ with $\mathbf{E}_{loc}$ and $\mathbf{E}_{inc}$ the local and incident fields, respectively. After decomposition of the electric fields on the (x,y) coordinates, the elements of J_E were obtained as $J_E = \begin{bmatrix} J_E^{xx} & J_E^{xy} \\ J_E^{yx} & J_E^{yy} \end{bmatrix}$. A similar treatment was performed for the elements of J_H with the magnetic fields.

The incident and local fields were obtained from numerical simulations (FDTD, Lumerical) only performed for incident illuminations linearly polarized along x and y. Figure 1 (b) (c) present the spectral dependence of the amplitude of the total electric field and phase of the radiation electric field in the center of the nanoslit for incident light polarized along x and y exciting the longitudinal and transverse modes of the nanoslit. These two illumination conditions were sufficient for the determination of the elements of J_E and J_H. The knowledge of J_{GEN} allowed then for the calculation of any electromagnetic property of the light in the center of the nanoslit for any incident polarized or wavelength. This was illustrated in the case of the angular dependence of the chirality density, defined as $C = -\frac{\varepsilon_0 \mu_0 \omega}{2} Im(\boldsymbol{E}^*.\boldsymbol{H})$, in the nanoslit (Figure 1 (e)). These calculated values can be compared with the numerical FDTD simulation results presented in Figure 1(d). This method not only reproduces the simulation results accurately, but also can quickly give feedback on the chiral properties for any polarization state or

wavelength, opening the way to the optimization of the illumination conditions for any (or combination of any) goal: chirality density as well ellipticity, electric and magnetic energies.

Figures 1 (a) 3D representation of the rectangular nanoslit in a thin gold layer of 40 nm. The vector **k** represents the direction of propagation of the linearly polarized incident plane wave, and θ, the angle of this polarization with respect to the nanoslit transverse axis (Ox). (b) Transverse mode and (c) longitudinal mode spectral responses of the amplitude and phase obtained for θ = 90° and 0°. (d) Variations of C_{enh} as a function of the incident polarization angle θ and wavelength in the center of the nanoslit obtained from FDTD simulations (angle θ step by 15°). C_{enh} defined as $C/|C_{cpl}|$, with C_{cpl} the chirality density of a circularly polarized light, without the aperture, carrying the same power as the linearly polarized excitation impinging on the nanoslit. (e) Variations of C_{enh} as a function of the incident polarization angle θ and wavelength calculated using the J_{GEN} matrix.

Microstar cavities: Ray-wave correspondence in the semiclassical regime

J. Kullig[1*] and J. Wiersig[1]

[1]Institut für Physik, Otto-von-Guericke-Universität Magdeburg, Magdeburg, Germany
[*]corresponding author: julius.kullig@ovgu.de

Abstract: Microstar cavities confine light in a star-shaped quasi-two-dimensional microcavity via successive perfect transmissions through the dielectric interface under Brewster's angle. Therefore, beam splitting effects are avoided and ray orbits without intensity loss are formed. We investigate the correspondence between the ray dynamics and the long-lived modes of the electromagnetic field in the semiclassical regime. A difference between clockwise and counter-clockwise propagation in traced back to nonlinear resonance chains in phase space.

A traditional whispering-gallery cavity confines light via total internal reflection at the dielectric interface. However, in 2020 the authors proposed a novel concept for the light confinement in a microstar cavity that completely avoids any kind of reflection [1]. The star-shaped cavity with $\nu>2$ spikes is designed by fixing the opening angle of the spikes to

$$a=\frac{\nu-2}{2\nu}\pi \qquad (1)$$

and the refractive index of the cavity to

$$n=\frac{1+\sin\left(\pi/\nu\right)}{\cos\left(\pi/\nu\right)}. \qquad (2)$$

Under these conditions a transverse electric polarized ray is guided along a periodic orbit that successively leaves and re-enters the cavity without loss of intensity as all the transmissions occur under Brewster's angle. The periodic orbit can be stabilized further by a slight focusing deformation of the microstar boundary, see Fig. 1a.

A convenient method to describe the dynamics in such systems is a phase-space representation. Here, the position and angle θ of rays that cross the x-axis are tracked, see Fig. 1b. For the deformed microstar the dynamics generates a regular region with a resonance chain in the phase space as shown in Fig. 1c. On the other hand, the boundary deformation of the microstar leads to a slight nonuniform loss in the generated regular phase-space region. The interplay of the loss gradient and the nonlinear resonance chain then leads to an interesting difference between clockwise (CW) and counter-clockwise (CCW) propagating rays (illustrated by blue and red arrows in Fig. 1b) [2]. The difference between both propagation directions can be analyzed by constructing classical eigenstates of the dynamics from the so-called Frobenius-Perron operator [2,3].

Additionally, full numerical wave simulations are performed to compute the optical modes in the microstar cavity. In consistency, the long-lived modes typically follow the classical orbit as shown in Fig. 1d. A further comparison can be done by a Husimi representation that projects the

modes into the phase space (not shown). It is demonstrated that in the semiclassical regime the modes localize on the classical phase-space structures of the regular region and, furthermore, have a similar difference between their CW and CCW components as the classical Frobenius-Perron operator eigenstates. Our work shows that microstar cavities are interesting systems to study ray-wave correspondence with unexpected phenomena as time-reversal symmetry can be naturally broken by a difference in CW and CCW ray propagation.

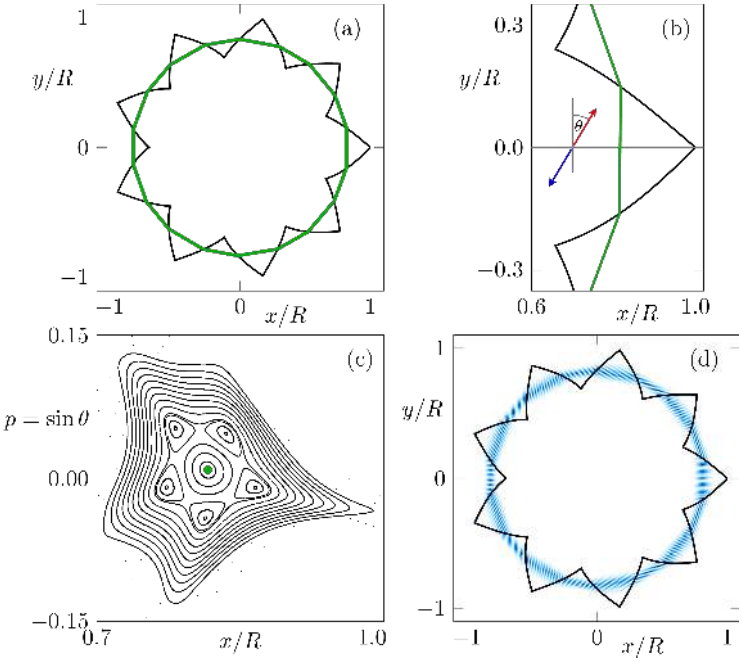

Figure 1: The green curve shows a periodic orbit in the deformed (black curve) microstar cavity. (b) Magnification of (a). (c) Phase space portrait of CCW propagating rays. The periodic orbit is marked as green dot. (d) Intensity pattern of a long-lived optical mode.

Resonant Photonic Galleries of Dielectric Particles

N. S. Solodovchenko[1], M. E. Bochkarev[1], K. B. Samusev[1,2], and M. F. Limonov[1,2*]

[1]Department of Physics and Engineering, ITMO University, St. Petersburg, 197101, Russia

Abstract: An original picture of photonic resonances in single dielectric particles (cylinder, ring, split ring, cuboid) is presented. The basic result is the separation of low-frequency scattering spectra into short galleries that start with a broad Fabry-Perot band and continue with narrow longitudinal modes. The existence of individual resonant galleries leads to the appearance of entire galleries of bound states in the continuum, in contrast to the repeatedly observed single bound states, and also to the appearance of exceptional points.

The modification of physical properties determined by topological transitions is the subject of intensive research in various fields of physics, and optical properties are no exception. Between the most famous elementary resonators, two topological transitions can be distinguished, namely, from a disk to a ring with a rectangular cross section and further to a split ring. Of interest is another transformation of the structure, although not accompanied by a change in topology, namely, the transition from a split ring to a cuboid. Thus, we obtain an interesting sequence for analyzing the modification of optical properties: disk → ring → split ring → cuboid.

To describe the photonic properties of dielectric resonators in the three-dimensional general case, we used numerical calculations that provide key information about the optical spectrum with resonant eigenmode frequencies (eigenvalues), field distribution (corresponding eigenfunctions), and mode *Q*-factors. In three-dimensional resonators, the eigenfunctions can be characterized by azimuthal (*m*), radial (*r)*, and axial (*z*) indices forming an ordered triple (*m, r, z*). We compared the results of our calculations with the experimental results obtained on ceramic samples with a high permittivity and low material losses in the gigahertz range. The results are based on an analysis of the low-frequency region of the spectra, where all spectral features can be unambiguously interpreted, including the Mie and Fabry-Perot resonances.

We have established that the topological transition from a disk to a ring with a rectangular cross section leads to a fundamental rearrangement of the photonic spectrum. The disk spectrum is characterized by an infinite set of equidistant whispering gallery modes. The low-frequency spectrum of the ring is divided into separate short galleries, each of which begins with a broad transverse Fabry-Perot resonance between two pairs of opposite walls of the ring and continues with a set of equidistant azimuthal high-Q resonances modes. By tuning the geometrical parameters of the ring, a structure with alternating broad transverse Fabry-Perot resonances in the strict sequence Lorentz – Fano – Lorentz – Fano –… was determined [1]. The Fano resonances [2] lead the galleries with even radial photonic indices, and the Lorentzian resonances lead the galleries with odd radial indices. The results of a study of the optical scattering spectra at a topological transition between a dielectric ring and a split ring are of no less interest. We observed a strong orientational dependence of the spectra as the angle of incidence of the plane wave on the ring relative to the slit varied.

Recently, bound states in the continuum (BIC) have been of great interest, which are characterized by exceptionally high Q-factors, which in theory reach infinity [3]. We studied the properties of BIC, which is

described by the Friedrich – Wintgen model [4], during the transition from a homogeneous dielectric cylinder to a ring with narrow walls with a gradual increase in the inner diameter [5,6]. Friedrich–Wintgen's BICs arise from two interacting resonances via a radiation continuum due to appropriate tailoring of the structural parameters. The results demonstrate a transition from BIC in the strong-coupling regime to BIC in the weak-coupling regime, which manifests itself in the transition from avoided crossing to photonic branches crossing.

However, the greatest interest from our point of view is the discovery of galleries of BICs, which, as far as we know, have not been observed before. Different photonic galleries of a ring with a rectangular cross section have different dependences on structural parameters; therefore, when the ring geometry changes, regions of anticrossing of entire galleries appear, which corresponds to the formation of BIC galleries by the Friedrich – Wintgen mechanism. We also discuss the eigen-solutions of non-Hermitian systems with emphasis on the presence of exceptional points (EPs) [7,8], where we observe the coalesce of two resonant modes with mutual coupling. In this case, the BIC mode switches from the high-frequency branch to the low-frequency branch.

Plasmonic nanocavities: From resonant modes to semi-persistent sub-radiant states

A. Demetriadou[1*]

[1]School of Physics and Astronomy, University of Birmingham, Birmingham, B15 2TT, United Kingdom
[*]corresponding author: a.demetriadou@bham.ac.uk

Abstract: Plasmonic nanocavities have the ability to significantly confine and enhance light, while at the same time efficiently radiate energy to the far-field. Due to these properties, unprecedented light-matter interactions have been realised at room temperature. In this talk, I will present the complex set of plasmonic modes supported by extreme plasmonic nanocavities, their impact on the excitation and radiative properties of the antenna, and how these properties can lead to generating sub-radiant entangled states between two or more quantum emitters.

Plasmonic nanocavities have gaps between two metallic nano-structures of just 1-2 nm, and have been used in the past few years to reach the light-matter strong coupling regime between molecular emitters and plasmons at room temperature [1,2]. One of the most common designs is the nanoparticle assembled on a mirror (NPoM) configurations (see fig.1). The extremely small gap between the two metallic structures, gives rise to a complex set of modes, each with a different field profile and radiative properties. Hence, a cavity is created that supports many different photonic modes that all simultaneously interact with all the quantum emitters (QEs) in the cavity.

Using an auxiliary-field eigenvalue method, we obtain the quasi-normal modes (QNM) [3] of the system. Although so far, theoretically plasmonic nanocavities were studied assuming that they are spherical (or truncated) nanoparticles on a mirror (fig.1A), in reality 'spherical' nanoparticles acquire three common polyhedral shapes during their synthesis: (i) cuboctahedron, (ii) rhombicuboctahedron and (iii) decahedron (seen in fig.1B-D).

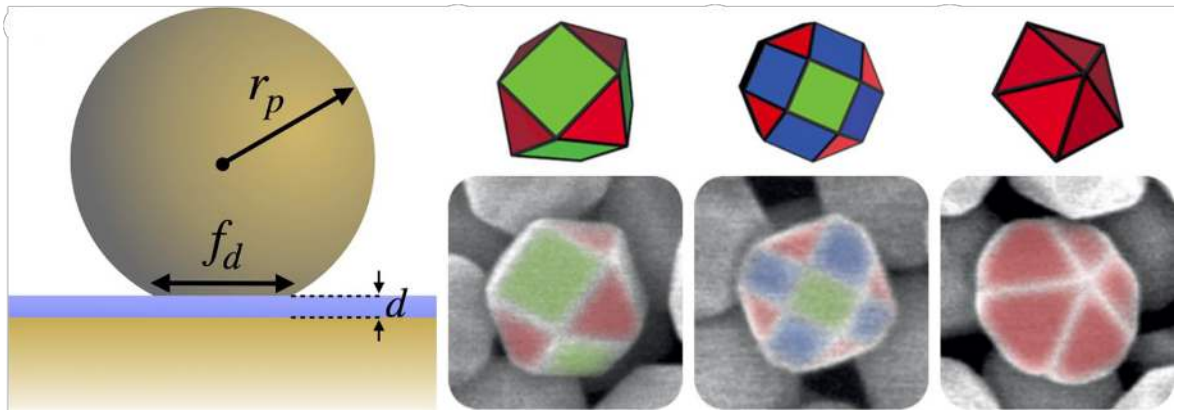

Figure 1: The nanoparticle-on-mirror (NPoM) configuration, and the three common shapes that spherical nanoparticles acquire during their synthesis.

The QNM mode expansion provides a complete description of the plasmonic modes in such nanocavities, and we show that the shape and symmetry of these plasmonic nanocavities dominate both their near- and far-field response, with intricate and rich optical behavior, both in the near- and far-field. We also show that the same nanoparticle shape gives very different results when assembled on the mirror with a different facet, even if the facet shape and size (i.e. geometry of the cavity) are identical.

The extreme light confinement in plasmonic nanocavities has opened the fascinating prospect of controlling

quantum matter with light, and ultimately generating quantum states at room temperature, avoiding the complex and cumbersome experimental methods required at cryogenic temperatures. We consider two (or more) quantum emitters residing in a NPoM nanocavity, and show that semi-persistent sub-radiant states emerge [4]. With a quantum electrodynamics description for an open cavity, we obtain both its quantum dynamics of the system (see figure 2) and the quantum extinction cross section:

$$\langle \sigma_ext \rangle = -\sqrt{\kappa_{in}}\,\frac{(\alpha\langle a^{\dagger}\rangle + \alpha^{*}\langle a\rangle)}{c|\alpha|^{2}}$$

where $\sqrt{\kappa_{in}}$ is the rate that energy couples into the system by a monochromatic source, α is the amplitude of the coherent state defined by the incident source's photon flux $c|\alpha|^2$ and $\{a, a^{\dagger}\}$ are the bosonic creation and annihilation operators.

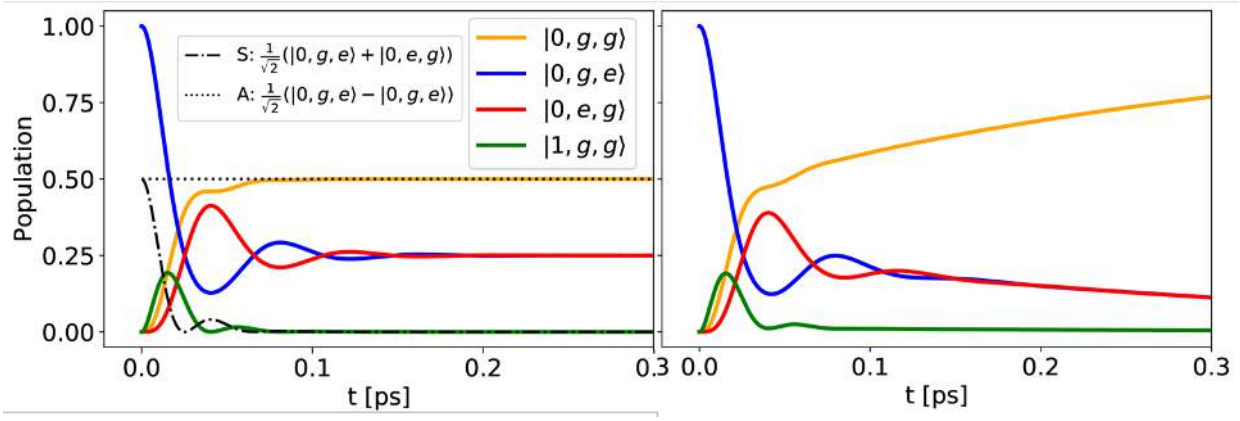

Figure 2: The quantum dynamics of two emitters in NPoM when (left) the emitters have no inherent loss and (right) with inherent loss.

The quantum dynamics of two or more quantum emitters placed in a plasmonic nanocavity, and reveal persistent sub-radiant states formed between them (shown in figure 2). Although the Rabi oscillations between the plasmon and emitters decay very fast (~within few tens of fsec), these sub-radiant states persist for up to 100fsec, depending on the inherent non-radiative losses of the molecular emitters chosen. Additionally, the quantum extinction cross section allows us to theoretically predict experimental observables, and in fact in the absence of quantum emitters reduces to the classical behavior of the plasmonic nanocavity.

AD would like to acknowledge support from the Royal Society and EPSRC.

Predicting nonlinear optical scattering with physics-driven neural networks

C. Gigli[1*], A. Saba[1], A.B. Ayoub[1], and D. Psaltis[1]

[1] Optics Laboratory, École polytechnique fédérale de Lausanne, CH-1015, Lausanne, Switzerland

Abstract: We present a physics informed deep neural network trained on Maxwell's equations, hence we named it MaxwellNet, which can act as a surrogate of numerical solvers and reduce computational times of three orders of magnitude compared to commercial software packages. Beyond demonstrating the possibility of studying linear and nonlinear scattering in presence of optical kerr effect, we show how this approach facilitates the inverse design of optical components with size comparable with light wavelength for which full wave simulations are normally required.

Deep neural networks are emerging as promising surrogates of nonlinear numerical solvers for their ability to map complex functions as the relation coupling material properties, geometry, and electromagnetic sources to scattered fields. These tools offer two advantages when compared to commercially available software packages: 1) they are naturally implemented to exploit the full computational power of GPUs and they don't require the inversion of very large matrices to predict solutions of Maxwell's equations which boost the calculation velocity of orders of magnitudes, 2) the gradients of the field predictions with respect to the given inputs can be easily and rapidly computed through backpropagation algorithms, making of them a well suited tool for inverse design. Here we propose to use a U-Net architecture to map the relationship between arbitrary refractive index distributions and the scattered field evaluated on the same grid for a fixed excitation source. In common data driven approaches, this process requires the creation of a large dataset of input-output pairs pre-computed with a numerical solver. Conversely, we propose to avoid the burden of dataset preparation by training the network directly on Maxwell's equations, see Fig. 1. We use the residual of Maxwell's equation as the proper physical loss to adjust the weights of network during the training. The electric and magnetic fields are discretized on the staggered Yee grid and the curl of fields is computed using the same approach as in finite differences frequency domain.

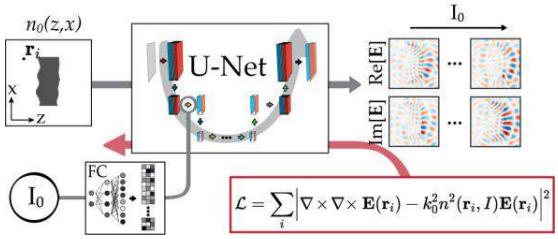

Figure 1 Tunable MaxwellNet with respect to incident power predicting optical Kerr scattering. Grey (red) arrows denote forward (backward) propagation. The model is based on a U-Net architecture taking in input the 2D refractive distribution of the material in the zx-plane $n(z, x)$ and returning the complex scattered field. By changing the incident beam intensity I_0, the weights of specific convolutional layers in the U-Net architecture are tuned so that the physical loss is simultaneously minimized for different working powers.

This work complement a previous demonstration on the implementation of MaxwellNet for predicting linear scattering from arbitrary refractive index distributions[1]. We focus here on the possibility to extend the method to

the prediction of optical scattering in presence of optical kerr effect. On one side this problem is much harder to simulate with commercial solvers and usually requires iterative approaches, and on the other it is of central interest in the photonic community to introduce an all-optical control mechanism to realize ultrafast switches.
If the central U-Net structure can correctly infer linear scattering problems, we do expect that by adjusting some of its weights it is also possible to model the intensity dependent index due to optical kerr effect. For this purpose, we introduce a second block which takes as an input the incident power and returns the kernels used in one convolutional layer in the encoding branch of the core U-Net[2].
As a proof of concept, we used the trained model for the shape optimization of 2D aspheric microlenses with focal properties resilient to power variations. The solution of the inverse problem in this case equals to find the best set of geometrical parameters (radius of curvature and conical constant of the two interfaces, and thickness of the lens) for which the field is focused at a distance $z_f = 14\,\mu m$ from the lens both for low and high incident powers , see Fig.2a. The adjustable weights of MaxwellNet allow to evaluate the objective function to optimize, in this case the field intensity at $z_f = 14\,\mu m$, at multiple powers and update the geometrical parameters accordingly. Fig.2b shows two major outcomes of the present work: 1) the possibility of performing thousands of fields evaluations and backpropagations in a short time, 2) the possibility to track the physical loss during the optimization process to ensure that the network predictions remain accurate and do not diverge to unphysical results. Fig.2c finally shows the field evaluation along the optical axis at low and high powers for the optimized structure which minimizes the field variations around the focal spot for different working conditions.

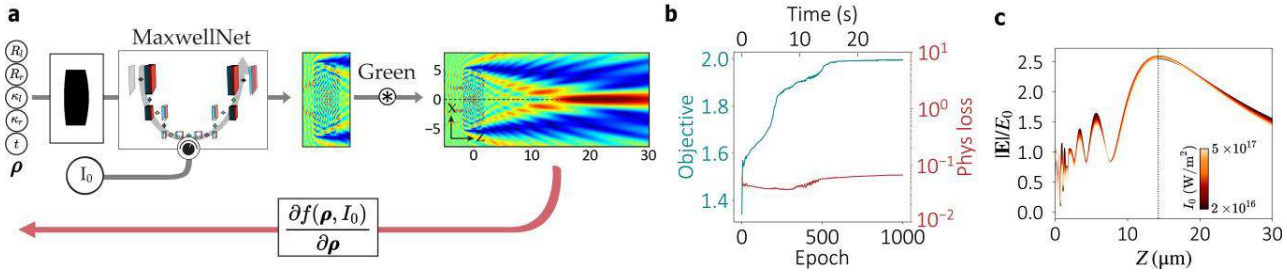

Figure 2 Lens design with MaxwellNet. (a) Sketch of the optimization algorithm. An initial lens design defined by the geometrical parameters ρ is provided to the trained MaxwellNet model which returns the total field |E|. We use Green convolution the retrieve the field amplitude close at the focal plane which constitutes the objective function *f* to maximize. The derivatives of *f* with respect to ρ are computed through backpropagation and we iterate until convergence. (b) Evaluation of the objective function (left axis) and physical loss (right axis) for the optimization of a lens focusing at $z = 14\mu m$ on the optical axis. (c) Normalized field amplitude profile along the optical axis predicted with MaxwellNet for 20 different intensities.

In conclusion, we provided a demonstration of a neural network trained on Maxwell's equations for intensity dependent refractive index distributions which can be used in conjunction with traditional numerical solvers for both speed up electromagnetic simulations and offer a new alternative for the inverse design of optical devices.

Polarization Singularities in Optical Near Fields: Topology and Chirality

Shubo Wang[1,2*], **Jie Peng**[1], **Shiqi Jia**[1], **and Ruo-Yang Zhang**[3]

[1]Department of Physics, City University of Hong Kong, Hong Kong, China

Abstract: In this talk, I will discuss polarization singularities emerging in the near fields of optical structures. I will show that simple optical structures can generate rich configurations of polarization singularities with intriguing topological and chiral properties. These properties are subtly related to the topology and symmetry of the structures and provide new degrees of freedom for light manipulations and new mechanisms for chiral light-matter interactions.

Polarization singularities are topological defects in the spatial distribution of light's polarization ellipses. They can emerge in various optical systems such as light scattering by small particles [1]. In two-dimensional systems such as photonic crystal slabs, they are intimately related to the boundary states in the continuum. In three-dimensional space, polarization singularities can give rise to interesting polarization configurations such as Möbius strips. We theoretically investigate the polarization singularities generated by simple optical structures (e.g., sphere and torus), and we explored their applications in chiral discrimination and optical force manipulation of small particles.

We find that the nontrivial topology of an optical structure ensures the birth of polarization singularities in the near fields, and bounds their spatial morphologies characterized by topological indexes [2]. The topological indexes of these singularities satisfy $\sum_{\mathbf{r}_s} I_{\mathrm{pl}}(\mathbf{r}_s) = \chi(M)$, where $I_{\mathrm{pl}}(\mathbf{r}_s)$ denotes the index of the polarization singularity at $\mathbf{r}_s$ and $\chi(M)$ denotes the Euler characteristic of the optical structure M. For example, a torus and a sphere will induce different polarization singularities with different total indices. This is decided by their different genus, i.e., torus has one "hole" while sphere has no "hole". In addition, introducing extra spatial symmetries can give rise to higher-order polarization singularities with intriguing polarization configurations inaccessible with conventional optical structures. By mapping the polarization singularities to non-Hermitian exceptional points, we provide a complete framework to understand their invariant properties in spatial evolutions (merging, bifurcation, and topological transitions).

We apply the chiral properties of polarization singularities in chiral discrimination [3]. Chiral discrimination is usually limited by the weak chiral response of enantiomers and the high complexity of the detection methods. We use the C lines (i.e., lines of polarization singularities) emerged in light scattering by a metal sphere to detect small chiral particles. The C lines carry optical chirality since they are intrinsically circularly polarized, and the optical chirality is strongly enhanced in the near fields. We calculated the absorption dissymmetry of the chiral particles at different positions on the C lines. It is found that the absorption dissymmetry can be much larger than that induced by circularly polarized plane-wave excitation, and it strongly depends on the anisotropy of the helices.

We also explore the application of polarization singularities in optical force manipulation of small particles [4]. Near-field optical forces are crucial to on-chip optical manipulations of small particles and molecules. We simulated the optical force and torque on small particles induced by the polarization singularities of a gold cylinder. It is found that the scattering near fields of the cylinder give rise to both electric and magnetic C lines. The chirality

of the C lines can induce complex optical force and torque on small particles, which manifest dramatic spatial variations in the near field region. The optical force and torque provide rich degrees of freedom for manipulating small particles in subwavelength scale.

Our study uncovers the subtle connections between the topological properties of optical near fields and the topology of optical structures. The novel properties of polarization singularities can find broad applications in chiral light-matter interactions, chiral quantum optics, optical sensing and metrology, etc. The study can also be extended to other classical waves such as sound waves.

Abstract: We present an approach to compute partial derivatives of eigenfrequencies corresponding to quasinormal modes using Riesz projections. The approach is based on contour integration with direct differentiation enabling an efficient numerical realization.

The knowledge on the partial derivatives of eigenfrequencies, the so-called sensitivities, is essential for fabrication of nanophotonic devices with a high quality factor [1], which is given by the scaled ratio of the real and imaginary parts of the corresponding eigenfrequency. Furthermore, the sensitivities are important for the numerical simulation of such nanoresonators since the accuracies of the eigenfrequencies are strongly influenced by their sensitivities. In this contribution, we review an approach, proposed in Ref. [2], for computing sensitivities of eigenfrequencies corresponding to quasinormal modes. The approach is based on Riesz projections, i.e., contour integrals. The contour integrals are computed by solving Maxwell's equations with a source term enabling an efficient numerical realization based on direct differentiation of the scattering solutions to Maxwell's equations. We apply the approach to compute the eigenfrequency sensitivities of a nanophotonic resonator [3] with respect to several shape parameters of the resonator. It is demonstrated that our approach allows partial derivatives to be computed with significantly less computational effort than is required by a standard approach.

Quasi-normal mode expansions of resonant scattering responses

J.T. Zimmerling[1*], and R.F. Remis[2]

[1]Uppsala Universitet, Department of Information Technology, Scientific Computing, Sweden
[2]Delft University of Technology, The Netherlands

Abstract: Electromagnetic field interactions with photonic resonators can be efficiently modeled using Quasi Normal Mode (QNM) expansions, especially near a resonator, where low-order expansions are often sufficient. However, we are often interested in the electromagnetic field far away from a resonator. Since QNMs diverge with increasing distance from the resonator, a straightforward QNM expansion of the field is not possible. Here, we propose a formulation that allows for field evaluations at arbitrary distances, using only QNM expansions inside a resonator.

Effect modelling and computation of electromagnetic responses of resonators is an important problem when designing photonic resonators. We are interested in modeling such responses for (possibly dispersive) electromagnetic resonators. Let $\boldsymbol{x}$ denote the position vector and let s denote the complex Laplace frequency. The electromagnetic field is excited by the distant volumetric electric current source $\boldsymbol{J}^{\mathrm{src}}(\boldsymbol{x}, s)$ supported in the domain Ω_{src}. The electric field is then measured using the volumetric receiver $\boldsymbol{J}^{\mathrm{rec}}(\boldsymbol{x}, s)$ supported in Ω_{rec}. In this contribution we are interested in the response $D(s)$ given by the interaction integral

$$D(s) = \int_{\mathbf{x}\in\Omega_{\mathrm{rec}}} \boldsymbol{J}^{\mathrm{rec}}(\boldsymbol{x}, s) \cdot \boldsymbol{E}(\boldsymbol{x}, s)\, \mathrm{d}V.$$

A (possibly dispersive) resonator characterized by the contrast current $\boldsymbol{J}^{\mathrm{sc}} = \chi\mathbf{E}$ is placed far from the support of the source and receiver and is embedded into a background medium. The support of the contrast is denoted by Ω_{sc}. The configuration is illustrated in Figure 1.

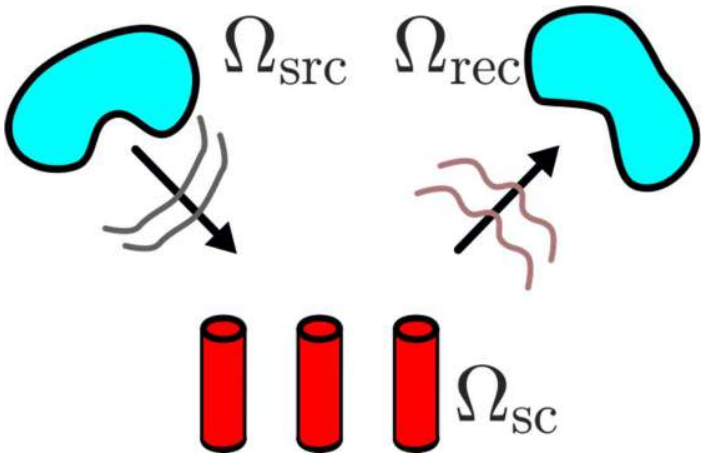

Figure 1: Illustration of a scattering problem where the electromagnetic response of a resonant configuration is of interest.

Let $\boldsymbol{G}(\boldsymbol{x}, \boldsymbol{x}', s)$ denote the Greens tensor of the configuration, then the response can be succinctly written as

$$d(s) = \int_{x \in \Omega_{\mathrm{rec}}} \boldsymbol{J}^{\mathrm{rec}}(\boldsymbol{x}, s) \cdot \int_{\boldsymbol{x}' \in \Omega_{\mathrm{src}}} \boldsymbol{G}(\boldsymbol{x}, \boldsymbol{x}', s) \cdot \boldsymbol{J}^{\mathrm{src}}(\boldsymbol{x}, s) \mathrm{d}V' \, \mathrm{d}V. \quad (1)$$

A common technique to approximate this response especially in the field of plasmonics or nano-photonics is to use so-called Quasi-Normal Mode (QNM) expansions. The Green function is essentially approximated using a few of its eigenfunctions which correspond to the resonance fields of the configuration [2,3,4]. To compute these QNMs multiple efficient numerical methods exists [review paper]. Unfortunately, since the resonator is embedded in an open system with radiation to infinity, the QNM fields diverge far from the resonators. Outside the resonator these fields are not complete, and a straightforward expansion is not possible.

Approaches to still be able to approximate field responses exist in [6,7,1] where the fields are regularized, via for instance the Dyson equation or causality principle. In this contribution we take a different path and rewrite the integral equation (1), using scattered field formalisms such that the Green function is only integrated over the domain Ω_{sc}. In this domain the QMNs form a good approximation space such that QNM expansions are successful in giving low-order description of the electromagnetic field response. We will present numerical examples to illustrate our formalism.

Optomechanics of Quasi-Bound States in the Continuum of Dielectric Metasurfaces

S. Zanotto[1*]

[1]CNR—Istituto di Nanoscienze, and NEST - Scuola Normale Superiore, Piazza San Silvestro 12, Pisa 56217, Italy

[*]corresponding author: simone.zanotto@nano.cnr.it

Abstract: Quasi-Bound States in the Continuum (Q-BICs) are here investigated by means of optomechanic spectroscopy. With this technique, the metasurface is driven into motion according to its mechanical eigenstates, and the time-dependent optical transmission is detected and demodulated at the mechanical frequency. Here we show that this method allows to reveal fine features of Q-BICs hardly observable with conventional spectroscopy. In addition, we believe that our work opens interesting technological perspectives for high-quality factor metasurface-based optical modulators.

Quasi-Bound States in the Continuum are currently a topic of intense investigation due to their unique property of being high-quality resonances with macroscopic (i.e., spatially extended over multiple wavelength) mode sizes. Meanwhile, Q-BICs have typically a large angular dispersion, which make them interesting for Fourier-space image processing. These features are both interesting and challenging: from one side Q-BICs are highly sensitive to perturbation and hence relevant for sensing, low-threshold lasing etc., from the other side they are difficult to detect and to fabricate with reproducibility. In our study, we have considered a slab metasurface based on a silicon holey membrane (Fig. 1d-e), that, according to common practice in fabrication technology, is realized on a silicon bulk carrier wafer through SiO_2 underetching. In this kind of sample, two Fabry-Pérot processes occur: one in the air spacer immediately below the metasurface, and another in the carrier wafer. The latter has a typical free spectral range comparable to the Q-BIC linewidth, making the direct detection of the Q_BIC through ordinary optical spectroscopy (i.e., transmission, reflection) challenging (Fig. 1a).

We thus leveraged on the optomechanical interaction intrinsic in the fact that the metasurface membrane is free to oscillate with drum-like modes, that in our case fall in the MHz range. By an ordinary lock-in type measurement, we detected the modulated transmittance, that shows the notable behavior illustrated in Fig. 1b. Here, the signature of the Q-BIC is much stronger than before, thus allowing a clearer and safer indentification of the optical resonance position and strength. What is more, relying to a coupled-mode model, it is possible to retrieve the static optical signal that would have originated from the metasurface alone, in absence of the multiple Fabry-Pérot resonances (Fig. 1c).

Our result is thus twofold: from one side it delineates a procedure to disembed the spectral signature of Q-BICs in typical slab-spacer-wafer platforms; from the other it defines a prototype for light modulators operating at MHz frequencies. Interestingly, those modulators can implement peculiar angular dispersions, and polarization response [2], all in a lossless fully dielectric environment.

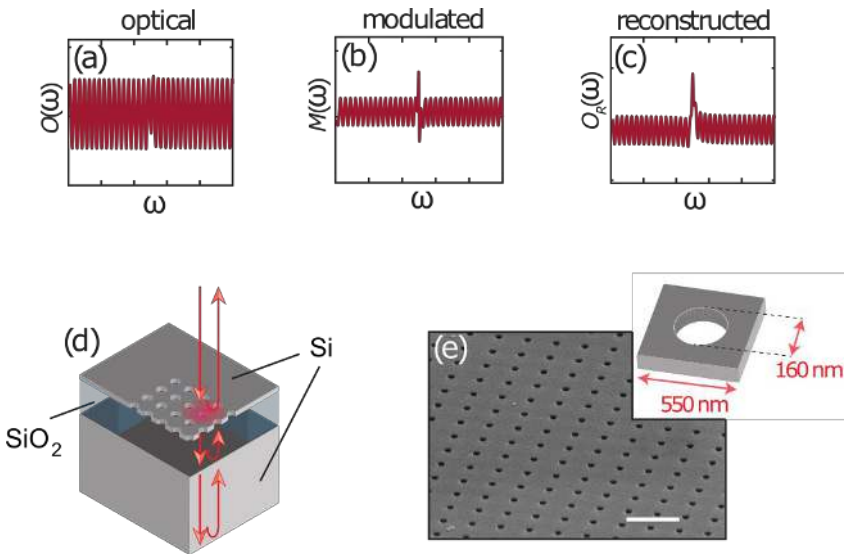

Figure 1: Schematic illustration of the modulation and reconstruction of optical Q-BIC resonances through optomechanical effect. The optomechanical interaction takes place since the metasurface membrane (d, e) is free to move out-of-plane, being constrained through underetched SiO_2 only at the sample edges. (a) Direct optical spectrum (i.e., transmission or reflection) This contains strong Fabry-Pérot contributes from the Si substrate. (b) Modulated optical signal detected e.g. through a lock-in when the membrane is moving. (c) Reconstructed Q-BIC resonances, following elaboration of the spectrum in (b).

Photon-Pair Generation in Resonant Dielectric Nanostructures

Maximilian A. Weissflog[1,2,*]

[1]Institute of Applied Physics, Abbe Center of Photonics, Friedrich Schiller University Jena, Albert-Einstein-Str. 15, 07745 Jena, Germany

Abstract: Resonant nonlinear nanostructures are evolving into a versatile platform for the generation of entangled photon-pairs with engineered properties. The talk will discuss recent advances in the theoretical description and experimental control of quantum photon-pair states, particularly the generation of maximally polarization entangled Bell states in single nanoresonators as well as spatial tuning of pair-emission in a nonlocal Lithium Niobate metasurface.

Photon-pairs are a crucial resource for many applications relying on quantum optical effects such as quantum communication, imaging, sensing and computing. While entangled photon-pairs were so far mainly generated via spontaneous parametric down-conversion (SPDC) in bulk-optical nonlinear components, recently resonant photonic nanostructures have been introduced as a new platform for SPDC [1,2]. The high degree of control on e.g. the polarization of classical nonlinearly generated emission from nanoresonators [3] suggests that they could in principle be further developed into sources of polarization entangled two-photon states. However, the large number of degrees of freedom in highly multimodal and open nanocavities made a formal description and design of entangled photon-pair sources challenging so far.

The talk will discuss how this issue is solved by combining a Green's function (GF) formalism that can handle SPDC in radiative or lossy systems [4] with an expansion of the GF into a limited number of quasinormal modes (QNMs) of the nanoresonator. Using this new approach, it can be shown that already simple nanoresonator geometries such as a single AlGaAs nanocylinder can generate maximally polarization entangled Bell states, revealing the intricate connection between resonant modes, nonlinear susceptibility tensor and the photon-pair detection configuration.

Next to the polarization degree of freedom, also the spatial emission properties of photon-pairs can be efficiently controlled in resonant nanoscale SPDC sources. Based on a metasurface consisting of a SiO2-grating on a Lithium Niobate thin film, I will show that the strong angular dispersion of the supported nonlocal guided mode resonances [5] can be used to continuously tune the emission angle of frequency-degenerate photon pairs by changing the SPDC excitation wavelength. Furthermore, our recent experiments prove that such a metasurface allows generation of entangled photon-pairs simultaneously in transmission, reflection and counter-propagating configuration.

In sum, I will discuss our recent progress in the development of a theoretical framework as well as experiments for photon pair-generation in resonant nanostructures with emphasis on the generation of polarization entangled states and spatial emission control.

Light scattering and dipole emission in resonant periodic structures

L. Zschiedrich[1*], F. Binkowski[2], P. Manley[1], M. Hammerschmidt[1], P.-I. Schneider[1], and S. Burger[1,2]

Abstract: We address the numerical computation of the emission and radiation of an isolated dipole within a laterally periodic structure such as a photonic crystal, a light emitting device or a meta lens. We utilize the Bloch-Floquet transform and its inverse to represent the solution as an integration of Bloch-periodic sub-solutions over the Brillouin zone. Due to the appearance of trapped modes and Wood anomalies this integration is numerically very challenging.

The emission and radiation of a dipole is highly influenced by its surrounding. State-of-the-art solvers are capable to deal with isolated dipoles placed within a finite computational domain of an arbitrary geometry and with a stratified background as the exterior space. For the treatment of a periodic environment we apply the Bloch-Floquet transform [1]. Then, for each point in the Brillouin zone it is required to solve a problem on the unit cell with a Bloch-periodic dipole as a source. Numerically, one encounters two major challenges. Firstly, the singularity of the dipole solution requires to split the field into a semi-analytical part comprising the singular field and a smooth correction field feasible for a numerical discretization. However, even the semi-analytical solution of a Bloch-periodic dipole is delicate to compute [2]. We therefore propose an alternative approach which only relies on the analytic solution for a dipole in homogeneous or stratified background and which perfectly fits into our Finite-Element framework. Secondly, to gain the overall solution we need to integrate over the Brillouin zone. We will show that arising resonances due trapped modes within the periodic structures renders this integration extremely costly. To mitigate the numerical efforts we apply an adaptive integration scheme.

Abstract: We propose a Mie-Tamm optical cavity structure (MTOCS) that can enhance the photon flux of a quantum emitter above 3 GHz within a small numerical aperture collection cone. Our design uses a nested cavity system in which the quantum emitter's emission is coupled to an extended Tamm mode through Mie resonances supported by a nanocylinder. This approach enables highly efficient light-matter interactions in nanophotonic systems, making it suitable for single-photon sources.

To achieve high-performance true single-photon sources, on-demand emission at rates exceeding the GHz regime is required. However, current semiconductor technologies face limitations due to the difficulty of extracting photons from the semiconductor, which is caused by the high refractive index of the host material. In our study, we analyze single-photon emitters that are embedded in a cylinder, which is defined vertically by a bottom distributed Bragg reflector (DBR) and a top metallic mirror, and laterally by dielectric confinement with a low refractive index layer (Figure 1(a))[1]. The goal is to optimize the flux and collection efficiency of single photons at the substrate-air interface. By doing so, we can utilize the top metallic mirror as an electrical contact to switch the single-photon emitter on and off, or to tune its properties. This design, combined with an embedded excitation source underneath, could potentially enable the creation of a monolithic electrically-driven and tunable single-photon source.[2]

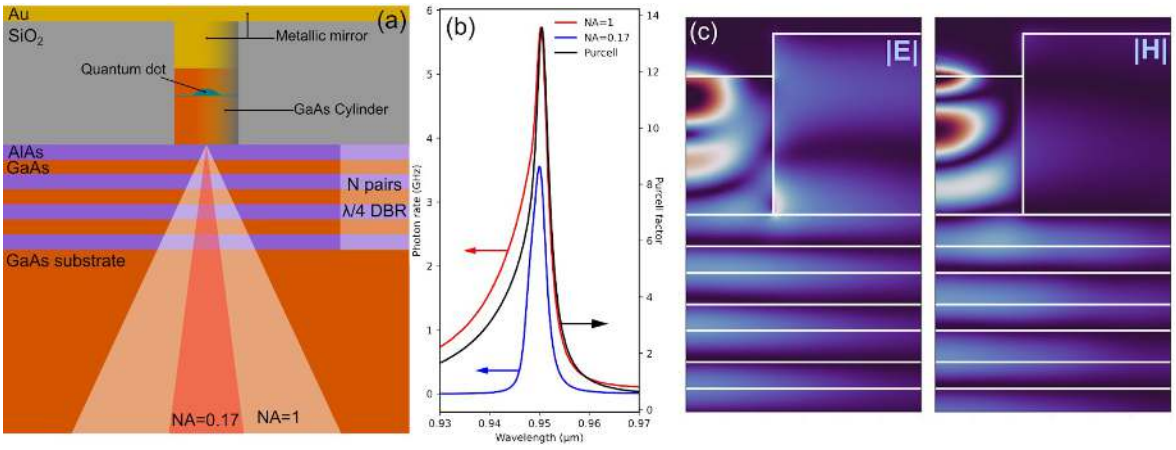

Figure 1. (a) Scheme of the MTOCS where the main elements are identified and two extraction cones of different NA are illustrated (not to scale). (b) Photon extraction rate in GHz (assuming a radiative lifetime of 1 ns) for the two NAs indicated

before and the Purcell factor. (c) Electric and magnetic field modulus at resonance showing the excitation of a Mie-resonance together with the planar front-wave in the DBR explaining the coupling between the cavities and the high directionality of the proposal.

To demonstrate the potential of our design on GaAs technology, we have chosen a specific configuration in which the substrate is made of GaAs and the dielectric layer as SiO_2, the distributed Bragg reflector (DBR) is composed of AlAs/GaAs bilayers, and the quantum emitter is an InAs quantum dot. Our analysis demonstrates that the proposed system is capable of achieving a photon emission rate of more than 3 GHz, collecting within a very narrow numerical aperture (NA) of 0.17 (as shown in Figure 1(b)). At the critical angle (NA=1), the emission rate can be larger than 5 GHz. We will present a detailed analysis of the different modes involved in enhancing the emission rate and directionality of the proposed nanocavity design. Additionally, we will explore potential modifications to the geometry that could reduce off-axis scattering and simplify the fabrication process and show the advances on the physical realization of the TMOC. We are currently in the process of fabricating a single-photon source based on the proposed TMCO design, and we will present our latest results on the device fabrication.

Calculating resonant states in optical systems: Exact theory and approximations

E. A. Muljarov

School of Physics and Astronomy, Cardiff University, Cardiff CF24 3AA, United Kingdom

*corresponding author: Egor.Muljarov@astro.cf.ac.uk

This talk will focus on recent advances of the resonant-state expansion (RSE) - a rigorous theory of optical resonances in open systems [1,2], allowing their accurate calculation and intuitive understanding. New achievements include variations of the RSE aiming to enhance its efficiency and reach, as well as some useful approximations following from the RSE, including single-mode and first-order approximations [3,4], for treating homogeneous and inhomogeneous perturbations, both inside and outside the optical systems.

Bound-State-in-the-Continuum Resonances in Monolithic Cavities on a Substrate

Cindy Péralle[1], Sushanth Kini Manjeshwar[2], Anastasiia Ciers[2], Witlef Wieczorek[2], and Philippe Tassin[1]

[1]Department of Physics, Chalmers University of Technology, 412 96 Gothenburg, Sweden
[2]Department of Microtechnology and Nanoscience, Chalmers University of Technology, 412 96 Gothenburg, Sweden

Abstract: We present a strategy to find photonic cavities with bound-state-in-the-continuum resonances that can be fabricated with planar fabrication methods on a substrate.

Due to their low mass and high reflectivity, photonic-crystal membranes are excellent candidates for vibrating end mirrors in optomechanical cavities. Cavities with photonic-crystal membranes can support a quasi-bound state in the continuum (BIC), i.e., a resonance exhibiting an optical quality factor only limited by dissipative loss. Such cavities promise to access new regimes in optomechanics [1], e.g., the single-photon strong-coupling regime for applications in precision sensing [2] and quantum information processing [3]. However, previously proposed designs turned out to be difficult to fabricate with state-of-the-art nanolithography techniques. Furthermore, it is difficult to find new nanophotonic structures with a bound state in the continuum, in particular if a substrate breaks the mirror symmetry of the cavity.

In this contribution, we will present our work on designing a new monolithic cavity on a substrate exhibiting a bound state in the continuum and, in the process, we will reveal a design methodology to turn cavities with an in-plane mirror plane into a cavity on a substrate.

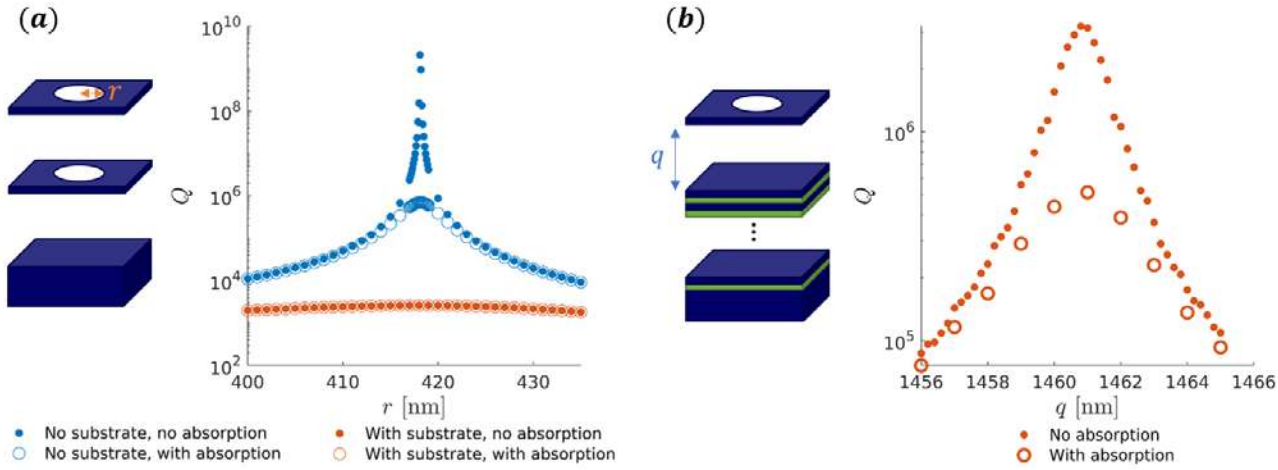

Figure 1: (a) Schematic of a cavity formed by two identical 2D photonic-crystal membranes and its quality factor around a BIC as a function of the hole radius r, without (blue) and with (orange) substrate, with (dots) and without (empty circles) material absorption. (b) Schematic of a cavity formed by one 2D photonic-crystal membrane and a DBR deposited on a substrate and its quality factor around a BIC as a function of the cavity length q, with (blue) and without (orange) material absorption.

We start from a cavity formed by two identical membranes patterned with cylindrical holes arranged in a square lattice in GaAs; such a cavity is known to exhibit a bound state in the continuum [1], but only when floating in air. For practical reasons, a substrate must be introduced close to the cavity. Unfortunately, a substrate allows light to escape the cavity through diffraction orders in the substrate, resulting in a radiative loss channel and destroying the bound state in the continuum.

In order to counter this effect, we propose a new design, illustrated in Fig. 1(b), replacing one of the photonic-crystal membranes by a DBR, specifically designed to reflect both the 0^{th} and 1^{st} orders of diffraction from the above 2D photonic-crystal membrane at a convenient wavelength of 1525nm. This design is derived from the previous cavity with two photonic-crystal membranes by taking advantage of the mirror symmetry plane in the original cavity. This allows us to preserve the bound state in the continuum and, at the same time, also eliminates the need to carefully align two patterned membranes. Indeed, in Fig. 1(b), we see that our new cavity again has a high quality factor. After an optimization process, we predict quality factors reaching about $5\times10_5$ when material absorption is included in the model. By eliminating the radiative loss channels through the substrate and making the system also easier to fabricate, our new design allows for a more practical observation of an optomechanical cavity exhibiting a bound state in the continuum.

Abstract: We discuss the prospects to observe quantum confinement effects in different types of optical excitations supported by systems ranging from single molecules to nanostructures. In contrast to plexitons, where the hybridization of a plasmonic mode and a fermionic excitation leads to a deviation from the uniform energy spacing in the bosonic ladder, we consider optical nonlinearities at the level of a single quantum. Practical implementations and applications are also discussed.

In this presentation, we discuss the prospects to observe quantum confinement effects in different types of optical excitations supported by systems ranging from single molecules to nanostructures. In contrast to plexitons, where the hybridization of a plasmonic mode and a fermionic excitation leads to a deviation from the uniform energy spacing in the bosonic ladder, we consider optical nonlinearities at the level of a single quantum. Practical implementations and applications are also discussed in systems that comprise plasmons in ultrathin metals[1,2] and quantum-phase materials,[3] excitons in transition metal dichalcogenides, and phonon polaritons in ionic insulators.[4]

Nanolasers: Dynamics and Phase Locking

Yeshaiahu (Shaya) Fainman, Sizhu Jiang, Suruj Deka and Athena Pan
Department of Electrical and Computer Engineering, University of California San Diego, La Jolla, CA, 92093-0407 USA

Abstract: We discuss nanoscale metal-dielectric-semiconductor resonant gain geometries to create a new type of light emitters focusing on three key aspects: second order intensity correlation characterizations, direct modulation and coupled nanolasers dynamics.

Introduction: Nanolasers have attracted considerable attention in the past two decades due to their advantageous characteristics such as ultrasmall footprint, lower power consumption, and high-speed operation that can benefit a plethora of applications. While most studies so far have been focused on individual lasers, the next phase would be applying these nanolasers in an array form for various applications, including imaging, biosensing, orbital angular momentum generation, virtual and augmented reality, and Lidar systems. We present the past and on-going research on nanolasers that is conducted in our group at UCSD, starting from the study on individual nanolasers to coupled nanolasers towards the realization of nanolaser array. Specifically, we discuss design of optically and electrically pumped nanolasers together with the second order intensity correlation characterization technique that helps to define the lasing threshold and different operating regimes of nanolasers when the conventional measurement is inadequate. We then discuss the wavelength tunability and intensity modulation of nanolasers followed by the studies on the phase-locking condition of nanolasers supported by experimental demonstration of mode selection in coupled nanolasers.

Design and characterization of nanolasers: Room-temperature optically pumped MDNLs that are subwavelength in all three dimensions have been demonstrated a decade ago [1]. In this design, metal cladding is used to provide the 3D optical confinement, and dielectric shield reduces the optical mode overlap with the lossy metal and thus lowers the lasing threshold. Thresholdless coaxial nanolasers have also been demonstrated in [2] with the light-in light-out curve (L-L curve) showing vanishing of a kink in the curve suggesting that the spontaneous emission (SpE) factor β approaches unity. To make nanolasers more useful for practical on-chip application, we experimentally demonstrate in [3], a new CW electrically pumped (e-pumped) nanolaser. For high energy efficiency and fast modulation speed nanolasers with a high spontaneous emission factor β are desirable, but their threshold characterization with traditional methods are not challanging. We developed a novel method to characterize the coherence properties of high-β nanolasers employing second-order intensity correlation ($g^2(\tau)$) [4]. Specifically, other than the height of the $g^2(0)$ peak as reported in the literature, it is first reported in [4] that the $g^2(\tau)$ pulse width also changes as a function of the pump intensity. The measurement technique is applied to a MDNL with β=0.25 and demonstrate that the SpE, ASE, and lasing regime can be fully characterized. We show that $g^2(\tau)$ pulse width shrinks below and near the threshold and broadens above the threshold when nanosecond pump pulses are employed.

Phase-locking in nanolasers: Understanding the phase-locking stability and the nonlinear dynamics of coupled nanolasers is essential for generating phase-locked laser arrays for high-power and steerable optical beam generation. Theoretical analysis of such laterally coupled lasers have been vastly investigated previously. However, these studies overlooked the effect of β, which is not-negligible for nanoscale lasers. In [5], we

reported the theoretical effects of varying β on the stability of phase-locking, with varying pump rates and frequency detuning considered. The stable and unstable regimes of the coupled lasers are identified through a bifurcation analysis over the coupled laser rate equations, with the details given in [5]. To demonstrate stable in-phase locking in nanolasers, we start with two coupled nanolasers that serve as a building block in laser array. The simulation results of simply arranging the two nanolasers next to each other show that the out-of-phase mode always have higher quality factor and lower lasing threshold. In our most recent work [6], we investigate addition of a coupling bridge in between two MDNLs, and study stability of in-phase and out-of-phase locking of such designs with the corresponding supermodes. We show that by controlling the length and the width of the bridge, we can control the resonance frequencies and the quality factors of the two supermodes, and thus obtain a coupling coefficient that supports an in-phase or out-of-phase locking modes.

We acknowledge partial support of NSF, ARO, DARPA, and ASML/Cymer Corporation.

Resonantly confining light in air: The dielectric Mie voids

M. Hamidi,[1] K. Koshelev,[2] M. Hentschel,[3] A. Canós-Valero,[1] Y. Kivshar,[2] H. Giessen,[3] and T. Weiss[1,3,*]

Abstract: Manipulating light at the nanoscale has become a central challenge in photonic metastructures, resonant metasurfaces, nanoscale optical sensors, and many more, and it is largely based on resonant light confinement in dispersive and lossy metals and dielectrics. We present the theoretical framework for resonantly confining light in air surrounded by high-index dielectrics and compare it with experiments. This confinement works down to the ultraviolet and can be understood to some extent via a generalization of the Babinet's principle to dielectrics.

In a recent publication [1], we demonstrated that individual voids embedded in high-index dielectric host materials support localized resonant modes with exceptional optical properties. Due to the confinement in air, the modes do not suffer from the loss and dispersion of the dielectric host medium. We show theoretically that the modes demonstrate highly local properties in the near- and far-field, which makes them non-interacting while arranged in lattices. The Mie void modes in dispersive dielectric materials, e.g., silicon, possess large quality factors, which become comparable or larger than that for silicon resonant nanoparticles in the visible and UV. We experimentally realize resonant Mie voids by focused ion beam milling into bulk silicon wafers and experimentally demonstrate resonant light confinement from visible down to the UV spectral range at 265 nm (4.68 eV). We further utilize the bright, intense, and naturalistic colours for nanoscale colour printing employing individual Mie voids as individual pixels.

It might be tempting to attribute the observed phenomena to the well-known Babinet's principle [2]. However, a straightforward application of this principle is not possible for connecting Mie voids to conventional dielectric resonators as their inverse structures. The reason is that Babinet's principle is an approximation for perfect electric conductors in the limit of infinitesimally thin films. Yet, we find that a generalization of this principle to dielectrics allows us to infer properties of Mie voids from those of their inverse counterparts. This provides design rules for achieving certain optical responses, which can be even extended to magnetic materials.

The concept of Mie voids paves the way towards the operation of functional high-index metasurfaces into the blue and UV spectral range, while the combination of resonant dielectric Mie voids with dielectric nanoparticles will more than double the parameter space for the future design of metasurfaces and other micro- and nanoscale optical elements. This extension will enable novel antenna and structure designs, which benefit from the full access to the modal field inside the void as well as the nearly free choice of the high-index material for novel sensing and active manipulation strategies.

Design and Simulation of Large-Scale Metalenses

J. Niegemann[1*], D. Huynh[2], F. Gomez[1], D. McGuire[1], and J. Pond[1]

[1]Ansys Canada Ltd., Canada
[2]Ansys Germany GmbH, Germany

Abstract: One of the biggest challenges in the characterization of meta-atoms is the large parameter space that needs to be explored. To design realistic metalenses, we usually need to characterize the individual meta-atoms by frequency, angles of incidence, polarization, and often multiple geometric parameters. Here, we present our approach to quickly construct large databases of meta-atoms. In addition, we demonstrate how such a database can then be used to efficiently simulate centimeter-sized meta-lenses.

Metalenses consist of carefully arranged meta-atoms with sub-wavelength structures. By adjusting and optimizing the geometry of these individual elements, we can tailor the phase, amplitude, and polarization of the transmitted (or reflected) light. Over the past few years, substantial progress was made in the simulation and manufacturing of metalenses [1] which has generated large interest from both academia and industry. However, the design and optimization of centimeter-sized meta-lenses remains challenging and there still is a need for improved simulation approaches.

In this presentation, we will first discuss and compare different numerical methods to characterize and optimize meta-atoms. In particular, we will consider the respective strengths and weaknesses of the finite-difference time-domain (FDTD) method and the rigorous coupled-wave analysis (RCWA) approach. Then, we will discuss our approach for constructing databases of meta-atoms which store the local amplitude, phase and polarization information of a specific unit cell as a function of frequency, angles of incidence, polarization, and multiple geometric parameters. To efficiently cover this parameter space, we make use of adaptive surrogate models. Finally, we also discuss how to use these databases to enable the fast but accurate simulation of large-scale metalenses in optical systems using raytracing.

Engineered Solid-State Quantum-Light Sources for Quantum Networking

Tobias Heindel[1]

[1]Institute of Solid State Physics, Technische Universität Berlin, Berlin, Germany
[*]corresponding author: tobias.heindel@tu-berlin.de

Abstract: In this talk I present our recent progress in the field of solid-state quantum light sources for applications in quantum networking. In this context I present recent advances in the numerical optimization and fabrication of quantum light sources, designed for the direct coupling to single-mode optical fibers, and their application in quantum communication testbeds operating at wavelengths around 800, 1300, and 1550 nm.

In recent years, tremendous progress has been achieved in the engineering of solid-state-based quantum light sources. In this context, semiconductor quantum dots (QDs) are among the most promising candidates for implementations of quantum information [1]. In my talk, I will present recent progress in this field, ultimately striving towards quantum networks at global scales. I will discuss the development of novel building blocks, including fiber-pigtailed quantum devices [2,3] and plug&play benchtop single-photon quantum key distribution (QKD) systems [4], to be assembled in local quantum communication networks in Berlin city, but also in inter-city links. I show how to optimize and certify the performance of QKD systems [5] and report on our recent efforts in transferring our knowledge to advanced protocols, different technology platforms (e.g. quantum emitters in 2D materials [6]), and telecom C-band wavelengths suitable for long-haul quantum communication [7]. Not least, a deep dive into coherent optical control experiments on quantum emitters reveals important implications for the realization of quantum-secured data links [8], thereby building the bridge from fundamental quantum optics to secure data communication exploiting photonic quantum technologies. Assembling these building blocks to functional multi-partite quantum networks is a grand challenge in quantum technologies which is tackled in my group.

Many people contributed to this work, including my group members L. Rickert, T. Gao, D. Vajner, K. Kaymazlar, M. Lach, N. Kewitz as well as the many team members of collaborating groups - I would like to express my gratitude to all of them. We further acknowledge financial support by the German Federal Ministry of Education and Research (BMBF) via the project “QuSecure” (Grant No. 13N14876), the BMBF joint project “tubLAN Q.0” (Grant No. 16KISQ087K), and the Einstein Foundation via the Einstein Research Unit “Quantum Devices”.

MAN: A freeware to compute and analysis modes of resonators

T. Wu[1*], D. Arrivault [1], W. Yan[2], and P. Lalanne[1]

[1] LP2N, Institut d'Optique Graduate School, CNRS, France

[*]corresponding author: tong.wu@institutoptique.fr

Abstract: In this talk, we introduce MAN (Modal Analysis of Nanoresonators) a software with many open scripts, which computes and normalizes the quasinormal modes (QNMs) of electromagnetic resonators.

Introduction: In this talk, we present MAN [1-2], an open-source software that uses the QNM basis for analyzing the response of virtually any resonators or antennas, be they composed of dispersive, anisotropic, or non-reciprocal materials, or operated at high (optical and near-IR waves) or low (RF waves) frequencies. MAN is conceived to educatively help the user analyze the physics of electromagnetic resonators towards the identification of the dominant QNMs to speed up the simulation of resonant structures and offer physical transparency in the design.

Result: Figure 1 shows the structure of the software. MAN is the result of a collective effort over the last decade. It gathers two solvers, QNMPole [3] and QNMEig [4], which have already acquired a good reputation as can be seen from the number of citations of the referent publications [3-4] or software downloads [2]. QNMEig provides a comprehensive interface to the commercial software COMSOL Multiphysics; QNMPole can be used with any software capable of solving Maxwell equations in the frequency domain. MAN additionally features many toolboxes that illustrate how to use the software for analyzing various emblematic geometries with a superposition of QNMs, therein providing a transparent interpretation of the physics.

Designing new materials is crucial for nonlinear nanophotonics, where strong local field enhancements are sought after in sub-wavelength structures. Since transparent optical materials are typically weakly nonlinear, special interest is currently directed at artificial composites that combine nonlinear media where the local field enhancement is provided by plasmonic nanoparticles.

In the context of nanoscale materials engineering, polymers have been studied as possible candidates for all-optical devices because of their relatively large $\chi^{(3)}$ susceptibility and fast response time. In particular, a significant effort has been devoted in understanding the properties of polyaniline (PANI), which also exhibits excellent environmental stability [1].

In this work, we measured the intensity-dependent complex refractive index of ethanol-based solutions with PANI and Ag nanoparticles via Z-scan [2], being motivated by their potential exploitation in all-optically controlled solid-state meta-lenses and ultrathin variable absorbers.

By moving a thin $\chi^{(3)}$ sample in and out of the focus of an intense coherent beam, the Z-scan trace is retrieved via the modulation of the transmittance through an iris placed after the sample. This enables to evaluate the real part of the refractive index, $\mathrm{Re}[n(I)] = n_0 + n_2 I$, which self-focuses or self-defocuses the Gaussian beam due to the optical Kerr effect. The imaginary part of $n(I)$ can also be inferred by completely opening the iris, which provides the two-photon-absorption coefficient β_2.

Our measurements were performed with 150 fs coherent pulses provided by an Amplitude Mango optical parametric amplifier at $\lambda = 400$ nm, where Ag nanoparticles exhibit a strong plasmonic resonance. Two different solutions in ethanol were characterized: with 2.3×10^{-6} mol/L of PANI, and 5.5×10^{13} Ag nanoparticles/L. In the former case, we found $n_2 = -4.4 \times 10^{-14}\mathrm{cm}^2/\mathrm{W}$ and $\beta_2 = -0.53$ cm/GW.

These results are promising towards the demonstration of solid-state Ag-PANI metasurfaces on a transparent substrate, which is currently under way.

Quasi-Normal Mode Expansion in Unbounded Photonic structures: Perfectly Matched Layers (PML) vs. Bayliss-Turkel (BT) Absorbing Boundary Condition

G. Demésy[1], A. Nicolet[1*], and F. Zolla[1]

[1]Aix Marseille Univ, CNRS, Centrale Marseille, Institut Fresnel, Marseille, France

[*]corresponding author: andre.nicolet@fresnel.fr

Abstract: This paper compares truncation methods, i.e. Perfectly Matched Layers (PML) vs. Bayliss-Turkel (BT) Absorbing Boundary Condition (ABC), of unbounded domains for their performance in the quasi-normal mode expansions involving a continuous spectrum.

The quasi-normal mode expansion has received a lot of attention in the last decade[1,2] and is now well understood for very general problems that may involve very general types of dispersive materials[3]. The main remaining pitfall is the treatment of the continuous spectrum associated with unbounded domains. For the direct scattering problems, the perfectly matched layers (PML) [3] have proved to be a very efficient tool. However, they are not always satisfactory for modal expansion problems: they can give good approximations to the leaky modes but the numerical representation of the continuous spectrum they provide can be a source of numerical inaccuracies. An alternative approach is to use absorbing boundary conditions (ABC). At first order, the simple impedance condition (Robin condition) is too simple, but higher order approximations such as the Bayliss-Turkel (BT) condition[4] are very interesting alternatives as it will be shown in numerical examples.

Exploiting and Engineering non-Hermiticity in Photonics

M.Gurioli[1*], N. Granchi[1,2], and F. Intonti[1,2]

[1]Department of Physics and Astronomy, University of Florence, Italy
[2]European Laboratory for Non-linear Spectroscopy, University of Florence, Italy
[*]corresponding author: massimo.gurioli@unifi.it

Abstract: The non-Hermiticity is an unavoidable feature of any photonics system based on sound models and experiments. It has been used for mapping and optimizing the Q factor of photonic modes. Here we discuss its exploitation for engineering three effects: i) exciton light traps via radiative Lamb shift, ii) Purcell effect beyond the dipole approximation and iii) shaping the Fano LDOS via engineering the cavity losses.

At the basis of many relevant photonic accomplishments is the control of the lineshape and spatial extension of the photonic local density of states (LDOS) and consequently the manipulation of any light-matter interaction process. The so-called Purcell effect, i.e. the enhancement of the spontaneous emission rate is controlled by the quality factor (Q) and the modal volume (V) of the microresonators [1]. Important progress has been achieved on the description of photonics as a non-Hermitian open system by means of quasi normal modes (QNMs) with complex eigenvalues, which has led to deep modification of the common picture for V [2]. The complex-valued character of V, with its imaginary part linked to the non-Hermitian nature of open systems, is now established and experimentally confirmed [3,4]. At the same time, non-Lorentzian LDOS lineshapes have been experimentally observed even in carefully designed photonic systems displaying relatively low optical losses [5]. More recently, the map of the imaginary part of the modal volume has been used for driving the optimization of the in-plane and out-of-plane Q factor of any photonic modes [6].

In this contribution we review three recent achievements where the complex modal volume is engineered and exploited: i) enhancement and control of the Lamb Shift for exciton light trapping [7], ii) tailoring the CDOS for shaping the Purcell effect beyond the dipole approximation [8] and iii) controlling the in-plane losses for shaping the Fano LDOS [9].

Chiral plasmonic nanostructures can play a crucial role in quantum optics and sensing, as they combine extremely enhanced electromagnetic near-fields with a strong sensitivity to the handedness of far-field radiation. Here we study the excitation of plasmonic double helices theoretically and experimentally in the visible and near-infrared regime. Full-field numerical modelling reveals the presence of several resonant plasmonic modes that can be selectively excited by left and right circularly polarized light. All observed modes are similar to those of a single helix, but show an overall stronger response. The mode symmetry of double helices corresponds to an antisymmetric charge distri- bution of straight two wire waveguides. The full description of the excitation mechanism is provided by extending our analytical model for single helices [1] by taking the near-field coupling of the two helical wires into account.

The helices are directly written with a focused electron beam [2,3]. The technique is based on electron-induced dissociation of a gaseous precursor in the vacuum chamber of an electron microscope and allows single-step 3D printing of complex geometries. The optical response of the helices is characterized by confocal transmission spectroscopy. This work is funded by German Research Foundation under grant no. HO 5461/3-1.

Abstract: The precision afforded by He-ion beam milling on monocrystalline gold and silver flakes presents an opportunity to tailor local fields at an unprecedented level of 1nm. This method enables the fabrication of intricate structural details, which can be used to create nanoresonators and antennas with unique properties. We leverage these capabilities to create devices that exhibit local symmetry breaking, ultrasmall mode volumes, and precise chiral scattering.

In a first project we exploit the capabilities of He-io beam milling to fabricate resonant optical antennas exhibiting a global antisymmetric mode, which causes very high field enhancement in the gap. We then locally break the symmetry of the antenna hotspot to efficiently generate second harmonic radiation by switching of the silencing effect (see Fig. 1).

Scale bar, 10 nm. c, Scanning electron micrograph of an asymmetric-gap antenna with tip apex radius of 3 nm and gap size of 8 nm. Scale bar, 50 nm. d, Tuning SHG emission by variation of the local degree of asymmetry.

In a second application we fabricate plasmonic nanoslit resonators with very small modal volumes to achieve strong coupling at ambient conditions To match the transition energy of single quantum dots to the nanoresonators we exploit a photoactivated, oxygen-driven blueshift of the quantum dot emission to tune its photoluminescence spectrum. As a result, we observe complete anticrossing spectra at ambient conditions (see Fig. 2).

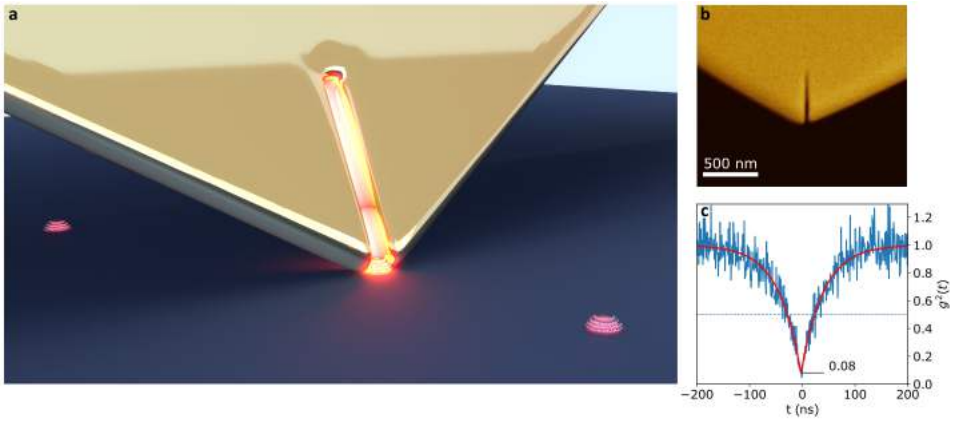

Fig. 2: A gold microplatelet scanning plasmonic nanoresonator in close contact to a quantum dot (artistic representation). b SEM image of a fabricated PNR. c 2nd-order autocorrelation function, $g^{(2)}$, of an individual QD.

Finally, we present light-driven microdrones, which can be steered in 2D in all degrees of freedom by means of plasmonic nanomotors (see Fig. 3). These motors are optical antennas which resonantly scatter unfocused circular polarized light into specific directions. This results in photon recoil forces which driven the microdrones.

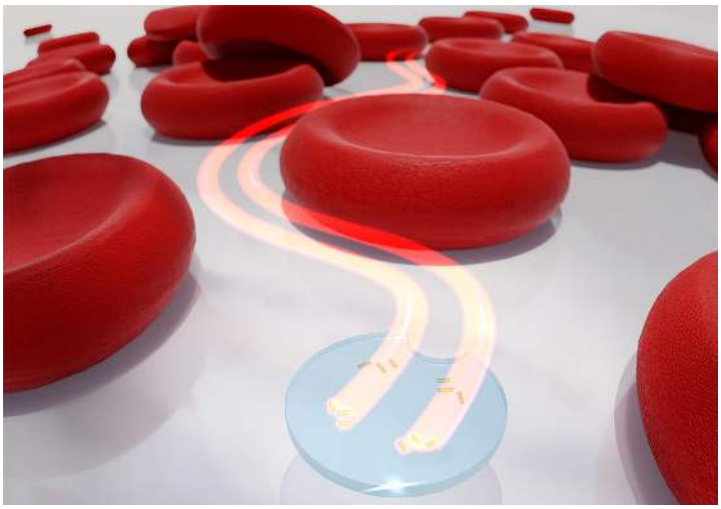

Fig. 3: A gold microplatelet scanning plasmonic nanoresonator in close contact to a quantum dot (artistic representation). b SEM image of a fabricated PNR. c 2nd-order autocorrelation function, g2, of an individual QD.

Self-assembled DNA-origami inverse diamond lattice with a photonic band gap in the UV

Gregor Posnjak[1*], Xin Yin[1], Paul Butler[2], Oliver Bienek[2], Mihir Dass[1], Ian Sharp[2], and Tim Liedl[1]

[2]Walter Schottky Institute, Technical University Munich, Germany

[*]corresponding author: gregor.posnjak@lmu.de

Abstract: Inverse diamond lattice is a potential photonic crystal that was predicted to show one of the widest and most robust photonic band gaps. We designed DNA origami-based self-assembling tetrapod structures which crystalize into an inverse diamond lattice with a periodicity of 170 nm. After chemically depositing silica and titania on the diamond structure we observe tunable reflection bands in the UV which are in good agreement with theoretical predictions of photonic properties of the system.

Photonic crystals are optical analogues of semiconductors, where the periodic modulation of the dielectric constant prevents photons with energies within certain ranges to propagate through the material [1]. This so-called photonic band gap is determined by the symmetry of the structure, its periodicity and the contrast between the regions of high and low dielectric constant. While there have been many realizations of different types of photonic crystals, materials with a direction independent, complete photonic band gap at visible wavelengths have been notoriously difficult to manufacture. One of the prime candidates for such a structure is the inverse diamond structure which is a diamond lattice where all the lattice points are connected to their nearest neighbors with rods [2,3]. Many different approaches for assembling such a structure at periodicities comparable to visible wavelengths have been proposed but realizing it has been proven difficult [4].

Here we demonstrate inverse diamond lattice assembly based on DNA origami-designed building blocks. DNA origami is a nanotechnology, which uses the predictable sequence-dependent binding of DNA strands to form objects of different shapes and functionalities [5,6]. We use it to design a self-assembled tetrapod building block, which we can polymerize into a 3D lattice. By carefully controlling the interactions between the individual tetrapods we can crystalize them into inverse diamond lattices with 170 nm lattice constant (Figure 1a). These crystals serve as the scaffolds on which we can deposit different materials. To manufacture the photonic crystals we first use wet chemistry to deposit a layer of silica that increases the structural stability during drying. On the dried crystal we deposit titania to increase the refractive index of the structure to open up the photonic band gap. We characterize the optical properties of the titania-coated crystals by measuring the reflected light spectra where we observe a reflection band in the UV region, the position and width of which depends on the thickness of the titania coating. The measurements show good agreement with simulations of the photonic properties of the structure (Figure 1b).

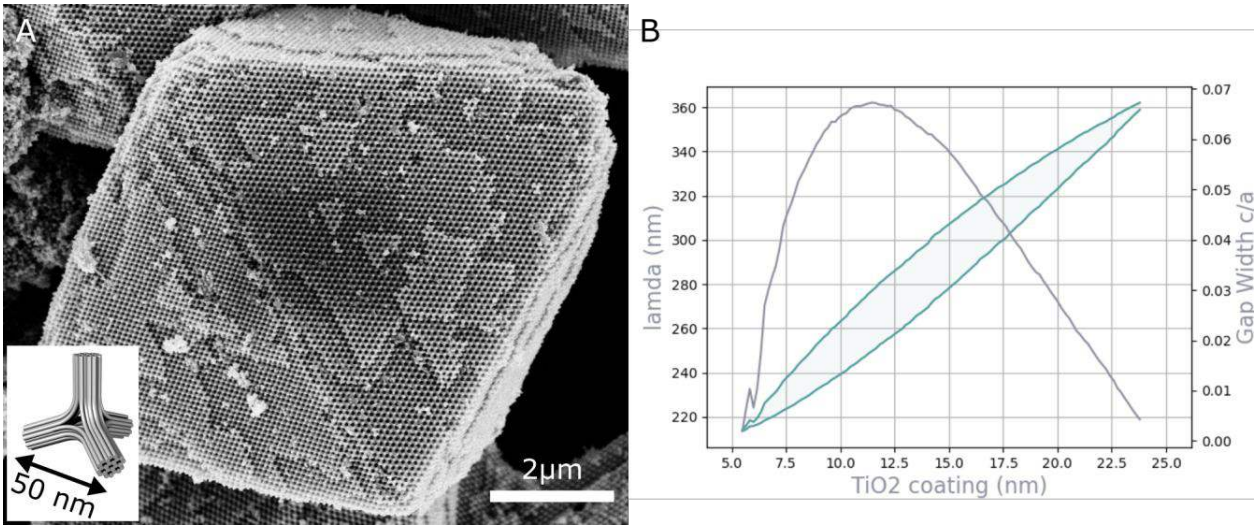

Figure 1. Left: Silica-coated diamond lattice with 170 nm periodicity. Inset: model of the DNA origami tetrapod building block. Right: The photonic bandgap opens in the UV and red-shifts with the increase of the titania thickness. Simulated with MPB [7] (http://ab-initio.mit.edu/mpb).

Photonic resonances are a viable mechanism to shape and switch the properties of light. Besides that, they allow tailoring light-matter interaction, opening new pathways in next-level optical metrology and precision experiments. Applications range from non-invasive nanometrology beyond conventional diffraction limits to compact and robust sensors and the world's most stable optical atomic clocks. This contribution provides an overview of selected metrological applications of photonic resonances and the most important physical properties to achieve optimum measurement precision.

Non-Abelian gauge fields for non-Hermitian systems

Yi Yang
Department of Physics, The University of Hong Kong, Hong Kong, China
*corresponding author: yiyg@hku.hk

Abstract: Non-Abelian gauge fields are versatile tools for synthesizing topological phenomena but have so far been mostly studied in Hermitian systems. We study them in non-Hermitian systems via a generalized Hatano--Nelson model with imbalanced non-Abelian hopping. Despite lacking gauge flux in one dimension, non-Abelian gauge fields create rich non-Hermitian topological consequences. Under only nearest-neighbor coupling, non-Abelian gauge fields enable Hopf-link bulk braiding topology, whose phase transition accompanies the emergence of exceptional points (EPs). At both ends of an open chain, non-Abelian gauge fields lead to the simultaneous presence of non-Hermitian skin modes, whose population can be effectively tuned. We present concrete optical realizations based on synthetic dimensions in driven ring resonators.

Auto-differentiable Computational Photonics and its application to optimization

B. Vial[1*] and Y. Hao[2]

[1]Department of Mathematics, Imperial College London, United Kingdom
[2]School of Electronic Engineering and Computer Science, Queen Mary University of London, United Kingdom
[*]corresponding author: b.vial@imperial.ac.uk

Abstract: We present the development of numerical methods for the resolution of Maxwell's equations implemented using open source libraries. All of them are endowed with automatic differentiation capabilities and typical inverse design examples using topology optimization will be presented.

In recent years, technological advances in nanofabrication have opened up new applications in the field of nanophotonics. To engineer and develop novel functionalities, rigorous and efficient numerical methods are required. In parallel, tremendous advances in algorithmic differentiation, in part pushed by the intensive development of machine learning and artificial intelligence, has made possible large-scale optimization of devices with a few extra modifications of the underlying code. In the past two decades, gradient-based topology optimization (TO) has become a widely used tool in computational electromagnetism and has allowed the inverse design of a broad range of devices such as invisibility cloaks, metamaterials and metasurfaces to name a few.

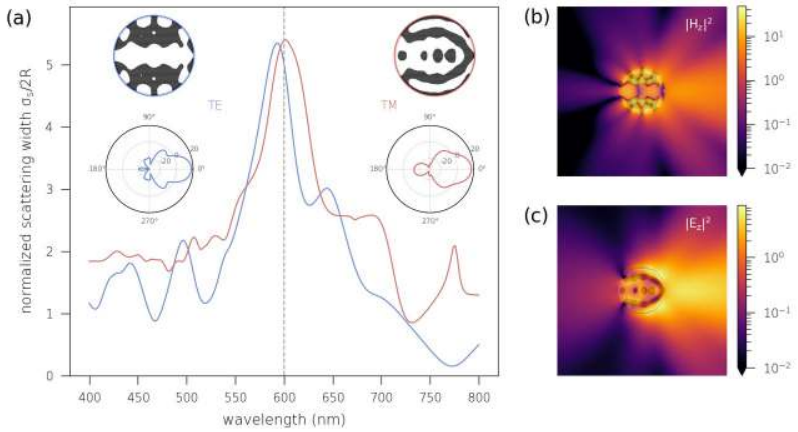

Figure 1: Optimized superscattering nanorods. (a): normalized scattering width as a function of the wavelength of the incident light (blue: TE polarization, red: TM polarization). The insets at the top show the optimized dielectric distribution (white for SiO2 and black for Si), and the bottom insets are the radiation patterns for the normalized scattering width, in dB. The field maps on the right panels show the square norm of the fields at the target wavelength λ_0=600 nm. (b): $|Hz|^2$ for TE polarization. (c): $|Ez|^2$ for TM polarization.

I will present the development of software libraries with automatic differentiation capabilities

[1]: a finite element method (FEM)-based code for 2D scattering problems, an implementation of the Fourier modal method (FMM) for stacked bi-periodic structures, and a plane wave expansion method (PWEM) to compute the eigenmodes of 2D photonic crystals. After describing the methods and the automatic differentiation [2] and topology optimization tools [3], we give examples of application for each: the design of supperscattering structures with the FEM, of a metasurface optimized to transmit maximally in a given diffraction order with the FMM, and maximization of bandgap and dispersion engineering in dielectric photonic crystals using the PWEM.

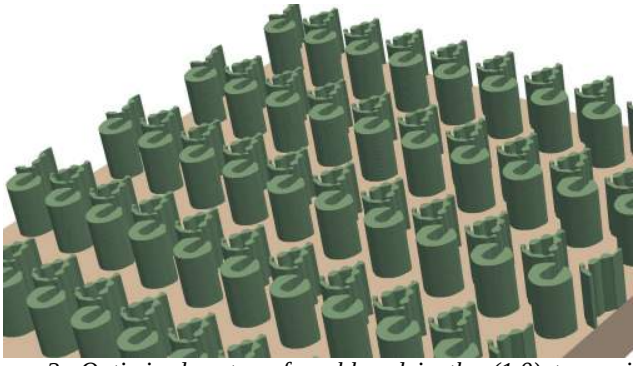

Figure 2: Optimized metasurface blazed in the (1,0) transmitted order for both polarizations using the FMM.

The availability of open-source codes for solving Maxwell's equations is of paramout importance in the growing field of metamaterials and photonics. Indeed, free software, besides being low cost, has many advantages such as being portable, customizable, and vendor-independent. Our implementation of the three numerical methods commonly used in photonics is freely available as Python packages: https://gyptis.gitlab.io (FEM), https://nannos.gitlab.io (FMM) and https://protis.gitlab.io (PWEM). In addition, the integration of automatic differentiability in our implementation makes the calculation of gradients with respect to inputs straightforward. As illustrated in this study, it allows the inverse design of photonic structures and metamaterials with improved performances or to explore intriguing effects such as supperscattering, polarization-tolerant blazed metasurfaces, or photonic crystals with large bandgaps and dispersion engineering.

This work was funded by the Engineering and Physical Sciences Research Council (EPSRC), UK, under grants (EP/N010493/1) and (EP/R035393/1).

Tailoring resonant interactions in suspensions of disordered particles to achieve near zero reflection

C. Blanchard[1,*], **T. Guerra**[1], **J. P. Hugonin**[2], and **O. Rozenbaum**[1]

[1]CNRS, CEMHTI UPR3079, Univ. Orléans, F-45071 Orléans, France

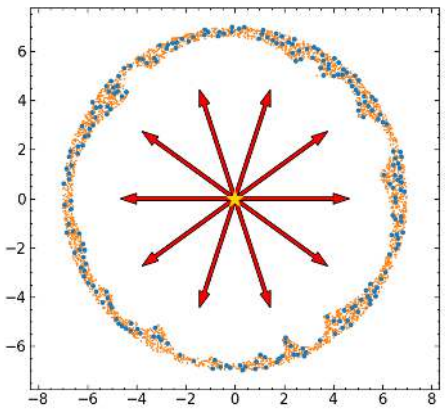
[*]corresponding author: cedric.blanchard@cnrs-orleans.fr

Abstract: We take advantage of the cooperative effects that take place in a suspension of randomly distributed nanoparticles to inhibit the reflection of an electromagnetic radiation incident on it. The strategy consists in coupling resonant and lossless particles. In a counterintuitive manner, the near zero reflection phenomenon relies here on particles which have the ability to strongly scatter light when they are considered individually.

The control of electromagnetic radiations has been prompted, in the last decades, by the combination of an increasing understanding of light/matter interaction in photonic materials and the maturation of nanofabrication techniques. In this context, a lot of attention has been put on systems with a well-defined structuration, either horizontal (photonic crystals, metasurfaces, etc.) or vertical (e.g., stratified media). Since the former is periodic and the latter is characterized by a refractive index which is a function of one Cartesian coordinate only, they can be classified as ordered media.

Despite appealing ease of fabrication, much less attention has been paid to disordered inhomogeneous media as a means to the control of electromagnetic radiation. This is probably due to the fact that a system of subwavelength particles, for instance, can be considered at first sight as merely homogeneous [1], with no special capabilities for the tailoring of the electromagnetic fields and hence unable to achieve competitive functional properties.

In this contribution, we are interested in suspensions of nanoparticles that are randomly distributed. We numerically show a design rule for a many-particle structure that allows to inhibit the reflection of a radiation that impinges on it, without specially design the incident waveform for this purpose [2].



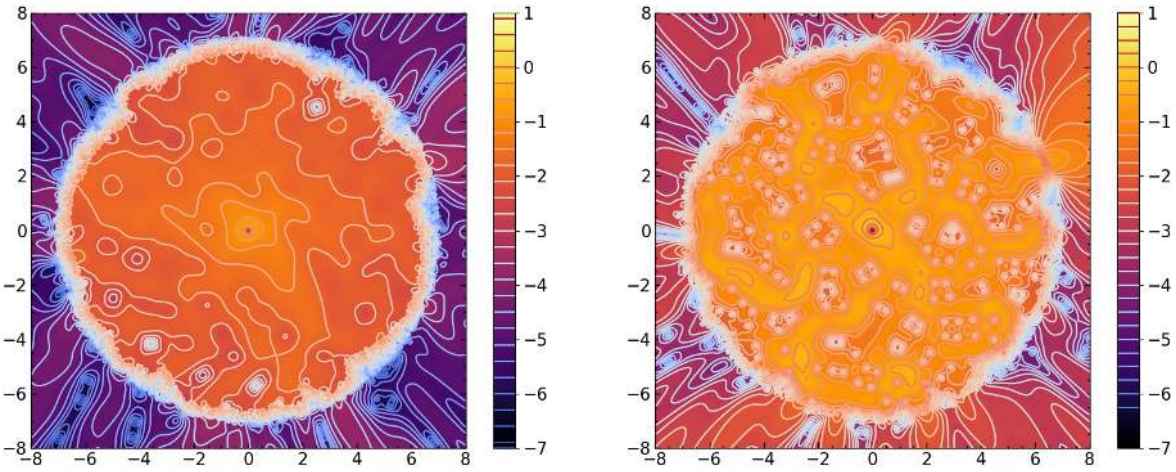


Figure 1: A disordered inhomogeneous medium: polydisperse nanoparticles arranged in the form of a shell. A point source is located at the center.

By exciting an individual particle near its resonance, it is theoretically possible to ensure high absorption cross section values. But when put in interaction with other resonating particles, absorption naturally tends to decrease because the multiple resonances that occur in the structure overlap. In other words, we are no longer in an ideal situation with a well-isolated resonance and, as a result, it is difficult to prevent a many-particle structure from reflecting part of the incident field. To circumvent this issue, we propose here a strategy that consists in incorporating lossless particles into the system of resonant particles.

Fig. 1 displays a cavity delimited by a system of particles, which overall constitutes a shell with irregular shape. A point source radiating isotropically at wavelength $\lambda = 2$ µm is located in the cavity. In Fig. 2(a) are plotted the contour lines of the Poynting vector (with logarithmic scale) after

(a) Optimized configuration (b) $n = 2 + i$

Figure 2: Contour plot of the Poynting vector in a many-particle core-shell structure which is illuminated by a point source.

optimization of the volume fraction, size and constitution of the particles. The energy flux is strongly absorbed in the shell and almost no energy escapes the structure despite the subwavelength thickness of the shell. In contrast, highly lossy particles of refractive index $n = 2 + i$ [3] with the same spatial distribution do not provide the same performance; it is plain from Fig. 2(b) that more energy escapes the structure, while the isolines are strongly perturbed in the cavity, indicating a greater amount of reflection at the inner interface of the shell.

In order to quantitatively calculate the degree to which the system is able to absorb energy, we have also arranged the polydisperse nanoparticles in the form of a large slab illuminated by a planewave. The reflectance is below few percent. In comparison, the reflectance before incorporating the lossless particles was about 20%.

Quasinormal Mode Theory for Nanoscale Electromagnetism informed with the Feibelman's d-Parameter Treatment

Qiang Zhou[1,2], **Pu Zhang**[1,2], **and Xue-Wen Chen**[1,2*]

[1]School of Physics and Wuhan National Laboratory for Optoelectronics, Huazhong University of Science and Technology, Wuhan, People's Republic of China

[*]corresponding author: xuewen_chen@hust.edu.cn

Abstract: We report a self-consistent quasinormal mode theory for nanometer scale electromagnetism where the possible nonlocal and quantum effects are treated through the Feibelman's *d*-parameters. With the frequency-dependent *d*-parameters to describe the quantum surface responses, which are reminiscent of the permittivity function, we formulate the source-free Maxwell's equations into a generalized linear eigenvalue problem to define the quasinormal modes. We then construct an orthonormal relation for the modes and consequently unlock the powerful toolbox of modal analysis.

The research field of nano-optics has flourished along with the development of concepts and techniques to shrink light to scales well below the diffraction limit. The subwavelength confinement primarily results from the plasmonic resonances in metal nanostructures. To capture the physics of such scenarios, *e.g.,* deciphering the optical eigen-modes [1, 2, 3], the nonlocal and quantum effects of the conduction electrons need to be treated properly. A trending approach in recent years is to leverage the Feibelman's *d*-parameters [4, 5] to account for the major quantum responses at metal surface. A rigorous quasinormal mode theory compatible with the *d*-parameter treatment thus would be elusive.

In the *d*-parameter treatment, the quantum responses manifest macroscopically as an effective surface current $\mathbf{K}$ and surface polarization $\mathbf{\Pi}$, which are approximated in the leading order as

$$\mathbf{K} = i\omega d_{\parallel}(\omega)[\![\varepsilon(\omega)]\!]\,\mathbf{E}_{\parallel}, \qquad \mathbf{\Pi} = d_{\perp}(\omega)[\![\varepsilon^{-1}(\omega)]\!]\,\mathbf{D}_{\perp}, \tag{1}$$

where the time convention $\exp(-i\omega t)$ is assumed. $\varepsilon(\omega)$ is the permittivity in bulk domains. We have adopted $[\![f]\!] = f^{+} - f^{-}$ to denote a difference across surface, and the notation $\perp/\parallel$ to denote the normal/parallel component of a vector. $\mathbf{K}$ and $\mathbf{\Pi}$ feed back to Maxwell's equations as secondary sources and consistently modify the overall optical responses. Since $d_{\parallel}$ is negligible in most situations with charge-neutral interfaces, we assume $d_{\parallel} = 0$ and focus on the surface polarization $\mathbf{\Pi}$ and the effective surface response function $f(\omega) = d_{\perp}(\omega)[\![\varepsilon^{-1}(\omega)]\!]$. Noticing that $f(\omega)$ is bounded at $\omega = 0$ and ∞, we may expand it over the simple poles $\widetilde{\omega}_{\beta}$ as

$$f(\omega) = \sum_{\beta=0}^{N} f_{\beta} \frac{\widetilde{\omega}_{\beta}}{\omega - \widetilde{\omega}_{\beta}}. \tag{2}$$

A pseudopole $\widetilde{\omega}_0 = 0$ is formally introduced for conciseness of expression. Thereupon, we introduce for each pole an auxiliary surface polarization $\mathbf{\Pi}_{\beta} = \omega\mathbf{D}_{\perp}/(\omega - \widetilde{\omega}_{\beta})$, with the constraint $\sum_{\beta=0}^{N} f_{\beta}\mathbf{\Pi}_{\beta} = \mathbf{\Pi}$. The surface response then is linearized regarding the frequency ω, with $(\omega - \widetilde{\omega}_{\beta})\mathbf{\Pi}_{\beta} = \omega\mathbf{D}_{\perp}$. Assuming that the metal is described by the Drude-

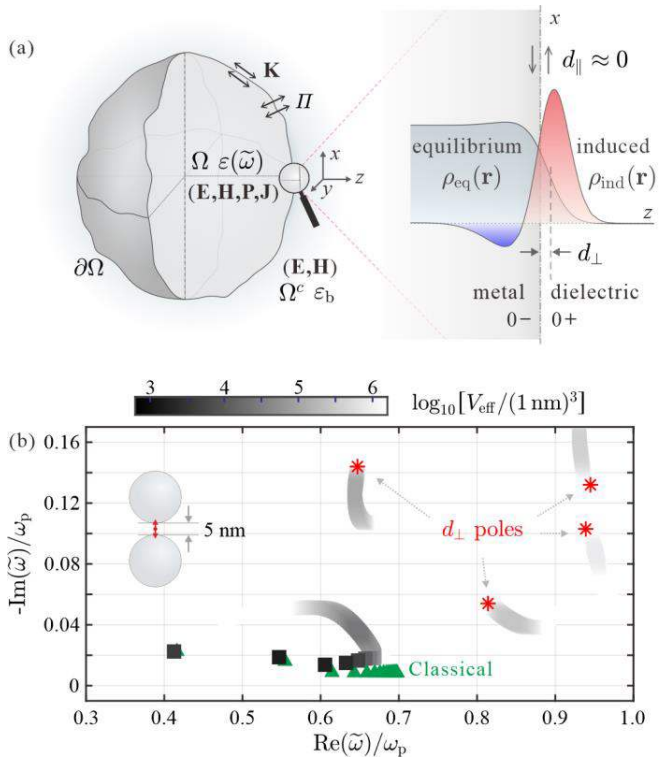

Fig. 1. Quasinormal mode analysis informed with the Feibelman's *d*-parameter treatment.

Lorentz model, the responses in bulk domains can also be linearized by introducing the auxiliary polarization $\mathbf{P}$ and the corresponding current density $\mathbf{J}$ [6]. In terms of the electromagnetic fields $\mathbf{E}$, $\mathbf{H}$, and the auxiliary fields $\mathbf{P}$, $\mathbf{J}$, $\mathbf{\Pi}_\beta$, the source-free Maxwell's equation can finally be formulated as a volume-surface composite linear eigenvalue problem, which set the stage for quasinormal mode analysis [3]. The orthonormalization relation of the modes then can be derived basing on the generalized Lorentz reciprocity, and validated by the reconstruction of the full numerical results through modal contributions. Such a quasinormal mode theory would facilitate the establishment of a general theoretical framework for nanometer scale electromagnetism

Quasi normal mode perturbation theory to achieve Q factor optimization of resonances in disordered photonic systems

N. Granchi[1*], F.Intonti[1], M. Gurioli[1] and G. Arregui[2]

[1]Department of Physics and Astronomy and LENS, University of Florence, Sesto Fiorentino (FI), Italy
[2]Department of Electrical and Photonics Engineering, DTU Electro, Denmark
[*]corresponding author: granchi@lens.unifi.it

Abstract: The optimization of the quality factor (Q) of photonic resonators is of great importance for applications exploiting both ordered and disordered systems. Here we propose a gradient-based automated optimization approach to maximize the Q of optical resonances in ordered and disordered dielectric slabs which uses first-order non-hermitian perturbation theory. By applying our method to optimize a selected Anderson mode in a random design exhibiting a Q-factor of 200, a new mode displaying $Q = 10^5$ is generated.

Photonic crystal cavities nowadays are the most widespread and versatile devices conceived to mold the flow of light at the nanoscale. They offer a versatile platform to study classical and quantum light-matter interaction in fields such as cavity quantum electrodynamics, non-linear optics, and cavity optomechanics. In parallel, other photonic systems, based on random distributions of point scatterers, have emerged and proposed as complementary alternative to ordered photonics [1]. They have been investigated for their basic physical insights, such as Anderson localization, and envisioned for several applications, due to their capability of exhibiting a higher spectral and spatial density of modes in a small spatial domain with respect to their ordered counterparts [1]. Conversely, the main disadvantage, mainly in purely random photonic systems operating at telecom wavelengths, is represented by the low Q factors that Anderson modes exhibits (typically ≈ 200). While the problem of Q factor optimization of photonic crystal cavities have been accomplished widely and successfully [2,3], in the case of Anderson modes localized in random structures, further complicated by the lack of an in-plane photonic band gap, it has never been addressed.

Here, we propose a gradient-based automated optimization approach to maximize the Q of a selected Anderson mode supported by a dielectric slab randomly patterned with air holes (Fig.1a). The method uses the theoretical framework of quasinormal modes (QNMs) [4] and relies on first-order non-hermitian perturbation theory to efficiently compute the gradients of Q relative to arbitrary material boundary displacements. Given its first order nature, the method requires only the calculation of the complex eigenfrequency and field profile of the QNM of interest. The optimization process, which determines a shift in the position of all holes in the structure (Fig.1b) to produce a Q-factor enhancement from 200 to 10^5 as well as a negligible average wavelength shift (Fig.1c). By monitoring the spatial distribution of the mode along the optimization we observe the mode central location and spatial distribution to change dramatically (Fig.1d), with a final spatial localization comparable with the one achieved in engineered photonic-crystal cavities ($Q/V \approx 10^6$ μm^{-3}). Our result might be relevant for the employment of random structures for lasing an sensing applications and constitute an important step toward the full engineering of the random photonic platform.

Abstract: Metamaterials rely on assembled artificial optical resonators, having strong interactions with light and presenting local field enhancements. This presentation aims at pointing out how colloid-based chemical engineering offers exciting routes to tailor the optical response, including polarizabilities and scattering diagram of nanoresonators.

Strong magnetic resonances, which when spectrally superposable with the electric resonances, are the cornerstone for achieving Huygens scatterers, were previously obtained with complex colloidal nanoresonators [1, 2]. We show that densely-packed spherical colloidal clusters of metallic nanoparticles present such properties. These colloidal clusters have garnered a lot of interest recently, because they involve localized resonant inclusions that are assembled into a Mie resonator. This multiscale resonant nature provides a lot of leverage in the engineering of the spectral scattering characteristics of the resonators.

We synthesized clusters of gold or silver nanoparticles using an emulsion-based formulation approach. This fabrication technique involves emulsification of an aqueous suspension of plasmonic nanoparticles in an oil phase, followed by controlled drying of the aqueous droplets. The structural control of the as-synthesized clusters, produced in large numbers, is demonstrated with microscopy and Xray scattering techniques. Each cluster comprises a few hundreds or thousands of nanoparticles, depending on the formulation parameters.

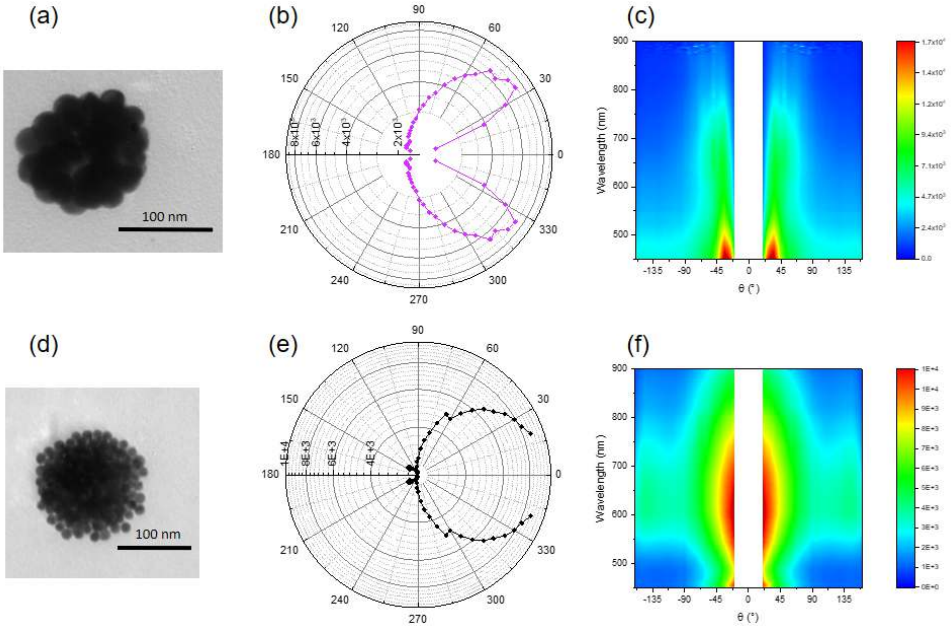

Fig 1. TEM images of a representative **(a)** Ag-cluster and (**d**) Au-cluster. Scale bars are 100 nm. Logarithmic polar plot of the experimental differential scattering cross-section for (**b**) Ag-clusters at wavelength

662 nm and (**e**) Au-clusters at wavelength 751 nm. Lines are guides for the eye. Experimental scattering color pattern representing the differential scattering cross-section values of (**c**) Ag-PVP clusters and (**f**) Au-clusters as a function of the scattering angle θ and of the wavelength λ. Measures were only made for positive values of θ but we assumed that differential cross-section values are identical for θ and -θ. All differential scattering cross-section values are represented in nm^2 per steradian units.

Using polarization-resolved multi-angle light scattering measurements, we conducted a comprehensive angular and spectroscopic determination of the complex colloid optical resonant scattering in the visible wavelength range [3]. We report on the clear experimental evidence of strong optical magnetic resonances and directional anisotropic scattering patterns (see Fig. 1). High-precision T-matrix computations were performed to described the object scattering while taking into account strong interparticle couplings and spatial dispersion effects within the colloids.

Our findings crucially show that the electric and magnetic resonances as well as the scattering patterns can be tuned by adjusting the inner cluster structure, modifying simple parameters of the fabrication method.

We acknowledge the help of A. Bentaleb for Xray scattering study, and of E. Nativ-Roth and O. Regev for Cryo-TEM imaging.

Purcell Enhanced Intrinsic Linear and Nonlinear Optical Responses in Colloidal Dielectric Resonators

Jeanne Heintz, Gauthier Roubaud, Samuel Grésillon, and Sébastien Bidault*

Institut Langevin, ESPCI Paris, Université PSL, CNRS, 75005 Paris, France
*corresponding author: sebastien.bidault@espci.fr

Abstract: We demonstrate an enhancement of the intrinsic linear and nonlinear spontaneous emission from silicon and gallium phosphide-based resonators by a conjunction of scattering, luminescence lifetime and nonlinear spectroscopies at the single particle level.

Subwavelength resonators featuring highly confined and enhanced electromagnetic fields are a versatile photonic platform to optimize light-matter interactions at the nanoscale thanks to the Purcell effect. Dielectric resonators made of high-index semiconductors are an exciting alternative to plasmonic systems by readily enhancing the magnetic component of light and by providing these enhancement effects in the core of the resonator while introducing negligible ohmic losses [1]. Dielectric resonators have thus been engineered to optimize spontaneous emission from extrinsic emitters, either based on electric [2] or magnetic [3] dipolar transition dipoles, but also to inhibit it [4].

In this work, we evidence how enhanced electromagnetic fields in the core of semiconductor-based resonators can be exploited to optimize their intrinsic linear (spontaneous emission) and nonlinear optical responses (multiphoton luminescence and harmonic generation). In particular, we develop new nanofabrication techniques based on mechanical grinding and laser-based melting to produce colloidal resonators made of silicon or gallium phosphide (Fig. 1-a). By performing in parallel linear and nonlinear single nanostructure spectroscopy, we demonstrate how geometrical resonances allow an improvement of multiphoton absorption and harmonic generation by several orders of magnitude while also providing Purcell-enhanced spontaneous emission. In particular, multiphoton luminescence peaks measured in Si resonators spectrally match their electric dipolar and quadrupolar modes (Fig. 1-b). Furthermore, luminescence lifetime and spectral measurements on single GaP resonators provide a direct evidence of Purcell-enhanced radiative emission from this low-quantum yield indirect semiconductor (Fig. 1-c).

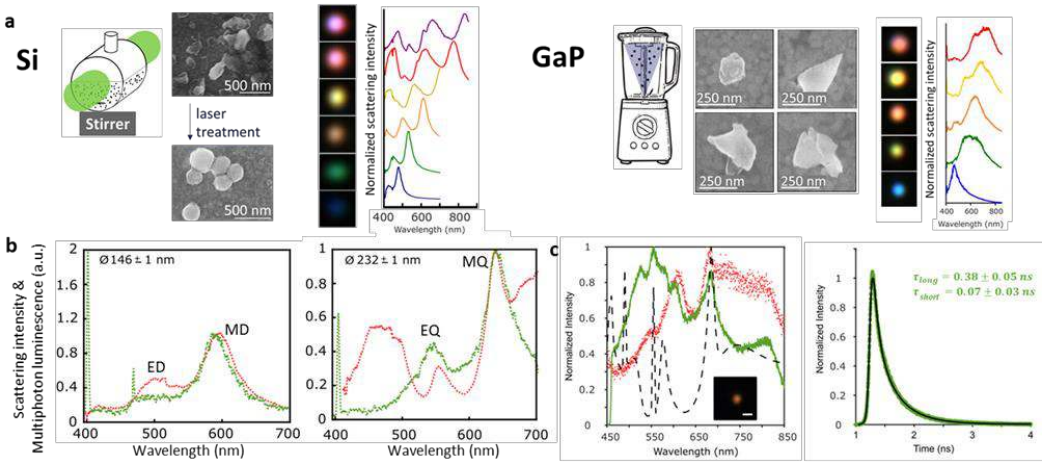

Figure 1: Si- and GaP-based resonators (a) featuring Purcell-enhanced multiphoton (b) or linear (c) emission.

Generalized Lorentz Model and Quasinormal Mode theory for Nonlocal Media

Xue-Wen Chen[*1,2]

[1]School of Physics and Wuhan National Laboratory for Optoelectronics, Huazhong University of Science and Technology, Wuhan, China.
[2]Wuhan Institute of Quantum Technology, Wuhan, China.
[*]corresponding author: xuewen_chen@hust.edu.cn

Abstract: Studies of extremely confined optical field down to (sub)nanoscale have been one forefront of optical physics. The related optical phenomena should be understood with the consideration of complex nonlocal effects, which pose a difficult hurdle for constructing a quasinormal mode theory. Here we introduce a generalized Lorentz model to describe the nonlocal effects, then provide a procedure to orthonormalize the quasinormal modes, establishing a general modal theory. Our theory enables drawing the mode evolution path during the quantum tunneling process.

Extreme nano-optics is one forefront of optical physics and has attracted enormous attention. In recent years, experimental demonstrations develop from the observation of nonlocal effects [1-2], quantum tunneling phenomena [3] to the discovery and application of extremely localized fields [4-5]. Along this line of research, the field of nano-optics enters a new regime, where classical local treatment of nanomaterials becomes invalid. As an example, metallic gaps of a few nanometers or smaller exhibit significant nonclassical effects from electron nonlocality, spillover at metal surfaces, Landau damping, and quantum tunneling. Since the optical response and light-matter interaction often can be conceptualized by the properties of a few modes [6], a proper mode analysis theory is essential to the burgeoning field of extreme nano-optics. However, the above mentioned complex nonlocal responses and quantum effects pose a difficult hurdle for constructing a canonical quasinormal mode (QNM) theory in such situations.

In this work, we develop a general theoretical framework of canonical QNM analysis with applicability to materials showing various kinds of nonlocal and quantum effects in the situation of extreme nano-optics, where classical local description of materials' optical response fails. Specifically, we creatively propose a generalized Lorentz Model to describe various nonlocal media, formulate source-free Maxwell equations for nonlocal media as a linear eigenvalue problem for modal analysis and derive a canonical orthonormal relation for the QNMs [7-8]. Moreover, the theory enables intuitively visualization of optical responses in quantum tunneling regime in terms of mode evolution for the first time. The framework established in this work entitles nano-optics to a powerful semi-analytical rigorous treatment of complex (sub)nanoscale structures.

Resonances in doubly anisotropic, high-index nanoplatelets

Abstract: Optical anisotropy plays a crucial role in the manipulation of light. Its strength is, however, limited to low values in conventional materials. Transition metal dichalcogenides possess both high refractive index and high birefringence due to their layered structure. Here we investigate optical resonances in nanoplatelets with both geometrical and refractive index anisotropies. A multipole expansion allows us to analyze their distinct influence on magnetic and electric resonances. Nanoplatelets thus create new opportunities to control light scattering and emission.

Anisotropy is the basis for a variety of bulk optical components, including polarizers, wave plates, modulators, and phase-matching elements. The constituting material's birefringence, Δn, determines the device size and performance. Thus, a large birefringence is beneficial because it leads to more compact and efficient devices. However, currently used materials such as inorganic solids like calcite and liquid crystals possess a relatively small birefringence with typical values of refractive index difference below 0.4. As a result, natural materials with giant anisotropy ($\Delta n > 1$) are in growing demand both for scientific and industrial purposes.

Transition metal dichalcogenides are promising birefringent materials due to their layered van der Waals structure, which naturally leads to a large intrinsic birefringence above unity. In particular, molybdenum disulfide (MoS_2) possesses the highest birefringence of all natural materials in the near infrared. Such a high birefringence is possible because of the presence of strong excitons, which endow MoS_2 with a high in-plane refractive index above 4.5 and makes it possible to have higher out-of-plane index contrast than lower index dielectrics. A high refractive index also enables the existence Mie-type resonances in MoS_2 nanostructures for enhancing and controlling light-matter interaction.

Here, we study the optical resonances sustained by nanoplatelets (thin nanodisks) made of high refractive index material with high optical anisotropy. Nanoplatelets have both geometrical and refractive index anisotropies . They sustain electric and magnetic multipolar resonances. We investigate the distinct impact of changes in height and birefringence on the tunability of the different resonances. We use a multipolar analysis to understand the influence of anisotropy on each resonance. We find that magnetic dipole resonances are particularly sensitive to changes in the material anisotropy. Due to their double anisotropy, nanoplatelets also show a strong dependence of their optical response on the direction of plane wave illumination. We relate the nature of the resonances under illumination with the same electric or magnetic field polarization and different directions of incidence and consider the impact of retardation effects. Finally, we show that nanoplatelets can also control the polarization and directionality of dipolar sources such as fluorescent molecules due to the preferential excitation of in-plane resonances.

In summary, we have studied high-refractive-index nanoplatelets with intrinsic out-of-plane anisotropy and large birefringence. These nanoresonators exhibit a rich variety of electric and magnetic multipolar resonances that are sensitive to geometry and anisotropy in distinct and different ways. We envision that films consisting of disordered but

oriented nanoplatelets could be used to enhance and direct light scattering and light emission, with applications in light-emitting devices and random lasers.

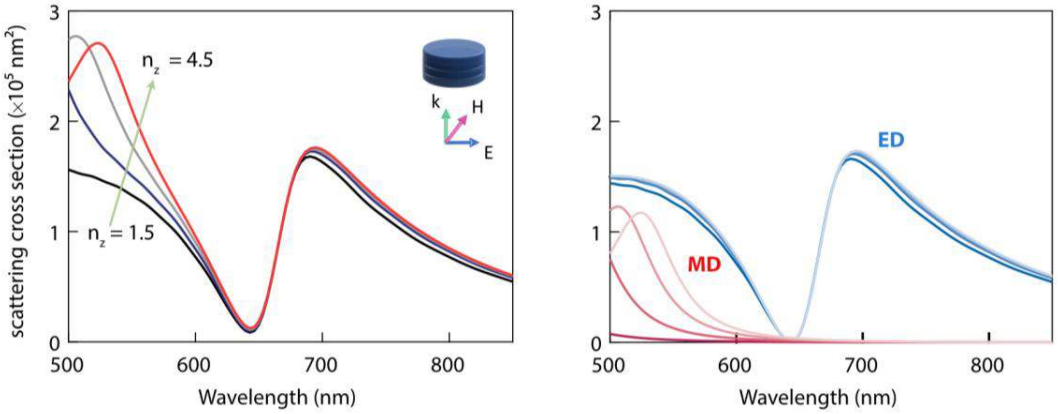

Figure 1. Resonances in high refractive index, birefringent nanoplatelets. Left: Scattering cross section resonances that depend on the optical anisotropy of the nanoplatelet material. Right: Multipolar decomposition of the resonances for different anisotropy values, indicating that the magnetic dipole (MD) resonance is more sensitive to birefringence than the electric dipole (ED) features.

Abstract: Design and investigation of nanophotonic structures for the optical implementation of different differential operators have attracted considerable attention in recent years. In this work, we present the optical computation of the Laplace operator of the profile of a three-dimensional optical beam incident on a resonant metal-dielectric layered structure composed of two metal-dielectric-metal structures, which, in turn, consist of an upper metal layer, a dielectric layer, and a lower metal layer.

Optical differentiation is a powerful technique that has the ability to extract valuable information about the spatial distribution of optical signals or the rate of change of an optical signal over time. That makes it an essential tool for researchers in a wide range of fields, including imaging, microscopy, and optical communication. Differentiation of optical signals can be achieved using various methods including resonant diffraction gratings (photonic crystal slabs), layered structures, and microresonators.

The resonant diffractive structure considered in this work consists of seven alternating metal (m) and dielectric (d) layers in the following order: "m-d-m-d-m-d-m" (see the inset in Fig. 1a). In [1], a numerical method was developed for designing such multilayer structures possessing a second-order reflection zero. Investigation of the optical properties of the considered metal-dielectric structures has shown that the quantity of the independent parameters of the structure, such as the materials of the layers, the thickness of the lower layer (which determines the thickness of the other layers), the angle of incidence of the beam, and the central frequency, allows us to fulfill the conditions for the optical computation of various differential operators [2].

As an example, let us consider a structure designed for the optical computation of the Laplace operator. The configuration of the structure is shown in Table 1. The developed structure enables optically computing the Laplace operator at oblique incidence (in the presented example, at an incidence angle of 36 degrees).

Layer material	Au	SiO_2	Ag	SiO_2	Ag	TiO_2	Au
Layer thickness, nm	10.0	132.3	8.6	52.2	33.6	74.4	105.0

Table. 1. Layer thicknesses of the considered metal-dielectric structure

Figure 1a shows the profile of the incident linearly polarized beam, which is an Hermite–Gaussian beam of the order (1, 0) with the x-component of the electric field $E_{x.inc}(x_{\text{inc}}, y_{\text{inc}}) = H_{1,0}(\sqrt{2}x_{\text{inc}}/\sigma, \sqrt{2}y_{\text{inc}}/\sigma)\exp(-x_{\text{inc}}^2/\sigma^2 - y_{\text{inc}}^2/\sigma^2)$, where $H_{m,n}(x,y)$ is the Hermite

polynomial and $\sigma = 20\ \mu m$ is the beam width. Figure 1b shows the reflected beam profile calculated numerically using the enhanced transmittance matrix approach [3], which corresponds to the Laplacian of the incident beam profile with a high accuracy (the normalized RMSD of the rigorously calculated reflected beam profile from its analytical representation amounts to only 0.61 %).

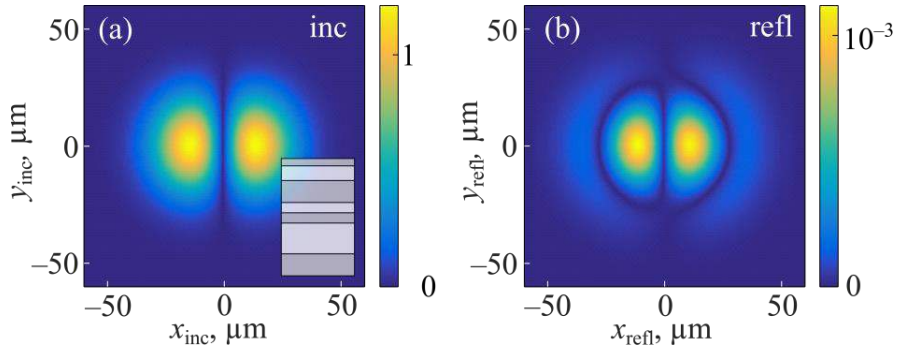

Fig. 1. Profiles of the incident (a) and reflected (b) beams. The MDM structure is shown in the inset to (a).

In conclusion, it was shown that the designed structure enables high-accuracy optical computation of the Laplace operator of the profile of the incident optical beam. The presented structure can also be used in image processing for optical edge detection. It is also worth noting that layered metal-dielectric structures provide an opportunity to optically compute other differential operators including temporal and spatial derivatives of various orders.

Optical properties of resonant gratings with spatially varying period

D. A. Bykov[1,2], E. A. Bezus[1,2], A. I. Kashapov[1,2], A. A. Morozov[1,2], V. V. Podlipnov[1,2], and L. L. Doskolovich[1,2*]

Abstract: We study guided-mode resonant gratings with the period linearly changing along the periodicity direction. At relatively small period change rates, such structures are used as linearly varying filters. However, when designing compact filters, the period change rate increases, which results in the appearance of multiple resonant peaks. We study this effect numerically and experimentally. We also develop a coupled-mode theory describing the optical properties of the investigated structures and providing a very good agreement with the simulation results.

Investigation of the resonant properties of subwavelength diffraction gratings continuously attracts considerable research interest [1]. The most important application of resonant gratings (RG) is in narrowband optical filters. In the design of spectrometric systems, one is required to divide the incident radiation into a large number of spectral channels. Spectral filters for such systems can be created by utilizing resonant structures with the parameters varying along a certain spatial dimension. This enables filtering different wavelengths in different areas of the structure. Such filters are usually referred to as linearly variable filters (LVFs). Along with the most well-known type of LVFs, namely, Bragg gratings with a wedged central layer, RGs with the period varying along the periodicity direction represent another promising LVF type [2, 3]. In addition to the application in spectrometers, gratings with varying parameters are also promising for refractive index sensing.

In this work, we investigated a guided-mode RG with the period varying linearly as $d(x) = d_0 + \alpha x$, where $\alpha = 2.5 \cdot 10^{-4}$ is the period change rate. The geometry of the studied structure is shown in Fig. 1; the parameters are presented in the figure caption. Such a grating was fabricated using e-beam lithography in a PMMA layer deposited on a TiO_2 thin film. The substrate and superstrate were fused silica and free space, respectively.

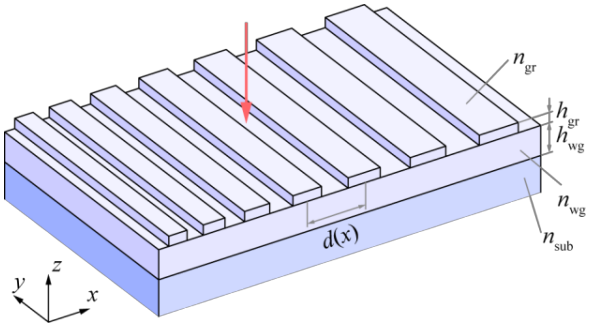

Fig. 1. Geometry of the guided-mode resonant grating with linearly varying period. Parameters: grating thickness $h_{gr} = 300\,\text{nm}$, grating fill-factor $f = 1/2$, grating period $d_0 = 330\,\text{nm}$, waveguide layer thickness $h_{wg} = 130\,\text{nm}$.

The measured reflected field distribution is presented in Fig. 2a. Its normalized averaged cross-sections are shown in Fig. 2b for three different wavelengths. One can see that instead of a single resonant peak with a spectrally-dependent position (as it is predicted by the local periodic approximation), several "secondary" peaks appear to the left and to the right to the central peak [3]. The magnitude and spacing of these peaks depend on the period change rate α. When α tends to zero, the secondary peaks disappear and the resonance acquires a conventional Lorentzian line shape.

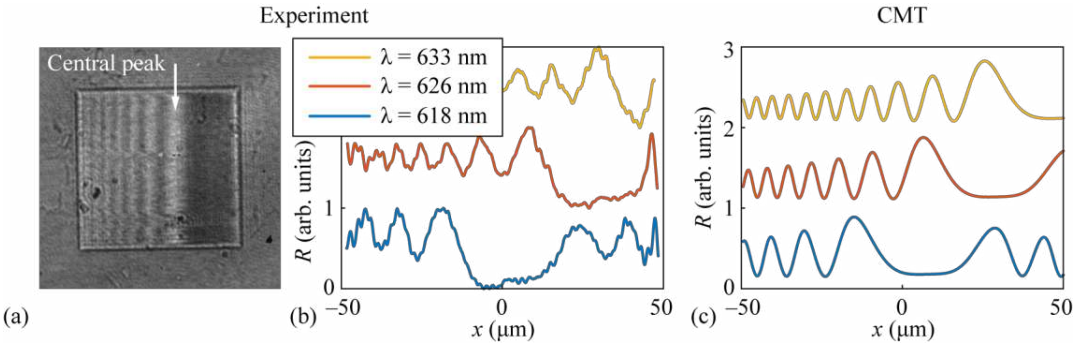

Fig. 2. Measured reflected field distribution (a) at $\lambda = 626$ nm and its normalized averaged cross-sections (b) at the wavelengths $\lambda = 633$ nm (upper lines), $\lambda = 626$ nm (middle lines), and $\lambda = 618$ nm (lower lines). The lines are vertically offset for clarity. Reflected field distributions predicted by the coupled-mode theory at the same wavelengths (c).

To explain the appearance of the secondary peaks evident in Figs. 1a and 1b, we developed a coupled mode theory with varying parameters. This theory describes the coupling of two counter-propagating modes of the waveguide layer and allows one to calculate the reflected and transmitted field distributions along the structure at a given wavelength of a normally incident plane wave. The CMT predictions shown in Fig. 2c are in good agreement with the experimental results. We also performed rigorous electromagnetic simulations using Fourier modal method [4] with the super-period approach (not presented here for the sake of brevity), the results of which are also in very good agreement with the CMT predictions.

Abstract: In this work, we study the optical properties of the a-$Si_{0.65}C_{0.35}$:H-based planar waveguide structure covered by a 2D array of gold nanodisks. The rectangular lattice of nanodisks allows controlling the wavelength of the TE and TM guided modes resonances separately and the single nanodisk size supports localized plasmon resonance. We show that the structure possesses different types of BICs which are the result of the interaction of guided modes and single-particle resonances.

The control of light propagation and localization at the subwavelength scale is of great interest due to the possibility of tailoring light-matter interaction. Traditionally, the utmost localization and enhancement of the electromagnetic field have been associated with plasmonic resonances in metallic nanostructures. However, material absorption in the metal shrinks the advantages of plasmonic effects.

Recently it was shown that in structures combining plasmonic and photonic resonances bound states in the continuum (BICs) can occur [1]. Since BICs are theoretically perfectly non-radiating modes, the use of their properties to metal-based nanostructures is promising for plasmonic Q-factor improvement.

In this work, we studied the optical properties of the structure consisting of a waveguide luminescent layer covered by the gold nanodiscs array. A plasmonic array arranged in the 2D lattice provides coupling of light to quasi-guided modes [2] while the size of a single nanodisk supports localized plasmon resonance.

The waveguide layer was created from the a-$Si_{0.65}C_{0.35}$:H film with the thickness of 150 nm deposited on a silica substrate by plasma-enhanced chemical vapor deposition (PECVD). The film composition with a specified C/Si ratio corresponds to a refractive index of approximately 2.5 and the photoluminescence peak maximum at 725 nm.

The array of gold disks was created on top of the waveguide layer by the e-beam lithography. The rectangular lattice allows to control of the wavelength of the quasi-guided resonances attributed to TE and TM guided modes separately. The periods of the lattice were 340x370 nm providing overlapping of the modes at the Γ-point (normal incidence of the light). The disk's diameter of 100 nm was chosen to adjust the LPR wavelength to the luminescence peak maximum.

To examine the resonant modes of the structure we performed angle-resolved reflection and photoluminescence spectra measurements by the Fourier-imaging spectroscopy method. Theoretical analysis of the optical response of the structure included numerical calculations of the structure’s eigenmodes and angle-resolved spectra performed by a Fourier modal method in the scattering matrix form [3].

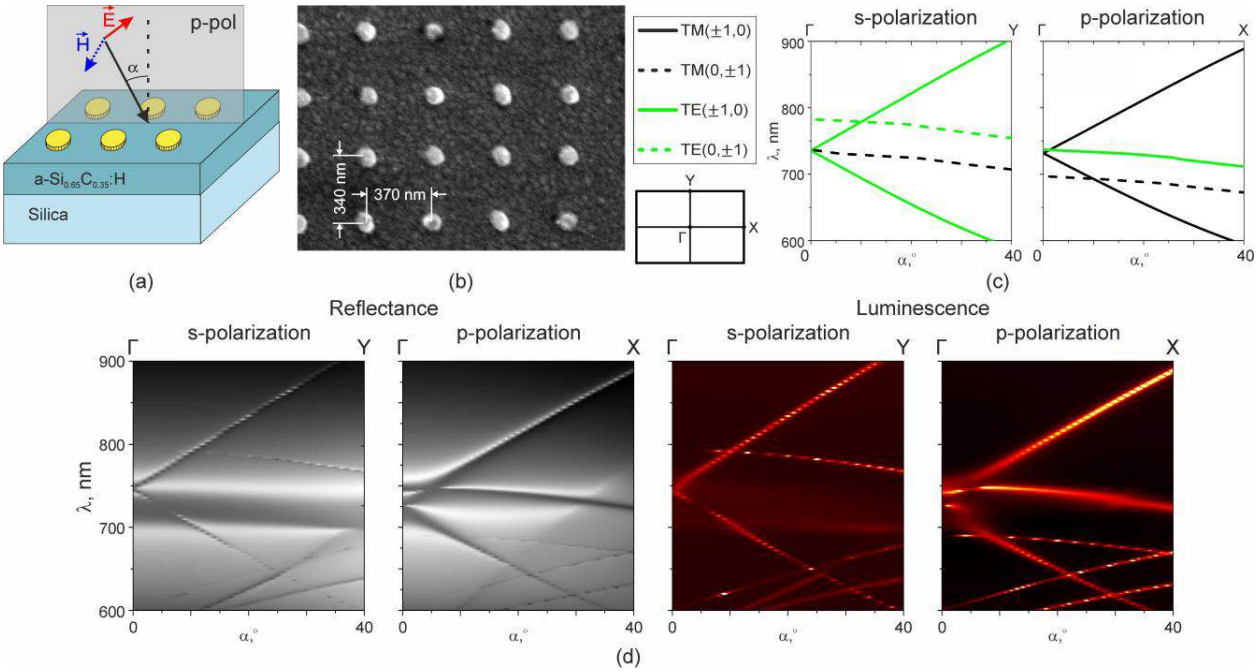

Figure 1. (a) Schematic view of the structure. (b) SEM top view image of the 2D array of the gold nanodisks. (c) Waveguide modes dispersion curves. (d) Angle-resolved spectral maps of the reflectance and photoluminescence calculated for the structure.

As a result, in the angle-resolved spectral maps, we observed features attributed to specific guided modes dispersion curves. Interaction of the quasi-guided and plasmon resonances leads to the polaritonic states formation. The anticrossing behavior is a clear evidence of the coupling between modes while the vanishing of the resonant lines at particular points indicates the formation of a bound state. The analysis of the results has shown that different types of BICs are present in the structure. These are symmetry-protected BICs at the normal incidence angle and accidental (Friedrich–Wintgen) BICs at the off-Γ points.

Metamaterials and Metasurfaces for Medical and Healthcare Applications

Super-Resolution Ultrasonic Cellular Imaging by Localization of Meta-Nanodroplets

Chengzhi Shi, PhD
Assistant Professor
George W. Woodruff School of Mechanical Engineering
Georgia Institute of Technology

Abstract

The ability to image cellular structures and morphology in deep tissues in vivo is essential for the fundamental study of developmental cell biology and physiology. Traditional cellular imaging techniques rely on imaging cells embedded in planar slices using histological staining ex vivo. Confocal and two photon microscopy techniques enable 3D reconstruction of cells in vivo, but are limited to superficial layers within several hundred micrometers of depth. Ultrasound imaging, on the other hand, has been safely used for decades to observe organ structures and behaviors deep in the body in vivo. However, the resolution of ultrasound imaging is typically limited to the wavelength scale (about 100 μm for 15 MHz) due to the diffraction limit, which can hardly be used to visualize microscale cellular structures. In this work, we used phase-transitioning perfluorocarbon meta-nanodroplets to break the diffraction limit. A pumping ultrasound at 3 MHz is used to stochastically activate the meta-nanodroplets and a 15 MHz probe ultrasound is used to reconstruct the image over time, which achieved 8.9 μm resolution. These meta-nanodroplets can be micro-injected into single cells via patch clamping technique for cellular imaging. Our work will pave the way towards ultrasonic cellular imaging in deep tissue in vivo, which will be essential for fundamental biological studies.

Abstract: A general approach based on cylindrical metasurface is proposed to design antennas for high field magnetic resonance imaging. It is applied to create two volume coils dedicated to brain imaging at 7T with a large aperture on the top. The first prototype is dedicated to preclinical imaging of rodent brain while the second one is committed for clinical application. Both prototypes have been tested in-vivo. Then, this approach combined to phase conjugation processing allows to control the magnetic field distribution.

Magnetic Resonance Imaging is unique tool for medical diagnosis. It is based on the Larmor precession of nuclear spin under strong static magnetic field. Because Larmor frequency belongs to the radiofrequency domain, antennas are required to excite the nuclear spins and probe their relaxation. Birdcage antennas introduced in 1985[1] are the most common antenna used to operate over an entire volume such as for brain imaging. Actually, such an antenna is composed of cylindrical periodic arrangement of *N* conductive legs which are connected at the extremity by conductive rungs. In order that the fundamental mode this structure resonate at the Larmor frequency, inductive and capacitive lumped elements are inserted. This design is very similar to a metamaterial transmission line that is closed on itself [2] composed of *N* unit cells. The wave propagation on the metasurface can be modeled thanks to the transmission matrix formalism that relates the input voltage and current to the output ones by the way of the 2x2 transmission matrix T:

$$\begin{pmatrix} U_2 \\ I_2 \end{pmatrix} = T \begin{pmatrix} U_1 \\ I_1 \end{pmatrix}$$

The eigenmodes of a loss-less transmission matrix are characterized by their self-impedance Z_0 ($Z_0 = \pm 2\sqrt{Z_1 Z_2 + Z_1^2}$) and their phase shift $\delta\theta$ ($\cos(\delta\theta) = 1 - 2Z_1/Z_2$). Actually because of the inductive coupling between legs, an effective inductance should be taken into account in the expressin of Z_2. In order to generate a magnetic field that couples with the nuclear spins, the antenna should be able to generate 2 circularly polarized magnetic field B1+ in transmit mode and B1- in receive mode. This condition only occurs if $\delta\theta$ fits the angular distance between the 2 legs and the line impedance of the metasurface is constant. We first use this approach to propose two birdcages with a large aperture. The small "opencage" (Fig. 1a and b) is dedicated to a preclinal 7T MRI[3] and the large one (Fig1c and d) to clinical 7T MRI[4]. The quality of the results obtained in-vivo and ex-vivo are as good as the ones provided by classical birdcages (see Fig. 2)

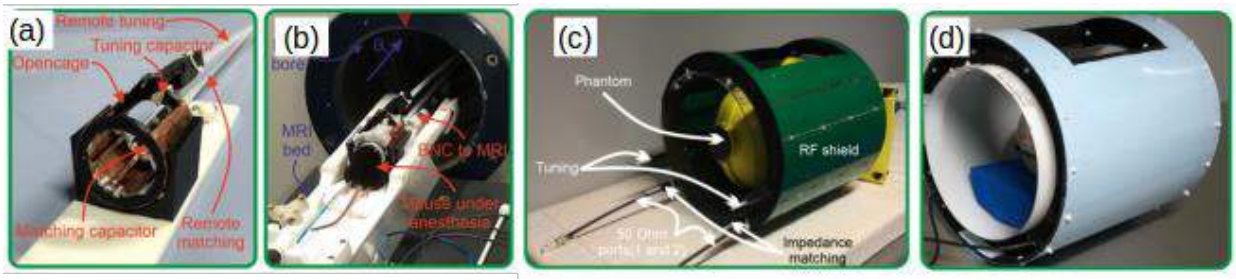

Figure 2: Photographies of the preclinical open-cage devoted to rodent brain imaging [(a) and (b)] and the clinical device dedicated to human brain imaging [(c) and (d)].

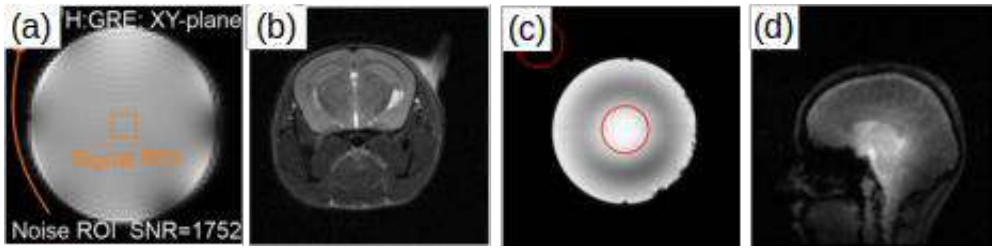

Figure 3: Magnetic resonance images obtained with the preclinical open-cage of a phantom cylinder (a) and of rodent head (b). Magnetic resonance images obtained with the clinical open-cage of a phantom cylinder (c) and of the head of a volunteer (d).

Both prototypes where tested ex-vivo and in-vivo. Finally, we combine the principle of phase conjugation and the metamaterial approach in order to shift the maximum of the magnetic field off the center axis. This approach is tested with phantom in a 17.2T preclinical MRI with a 3D printed prototype (see Fig. 3a). One image obtained when only one port is fed is shown in Fig. 3c. It qualitatively corresponds to the expected map resulting for the simulation.

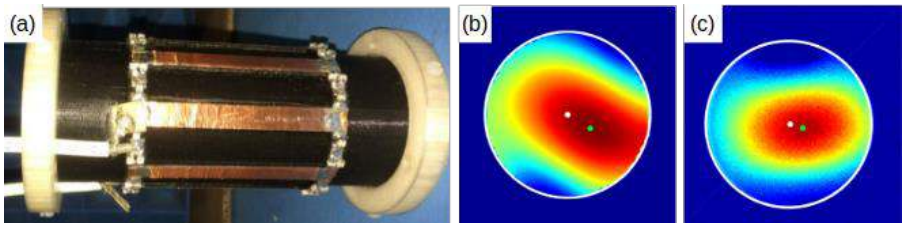

Figure 3: Magnetic resonance images obtained with the preclinical open-cage of a phantom cylinder (a) and of rodent head (b). Magnetic resonance images obtained with the clinical open-cage of a phantom cylinder (c) and of the head of a volunteer (d).

Abstract: In this work, we introduce a nonlocal-inspired metamaterial that enhances the performance metrics of antennae used in biomedical applications, such as glucose sensing and other applications.

Since its conception, the paradigm of metamaterials has continuously delivered a novel design approach with many applications in energy control and harvesting[1]. These paradigms have been exploited for specific biomedical applications with promising results[2]. In this domain, recent works on metamaterials shed light on a particular category of nonlocal metamaterials. While local metamaterials transversely vary, their nonlocal counterparts are typically transversely homogenous while they typically can be longitudinally inhomogeneous[3]. A characteristic example is a stack of dielectric layers with proper permittivity recently used as spaceplates and for enhancing the performance of optical and lensing systems[3]. Interestingly, nonlocal metamaterials share many similarities with the broader category of grated refractive index (GRIN) lenses often encountered in microwave engineering. Finally, inverse design in metamaterial research offers new possibilities by expanding the available design space of microwave components, such as antennas for conventional and unconventional functionalities[4]. Therefore, adopting nonlocal metamaterials principles and inverse design for specific biomedical applications is an obvious pathway. Biosensing, bioimaging, and telemetry usually require an antenna design with an extremely sensitive response and a compact and robust setup to operate close to or inside a highly lossy medium that is the human body[5].

This work introduces the design methodology for a non-local-inspired metamaterial for antenna enhancement. First, we assume a region typically given by the application requirements. This is the space where the unknown nonlocal-inspired metamaterial will be placed. In principle, this slab consists of a continuous inhomogeneous permittivity profile. We then discretize this in the longitudinal direction in slices of unknown permittivity and width. At this stage, we inverse design the desired profile (ε, width) that yields desirable~~specific~~ goals/constraints using standard optimization technics, such as a genetic algorithm. Then, assuming a given set of thicknesses and permittivities, we proceed to the implementation phase. The slabs can be implemented via chemical[6,7] or metamaterial[1] synthesis approaches in this phase. Chemical synthesis is the process where the desired permittivity and thickness are chemically/mechanically achieved. The metamaterial synthesis follows the metamaterial design principles, where effective permittivity emerges from the properly designed constituents. Each methodology has its advantages, especially in terms of robustness and manufacturability.

For example, we demonstrate the case of an antenna array (4 patches) specially designed for a K-band (37GHz) sensor for biomedical applications. The enhancement of the performance of such an antenna is evident with the usage of a thin layer of desired profiles (permittivities and widths). These layers are subsequently implemented via properly designed metamaterials. ~~We note that this~~This inverse-design nonlocal-inspired design approach

essentially expands other typical design approaches, such as the design of matching layers or GRIN lenses to enhance antenna systems.

Abstract: Reconfigurable Metamaterials introduce manifold degrees of freedom into MRI to overcome limitations of present technological capabilities. Reconfigurability in this respect does not only include tailored and controllable spatial sensitivity profiles w.r.t. the interaction with incident fields, but also the precise control in the time domain. The state of the art and various use-cases of static, dynamic, reconfigurable, and interactive metamaterials as well as control strategies are shown. Applications range from SNR enhancement to spatial encoding patterns for reduced gradient fields.

Magnetic Resonance Imaging (MRI) is a powerful, non-invasive, and indispensable medical imaging modality. The involved technology has been improved for decades and state-of-the-art imaging makes use of i) advanced hardware components such as multi-channel, tailored Tx/Rx coils, and ii) modern software solutions such as vendor-independent pulse sequence design frameworks [6] and AI-based image reconstruction strategies. MRI is an essential part of clinical diagnostics and therapy control due to the variety of tissue contrasts. However, physiological limitations hamper technically possible advancements. A prime example is peripheral nerve stimulation caused by the gradient field switching that sets clear limits on the imaging speed. Whilst higher static B_0 fields of 7 T and beyond may also improve the signal-to-noise-ratio (SNR), they are related to higher costs and come with other disadvantages such as standing waves in the field-of-view at the same time.

The use of **Metamaterials** (MTMs) in the field of MRI is a recent development that offers a great potential to overcome some of the aforementioned limitations. Standard applications of MTMs in MRI are the SNR enhancement, imaging speed-up, and field homogenization [1-3]. MTMs may even outperform local, conventional Rx coils in specific applications when used in combination with an MRI scanner's integrated body coil [1,3]. A similar impact is seen in the field of bio-electronic in general [4]. However, the full potential of MTM-based solutions can only be unleashed if reconfigurable designs are employed in combination with advanced control and optimization paradigms. True **reconfigurability** means active, spatio-temporal control of a metamaterial's sensitivity profile, i.e., the tailored interaction with incident fields in its vicinity, which may also vary over time. In contrast, a static MTM always reacts in the same way to excitations and a dynamic one may be sensitive to, e.g., the imaging phase in MRI as demonstrated in [2,3,5]. A MTM that allows for, at least, fine-tuning of its resonance frequency exhibits a very low degree of reconfigurability [3]. In this case, patient- or vendor-specific adaptions become possible and such a design must be considered the bare minimum for meaningful applications. Control and optimization, down to the unit cell scale, must include MRI scanner synchronization and a wireless interface to manipulate the MTM before and during an MRI scan.

In Fig. 1, an MRI-tested prototype for a wirelessly reconfigurable (in one dimension) metasurface is shown. The use of digital capacitors (dcaps) in combination with a low-power microcontroller allows to interface the MTM via BLE even during an MRI scan. The same figure also shows an example of a tunable and dynamic

MTM that uses a dcap and a crossed diode pair. It allows to i) fine-tune the resonance and ii) react autonomously to the incident power level such that in Tx there is no recognizable effect whilst in Rx the SNR is enhanced significantly, c.f. [3].

Advanced, three-dimensional, reconfigurable MTMs in the future will allow for more dynamical use-cases such as spatial signal encoding via time-dependent resonant patterns, realization of virtual coil channels in Tx/Rx, electronic focusing, flexible designs of wireless coils that benefit imaging efficiency and patient comfort. Necessary developments will be outlined, which include, e.g., the embedding into a sequence development framework such as GammaStar [6], or the optimization and image reconstruction via AI-based tools.

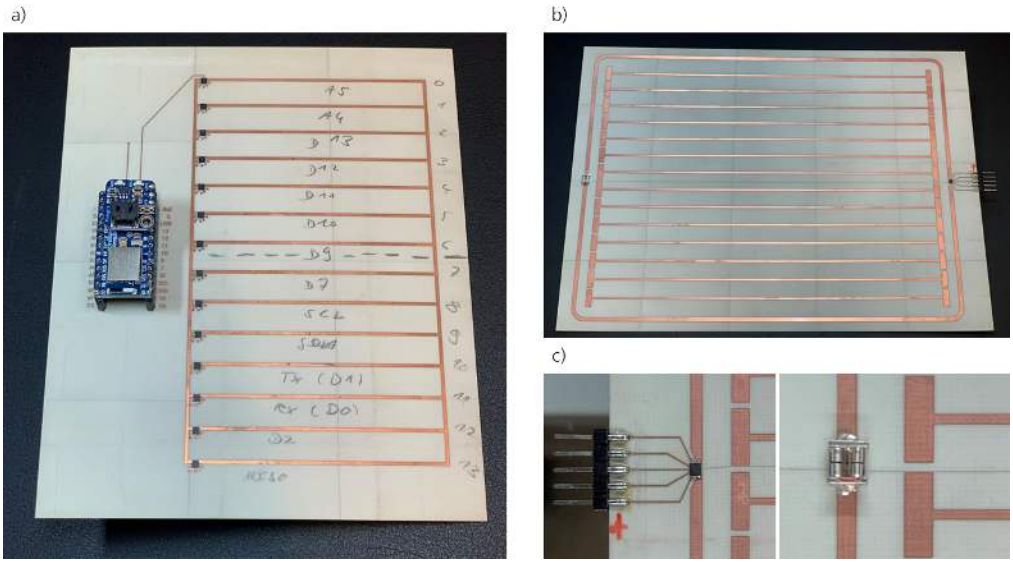

Figure 1 Prototypes of reconfigurable MTMs manufactured at Fraunhofer MEVIS. A 14-dcap, one-dimensional MTM with embedded microcontroller (a) allows for spatio-temporal, BLE-based control. A tunable, smart MTM allows for resonance frequency adjustments and automatic Tx detuning (b) via a dcap and crossed diode pair (c), respectively.

Abstract- Achieving higher sensitivity in THz metasurfaces requires a larger Q-factor to minimize losses. EIT-like and perfect absorber metasurface can reduce losses and gain higher sensitivity. Here, we designed a novel THz absorber metasurface and its EIT-like counterpart and compared their sensing performance. Using EM simulation and varying the sample's refractive index, a theoretical sensitivity of 842GHz/RIU and 560GHz/RIU achieved for absorber and EIT-like metasurface, respectively. These findings validate the effectiveness of both biosensors, with absorbers showing greater potential for biosensing.

[3]Multiwave Imaging

3T MR scanners are popular in a clinical context, offering higher SNR compared to the widely deployed 1.5T. Higher field strength leads to shorter scanning times or higher resolution images. However, when 3T MRI is used to image large cross-sectional areas such as the abdomen, thorax, or spinal cord, inhomogeneities in the radiofrequency (RF) field appears and can affect the image quality [1]. On that basis, alternatives are needed if one intends to scan large central body parts at 3T.

Both high dielectric pads and high permittivity ceramics blocks have been used as efficient solutions with the aim of mitigating RF inhomogeneities [2] [3]. However, ceramic materials are very limited in terms of dimensions.

Here, original metasurface pads are presented as an alternative approach to mitigate RF inhomogeneities. Several designs which can be integrated within standard MRI equipment will be presented with a particular attention dedicated to field penetration efficiency and safety in the field of whole-body imaging.

Metamaterials for 7T Ultra High Field MRI

Redha Abdeddaim[1], Marc Dubois[2], Stefan Enoch[1]
[1]Aix-Marseille Universite, CNRS, Centrale Marseille, Institut Marseille Imaging, Institut Fresnel, [2]Multiwave Imaging

Ultra-high field MRI head coils are characterized by a specific B1+ magnetic field distribution leading to signal and contrast inhomogeneities over the image in relevant regions of interest such as the temporal lobes of the brain and the cerebellum[1]. This issue has been previously targeted by different passive RF shimming approaches such as high permittivity dielectric pads or metamaterials[2].

Passive RF shimming is based on the insertion of passive structures between the subject and the coil. Devices such as high-permittivity dielectric pads or metamaterials have been assayed as potential solutions. These structures are inductively coupled to the main transmit RF coil. Induced currents (displacement or conduction currents) can generate a secondary RF field that redistributes the initial B1+ field. In the present study, we present how metamaterials can improve the B1+ field over each temporal lobe without deterioration of the RF performances in other brain areas and with minimal impact on patient comfort[3]. Different shapes and types of metamaterials will be presented and compared in order to identify the optimal configuration considering the targeted field intensity increase[4].

Segmentation of individual muscles in MR images from patients with neuromuscular diseases

D. BEN DAHAN

Aix Marseille Université, CNRS, CRMBM UMR 7339, Faculté de Médecine de la Timone, 27 Bd. J. Moulin, 13005 Marseille-France

Abstract : Segmentation methods developed at CRMBM for the semi or fully automatic delineation of individual muscles in MR Images will be presented and the corresponding performances will be discussed.

Neuromuscular Diseases (NMDs) are genetic disorders progressively affecting nerves and/or muscles thereby leading to a loss of motor function (1). From an MRI perspective, the contrast available between fat and water is very useful to assess and possibly quantify the severity of the fat infiltration occurring throughout these disorders and to follow-up the corresponding natural history. Rather counter-intuitively, this fat infiltration largely differs among patients with a given disorder and even among different muscles within a given patient. On that basis, the assessment of MRI changes in NMD patients should be combined to methods allowing to delineate individual muscles from 3D datasets. The MSK research group at CRMBM has developed over the last few years semi-supervised and fully automated approaches with the aim of segmenting individual muscles from 3D MRI datasets and use the corresponding labels to compute specific biomarkers values within e ach label. As part of the presentation, we will show that the different methods are very sensitive to fat infiltration and will illustrate the accuracy of the quantified biomarkers with the different methods.

On the design, control, and AI-driven optimization of reconfigurable metamaterials for Magnetic Resonance Imaging

Abstract: Reconfigurable metamaterials offer the possibility to drastically improve various metrics in Magnetic Resonance Imaging. Among those are, e.g., speed, efficiency and local signal-to-noise ratio. To extremize a given target function, suitable optimization strategies must be followed. Here we report on the design of first prototypes, including their functionality, wireless control and conventional as well as AI-driven optimization. Simulations, on-bench measurements, deep learning optimization results, and MRI scans are shown to demonstrate a proof-of-principle.

Magnetic Resonance Imaging (MRI) is a powerful, non-invasive, and indispensable medical imaging modality. **Reconfigurable metamaterials** (MTMs) introduce many degrees of freedom that allow to lift the imaging performance to the next level and overcome some technological limitations. MTMs have become increasingly popular in MRI for a variety of applications. Specifically, they have been utilized for the signal-to-noise-ratio (SNR) enhancement in standard MRI scans [1-3] and may even have superior performance to conventional Rx coils [1,2]. However, all realizations presented in the available literature offer only a very low degree of reconfigurability, if any. In particular, resonance frequency fine-tuning must be ensured to cope with vendor-dependent and patient-specific effects. Manual tuning strategies are too far from clinical use and, thus, only a digital and wireless control shall be employed, ideally supplemented by an on-board logic.

In Fig. 1, a one-dimensional MTM prototype is shown that resembles a low-pass open birdcage coil design and includes N = 14 digital capacitors (dcaps) which can be individually controlled via Bluetooth (BLE) from a host device. A dedicated user interface allows to easily change the MTM's momentary configuration, which is verified by on-bench measurements and MRI scans. To optimize a target function, e.g., SNR in a region of interest, or a predefined field profile, conventional as well as AI-based optimization strategies can be followed. Possible applications are magnetic field shaping (electronic on-demand focusing or shielding of medical devices), the realization of virtual coil channels, and patient-specific imaging approaches. A desired field profile may be the result of many different sets of parameters and the inverse problem must be tackled.

Deep Learning (DL) approaches are especially well-suited for solving such non-linear optimization tasks. To overcome the inverse problem, a well-trained neural network can be used to find an appropriate set of parameters. On-bench as well as MRI tests will be reported on and results of the DL-based optimization using measurement and simulation data will be shown with a focus on generic field shaping capabilities. In Fig. 2, simulations results for a next-generation, two-dimensional prototype are shown, which is optimized for the purpose of local SNR enhancement. Analytical models assist in the design and complement numerical methods.

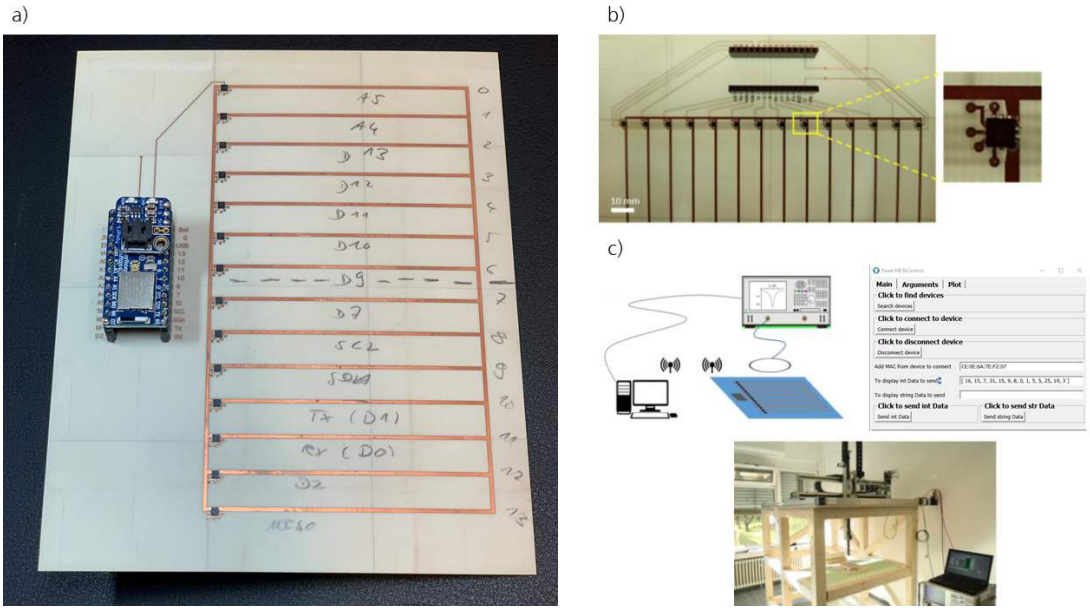

Figure 1 Prototype of a reconfigurable MTM manufactured at Fraunhofer MEVIS. A 14-dcap, one-dimensional MTM with embedded microcontroller (a) allows for spatio-temporal, BLE-based control. Connection traces are manufactured on the back-side of the PCB (b) and the BLE connection to a computer allows to individually control all dcaps from a dedicated user interface during on-bench measurements (c).

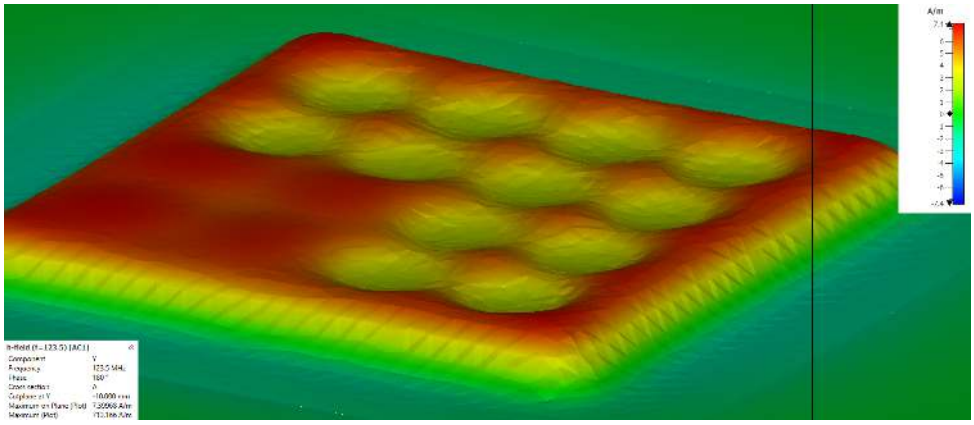

Figure 2 Exemplary magnetic field shaping with a two-dimensional, reconfigurable MTM based on 4x4 split ring resonator unit cells.

Boosting received magnetic field (B_1^-) strength using wearable metasurface-based add-ons for 1.5T MRIs

Jegyasu Gupta[1, *], Tanmay Bhowmik[1], Ratnajit Bhattacharjee[1], and Debabrata Sikdar[1]

[1]Department of Electronics and Electrical Engineering, Indian Institute of Technology Guwahati, Guwahati 781039, Assam, India

[*]Corresponding author: jegyasu19@iitg.ac.in

Abstract: Magnetic resonance imaging (MRI) is a popular non-invasive diagnostic technique for examining human body tissues and organs. Metasurfaces have the ability to boost the received magnetic field (B_1^-) locally inside an MRI scanner. However, the metasurfaces reported in the literature for 1.5T MRI are not flexible enough to conform around different shapes of the subject's body parts undergoing scan. Here, we present a wearable metasurface-based "add-on" comprising copper-based apertures for boosting B_1^- in the region-of-interest (ROI) for 1.5T MRI.

Introduction: Magnetic resonance imaging (MRI) is a popular clinical diagnostic tool that uses non-ionizing radiation to ensure the safety of patients undergoing scans. In MRI, the image resolution depends on the received magnetic field (B_1^-) which can be increased by boosting the applied static magnetic (B_0) inside the MRI scanners [1]. However, this leads to an increased RF power deposition *i.e.* specific absorption rate (SAR) inside the body tissues which could cause safety concerns for patients with metallic implants and demand costly state-of-the-art hardware installation $[2-3]$. Metasurfaces or 2D metamaterials, whose electromagnetic properties and near-field distribution can be tailored by engineering their sub-wavelength unit cells, have shown potential in boosting the received magnetic field of 1.5T MRI scanners [4]. Several metamaterial designs based on split-ring resonators, swiss rolls, and wire-based resonators have been reported so far to enhance B_1^- for 1.5T MRI systems [5]. However, due to their large physical dimensions, the utilization of the reported metamaterial designs in clinical MRI applications is limited $[6-7]$. Further, these reported metasurfaces, for boosting the B_1^- of 1.5T MRI, are not flexible enough to cover different body parts such as head, legs, *etc*. undergoing scan $[6-8]$. This manuscript proposes a wearable (conformably attachable) metasurface-based add-on comprising copper apertures on a polyimide substrate for enhancing magnetic field localization inside a curved phantom mimicking human properties.

Design: The unit cell of the proposed metasurface comprises a polyimide substrate (of thickness $h = 1$ mm) sandwiched between the complementary bowtie-based aperture and square patch, as shown in Fig. 1(a). The design parameters of

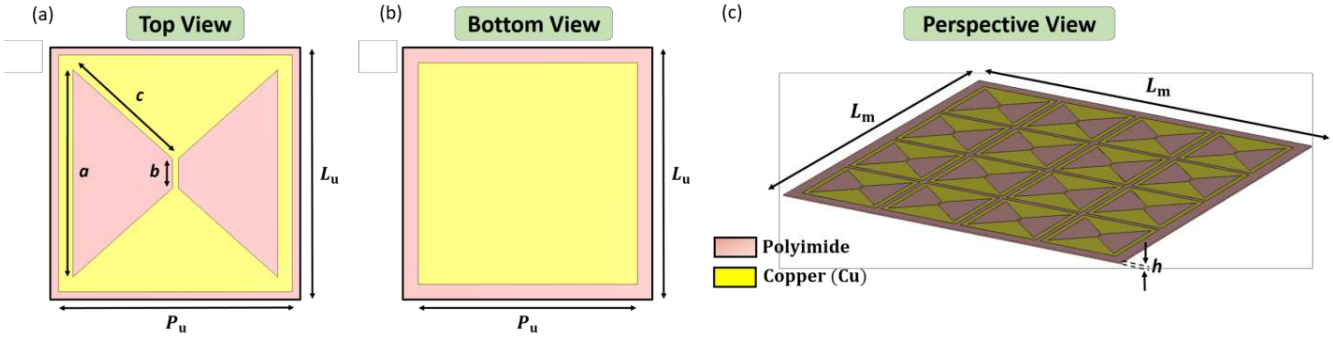

Fig.1.(a) Top (b) Bottom and (c) Perspective views of the proposed metasurface-based add-on with copper apertures on a flexible polyimide substrate.

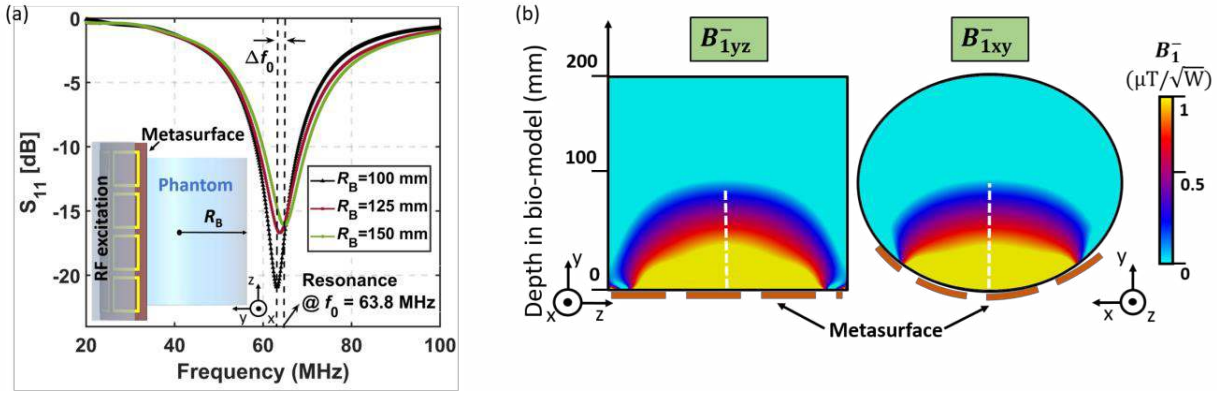

Fig.2. (a) Frequency response of the reflection coefficient of the metasurface in the scanning setup (inset), when excited by a quadrature-fed RF loop coil. (b) Received magnetic flux density (B_1^-) along (b) yz and xy plane with the metasurface at the bottom of phantom (with $R_B = 150$ mm).

complementary bowtie patch are: $a = 70$ mm, $b = 10$ mm, $c = 70$ mm, $P_u = 70$ mm, and $L_u = 80$ mm. The thickness of both copper patches on the top and bottom of the metasurface's substrate is 0.035 mm. A 4×4 array of unit cells (with dimensions $L_m \times L_m = 340$ mm $\times 340$ mm) is considered for the numerical analysis to study the enhancement in the received magnetic field inside a human properties mimicking phantom.

Results and Discussion: The metasurface is wrapped around the cylindrical phantoms of different bending radii ($R_B =$ 100 mm, 125 mm, and 150 mm), which mimics different human body parts. S-parameters are extracted from the simulation setup for the resonance analysis of metasurface in differently bent states, as shown in Fig.2(a). There is a very nominal shift ($\Delta f_0 \leq 2$MHz) in the resonating frequency ($f_0 = 63.8$ MHz) of the metasurface for various bend radii with a return loss $>$ 15 dB at f_0 for the radii. The circulating currents (*i.e.* magnetic dipoles) are generated on the resonating copper apertures of the metasurface by the magnetic flux of the RF loop coil. This significantly boosts the received magnetic field (B_1^-) inside the phantom ($R_B =$ 150 mm), as can be seen in Fig. 2(b).

Conclusion: We present a design of a wearable and body-conformal metasurface-based 'add-on', which can be wrapped around different body parts (with different curvatures) going inside the clinical MRI scanners. This will enable enhancement in received magnetic field in the region undergoing scan, leading to an enhancement in the quality of MR images.

Abstract: We investigate how one can control topological and non-Hermitian properties by manipulating the symmetry of dielectric structures. First, we show one can create and annihilate various topological singular points starting from the topological charge of high-symmetry points or exceptional points by breaking the symmetry. Second, we demonstrate that the reciprocal non-Hermitian effect appears in simple uniform media by breaking the symmetry of the dielectric tensor.

Recently, various intriguing and non-trivial properties have been found in topological and non-Hermitian photonics. Many of these properties result from breaking the intrinsic symmetries of initial structures. In this talk, we investigate how one can manage topological and non-Hermitian properties, such as topological charges and the non-Hermitian skin effect by manipulating the spatial symmetry.

Among various topological properties of photonic crystals, we are interested in topological polarization singularity, which appears in the far-field radiation field from photonic crystals. This singularity is described by the topological charge which is derived from vectorial properties of eigenmodes in photonic crystals. Hence, this topological property does not have a counterpart in topological physics in solid-state materials governed by scalar wavefunctions. Generally, topological singular points exist at high-symmetry points in the reciprocal lattice of photonic crystals. If one breaks the intrinsic symmetry of this initial highly-symmetric photonic crystals, various non-trivial topological singular points can be generated and these points can be moved away from high-symmetry points in the reciprocal space. We previously demonstrated that non-trivial off-Γ BICs (bound states in the continuum) and circularly-polarized singular points can be generated from a trivial BIC at Γ point by breaking the C_6 rotational symmetry of the triangular lattice [1]. In this talk we extend this idea to other examples including the case starting from Dirac points in the C_6 symmetry. We will also show experimental results with fabricated photonic crystal slabs.

Next, we investigate a topological charge in non-Hermitian photonic crystals. As well known, non-Hermitian photonic crystals exhibit exceptional points (EPs) in the reciprocal space. Although it is well known that EPs appear for PT-symmetric structures, EPs can appear when the spatial symmetry of the imaginary effective refractive index (Im n) is broken. EP exhibits topological properties described by the vorticity defined by the phase rotation of the complex eigenfrequency. Employing graphene-loaded C_4 square-lattice photonic crystals, we show that the topological charge can be generated from the EP by breaking the spatial symmetry of Im n, and one can further manipulate generation and annihilation processes of EPs and topological singular points by breaking the spatial symmetry of Re n.

Lastly, we investigate non-Hermitian skin effect in dielectric media. Although the non-Hermitian skin effect has been mostly discussed in non-reciprocal discrete systems described by the tight binding model, recently, the non-Hermitian skin effect has been confirmed in reciprocal non-Hermitian photonic crystals which cannot be

expressed by the tight binding model. In the case for non-Hermitian photonic crystals, it is important to break the symmetry of the crystal structure itself [2] or of the dielectric tensor [3] to realize the skin effect. Here we show that the non-Hermitian skin effect appears even for uniform media without any crystal lattice if the dielectric tensor has a certain asymmetry and gain or loss component. We will discuss the relationship between the symmetry and this novel skin effect.

Abstract: More than a decade ago, topological photonics emerged with the discovery of the first photonic topological insulator, which was a two-dimensional (2D) periodic lattice of gyromagnetic rods or a magnetic photonic crystal. Although electronic topological insulators were successfully generalized from 2D to three-dimensional (3D) in the past decade, the development of 3D photonic topological insulators has been highly challenging. In this talk, we present some of our recent research on 3D magnetic topological photonic crystals.

The field of topological photonics [1] investigates a novel class of photonic states that exhibit topological protection, similar to the behavior of electrons in topological quantum matter. This field began a decade ago with the realization of the first photonic topological insulator, a periodic lattice of gyromagnetic rods or a magnetic photonic crystal [2]. This achievement marked the first demonstration of the Chern insulator phase [3], even before its condensed-matter realization [4], highlighting the benefits of using photonic crystals for demonstrating challenging physics.

The generalization of topological insulators from 2D to 3D was a remarkable breakthrough in topological physics, upgrading topological states from edge states to surface states [5,6]. However, the realization of their photonic analogues in 3D, known as 3D photonic topological insulators, remains extremely challenging, with only a few realizations to date [7]. Recent studies in condensed matter systems have offered new avenues for exploration in magnetic topological insulators and magnetic topological semimetals. It is thus of particular interest to explore the potential of 3D magnetic topological photonic crystals [8].

In this talk, I will present some of our recent studies on three-dimensional (3D) magnetic topological photonic crystals.

Title:

Topological Transport in a Nanoscale Optomechanical Array

Abstract:

I will present the results of a recent theory-experiment collaboration with the lab of Oskar Painter at Caltech [Nat. Comms, 13, 3476 (2022)]. We were able to design and realize the largest optomechanical array to date, using a new concept that we term a multiscale optomechanical crystal. We engineered it to produce a phononic topological metamaterial at the nanoscale, exploiting the Valley Hall effect. Thanks to the sensitivity of optomechanical measurements, we were able, for the first time, to measure the topologically protected transport of thermal excitations. This experiment paves the way towards unlocking the full toolbox of optomechanics for the field of nanoscale topological phonon transport.

Abstract: We study the exotic behaviors and topological phases of photonic time crystals (PTCs) and emulate their Integer Quantum-Hall Effect in parameter space. By exploiting the eigenvalue approach of frequency vs. momentum, we verify their quantized topological invariant and disclose topological edge states at temporal boundary. To experimentally disclose their edge bands, we propose a simple approach of scattering parameters at a dedicated time relating them to the eigenmodes. We also reveal exclusive features of PTCs not observed in spatial counterpart.

Topological photonic crystals have been investigated intensively owing to their unusual topological properties like the robust edge modes immune from the backscattering, enabling opportunity for useful applications in classical and quantum optics[1]. Meanwhile, the photonic time crystals (PTCs), the analogs of spatial photonic crystals, are created by enforcing periodic temporal switching on parameters of the media. It is out of curiosity whether topological phenomena in photonic crystals can be similarly observed in PTCs. Two groups have recently inspected the topological aspects of photonic/phononic time crystals by studying 1D spatially homogenous and temporally alternative media which emulates the Su-Schrieffer–Heeger(SSH) models in the time domain[2,3], the disorder PTCs were also studied and some interesting phenomena related to temporal Anderson localization were disclosed[4,5].

Here, we study the extreme wave phenomena and topological properties of PTCs analogy to IQHEs. We develop the frequency vs. momentum approach to efficiently study the eigenstates of PTCs and topological properties of large temporal systems like photonic time quasicrystals, and prove their temporal Chern numbers, calculated from eigenstates of Floquet effective Hamiltonian, are integer quantized. To verify the bulk-edge correspondence, we generate the temporal trivial boundaries by creating switching event with large permittivity right after PTCs. As a result, the band structures of such temporal heterojunctions display gapless edge bands in the momentum bandgaps, of which the eigenstates are localized at the temporal interfaces between PTCs and TCSs. To measure the dispersion of topological edge states via the external excitation, we compare two measurement schemes and record the scattering parameters after the switching events from PTCs to TCSs or from TCSs to PTCs, and only the latter precisely captures the temporal edge bands crossing the momentum bandgap of the bulk bands, which is a unique feature for PTCs. Finally, we demonstrate the temporal topological Thouless pumping on multiple periods of PTCs, and show the transition behaviors of excited waves from the left temporal boundary, to the bulk and to the right temporal boundary. Due to the causality relation, topological edge states exhibit temporal localization on the second or later period depending on their Floquet Bloch phase, which is another exceptional feature not found in their spatial counterparts. Our findings are confirmed by full-wave simulations, and the results provide new avenues for studying topological properties of time-varying

media and enable interesting functionalities of PTCs beyond the spatial counterparts. The simple yet rich temporal models can be expediently implemented in the state-of-art photonic experiment.

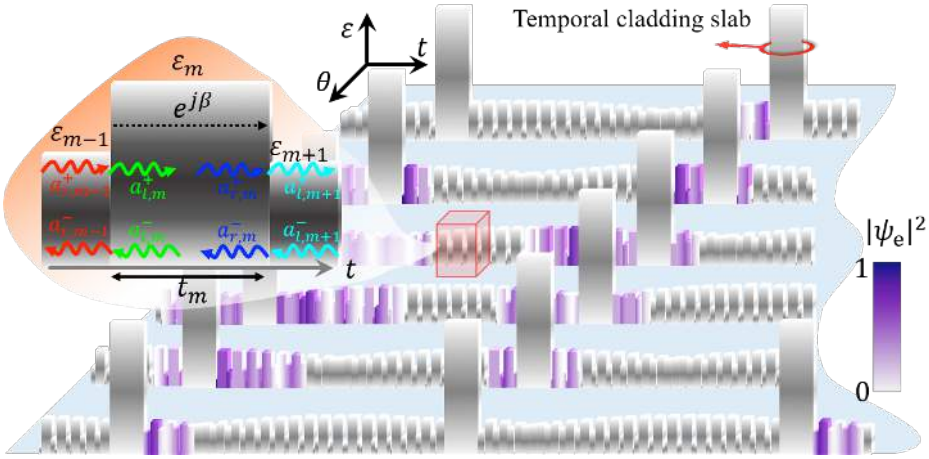

Figure 1: schematics of photonic time crystals (PTCs) with permittivity ε_m and time step δt_m modulated as a function of time slab index m and phason parameter θ accordingly. The temporal cladding slabs (TCSs) with a large permittivity ε_{tcs} act as the trivial regime next to PTCs (not to scale). The color of the pillars represents the magnitudes of edge wave functions $|\psi_e|^2$ evolving with θ, and exhibit period doubling oscillation in the time domain due to properties of Floquet Bloch waves. Inset shows forward and backward waves at different temporal interfaces formed by various time slabs. The propagation phase accumulated in each time slab is made the same and denoted as β.

Abstract: The exploration of novel topological physics is one of the most fascinating frontiers in recent years. So far, most studies on topological states have focused on systems in Euclidean space. Here, we report on the construction of various topological phases in hyperbolic space, which is non-Euclidean space with constant negative curvature. We firstly reveal the boundary-dominated Chern topological states in hyperbolic spaces. Moreover, based on the unique property of non-Abelian Fuchsian translation group, the 2D hyperbolic topological states with non-zero second-order Chern numbers are constructed. These exotic hyperbolic topological states have been experimentally observed by electric circuit networks.

The discovery of novel topological states has served as a major branch in physics and material sciences. To date, most of the established topological states have been employed in Euclidean systems. Recently, the experimental realization of the hyperbolic lattice with a constant negative curvature has attracted much attention. Here, we demonstrate both in theory and experiment that exotic topological states with first-order and higher-order Chern numbers can exist in hyperbolic space [1, 2].

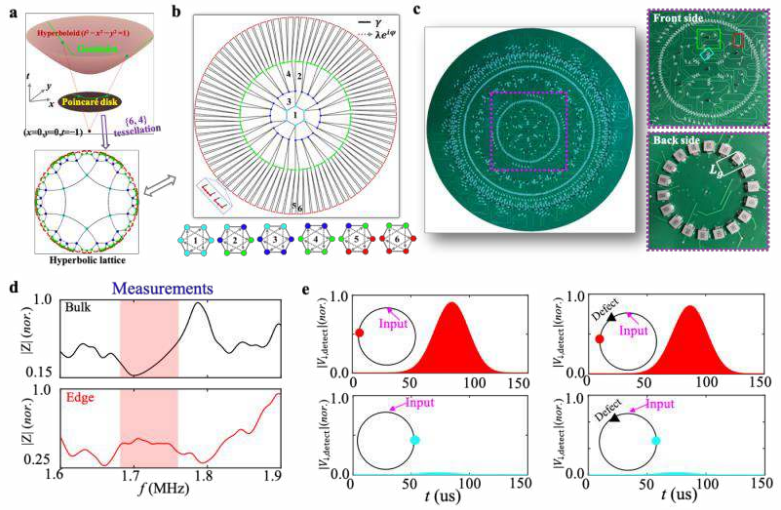

Fig. 1. Lattice model and electric circuits of hyperbolic Chern insulators.

1. Boundary-dominated topological states of hyperbolic Chern insulators. We extend the Haldane model originally defined in Euclidean space to the hyperbolic lattice {6, 4}. It is noted that the property of hyperbolic tight-binding lattice model depends on the connection of all vertices, and is regardless of the configuration of vertices. Hence, the hyperbolic lattice could also be illustrated by arranging the vertices in the form of quasi-concentric rings, and maintaining the connection of all vertices unchanged. In this case, the finite hyperbolic lattice {6, 4} with a sixfold rotation invariance in Poincaré disk (shown in Fig. 1a) is equivalent to the successive quasi-concentric rings with L=4 layers, as shown in Fig. 1b. For clarity, we mark lattice sites in the first, second, third and fourth layers by cyan, blue,

green and red dots, respectively. By introducing nearest-neighbor (NN) hoppings and direction-dependent next-nearest-neighbor (NNN) hoppings in each hexagon, the hyperbolic Haldane model is achieved. Detailed coupling patterns in hexagons composed of lattice sites from different layers are illustrated in right insets of Fig. 1b, where solid lines and dashed arrow lines correspond to NN hoppings and NNN hoppings, respectively. We numerically demonstrate that such a hyperbolic Haldane model possesses non-trivial real space Chern numbers and boundary-dominated one-way topological edge states. In experiments, we design hyperbolic Chern circuits to observe the hyperbolic Chern topological states. Fig. 1c illustrates the photograph image of the fabricated circuit sample with L=3. The front and back sides of enlarged views (enclosed the pink dashed block) and the schematic diagram of NN and NNN couplings are plotted in right insets. Based on the site-resolved impedance responses and dynamics of voltage packets, as shown in Fig. 1d, the boundary-dominated hyperbolic topological states have been observed.

2. Hyperbolic band topology with second Chern numbers. Motivated by the hyperbolic band theory, the hyperbolic topological band insulators with non-trivial first Chern numbers have been theoretically created. Here, we construct the hyperbolic topological band insulator with nontrivial second-order Chern numbers. Fig. 2a illustrates the Bravais lattice of designed hyperbolic model in a Poincaré disk, where the translational symmetry of a {8,8} hyperbolic tiling exists. Each unit cell (enclosed by the pink block), which is the fundamental tile in 2D hyperbolic space, contains four sublattice sites, as marked by colored dots in bottom inset. The infinite hyperbolic model can be constructed by tiling the 2D hyperbolic space with the unit cell along eight translational directions, which are marked by colored arrows. The inter-cell coupling patterns along these directions are illustrated in four subplots of Fig. 2b. Following the hyperbolic band theory, our proposed lattice model in 2D hyperbolic space can be described in the momentum space. In particular, we can equip inter-cell couplings of the hyperbolic unit cell with twisted boundary conditions along four translation directions, where the $U(1)$ phase factors e^{ikj} (j=1, 2, 3, 4) along eight directions are introduced. We find that such a model sustains non-trivial second-order Chern numbers. In experiments, we design and fabricate hyperbolic circuit networks with twelve units to observe the hyperbolic band topology with second Chern numbers. Fig. 2c illustrates the photograph image of the fabricated circuit sample. Based on the site-resolved impedance measurements, the non-trivial hyperbolic edge states with non-trivial second-order Chern numbers have been observed.

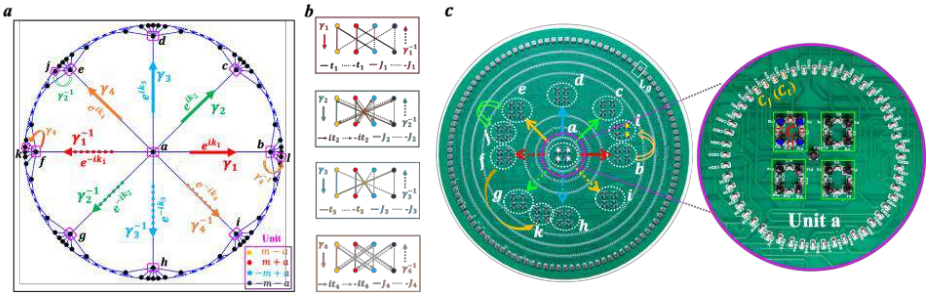

Fig. 2. Lattice model and electric circuits of hyperbolic band topology with second Chern numbers.

Optical holography and coding based on topological light field in real space

L. J. Kong, and X. D. Zhang*

Key Laboratory of advanced optoelectronic quantum architecture and measurements of Ministry of Education, Beijing Key Laboratory of Nanophotonics & Ultrafine Optoelectronic Systems, School of Physics, Beijing Institute of Technology, 100081, Beijing, China

Abstract: Optical knots and links have attracted great attention because of their exotic topological characteristics. Recent investigations have shown that the information encoding based on optical knots could possess robust features against external perturbations. However, as a superior coding scheme, it is also necessary to achieve a high capacity, which is hard to be fulfilled by existing knot-carriers owing to the limit number of associated topological invariants. Thus, how to realize the knot-based information coding with a high capacity is a key problem to be solved. Here, we create a type of nested vortex knot, and show that it can be used to fulfill the robust information coding with a high capacity assisted by a large number of intrinsic topological invariants. In experiments, we design and fabricate metasurface holograms to generate light fields sustaining different kinds of nested vortex links. In addition, we introduce optical topological structures into holographic technology and establish a new topological holographic coding. We verify the feasibility of the high-capacity coding scheme based on topological optical knots in experiment.

The research on topological properties has received extensive attention. In addition to the research on the topological characteristics in momentum space, the topological structure light fields and acoustic fields in real space, such as knot and link, have also attracted great attention because of their exotic topological characteristics [1–3]. Recent investigations have shown that the information encoding based on optical knots could possess robust features against external perturbations [4]. However, the capacity in this topological coding scheme based on the optical framed knots is very limited. Here, we theoretically propose and experimentally create the nested vortex knots in light fields to construct a topological coding scheme with high capacity. In addition, we introduce optical topological structures into holographic technology, demonstrate an entirely new concept of optical topological holography and establish a new topological holographic coding [5].

1. The theory of constructing nested vortex knots and links and coding scheme. We theoretically designed a nested knotted structure contains multiple topological invariants. As an example, a nested three-strand braid with twisted three times is shown in Fig. 1a. It contains three strands marked by green, red and blue. In order to show it more clearly, an enlarged view of the starting end plane is shown in Fig. 1b. The braid with a radius of r_1 is called the first-generation braid. Then, each strand with a radius of r_2 contains a sub-braid (called the second-generation braid, which is composed of three twined sub-strands). Similarly, each sub-strand with a radius of r_3 contains a sub-sub-braid (the third-generation braid, composed of three twined sub-sub-strands). Keep going in this way, we can finally construct a general nested braid structure with a fractal-like geometry. Finally, the nested link (as shown in Fig. 1c) can be obtained by using stereographic projection.

2. Coding scheme based on the nested knots and links. As shown in Fig. 1a, the braid structure corresponding to this new nested knot can contain multiple zero lines at different generation. And every zero line contains a topological invariant - the winding number $w_{\mathbf{M}_i}$. Using these topological invariants as information carriers, we design a high-capacity topological coding scheme. First of all, Alice, the sender of the message, converts the

message into a set of numbers $\{w_{\mathbf{M}_i}\}$ by using a certain program, and calculates the total values of winding numbers, W. Then, Alice chooses a positive integer α, assigns prime numbers $p_{\mathbf{M}_i}$ to the winding number $w_{\mathbf{M}_i}$, and calculates β as

$$\beta = \prod_{i=1}^{i=n} \left[\prod_{m_1=1}^{m_1=N_1} \prod_{m_2=1}^{m_2=N_2} \cdots \prod_{m_i=1}^{m_i=N_i} p_{\mathbf{M}_i}^{\left(\alpha^{w_{\mathbf{M}_i}} - W\right)} \right].$$

At the same time, a nested knotted structure (N_k) is generated, the set of winding numbers is exactly the $\{w_{\mathbf{M}_i}\}$. Then, Alice sends the pair of numbers (α, β) and the N_k to Bob in real time. After receiving these, Bob computes $\mathbb{N}_{\alpha,\beta}(W)$ with its definition, decodes the $\{w_{\mathbf{M}_i}\}$ by using prime factorization, and obtains the Alice's message.

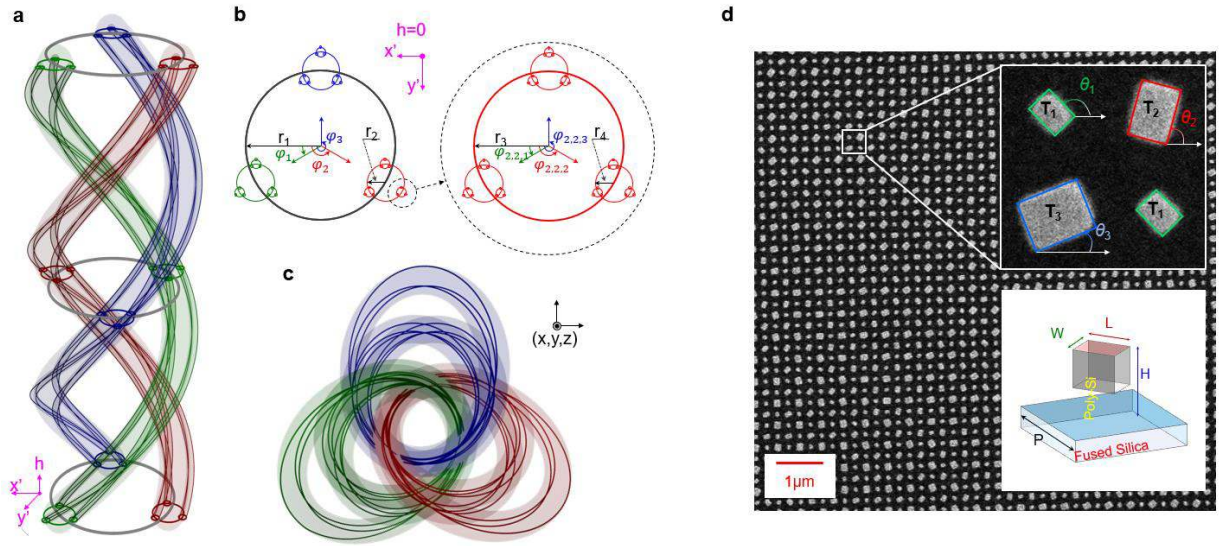

Figure 1. A nested three-strand braid with twisted three times (a, b, c) and the designed metasurface (d).

3. The Experimental demonstration. Compared with the knotted or linked structures generated previously, the nested knotted and linked structures are more complicated. Therefore, it is very difficult to construct nested knots at a single wavelength. In order to solve this problem, we design a metasurface hologram (as shown in Fig. 1d) to precisely manipulate the phase singularity of the light field at three frequencies, and experimentally realized all-optical nested knots. Furthermore, we also demonstrate both theoretically and experimentally topological holography and robust information storage with optical knots and links.

Abstract: Coupled fibre rings implement synthetic multiplexed lattices for light pulses with great flexibility to study fundamental topological properties. We measure both the intensity and the phase of the eigenvectors in a two dimensional two bands model and we extract the Berry curvature and the Chern number of the bands across topological phase transitions. The measured topological indices match perfectly the observed number of edge states in each gap at an interface, and the expected value of the Rudner invariant.

Anomalous topological insulators are paradigmatic examples of lattice systems whose topological properties arise from periodic modulations in time. The periodic driving of the lattice gives rise to a spectrum of modes that is not only periodic in space but also in quasienergy. This feature opens the possibility of having bands with topological chiral edge states traversing the gap while showing trivial Chern indices [1]. Despite the fundamental importance of these topological phases, simultaneous measurement of the anomalous bulk invariants and the presence of topological edge states has been hindered due to the stringent experimental constraints to access global and local properties in the same system.

Using a two-dimensional synthetic lattice implemented in a coupled fibre ring setup, we provide an experimental verification of the bulk-edge correspondence in anomalous and Chern topological insulators. The two band system we implement for light pulses is characterised by trivial and nontrivial Chern numbers. Using a heterodyne detection technique [2] we measure both the intensity and the phase of the eigenvectors, and we extract the Berry curvature and the Chern number of the bands. By inspecting the local changes of the Berry curvature at a topological phase transition we also measure the winding number characterising the anomalous phases. The measured topological indices match perfectly the observed number of edge states in each gap when an interface with vacuum is engineered in the experiment. These experimental observations are well described by an extension of the Rudner invariant [1] and provide the first experimental verification of the Bulk edge correspondance in Floquet-Chern insulators.

Abstract: Implementation of topological concept to phonon could have large impact on sound manipulation since novel features including low-dissipation, localization, and unidirectionality could be involved. Intensive studies have realized various topological acoustic waveguides, but most of the demonstrations are limited to kHz to MHz soundwaves. Here, we experimentally show GHz topological surface acoustic waves (SAW) using a nano-scaled phononic device and novel imaging technique. Our realization can be useful for superior SAW device for microwave communication.

In the last decade, the topological properties in condensed matters have been attracting much attention. The basic physics of topological insulators, Weyl semimetals, and topological superconductors have been extensively studied. The application to quantum computation or novel spintronic application has been considered.

The topological concept is now extended also to rather classic waves such as acoustic waves [1]. By constructing an artificial periodic structure denoted as phononic crystal, the topological nature such as low-dissipation, localization, and unidirectionality can be implemented to the acoustic waves. Despite their efforts, however, most experiments have remained limited to airborne sound at kHz region or elastic waves at MHz region [1]. There are two reasons for this: The most critical reason would be the increased difficulty of fabricating the sub-micron scaled device. The other reason would be high frequency measurement with high spatial resolution. Especially for GHz sounds, one cannot use classical probes such as microphone and also optical ones because the required spatial resolution is smaller than 1 μm, which is below the diffraction limit of visible light. However, it seems important to realize topological acoustic properties at these high frequencies, especially in the GHz range, since these microwave frequencies are compatible with commercial telecommunication applications. In addition, surface acoustic wave (SAW) devices with GHz working frequency are becoming increasingly important for the development of quantum technologies [2] such as quantum transduction among disparate systems and quantum control of SAW.

In this paper, we show that the topological nature can be introduced to GHz SAW device composed of a piezoelectric substrate with nano-scaled surface patterning by pillars [3]. By means of scanning microwave impedance microscopy, we directly visualized frequency dependence of the nano-scaled acoustic dynamics operating at GHz range and found acoustic edge mode when the frequency is within the band gap, consistent with the topological nature. The realization of a topological waveguide in a simple pillar structure on a substrate might pave a new path to the development of topological SAW devices for a wide range of usages such as quantum computing, sensing and communication applications.

Abstract: Non-Hermitian photonics has established entirely new ways for flexible control of light, which has sparked considerable interest in connection with topological physics. Here, we propose a new concept of *non-Hermitian synthetic dimension* and reveal its capability in manipulating the topological states, e.g., zero and Floquet π states. Significantly, we unveil new types of high-dimensional Weyl states hidden in this non-Hermitian dimension. We anticipate our integrated photonics platform to reveal more complex non-Hermitian topology in the future.

Topological photonics has successfully opened up a new degree of freedom for light manipulations. Recently, the study of high-dimensional topological effects by *synthetic dimension* has sparked considerable interest. Compared with the existing construction of synthetic dimensions in the Hermitian systems, the introduction of non-Hermitian parameters will increase the dimension of the system and is expected to form a new topological phase of matter. Here, I would like to show two fascinating examples demonstrated in integrated silicon waveguide platforms. One is the recovery of topological zero/π modes in static/driven systems from topologically trivial lattices by non-Hermitian synthetic modulations [1,2]. Such a non-Hermitian potential is further extended as a new synthetic dimension in another example. By carefully modulating the loss arrangement in the waveguides, new Weyl interface states were successfully observed in optical regimes [3]. They significantly originate from the *non-Hermitian order* transition, which are quite different from many previous interface modes caused by the *topological order* transition. Our works enrich non-Hermitian topological physics, which would possibly stimulate more interesting phenomena beyond this.

Abstract: We show beam trajectory bending, meandering, bifurcating and beam splitting by distorted photonic crystals which possess adiabatic change (lattice distortion) in photonic crystal lattice properties.

A Photonic crystal (PC) is an artificial material that is constructed by periodically arranging two or more dielectric media with different relative permittivity. Due to such periodicity, PCs possess a photonic band structure that controls the group velocity of light waves and that lead exotic beam trajectory such as negative refraction and superprism effect. Recently, we defined a PC that exhibits adiabatic change (lattice distortion) in the lattice constant as a distorted PC (DPC). In contract to the above-mentioned effects, even in isotropic dispersion region (low-frequency range), the light trajectory can be bent in DPCs. Some specific examples of schematic DPCs and beam trajectories in their DPCs are shown in Fig. 1. Although all DPCs maintain the averaged refractive index in the unit cells homogeneously, the beam trajectories show bending (Fig. 1 (f)), meandering (Fig. 1 (g)), bifurcating and beam splitting (Fig. 1 (h)), in contrast to the straight trajectory in non-distorted (normal) PC (Fig. 1 (e)). These beam trajectory steering effects can evaluate from the viewpoints of differential geometry [1] and adiabatic change of equi-frequency contours [2-3]. Since no spatial varies of refractive index, these light propagation controls using lattice distortion will be new approach in the fields of transformation optics. Details will be reported at the conference.

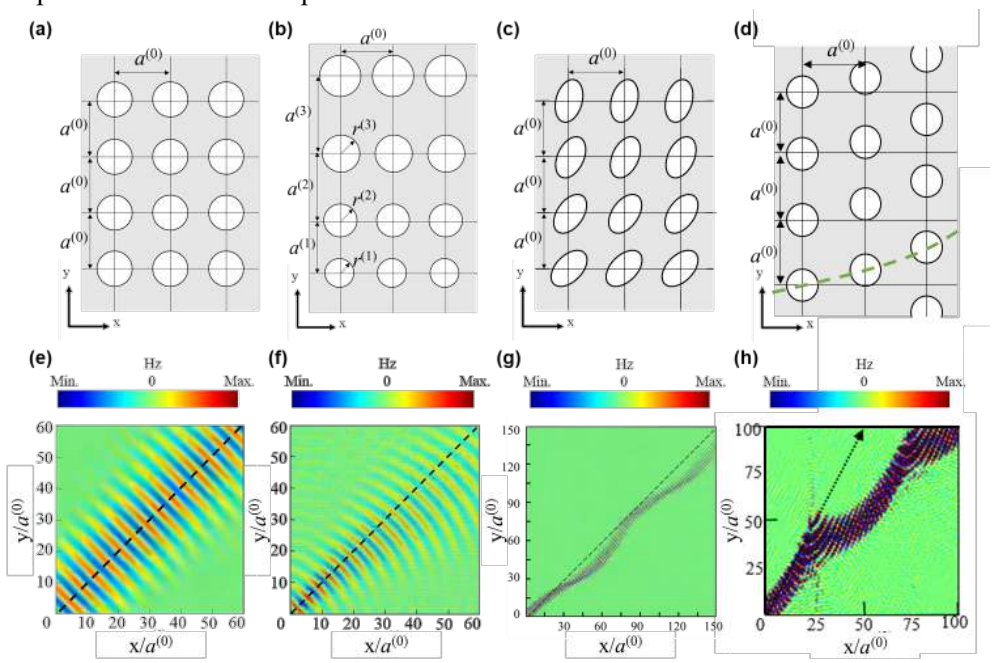

Fig. 1 (a)-(d) Schematic lattice-points arrangements of the DPCs based on a square-lattice PC. (a) non-distorted PC, (b) position-(lattice constant-) DPC, (c) shape-DPC, (d) slip-DPC. (e)-(h) Numerical simulation results of light trajectory (H_z-polarization, frequency is 0.2 $c/a^{(0)}$). (e), (f), (g), (h) correspond to the structures of (a), (b), (c), (d) respectively.

Filling anomalies and chiral winding numbers in higher-order topological metamaterials

Wladimir A. Benalcazar[1,*]

[1] *Department of Physics, Emory University*

(Dated: March 17, 2023)

Abstract

I will present the classification of topological bands in one- and two-dimensional crystalline metamaterials based on "filling anomalies" and their accompanying "symmetry indicator invariants." I will first show how this classification facilitates the diagnosis of metamaterial analogs of obstructed atomic limits, fragile phases, and stable topological phases that include bands with Dirac points and Chern numbers. Then, I will present phases outside of that classification; these are chiral-symmetric higher-order topological phases whose invariants, "multiple chiral numbers," indicate the number of degenerate mid-gap states at each corner. Finally, I will show an experimental realization of such a phase in an acoustic metamaterial.

Abstract: We introduce the concept of adiabatic topological photonic structures, which allows us to overcome many of the limitations of topological photonic metasurfaces. Adiabatic variation of the mass terms at the domain walls makes topological boundary modes less sensitive to details of the lattice, perceiving the structure as an effectively homogeneous Dirac metasurface. As the result, the modes exhibit longer radiative lifetime and propagation distance, while retaining their topological resilience.

Topological phases of matter represent a new realm of physics that has been attracting significant attention across diverse fields, from inherently quantum systems (e.g., condensed matter and lattices of trapped ions) to purely classical photonic and acoustic metamaterials. In the context of photonics, topological phases offer resilience to defects and disorder and bring novel opportunities to control light with pseudo-spin degrees of freedom. However, topological photonic systems can suffer from limitations associated with their bosonic nature, including partial breakdown of topological properties due to their symmetry-protected origin and radiative leakage. In this article, we introduce the concept of adiabatic topological photonic interfaces, which helps to overcome many of these issues. We demonstrate theoretically and confirm experimentally that adiabatic topological metasurfaces with slowly varying synthetic gauge fields significantly improve trapping of optical modes, and also offer excellent guiding features in both spin-Hall and valley-Hall topological photonic structures, which are the most commonly used in the design of symmetry- protected topological devices. Adiabatic variation of the mass terms at the domain walls leads to the delocalization of topological boundary modes, which makes them less sensitive to details of the lattice, perceiving the structure as an effectively homogeneous Dirac metasurface [1]. As the result, the modes showcase enhanced bandgap crossing behavior, longer radiative lifetime, and propagation distance, while retaining their topological resilience. At the same time, localized modes trapped due to the 2D variation of the mass term [2] exhibit high quality factors and controllable radiative properties, which, along with non-zero angular momentum of their far field, makes them of great interest for applications.

Nanophotonic structures to control propagation, emission and topological behavior of light

Ganapathi Subramania

Semiconductor materials and device sciences, Sandia National Laboratories,

Albuquerque, NM 87185

Abstract: This work describes controlling light propagation, emission and topological behavior of light using seminconductor based nanophotonic structures.

Controlling light at the scale of few wavelengths of is enabled by nanophotonic structures such as photonic crystals, metamaterials and metasurfaces and have emerged as key components in modern photonics. With suitable design these nanophotonic structures offer new capabilities as well as versatility in controlling various aspects such as light-propagation, polarization, emission, photon statistics, topological property etc. greatly influencing chipscale photonics. The talk will cover research carried out along with my colleagues at Sandia using nanophotonic architectures. This will include work on light emission and lasing from III-nitride based photonic crystals, and dynamic index modulation and nanofabrication control with electrochemical and photolectrochemical etching[1-3]. Furthermore, we will discuss topologically non-trivial photonic structures[4] that exhibit one-way scatter-free light transport and their implementation in silicon-on-insulator material that can have important applications in optical and quantum communications.

Harness Light with Spinor Wavefunction

Xiao Hu*

International Center for Materials Nanoarchitectonics (MANA), National Institute for Materials Science (NIMS), Japan
*corresponding author: Hu.Xiao@nims.go.jp

Abstract: Dirac dispersions are associated with spin degree of freedom. Electromagnetic modes in honeycomb photonic crystals exhibiting Dirac-type frequency dispersions are characterized by synthetic spin and described in terms of spinor wavefunctions. We show that spinor wavefunctions can be exploited for harnessing light and achieving novel features.

Honeycomb structures host Dirac-type energy and/or frequency dispersions where spin degree of freedom appears with spinor wavefunctions [1]. It was shown that deforming the honeycomb structure in a semiconductor photonic crystal in ways respecting C_{6v} symmetry, one opens gaps at Γ point in the Dirac-type dispersion accompanied by a p-d band inversion, where the frequency difference between p and d modes defines the Dirac mass. The structure with negative Dirac mass (p-mode with higher frequency) constitutes a photonic analogue of quantum spin Hall effect [2].

Unlike the case of electron with spin as an intrinsic property, the photon spinor wavefunctions with basis formed by the p and d modes are defined in real space, which yields a unique interference between the two spinor components. In this talk, I discuss how this real-space spinor wavefunction works for the topological interface propagations in semiconductor topological photonic crystals [3], in parallel to the seminal Jackiw-Rebbi soliton solution for s=1/2 fermionic field. I then show that one can harness the topological waveguide mode in terms of the light spinor compatible with nanofabricated photonic crystal structures. As another interesting example, I reveal how the light spinor wavefunction can be explored for realizing a high-performance topological cavity surface emission laser (TCSEL) with frequency slightly below the lower band edge [4,5].

Topological photonic integrated circuits for controlling optical vortex signal

T. Amemiya[1*], H. Kagami[1], S. Okada[1], I. Sakamoto[1], N. Nishiyama[1], and X. Hu[2]

[1]Department of Electrical and Electronic Engineering, Tokyo Institute of Technology, Tokyo 152-8552, Japan,

Abstract: Topological photonics brings the concept of mathematical topology into the field of optics, which allows us to systematically handle information derived from the topology of light, such as optical spin and orbital angular momentum. In this talk, starting from the concept of topological photonic integrated circuits, we describe analytical methods, fabrication technology, and its application to optical circuits.

1. Introduction

Tracing the topology of electronic systems in topological insulators and Weyl semimetals into photon systems is called 'topological photonics' and has rapidly progressed in recent years [1]. In particular, for a typical photonic structure in which multiple dielectrics having C_6 symmetry are arranged in a honeycomb lattice, unprecedented optical phenomena can be realized because the unit cell has a higher degree of freedom in that configuration than that of a conventional photonic crystal whose unit cell comprises one dielectric. The most well-known phenomenon of topological photonics is the topological edge state which enables the propagation of optical vortices in optical circuits. Therefore, by replacing a part of the conventional optical circuit with a topological photonics system, we aim to realizing various controls of optical vortex signal in the photonic integrated circuit (TPICs: Topological Photonic Integrated Circuits) [2-5]. Since the optical vortex carries information on the helical cycle of the wave front, it is attracting attention as a key technology for high-capacity transmission.

2. Infrared photonic band microscope for high-speed measurement of topological photonic crystal

In the field of topological photonics, it is well known that the ℤ2 topology is expressed by using photonic structures consisting of a honeycomb lattice of unit cells, where the dielectrics are arranged with C_{6v} symmetry [6]. In the above structure, interaction is required not only between unit cells but also inside them. Thus, these systems require extremely fine structural design and fabrication compared to conventional photonic crystals. This is particularly noticeable in the optical communication band, which is considered as the most useful application area for these systems.

In this study, we developed and commercialized an infrared photonic band microscope based on hyperspectral Fourier image spectroscopy (Fig. 1) [7-9]. Developed microscope obtained a Fourier image for each wavelength

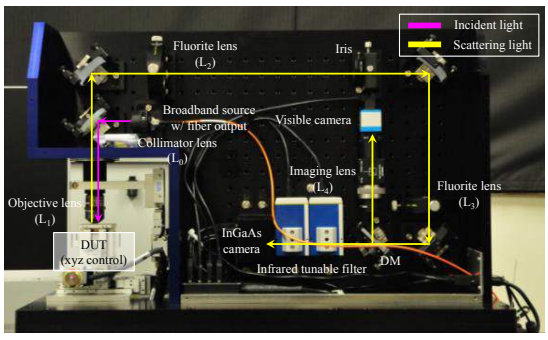

Fig. 1. Configuration of photonic band microscope.

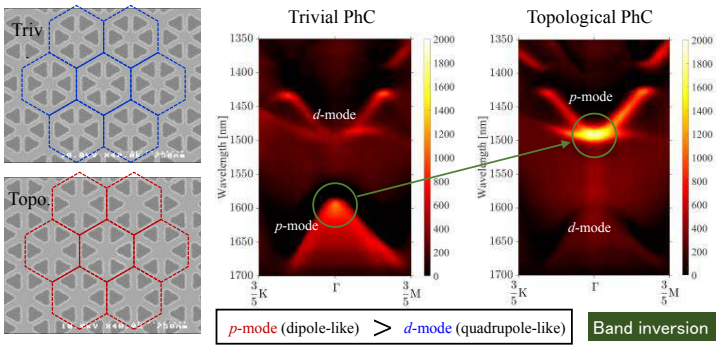

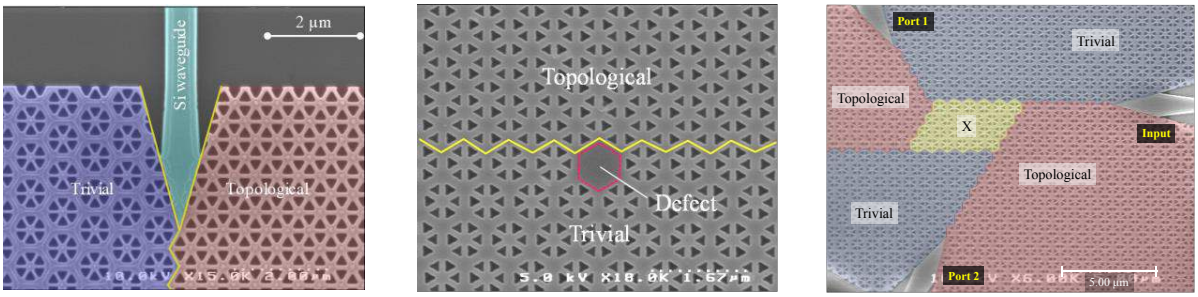

Fig. 2. Measured photonic band of two topological PhC with different topology

by using infrared hyperspectral imaging, following which it reconstructed a photonic band diagram based on these images. Figure 2 shows measured photonic band of two topological photonic crystals with different topology. Photonic band gap was observed at the wavelength of 1.55 μm near the Γ point for both photonic crystals. The intensities of the upper and lower band gap edges close to the Γ point are reversed. In general, the reflection intensity of the *d*-wave in the electromagnetic mode tends to be weaker than that of the *p*-wave [X]. Therefore, the experimental results show that the electromagnetic modes of the *p*-wave and *d*-wave are band inverted, which suggests the expression of different topologies.

3. Each element for constructing TPICs

Toward the topological photonic integrated circuits (TPICs), we have proposed the following four basic components. They are: (i) topological waveguide for propagating optical vortex signals with a specific charge number [2]; (ii) topological mode converter to realize highly efficient horizontal coupling from a normal waveguide to a topological waveguide (Fig. 3a) [3]; (iii) topological vertical coupler to realize highly efficient coupling from free space to a topological waveguide (Fig. 3b) [4]; (iv) topological splitter for branching optical vortex signals (Fig. 3c) [5]. The day's presentation will touch on all of the above, but this paper will focus specifically on the topological splitter.

Figure 3c illustrates the operating principles of topological splitter using the ℤ2 topological photonic phase. The device consists of five domains, namely, the two trivial photonic domains, two topological photonic domains, and a variable photonic domain (domain X). Here, we consider controlling the intensity ratio of the optical vortex signal emitted from output 1 and 2 by arranging a suitable photonic structure in the central domain X. When the trivial photonic structure or topological photonic structure was arranged in the domain X, the input was directly connected to each output through a topological edge state waveguide, and the optical vortex signal was output only to port 1 or port 2. Furthermore, when a zero-bandgap photonic structure—where all electromagnetic modes are degenerated in the center of the Brillouin zone—was arranged in the domain X, the intensity ratio of the optical vortex signal emitted from output 1 and 2 approached 1:1.

High-throughput generation of topological metamaterials

S. D. Huber

[1]AInsitut for Theoretical Physics, ETH Zurich, CH-8093 Zürich
sebastian.huber@phys.ethz.ch

Abstract: There is a wide range of design principles for topological metamaterials. All the indices characterizing of such topological materials also have a correspondence in terms of crystalline symmetries. In this framework, all metamaterials fall under the category of fragile topological insulators. Here we present an algorithm how to find fragile topological bands in two spatial dimensions. We generate all possible fragile bands, up to several ten-thousand structures per unique class and perform a statistical analysis of the so-obtain topological metamaterials.

Crystalline topological insulators can be described using the framework of topological quantum chemistry: Using band induction, all *trivial* bands can be exhaustively tabulated [1]. Using this table, one can in turn test any band-structure: If it is not in the table of trivial bands it has to be topological. Amongst those, there are two classes: strong and fragile ones, where in the absence of spin-orbit interactions for spin-1/2 particles, only the latter can be realized. In fact also those fragile ones have been tabulated for two spatial dimensions [2]. In other words: there exists a list all possible physically realizable two-dimensional topological insulator states for classical systems.

We devise a search algorithm to find all of these states. Using an advanced evolution algorithm, the Covariance Matrix Adaptation Evolution Strategy (CMA-ES) we find up to several ten thousands samples for each possible topological band systems. We perform a statistical analysis on their relative frequency, their topological content, as well as their surface physics.

With this tool we allow for on-demand large-throughput searches for topological bands, tailored to specific applications.

Abstract: Ways to effectively realize lattice models utilizing a frequency degree of freedom of photonic resonators as an effective "synthetic" dimension have been actively studied in photonic community. Since the frequency degrees of freedom is used as a spatial degree of freedom in realizing lattices, its conjugate variable, which is time, plays a role analogous to momentum. We propose how to detect the bulk topological invariant of one-dimensional topological lattices in such a synthetic frequency lattice in the presence of losses.

Synthetic dimensions provide a unique way to realize various lattice models in photonic setups by using non-spatial degrees of freedom as dimensions [1-3]. Recently, of particular interest in photonic community is the synthetic frequency lattice where frequency modes of resonators span a synthetic dimension which can be exploited to realize topological lattice models [4,5]. Topological lattice models are lattices whose energy eigenstates in momentum space exhibit nontrivial shape, or topology [6].

In a synthetic frequency dimension, an equivalent of momentum space is time. Although bulk energy band in a synthetic frequency dimension has been experimentally measured [7,8], it is still unclear how one can detect bulk topological number in such situations, in particular in the presence of inevitable losses of photons.

In this talk, we propose some methods to detect the bulk topological invariant of one dimensional topological models along a synthetic frequency dimension in the presence of a chiral symmetry. We show that a clear signature of bulk topological number, i.e. the winding number, can be obtained by looking at an analog of the mean chiral displacement [9] in driven-dissipative setups.

Abstract: We introduce a novel class of Floquet topological insulators simultaneously hosting Chern-type and anomalous edge states. The driving mechanism is implemented using laser-written waveguides arranged in a chained honeycomb lattice, allowing us to observe its different chiral edge states.

Floquet topological phases in photonic lattices [1] are typically realized by helical modulation [2] or the imposition of discrete coupling protocols [3,4]. In this work, a new method that allows for the distinct characteristics of these approaches to coexist while overcoming technical limitations such as curvature losses by virtue of entirely straight waveguides is presented and experimentally demonstrated. Our driving scheme leverages interstitial sites whose on-site potential

$$\mathrm{V}_j(t) = 1 + \sin\left(\frac{2\pi t}{T} + \frac{2\pi j}{3}\right) \quad j \in \{1,2,3\}, \tag{1}$$

is sinusoidally modulated with a Floquet period T and systematically phase-shifted counterclockwise in steps of $2\,\pi/3$ around the primary sites of a conventional honeycomb lattice (s. Fig. 1a) [5]. In this vein, chirality is induced while preserving the sublattice symmetry. In the static case ($V_j = 0$), the band structure comprises two copies of the conventional honeycomb spectra symmetrically arranged around a zero-energy degenerate flat band that hosts compact and localized states (CLS) exclusively residing on the interstitial sites. In the presence of the Floquet drive, two additional band gaps emerge at the Dirac points (s. Fig. 1b), giving rise to conventional Chern-type edge states as evidenced by the nontrivial Chern numbers $\mathcal{C}$ of the adjacent bands. Crucially, at the same time, a second type of chiral states bifurcate from the flat band. In accordance with their anomalous nature, they are described by winding numbers $\mathcal{W} = 1$.

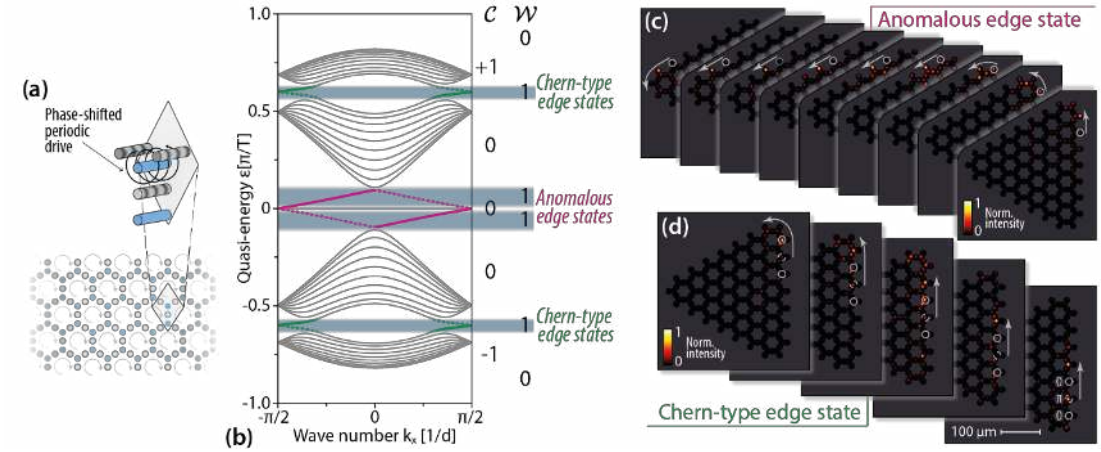

Fig. 1: Chain-driven honeycomb lattice. (a) The chained honeycomb lattice comprises interstitial sites (grey), that are sinusoidally modulated in their onsite potential and placed between adjacent principal elements (blue). (b) The Floquet drive creates bandgaps at the Dirac points, inducing a non-trivial topology (Winding number of blue shaded gaps becomes $\mathcal{W} = 1$) and coexisting Chern-type and anomalous boundary states emerge. (c,d) Both edge states propagate around corners along the edge in a protected fashion.

In order to experimentally study the propagation dynamics in this system, we implement the chain-driven honeycomb structure in femtosecond laser-written waveguide lattices [7], where the light evolution is described by a Schrödinger-type equation in which the refractive index profiles of the individual waveguides act as potential wells of the lattice atoms. In this vein, the on-site potential is directly related to the effective refractive index contrast each waveguide, allowing for it to be modulated at will along the propagation coordinate *z* that takes the role of time by appropriate changes to the writing speed. By injecting light into the encircled sites depicted in Fig. 1 c,d, the helical states were populated and their protected edge propagation around the corners was observed. In this vein, the dispersive nature of the Chern-type and compactness of the anomalous edge state are demonstrated.

In addition to the the helical states, the fraction of the flat band that persists in the driven lattice can be populated in the form of quasi-CLS in the bulk. This correspondence opens up the possibility to set the light in motion by exciting the anomalous chiral state, to temporarily trap it with high efficiency in CLS by suspending the modulation of the interstitial sites at an appropriate time, and resuming it as desired to allow the wave packet to continue along its way. The presented Floquet mechanism is general, and can be applied to other lattice geometries and any topological platform that allows for a control of the on-site potential.

Surface states in double diamond nodal line photonic crystals

Haedong Park and Sang Soon Oh*

*corresponding author: ohs2@cardiff.ac.uk

Abstract: We theoretically observe photonic surface states related to nodal lines in the momentum space. First, we demonstrate nodal lines' phase transition by a structural deformation of dielectric photonic crystals. We also calculate the Zak phases using them. Finally, we show the surface states in our photonic crystals.

Since the discovery of the topological insulator [1], most studies have focused on the proposal of crystal structures that exhibit topological phases. The prosed crystal structures include metallic [2], photonic [3], and acoustic [4] crystals. The topological phases are closely related to degeneracies such as the Dirac [5] and Weyl points [6] and nodal lines [7]. However, there have been relatively few studies on boundary states associated with nodal lines. Although drumhead surface states have been observed, the surface states driven by multiple nodal lines have not been explored.

This study explores the photonic surface states using the nodal line photonic crystals. We adopt a dielectric and anisotropic double diamond structure, introduced in Ref. [3]. This double diamond crystal exhibits a nodal link (the most famous shape among the nodal lines) in the momentum space. Next, we apply a structural deformation. The deformation drives the phase transitions of nodal lines so that the nodal link transforms to another shape. We analyze its topological nature using the following Euler class, an integer topological invariant [8-10]:

$$\chi_{mn}(\mathcal{D}) = \frac{1}{2\pi}\left[\int_{\mathcal{D}} \mathrm{Eu}^{mn} dk_a dk_b - \oint_{\partial\mathcal{D}} \mathbf{a}(\mathbf{k}) \cdot d\mathbf{k}\right] \quad (1)$$

where $\mathrm{Eu}^{mn}(\mathbf{k}) = \langle \nabla_{\mathbf{k}} u_{\mathbf{k}}^m | \times | \nabla_{\mathbf{k}} u_{\mathbf{k}}^n \rangle$ is the Euler form and $\mathbf{a}(\mathbf{k}) = \langle u_{\mathbf{k}}^m | \nabla_{\mathbf{k}} u_{\mathbf{k}}^n \rangle$ is the Euler connection. We also calculate the Zak phase for the nodal lines' situation from the following Wilson loop:

$$\mathcal{W}_{pq}(C) = \mathcal{P} \exp\left[i \int_C \langle u_{qk} | i\nabla_k | u_{pk} \rangle \cdot d\boldsymbol{k}\right] \quad (2)$$

Based on the above information, we search the surface states of the photonic array that consists of many double diamond unit cells. The array is periodic along the two lattice vectors. Along the remaining direction, the array is finite and terminated by the perfectly electric conductor (PEC) boundaries. We believe this study will provide a new insight on topologically protected modes in multigap systems and widen the scope of topological physics to electromagnetic waves in three-dimensional photonic crystals.

Abstract

Bound states in the continuum (BICs) in optical systems have been utilized to achieve resonant modes with high quality-factors (Q) as BIC modes provide strong light confinement by suppressing out-of-plane radiative losses. In recent years, BICs have been applied in various fields, including nonlinear optics, sensing, and lasing in the visible or near-infrared region. Here, we report a laser based on symmetry-protected BIC with single-mode ultraviolet (UV) emission and a small full-width at half-maximum (FWHM) of 0.10 nm.

1. Introduction:

Optical bound states in the continuum (BICs) existing in sub-diffraction periodic structures such as photonic crystals are special modes in which light is in completely localized states without radiating to the far field. By fully suppressing radiative losses, light confinement with extremely high-quality factors (Q) of near infinity is likely to be achieved for infinitely extending periodic structures. For real devices with only finite spaces, quasi-BIC modes can still support optical modes with relatively high Q when compared to typical diffraction-coupled band-edge modes. Thus, quasi-BICs have been utilized to build passive devices in the form of metasurfaces or photonic elements. In recent years, lasers based on quasi-BICs within the near-infrared (NIR) or the visible region have also been reported. Due to the advantages of BIC in light confinement, BIC-based lasers can support narrow-linewidth lasing with out-of-plane emission while the devices' sizes remain small. However, ultraviolet (UV) microlasers based on BICs have not been reported. Since tiny UV light sources hold important applications in various fields, including high-resolution bio-imaging, laser therapy, spectroscopy, and lithography, UV microlasers with narrow linewidths and highly directional emissions are strongly desired.

2. Results and Discussion:

Here, we demonstrate a UV laser based on BICs consisting of a one-dimensional (1-D) periodic line-and-space structure, which is made up of a patterned electron beam (e-beam) resist, on top of a standard GaN thin film. The proposed periodic resist structure supporting a quasi-BIC mode can be directly fabricated by a single-step e-beam lithography process. With the strong light confinement provided by the quasi-BIC mode, a single-mode UV lasing action at around 376.5 nm with a small full-width at half-maximum (FWHM) of 0.10 nm was observed when the system is pumped by a 355-nm pulsed laser. Such a lasing linewidth is among the narrowest in the reported GaN-based single-mode UV microlasers. Also, the laser exhibits highly directional out-of-plane emission as the collected far-field emission pattern shows a low beam divergence of 1.5˚. Furthermore, the wavelength of lasing emission was found controllable over a wide range with a resolution of 0.45 nm per step by adjusting the structure period (Λ) and operating temperature (T). It is noted that lasing can be achieved at 383 K, exhibiting the potential for applications under high-T environments. Lastly, this work discussed the effect of the laser size on the lasing threshold. The threshold of the fabricated lasers was found to grow as the laser size was shrunk, and no more stable lasing can be achieved for samples having a side length smaller than 8 μm.

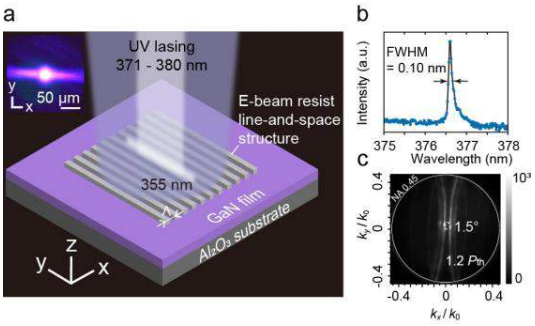

Figure 1. Ultraviolet laser based on bound states in the continuum. (a) The schematic of the proposed laser. The inset shows the optical image when lasing occurs. (b) The emission spectrum of lasing. (c) The far-field emission pattern of lasing.

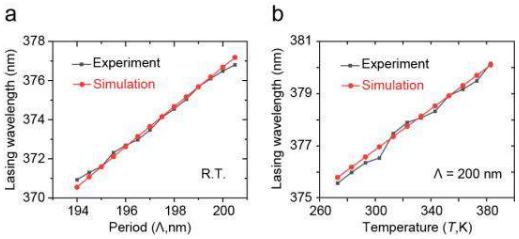

Figure 2. Sub-nm wavelength control of lasing achieved by adjusting the (a) structure period (Λ) or (b) operation temperature (*T*).

3. Conclusions:

With the superior mode properties of BICs, the presented BIC-based UV laser can support single-mode lasing with an extra narrow linewidth and highly directional emissions. Additionally, the achieved wavelength control can be useful in photochemical, analytical, or spectroscopic applications. We envision this work to pave the way for BIC-based active devices in the UV region.

Abstract: We analyzed a bilayer photonic structure consisting of two topologically distinct square lattices with π flux by using a tight-binding model. In the weak interlayer coupling regime, a topological corner state exists at each corner of the finite bilayer lattice, while it disappears when the coupling strength exceeds a critical value, indicating the occurrence of a topological phase transition induced by the interlayer coupling. This phenomenon could be applicable to control light localization in bilayer photonics systems.

Topological photonics [1] can provide novel approaches for controlling light, gathering great attention. In addition to a conventional topological insulator, a higher-order topological insulator (HOTI) has been discovered which hosts topological states two or more dimensions lower than the system [2]. A 2D HOTI can support 0D corner states besides 1D edge states and the topological corner states have been investigated in various kinds of 2D photonic platform [3,4,5]. Optical cavities based on the topological corner states have been applied to nanocavity lasers [6], nonlinear optics [7], and cavity QED experiments [8]. The platform for exploring photonic corner states has recently been extended to multilayer systems such as bilayer photonic graphene [9]. On the other hand, a bilayer structure stacking 2D photonic HOTI has not been discussed yet as a possible platform. In this work, we consider a stack of two π-flux square lattices based on the Benalcazar–Bernevig–Hughes (BBH) model [2], which describes a photonic quadrupole topological insulator, recently realized using an array of ring resonators [10]. Our calculations demonstrate that tuning the interlayer coupling strength induces a phase transition and controls the emergence and disappearance of topological corner states.

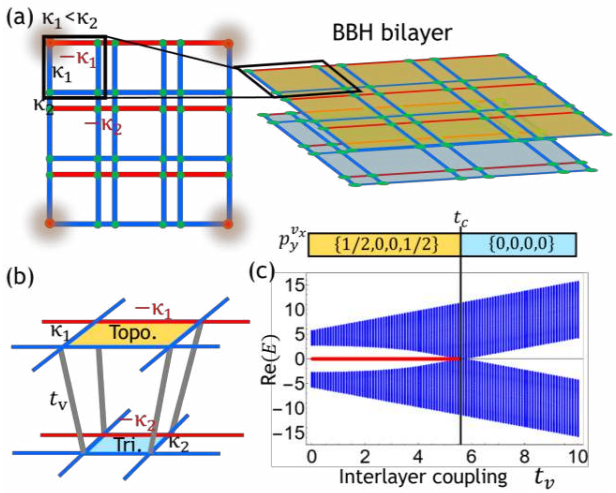

Figure 1: (a) A finite 2D BBH layer where κ_1 and κ_2 denote the intra- and inter-cell coupling strengths. Blue and red bonds represent the positive and negative couplings, respectively. Corner states appear when $\kappa_1 < \kappa_2$. (b) A unit cell of bilayer system where the top and bottom layers are topological and trivial, respectively. (c) Energy spectrum for the bilayer system. Red line corresponds to four corner states at E=0. The polarization is depicted in the above with a critical interlayer coupling t_c. Parameters are chosen as κ_1=1, κ_2=3 and N=20.

In the BBH model, π flux is inserted by introducing the negative coupling, as shown with the red bond in Fig. 1 (a). We vertically stack topologically distinct layers by considering the coupling between vertical nearest neighbor sites t_v. Fig. 1 (b) shows a unit cell of the finite bilayer lattice, where the top and bottom layers are

topological and trivial, respectively. Each layer is a 2D lattice consisting of $N \times N$ sites. In Fig. 1(c), we show the energy spectrum when t_v is varied. Red line corresponds to four corner states which locate dominantly at each corner of the topological layer. In the weak interlayer coupling regime, the corner states exist at E=0, while they disappear when t_v exceeds a critical value $t_c = \sqrt{2}(\kappa_1 + \kappa_2)$. Sudden disappearance of the corner states implies a possible non-trivial phase transition by increasing interlayer coupling.

The nested Wilson loop gives the bulk topological invariant of the BBH model [7]. Here, we adapt this formalism to the bilayer system and discuss the possible non-trivial boundary associated with t_v. The polarizations are obtained as follows:

$$p_y^{v_x^{\pm}} = -\frac{i}{2\pi}\frac{1}{N_x}\sum_{k_x}\log[\tilde{W}^{\pm}_{y,k_x}] \qquad (1)$$

where $\tilde{W}^{\pm}_{y,k_x}$ is a nested Wilson loop. The bilayer system has four pairs of doubly degenerate bands. By adapting the Wilson loop, the non-degenerate Wannier bands are obtained from four occupied bands (Fig.2). After calculating the nested Wilson loop, we obtain polarizations as p_y={1/2, 0, 0, 1/2} for $t_v < t_c$ and p_y= {0, 0, 0, 0} for $t_v > t_c$. The polarizations change when t_v exceeds t_c, which is in agreement with our results on the disappearance of corner states in the finite system. Note that similar topological phase transitions are observed in trilayer BBH systems.

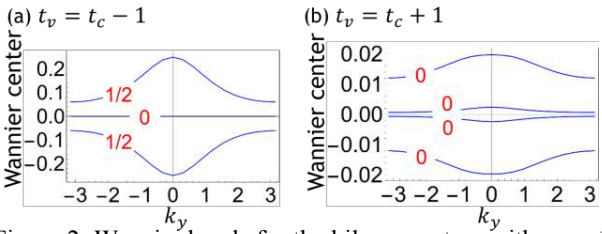

Figure 2: Wannier bands for the bilayer system with κ_1=1 and κ_2=3. The numbers in red represent the polarization. (a) Two bands have quantized polarization for $t_v < t_c$. (b) All four bands have zero quadrupole moment for $t_v > t_c$.

In summary, we analyzed a bilayer structure by stacking two topologically distinct lattices and found a phase transition induced by the interlayer coupling. We believe that our work provides a new insight on controlling light localization in multilayer photonics systems.

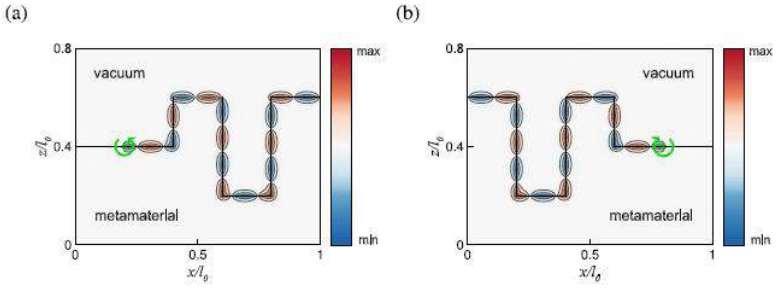

Photonic topological phases in pseudochiral metamaterials

Ruey-Lin Chern* **and Ti-Jung Hsu**

Institute of Applied Mechanics, National Taiwan University, Taiwan
*corresponding author: chernrl@ntu.edu.tw

Abstract: We investigate the photonic topological phases in pseudochiral metamaterials characterized by magnetoelectric tensors with symmetric off-diagonal chirality components. The underlying medium is considered a photonic analogue of the type-II Weyl semimetal featured with two pairs of tilted Weyl cones in the frequency-wave vector space. Surface modes at the interface between vacuum and the pseudochiral metamaterial exist in their common gap in the wave vector space, which form two pairs of crossing surface sheets that are symmetric about the transverse axes.

In this study, bulk modes of the pseudochiral metamaterials are represented by two decoupled quadratic equations as a certain symmetry of the material parameters is included. When the 'spin'-degenerate condition [1] is satisfied, the bulk modes are featured with two pairs of Weyl cones symmetrically displaced in the frequency-wave vector space. The electromagnetic duality allows for the photonic system to be decoupled as two subsystems for the hybrid modes defined as the linear combinations of electric and magnetic fields. By introducing the pseudospin states as the basis for the hybrid modes, the photonic system can be described by a pair of spin-orbit Hamiltonians with spin 1 [2,3] that respect the fermionic-like pseudo time-reversal symmetry. The topological properties of the photonic system are determined by the nonzero spin Chern numbers calculated from the eigenfields of the Hamiltonians. Surface modes at the interface between vacuum and the pseudochiral metamaterial exist in their common gap in the wave vector space, which are analytically formulated by algebraic equations. In particular, the surface modes are tangent to both the vacuum light cone and the Weyl cones, which form two pairs of crossing surface sheets in the frequency-wave vector space. At the Weyl frequency, the surface modes that connect the Weyl points form four Fermi arc-like states as line segments. The topological features of the pseudochiral metamaterials are illustrated with the robust transport of surface modes at an irregular boundary, which are able to bend around sharp corners without backscattering, as shown in the following figure.

Abstract: The excitation laser polarization and coupling geometry metastructures define the spin-orbit interaction of surface plasmon polaritons at metal-vacuum interfaces. We image the topological plasmonic fields by photoemission electron microscopy with nanometer spatial and femtosecond temporal resolution, to deduce the generated space-time spin textures of plasmonic vortex fields and how they can dress the space-time invariance of matter.

The polarization of optical fields interacting with lithographically structured metasurfaces defines the polarization structure and focusing of surface plasmon polariton (SPP) fields at metal-vacuum interfaces.[1-5] As the evanescent SPP waves propagate, their spin angular momentum (SAM) is locked transversely to their propagation vector k giving them a chiral property, where changing the sign of k, changes the sign of SAM.

Given this spin-momentum locking, as SPP fields propagate and form standing waves, they create field and spin phase discontinuities that can globally be defined as plasmonic vortices.[5] We image the space-time evolution of plasmonic vortices by performing interferometric time-resolved two-photon photoemission electron microscopy.[6] Nonlinear two-photon photoemission of electron spatial distributions from silver/vacuum interfaces are imaged with electron optics. Movies of the SPP propagation at the local speed of light, with sub-wavelength spatial resolution and ~100 as/frame time-step advance are obtained by interference between phase correlated SPP and time-delayed optical probe fields enabling us to stop plasmonic fields in space and time to perform their attosecond phase-correlated imaging.[1] The vortex fields appear as geometrical structures, where near PHz fields at vortex cores become stationary in space, and their periodic oscillation is converted into PHz field rotation. The consequent electromagnetic spin acquires bianisotropic textures that can mimic those of magnetic monopoles, and their fields can break spatially and temporally the time-reversal symmetry.

As an example of plasmonic vortex fields, in Figure 1, we show calculated spatial field distribution that are generated by SPP coupling structures with triangular, square, pentagonal, ...N-gon, to circular symmetry. The figure shows the S3 stokes polarization parameter with the contrasting colors signifying the opposite sign, when circularly polarized light interacts with the N-gon coupling structures. The textures evolve from ordered periodic 3-, 4-, and 6-gon structures that tile the two-dimensional space, to ordered aperiodic quasicrystalline structures, and eventually evolve to a circular structure where the central polygon with the N-gon symmetry acquires a meron, or half-skyrmion topological charge.[1] As N increases, the central meron becomes surrounded by an oppositely charged meron, which together form of a skyrmion texture for a circular structure.

We explore different ways to generate plasmonic vortices that host topological spin textures, and explore how they evolve in space and time. While the supporting plasmonic material silver is not topological, the plasmonic fields can transiently impose space-time bianisotropy, or couple to topological materials in their nearfield. The ability to impose bianisotropy by plasmonic fields enables us to explore the rich physics of ultrafast structured

light. Beyond microscopy, the structured light in vortex form provides insights into the cosmological structure formation.[1]

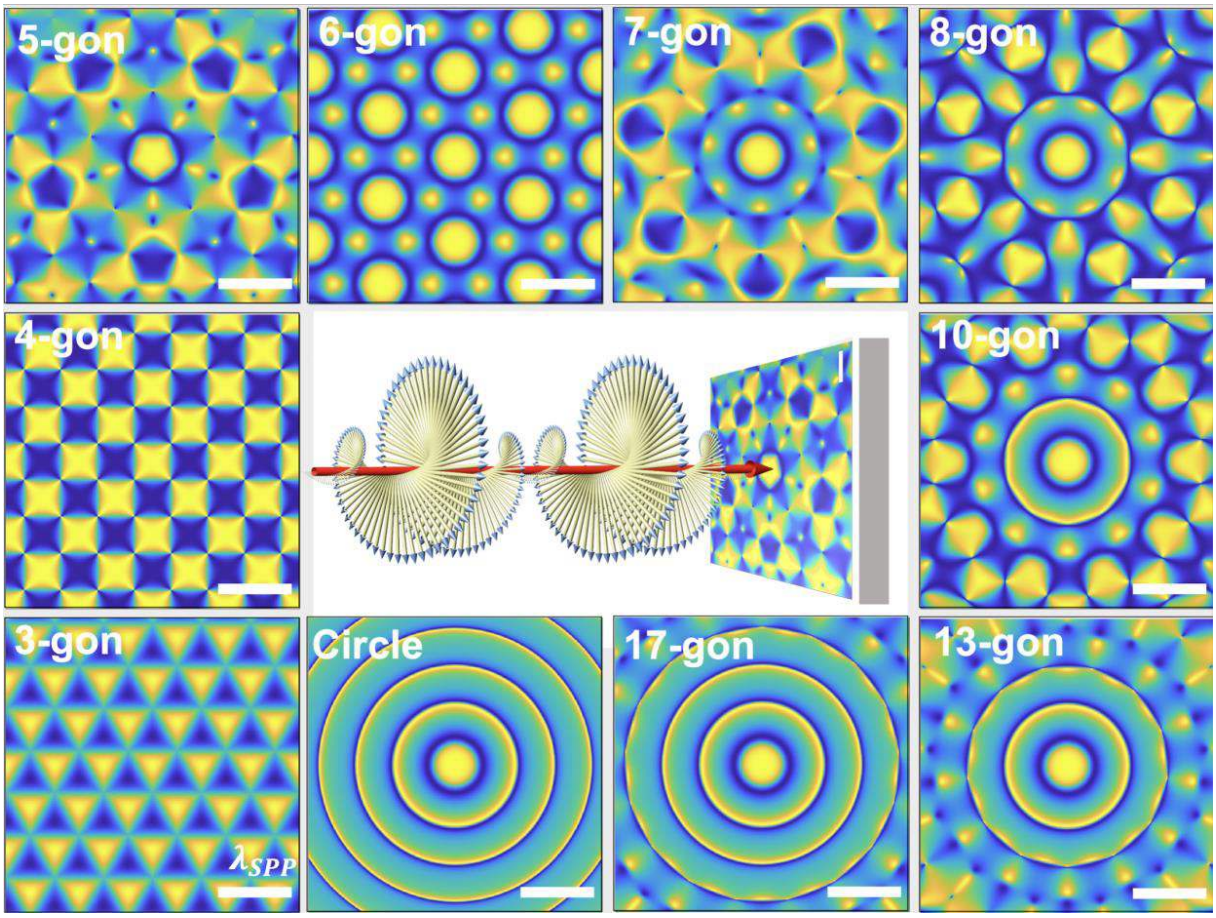

Figure 1. Figure 1. The calculated Stokes S_3 parameter of SPP fields with spin-orbit coupling defined by circular polarization and N-gon symmetry. The center is a schematic of the experimental technique.

Abstract: The generation of vortex light beams, carrying orbital angular momentum (OAM), has seen a shift from using bulky optics to subwavelength structured planar devices. Here, we look at how planar devices are pushing the boundaries in generating complex light fields, from high-purity vortex beams to the dynamic topologies of vortex arrays tailored directly at the source. We will see how multiplexing OAM with other degrees-of-freedom, in particular space-time beams, has the potential to enable exciting insights and applications in optics.

The notion of integrating many degrees of freedom to form complex structured light fields holds untapped promise, from the generation of classical and quantum states of light, the exploitation of linear and nonlinear light-matter interactions, to the advancement of applications in microscopy, spectroscopy, holography, and communication [1]. To realize the full potential of structured light, advanced manipulation of each optical mode is required, among which, metasurfaces are one of the most powerful platforms. They are planar nanostructured materials implementing a spatially varying optical response that allows to mold the light wavefront in amplitude, phase, and polarization. These devices offer unprecedented control in generating vortex beams with large topological charge and high mode purity, a necessity if one wants to take advantage of the infinite Hilbert space offered by vortex beams [2].

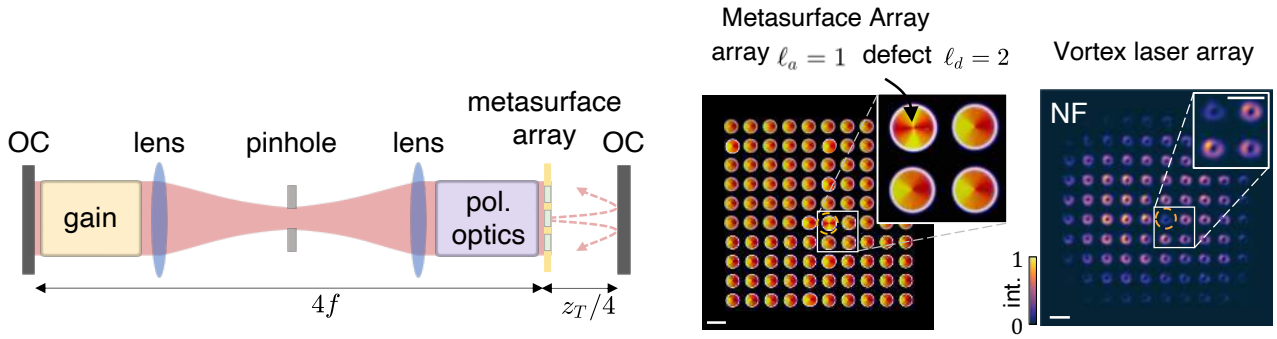

Figure 1: Schematic of a metasurface laser cavity. An array of 100 metasurfaces used to impart spin-orbit transformations inside the laser cavity. Generated array of coupled vortex lasers showing the topological charge of the 'defect' device being healed to that of the topological charge of the array.

Different from reshaping a conventional "Gaussian" laser beam, some applications could benefit from the inherent dynamic complexities of light structured directly at the source. By placing an array of metasurface devices inside a laser cavity resonator, combining non-Hermitian coupling, we can mix the vortices and couple. By allowing the modes to dynamically evolve in a resonator system, we realize a platform to explore complex topological transformations and collective vortex effects at the source. In this regard, we have demonstrated a

coupled laser cavity in which a hundred metasurfaces create an optical vortex array, allowing for OAM tuning (despite the static nature of the metasurfaces) and built-in robustness leading to the self-healing of topological defects, thanks to the iterative nature of the system and a fine balance of gain and loss [3].
