SPONSORS I EXHIBITORS

Gold Sponsor

The Synopsys Optical Solutions Group provides design tools that model all aspects of light propagation. Our innovative software packages include CODE V® imaging design software, LightTools® illumination design software, the LucidShape® products for automotive lighting, and the RSoft™ Photonic Device Tools for passive and active photonic devices. And our optical measurement solutions give customers access to precision light scattering data for materials and media used in optical systems.

At META 2024, Synopsys will demonstrate MetaOptic Designer, an unprecedented inverse design tool that takes user-specified criteria and generates metalenses/metasurfaces for optimal design performance. Metalens design traditionally requires extensive physics knowledge and many hours of development. MetaOptic Designer removes these barriers with exclusive AI that automatically yields the best metalens designs as fast as possible.
Learn more about Synopsys Optical Solutions at:
https://www.synopsys.com/optical-solutions.html.

Silver Sponsor

Ansys Optics tools empower designers to expedite the development of groundbreaking optical products while improving performance, reliability, and yield. These solutions offer robust design, optimization, and verification simulation software backed by world-class support. With a suite of top-tier optical solvers, Ansys Optics provides user-friendly workflows for precise multiscale system design, from the nano to macro scale, enabling the design of diverse applications across various industries.

Ansys Optics enables photonics and optical design from meta-atoms to centimeter-scale metalenses by seamlessly leveraging the combination power of Lumerical FDTD, RCWA and Zemax OpticStudio.

Grants Program Sponsor

ACS Publications supports researchers through journals, eBooks, scientific programs, and the news magazine Chemical & Engineering News. With a comprehensive portfolio of 80+ journals, including 16 "gold" completely open access journals, ACS Publications has a home for every type of research. Journals include ACS Photonics, Nano Letters, ACS Nano, ACS Applied Materials & Interfaces, and JACS.

Other Partners

Osaka University is a national research university in Osaka, Japan. The university traces its roots back to Edo-era institutions Tekijuku (1838) and Kaitokudo (1724), and was officially established in 1931 as the sixth of the Imperial Universities in Japan, with two faculties: science and medicine. Following the post-war educational reform, it merged with three pre-war higher schools, reorganizing as a comprehensive university with five faculties: science, medicine, letters, law and economics, and engineering. After the merger with Osaka University of Foreign Studies in 2007, it became the largest national university in Japan by undergraduate enrollment.

Tokyo Institute of Technology Tokyo Tech is the top national university for science and technology in Japan with a history spanning more than 140 years. Of the approximately 10,500 students at the Ookayama, Suzukakedai, and Tamachi Campuses, half are in their bachelor's degree program while the other half are in master's and doctoral degree programs. International students number 1,800. There are 1,100 faculty and 600 administrative and technical staff members.

Université Paris-Saclay is a research university based in Paris, France. Université Paris-Saclay offers a comprehensive and varied range of Undergraduate, Master's and PhD degrees, renowned internationally thanks to the University's reputation for research excellence and the commitment of its academic staff. The University's constituent faculties, institutes and component institutions all contribute to the curricula with cutting-edge specialised courses in Science and Engineering, Life Sciences and Health, and Social Sciences and Humanities.
Université Paris-Saclayis ranked 1st in France and 13th in the world according to the Academic Ranking of World Universities (ARWU).

AEM - Advanced Electromagnetics is a peer-reviewed, Gold Open Access journal. It covers recent international research results in the general field of Electromagnetic Waves, Antennas and Propagation. Authors of articles published in Advanced Electromagnetics retain the copyright of their articles and are free to reproduce and disseminate their work (under a Creative Commons Attribution License). AEM is widely indexed and has a Scopus CiteScore of 2.2 (2021).

Nanophotonics (De Gruyter) covers recent international research results, specific developments in the field and novel applications. It publishes all article in a Gold Open Access model and belongs to the top journals in the field. Nanophotonics focuses on the interaction of photons with nano-structures, such as carbon nano-tubes, nano metal particles, nano crystals, semiconductor nano dots, photonic crystals, tissue and DNA.

PLENARY SPEAKERS

Harry Atwater

California Institute of Technology, USA

is the Otis Booth Leadership Chair of the Division of Engineering and Applied Science, and the Howard Hughes Professor of Applied Physics and Materials Science at the California Institute of Technology. Atwater's scientific effort focuses on nanophotonic light-matter interactions. His work spans fundamental nanophotonic phenomena and applications, including active wavefront shaping of light using metasurfaces, optical propulsion of lightsails, quantum and 2D nanophotonics as well as solar energy conversion, on earth and in space.

Atwater was an early pioneer in nanophotonics and plasmonics and gave a name to the field of plasmonics in 2001. He is Chair of the LightSail Committee for the Breakthrough Starshot program. Currently Atwater is also the Director for the Liquid Sunlight Alliance (LiSA), a Department of Energy Hub program for solar fuels, and was also the founding Editor in Chief of the journal ACS Photonics. Atwater is a Member of the US National Academy of Engineering, a Fellow of APS, MRS, SPIE and Optica, a Web of Science Highly Cited Researcher from 2014-2023, and is recipient of numerous awards, including the 2021 von Hippel Award of the Materials Research Society.

Hui Cao

Yale University, USA

Shaping light propagation in complex media

Hui Cao is the John C. Malone Professor of Applied Physics, a Professor of Physics, and a Professor of Electrical Engineering at Yale University. She received her Ph.D. degree in Applied Physics from Stanford University in 1997. Prior to joining the Yale faculty in 2008, she was on the faculty of Northwestern University for ten years. Her technical interests and activities are in the areas of mesoscopic physics, complex photonic materials and devices, nanophotonics, and biophotonics. Cao is a Fellow of IEEE, AAAS, APS and OSA, and an elected member of the National Academy of Sciences, and the American Academy of Arts and Sciences.

Shaping light propagation in complex media

By breaking the diffusion limit, we deliver optical energy into a target region of arbitrary size and shape anywhere inside a strong-scattering system. We further demonstrate an order of magnitude enhancement of remitted signals that carry information from deep inside a diffusive medium.

Franco Nori

Riken (Japan) and University of Michigan, USA

Topological dissipation in a time-multiplexed photonic resonator network and topological temporally mode-locked lasers

Franco Nori is a Chief Scientist at RIKEN, with a concurrent position at the University of Michigan. He received his PhD from the University of Illinois, and afterwards became a postdoc at the Institute for Theoretical Physics, University of California, Santa Barbara. His research group has done pioneering interdisciplinary studies at the interface between nanoscience, photonics, quantum optics, dissipative quantum open systems, quantum information processing, superconducting quantum circuitry, opto-mechanics, and condensed matter physics. He has been listed by the Web of Science as a "Highly Cited Researcher" (less than 0.1% are selected) in Physics for the past seven consecutive years: from 2017 to 2023. He is an Elected Fellow of the American Physics Society (APS), Institute of Physics (IoP), American Association for the Advancement of Science (AAAS), and Optical Society of America (OSA) [this last one "for fundamental contributions to quantum information science and optics, including circuit quantum electrodynamics, and the interface between quantum optics and quantum circuits"]. He received the 2014 Prize for Research in Physics, from the Matsuo Foundation, Japan; and the 2013 Prize for Science, by the Minister of Education, Culture, Sports, Science and Technology, Japan. Also, an "Excellence in Research Award" and an "Excellence in Education Award" from the University of Michigan. He is an Elected Member of the Academia Europaea, the Latin American Academy of Sciences, and a Foreign Member of the Swedish Royal Society of Arts and Sciences, in Gothenburg, Sweden. He won the 2023 W.E. Lamb Medal, and the 2024 Charles H. Townes Medal (from the OSA), both for research on Quantum Optics, Quantum Electronics and Quantum Information.

Topological dissipation in a time-multiplexed photonic resonator network and topological temporally mode-locked lasers

This talk provides an overview of recent results on topological dissipation in a time-multiplexed photonic resonator network, and topological temporally mode-locked lasers. A very brief summary will also be made of recent work on non-Abelian effects in dissipative photonic topological lattices.

Takashige Omatsu

Chiba University, Japan

Materials manipulation with structured light fields

Takashige Omatsu received his BS and PhD degrees in applied physics from the University of Tokyo in 1983 and 1992, and he has been a professor at Chiba University since 2007. He is currently working as a director of Molecular Chirality Research Center, Chiba University. He has been investigating the generation of structured light on a nano/ micron scale and pioneering nano/micro fabrications using structured light. He has already published 200+ journal papers, 250+ international conference papers, and 14 patents (including 2 US-patents), and he has performed 150+ invited presentations. Prof. Omatsu is working as the founding editor-in-chief of Optics Continuum (Optica), and he is also serving as a chair of the CLEO Pacific Rim Steering Committee. He was elected Optica, SPIE and JSAP fellow. Also, he was awarded Prize for Science and Technology, MEXT in 2016.

Materials manipulation with structured light fields

Structured light fields, such as optical vortex, has been currently growing up to a particle-like optical field (optical skyrmion). We review state-of-the-art structured materials fabrication and new materials manipulation with structured light fields.

Daria Smirnova

Australian National University, Australia

Localized states trapped by topological defects in photonic and hybrid metasurfaces

Daria Smirnova received her Ph.D. in Physics in 2016 from the Australian National University (ANU), followed by work experience in the USA, Russia, Japan, and Australia. Since 2019, she has consecutively held two prestigious fellowships supported by the Australian Research Council: the Discovery Early Career Researcher Award and, currently, the Future Fellowship at the ANU. In 2020, Daria was honoured as one of Australia's leading young researchers in The Australian's Special Report. Her research interests span over nonlinear physics, multipolar electrodynamics, nanophotonics, and topological photonics. The quality and impact of her works have been recognized through awards from international organizations, including the International Union of Pure and Applied Physics (IUPAP), MIT Technology Review, Elsevier, L'Oreal-UNESCO, the journal Nanophotonics, and the Australian and New Zealand Optical Society.

Localized states trapped by topological defects in photonic and hybrid metasurfaces
This talk will report novel phonon-polariton states trapped by topological defects in a silicon metasurface integrating hexagonal boron nitride (hBN). Spatially localized polaritonic modes originate from the coupling of electromagnetic fields with phonon vibrations in hBN.

KEYNOTE SPEAKERS

Gerrit Ernst Wilhem Bauer

University of the Chinese Academy of Science (China) & Tohoku University (Japan)

Gated Spin Communities

Gerrit Ernst Wilhem Bauer (*1956) was raised in the Gronau/Westfalen, Germany. He studied chemical engineering at Twente University in the Netherlands (M.Sc. 1980), experimental physics at the Hahn-Meitner Institute in Berlin (Ph.D. 1984) and theoretical physics as a JSPS Postdoctoral Fellow at the University of Tokyo. He spent 6 years at the corporate Philips Research Laboratories in Eindhoven (NL). He became professor in Theoretical Physics at Delft University of Technology in 1992, at the Tohoku University in Japan in 2011, and at the UCAS in China in 2022. He is presently Chair Professor at the Kavli Institute for Theoretical Science in Beijing as well as Professor and PI at the Advanced Institute of Material Science of Tohoku University on a shared basis. He is a Fellow of the American Physical Society and The Japan Society of Applied Physics. He received a.o. the Humboldt Research Award 2023. His published oeuvre in (mainly) theoretical condensed matter physics can be found under his Researcher ID F-8273-2010.

Gated Spin Communities
Conducting contacts modulate and control the magnetodipolar interaction that causes chirality of the magnetization and energy transport by spin waves at interfaces and in thin films. Metallic normal, ferromagnetic, and superconducting gates thereby generate new functionalities in magnonic circuits and devices.

Davide Bigoni

University of Trento (Italy)

Metamaterials with architected instabilities

Davide Bigoni has been holding a full professor position at the University of Trento (Italy) since 2001, where he is leading a very active group in the field of Solid ad Structural Mechanics. He was elected in 2009 Euromech Fellow (of the European Mechanics Society), received in 2012 the Ceramic Technology Transfer Day Award (of the ACIMAC and ISTEC-CNR), and in 2014 he was awarded the Doctor Honoris Causa degree at the Ovidius University of Constanta. He has received the Panetti and Ferrari Award for Applied Mechanics (from the Accademia delle Scienze di Torino), in 2018 he was Guest Lecturer for the Midwest Mechanics Seminars, in 2019 he was nominated Fellow of the Istituto Lombardo, Accademia di Scienze e Lettere, he was awarded a 60th Anniversary Issue of the Journal of the Mechanics and Physics of Solids. His research has been featured on 8 covers of International Journals. He has coordinated and has been involved in 3 European grants between academia and industry. He has been awarded 2 ERC advanced grants from the European Research Council, the first in 2013 and the second in 2021. He is co-editor of the Journal of Mechanics of Materials and Structures, is associate Editor of Mechanics Research Communications and member of the editorial boards of: Archives of Mechanics, International Journal of Solids and Structures, Journal of Elasticity, Journal of the Mechanical Behavior of Materials, Acta Mechanica Sinica, and International Journal of Applied Mechanics. He is reviewer for more than 150 international journals. He was vice chair of the panel PE8 for the European Research Council Starting Grants.

Metamaterials with architected instabilities
Homogenization is used for periodic elastic grids subject to axial prestress, to obtain equivalent elastic materials. The latter can be tailored to exhibit material instabilities driven by the microstructure of the grid and its level of prestress. Instabilities include shear band fromation and Hopf bifurcation, thus leading to odd elasticity.

Costantino De Angelis

Brescia University (Italy)

Analog computing with nonlinear flat optics

Costantino De Angelis received his PhD from the University of the Padova (1993) where he served as Assistant Professor of Electromagnetic Fields and Photonics. In 1998 he joined Brescia University where he is Full Professor of Electromagnetic Fields and Photonics since 2004. He is the head of the NORA group at the University of Brescia (https://nora.unibs.it/home) and his current research interest include nonlinear optics, nanophotonics, and optical metamaterials. He is a Fellow of OPTICA (the Optical Society of America).

Analog computing with nonlinear flat optics
Digital signal processing has revolutionized many fields of science and engineering, but it still shows critical limits; a long-sought solution is optical analog computing. We demonstrate here that nonlinear phenomena combined with engineered nonlocality in flat optics can be leveraged to synthesize Volterra kernels able to outperform linear devices.

Ortwin Hess

Trinity College Dublin (Ireland)

Nanoplasmonics as Enabler of Ultrafast Quantum Nanophotonics at Ambient Temperatures

Ortwin Hess currently holds the Chair Professorship of Quantum Nanophotonics and an SFI Research Professorship in the School of Physics and the CRANN Institute of Trinity College Dublin, The University of Dublin, Ireland. He is Editor-in-Chief of the gold open-access journal APL Quantum. Ortwin is a Fellow of the Institute of Physics (FInstP), a Fellow of Optica (formerly OSA) and a Professorial Fellow of Trinity College Dublin. Previously, Ortwin held the Leverhulme Chair in Metamaterials in the Blackett Laboratory at Imperial College London, UK. From 2003 to 2010 he was a full professor at the University of Surrey (Guildford, UK) and visiting professor at Stanford University, USA, and at the Ludwig-Maximilians University of Munich, Germany. Ortwin obtained the Dr.-rer-nat. (PhD) degree from the Technical University of Berlin, Germany in 1993 and the Habilitation (Dr.-habil.) at the University of Stuttgart, Germany in 1997. Ortwin's research interests bridge quantum nanophotonics with semiconductor and metamaterials physics, laser science and bio-medical photonics. He discovered the 'trapped-rainbow' principle, had the idea of stopped-light lasing and made defining contributions to the fields of spatio-temporal dynamics of semiconductor lasers, ultraslow light in metamaterials, complex quantum dot photonics and photonic crystals and strong coupling in nanoplasmonics. Ortwin pioneered active nanoplasmonics and optical metamaterials with quantum gain for which he has been awarded the Royal Society Rumford Medal.

Nanoplasmonics as Enabler of Ultrafast Quantum Nanophotonics at Ambient Temperatures
We discuss how nanoplasmonic-cavity strong coupling and ultrafast plasmonic near-field evolution can be exploited to achieve high-speed nanophotonic quantum operations at ambient temperatures, including dynamic multi-partite entanglement, and introduce a novel strategy for preparation and 'immortalization' of selected plasmon-exciton polariton states by means of quantum coherent perfect absorption

Malcolm Kadowala

University of Glasgow (UK)

Chiral Nanophotonics: Enabling Ultrasensitive Detection in Biophysical Measurements

Malcolm Kadowala is the Gardiner Chair of Chemistry at the University of Glasgow. He has pioneered the use of chiral plasmonic metamaterials for the study of biomaterials. His seminal paper on the demonstration of the application of chiral near fields for biomaterial characterisation (Nature Nano) has been cited >1100 times (Google Scholar). He was awarded a JSPS visiting Professorship at the Institute of Molecular Sciences, Japan in 2015, was a visiting Professor at the Dept of Physics, Osaka Metropolitan University, in 2018, and was awarded a Leverhulme research fellowship (2019-2021).

Chiral Nanophotonics: Enabling Ultrasensitive Detection in Biophysical Measurements
This talk will explore how the emerging field of chiral nanophotonics can overcome this barrier. By harnessing the unique properties of nanostructures, we can significantly enhance the interaction between light and chiral molecules. This allows for highly sensitive CD measurements, potentially reaching the single-molecule level.

Christoph Lienau

University of Oldenburg (Germany)

Two-dimensional electronic spectroscopy of many-body correlations in quantum materials

Christoph Lienau is a professor for experimental physics at the University of Oldenburg with an in interest in ultrafast dynamics of nanoscale systems. He studied physics in Göttingen and received a Ph.D. in Physical Chemistry in 1992. He then started postdoctoral work with Ahmed H. Zewail at Caltech as a Fellow of the German Science Foundation. In 1995 he accepted a position as senior member of the scientific staff at the newly founded Max Born Institute in Berlin in the department of Thomas Elsässer. Here, he founded a research activity in “Ultrafast nano-optics”. In 2006, he received a full professorship at the Institute of Physics in Oldenburg. He has published more than 250 articles in refereed journals and has given more than 150 invited and plenary talks at international conferences. Christoph served as head of the Semiconductor Physics Division of the German Physical Society and as Dean of the School of Mathematics and Natural Sciences in Oldenburg. He is a Fellow of the Optical Society of America and a Visiting Fellow of Chinese Academy of Sciences.

Two-dimensional electronic spectroscopy of many-body correlations in quantum materials
Two-dimensional electronic spectroscopy with few-femtosecond resolution is an emerging tool for probing quasi-particle interactions in quantum materials. The talk will discuss its use for exploring the quantum dynamics of strongly-coupled J-aggregate exciton/surface-plasmon hybrids, ultrafast intervalley couplings in atomically-thin semiconductors and for tailoring the nonlinearities of such semiconductors in plasmonic cavities.

Stefan Maier

Monash University (Australia) & Imperial College London (UK)

Silicon carbide as a platform for mid-IR metasurfaces

Stefan Maier is the Head of the School of Physics and Astronomy at Monash University and the Lee-Lucas Chair in Experimental Physics at Imperial College London. His main research interests lie in metasurfaces and nanophotonics for energy conversion, sensing, and optoelectronics. He is a Fellow of the Australian Institute of Physics, the Institute of Physics (UK) and Optica. He also currently serves as editor-in-chief for Nanophotonics. Stefan obtained his PhD in Applied Physics at Caltech, and held academic positions at the University of Bath and LMU Munich. He has been on the ICI Highly Cited list since 2017.

Silicon carbide as a platform for mid-IR metasurfaces
Silicon carbide enables strongly confined surface phonon-polaritons in the mid-infrared. We demonstrate the use of this materials platform for phonon-polariton metasurfaces supporting vortex and quasi bound-states-in-the-continuum resonances. Additionally we present results of active metasurfaces operating in the visible regime based on conductive polymers.

Agnès Maurel

Institute Langevin (France)

Acoustic grating with space-time modulation

Agnès Maurel is a research director at CNRS and conducts her research at the Langevin Institute in Paris. She studied physics at the École Normale Supérieure de Lyon and obtained her PhD in Paris, after which she completed postdoctoral fellowships at Stanford University and the Universidad de Chile. She studies wave propagation in complex media in the fields of acoustics, electromagnetism, elasticity, and water surface waves. She has been an associate editor for Wave Motion and the Journal of the Acoustical Society of America, and she is currently an associate editor for the Journal of Theoretical, Computational and Applied Mechanics. In recent years, her research has focused on the modeling of microstructured materials, including metamaterials and metasurfaces.

Acoustic grating with space-time modulation
We present a theoretical and numerical analysis of the diffraction of acoustic waves by space-time modulated gratings with rigid-type modulations. We report results exemplifying the non-reciprocal behavior of the grating, in relation with spatial and temporal harmonics.

Nam-Gyu Park

Sungkyunkwan University (Korea)

In the Quest for the Viable Perovskite Solar Cells

Nam-Gyu Park is a Distinguished Professor at the School of Chemical Engineering and Director of the SKKU Institute of Energy Science and Technology (SIEST), Sungkyunkwan University (SKKU). He received his B.S. degree in chemical education, and M.S. and Ph.D. degrees in chemistry from Seoul National University in 1988, 1992, and 1995, respectively. He worked as a postdoctoral researcher at ICMCB-CNRS, France, from 1996 to 1997 and at National Renewable Energy Laboratory, USA, from 1997 to 1999. He was director of the solar cell research center at the Korea Institute of Science and Technology (KIST) from 2005 to 2009 and senior researcher at the Electronics and Telecommunications Research Institute (ETRI) from 2000 to 2005 before joining SKKU as a full professor in 2009. He is a fellow of the Korean Academy of Science and Technology (KAST) since 2017. He has been working on photovoltaics since 1997. He was the first to report a long-term stable perovskite solar cell in 2012. This opened a new research area, so-called perovskite photovoltaics. He was selected as Citation Laureate (top 0.01% scientist); a New Class of Nobel Prize-Worthy Scientist on September 20, 2017, and included in highly cited researchers (HCR, top 1% scientists) from 2017 to 2023 by Clarivate Analytics. He received awards including the Scientist Award of the Month (2008), KIST Award of the Year (2009), Dupont Science and Technology Award (2010), SKKU fellowship (three times in 2013, 2018, and 2021), PVSEC Hamakawa Award (2015), Dukmyung KAST Engineering Award (2016), ACS-KCS Excellence Award (2018), Ho-Am Prize (Samsung, 2018) and Rank Prize (UK, 2022). Prof. Park has currently more than 390 refereed publications and more than 70 patents. He received an H-index of 116 from Google Scholar (105 from Web of Science and 108 from Scopus). He is the Senior Editor of ACS Energy Letters and serves on the Editorial Advisory Board for Chem. Rev., ChemSusChem, and Solar RRL.

In the Quest for the Viable Perovskite Solar Cells
Research endeavors focus on enhancing stability and exploring tandem structures for electricity generation in both terrestrial and space applications. The perovskite solar cell stands poised as the most promising energy solution, with its potential impact on sustainable energy surpassing current expectations once stability and lead immobilization challenges are effectively addressed.

Vladimir M. Shalaev

Purdue University, USA

Extreme Space-Time Optics & Quantum Meta-Photonics

Vladimir M. Shalaev, Scientific Director for Nanophotonics at Birck Nanotechnology Center and Distinguished Professor of Electrical and Computer Engineering at Purdue University, specializes in nanophotonics, plasmonics, and optical metamaterials. Vladimir M. Shalaev has received several awards for his research in the field of nanophotonics and metamaterials, including the Max Born Award of the Optical Society of America for his pioneering contributions to the field of optical metamaterials, the Willis E. Lamb Award for Laser Science and Quantum Optics, IEEE Photonics Society William Streifer Scientific Achievement Award, Rolf Landauer medal of the ETOPIM (Electrical, Transport and Optical Properties of Inhomogeneous Media) International Association, the UNESCO Medal for the development of nanosciences and nanotechnologies, OSA and SPIE Goodman Book Writing Award. He is a Fellow of the IEEE, APS, SPIE, MRS and OSA. Prof. Shalaev has authored three books, thirty invited book chapters and over 500 research publications.

Extreme Space-Time Optics & Quantum Meta-Photonics
We discuss all-optical modulation with single photons using electron avalanche, resulting in record-high nonlinearities. Then we show that transparent conducting oxides (TCOs) operating in the near-zero index regime can provide strong single-cycle modulation, enabling novel photonic time crystals. Finally, we discuss scalable quantum photonics with single-photon emitters in silicon nitride.

Kaoru Tamada

Kyushu University (Japan)

High Spatiotemporal Resolution Live Cell Imaging on a Plasmonic Metasurface

Kaoru Tamada is a Senior Vice President and Distinguished Professor in Kyushu University, Japan. After 7 years industrial experience, she moved to University of Wisconsin-Madison. After the experiences in RIKEN, AIST, MPIP and NUS, she became associate professor at Tokyo Tech in 2005. She moved to Research Institute of Electrical Communication (RIEC), Tohoku University, as a full professor in 2007 and Institute for Materials Chemistry and Engineering (IMCE), Kyushu University, in 2011. Her research interests include 2D self-assembly of organic molecules, metal and semiconductor nanocrystals, and their device applications. She obtained several awards for her achievement in nanoscience. She is a member of Science Council of Japan, Project Officer of JST SICORP e-ASIA program and Vice President of the Japan Society of Applied Physics. She is the associate editor of ACS Applied Nano Material sand advisory board member of several international journals.

High Spatiotemporal Resolution Live Cell Imaging on a Plasmonic Metasurface
Self-assembled monolayers composed of metal nanoparticles can be regarded as metasurfaces with high refractive index and extinction coefficient due to collective excitation of coupled localized surface plasmon resonance. This plasmonic metasurface confines light to the nanointerface and enhances fluorescence, thus enabling high-speed interfacial imaging with high axial and lateral resolution.

Mona Tréguer-Delapierre

University of Bordeaux (France)

Controlling nanomaterial properties using organization

Mona Tréguer-Delapierre is a Professor of Chemistry at the University of Bordeaux leading research in nanoparticle synthesis and assembly at the Institute of Chemistry of Condensed Matter of Bordeaux (ICMCB). She received her PhD from the University of Orsay (Paris-Saclay) and was a postdoctoral fellow at the University of Notre Dame (USA). She is the recipient of awards from the Chancellerie des Universités de Paris and H&M Zimmer of the University of Cincinnati. Her current research interests focus on how nanoparticles can be manipulated in 2D or 3D to engineer nanostructured materials with unusual optical effects.

Controlling nanomaterial properties using organization
We demonstrated a new concept for making nanostructures with unusual optical properties by organizing metal nanoparticles. In research and industry, molecules from drugs and polymers are made by combining high-yield chemical reactions in series. We have extended this approach to the nanoscale: we make metamolecules by combining high-yield colloidal reactions.

Din Ping Tsai

City University of Hong Kong (Hong Kong)

Intelligent Meta-lens for Imaging Underwater, Aerial and Land

Din Ping Tsai is currently Chair Professor of the Department of Electrical Engineering, City University of Hong Kong. He is an elected Fellow of AAAS, APAM, APS, AAIA, COS, EMA, IAE, IEEE, JSAP, NAI, OSA, SPIE, and TPS, respectively. He is the author and co-author of 372 SCI papers, 65 book chapters and conference papers, and 39 technical reports and articles. He was granted 69 patents for 45 innovations. He was invited as an invited speaker for international conferences or symposiums more than 340 times (30 Plenary Talks, 62 Keynote Talks). He received more than 40 prestigious recognitions and awards, including "Global Highly Cited Researchers," Web of Science Group (Clarivate Analytics) in 2020 and 2019, respectively; China's Top 10 Optical Breakthroughs in 2020 and 2018, respectively; "Mozi Award" from International Society for Optics and Photonics (SPIE) (2018); etc.

Intelligent Meta-lens for Imaging Underwater, Aerial and Land
We have developed a series of intelligent meta-lens systems for underwater, land, and aerial imaging and sensing. We reported the design, fabrication, characterization, and applications of the monocular, binocular, and multilocular meta-lens.

Anatoly V. Zayats

King's College London (UK)

Optical spin topologies in plasmonics and metamaterials

Anatoly V. Zayats is a Chair in Experimental Physics and the head of the Photonics & Nanotechnology at the Department of Physics, King's College London, where he also leads Nano-optics and Near-field Spectroscopy Laboratory (www.nano-optics.org.uk). He is a Co-Director of the London Centre for Nanotechnology and the London Institute of Advanced Light Technologies. His current research interests are in the areas of nanophotonics, plasmonics, metamaterials, optical spin-orbit coupling, plasmonically-derived hot carriers, scanning probe microscopy, nonlinear and ultrafast optics and spectroscopy, and optical properties of surfaces, thin films, semiconductors and low-dimensional structures. He is a founding co-editor-in-chief of Advanced Photonics journal. He is a Fellow of the Institute of Physics, the Optical Society of America, SPIE, the Royal Society of Chemistry and elected Member of Academia Europaea.

Optical spin topologies in plasmonics and metamaterials
We will discuss spin-orbit coupling in interaction of complex vector beams with plasmonic metamaterials. Spin-orbit coupling and topology of evanescent waves and vector beams propagating in free space and metamaterials in different dispersion regimes will be considered.

Jinfeng Zhao

Tongji University (China)

Elastic spin angular momentum in metamaterials and classical structures

Jinfeng Zhao received M.S. degree in solid mechanics from Tongji University and Ph.D. degree in physics from University Pierre and Marie Curie. He is currently working in Tongji University. Prof. Zhao has coauthored 60 journal articles, including Phys. Rev. Lett., Nat. Commun and J. Mech. Phys. Solids. He owns 20 Chinese patents. He has been selected as excellent young scholar by Shanghai Society of Theoretical and Applied Mechanics (2021). He has made over 10 invited and oral presentations in academic conferences. His research interests lie in chiral elasticity, metamaterials, phononic crystals and ultrasonic non-destructive evaluation. He has made significant experimental contribution to reveal the elastic spin angular momentum (SAM) in both classical structures and topological metamaterials. He has observed broadband super-diffraction wave focusing both inside and outside graded devices. He builds up graded Helmholtz resonators with IXPP films that lead to dual function, i.e. noise reduction and energy harvesting.

Elastic spin angular momentum in metamaterials and classical structures
Topological phenomena of bosonic-like waves have attracted wide interests during the last few years. Spin angular momentum (SAM) provides new insights from the local point of view. Here, we experimentally investigate SAM in metamaterials and classical structures. Multi-dimensional wave routing is achieved due to the SAM-wavenumber locking mechanism.

TUTORIALS

Prof. Franco Nori

Riken (Japan) and University of Michigan (USA)

Wednesday 17th July
14:00 - 15:00 — Main Hall

Topological Origin of Surface Maxwell Waves and Surface Acoustic Modes

Franco Nori is a Chief Scientist at RIKEN, with a concurrent position at the University of Michigan. He received his PhD from the University of Illinois, and afterwards became a postdoc at the Institute for Theoretical Physics, University of California, Santa Barbara. His research group has done pioneering interdisciplinary studies at the interface between nanoscience, photonics, quantum optics, dissipative quantum open systems, quantum information processing, superconducting quantum circuitry, opto-mechanics, and condensed matter physics. He has been listed by the Web of Science as a "Highly Cited Researcher" (less than 0.1% are selected) in Physics for the past seven consecutive years: from 2017 to 2023. He is an Elected Fellow of the American Physics Society (APS), Institute of Physics (IoP), American Association for the Advancement of Science (AAAS), and Optical Society of America (OSA) [this last one "for fundamental contributions to quantum information science and optics, including circuit quantum electrodynamics, and the interface between quantum optics and quantum circuits"]. He received the 2014 Prize for Research in Physics, from the Matsuo Foundation, Japan; and the 2013 Prize for Science, by the Minister of Education, Culture, Sports, Science and Technology, Japan. Also, an "Excellence in Research Award" and an "Excellence in Education Award" from the University of Michigan. He is an Elected Member of the Academia Europaea, the Latin American Academy of Sciences, and a Foreign Member of the Swedish Royal Society of Arts and Sciences, in Gothenburg, Sweden. He won the 2023 W.E. Lamb Medal, and the 2024 Charles H. Townes Medal (from the OSA), both for research on Quantum Optics, Quantum Electronics and Quantum Information.

Topological Origin of Surface Maxwell Waves and Surface Acoustic Modes
Interfaces between optical media (including dielectrics, metals, negative-index materials) can support surface electromagnetic waves, which now play crucial roles in plasmonics, metamaterials, and nanophotonics. We have shown [K. Y. Bliokh et al., Nat. Commun. 10, 580 (2019)] that surface Maxwell waves at interfaces between homogeneous isotropic media described by real permittivities and permeabilities have a topological origin explained by the bulk-boundary correspondence. This is explained by the nontrivial topology of the non-Hermitian photon helicity operator in the Weyl-like representation of Maxwell equations. The corresponding topological invariant, which determines the number of surface modes, describes the winding of the complex helicity spectrum across the interface. Our theory provides a new twist and insights for several areas of wave physics: Maxwell electromagnetism, topological quantum states, non-Hermitian wave physics, and metamaterials. We have also analyzed [K. Y. Bliokh et al., Phys. Rev. Lett. (2019)] another type of classical waves: longitudinal acoustic waves corresponding to spinless phonons. We show that surface acoustic waves, which appear at interfaces between media with opposite-sign densities, can be explained by similar topological features and the bulk-boundary correspondence. However, in contrast to photons, the topological properties of sound waves originate from the non-Hermitian four-momentum operator in the Klein-Gordon representation of acoustic fields.

Dr. Rachel Won

Nature Photonics, UK

Thursday 18th July
14:00 - 15:00 — Main Hall

Writing and Submitting Your Papers

Rachel Won is an International Editor of Nature Photonics. She joined the journal in June 2006 as one of four Founding Editors. Before that, Rachel worked for Aston University's Business Partnership Unit in Birmingham, UK, as a Medici Fellow commercializing research output of the university, particularly that of photonics research. She obtained her PhD in microwave photonics and nonlinear optics as a member of Aston's Photonics Research Group. She worked for Philips Optical Storage in Singapore as an Optics Engineer after completing her Master's degree study in Nanyang Technological University of Singapore doing research in optical fibre sensing. She holds a Bachelor's degree from the National University of Malaysia. She is a Fellow of OPTICA and the International Society of Optics and Photonics (SPIE).

Writing and Submitting Your Papers
This talk covers the detailed information and guidelines on scientific paper preparation and submission, including tips for writing an effective cover letter, an informative abstract, a comprehensive introduction and an attractive paper, and editorial and peer-review processes. You will also get to know how to choose a journal for submission, what editors seek, how your papers are reviewed and how to make an appeal.

INDUSTRIAL WORKSHOPS

SYNOPSYS®

16th & 17th July, 16:40 - 17:40 — Room 3

From Design to Manufacture - Complete Inverse Design Flow for MetaOptics

Chenglin Xu, Bryan Stone, JiSoo Park

Synopsys offers solutions to metalens design and manufacturing challenges, including tools for hybrid refractive metalens systems that consider manufacturing tolerances. This workshop is presented in two parts:

1. July 16: Introduction to MetaOptic Designer;
2. July 18: Demo of hybrid metalens system design and virtual fab simulation.

The workshop is free and open to all META conference attendees.

GUIDELINES FOR PRESENTERS I **IN-PERSON**

Oral Presentations

Each session room is equipped with a stationary computer connected to a LCD projector. Presenters must load their presentation files in advance onto the session computer. Technician personnel will be available to assist you.

Scheduled time slots for oral presentations are 15 mn for regular, 20 mn for invited presentations, 30 mn for keynote talks and 35 mn for plenary talks, including questions and discussions. Presenters are required to report to their session room and to their session Chair at least 15 minutes prior to the start of their session.

The session chair must be present in the session room at least 15 minutes before the start of the session and must strictly observe the starting time and time limit of each paper.

Poster Presentations

Presenters are requested to stand by their posters during their session. One poster board, A0 size (118.9 x 84.1 cm), in portrait orientation, will be available for each poster. Pins or thumbtacks are provided to mount your posters on the board. All presenters are required to mount their papers 30mn before the session and remove them at the end of their sessions. Posters must prepared using the standard AES poster template (available on the conference website).

Getting to Venue

Toyama City is the largest city and capital of Toyama Prefecture in the Hokuriku Region of northern Chubu. The city is a former castle town and is historically a center of medicine. Due to its position on the Hokuriku Shinkansen (high speed “bullet train” rail line), Toyama is a popular stop for tourists on the way to other attractions in the area such as the Tateyama Kurobe Alpine Route.

Travel Information

Toyama is easily reachable from both within and outside Japan, positioned at an approximate equal distance from the country’s three major cities: Tokyo, Osaka, and Nagoya. It takes just 2 hours and 8 minutes from Tokyo via the Hokuriku Shinkansen (“bullet train"). Additionally, Toyama Airport offers connections from Tokyo and Sapporo, as well as direct flights from Shanghai, Taipei, Dalian, and Seoul.

For travelers arriving in Tokyo, there are two primary international airports: Haneda Airport and Narita Airport. Regardless of your arrival airport, you can take a train or bus to Tokyo Station and then catch the Hokuriku Shinkansen to Toyama Station, which typically takes about 2 hours and 30 minutes.

If you land at Haneda Airport, there’s another option available: transferring to a domestic flight bound for Toyama Airport, with three ANA flights available daily. Upon arrival at Toyama Airport, a convenient shuttle bus service can transport you to the city center in just 30 minutes.

- Getting to Toyama (Link to the Official Toyama City Travel Guide “Toyama Net”)
- Getting to Toyama (Link to the Official Toyama Travel Guide “Visit Toyama”)

Chunyu Huang, Yu Luo, Yule Zhao, Xiaofei Ma, Zhiwei Yan, Ziyi Liu, Chong Sheng, Shining Zhu, Hui Liu

Fano line shapes generated by excitonic nanoparticles (pp. 276)
Shinji Hayashi

Tunable Second Harmonic Generation from Lithium Niobate Metasurfaces (pp. 278)
Mengxin Ren, Lun Qu, Lu Bai, Zhengqing He, Wei Wu, Jingjun Xu

Chiral emission from perovskite metasurfaces and metacavities (pp. 279)
Young Chul Jun

Amorphous dielectric materials with complete photonic band-gaps in 3D (pp. 281)
Abraham de Jesus Aguilar Uribe, Marian Florescu, Frank Scheffold

Fundamental studies for new device applications in two-dimensional plasmonic crystals through analytical demonstrations in the submillimeter-wave band (pp. 283)
Go Itami, Osamu Sakai

Full-space Janus Metasurface for Direction-duplex Quad-channel Electromagnetic Wave Manipulation (pp. 285)
Weixu Yang, Shufang Dong, Ke Chen, Yijun Feng

Topological phase-supporting materials for nanophotonic sensing (pp. 287)
Gustavo Cruz, Sayan Roy, Arnab Banerjee, Peter Bermel

A polarization-tunable coloration with wide dynamic range using highly lossy material-based metal/dielectric/metal-subwavelength grating (pp. 289)
Yuusuke Takashima, Kentaro Nagamatsu, Masanobu Haraguchi, Yoshiki Naoi

In situ modification of the Quantum Hall effect with cavity vacuum fields (pp. 291)
Josefine Enkner, Lorenzo Graziotto, Felice Appugliese, Dalin Borici, Mattias Beck, Christian Reichl, Werner Wegscheider, Giacomo Scalari, Cristiano Ciuti, Jerome Faist

Nonlinear optics in low-index bulk media: past, present, and future (pp. 293)
Wallace Jaffray, Sven Stengel, Alexandra Boltasseva, Vladimir Shalaev, Andrea Di Falco, Marcello Ferrera

Ceramic metasurfaces for biophotonics applications in the visible range (pp. 295)
Mohammad Biabanifard, Tomasz Plaskocinski, Jianling Xiao, Andrea Di Falco

Magnetic control of electrically uncharged magneto-optical particles (pp. 297)
Manuel Marques, Shulamit Edelstein, Pedro A. Serena, Beatriz Castillo Lopez de Larrinzar, Antonio Garcia Martin

Development of Nonclassical Light Sources for Time-Resolved THz detection (pp. 299)
D. Adamou, L. Hirsh, T. Shields, S. Yoon, A. C. Dada, J. M. R. Weaver, D. Faccio, L. Caspani, M. Peccianti, Matteo Clerici

Mid-infrared topological edge modes in the symmetric and asymmetric photonic crystal slabs fabricated in SOI wafers (pp. 300)
Afshan Begum, Yuanzhao Yao, Takashi Kuroda, Yoshihiko Takeda, Naoki Ikeda, Takaaki Mano, Kazuaki Sakoda

The interplay of gain and loss in room-temperature planar polaritonic systems (pp. 302)
Anton Samusev

Continuous mechanical machining of asymmetric nanogratings with tailored period and shape by azimuthal

rotation-controlled nanoinscribing (pp. 304)
Jong G. Ok

Dynamic Thermoplasmonic Control of Colloids, Molecules and Liquids (pp. 306)
Martin Fränzl, Desmond Quinn, Diptabrata Paul, Frank Cichos

Recent progresses on quantum-enhanced nonlinear imaging (pp. 308)
Thomas Dickinson, Ivi Afxenti, Giedre Astrauskaite, Lennart Hirsch, Samuel Nerenberg, Ottavia Jedrkiewicz, Alessandra Gatti, Daniele Faccio, Caroline Müllenbroich, Matteo Clerici, Matteo Clerici, Lucia Caspani

Recent progress on chip-based Brillouin interactions (pp. 310)
Moritz Merklein

Topological transformations of vortex rings in paraxial laser beams (pp. 311)
Zhamila Kulchukova, Anton Desyatnikov

Artificial Neural Networks and Quantum Information Processing using Integrated Photonics (pp. 313)
Imtiaz Alamgir, Luigi Di Lauro, Stefania Sciara, Abdul Rahim Aadhi, Celine Mazoukh, Hao Yu, Bennet Fischer, Nicolas Perron, Nicola Montaut, Mario Chemnitz, Brent E. Little, Sai T. Chu, David J. Moss, Zhiming Wang, Roberto Morandotti

Scalable Chiral Photonic Architectures via Soft Nanoimprinting lithography (pp. 315)
Jose Mendoza-Carreño, Xiaoyu Qi, Isabel Alonso, Miquel Garriga, Luis Alberto Pérez, Agustín Mihi

Dynamically switchable phase contrast imaging with metaoptics (pp. 316)
Shaban Sulejman, Lincoln Clark, Haiwei Wang, Lukas Wesemann, Ann Roberts

Coherent Array of Superconducting Qubits as a Sensitive Microwave Antenna (pp. 318)
Patrick Navez, Alexander Balanov, Sergey Savel'ev, Alexandre Zagoskin

Graphene-based 2D Plasmonic Metamaterials for Terahertz Detectors (pp. 320)
Taiichi Otsuji, K. Tamura, Chao Tang, A. Satou, H. Fukidome, Y. Takida, H. Minamide, M. Ryzhii, V. Mitin, M. S. Shur, V. Ryzhii

Observation of off-Γ BIC in photonic crystals in both k- and real spaces (pp. 322)
Yuto Moritake, Taiki Yoda, Masaya Notomi

Dynamic plasmonics based on conducting polymers (pp. 324)
Shangzhi Chen, Magnus Jonsson

Integrated microlasers on a Bloch surface wave platform (pp. 325)
Yang-Chun Lee, Ya-Lun Ho, Bo-Wei Lin, M.-H. Chen, Di Xing, Hirofumi Daiguji, Jean-Jacques Delaunay

Tailoring the optical properties of 3D photonic crystals coated with Aluminum Zinc Oxide in the telecommunication wavelength (pp. 327)
Dimitra Ladika, Anna Theodosi, Odysseas Tsilipakos, Argyro Klini, Panagiotis Loukakos, Maria Kafesaki, Maria Farsari, David Gray

A Compact Silicon Photonic Crystal Spectrometer with Unprecedented Resolution (pp. 329)
Takasumi Tanabe, Junnosuke Kokubu, Ryo Sugano, Jinwei Zhang

Controlling the radiation space and wavelength with MIM metasurface in mid infrared wavelength (pp. 331)
Yoshiaki Nishijima, Tsuyoshi Kawaida, Megumi Tanaka, Kazuma Sekiya

Origin of high transmission via sharp bends of photonic-crystal waveguides with and without inversion symmetry (pp. 333)
Wei Dai, T. Yoda, Y. Moritake, Masaya Notomi

Attosecond Electron Microscopy (pp. 335)
Joel Kuttruff, David Nabben, Levin Stolz, Andrey Ryabov, Peter Baum

In-Operando Optical Spectroscopy of Field-Effect-Gated Transparent Conductive Oxides (pp. 337)
Michele Magnozzi, Maria Sygletou, Stefano Colace, Riccardo Magrin Maffei, Stefania Benedetti, Alessandro di Bona, Aleksandr Petrov, Piero Torelli, Emilio Bellingeri, Maurizio Canepa, Francesco Bisio

Ge-Sb-Te material for applications in photonics (pp. 339)
Mikhail Rybin

Field homogenization recipe for brain MRI (pp. 341)
Kyounsub Yoon, Sunkyu Yu, Namkyoo Park

Superoscillatory tweezer arrays for subwavelength trapping and manipulation of cold atoms (pp. 342)
Vincent Mancois, Kelvin Lim, Haijun Wu, Nikolay Zheludev, Yijie Shen, David Wilkowski

Epsilon-Near-Zero Regime in the Infrared for Ultrafast Switching (pp. 344)
Carl Davies, Andrei Kirilyuk

Advanced high contrast grating designs for biosensing applications (pp. 346)
Leonid Y. Beliaev, Giovanni Finco, Sungyeoung Kim, Larissa Vertchenko, Bjørn F. S. Nielsen, Mads V. Evensen, Ada-Ioana Bunea, Radu Malreanu, Lars René Lindvold, Osamu Takayama, Peter E. Andersen, Andrei V. Lavrinenko

Optoelectronic control of quantum optical phenomena with graphene (pp. 348)
Joel Cox

An electrically tunable polarization-selective photonic crystal based on a microcavity filled with a self-assembled uniformly lying helical liquid crystal (pp. 349)
Marcin Muszyński, Przemysław Oliwa, Pavel Kokhanchik, Piotr Kapuściński, Eva Oton, Rafał Mazur, Przemysław Morawiak, Wiktor Piecek, Przemysław Kula, Witold Bardyszewski, Barbara Piętka, Daniil Bobylev, Dmitry Solnyshkov, Guillaume Malpuech, Jacek Szczytko

Lasing of gain-doped plasmonic nanoshells: Threshold, emission linewidth and giant pull-out effects (pp. 351)
Ashod Aradian, Andres Cathey, Karen Caicedo, Milena Mora, Melissa Infusino, Alessandro Veltri

Manipulating the Exotic Quasi-Particles of van der Waals Correlated Antiferromagnet (pp. 353)
Han Htoon

Advanced Terahertz-Wave Phase and Polarization Control Devices Powered by Metasurfaces (pp. 355)
Yuehong Xu, Hiroaki Minamide

Manipulating Chemical Reactions with Light (pp. 357)
Z. Fusco, A. Edirisooriya, N. Lyu, C. David, Fiona Beck

Soft Metamaterials for Innovative Medical Devices (pp. 359)
Jianfeng Zang, Hanchuan Tang, Ye Tian, Zhangqi Pan

Design of Thin Film Metamaterial Absorber for IoT Application (pp. 361)
Tatsunosuke Matsui, Tomoki Narita, Sho Yoshikawa

Low-noise metamirrors for the visible spectral range (pp. 363)
Johannes Dickmann, Thomas Siefke, Jana Hartmann, Nico Wagner, Mika Gaedtke, Andreas Waag, Stefanie Kroker

Metamaterials based Pixelated Thermal Signature Control (pp. 365)
Zhuo Li, Xiu Liu, Yibai Zhong, Lin Wang, Tak Sing Wong, Han Wang, Jing Kong, Xu Zhang, Sheng Shen

Multipole coupling for control light propagation and trapping in dielectric and hybrid metasurfaces (pp. 367)
Andrey Evlyukhin, I. Allayarov, A. Calà Lesina, B. N. Chichkov

Structural Properties of Nanoporous Gold Metamaterial for Optical Applications (pp. 368)
Xinyan Wu, Fatemeh Ebrahimi, Maurice Pfeiffer, Nadiia Mameka, Manfred Eich, Alexander Petrov

Hot-electron induced chemistry using chiral and non-chiral plasmonic nanostructures (pp. 370)
Shashank Gahlaut, Christina Beresowski, Sergio Kogikoski Jr., Ilko Bald

Plasmon-enhanced nanospectroscopy for molecular sensing and control (pp. 371)
Taka-aki Yano

Ultrabroadband polarization-independent directional thermal emission (pp. 372)

Ziwei Fan, Taeseung Hwang, Sam Lin, Yixin Chen, Zi Jing Wong

Förster resonance energy transfer in absorbing environment (pp. 374)
Lyudvig Petrosyan, Mikhail Noginov, Tigran Shahbazyan

Resonances in doubly anisotropic, high-index nanoplatelets (pp. 376)
Bingying You, Tom Sistermans, Alberto Curto

Electromagnetic enhancement induced by subradiant plasmon resonance demonstrated by single plasmonic systems (pp. 378)
Tamitake Itoh, Yuko S. Yamamoto

Van Der Waals Polaritonic Crystals and Their Nanostructures (pp. 380)
Huanjun Chen, Zebo Zheng, Wuchao Huang, Shaozhi Deng

Scaling Challenges in Watts Level PCSELs (pp. 382)
Weidong Zhou, Chhabindra Gautam, Mingsen Pan

Integrated quantum photonic sources (pp. 383)
Xifeng Ren

Intracavity metasurfaces in fiber lasers for linear and nonlinear applications (pp. 384)
Lili Gui, Chuanshuo Wang, Hao Chen, Chao Meng, Xianglong Mei, Hailun Xie, Zhijin Chen, Fengbin Lin, Fei Ding, Sergey I. Bozhevolnyi, Kun Xu

High Q-factor coupled Fabry-Perot plasmonic nanoresonator (pp. 386)
Baptiste Fix

Multipolar description of the scattering of dense clusters of metallic nanoparticles (pp. 388)
Maeva Lafitte, Ranjeet Dwivedi, Philippe Barois, Alexandre Baron, Olivier Mondain-Monval, Virginie Ponsinet

Rayleigh surface waves of extremal elastic materials (pp. 390)
Yu Wei, Yi Chen, Wen Cheng, Xiaoning Liu, Gengkai Hu

Highly damped plasmonic and ferromagnetic metamaterials for wireless opto-magnetic actuation and detection (pp. 392)
Aritz Lafuente, Arnon Fluksman, Alejandro G. Roca, Ofra Benny, Josep Nogues, Mar Alvarez, Borja Sepulveda

Silicon-Nitride photonics for high-throughput biosensing applications (pp. 394)
Niels Verellen

Organic epsilon-near-zero and hyperbolic dispersion optical films (pp. 395)
Jeong Weon Wu

Deep ultraviolet meta-emitter boosted by bound states in the continuum (pp. 397)
Omar A. M. Abdelraouf, Aravind P. Anthur, Xiao Renshaw Wang, Qi Jie Wang, Hong Liu

Tailoring THz radiation pattern through intrapulse and interpulse difference-frequency generation at the nanoscale: modeling and perspectives (pp. 399)
Unai Arregui Leon, Luca Carletti, Davide Rocco, Costantino De Angelis, Giuseppe Della Valle

Versatile plasmonic colors with pixelated metasurface (pp. 401)
Maowen Song, Y. Lu, T. Xu

Efficient nonlinearities in metasurfaces enabled by bound states in the continuum (pp. 403)
Hayk Harutyunyan

Laser production of nanofibers (pp. 404)
Felix Quintero, Joaquin Penide, Raul Barciela, Monica Fernandez-Arias, Antonio Riveiro, Jesus del Val, Rafael Comesana, Fernando Lusquiños, Juan Pou

Silicon Nitride Platform for Quantum Photonics and Quantum Phononics (pp. 406)
Khaled Mnaymneh

Thermochromic thermal radiator based on angle selective thermal radiation applicable under direct solar irradiance (pp. 407)
Makoto Shimizu, Ryu Onozaki, Rihab Benlyas, Zhen Liu, Hiroo Yugami

High-performance Ultraviolet Metasurfaces based on Wide bandgap Dielectrics (pp. 408)
Cheng Zhang

Finite Difference Driven and Eigenmode Modelling of Polaritonic Systems (pp. 409)
Michele Tamagnone, Harsh Gupta, Tatiana Contino, Muhammad Atif Yaqub, Muhammad Waseem Ashraf

Strong Coupling with Different Photonic Modes within Single GaN Microstructure (pp. 410)
Yong-Hoon Cho

Engineered composites and plethora of on-demand functionalities and applications (pp. 411)
Dorota A. Pawlak, P. Piotrowski, M. Tomczyk, K. Sadecka, K. Bandopadhay, N. Aghad, K. Markus, A. Abbas, S. Saha, A. Materna, A. Bellardini, C. Sibilia

“Meta”-Optical Fibers (pp. 412)
Andrew Palmer, Yucheng Jin, Stuart Love, Yujin Zha, Beyonce Hu, Ho Wai Howard Lee

Tuning Nanoscale Photocurrent Direction and Terahertz Polarization State via Incident Light Polarization in Optoelectronic Metasurfaces (pp. 413)
Hou-Tong Chen, Jacob Pettine, Yunseok Choi, Chun-Chieh Chang

Control of non-hermitian degeneracy using intersubband polaritonic metasurfaces (pp. 414)
Hyeongju Chung, Beomjoon Kim, Gerhard Boehm, Mikhail A. Belkin, Jongwon Lee

Active layer morphology of organic and perovskite photovoltaics – a study based on grazing-incidence X-ray and neutron scattering (pp. 416)
Xinhui Lu

Optical spin waves (pp. 417)
Vage Karakhanyan, Roland Salut, Miguel Angel Suarez, Nicolas Martin, Thierry Grosjean

An ultra-low loss alumina waveguide platform for nonlinear photonics in the visible and UV (pp. 419)
Elissa McKay, Natale G. Pruiti, Matteo Clerici, Marc Sorel

Non-equilibrium light-matter interactions in photonic temporal crystals (pp. 420)
Bumki Min

Ultra-large Area Coherent Lasing Action through Hermitian/non-HermitianControl in Photonic Crystals (pp. 421)
Susumu Noda

Enhanced Optical Interactions in Nonlinear Topological Photonic Nanostructures (pp. 422)
Nicolae Panoiu

EM-Flow: A Conditional Reversible Flow-Based Deep Learning Model for Intelligent Electromagnetic Sensing by Reprogrammable Metamaterial (pp. 423)
Hongrui Zhang, Yanjin Chen, Mingyi Li, Hengxin Ruan, Lianlin Li

Bio-inspired metalens array for directional detection in 3D light imaging and ranging (pp. 428)
Clément Majorel, Amir Loucif, Emil Marinov, Renato Juliano Martins, Adelin Patoux, Virginie Brandli, Patrice Genevet

Symmetry Breaking in Bio-Inspired 2D Aluminum Networks probed by Electron Energy Loss Spectroscopy (pp. 429)
Jelena Wohlwend, Marcello Pozzi, Georg Haberfehlner, Ralph Spolenak, Henning Galinski

Investigating disorder in synthetic and biological 3D photonic structures with volume imaging (pp. 431)
Viola Bauernfeind, Kenza Djeghdi, Ullrich Steiner, Bodo D. Wilts

Controlling light and heat with Conducting Polymers and Cellulose (pp. 433)
Magnus Jonsson

Structural colors: toward AI-enabled design and solution-based fabrication (pp. 434)
Weijie Feng, Anwesha Saha, Taigao Ma, Haozhu Wang, L. Jay Guo

Self-Assembled Structural Color Colorimetric Sensor for Smart Phone based Bio-Chemical Sensing (pp. 436)
Pablo Cencillo, Mahdi Soudi, Debashis Chanda

Towards a machine learning approach for print parameter prediction in three-dimensional multiphoton laser lithography (pp. 438)
Sven Enns, Nicolas Lang, Julian Hering-Stratemeier, Georg von Freymann

High-performance optical diffuser inspired by Morpho butterfly's optical properties (pp. 440)
Akira Saito, Kazuma Yamashita, Kana Taniguchi, Shuta Sakamoto, Takuma Hattori, Yuji Kuwahara

Cross-reactive plasmonic arrays as artificial tastebud sensors (pp. 442)
Justin R. Sperling, Chad Sipperley, Rudi Schick, William J. Peveler, Alasdair W. Clark

Light-matter interaction on a chip

Deep Neural Networks for Prediction of Structure Parameters and Far-field Radiation Patterns of Nano-antenna (pp. 444)
Yi-Chiang Chang, Yung-Chiang Lan

Lithium niobate nanostructures: fabrication and nonlinear wavefront control (pp. 446)
Yunan Liu, Leyong Hu, Bo Wang, Junjie Li

Ultrathin Water-Immersion Metalens in the Visible (pp. 448)
Pei Ying Ho, Yu Chia Chung, Jia Hua Lee, Bo Ray Lee, Yao Wei Huang, Ray Hua Horng, Ming Lun Tseng

Lithium-plasmon-based low-powered dynamic color display (pp. 450)
Jie Liang, Yan Jin, Jia Zhu, Lin Zhou

Linearly Polarization-Sensitive Monolayer MoS2 Plasmonic Phototransistors (pp. 452)
Chen-Yu Wang, Shane Yeh, Jui-Han Fu, Cheng-Han Lin, Tzu-Yu Peng, Jia-Wern Chen, Feng-Yang Tsai, Vincent Tung, Yu-Jung Lu

Active Multitasking Metasurfaces: Simultaneous and Independent Steering of Frequency-Shifted Beams (pp. 454)
Prachi Thureja, Jared Sisler, Michael D. Kelzenberg, Ruzan Sokhoyan, Harry A. Atwater

Grayscale Electron Beam Lithography Direct Patterned Antimony Sulfide (pp. 456)
Wei Wang, Uwe Hübner, Tao Chen, Anne Gärtner, Joseph Köbel, Tanveer Ahmed Shaik, Astrid Bingel, Volker Deckert

Full-Stokes metasurface polarimetry based on multidimensional polarization conversion (pp. 458)
Chenglong Zheng, Huaping Zang, Peinan Ni

Impedance-matched zero-index metamaterials: from waveguide to antenna (pp. 460)
Yang Li

Reconfigurable Acoustic Metasurfaces for Controlling Disordered Sound Fields (pp. 462)
Guancong Ma

Enhanced Photogating Gain in Scalable MoS2 Plasmonic Photodetectors via Resonant Metasurfaces (pp. 463)
Yu-Jung Lu

Monocular metasurface camera for single-shot multi-dimensional imaging (pp. 464)
Yuanmu Yang

Active and Nonlinear Metasurfaces with the Generation and Relaxation of Plasmonically Induced Hot Carriers (pp. 465)
Wenshan Cai

Dirac Mass Gap Induced by Optical Gain and Loss (pp. 467)
Yidong Chong, Letian Yu, Haoran Xue, Yun Yong Terh, Ruixiang Guo, Eng Aik Chan, Cesare Soci, Baile Zhang

Third-harmonic generation in near-zero index heterogeneous nanostructures (pp. 469)

Matteo Silvestri, A. Sahoo, Luca Assogna, Paola Benassi, Carino Ferrante, Alessandro Ciattoni, Andrea Marini, Andrea Marini

Manipulation of Electron Beams by Laguerre-Gaussian Modes (pp. 471)
Yung-Chiang Lan, Ming-Chieh Lin

Methods for characterization of wafer scale SERS substrates (pp. 473)
Matthew Singer, Ryan Priore, Longfei Ye

Si Metasurfaces for DUV Plasmonics and Biomolecular Spectroscopy (pp. 475)
Bo Ray Lee, Mao Feng Jiang, Pei Ying Ho, Kuan-Heng Chen, Jia Hua Lee, Min-Hsiung Shih, Der-Hsien Lien, Tzu-En Lin, Ray-Hua Horng, Ming Lun Tseng

Compact depth sensing and facial recognition from integration of metasurface and photonic-crystal surface-emitting laser (pp. 477)
Yao-Wei Huang

Subradiant plasmonic cavities make bright polariton states dark (pp. 478)
J. E. Yim, Z. T. Brawley, Matthew T. Sheldon

Dynamic optical MEMS metasurfaces (pp. 480)
Fei Ding

Gap plasmon structures constructed by oligonucleotides and integrated with fluorophores (pp. 481)
Wan-Ping Chan, Yu-Long Lin, Shiuan-Yeh Chen

Three-dimensional co-axial double cylinder metasurface for high-sensitive gas molecular sensing (pp. 483)
Takuo Tanaka

Photoluminescent gratings and metasurfaces (pp. 484)
Pierre Berini

Electrochemically-tunable oxide materials for metasurfaces and large-area, additive patterning (pp. 486)
Vivian Ferry

Nonlinear all-dielectric metasurfaces driven by multipolar resonances and quasi-bound states in the continuum (pp. 488)
Hui-Hsin Hsiao

Metamaterial assisted super-resolution microscopy (pp. 490)
Zhaowei Liu

Multiparameter Sensing of On-Chip Infrared Photodetectors Enabled by Metasurfaces (pp. 491)
Mingjin Dai, Qi Jie Wang

Real-Time Multidimensional Imaging with an Encoding Metasurface (pp. 492)
Lidan Zhang, Chen Zhou, Hyunju Ahn, Shengyuan Chang, Md Tarek Rahman, Tunan Xia, Zhiwen Liu, Xingjie Ni

Introducing Circular Dichroism with Chiral Bound State in the Continuum (pp. 493)
Cheng-An Mao, Wen-Hui (Sophia) Cheng

Spherulite based Metasurfaces (pp. 494)
Jingbo Sun, Y. Liu, L. Zhou, Y. Shen, J. Zhou

Dispersion engineering of mid-IR polaritons in van der Waals crystals (pp. 496)
Sergey Menabde, Min Seok Jang

Experimental demonstration of ENZ-enhanced optical nonlinearity in ultrathin TiN epilayers (pp. 497)
F.-T. Tseng, I-H. Ho, S. Gwo, Hyeyoung Ahn

Absorption-Based Nanophotonic Quantum Sensing on Resonant Metasurfaces (pp. 499)
Laura Kim

Local high quality factor metasurfaces for extremely low threshold,nonlinear image filtering and efficient programmable

wave shaping (pp. 501)
Mark Lawrence, Lin Lin, Bo Zhao, Samuel Ameyaw

Nonlinear Mid-infrared Metasurfaces for Harmonic Generation and Deep-Subwavelength Nanomachining (pp. 502)
Maxim Shcherbakov

Near-field manipulation of angular momentum of light (pp. 504)
Haoran Ren

Controlling Far-Field Radiation with Photoluminescent and Incandescent Metasurfaces (pp. 506)
Anne Nguyen, Elise Bailly, Jean-Paul Hugonin, Jean-Jacques Greffet, Benjamin Vest

Nanoscale Extended Chirality Density Enhanced by Plasmonic Nanoresonator (pp. 508)
Hanwei Wang, Yulei Shen, Gayatri Chandran, Yang Zhao

Electrochemically Active Metasurface and Multispectral Light and Heat Management (pp. 510)
Po-Chun Hsu

Building Uncooled Infrared Camera based on One Atom Thick Graphene (pp. 512)
Debashis Chanda

Palladium Nanorods Overlayer Induced Electrostatic Contribution to Silicon Rib Waveguide Sensitivity (pp. 513)
Anastasia Novikova, A. Katiyi, A. Karabchevsky

Resonances Governed by Lattice Induced Multipole Coupling in Metasurfaces with Inversion Symmetry (pp. 515)
Izzatjon Allayarov, Andrey B. Evlyukhin, Antonio Calà Lesina

Vibrational Strong Coupling for Cavity catalysis of an Enantioselective Reaction (pp. 516)
Jaibir Singh, Pallavi Garg, Ramasamy Vijaya Anand, Jino George

Real time optical and mechanical environmental sensing based on nano-optomechanical disk resonators (pp. 518)
Elena Sentre-Arribas, Alicia Aparicio-Millan, Aristide Lemaître, Ivan Favero, Javier Tamayo, Montserrat Calleja, Eduardo Gil-Santos

Simulation of spatial rogue waves in a solid-state laser with transverse mode-locking (pp. 520)
Roza Navitskaya, Ihar Stashkevitch, Stanislav Derevyanko, Alina Karabchevsky

Novel Plasma Treatments for AlZnO Local Modulation and its Application on Fabrication of Planar Infrared Metasurfaces (pp. 522)
Kai Sun, Tom Howe, Cornelis H. de Groot, Otto Muskens

Inverse design for arbitrary optical materials and integrated nanophotonics (pp. 524)
Abhishek Nanda, Johannes Gedeon, Emadeldeen Hassan, Michael Kues, Antonio Calà Lesina

Photonics based non-invasive wearable devices for health monitoring. (pp. 526)
Edik Rafailov

Meta-optics for multi-dimensional manipulation of light

Crystallization of Induce Optical Vortex by Bessel Beams (pp. 528)
Sahil Sahoo, Yuri Gorodetski

Magnetoelectric effect in magnetic toroidal metal HoAgGe (pp. 530)
Akimitsu Kirikoshi, Satoru Hayami

Ultrafast Switching of Magnetization using Chiral Optical Phonons (pp. 532)
Carl Davies, F.G.N. Fennema, Arata Tsukamoto, Ilya Razdolski, Alexey V. Kimel, Andrei Kirilyuk

Realization of Wilson fermions in topolectrical circuits (pp. 534)
Huanhuan Yang, Lingling Song, Yunshan Cao, Peng Yan

Quantification of chirality based on electric toroidal monopole: Application to a twisted methane molecule (pp. 536)

Akane Inda, R. Oiwa, S. Hayami, H. M. Yamamoto, H. Kusunose

Gyromagnetic Double-zero-index Metamaterials Enable Ultrarobust Generation of Optical Spatiotemporal Vortices (pp. 538)
Xiaohan Cui, Ruo-Yang Zhang, Yuan-Song Zeng, Geng-Bo Wu, C. T. Chan

Control of Circularly Polarized Light Using Electron Beam (pp. 540)
Takumi Sannomiya

Classifying Topology in Open Photonic Systems (pp. 542)
Alexander Cerjan

Chiral and non-chiral magnetic texturing in antiferromagnetic Cr2O3 (pp. 543)
Oleksandr Pylypovskyi

Planar resonant metasurfaces with 3D intrinsic chirality (pp. 545)
Zi-Lan Deng, Meng-Xia Hu, Xin Li, Qian-Mei Deng, Feng-Jun Li, Xiangping Li

Generation of Ultra-compact Optical Vortex Through Photonic Spin-orbit Interactions in Nanostructures and Its Super-resolution Imaging (pp. 547)
Benfeng Bai

Chiral structures fabrication with structured light possessing orbital angular momentum (pp. 548)
Takashige Omatsu

Thermally induced dynamics of magnetic skyrmions and their device functions (pp. 550)
Masahito Mochizuki, Xichao Zhang, Junnosuke Matsuki

Topological magneto-optical effect induced by skyrmion lattice formation (pp. 552)
Yoshihiro Okamura, Y. D. Kato, M. Hirschberger, Y. Tokura, Y. Takahashi

Symmetry Breaking in Colloidal Metal Nanostructures by Circularly Polarized Light Directed Galvanic Replacement Reaction (pp. 553)
Monika Ghalawat, Daniel Feferman, Artur Movsesyan, Wanting He, Zhiming Wang, Dongling Ma, Alexander Govorov, Gil Markovich

Spin wave amplification through superradiance (pp. 554)
Xiangrong Wang, K. Y. Jing, X. Gong

Algebra of Optical Phase Dislocations (pp. 557)
Yuri Gorodetski

Peltier effect of phonons driven by electromagnetic waves (pp. 559)
Hiroaki Ishizuka, Masahiro Sato

Spatiotemporal Light Structuring (pp. 561)
Michael Almeida de Oliveira, Antonio Ambrosio

Orbital angular momentum of magnons in confined magnetodielectrics (pp. 562)
Eugene Kamenetskii

Exploring Strategies for Enhancing the Sensitivity of Chiroptical Spectroscopy with Aluminum Nanoplasmonics (pp. 563)
Bjoern Reinhard

A Scalar Product for Computing Fundamental Quantities in Matter (pp. 565)
Ivan Fernandez-Corbaton, Maxim Vavilin

Off-resonance Spin-locked Metasurfaces based on Quasi-Bound States in the Continuum and Nonreciprocal Chiral Splitters (pp. 567)
Zuojia Wang, Haochen Yang, Yujie Zhang, Guang Chen, Liqiao Jing

Detecting the symmetry breaking of the quantum vacuum in a QED system (pp. 569)
Tiefu Li

Si metasurface on a magneto-optical thin film for enhancing nonreciprocal polarization rotation (pp. 570)
Yasutomo Ota, Siyuan Gao, Tatsuya Kitai, Kota Taniguchi, Takeru Yambe, Satoshi Iwamoto

Manifestation of crystal chirality in quasiparticles (pp. 572)
Takehito Yokoyama

Pseudomagnetic fields in photonic crystals with synthetic strain: Observation of Landau levels and chiral edge states (pp. 573)
René Barczyk, L. Kuipers, Ewold Verhagen

Control of high harmonic generation and photo current in graphene by tuning laser polarization and combing two laser fields (pp. 575)
Masahiro Sato, Minoru Kanega

CP2 triple-Q state in the SU(3) Kondo lattice model (pp. 577)
Yutaka Akagi

Non-Hermitian Aharonov-Bohm effect under imaginary magnetic fields (pp. 579)
Tomoki Ozawa

Exploring magneto-optical and nonlinear processes using a polarimeter optical spectrum analyzer (pp. 580)
Eyal Buks

Deep-learning-based end-to-end metalens imaging (pp. 581)
Joonhyuk Seo, Jaegang Jo, Joohoon Kim, Joonho Kang, Chanik Kang, Seongwon Moon, Eunji Lee, Jehyeong Hong, Junsuk Rho, Haejun Chung

Cavity materials: Virtual Photons, Real Effects (pp. 583)
Qing-Dong Jiang

Dynamical control of topological solitons in ferroelectrics and dynamical multiferroicity via twisted light (pp. 584)
Lingyuan Gao, Sergei Prokhorenko, Yousra Nahas, Laurent Bellaiche

Exploring chiral nanogap structures using inverse topology design (pp. 586)
Atsushi Taguchi

Emergent One-Dimensional Helical State on the Surface Opposite to a Step Edge in Higher-Order Topological Insulators (pp. 588)
Akihiko Sekine, Manabu Ohtomo, Kenichi Kawaguchi, Mari Ohfuchi

Chirality-induced polarized phenomena in chiral inorganic materials (pp. 590)
Yoshihiko Togawa

Three-dimensional topological spin textures in chiral magnets (pp. 592)
Jiadong Zang

Nonreciprocal Optical Responses and Diode Effect in Superconductors: Quantum Geometry, Topological Superconductivity, and Exotic Pairing (pp. 593)
Hiroto Tanaka, Akito Daido, Hikaru Watanabe, Naratip Nunchot, Kyohei Nakamura, Shun Asano, Youichi Yanase

Toroidal-assisted Metasurface for High-performance Nanophotonics (pp. 595)
Pin Chieh Wu

Antiferromagnetic skyrmion lattice of the 4-sublattice tetrahedral order (pp. 596)
Tomoki Hirosawa, Maria Azhar, Alexander Mook

Chiral optical forces in integrated photonic waveguides for sorting enantiomers (pp. 597)

Multidimensional manipulation of LightFrom metasurfaces to liquid crystals (pp. 653)
T. Huang, Y. Xie, Z. Zhou, D. Zhang, Zile Li, G. Zheng

Metalens for Accelerated Optoelectronic Edge Detection under Ambient Illumination (pp. 654)
Shuai Wang

Strong light-matter interactions in plasmonic/dielectric metasurfaces

Observation of Projective Embedded Topology and Trijunction-Induced Topological State in Acoustic Lattices (pp. 657)
Hau Tian Teo, Yang Long, Kailin Song, Haoran Xue, Baile Zhang

Broadband sound attenuation under grazing flow via metamaterial-based acoustic liner (pp. 659)
Sibo Huang, Yong Li, Jie Zhu, Din Ping Tsai

Resonant enhancement of optoacoustic response in van der Waals materials (pp. 661)
Anton Samusev, Alex Carr, Claudia Ruppert, Giulia Magnabosco, Nicolas Vogel, Tetiana Linnik, Andrew Rushforth, Alexey Scherbakov, Manfred Bayer, Andrey Akimov

Subwavelength-Scale Variability Impact on Hypersonic 1-D Phononic and Photonic Crystals (pp. 663)
Omid Reza Ranjbar-Naeini, Gloria Conte, Jouni Ahopelto, Clivia Marfa Sotomayor Torres

Acoustic diffusers by phase-control acoustic metamaterials for reflected and transmitted waves (pp. 665)
Jia-Hong Sun, Yu-Wei Chen, Ching-Yun Chang

Non-Hermitian topological systems using nonreciprocal electroacoustic elements (pp. 667)
Anis Maddi, Guillaume Penelet, Vincent Pagneux, Vassos Achilleos

The role of elastic interfaces in a reduced relaxed micromorphic formulation of finite-size mechanical metamaterials (pp. 669)
Leonardo Andres Perez Ramirez, Jendrik Voss, Gianluca Rizzi, Svenja Hermann, Plastiras Demetriou, Angela Madeo

Unified model for multiple scattering problems in one-dimensional elastic waveguides (pp. 671)
Mario Lazaro, Vicente Romero-García, Luis M. García-Raffi, Richard V. Craster

Inverse Design of Broadband Acoustic Lens using Gradient-Based Optimization (pp. 673)
Feruza Amirkulova, Samer Gerges, Jovana Samaniego

Robustness evaluation of merged topological bound states in the continuum (pp. 675)
Jiamin Guo, Zhongming Gu, Jie Zhu

Observation of D-class topology in an acoustic metamaterial (pp. 677)
Shi-Qiao Wu, Wenting Cheng, Xiao-Yu Liu, Bing-Quan Wu, Emil Prodan, Camelia Prodan, Jian-Hua Jiang

3D printed polarizer for shear elastic waves (pp. 679)
Taeyul Choi, Yuqi Jinin, Teng Yang, Arup Neog, Arkadii Krokhin

Coherent excitation of torsional mechanical modes in coupled nanoantennas (pp. 681)
Jorge M. Garcia, Beatriz Castillo Lopez de Larrinar, Chushuang Xiang, N. Daniel Lanzillotti-Kimura, Antonio Garcia-Martin

Acoustic Realization of Multiple Topological Corner Modes in a Coupling-inverted Phononic Crystal (pp. 682)
Dongyi Wang, Guancong Ma

Single-pixel imaging based on time-modulated gratings and compressive sensing (pp. 684)
Pawel Packo, Daniel Torrent

Fast Quasiadiabatic Driving with 2D Optimization in Elastic Waveguides (pp. 686)
Dong Liu, Yiran Hao, Jensen Li

Dispersion relationship of weakly scattered media (pp. 688)
Mario Lazaro, Vicent Romero-García, Luis García-Raffi, Richard Craster

Braiding of Bloch eigenmodes in a non-Abelian topological phase with quaternion charge (pp. 690)
Xiaoming Wang, Guancong Ma

Tunable magnetic lattices as a platform for controlling sound waves (pp. 692)
Osama Bilal

Using Ping-Pong balls to reduce ambient noise (pp. 694)
Yan Pennec, Eric Cochin, Gaëtan Lévêque, Bahram Djafari-Rouhani

Modeling wave propagation and boundary effects in acoustic metamaterials by a relaxed micromorphic continuum (pp. 696)
Angela Madeo, Jendrik Voss, Svenja Hermann, Gianluca Rizzi, Felix Erel-Demore, Leonardo A. Perez Ramirez, Plastiras Demetriou, Patrizio Neff

Design strategies for amplitude and phase acoustic holograms in biomedical ultrasound (pp. 698)
Noé Jiménez, Diana Andrés, Alba Eroles-Simó, Alicia Carrión, Francisco Camarena

Topological Shear Band Engineering in Mechanical Metamaterials (pp. 700)
Jingyi Zhang, Jingran Liu, Anton Souslov, María Teresa Pérez Prado, Javier Segurado, Maciej Haranczyk, Johan Christensen

Viscous phononic supercrystal (pp. 701)
Arkadii Krokhin, Martin Ibarias, Jose Sanchez-Dehesa

Enhanced Understanding through Experimental Study: Disorderly Arrangement of Vertical GaN Nanowires in Polymer Materials (pp. 703)
F. Soldevila, A. Huynh, E. Charron, B. Bonello, B. Perrin, A. Chevillard, N. Gogneau, M. Tchernycheva, Olga Boyko

Control of FRET in radio frequencies with metasurfaces, in other words, dipole-dipole interactions in the near field of a metasurface (pp. 705)
Kseniia Lezhennikova, Kaizad Rustomji, Boris Kuhlmey, Tryfon Antonakakis, Pierre Jomin, Stanislav Glybovski, Martijn De Sterke, Jérôme Wenger, Redha Abdeddaim, Stefan Enoch

Non-resonant extraordinary acoustic transmission (pp. 707)

Static Loading Challenges of Three-Dimensional Ultrawide Phononic Crystals and Elastic Metamaterials (pp. 708)
Cetin Yilmaz

Thermal rectification in graphite Tesla valve based on phonon hydrodynamics (pp. 710)
Masahiro Nomura

Exploring Tunable Poisson's Ratio in Origami Metamaterials (pp. 712)
Diego Misseroni

Twofold topological transition induced by third-nearest-neighbor hoppings in anartificial elastic polyacetylene (pp. 713)
Rafael Méndez-Sanchez, Yonatan Betancur-Ocampo, Bryan Manjarrez-Montañez, Angel Martínez-Argüello

Non-Hermitian Metasurfaces for Extraordinary Elastic-wave Manipulations of Higher-order Diffractions (pp. 715)
Bing Li, Jiali Cheng, Bochen Ren

Non-adiabatic phononic control of polariton Bose-Einstein condensates (pp. 717)
Alexander Kuznetsov, Klaus Biermann, Paulo Ventura Santos

Mechanical tuning of topological waveguiding in auxetic metamaterial (pp. 719)
Federico Bosia, Giorgio Carta, Maryam Morvaridi, Vinicius Fonseca Dal Poggetto, Antonio Gliozzi, Charles Croenne, Marco Miniaci, Nicola Pugno, Michele Brun

Tunable Topological Properties in Phononic Crystals via Photoresponsive Polymers (pp. 721)
Antonio Gliozzi, Federico Bosia, Bryn Davies, Gregory Chaplain, Marco Miniaci, Emiliano Descrovi, Richard Craster

Ultrasonic Hologram for Bi-directional Diffusion by Phase Controlling the Scattering Coefficients (pp. 723)
Eric Ballestero, Josep Rodríguez-Sendra, Jean-Philippe Groby, Noé Jiménez, Vicent Romero Garcia

Experimental study of sonic velocity modulations and time interfaces in a controllable piezoelectric phononic crystal (pp. 725)
Charles Croënne, Sarah Tessier Brothelande, Florian Allein, Jérôme O. Vasseur, Bertrand Dubus

On the role of phase in nonreciprocal vibration transmission in passive and active phononic lattices (pp. 727)
Ali Kogani, Jiuda Wu, Behrooz Yousefzadeh

Harnessing topology and nonlinearity for advanced elastic wave control (pp. 729)
Georgios Theocharis

Advancements in Vibration Energy Harvesting through Metamaterials: Insights from the MetaVEH Project (pp. 730)
Andrea Colombi, B. Zhao, R. Ardito, J. M. De Ponti, R. V. Craster

Topological states in periodic and disordered elastic metabeams (pp. 732)
Runcheng Cai, Yabin Jin, Yan Pennec, Laurent Carpentier, Xiaoying Zhuang, Bahram Djafari Rouhani

Diffusive Acoustic Metasurfaces for Single-element Photoacoustic Imaging (pp. 734)
Alejandro Cebrecos, Irene Pi-Martín, Roby Weeteling, Juan José García-Garrigós, Noé Jiménez

Broadband and low frequency acoustic absorber with frozen sound (pp. 736)
Anis Maddi, Come Olivier, Gaelle Poignand, Guillaume Penelet, Vincent Pagneux, Yves Aurégan

PT-latent symmetries (pp. 738)
Malte Röntgen, Xuelong Chen, Wenlong Gao, Vincent Pagneux, Vassos Achilleos

Physically Interpretable Data-Driven Modeling and Control of Wave Dynamics (pp. 740)
Tristan Shah, Feruza Amirkulova, Stas Tiomkin

Any Dispersion You Want - Demystifying Roton, Maxon, Saddle Point, and Higher-order van Hove Singularities via Nonlocal Phononic Crystals (pp. 741)

S. Paul, F. Chen, K. J. Deshmukh, B. Deng, A. Kazemi, X. Zhu, H. C. Fu, Pai Wang

Negative refraction in a single-phase flexural metamaterial with hyperbolic dispersion (pp. 743)
Kim Pham, Agnès Maurel, Jean-Jacques Marigo

Acoustic grating with space-time modulation (pp. 745)
Agnes Maurel, Kim Pham

Theoretical Bound of Symmetric Metasurfaces (pp. 747)
Chan Wook Park, Yoon Young Kim

AI-empowered acoustic metamaterials and their applications (pp. 749)
Bin Liang

Efficient electromechanical coupling to an optomechanical nanobeam (pp. 751)
Tapani Makkonen, Oili Ylivaara, Sara Pourjamal, Jouni Ahopelto

Acoustic and Optic drills by dynamic high-order Bessel beam mixing (pp. 753)
Kestutis Staliūnas, Gabrielius Kontenis, Noe Jimenéz

Superlattice nanowires: a versatile platform for phonon engineering (pp. 755)
Aswathi K. Sivan, Begoña Abad, Omer Arif, Johannes Trautvetter, Tommaso Albrigi, Alicia Ruiz Caridad, Chaitanya Arya, Diego de Matteis, Francesca Rossi, Valentina Zannier, Lucia Sorba, Riccardo Rurali, Ilaria Zardo

Optomechanical measurement of liquids in unconventional regimes (pp. 756)
Ivan Favero

Explorations with nonlinearity and coupled orbitals in mechanical andmagneto-mechanical topological crystalline insulators (pp. 757)
G. Liu, I. Grinberg, V. Workman, J. Noh, W. A. Benalcazar, M. Lin, Y. Ma, C. W. Peterson, J. Zhao, A. Mangu, C. Harris, T. L. Hughes, Gaurav Bahl

X-ray Transient Gratings: Access to Nanoscale Acoustics, Magnonics, and More (pp. 758)
Keith A. Nelson

Dielectric metasurfaces for nonlinear asymmetric imaging (pp. 759)
Davide Rocco, Andrea Locatelli, Luca Carletti, Maria Antonietta Vincenti, Costantino De Angelis

Effect of Thermal Annealing on Surface Plasmon Properties of Gold and Silver Nanodisk Structures for Live Cell Imaging (pp. 761)
Kota Yamasaki, Ryohei Hatsuoka, Tetsuya Matsuyama, Kenji Wada, Koichi Okamoto

Electromagnetic response of liquid crystal based tunable high refractive index dielectric rings metasurfaces (pp. 763)
Pratiksha Sakhare, Jayasri Dontabhaktuni

Self-Aligned Nanoring Doublet as a Single Particle Nanocavity for Strong Coupling (pp. 765)
Kyungwha Chung, Luke Lee

All-optical phase rotation in strongly coupled light-matter systems (pp. 766)
Fedor Benimetskiy, Paul Walker, Sylvain Ravets, Maurice Skolnick, Jacqueline Bloch, Dmitry Krizhanovskii

Long-range super-Planckian heat transfer between nano-emitters in a resonant cavity (pp. 768)
Kiryl Asheichyk, Philippe Ben-Abdallah, Matthias Krüger, Riccardo Messina

Weyl points and chiral states in correspondence of Bound States in Continuum connected by Fermi arc (pp. 770)
Vito Mocella, Fabrizio Sgrignuoli, Bryan Guilcapi Alulema, Silvia Romano, Gianluigi Zito, Bruno Miranda, Aida Seifalinezhad, Ivo Rendina

Embedding plasmonic gratings for enhanced polarized photodetection and imaging in the near-infrared (pp. 772)
Tong Yu, Cheng Zhang, Ying Luo, Xiaofeng Li

Strong coupling between surface plasmons and magnetic polaritons in a borophene-based hybrid system (pp. 774)

Ye Ming Qing

Condensation and Transport of Organic Exciton-Polaritons from Bound States in the Continuum (pp. 776)
Matthijs Berghuis, Jose Luis Pura, Gabriel Castellanos Gonzales, Mohammad Ramezani, Diego Romero Abujetas, Shunsuke Murai, Erik van Heist, José Sanchez Gil, Jaime Gómez Rivas

Engineering Light-Matter Interactions at the Nanoscale for Functional Devices (pp. 778)
Zhaogang Dong

Plasmonics and metamaterials for controlling optical properties and device applications through strong light-matter interactions (pp. 780)
Koichi Okamoto

Continuous wave-pumped second-harmonic generation and application from GaSe-assisted microfiber (pp. 782)
Biqiang Jiang, Zhen Hao, Yuxin Ma, Xuetao Gan, Jianlin Zhao

Light-matter strongly coupled states in optical microcavities using highly oriented organic molecular crystals (pp. 784)
Kenichi Yamashita

Infrared photodetectors based on 2D heterostructures modulated by photogating (pp. 786)

Beyond Singularities: New Frontiers in Centrosymmetric Gain-Enhanced MetalNanoparticles and Their Applications (pp. 813)
Karen Caicedo, Milena Mora, Nicole Recalde, Maria Antonia Iatí, Rosalba Saija, Onofrio M. Maragò, Ashod Aradian, Melissa Infusino, Alessandro Veltri

Femtosecond pulse shaping with semiconductor Huygens' metasurfaces (pp. 815)
Katsuya Tanaka, D. Arslan, M. Weissflog, N. Geib, K. Gerold, A. Szeghalmi, M. Ziegler, F. Eilenberger, T. Pertsch, I. Staude

Bottom-up fabricated metasurfaces with correlated disorder for the light management in solar cells (pp. 817)
Prerak Dhawan, Maria Gaudig, Peter Piechulla, Alexander Sprafke, Ralf Wehrspohn, Carsten Rockstuhl

Creating Meta-Atoms Based on Gold Nanoparticle Assemblies on Polymer Microspheres (pp. 819)
Hiroshi Yabu

Aggregation of Core/Shell Quantum Rods in Composite Polymer Film for Polarization Conversion (pp. 821)
Yutaka Okazaki, Shusaku Kubota, Kan Hachiya, Takashi Sagawa

Development of Colloidal Silicon Nanoparticles and Composites for Photonic Applications (pp. 823)
Hiroshi Sugimoto, Minoru Fujii

Full-wafer fabrication of all-inorganic metalenses, waveguides and diffractive optics via direct nanoimprint lithography (pp. 825)
Dae Eon Jung, Vicent Einck, Alex Dawicki, Lucas Verrastro, Amir Arbabi, James Watkins

Transient dissipative structures in surface plasmon polaritons propagation (pp. 827)
Stanislav Derevyanko, Marat Spector

Optical to Terahertz Frequency Conversion using near Zero-index Nonlinear Hybrid Waveguides (pp. 829)
Chong Sheng, X. F. Ma, N. Y. Wang, R. Z. Cao, C. Sheng, S. N. Zhu, H. Liu

Low-frequency sound insulation and ventilation with spiral metastructure (pp. 831)
Shanjun Liang, Wenjian Kuang

Plasmonic Enhancement of the Performance of Integrated Phase-Change Memory and Computing Devices (pp. 833)
Junchao Song, Nikolaos Farmakidis, Ivonne Bente, Emanuele Gemo, June Sang Lee, Xuan Li, Samarth Aggarwal, Wen Zhou, Nathan Youngblood, Johannes Feldmann, Wolfram Pernice, Harish Bhaskaran, David Wright

Optical induced temperature change for ionic thermoelectric applications (pp. 835)
Dan Zhao, M. N. Liao, Magnus Jonsson

Picosecond dynamics of electromagnetically-induced transparency in infrared metamaterials (pp. 837)
The Linh Pham, Kacper Pilarczyk, Nils Deßmann, Fei Han, Joris Van de Vondel, Niels Verellen, Thanh Tung Nguyen, Ewald Janssens

Automated Design Flow for Hybrid Metalens System with Manufacturing Awareness (pp. 839)
Maryvonne Chalony, Yijun Ding, Larry Melvin, Bernd Kuechler, Bryan Stone, Evan Heller, Mayank Bahl, Rob Scarmozzino, Rob Scarmozzino, Chenglin Xu

The fabrication and application of 3D metamaterials (pp. 841)
Changzhi Gu, Yang Guo

Low-power Laser Coloration by Oxidation and Deformation of Self-assembled AL-PS Metamaterial (pp. 843)
Maxim Elizarov, Ning Li, Fei Xiang, Andrea Fratalocchi

Binocular Meta-lens for Computer Vision (pp. 845)
Xiaoyuan Liu, Mu Ku Chen, Takuo Tanaka, Din Ping Tsai

Plasmonic Nanoplatforms - A New Generation of Efficient Heat Generators for Thermoplasmonic Detection (pp. 847)
Andreea Campu, Simion Astilean, Monica Focsan

Hyperband Multi-functional Metasurface based on Double-walled Carbon Nanotubes (pp. 848)
Jin Zhang, Peng Liu, Zhipei Sun

Conducting polymer-cellulose devices for tunable infrared and THz optics (pp. 850)
Chaoyang Kuang, Shangzhi Chen, Magnus Jonsson

Boosting the tunability of Mid-infrared Metasurfaces based on graphene field-effect transistors (pp. 852)
Fei Han, The Linh Pham, Kacper Pilarczyk, Nguyen Thanh Tung, Dinh Hai Le, Guy A. E. Vandenbosch, Joris van de Vondel, Niels Verellen, Xuezhi Zheng, Ewald Janssens

Towards Plexcitonics: Direct Plasmonic Nanostructures Lithography on 2D Transition Metal Dichalcogenides (pp. 854)
Ermes Peci, Lorenzo Ramò, Michele Magnozzi, Emma Spotorno, Valentina Venturino, Maria Sygletou, Maria Caterina Giordano, Giorgio Zambito, Francesca Telesio, Maurizio Canepa, Francesco Bisio

Laser-based 3D printing of structures to control electromagnetic radiation: Bridging 2D, 2.5D, and 3D (pp. 856)
Gordon Zyla, Odysseas Tsilipakos, Dimitrios Zografopoulos, Savvas Papamakarios, Maria Farsari

Slime mold algorithm for topology optimization of photonics structure (pp. 858)
Kofi Edee, G. Granet, P. Bonnet

Tailoring gold plasmonic metasurfaces for efficient harmonic generation (pp. 860)
Shroddha Mukhopadhyay, Crina Maria Cojocaru, Maria Antonietta Vincenti, Kent Hallman, Agustin Mihi, Michael Scalora, Jose Trull

Synthesis and plasmonic properties of Fe3O4-Au-Pd hybrid nanoparticles (pp. 862)
Yukie Yokota, Mao Takeda

From synthesis to assembly: a Silicon based metasurface fabrication (pp. 864)
Juan Xin, Julien Proust, Jerome Plain

All-Garnet Magnetooptical Microcavity (pp. 866)
Taichi Goto

Microscale concave interfaces: a new reflective colorimetric platform (pp. 868)
Jacob Rada, Chi Zhou, Qiaoqiang Gan

Periodically nanostructured anisotropic coatings for spatial filtering and polarization control (pp. 870)
Julianija Nikitina, Matas Plukys, Darius Gailevičius, Kestutis Staliunas, Lina Grineviciute

Engineering spin-orbit coupling of light in weak and strong light-matter coupling regimes for topological photonics (pp. 872)
Jacek Szczytko, M. Muszyński, P. Oliwa, P. Kapuściński, P. Kokhanchik, M. Kędziora, K. Łempicka-Mirek, E. Oton, R. Mazur, P. Morawiak, W. Piecek, P. Kula, D. Bobylev, D. Solnyshkov, G. Malpuech, W. Bardyszewski, B. Piętka

Energy- and Time-resolved NIR to Visible Upconversion Luminescence from SingleNaYF4:Yb3+,Tm3+ Nanoparticles on Self-assembled Chiral Metasurfaces (pp. 874)
A. Ahmed, K. Y. Chiok, S. May, A. Baride, R. B. Anderson, S. Zhou, Steve Smith

Advanced Computational Electromagnetics for the Analysis and Design of Nanophotonic Devices

Refined Quantum Hydrodynamic Model for Deep Nanoscale Plasmonics with Noble Metal and Dielectrics (pp. 876)
Xue-Wen Chen

Innovative Approach: Inverse Design of 2D Slanted Gratings through the Fusion of Polynomial Modal Method, Neural Networks and Slime mold algorithm and/or Harris Hawkes optimizer, with Application in Augmented Reality (pp. 878)
Kofi Edee, G. Granet

Nanophotonic chirality transfer to dielectric Mie resonators (pp. 880)
Ershad Mohammadi, TV Raziman, Alberto G. Curto

Consensus ADMM for Photonic Design (pp. 882)

Plasmon-enhanced fluorescence immunosensor using polymer-coated silver nanoparticles (pp. 1269)
Nahoko Okimi, Setsuko Yano, Yoshie Komatsu, Toshifumi Nanjyo, Mitsuhiro Uesugi, Ryo Kato, Takuo Tanaka, Fumihisa Kitawaki, Taka-aki Yano

Orthogonal chemical toolbox for antifouling biointerface on gold nanoparticle arrays serving in plasmonic biosensing applications (pp. 1271)
D. Cattozzo Mor, A. B. Plšek, V. T. Vu, G. Aktug, Z. Hubička, Chun-Jen Huang, Jackub Dostalek

Utilizing Flexible Polymer Linkers in a Continuous Monitoring Plasmonic Biosensor for Detecting Low Molecular Weight Analytes (pp. 1273)
Gizem Aktug, N. Asai, V. Van-Truc, C-J Huang, C. Monteiro da Santa, S. Park, K. Sergelen, Jackub Dostalek

Understanding on Light-matter Interaction in Chiral Plasmonics (pp. 1275)
Jeong Hyun Han, Ryeong Myeong Kim, Ki Tae Nam

Spectrometer-free colorimetric plasmonic biosensor for detection of food allergens (pp. 1276)
Daiki Hirabayashi, Kotaro Kajikawa, Mana Toma

High-speed near-field optical microscopy: super-resolution plasmonic imaging for biological studies (pp. 1277)
Takayuki Umakoshi

Recent advances in metasurface fluorescence biosensors for diverse targets (pp. 1279)
Masanobu Iwanaga

Polymeric Grating Prism-based Dual-mode Miniature Surface Plasmon Resonance Sensor (pp. 1281)
Akira Baba, Wisansaya Jaikeandee, Chutiparn Lertvachirapaiboon, Kazunari Shinbo, Keizo Kato, Sanong Ekgasit

Plasmonic biosensor platforms for digital single molecule assay readout (pp. 1282)
Katharina Schmidt, Naoto Asai, Gizem Aktug, Dario Cattozzo Mor, Prasanth Asokan, Stefan Fossati, Yevhenii Morozov, Andreas Weinhaeusel, Tomas Riedel, Andres de los Santos Pereira, Jakub Dostalek

Plasmonic Immunosensor Platform Composed of a Capture Interface Formed by Photochemical Reaction (pp. 1284)
Keiko Tawa

Recent Trends in Metaoptical and Plasmonic Systems

High Diffraction Efficiency Top-hat Beam Shaper Metasurface for Fluorescence Observation (pp. 1287)
Tomoki Shimatani, Jie Li, Ryota Yamada, Satoshi Ikezawa, Kentaro Iwami

High Transmittance 3D Metasurface Holograms Made of SiN for Multicolor Projection with Time-division-multiplexing Method (pp. 1289)
Tamaki Onozawa, Junpei Beppu, Masakazu Yamaguchi, Kentaro Iwami

Hyperspectral Imaging for Flat Optics enabled by Dielectric Metasurfaces (pp. 1291)
Marie Braasch, Thomas Pertsch, Phillip Manley, Sven Burger, Berthold Wegner, Paul Heimel, Tzenka Miteva

Development of Vapor Cells Based on Tri-functional Metasurface for Microfabricated Atomic Clock (pp. 1292)
Ryosei Ito, Ponrapee Prutphong, Katsuma Aoki, Satoshi Ikezawa, Motoaki Hara, Kentaro Iwami

All-optical spectral control by perfect absorber based on quadrupole resonance and photothermal effect (pp. 1294)
Seiya Shinkai, Junichi Takahara

Development of wide-angle metalenses capable of simultaneously capturing near and far-view images (pp. 1296)
Atsushi Hasegawa, Ryota Yamada, Keisuke Ozawa, Yuki Abe, Mineki Taoka, Takeshi Yamagishi, Kentaro Iwami

Enhancing the photo sensitivity of photo detector using nanophotonics approach (pp. 1298)
Soh Uenoyama

Enhancement of photothermal nonlinear scattering from Mie-resonant silicon nanostructures (pp. 1300)
Kentaro Nishida, Shi-Wei Chu

High-sensitivity image sensors based on dispersion-engineered metalenses (pp. 1302)
Masashi Miyata

Reconstructive Spectrometer Using Plasmonic Photodetector (pp. 1304)
Yuuki Kaneda, Eslam Abubakr, A. Abadi, Shun Yasunaga, Masaaki Oshita, Tetsuo Kan

Spatiotemporal Metamaterials and Metasurfaces

Physics-Driven Vector-Quantized Autoencoder for Space-Time-Coding Matrix (pp. 1307)
Xiao Qing Chen, Lei Zhang

Enhanced optical effects based on the bound states in the continuum (pp. 1309)
Haitao Jiang, Zhiwei Guo, Yong Sun

Down-conversion of terahertz wave frequencies by mode coupling at temporal boundaries in semiconductor waveguides (pp. 1310)
Keisuke Takano, Satoko Uchiyama, Shintaro Nagase, Yuka Tsuchimoto, Toshihiro Nakanishi, Yosuke Nakata, Joel Pérez-Urquizo, Julien Madéo, Keshav Dani, Fumiaki Miyamaru

Waveform-Selective Metasurfaces Varying in Time and Space at the Same Frequencies in Accordance with Pulse Width (pp. 1312)
Hiroki Wakatsuchi, Ashif Aminulloh Fathnan

Direction-of-arrival (DOA) estimation with a programmable space-time-modulated metamaterial receiver (pp. 1314)
Shaghayegh Vosoughitabar, Chung-Tse Michael Wu

Acoustic Fiber via Rotational Motion (pp. 1316)
Mohamed Farhat, Ying Wu

A Physical Unclonable Function Based on Time-Modulated Systems with Exceptional Points of Degeneracy (pp. 1317)
Pai-Yen Chen

Near-infrared metasurface with simultaneous control of dielectric and magnetic properties in the 100-THz band (pp. 1318)
Harumi Asada, Kumiko Ryu, Takehito Suzuki

Application of Deutsch-Jozsa Algorithm via an Inverse-Designed Polyimide Metamaterial (pp. 1320)
A. Blackwell, R. Yahiaoui, Y- H. Chen, P- Y. Chen, T. A. Searles, Zizwe A. Chase

Recent advances in non-Hermitian metamaterials

Realization of Geometry-Dependent Skin Effect in a Reciprocal Two-Dimensional (pp. 1323)
Mengying Hu, Kun Ding

Arbitrary Chern Vectors in Non-Reciprocal 3D Acoustic Crystals (pp. 1325)
Yan Meng, Linyun Yang, Xiang Xi, Yihao Yang, Gui-Geng Liu, Baile Zhang, Zhen Gao

Observation of Discrete-Light Temporal Refraction by a Quantized Moving Gauge Potential Barrier (pp. 1327)
Chengzhi Qin, Bing Wang, Stefano Longhi, Peixiang Lu

Heat circulation metadevices (pp. 1329)
Ran Ju, Pei-Chao Cao, Dong Wang, Minghong Qi, Liujun Xu, Shuihua Yang, Cheng-Wei Qiu, Hongsheng Chen, Ying Li

The Manipulation of Topological Modes and Anderson Localized Modes via non-Hermicity (pp. 1331)
Xulong Wang, Wei Wang, Guancong Ma

Acoustic orbital-related topological states and phase transitions (pp. 1333)
Feng Gao, Yu-Gui Peng, Xuefeng Zhu

Non-Hermitian skin effects in anisotropic metamaterials (pp. 1335)
Y. Tian, Xiujuan Zhang

Nanophotonics in Biomedical Applications

Ultrafast Photonic PCR with All-Solution Processed Perfect Absorber (pp. 1337)
Seho Lee, Abdulrahman Alsaadi, Inki Kim

Au film-porous anodic aluminum oxide-Al hybrid nanomaterial-based optical biosensor for detection of the VEGFA protein. (pp. 1338)

Uldis Malinovskis, Amanda Reke, Raimonds Poplausks, Aleksandrs Dutovs, Oskars Putans, Irina Oliseveca, Donats Erts, Indrikis Muiznieks, Juris Prikulis

Biomedical applications of laser reirradiated metallic nanoparticle (pp. 1340)

Ana María Vilas, Mohamed Boutinguiza, M. Fernández-Arias, Daniel Rodríguez, Oscar Barro, Felipe Arias-Gonzalez, Pablo Pou-Alvarez, Ramon Soto, Juan Pou

New materials for photonics

Demonstration of hybrid photonic crystal nanocavity using atomically thin van der Waals flakes (pp. 1343)

Chee Fai Fong, Daiki Yamashita, Nan Fang, Shun Fujii, Yih-Ren Chang, Takashi Taniguchi, Kenji Watanabe, Yuichiro Kato

The reduced loss of guided exciton-polariton modes in WS2 multilayers by hBN- encapsulation (pp. 1345)

Ho Seung Lee, Junghyun Sung, Dong-Jin Shin, Su-Hyun Gong

Titanium nitride as a an alternative metamaterial fabricated via gas nitridation (pp. 1347)

Liya Tony, I. Packia Selvam, Sankara Narayanan Potty

Super-resolution imaging of sulfur vacancies in 2D molybdenum disulfide using expansion microscopy and dSTORM (pp. 1350)

Pin-Jen Wang, Ting-Jui Ben Chang, Hui-Jen Lin, Shun-Min Yang, Mor Pal Vikram, Kai-Chun Huang, Tsung-Hsin Liu, Chih-Yang Huang, T. Tony Yang, Ann-Shyn Chiang, Yeu-Kuang Hwu, Chun-Wei Chen, Li-Chyong Chen, Han-Chun Wu, Shi-Wei Chu

Exciton-polaritons in van der Waals heterostructures coupled to optical bound state in the continuum (pp. 1352)

Dong-Jin Shin, HyunHee Cho, Woo Hun Choi, Ho Seung Lee, Su-Hyun Gong

All-Optical Excitation and Control of Ultrafast Lattice Dynamics in WSSe (pp. 1354)

Sergio Rey, Martin Cross, Malte Welsch, Frederik Schroeder, Binbin Zhou, Nicolas Stenger, Peter Jepsen, Edmund Kelleher

Metal-Insulator Transition in Vanadium Dioxide Inspected by Analytical Electron Microscopy (pp. 1356)

Jan Krpensky, Michal Horak, Jakub Planer, Peter Kepic, Jiri Kabat, Andrea Konecna, Vlastimil Krapek

TDBC microstructures made by local photo-bleaching in J-aggregate thin organic layers for photonics applications (pp. 1358)

Komlan Gadedjisso-Tossou, Antoine Bard, Kevin Chevrier, Clémentine Symonds, Jean-Michel Benoit, Joel Bellessa, Alban Gassenq

Ultrathin bismuth and antimony films as alternative materials towards versatile and sustainable metastructures (pp. 1360)

Fernando Chacon-Sanchez, Carlota Ruiz de Galarreta, Rosalia Serna

Harmonic enhancement via a time-varying Fabry-Perot resonator (pp. 1362)

Theodosios Karamanos, Stamatios Amanatiadis, Nikolaos Kantartzis, Fabrice Lemoult

Identify Defect and Strain of Monolayer WSe2 through Exciton Anisotropy (pp. 1364)

Shu-Hsien Chen, Sih-Wei Chang, Hsuen-Li Chen

Second optical harmonic generation in high-Q dielectric metasurfaces integrated with transition metal dichalcogenide films (pp. 1366)

Alena Nazarenko, Anna Chernyak, Alexander Musorin, Alexander Shorokhov, Andrey Fedyanin

Structured Light Generation Using Spherulite in Linear and Nonlinear Realm (pp. 1368)

Yuanfeng Liu, Le Zhou, Youcheng Xu, Yongzheng Wen, Natalia M. Litchinitser, Yang Shen, Jingbo Sun, Ji Zhou

Cost-Efficient Deterministic Engineering of Quantum Light Emission in Two-Dimensional Semiconductors (pp. 1370)

Snezana Lazic, Sanja Djurdjić Mijin, Ismael de Pedro Embid

Investigating the Optical Properties of Thin Films Coated with MWCNTs (pp. 1372)

Md Saiful Islam, Furuta Hiroshi

Optical antennas and plasmonics-based devices

Versatile Flexible Plasmonic Chip for Non-Invasive Dual Modal Glucose Detection (pp. 1375)
Andreea Campu, Simion Astilean, Monica Focsan

Developing Spatiotemporal Modulated Graphene-Based Waveguide to Integrate the whole Terahertz Transceiver Front-End in one Device (pp. 1376)
Mahsa Valizadeh, Leila Yousefi, MirFaez Miri

Vanadium dioxide for compensation of angle-dependent shifts in structural color filters (pp. 1378)
Katarína Rovenska, Filip Ligmajer, Peter Kepic, Beata Idesova, Jan Chochol, Jiří Liska, Tomas Sikola

Chiral spin-preserving reflection in helicoid-based plasmonic metamaterials (pp. 1380)
Eunji Im, Hyeohn Kim, Ji-hyeok Huh, Ki Tae Nam, Seungwoo Lee

Plasmon-enhanced photovoltaics, photocatalysis, and solar fuels

Noble Metal - Chalcopyrite Hybrid Nanostructures for Enhanced Plasmonic Photocatalysis (pp. 1383)
Bjoern Reinhard

Light-accelerated NiFe oxyhydroxides-alloy photoanode metasurfaces for efficient and stable solar water-splitting (pp. 1385)
Fei Xiang, Ning Li, Arturo Burguete-Lopez, Zhao He, Maxim Elizarov, Andrea Fratalocchi

Plasmonic-enhanced Fabry-Perot cavity for photocatalysis application (pp. 1387)
Ning Lyu, Anjalie Edirisooriya, Zelio Fusco, Fiona Beck, Christin David

Hot electron induced photoreduction of Fullerene C60 using coupled plasmonic - Fabry-Perot systems (pp. 1389)
Anjalie Edirisooriya, Ning Lyu, Zelio Fusco, Fiona Beck

MAPLE simulation for multilayer-layers solar cell based in ZnS- CZTSSe (pp. 1391)
Hala El-Khozondar, A. N. Sahmoud, R. J. El-Khozondar, Y. F. Nassar

Research on the enhancement of photocatalytic activity of bismuth-based materials by plasma effect (pp. 1393)
Derek Hao

Large-area self-organized plasmonic gold nanowire matrix for advanced photochemical applications (pp. 1395)
Giulio Ferrando, Matteo Gardella, Long Duy Pham, Hieu Si Nguyen, Chi Le Ha, The Hung Mai, Giorgio Zambito, Matteo Barelli, Maria Caterina Giordano, Francesco Buatier De Mongeot

Templated Self-Assembled Plasmonic Metasurfaces. From Lasing and Sensing to Photocatalysis (pp. 1397)
Tomas Tamulevičius, Klaudijus Midveris, Gvidas Klyvis, Tomas Klinavičius, Muhammad Haris, Nadzeya Khinevich, Asta Tamulevičienė, Mindaugas Juodėnas, Domantas Peckus, Joel Henzie, Sigitas Tamulevičius

Near Unity Index Meta-surface for Effective Reduction of CO2 to Methanol (pp. 1399)
Joel Yi Yang Loh

Plasmonics and nano-optics

A Direct Approach towards Nanoscale Mapping of Plasmonic Heat Generation in Nanostructures (pp. 1402)
Serene Pauly, Amit Kumar

Optimized Near-infrared Absorption of Reflective Aluminum Gratings: Theoretical and Experimental Investigation (pp. 1404)
Roy Avrahamy, Dror Cohen, Benny Milgrom, Ben Amir, Daniel Belker, Asi Solodar, Erez Golan, Oren Sadot, Amiel Avraham Ishaaya

Analyzing Absorption Mechanisms of Plasmonic and Dielectric Surface Lattice Resonance Embedded in Absorptive Medium (pp. 1406)
Joshua T. Y. Tse, Shunsuke Murai, Katsuhisa Tanaka

Spin angular momentum of enhanced electric fields around a plasmonic nanostructures excited by circularly polarized light (pp. 1408)
Naoki Ichiji, Takuya Ishida, Ikki Morichika, Tetsu Tatsuma, Satoshi Ashihara

On the quantization of non-Hermitian nanophotonic systems (pp. 1410)
Luke Hands, Angela Demetriadou, Ben Yuen

Lattice resonances in multipartite periodic arrays with electric and magnetic response (pp. 1412)
Juan R. Deop-Ruano, Juan J. Alvarez-Serrano, Luis Cerdan, Vincenzo Aglieri, Andrea Toma, Alejandro Manjavacas

Plasmonic anisotropy of metallic nanoparticles induced by uniaxially-stretched graphene substrates (pp. 1414)
Chihiro Yamano, Shin-nosuke Ozeki, Ryo Kato, Takuo Tanaka, Taka-Aki Yano

High-Q and Small Size Cavity with Mie Scattering Mirror (pp. 1415)
Bokyung Kim, Seokhyeon Hong, Youngsoo Kim, Seung Hyeon Hong, Juhan Lee, Soon-Hong Kwon

Mie-assisted photonic memories based on the phase change of silicon nanoparticles (pp. 1417)
Jhih-Jia Chen, Te-Hsin Yen, Kentaro Nishida, Junichi Takahara, Mihail Petrov, Shi-Wei Chu

Hybrid full-space metalens for ultraviolet light (pp. 1419)
Beata Idesova, Filip Ligmajer, Ondřej Červinka, Tomas Sikola

High NA multifocal array metalens (pp. 1421)
Hyemi Park, Yongjae Jo, Inki Kim

Lensless localized surface plasmon resonance sensor using porous anodic alumina based nanostructured metal-insulator-metal multilayers (pp. 1423)
Aleksandrs Dutovs, Amanda Reķe, Uldis Maļinovskis, Raimonds Popļausks, Donāts Erts, Juris Prikulis

Integrated Plasmo-Photonic Bimodal Interferometer for Temperature Sensing (pp. 1425)
Lamprini Damakoudi, Stelios Simos, Konstantinos Fotiadis, Dimosthenis Spasopoulos, Evangelia Chatzianagnostou, Omkar Bhalerao, Stephan Suckow, Max Lemme, Eleftherios Lidorikis, Nikos Pleros, Konstantinos Vyrsokinos

Self-referenced integrated plasmo-photonic sensor for temperature compensated refractive index sensing measurements (pp. 1427)
Stelios Simos, Lamprini Damakoudi, Evangelia Chatzianagnostou, Konstantinos Fotiadis, Dimosthenis Spasopoulos, Dimitris Bellas, Omkar Bhalerao, Stephan Suckow, Max Lemme, Nikos Pleros

Self-Assembled Plasmonic Nanoparticles for Photocatalysis (pp. 1429)
Asta Tamuleviciene, Klaudijus Midveris, Tomas Klinavicius, Muhammad Haris, Mindaugas Juodenas, Domantas Peckus, Sigitas Tamulevicius, Tomas Tamulevicius

Fluorescence enhancement of novel azulene-tetrazoles using metasurface structures (pp. 1430)
Veronica Anastasoaie, Iuliana Mihalache, Roxana Tomescu, Adrian Dinescu, Eleonora-Mihaela Ungureanu, Oana Brincoveanu, Dana Cristea

Manipulation of 2-Dimensional layers of plasmonic nanoparticles using a SAW device (pp. 1432)
Chandresh Sindal, Julien Reboud, Narayana M. S. Sirimuthu, Alasdair W. Clark, Jonathan M. Cooper

Optical response of Smooth and rough Mono and bilayers of plasmonic materials (pp. 1434)
Jorge Alberto Polito Lucas, Ana Lilia Gonzalez

Infrared Surface Lattice Resonances using Plasmonic Transition Metal Nitrides (pp. 1436)
Hsing-Yu Kuo, Tzu-Yu Peng, Jia-Wern Chen, Yu-Jung Lu

Highly-Sensitive Broadband Gap-Plasmon-Enhanced NbN Superconducting Single Photon Detectors (pp. 1438)
Feng-Yang Tsai, Jing-Wei Yang, Jia-Wern Chen, Li-Min Wang, Yu-Jung Lu

Revisable Tuning of Tamm Plasmon Polaritons (pp. 1440)
Ming-Jyun Ye, Kuo-Ping Chen

Large-area, two-dimensional single-crystal gold for low-loss nanoplasmonics (pp. 1442)

Chenxinyu Pan, Yuanbiao Tong, Anatoly V. Zayats, Limin Tong, Pan Wang

Chirality switchable molecular traps based on plasmonic metastructures with intertwined Fibonacci spirals (pp. 1443)
Chung-Kai Tseng, Tang-Chun Liu, Diksha Thakur, Chao-Yi Tai

Metal-dielectric gratings with broad geometric range for angle interrogation of surface plasmons (pp. 1445)
Shafeek Abdul Samad, Nityanand Kumawat, Priyamvada Venugopalan, Sunil Kumar

Modulable Chiral Plasmonic Activates via Stimulus Triggered Shape-Morphing (pp. 1447)
Yisheng He, Chunhong Ye

Utilizing a microcone array to control the distance between a microsphere and a SERS substrate for photonic nanojet-mediated SERS (pp. 1449)
Chen-Ting Hung, Yan-Ru Liu, Yih-Fan Chen

Investigating the charge carrier dynamics in an array of Split-H ladder (SHL) of Au on amorphous SiO2 (pp. 1451)
Nikita Vashistha, R. Sharma, T. N. Narayanan, R. S. Singh, Mahesh Kumar Sharma

Investigating Nonlinear Optical Switching via Nanosecond Z-scan: Coupling Saturable Absorption in Gold with Reverse Saturable Absorption in Strontium Titanate (pp. 1453)
Nikita Vashistha, Hitheshwar Prasad, N. Sri Ram Gopal, Rajiv K. Singh, Sandeep Singh, S. P. Singh, Mahesh Kumar

Hybrid Plasmonic Waveguide NFT for HAMR Heads (pp. 1455)
Will Lee, Andres Neira, Beverley McConnell, Robert Bowman

Titanium nitride (TiN) nano and microstructures as novel highly efficient SERS platform (pp. 1457)
Jan Krajczewski, Aleksandra Michałowska, Nozka Libor

Self-assembled silicon photonic cavities with atomic-scale confinement and self-aligned integration with photonic circuits (pp. 1459)
Ali Nawaz Babar, Thor August Schimmell Weis, Konstantinos Tsoukalas, Shima Kadkhodazadeh, Guillermo Arregui, Babak Vosoughi Lahijani, Søren Stobbe

Tamm Assisted Metasurfaces for classical and quantum photonics applications (pp. 1461)
Edmund Harbord, Huili Hou, Talal Alshammari, Mengxun Bai, David Dlaka, Angela Stephens, Jon Pugh, Ruth Oulton, Martin Cryan

Cd(Zn)O nanostructures for SEIRA sensing in de Mid-IR (pp. 1463)
Pablo Ibañez-Romero, Eduardo Martinez Castellano, Javier Yeste, Fernando Gonzalez-Posada, Thierry Taliercio, Vicente Muñoz-Sanjosé, Miguel Montes Bajo, Adrian Hierro

Plasmonic hydrogen sensor at the ppm level based on the plasmon-triggered switching (pp. 1465)
Pascal Giraud, Hugo Bruhier, Isabel Verrier, Salma Rajab Pacha, Christelle Varenne, Jérôme Brunet, Amadou Ndiaye, Yves Jourlin

Industrial WorkShop I: From Design to Manufacture - Complete Inverse Design (pp. 1467)
Chenglin Xu, Bryan Stone, JiSoo Park

Magnetically Controllable Multimode Interference in Topological Photonic Crystals (pp. 1468)
Weiyuan Tang, Mudi Wang, Shaojie Ma, C. T. Chan, Shuang Zhang

Coupled thermal and mechanical phenomena induced by the fluctuations of the electromagnetic field (pp. 1470)
Juan R. Deop-Ruano, Alejandro Manjavacas

Super-resolution elasticity imaging with nanobells (pp. 1472)
Rafael Fuentes Dominguez, Marina Paris Ogayar, Kerry Setchfield, Richard Smith, Daniel Jaque, Matt Clark

Super Resolution Imaging of Resonance Mode Inside Silicon Nitride Nanowire Based on Photothermal Nonlinearity (pp. 1474)
Yu-An Chen, Te-Hsin Yen, Kentaro Nishida, Chih-Wei Chang, Shi-Wei Chu

Acoustic and seismic metamaterials

Design of composite mufflers based on dissipative and reactive units (pp. 1477)
Yuzhen Yang, Han Jia, Quanquan Shi, Jun Yang

Frequency-selective valley edge waveguiding in topological phononic-crystal plates (pp. 1479)
Jin-Chen Hsu, Chun-Hao Wei, Che-Ting Huang

From Air to Water: Expanding Inverse-Design Applications in Ultrasonic OAM (pp. 1481)
Chuanxin Zhang, Xue Jiang, Dean Ta

Water-Air Acoustic Communication Based on Broadband Impedance Matching (pp. 1483)
Han Jia, Yuzhen Yang, Jun Yang

Tailoring acoustic complex media for optimal wave mode conversion (pp. 1485)
Hongkuan Zhang, Guancong Ma

Optimally designed ultra-thin underwater metamaterial absorber (pp. 1487)
Nan Gao, Sichao Qu, Alain Tinel, Bruno Morvan, Vicente Romero-García, Jean-Phillippe Groby, Ping Sheng

Fast-speed Ultrasonic Imaging Using a Single Sensor by Combining Disordered Metasurface and Artificial Intelligence (pp. 1489)
Wei Wang, Jie Hu, Jingjing Liu, Bin Liang, Jianchun Cheng

Chiral and hyperbolic metamaterials

Dielectric metasurface for wave-vector variant and circular polarization dependent transmission (pp. 1492)
Helene Wetter, Wenlong Gao, Falk Rehberg, Jan Wingenbach, Stefan Schumacher, Thomas Zentgraf

Photonic Modes in Gyrotropic-Hyperbolic Heterostructures (pp. 1494)
Daniele Battesimo Provenzano, Giuseppe Carlo la Rocca

Understanding The Reflective Footprint of Ghost and Leaky Hyperbolic Polaritons in Crystal Quartz (pp. 1496)
Mark Cunningham, Adam Lafferty, Mario Gonzalez Jimenez, Rair Macêdo

Enhanced chirality with Mie resonance-based multi-cylinder chiral metasurfaces (pp. 1498)
Seung Hyeon Hong, Seokhyeon Hong, Youngsoo Kim, Bo Kyung Kim, Juhan Lee, Soon-Hong Kwon

Unidirectional mode excitation due to magnetochiral effects (pp. 1500)
Hiroyuki Kurosawa, Keisuke Itoh, Tetsuya Ueda

Machine learning for metamaterial design

End-to-End Framework for Designing Broadband Achromatic Metalens in High-quality Long-infrared Imaging (pp. 1503)
Qizhou Wang, Daniele Veraldi, Arturo Burguete-Lopez, Maksim Makarenko, Andrea Fratalocchi

Free-form inverse design of dynamically tunable metamaterial absorber for Mid-Infrared applications (pp. 1505)
Ram Prakash Shanmugam, Aastha Jain, Rajesh Kumar, Anirban Mitra

Broadband large-scale photonics inverse design enabled by experimental machine learning (pp. 1507)
Maksim Makarenko, Sergey Rodionov, Qizhou Wang, Fedor Getman, Andrea Fratalocchi

Artificial intelligence optical hardware empowers real-time ultra-sensitive detection of dopamine at 10−11 mol/L (pp. 1509)
Ning Li, Qizhou Wang, Zhao He, Arturo Burguete-Lopez, Fei Xiang, Andrea Fratalocchi

Metamaterial-based devices

Fabrication of visible metalenses by thermal oxidation of silicon nanopillars (pp. 1512)
Taiyu Okatani, Rei Ando, Naoki Inomata, Yoshiaki Kanamori

Water sensors using soft films with metamaterials (pp. 1513)

Chia-Yi Huang, Harry Miyosi Silalahi

Polarization-Insensitive Ultra-Broadband Terahertz Metamaterials for 6G Applications (pp. 1514)
Bhagwat Singh Chouhan, Partha Pratim Barman, Bhumidhar Barman, Gagan Kumar

Bismuth-based color generation devices : from traditional optical cavities to gap-surface plasmon metastructures (pp. 1516)
Fernando Chacon-Sanchez, Carlota Ruiz de Galarreta, Rosalia Serna

Metasurface-Driven Hyperspectral Video Camera and Real-Time Spectral Analysis applications (pp. 1518)
Arturo Burguete Lopez, Qizhou Wang, Maksim Makarenko, Andrea Fratalocchi

MEMS-based double filter configuration for air gap sensing in tunable Fabry-Pérot filter (pp. 1520)
Pratyasha Sahani, S. Nabana, T. Okatani, N. Inomata, Y. Kanamori

Metamaterial Range Extended And Field localized Parity-Time Symmetrical Wireless Power Transfer System (pp. 1522)
Abdulrahman Mohammed Alsaadi, Inki Kim

Technology of auxetic-structured substrate for skin attachable conformal sensor (pp. 1524)
Jae-Hwan Lee, Tae-Gyong Kim, Jun-Sang Lee, Seung-Kyun Kang

Flexible Metasurface as an Efficient Resonator for 7T MRI (pp. 1526)
Santosh Maurya, Eiska Tegareh, Rita Schmidt

Fabrication of delay lines using spoof-surface-plasmon-polariton waveguides coupled with split-ring resonators for microwave integrated circuits (pp. 1528)
Minh Nguyen, Nobuaki Kikuchi, Toshiyuki Kodama, Taiyu Okatani, Naoki Inomata, Yoshiaki Kanamori

Numerical investigation of dielectric metasurfaces for refractive index-based sensing applications (pp. 1530)
Roxana Tomescu, Cristian Kusko, Veronica Anastasoaie, Dana Cristea

Advancements in polarization-sensitive metasurfaces (pp. 1532)
Ondřej Červinka, Martin Hrtoň, Jakub Lelek, Filip Ligmajer, Stěpan Vénos, Libor Ulehla, Tomas Sikola

Conductivity responsive effective permittivity control in GaAs tunable metamaterials (pp. 1534)
Minyeul Lee, Sungyoung Yoon, Jonghwa Shin

Real-time terahertz modulation with gold-MoS2 metasurface (pp. 1536)
Jianhong Zhang, Fangfang Ren, Jiandong Ye, Xiaoli Ji, Hai Lu

Realizing an acoustic T-shaped superscatterer with inverse design (pp. 1538)
Di Wang, Jie Zhu, Zhongming Gu

Design of a 3D Reconfigurable Intelligence Surface (pp. 1540)
Sung-Sil Cho, Biswarup Rana, Ic-Pyo Hong

Flexible metamaterial absorber on custom-engineered polymer nanocomposites as substrates (pp. 1542)
Kumaran Rengaswamy, Siva Bhagavathi L. G., Rahul Manohar O., Anjali Murugan, Vijayashri V., Chitti Venkata Krishnamurthy, Subramanian Venkatachalam

Dynamic medium based on tunable transmissive metasurfaces (pp. 1544)
Zhedong Wang, Chao Qian, Hongsheng Chen

An active Fabry-Pérot interferometer operated at terahertz frequencies based on pitch-variable subwavelength gratings (pp. 1546)
Ying Huang, Yangxun Liu, Taiyu Okatani, Naoki Inomata, Yoshiaki Kanamori

300-GHz-band transmission-type beamforming metasurface for an outdoor-to-indoor signal coverage extension for future wireless networks (pp. 1548)
Adam Pander, Hibiki Kagami, Daisuke Kitayama, Hiroyuki Takahashi

Giant Optical Anisotropy in Van der Waals Materials: Perspectives and Challenges (pp. 1550)

Valentyn Volkov, Georgy Ermolaev, Dmitry Grudinin, Kirill Voronin, Andrey Vyshnevyy, Arslan Mazitov, Gleb Tselikov, Ivan Kruglov, Davit Ghazaryan, Luis Martin-Moreno, Alexey Arsenin, Konstantin Novoselov

A Broadband Metamaterial-Based Electromagnetic Absorber with the Capability of being Fabricated by 3-D Printers (pp. 1552)

Mohammad Javadi, Leila Yousefi

Metamaterials and negative index materials

An Effective Medium Description for Cylinder- and Coated-cylinder- Multifunctional Metamaterials (pp. 1555)

Anna Tasolamprou, Charalampros Mavidis, Maria Kafesaki

Enhancing bandwidth in GHz metamaterials through superposed Lorentzian Resonances (pp. 1557)

Yun Hyeong, Hyeonjin Park, Jonghwa Shin

The Bandgap Characteristics of Wave Dispersion in Monocoupled Metamaterial (pp. 1559)

Abhigna Bhatt, Arnab Banerjee

Dissipative Triatomic Metamaterial for Broadband Asymmetric Elastic-wave Transmission (pp. 1561)

Sagr Alamri, Bing Li

The critical size of hybrid metal-dielectric nanoslits guide mode resonance optical filters by the spatial Fourier transform analysis (pp. 1563)

Rong He, Cheng Chen, Yuxiang Zheng, Liangyao Chen, Junpeng Guo

Bias-free optical metamaterial with nonreciprocal magnetoelectric response (pp. 1565)

Shadi Safaei Jazi, Ihar Faniayeu, Rafael Cichelero, Dimitrios C. Tzarouchis, Mohammad Mahdi Asgari, Alexandre Dmitriev, Shanhui Fan, Viktar Asadchy

First-principles prediction of nonlinear optical response in silicon nanostructures (pp. 1567)

Gosuke Matsuura, Shunsuke Yamada, Mitsuharu Uemoto

Electro-Optical Switching in Nonlinear Metasurfaces (pp. 1569)

Matthew Feinstein, Alexander Andronikides, Euclides Almeida

Metasurfaces and flat optics

Tunable filter based on the Brewster effect in metafilms: From all-pass filter to narrowband perfect absorber (pp. 1572)

Tomohiro Hoshino, Yasuhiro Tamayama

Robustness of Active Phase-Change Metasurfaces against High-Power Sources (pp. 1574)

George Braid, Carlota Ruiz de Galarreta, Joe Pady, Andrew Comley, Jacopo Bertolotti, C. David Wright

Centimeter-scale cylindrical metalens (pp. 1576)

Kyungtae Kim, Junsuk Rho

Diverse reconfigurability in far- and mid-infrared few-layer metasurfaces capable of polarization manipulation: case of phase-change materials (pp. 1578)

Andriy Serebryannikov, Akhlesh Lakhtakia

Materials manipulation with structured light fields

Takashige Omatsu[1,2]

[1]Grasuate School of Engineering, Chiba University, Japan
[2]Molecular Chirality Research Center, Chiba University, Japan
[*]corresponding author: omatsu@faculty.chiba-u.jp

Abstract: Structured light fields, such as optical vortex, has been currently growing up to a particle-like optical field (optical skyrmion). We review state-of-the-art structured materials fabrication and new materials manipulation with structured light fields.

Structured light fields with designed spatial variations in amplitude or polarization, such as optical vortices and vector vortices, possess an annular spatial intensity profile and an orbital angular momentum (OAM) associated from a helical wavefront with an on-axis phase singularity. They have been intensely studied in a myriad of fundamentals and applications: for instance, optical trapping and manipulation, optical and quantum communications, super-resolution microscopy, and materials fabrication.
In particular, it has been discovered that the optical vortices enable the twist of irradiated materials at a nano- and micron-scale to form chiral structures, and thus, a variety of chiral structures, formed of metals, semiconductors, dielectrics, polymers, and crystals have been demonstrated. Such chiral structures will potentially pave the way towards the development of chiral meta-surfaces for detection and control of chiral chemical reaction at high time and cost efficiencies.

Magnetic skyrmions with topologically protected spin textures, assigned with the topological number, have been investigated as a new carrier for new generation magnetic data storages. A full Poincare beam possesses all polarization states on the Poincare sphere onto its cross section, and it is also attracting much attention in optical science and photonics as an analogous quasiparticle of light, termed optical skyrmions. Optical skyrmions, formed of the coherent superposition of orthogonally circularly polarized fundamental Gaussian and Laguerre-Gaussian modes with appropriate relative phase, exhibit topologically protected polarization textures. Going beyond conventional structured light fields such as optical vortices and vector vortices, optical skyrmions will offer new fundamental physics via exotic light matter interactions, however, they are still unmatured as a research topic. In fact, there are few reports of the interaction between optical skyrmions and materials.

In this paper, we review the state-of-the-art chiral nano/micro-structures with structured light fields, and we also address the demonstrations of new approaches to materials manipulation with quasi-particles of light, optical skyrmions.

Shaping light propagation in complex media

Hui Cao

Department of Applied Physics, Yale University, New Haven, Connecticut06520, USA

hui.cao@yale.edu

Abstract:

Wave propagation in a random scattering medium has long been described by the diffusion equation. Recently, spatial wavefront shaping technique is utilized to overcome the diffusion in order to control coherent light propagation in random scattering media. By breaking the diffusion limit, we deliver optical energy into a target region of arbitrary size and shape anywhere inside a strong-scattering system. We further demonstrate an order of magnitude enhancement of remitted signals that carry information from deep inside a diffusive medium, illustrating the potential of coherent wavefront control for noninvasive diffuse-wave imaging applications.

Localized states trapped by topological defects in photonic and hybrid metasurfaces

Daria Smirnova

Research School of Physics, Australian National University, Canberra, ACT 2601, Australia
daria.smirnova@anu.edu.au

Abstract: The miniaturization of photonic technologies calls for a wise integration of photonic and material components for fully functional fast-speed integrated devices based on enhanced light-matter interactions. Topological photonic systems were recently proposed as a promising platform to couple structured modes of light on chip with solid-state matter excitations to establish resilient forms of polaritonic transport. This talk will report novel phonon-polariton states trapped by topological defects in a silicon metasurface integrating hexagonal boron nitride (hBN). Spatially localized polaritonic modes originate from the coupling of electromagnetic fields with phonon vibrations in hBN. The point defect mode is, in particular, identified to possess unique features stemming from its topological origin: a chiral polarization texture, a singular radiation leakage profile, and the possibility of being selectively excited through coupling to spin-polarized edge waves at heterogeneous topological interfaces.

Active Metasurfaces in Space and Time

Harry A. Atwater

California Institute of Technology, USA
*corresponding author: haa@caltech.edu

Abstract: Electro-optically tunable active metasurfaces that enable dynamic modulation of reflection and transmission amplitude, phase, and polarization using resonantly excited materials and phenomena are powerful design elements for meta-imaging and computation. As flat, low-profile optical elements, active metasurfaces have potential serve as cascadable, programmable components in optical meta-imaging systems, such as lens-less cameras and single-photon imaging systems. In this talk, I will discuss metasurfaces with high quality factor, local, resonant elements capable of two-dimensional phase gradient generation, in both passive and active metasurface designs. I will also describe active metasurfaces with both spatial and temporal phase gradients, and an active metasurface as a lens-less imaging system, and compare the characteristics to conventional lens-coupled image sensors.

Machine learning for metamaterials and metasurfaces

Elastic spin angular momentum in metamaterials and classical structures

Jinfeng Zhao[1*], Yao Huang[1], Yuxuan Zhang, and Yongdong Pan[1]

[1]School of Aerospace Engineering and Applied Mechanics, Tongji University, 100 Zhangwu Road, 200092, Shanghai, China

[*]corresponding author: jinfeng.zhao@tongji.edu.cn

Bosonic-like waves in topological metamaterials and/or phononic crystals have raised wide interest owing to their exotic features. The chirality of topological edge states (TES), known as pseudo-spin, is an important feature for performing robust wave manipulation. Unlike the mathematical concept of pseudo-spin, the spin angular momentum (SAM) of elastic waves describes their local but intrinsic chirality. The SAM of some guided modes locks to the wave direction, which leads to unidirectional routing in both metamaterials and classical structures.

Here, we successfully measure the elastic spin of acoustic Rayleigh and Lamb modes along different directions, and demonstrate spin-wavenumber locking over a broad frequency range [1]. Subwavelength chiral meta-sources are constructed thanks to a special design, and give rise to observed unidirectional routing of Rayleigh and Lamb modes. Moreover, by using one chiral source, simultaneous opposite routing is demonstrated for symmetric and antisymmetric Lamb modes in a single elastic plate [2].

Interestingly and importantly, we extend elastic SAM to valley metamaterials, and observe the previously overlooked elastic spin-valley locking mechanism [3]. Based on theoretical, numerical and experimental results, the SAM of valley chiral TES is found to relate both to spatial position and wavenumber. Putting a chiral source at a representative position on the metamaterial allows one to achieve unidirectional wave routing. The resulting wave direction agrees well with that expected according to the spin-wavenumber locking mechanism. This research shows that elastic SAM offers a new tool to explore valley metamaterials, and should be applicable other mode types in relevant topological metamaterials.

Metamaterials with architected instabilities

Davide Bigoni[1*]

[1]Instabilities Lab, University of Trento, Via Mesiano 77, 38123 Italy
[*]Corresponding author: davide.bigoni@unitn.it

Abstract: Homogenization is used for periodic elastic grids subject to axial prestress, to obtain equivalent elastic materials. The latter can be tailored to exhibit material instabilities driven by the microstructure of the grid and its level of prestress. Instabilities include shear band fromation and Hopf bifurcation, thus leading to odd elasticity.

A design strategy is introduced for metamaterials displaying tailored instabilities. When the latter occur at the microscale, they are analyzed with a Floquet-Bloch wave technique, while analysis of macroinstabilities leads to the definition of an equivalent elastic material. This material can be obtained via homogenization theory for periodic elastic structures, subject to a state of axial prestress and incremental deformation involving axial and shear forces and bending moment [1]. Macroinstabilities in the form of shear bands usually occur only for compressive prestress, so that the stability domain for the equivalent material results unbounded in tension. We show that it is possible to design a material for which the stability domain is bounded, in other words, for which shear bands may form under tensile loads. The architecture of this structure is shown in Fig. 1 and the analysis of its dynamic behaviour leads to multiple band gaps, flat bands, and Dirac cones [2].

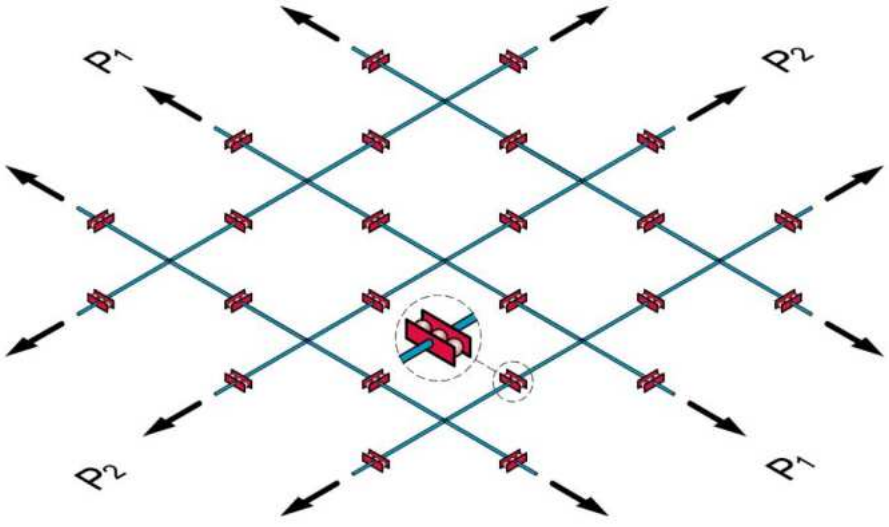

Fig. 1 - A grid of elastic and axially-preloaded rods, jointed through sliding constraints, provides an example of a metamaterial with a bounded (thus even including tension) stability domain. The fact that tensile preload may be applied precludes out-of-plane instabilities, so that the material can be used for structural membranes. In dynamics, the grid shows multiple band gaps, flat bands, and Dirac cones, while its equivalent homogeneous material provides an uncommon example of a material losing ellipticity at the parabolic boundary, thus evidencing ‘stress channelling’, corresponding to shear bands parallel (orthogonal) to the direction of the tensile (compressive) applied preload, P1 and P2.

The possibility of a Hopf bifurcation is introduced, as related to the presence of follower loads [3], or nonholonomic constraints [4], or discontinuity in the constraint curvature [5]. When this instability is implemented in a material [6], apparently work is produced in a closed strain cycle, so that conservation of energy is apparently violated. As mentioned, this violation is only apparent, as the material is able to "suck and release" energy from the environment. When a material is subject to a Hopf bifurcation, mechanical waves propagate through it without decaying, rather with amplification, because energy is extracted from the surroundings, Fig. 2.

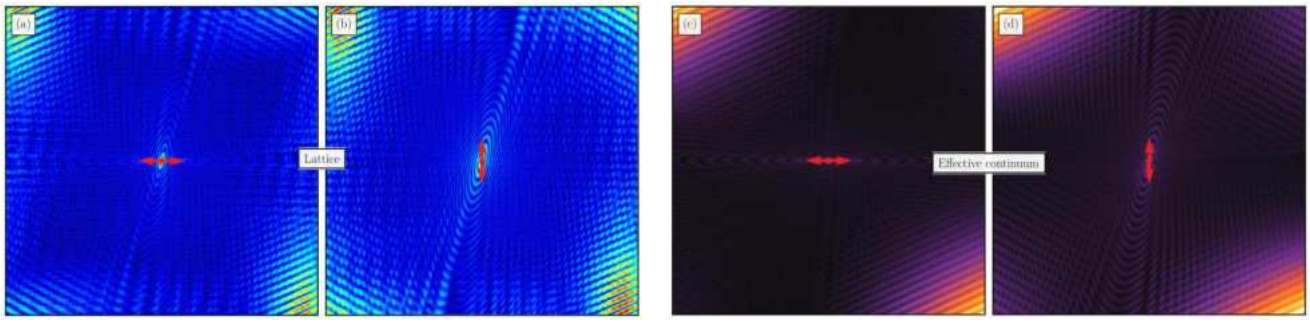

Fig. 2 - Time-harmonic forced response of an anisotropic lattice (a, b) and of the corresponding effective continuum (c, d), displaying flutter instability. The response is typical of the behavior of a dynamically unstable material, evidencing blowing-up waves traveling away from the forcing source but localized along two preferential directions.

The behaviour shown in the figure is typical of odd elasticity, violating hyperelasticity, and opens the way to new and unexpected applications in the field of metamaterials.

Silicon carbide as a platform for mid-IR metasurfaces

Stefan A Maier[1,2]

[1]School of Physics and Astronomy, Monash University, Clayton, Victoria 3800, Australia
[2]Department of Physics, Imperial College London, London SW7 2AZ, UK
Stefan.Maier@monash.edu

Abstract: Silicon carbide enables strongly confined surface phonon-polaritons in the mid-infrared. We demonstrate the use of this materials platform for phonon-polariton metasurfaces supporting vortex and quasi bound-states-in-the-continuum resonances. Additionally we present results of active metasurfaces operating in the visible regime based on conductive polymers.

Surface-phonon polaritons, hybrid light/matter modes based on the coupling between the electromagnetic field and transverse optical phonons in the restrahlen band of polar dielectrics, are a promising route towards deep sub-wavelength mid-IR photonics. We examine the use of silicon carbide as a platform for surface phonon-polariton metasurfaces. Thin membranes of this material allow for the generation of even and odd surface phonon-polariton coupled modes, the dispersion of which we investigate using near-field optical microscopy [1]. Structuring of the sicilon carbide surface then enables the creation of functional mid-IR photonics structures, which we demonstrate for the cases of vortex modes and quasi bound-state-in-the-continuum resonances. We further present geometries based on out-of-plane symmetry breaking as a means for tailored surface enhanced infrared absorption (SEIRA) sensing [2] with a metallic metasurface.

The second part of the presentation focuses on the active tuning of metasurfaces enabled via switchable conductive polymers [3].

In the Quest for the Viable Perovskite Solar Cells

Nam-Gyu Park

School of Chemical Engineering, SKKU Institute of Energy Science and Technology (SIEST), Sungkyunkwan University, Suwon 16419, Republic of Korea

(npark@skku.edu)

Meeting the escalating electricity demands of our advancing society, particularly at the terawatt scale, requires achieving high power conversion efficiency and low cost per peak watt in solar cell technology simultaneously. Prior to the introduction of perovskite solar cells, only a limited array of materials and technologies could meet both criteria. This presentation traces the evolution toward the development of practical solid-state perovskite solar cells. Beginning with an overview of initial technologies, the discussion progresses to the emergence of solid-state perovskite solar cells. Early efforts involved the use of quantum dot inorganic materials, such as nanocrystalline lead sulfide, as light harvesters. Despite their potential, these materials encountered significant challenges, primarily surface-defect-mediated recombination. Acknowledging these limitations, methylammonium lead triiodide ($MAPbI_3$) perovskite emerged as an alternative to inorganic quantum dots. However, initial implementations as sensitizers in liquid-electrolyte-contained structures yielded disappointing results, with efficiencies as low as 3-4% in 2009 and the dissolution of $MAPbI_3$. A breakthrough occurred in 2012 when a pioneering study demonstrated a 9.7% efficient and 500-hour-stable perovskite solar cell, leveraging $MAPbI_3$ and a solid hole transporting material. This pivotal advancement rendered perovskite solar cells a viable and durable technology. Subsequent years witnessed rapid growth in perovskite photovoltaic research, with efficiencies exceeding 26% using $FAPbI_3$, rivaling or surpassing existing technologies. Current research endeavors focus on enhancing stability and exploring tandem structures for electricity generation in both terrestrial and space applications. The perovskite solar cell stands poised as the most promising energy solution, with its potential impact on sustainable energy surpassing current expectations once stability and lead immobilization challenges are effectively addressed.

Gated Spin Communities

Abstract: Conducting contacts modulate and control the magnetodipolar interaction that causes chirality of the magnetization and energy transport by spin waves at interfaces and in thin films. Metallic normal, ferromagnetic, and superconducting gates thereby generate new functionalities in magnonic circuits and devices.

Chiral spin waves [1]: Spin waves are the excitations of the magnetic order parameter in magnetic materials that are quantized into magnons. The energy spectrum of spin models with near-neighbor exchange interactions is parabolic for long wavelengths but it becomes strongly anisotropic in the presence of the magnetic dipole-dipole. The so-called Damon-Eshbach magnetostatic spin wave modes of bulk ferromagnets propagate with wave vector **k** normal to the magnetization **m** and are localized and locked at surfaces with normal **n** by the right-hand rule $\mathbf{k} \,||\, \mathbf{m} \times \mathbf{n}$, *i.e.* they are "chiral". This property is topologically protected in half-infinite ferromagnets. The propagation direction of the upper and lower surface modes of a magnetic slab is opposite. In ultrathin ferromagnets the surface modes on both sides morph into the lowest perpendicular standing spin wave modes with amplitudes that are constant over the film thickness. In that limit the spin waves are not chiral anymore. However, the magnetic stray fields on one side of the film are finite only when $\mathbf{k} \,||\, \mathbf{M} \times \mathbf{n}$, but vanish identically when $\mathbf{k} \,||\, -\mathbf{M} \times \mathbf{n}$. In the Damon Eschbach configuration inductive sources and detectors such as metallic strip lines on a given surface thereby interact only with spin waves that propagate in one direction. Magnon transport spectroscopy, Brillouin light-scattering, and diamond NV-center microscopy confirm the chirality of magnon transport in thin films of yttrium iron garnet (YIG). The chirality can be employed as microwave isolators in magnonic circuits.

Gating: The proximity of metallic gates affects a magnet by the diamagnetic eddy currents induced by the magnetic stray fields that are emitted by the spin waves. In normal metals they are dissipated according to Ohm's Law and thereby form an additional damping channel that increases the Gilbert damping constant on top of its intrinsic value. This effect can be distinguished from that of conventional spin-pumping by its wave number dependence or by inserting a thin insulating barrier that suppresses the short-range exchange but not the long long-range dipolar interaction. Moreover, the chirality of the stray field translates into non-local chiral damping, i.e. affects only spin waves that obey the right-hand rule. The induced eddy currents also generate Oersted magnetic fields that blue shift the magnon frequencies [2]. Superconducting gates therefore act as non-dissipative repulsive potential barriers for propagating spin waves [3].

The spin wave propagation and transport with chiral damping is a non-Hermitian Hamiltonian problem. Its numerical solution for finite systems leads to a chiral spin wave skin effect in which magnon accumulates at one edge. Three terminal thin film magnon "transistors" may consist of thin films of magnetic insulators gated by floating magnetic metal films. Here the angle between the thin film and gate magnetization controls the heat and spin currents between the source and drain, leading to a switchable spin wave Peltier effect [4]. When modelling the dissipative gate by a thermodynamic reservoir the two-terminal non-Hermitian problem becomes a three terminal Hermitian one. In the case of ballistic spin waves, the problem is equivalent to the integer quantum

Hall effect in the two-dimensional electron gas as sketched in Figure 1. The Landauer-Büttiker scattering theory of transport reveals that up to half of the source-drain currents may be diverted into the gate.

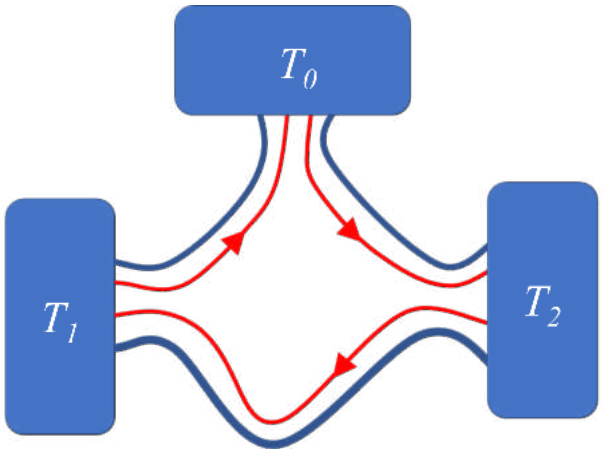

Figure 1: Two-terminal chiral spin wave transport in metal-gated thin magnetic films mapped onto the three-terminal contact configuration of the integer quantum Hall effect in the two-dimensional electron gas at filling factor 1. T_1 and T_2 are the temperatures of the source and drain, while the gate temperature T_0 is at the thermal equilibrium. Only the right moving spin waves generate eddy currents in the gate. This is equivalent to the electronic chiral edge channels of which only the upper one may flow into and out of the third reservoir.

Surprisingly, chiral damping also affects the scattering of spin waves by semi-transparent potential barriers [5]. With the right chirality they may profit from a sufficiently strong damping by an anomalous transmission probability that can be strongly enhanced from the intrinsic one up to unity. We analyze the numerical results by simple analytic model calculations for short-range scatterers.

We hope that our predictions will be useful for future spin-wave computing applications by enabling easy reprogramming and heat management of magnonic circuits.

Optical spin topologies in plasmonics and metamaterials

Anatoly V. Zayats[1*]

[1]Department of Physics and London Centre for Nanotechnology, King's College London, Strand, London WC2R 2LS, United Kingdom

[*]corresponding author: anatoly.zayats@kcl.ac.uk

Abstract: We will discuss spin-orbit coupling in interaction of complex vector beams with plasmonic metamaterials. Spin-orbit coupling and topology of evanescent waves and vector beams propagating in free space and metamaterials in different dispersion regimes will be considered.

Light waves carry both spin and angular optical momenta and their interaction can be influenced by symmetry of the electromagnetic field and/or anisotropy of the medium where light propagates [1]. The ability to engineer and manipulate the properties of vector optical wavefronts and pulses with non-uniform polarisation is important in various applications including imaging, metrology, optical communications as well as biomedical and quantum technologies [2]. Spin-orbit coupling provides interesting applications in polarisation-enabled control of optical signals, or in reverse, controlling light polarisation. This coupling in evanescent fields is mediated by the transverse spin and results in complex topological field structures analogous to prototypical condensed matter phenomena, such as quantum spin-Hall effect, skyrmions, merons, and others [1,3-5]. At the same time, the interactions between propagating vector votes beams and the metamaterial strongly depends on the longitudinal field of the beam, which can be enhanced by the focusing, and whose morphology depends on the characteristics of the initial state of polarisation chosen [6,7]. These interactions may completely modify the initial polarisation state of the transmitted beam, in many cases resulting in its azimuthalisation or vortex modification [8,9]. The spin-orbit coupling is important for controlling waveguiding and for nonpolarized light [10-12].

In this talk, we will discuss spin-orbit coupling in guided waves and complex vector beams, both carrying longitudinal fields, their topological manifestations, interaction with anisotropic and epsilon-near-zero metamaterials, and the applications. Topologically protected states in guided and propagating beams, and polarisation structure stability and transformations will be considered. Strongly anisotropic metamaterials provide a flexible platform for tailoring complex vector beams and pulses for harvesting functionalities and applications of complex light beams with complex polarisation and phase distributions in numerous photonic and quantum technologies, imaging and metrology.

Abstract: We have developed a series of intelligent meta-lens systems for underwater, land, and aerial imaging and sensing. We reported the design, fabrication, characterization, and applications of the monocular, binocular, and multilocular meta-lens.

Meta-lens is a planar optical device that can control the wavefronts of light via subwavelength nano-antennas. [1-4] Nano-antennas of various structures can provide all kinds of modulation of phase, amplitude, polarization, etc., for a wide range of applications. Traditional optical imaging systems usually consist of a group of lenses to correct spherical or chromatic aberration, which are bulky. When using more than one camera, there will be a set of complex data transformations to calibrate the whole imaging system. Meta-lenses are more flexible to match various scientific and technical application scenarios than the traditional optical lens, especially in space-constrained and fragile environments, such as drones, autonomous driving, and micro-submarines.

Due to the limited and specific light field information obtained by single-lens imaging, an intelligent and compact depth-sensing meta-device is proposed for autonomous land driving, as shown in Fig. 1(a). With the support of deep learning, the array of 3600 achromatic metalenses integrates the functions of light field imaging and structured light imaging, which is suitable for different scenes at all light levels. For the exploration of the aquatic environment, a novel GaN binocular meta-lens is specifically designed and fabricated to demonstrate underwater stereo vision (see Fig. 1(b)). Proposed underwater binocular meta-lens stereo vision can realize real-time depth imaging with neural networks. The intrinsic superhydrophobicity of nanostructured GaN meta-lens enables its anti-adhesion, stain-resistant, and self-cleaning functions. For the demands of compact, miniaturized, portable, lightweight, and low energy consumption, we demonstrate a GaN-based polarization-independent metalens camera on a drone, as shown in Fig. 1(c). The meta-lens can realize aerial photography and landing assistance for drones and reduce the weight burden to prolong flight time. Meta-lens will significantly benefit future imaging and sensing applications in aerial, land, and underwater environments.

Figure 2 presents the characterization and depth imaging results of the meta-lenses for aerial, land, and underwater imaging. The scanning electron microscope (SEM) images in Fig. 2(a,b,d) show the detailed nanostructures of the meta-lens, revealing the well-defined cylindrical nanostructures with various diameters that are arranged according to the focusing phase distribution. Fig. 2(c) displays an optical photograph of the GaN meta-lens on a sapphire substrate, which is easily recognizable by the naked eye. We process the captured image data using conventional neural networks to obtain fast and accurate depth map results. The depth imaging result in Fig. 2(e) demonstrates that our intelligent meta-device is equally effective for objects with gradually varying depths. Overall, our results indicate that the proposed meta-lenses hold significant

potential for imaging and sensing applications in aerial, land, and underwater environments.

Abstract: Digital signal processing has revolutionized many fields of science and engineering, but it still shows critical limits; a long-sought solution is optical analog computing. We demonstrate here that nonlinear phenomena combined with engineered nonlocality in flat optics can be leveraged to synthesize Volterra kernels able to outperform linear devices.

Flat-optics devices exhibiting a linear local (LL) response are defined by a position-dependent, linear transfer function $T_{LL}(\mathbf{r})$, which can be locally tailored by engineering metaatoms arranged within metasurfaces. An input signal, defined in real space as $I_\omega(\mathbf{r})$, is filtered linearly and locally, and transformed into an output $O_\omega(\mathbf{r})=T_{LL}(\mathbf{r})I_\omega(\mathbf{r})$. Wavefront engineering is arguably the most prominent application for LL systems [1]. Spatial dispersion, i.e., nonlocality, is usually regarded as a nonideality in LL flat-optics devices. However, the nonlocal response of metasurfaces has been recently indicated as an effective means to achieve advanced functionalities based on the independent control of spectral and angular selectivity [2].

To date, investigations into nonlocality have primarily focused on the linear-optics regime. The action of linear nonlocal (LN) systems is well described by a k-dependent transfer function $T_{NL}(\mathbf{k})$, which describes how the metasurface filters the angular spectrum of an input function, according to $O_\omega(\mathbf{k})=T_{NL}(\mathbf{k})I_\omega(\mathbf{k})$. Nonlocal metasurfaces are well suited for analog computing and image processing. For example, n-th order differentiation is easily achieved with transfer functions of type $(jk)^n$, while integration is obtained by synthesizing transfer functions of the type $(jk)^{1/n}$ [3].

Despite the advantages, linear approaches — both local and nonlocal — face limitations related to the restricted numerical aperture and frequency bandwidth, and the inherent linearity of the mathematical operations that one can engineer. Here we demonstrate that the combination of nonlinear and nonlocal effects in the same flat-optics device is a powerful strategy to achieve advanced image processing and analog computing functionalities with reduced structural complexity and increased efficiencies in terms of angular and frequency bandwidth [4]. The concept of nonlinear nonlocal (NN) flat-optics is illustrated in Fig. 1, highlighting the differences with respect to LL and LN approaches.

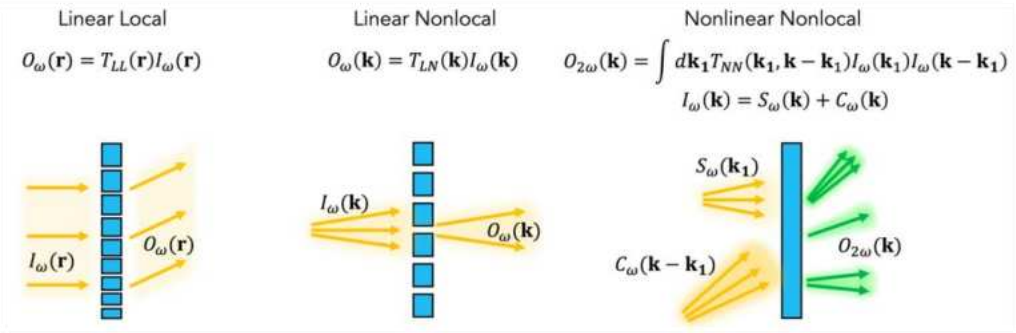

Fig. 1: Comparison between the transfer functions of flat-optics elements with LL, LN, and NN responses. Typical operation of the three systems. **a** Beam deflection (LL system). **b** Passive filtering of spatial-frequencies (LN system). **c** Nonlinear mixing of spatial frequencies (NN system)

We will provide illustrative examples that show the potential of NN flat-optics in analog computing. In the operation schematically illustrated in Fig. 2, we consider a gallium arsenide (GaAs) thin film. The film is excited by two coherent fields: a control field and a signal field. In a simple experimental setup, the control field (C_ω) may be for example a gaussian beam with very large cross section impinging at oblique incidence. The signal field (S_ω) is a small-divergent and normally-incident beam with transverse cross section defined by an arbitrary function.

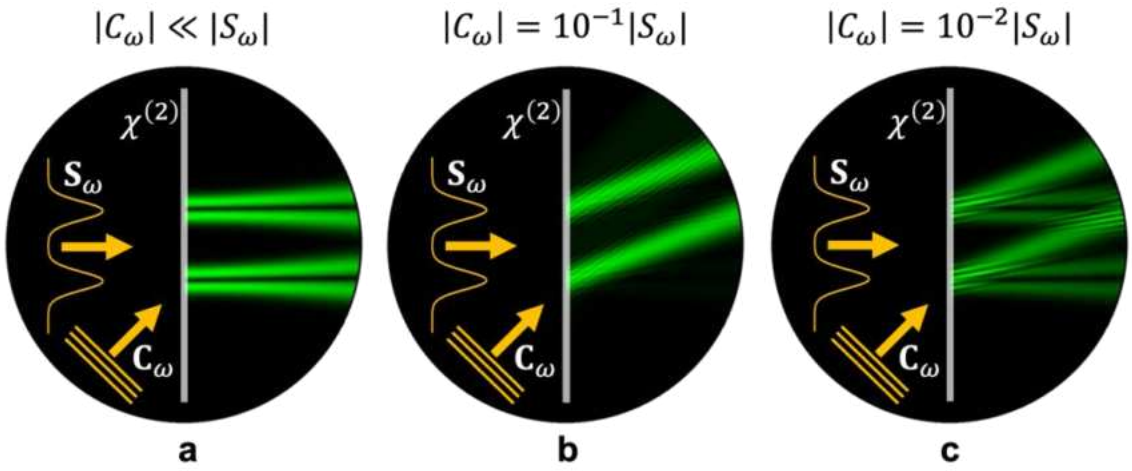

Fig. 2. Functionalities of a nonlinear nonlocal (NN) flat-optics element made of a thin film of gallium arsenide. The system is illuminated by two coherent beams: a control (C) and a signal (S), reported in orange. **a** When the amplitude of the control is much smaller than the amplitude of the signal, nonlinear edge detection is performed at the SH (the green beam transmitted is the "edge" of the signal, i.e., it is proportional to the derivative of the signal). **b** Nonlinear beam deflection is dominant. **c** SHG performs simultaneous nonlinear edge detection and nonlinear beam deflection of the signal. The deflection angle is determined by the angle of incidence of the control signal.

The example reported in Fig. 2 showcases the intriguing and unique capabilities of NN systems: (i) Analog computing and image processing functionalities that typically require patterned metasurfaces in the linear regime, such as beam deflection (or anomalous refraction) and edge detection, may be achieved by leveraging the nonlinear and nonlocal response of unpatterned thin films; (ii) The response of a NN system is intensity dependent, hence tunable; (iii) The filtering operations are inherently nonlinear; (iv) Since this approach does not rely on any electromagnetic resonance, it is also free from any fundamental constraint on the operational spectral bandwidth, as it happens instead for linear devices based on patterned metasurfaces; (v) Other input-output transformations may be foreseen by properly using the control function as a means to "write" other functionalities.

Two-dimensional electronic spectroscopy of many-body correlations in quantum materials

Christoph Lienau[1]

[1]Institut für Physik, Carl von Ossietzky Universität Oldenburg, 26111 Oldenburg, Germany
[*]corresponding author: Christoph.lienau@uni-oldenburg.de

Abstract: Two-dimensional electronic spectroscopy with few-femtosecond time resolution is an emerging tool for probing quasi-particle interactions in quantum materials. The talk will discuss its use for exploring the quantum dynamics of strongly coupled J-aggregate exciton/surface plasmon polariton hybrids, ultrafast manybody and intervalley couplings in atomically thin semiconductors and for tailoring the nonlinearities of such semiconductors in plasmonic cavities.

Many of the exciting properties of novel types of quantum materials, from polariton condensation to light-induced superconductivity arise from strong couplings among electrons, phonons, spins and photons in the material. These couplings give rise to the formation of new hybrid excitations, quasi-particles, with optical and electronic properties that can be vastly different from those of the uncoupled excitations. Two-dimensional electronic spectroscopies (2DES), replacing the excitation pulse in common pump-probe spectroscopies by a phase-locked pulse pair, can give unique insights into such couplings [1,2]. Cross peaks in the 2DES, oscillating as a function of time delay between pump pair probe, provide definite spectroscopic signatures for such couplings, making 2DES with few-femtosecond time resolution [3] a method of choice for unraveling the microscopic physical processes that govern quasi-particle formation in quantum materials.

In my talk, I will give an introduction into these multidimensional electronic spectroscopies and their applications to selected nanoscale materials. In a first example, I will use them to unravel the optical nonlinearities excitons in J-aggregated organic semiconductors [4,5] that are strongly to surface plasmon polaritons [1]. The data show how strong coupling transforms the usual diffusive hopping exciton transport in organics into a coherent transport of excitons over mesoscopic distances at room temperature. I will then discuss how 2DES can be employed to sensitively probe many-body interactions and intervalley couplings in atomically thin semiconductors, revealing the latter through ultrafast, 11-fs oscillations of exciton peaks. When coupling these excitons to plasmonic nanoresonators, new hybrid particles arise with optical nonlinearities that are vastly enhanced over those of both monolayer excitons and the plasmons. 2DES reveals how many-body correlations enhance the nonlinearities, opening up new pathways for tailoring optical nonlinearities in hybrid systems of atomically thin semiconductors that are coupled to external cavities. All these examples give strong indications that many-body interactions among two-quantum excitations are crucial for understanding the optical nonlinearities of such hybrid systems.

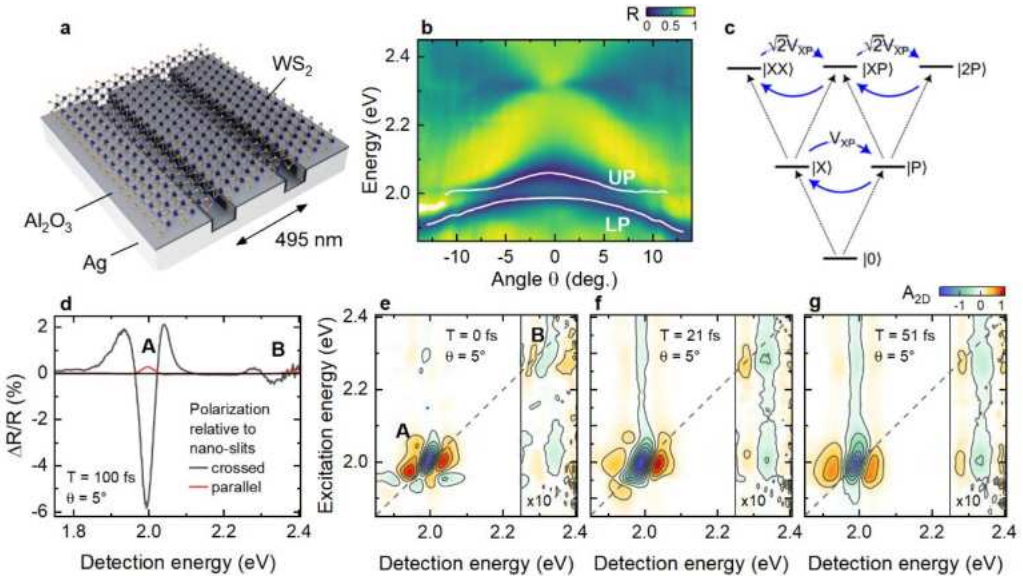

Fig. 1. a) Sketch of the hybrid sample comprising a periodic nano-slit array (20x50 µm²) milled into a silver film and coated with a 5-nm layer of Al_2O_3. The nanostructure is covered with an exfoliated monolayer of WS_2. b) Angle-dependent linear reflectivity showing an anti-crossing at an incidence angle of $\theta = \pm 5°$ forming upper (UP) and lower (LP) polariton branches with a coupling strength of $V_{XP} =$ 23 meV. c) Level scheme of strong coupling between the A exciton $|X\rangle$ and plasmon $|P\rangle$ including one- and two-quantum excitations. d) Differential reflectivity at $\theta = 5°$ and a waiting time of $T = 100$ fs for pulses polarized perpendicular to the nano-slits (black) and along the slits (red). A giant enhancement of the nonlinearity by a factor of ~20 is demonstrated, arising from the hybridization between $|X\rangle$ and $|P\rangle$. e)-g) 2DES maps for selected waiting times. Two polariton manifolds for the A and B exciton and cross-peaks are observed.

High Spatiotemporal Resolution Live Cell Imaging on a Plasmonic Metasurface

Kaoru Tamada

Kyushu University, Japan

Abstract: Self-assembled monolayers composed of metal nanoparticles can be regarded as metasurfaces with high refractive index and extinction coefficient due to collective excitation of coupled localized surface plasmon resonance (LSPR). This plasmonic metasurface confines light to the nanointerface and enhances fluorescence, thus enabling high-speed interfacial imaging with high axial and lateral resolution up to the theoretical limit even under wide-field microscopy. By using this imaging method, we were able to observe unique cell dynamics at the molecular level that have not been visualized before; such as a spider-web-like fibrous nascent adhesion spreading radially at the initial stage of cell adhesion and also asymmetrical motility of metastatic breast cancer cells discriminated from non-tumorous cells.

Chiral Nanophotonics: Enabling Ultrasensitive Detection in Biophysical Measurements

Malcolm Kadowala[1*]

[1] School of Chemistry, Joseph Black Building, University of Glasgow, Glasgow, G12 8QQ, UK
[*]corresponding author: malcolm.kadodwala@glasgow.ac.uk

Abstract: Spectroscopic techniques using circularly polarized light offer a powerful tool to analyze chirality, a crucial property in biomaterials. These techniques rely on the differential interaction of left- and right-handed circularly polarized light with chiral molecules. However, the inherently weak signal strength of circular dichroism (CD) limits their sensitivity. This talk will explore how the emerging field of chiral nanophotonics can overcome this barrier. By harnessing the unique properties of nanostructures, we can significantly enhance the interaction between light and chiral molecules. This allows for highly sensitive CD measurements, potentially reaching the single-molecule level.

Extreme Space-Time Optics & Quantum Meta-Photonics

Vladimir M. Shalaev

Purdue University
West Lafayette, Indiana, USA
corresponding author: shalaev@purdue.edu

Abstract: We first discuss all-optical modulation with single photons using electron avalanche, resulting in record-high nonlinearities. Then we show that transparent conducting oxides (TCOs) operating in the near-zero index (NZI) regime can provide strong single-cycle modulation, thus enabling novel photonic time crystals. Finally, we discuss scalable quantum photonics with single-photon emitters in silicon nitride that we recently discovered as well as the intriguing possibility to generate indistinguishable single photons by using plasmonic speedup that could enable important quantum photonics applications, including quantum communication and quantum computing.

Controlling nanomaterial properties using organization

M. Tréguer-Delapierre

ICMCB-CNRS UMR5026, U.Bordeaux, Pessac, France

mona.treguer@icmcb.cnrs.fr

We recently demonstrated a new concept for making nanostructures with unusual optical properties by organizing metal nanoparticles. In research and industry, molecules from drugs and polymers are made by combining high-yield chemical reactions in series. We have extended this approach to the nanoscale: we make metamolecules by combining high-yield colloidal reactions. Metamolecules are highly symmetric nanoclusters of metal and dielectric. They are needed for exotic optical materials like metafluids or for creating new light sources but they are notoriously difficult to make because of the precision required. We addressed this challenge by combining inorganic growth, polymerization and metal deposition. Though no individual reaction is new, the way we combine them is-much as the novelty in an organic synthesis scheme lies in determining what series of reactions will yield a target molecules. I will present the potential of this novel strategy. Through painstaking single-cluster spectroscopy measurement and comparison to simulation, I will show that the morphology is controlled to nanometer-scale precision. Previous approaches to making metamolecules fall into two classes: lithography, which offers control over morphology but limited throughput, and self-assembly, which offers high precision but limited control over yield. Our approach fits into neither category, et offers the best of both: high precision, high morphology yield, and bulk scale-up. It can be adapted to many other material systems. Moreover, I will present novel strategies regarding the organization of nanoparticles onto a substrate for mastering the visual appearance of an object at the macroscale (3). The coupling of nanoscale resonances and mesoscale interferences can be used to engineer spectrally and angularly the reflected light and lead to novel visual effects that are particularly impressive when changing viewing conditions (4). I will show how to use these studies to make useful materials and to gain a deeper understanding of the optics of materials at the nanoscale.

Nanoplasmonics as Enabler of Ultrafast Quantum Nanophotonics at Ambient Temperatures

Ortwin Hess[1]

[1]Trinity College Dublin, Dublin 2, Ireland
[*]corresponding author: ortwin.hess@tcd.ie

Abstract: We discuss how nanoplasmonic-cavity strong coupling and ultrafast plasmonic near-field evolution can be exploited to achieve high-speed nanophotonic quantum operations at ambient temperatures, including dynamic multi-partite entanglement, and introduce a novel strategy for preparation and 'immortalization' of selected plasmon-exciton polariton states by means of quantum coherent perfect absorption.

Spontaneous emergence of eyes in reinforcement learning agents

Department of Electrical and Computer Engineering, University of Wisconsin, Madison, Wisconsin 53706, U.S.A

A living animal exhibits remarkable ability to survive. It processes sensory input and takes actions to maximize the likelihood of survival. Researchers have been inspired to develop similar artificial agents powered by reinforcement learning—for instance, the DeepMind agent, which learns to play Atari arcade games. In the recent development, the ability to process raw sensory data such as the images, instead of handcrafted features, is one of the most important enablers, making it possible to train agents for different applications at scale. However, these agents are still different from fully autonomous agents such as living beings who not only process raw sensory data but also develop sensory function as part of their learning process. In this article, we show that an artificial agent powered by reinforcement learning can also spontaneously develop sensory functions. It can build its own bridge to connect the digital world to the physical one. This capability could be used to develop resilient agents that are adaptive in changing environments.

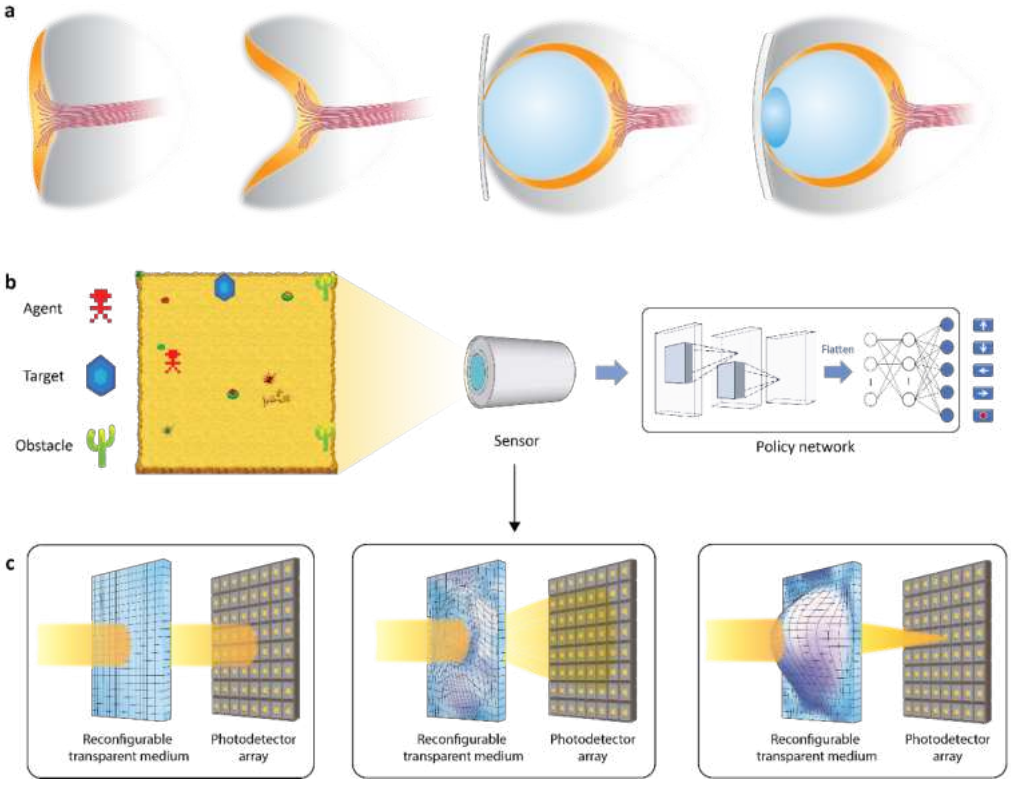

Figure 1. The evolution of ancient eyes and the spontaneous emergence of eyes in artificial agents. (a) Four evolutionary stages of eyes. (b) A simplified scenario to replicate the animal evolution process. On the left is a world with an agent, a target, and obstacles. The artificial agent is composed of a sensor and a neural network which function as the eyes and brain of an animal, respectively. It observes the world through the sensor and responds with action. (c) The sensor consists of a reconfigurable transparent medium and an array of light-sensitive detectors. The agent can adjust the shape of the transparent medium in the learning process. The three panels show the reconfigurable sensor at the beginning (left), intermediate (middle), and final (right) stages of the development.

A universal infrared absorption analysis system using deep learning

Abstract: We focused on reducing the experimental cost of obtaining mid-infrared absorption spectra using machine learning techniques. The large amount of spectral data from HITRAN and quantum scientific calculations can be a useful method effective prediction to the experimental spectra.

1. Introduction

MIR absorption is focused in the field of molecular sensing using plasmon materials and metasurfaces. Mid-infrared spectroscopy is a sensing technique that utilizes the vibrational and rotational absorption of molecules. Its non-destructive nature and maintenance advantages are leading to increasing expectations in various environmental monitoring [1,2]. In the context of simultaneous detection of multiple molecules, the complex spectra due to inter and intra-molecular interference has prompted investigations into analysis methods using deep learning [3,4]. However, the significant amount of data required for training and the necessity for acquiring new data when using different measurement instruments pose challenges. Therefore, the aim of this study is to construct a generalized qualitative and quantitative gas analysis method resilient to the effects of different measurement instruments by training models using spectral data obtained from quantum chemical calculations.

2. Experiments

2-1. Qualitative analysis model

The model was trained using spectral data of nine different molecules calculated with Gaussian [5]. The structure of the model involves dividing the spectral data into frequency bins, inputting them into a Convolutional Neural Network (CNN), and combining the outputs to obtain the final output. Data augmentation was performed by shifting and scaling each spectral data peak and combining them to create training data consisting of 14,000 samples and test data consisting of 6,000 samples. After training the model, accuracy was measured using experimental data obtained from the infrared absorption spectral database HITRAN [6].

2-2. Quantitative analysis model

For quantitative analysis, actual spectral data of N2O and CH4 with concentration labels ranging from 0 to 1000 ppm, as well as actual spectral data equivalent to 1000 ppm of H2O, were obtained. Two training datasets were created: one containing actual spectral data of the target molecule (N2O) mixed with spectra of 10 molecules from HITRAN as noise, and the other containing actual spectra of CH4 and H2O as noise. Subsequently, a model focusing on image recognition was trained using the dataset based on HITRAN. Two types of datasets, one from HITRAN and the other from actual measurements, were used to assess both training prediction accuracy and generalization prediction accuracy.

3. Results and discussions

3-1. Qualitative analysis model

We obtain the accuracy measurement results for each molecular species. Additionally, the accuracy measurement results when using experimental data from HITRAN for training with a similar model are also obtained for comparison. Identification accuracy varies by molecule, reaching a maximum of 98%. However, the minimum accuracy is 53%, indicating impractical precision. Two main reasons account for the low accuracy: firstly, overlapping peaks between the peaks of the molecule in question and those of other molecules; secondly, discrepancies between the simulation data used for training and the experimental data. However, since identification is achieved when the domain of the training and test data is the same, it is believed that the latter factor has a more significant impact.

3-2. Quantitative analysis model

We constructed a total of nine models using three types of image classification models (RegNet, EfficientNet-V2, ConvNeXt) as the central learning models. These models were trained using three different patterns: normal learning, fine-tuning with pre-trained weights from ImageNet, and transfer learning where pre-trained weights were fixed. The top three models' training prediction accuracy and generalization prediction accuracy are analysed. Since the concentration labels in the dataset are incremented by 50 ppm, the target values for RMSE and MAE are 25. However, all models exceeded this value sufficiently in terms of training prediction accuracy. Additionally, predictions for the actual measurement dataset, which was not used for training, were below 25, demonstrating the models' robustness to real-world noise by leveraging the robustness against HITRAN noise.

4. Conclusions

We demonstrated the feasibility of qualitative and quantitative analysis of experimental spectra using data from HITRAN and quantum science calculations. However, the performance was inferior when using the same data for training and accuracy assessment, and identification was challenging for certain molecules. To address this issue, creating regression models to minimize discrepancies between simulation and experimental data is desired. In quantitative analysis, it is essential to appropriately select the 10 molecules introduced as noise. For future prospects, we aim to establish a method that adapts to a broader range of noise molecules by constructing multiple quantitative analysis models with different noise molecules and conducting ensemble predictions based on the results from qualitative analysis models.

Email: chaoq@intl.zju.edu.cn

Abstract: Recent breakthroughs in deep learning have ushered in an essential tool for optics and photonics, recurring in various applications of material design, system optimization, and automation control. In this talk, we will share the recent advances in how to streamline metasurface design and develop self-driving meta-devices.

Summary: Deep learning-enabled on-demand metasurface design and adaptive meta-devices have been the subject of extensive expansion, as it can alleviate the time-consuming and low-efficiency shortcomings in conventional numerical simulations and dependent working manner. The unique advantages of deep learning lie in its data-driven signature to help the model discover useful information from a moderate amount of data with strong nonlinear fitting and generalization ability. Therefore, Deep learning has spawned new ways of gamifying conventional design procedure with case-by-case numerical simulations and bottom-up guidance strategy. In this talk, we will share the recent advances made in how to expedite three classes of metasurface design: forward prediction, inverse design, and spectral correlation. Furthermore, we will show how to develop automatic meta-devices that can automatically respond to external stimuli and dynamic environments without human intervention. Examples include chameleon-like self-adaptive invisibility cloak, wireless channel management, and optical illusion. At the same time, future challenges and perspectives are pinpointed, including data curation and knowledge migration, with the vision of free management of entire electromagnetic space.

Abstract: In this work, we proposed an efficient inverse design algorithm for a liquid-crystal based programmable metasurface through adding a physics layer, which is developed based on a modified coupled mode theory, into a residual neural work. We experimentally demonstrated an inversely designed programmable metasurface for beam steering application.

The electromagnetic response of metasurfaces is governed by Maxwell's equations and some other derivative physics-domain knowledge. Incorporating the physics-domain knowledge along with numerical methods has unlocked a myriad of routes to reshape the wavefront of electromagnetic waves at a subwavelength scale. Despite the significant progress, metasurfaces still suffer from constrained performance due to the limited design space and time-consuming forward design process. Recently, the rapidly developed data-driven deep learning algorithms have brought new vitality to the inverse design of metasurfaces, enabling the exploration of designs beyond regular shapes [1-3]. However, most of these design algorithms are statistically brute-force, treating the neural networks as "black-boxes". Therefore, these methods may be functional for designing but might not provide additional implicit physics laws or principles. [4-5] Here, we propose a novel physics-informed inverse design (PIID) method for precisely customizing a programmable LC-based terahertz steering metasurface. The physics domain knowledge, analytically developed based on a modified coupled mode theory (mCMT) with substrate effect included, is integrated into a residual multilayer perceptron (ResMLP) as a physical layer. The inverse design is based on the neural adjoint method [6]. We showed that without knowing the whole spectra information, our algorithm allows the inverse design only from three indicators: the required phase tuning $\Delta\varphi$ and reflection amplitude R at a specific frequency ω_D. The inclusion of an additional physics layer also facilitates the discovery of the correlation between geometries and resonant properties. Using this method, an inversely designed metasurface exhibits phase tuning of about 300° with a reflection amplitude over 0.9 at 465 GHz. Finally, we successfully demonstrated an inversely designed multi-bit programmable metasurface, which can be coded in 1-bit, 2-bit, and tri-state sequences arbitrarily, therefore able to steer the approximately normal incidence with deflected angles up to 65°. Our work underscores that incorporating physics domain knowledge can significantly streamline the inverse design process for highly performing metasurfaces, therefore opening up numerous avenues for various applications.

Short Abstract:
This talk is focused on reducing the complexity of machine-learning (ML) approaches for the design and knowledge discovery in large-scale nanophotonic structures. The key aspects of this work are: 1) using manifold-learning approaches for minimizing the dimensionality of the response and design spaces, 2) working in a dimensionality-reduced design space to considerably increase the size of the supercell, and 3) pruning the resulting networks to highly reduce the complexity of the ML algorithms. Using these techniques, metaphotonic devices with 100's of features in their supercell can be analyzed and designed. Furthermore, the use of optimally defined metrics for ML algorithms for knowledge discovery and finding helpful information about the properties of photonic nanostructures will be discussed. Practical examples involving the design, fabrication, and characterization of metaphotonic structures using the ML techniques in this work will also be demonstrated.

Design of Radiative Cooling Metamaterials by Generic Algorithm and Neural Network

Kotaro Kajikawa*

Tokyo Institute of Technology, Japan

*corresponding author: kajikawa@ee.e.titech.ac.jp

Abstract: Radiative cooling (RC) materials, cooling objects without electricity, are an essential research target for a sustainable society. The RC materials are required to have high transmittance in the visible and high emissivity in near-infrared regions. We study a genetic algorithm and neural network to design RC materials.

The development of radiative cooling (RC) materials, which can cool objects and buildings without electricity [1], is an important research topic for realizing a sustainable society. In particular, developing RC materials for solar cell cooling is an urgent task. The properties required for RC materials are high transmittance in the visible and near-infrared regions and high emissivity in the atmospheric window (ATW) region. ATW is a wavelength band with high atmospheric transmissivity, and heat can be released into the universe through this wavelength band. This phenomenon is responsible for the cold temperatures on sunny winter mornings.

One way to achieve these properties is to use a layered structure of oxide dielectrics. This is because the desired optical properties can be designed by superimposing the properties of each dielectric. This study used a genetic algorithm (GA) to design RC materials with multilayer layered films. GA is an evolutionary computation in which various parameters evolve toward a desired property using an algorithm miming biological heredity. In GA, emissivity calculation must be repeated many times, and the calculation must be fast. Although the optical properties of a multilayer structure can be obtained rigorously by analytical calculations, the amount of calculation increases as the number of layers increases. Therefore, using analytical calculations to calculate the optical properties of a 9-layer multilayer film is unrealistic, as this study did. Therefore, emissivity was predicted using neural networks (NNs) to speed up the process. NN takes time to prepare the dataset, but it is possible to predict the results quickly once it is prepared [2,3]. As a result, we achieved a speed that was more than 1000 times faster than the usual analytical emissivity calculation in the GA-based design of RC materials for the 9-layer multilayer laminate film.

Abstract: We propose a deep learning (DL) strategy for reconstructing images captured with wide field-of-view (WFOV) metalenses. The DL employs a generative adversarial network (GAN) to correct chromatic aberration and image distortion in metalens imaging. Our image collection setup, combined with GAN model, significantly improves computational fidelity and metalens imaging performance.

1. Introduction

Metalenses offer a compact, flat form factor that enables precise control over wavefronts, positioning them as strong contenders to take over from bulky, traditional optical systems in cameras. [1], [2]. However, the inherent dispersive qualities of metalenses can result in considerable chromatic dispersion in sensor imaging. Designing metalenses with a WFOV poses additional challenges, including image distortion and reduced resolution at the edges.

In this paper, a WFOV metalens optical system utilizing commercial cameras and a deep learning (DL) image reconstruction approach was developed to tackle these issues. We implemented a novel GAN architecture in our DL model to rectify image distortion and recover the original resolution of the image. With this well-tuned network, the restored image's structural similarity (SSIM) increased 10dB on average compared with the raw image.

2. Wide Field-of-View Metalens Design

The general schematic of the designed wide field-of-view metametamelens is shown in Fig. 1. The targeted wavelength of the metalens is 525nm. It is consisted of a spacer, an adhesive layer, and a substrate (where meta-atoms reside on). Following the design process detailed in [3], the designed metalens can achieve 180-degree field of view with a lens diameter of 7mm, and a F-number of 1.8.

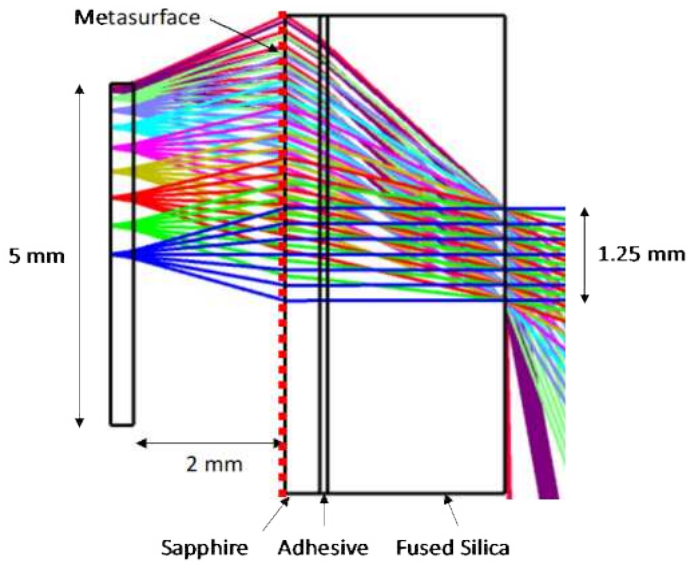

Fig. 1. General schematic of the designed metalens with 180-degree field-of-view.

3. MetaLens Imaging Reconstruction

To reconstruct the image, we designed our model based on the MIRUnet [4] model. In addition to the original model, a VGG-style discriminator was added to enhance image detail and suppress distortion. The detailed training data collection process is shown in Fig. 1a and the structure of MIRGAN is shown in Fig. 1b.

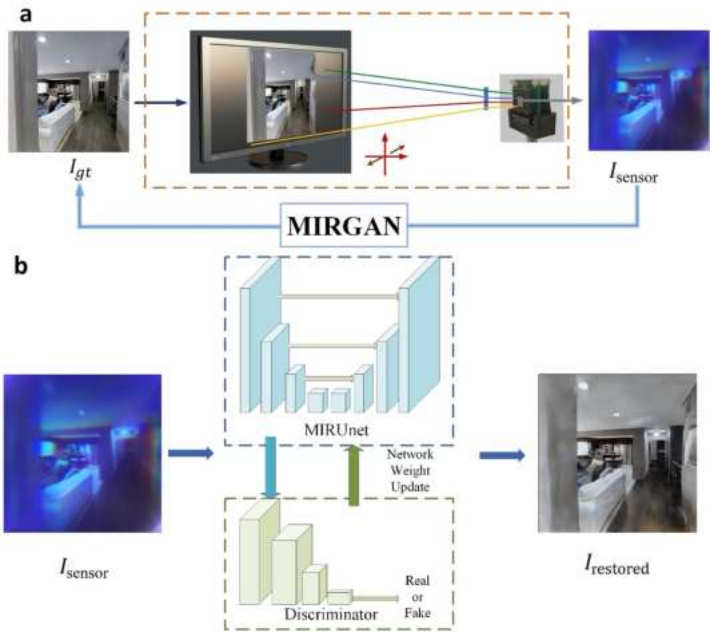

Fig. 2. (a) The training data collection setup: The experiment involves displaying the ground truth image (I_{gt}) on an LCD screen and then capturing it with a commercial camera equipped with a metalens (I_{sensor}). (b) Overview of MIRGAN: The structure of MIRGAN consists of the MIRUnet serving as the DL model generator and a VGG-style network acting as the discriminator.

Once fully trained, our DL model is capable of removing chromatic dispersion and geometric distortion in WFOV metalens imaging, while maintaining fine textures. Examples are shown in Fig. 2.

Fig. 3. Examples of image reconstruction using the proposed network.

Free-Form Inverse Design Driven by Machine Learning

Timo Gahlmann and Philippe Tassin

Department of Physics, Chalmers University of Technology, 41296 Göteborg, Sweden

Abstract: We present an overview of our work on free-form inverse design of nanophotonic devices. We have developed a CGAN network that can provide lithographic masks for a meta-atom with desired transmission and reflection properties. We show examples of metasurfaces with refractive properties and even with meta-atoms with interdependent properties.

We will present a machine-learning approach to the inverse design of nanophotonic devices, i.e., optical devices with subwavelength patterning. Such devices allow us to control light at unprecedented levels, resulting in nontrivial scattering response, e.g., for holograms and retroreflectors. A nanophotonic device often consists of an array of scattering elements, each of which needs to have a specific transmission (or reflection) amplitude and phase. The challenge is, then, to find the shape and materials of meta-atoms with the desired scattering response. This engineering problem is called inverse design.

In this contribution, we will discuss a machine-learning approach [1,2] to inverse design. Our approach is based on a conditional generative adversarial network, as a way addressing the one-to-many problem in inverse design [3]. We discuss a range of machine-learning techniques that we have tested, including the use of expert models, noise in the input channels of the discriminator, and data augmentation, and how their use can—or cannot—improve or speed up neural networks for inverse design [4]. We will provide guidance for best practice and an overview of techniques that work.

Neural networks provide the big advantage that they can quickly generate a design for a meta-atom with desired transmission amplitude and phase once they are trained. The training of the neural networks still requires a large number of simulations of the nanophotonic device (with different geometries) to be used as training data, but they can be run in parallel on high-performance computer clusters. We will compare their time complexity with physics-informed gradient-descent topological optimization and conclude that machine learning is useful for systems described by large simulation models and/or when many similar designs need to be generated.

Finally, we will illustrate our machine-learning approach with several examples.

We acknowledge support from Chalmers' Excellence Initiative Nano and from the Swedish Research Council under Grant No. 2020-05284. The training data generation and ANN training were performed on resources provided by the Swedish National Infrastructure for Computing (NAISS), at the Chalmers/C3SE and KTH/PDC sites, partially funded by the Swedish Research Council under Grant No. 2022-06725.

Do we need machine learning to predict wave scattering in metasurface-programmable unknown complex media?

Philipp del Hougne[1]

[1]Author Affiliation, Country
[*]corresponding author: philipp.del-hougne@univ-rennes.fr

Abstract: I discuss recent results on physics-compliant modeling of metasurface-programmable complex media, the estimation of these models' parameters (and associated ambiguities), and the relation of this area to optimal blind focusing on perturbation-inducing targets inside complex media. Physics-compliant models present 10X advantages over deep learning because of their naturally built-in constraints.

Across scales and wave phenomena, the massive tunability of complex scattering systems with programmable metasurfaces is emerging to tailor wave-matter interactions. The most prominent example are currently so-called smart radio environments. Solving the inverse-design problem of how to configure the metasurface for a desired functionality would strongly benefit from an accurate forward model. Given the unknown and overwhelmingly complex nature of the complex medium, a wide-spread belief is that only deep learning could approximate the forward mapping from metasurface configuration to scattered fields.

In this talk, I will discuss various principled learning-free approaches to the problem that rely on physics-compliant models and suitable parameter estimation. Compared to deep-learning benchmarks, these physics-compliant models present multiple 10X advantages [1]:

- Orders of magnitude better accuracy
- Orders of magnitude fewer parameters
- Orders of magnitude fewer required calibration examples

Moreover, the scaling of these performance indicators with the number of considered scattering coefficients is favorable. Most importantly, unlike physics-agnostic deep-learning approaches, physics-compliant models have naturally built-in constraints that enable the retrieval of the parameters under very frugal conditions, e.g., without ever measuring phase. This unlocks regimes of wave control that are – to the best of my knowledge – inaccessible with any other approaches, such as coherent control of metasurface-programmable complex media without ever measuring phase.

I will share recent results on parameter estimation of such physics-compliant models of metasurface-parametrized complex media [1], [2], and discuss the role of ambiguities in the parameter values.

Moreover, I will discuss other insights that can be derived from such models for seemingly unrelated problems, such as the optimal focusing of waves on a perturbation-inducing target inside a complex medium [3].

Finally, I will point out some areas for future work for which I do believe that deep learning may be necessary, notably in the context of dynamic complex media [4].

Abstract: Deep neural network can capture the highly nonlinear, complex relationship between nanostructure geometry and its optical properties, and proves accurate inverse design of near-field enhancement, far-field spectrum and phase changes etc, which can be helpful for exploring subtle, complex multifunctional nanophotonics for sensing and energy conversion applications.

The electromagnetic response of nanophotonics is highly sensitive to their geometric parameters. In multi-dimensional parameter space, conventional full-wave simulation and numerical optimization can consume significant computation time and resources. It is also highly challenging to find the globally optimized result and perform inverse design for highly nonlinear data structure. In this talk, we demonstrate that deep neural network can capture the highly nonlinear, complex relationship between nanostructure geometry and its near- and far- field properties. Our deep learning approach proves accurate inverse design of near-field enhancement, far-field spectrum and phase changes etc, which can be helpful for exploring subtle, complex multifunctional nanophotonics for sensing and energy conversion applications (Figure 1a-d). We will also discuss the combined nanoimprinting lithography and reactive ion etching method to form large-area, low-cost nanophotonic devices and their facile optical sensing applications (Figure 1e,f).

The lateral geometry and material property of plasmonic nanostructures are critical parameters to tailor their optical resonance for sensing applications. While lateral geometry can be easily observed by scanning electron microscope or atomic force microscope, characterizing materials property of plasmonic device is not straightforward and requires delicate examination of material composition, cross-sectional thickness and refractive index. In this study, deep neural network is adopted to characterize these parameters of unknown plasmonic nanostructures through simple transmission spectra. The network architecture is established based on simulated data to achieve accurate identification of both geometric and material parameters. We then demonstrate the network training by a mixture of simulated and experimental data can result correct material property recognition. Our work may indicate a simple and intelligent characterization approach of plasmonic nanostructures by spectroscopic techniques (Figure 1g,h).

Abstract: Optical-nanoresonator arrays with a large scale or varying arrangement have important applications such as metasurfaces or optical-force manipulations, but their electromagnetic modeling using traditional full-wave numerical methods requires huge computational amount with poor physical intuitiveness. Here we report a coupling theory of quasinormal mode (QNM) to address such challenges.

Optical-nanoresonator arrays can simultaneously support localized resonance and mutual coupling between resonators, and have important applications such as periodic arrays supporting surface lattice resonance or non-periodic arrays forming metasurfaces [1]. For electromagnetic modeling of optical-nanoresonator arrays with a large scale (from tens to thousands of wavelengths) or varying arrangement (such as in the inverse design or optical-force manipulation), traditional full-wave numerical methods (such as finite element method) suffer from a huge computational load and poor physical intuitiveness. The recently developed coupling theories of QNM [2,3] could provide a recipe but still have limitations in rigorousness and application scope.

Here we report a QNM coupling theory for an efficient and intuitive modeling of optical-nanoresonator arrays with a large scale or varying arrangement [4-6]. In the theory [4], the scattered field $\mathbf{\Psi}^s(\mathbf{r},\omega)=[\mathbf{E}^s,\mathbf{H}^s]$ for P coupled nanoresonators is expressed as a superposition of the scattered fields of each individual resonator, $\mathbf{\Psi}^s(\mathbf{r},\omega)=\Sigma_{p=1}^{P}\mathbf{\Psi}_p^s(\mathbf{r},\omega)$, where ω denotes the excitation angular frequency. The scattered field $\mathbf{\Psi}_p^s$ of the p-th resonator is expanded upon the basis of its QNM field $\tilde{\mathbf{\Psi}}_{p,m}(\mathbf{r})=[\tilde{\mathbf{E}}_{p,m},\tilde{\mathbf{H}}_{p,m}]$,

$$\mathbf{\Psi}_p^s(\mathbf{r},\omega)=\sum_{m=1}^{M_p}\alpha_{p,m}(\omega)\tilde{\mathbf{\Psi}}_{p,m}(\mathbf{r}). \tag{1}$$

After obtaining the QNMs by solving the source-free Maxwell's equations, the QNM expansion coefficients $\alpha_{p,m}(\omega)$ in Eq. (1) can be determined by solving the following set of linear equations,

$$[\omega\mathbf{I}-\mathbf{K}(\omega)]\mathbf{a}(\omega)=\mathbf{b}(\omega). \tag{2}$$

In Eq. (2), $\mathbf{a}$ is a column vector with its (p,m)-th element being $\alpha_{p,m}$, $\mathbf{I}$ is the identity matrix, $\mathbf{K}$ is a matrix with its (p,m)-row and (q,n)-column element $\kappa_{(p,m),(q,n)}$ describing the coupling between the QNMs $\tilde{\mathbf{\Psi}}_{p,m}$ and $\tilde{\mathbf{\Psi}}_{q,n}$, and $\mathbf{b}$ is a column vector with its (p,m)-th element $\beta_{p,m}$ describing the excitation of $\tilde{\mathbf{\Psi}}_{p,m}$ by the background field $\mathbf{\Psi}^b$ as the excitation source. The total field is obtained as $\mathbf{\Psi}=\mathbf{\Psi}^s+\mathbf{\Psi}^b$.

For modeling optical-nanoresonator arrays with varying arrangement (i.e., varying relative positions or number of resonators), one can reuse the already solved QNMs of each individual resonator and only needs to recalculate the $\mathbf{K}$ and $\mathbf{b}$ and then solve Eq. (2), which requires much less computational amount than repeatedly

solving the Maxwell's equations of the array as done by traditional full-wave numerical methods. Such advantages can be shown in the calculation of optical force of multiple nanoparticles [5].

For modeling optical-nanoresonator arrays with a large scale, the QNM-coupling theory suffers from the far-field divergence of QNMs [2-4]. To address the issue, in the near-field region, far-field region, and their inbetween transition region, we propose to use the QNM field, the plane-wave expansion calculated by stationary-phase principle, and the scattered-field reconstruction, respectively, to achieve an accurate and efficient calculation of regularized QNM, which has no far-field divergence and are then used to replace the QNMs in Eqs. (1) and (2) [6]. Figure 1(b) shows that our theory can achieve an efficient modeling of optical-nanoresonator arrays with an overall size exceeding 50×50 wavelengths, which is challenging if using traditional full-wave numerical methods.

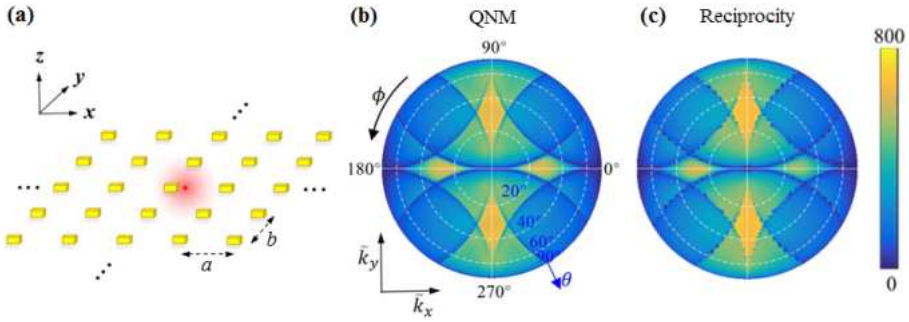

Fig. 1. (a) A periodic array of gold single-nanowire antennas in air (period a=b=1125 nm) excited by an x-polarized electric-current point source (red dot) of wavelength 1127 nm. Each antenna has a length 247 nm and a square cross-section of side length 40 nm. The source is located 20 nm away from the center of the right surface of the central antenna. (b) For an array size of 51×51, the far-field radiation-intensity angular distribution $P(\tilde{k}_x,\tilde{k}_y)$ calculated by the QNM-coupling theory (θ and ϕ being polar and azimuthal angles). (c) For an infinite periodic array, $P(\tilde{k}_x,\tilde{k}_y)$ calculated by the reciprocity method that relies on a full-wave Fourier modal method.

Disentangling Absorption and Radiation Decay in Optical Nanoresonators

K. Koshelev[1*]

Abstract: We derive exact expressions for the radiative and absorption decay rates of an individual quasi-normal mode of an optical resonator composed of highly dispersive and dissipative media, extending the time-averaged energy conservation theorem beyond the regime of weak losses. We confirm the theory with calculations for exactly solvable resonator geometries.

Optical resonators play an essential role in current developments in optics from optical metamaterials and integrated photonic circuits to sensing and strong light-matter coupling. In nanophotonics, optical resonators represent non-conservative systems with the radiative and non-radiative decay pathways, which complicates their mathematical description due to the non-applicability of standard Hermitian approaches. Recent studies outlined that quasi-normal modes (QNMs) represent the most natural way of description of such open resonators [1]. In the last years, there has been a substantial progress in resolving mathematical difficulties with the QNMs, including their normalization and spectrum incompleteness outside of the resonator volume for complex geometries [2].

The mode decay rate governs a variety of light-matter interaction effects in photonic structures, including spontaneous emission rate, Raman and nonlinear response enhancement, and lasing threshold value. For dispersive and absorptive photonic structures, the separation of decay rate into radiative and non-radiative contributions is of special importance, as their ratio could be detrimental for critical coupling, Purcell factor, or optical harmonic generation. To date, studies reporting on an accurate separation of radiative and non-radiative contributions are limited to complex multimodal approaches [3, 4] or weakly dispersive and weakly dissipative systems [5].

In this work, we derive the exact expression for the radiative and non-radiative decay rates for an individual QNM mode of a non-magnetic optical resonator with an arbitrary magnitude of permittivity dispersion and absorption, including highly dispersive and dissipative media, as schematically shown in Fig. 1(a).

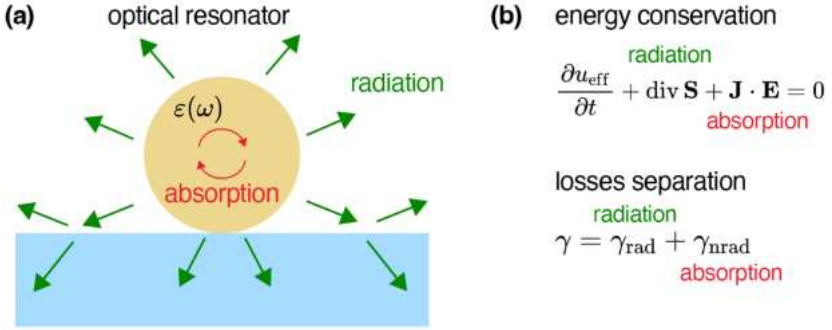

Figure 1. (a) Schematic of an optical resonator with permittivity dispersion and absorption losses. (b) Energy conservation theorem and exact decay rate separation into two independent pathways.

Using the divergence theorem, we show that for some m-th QNM mode with the complex frequency $\Omega_m = \omega_m - i\gamma_m$, an analogue of time-averaged energy conservation theorem can be written as [see Fig. 1(b)],

$$-\frac{\gamma_m}{8\pi}\int dV\left(\mathrm{R}_{\gamma_\mathrm{m}}[\varepsilon(\Omega_m)]|\mathbf{E}_m|^2 + |\mathbf{H}_m|^2\right) + \frac{c}{8\pi}\oint d\mathbf{S}\cdot\mathrm{Re}[\mathbf{E}_m\times\mathbf{H}_m^*] + \frac{\omega_m}{8\pi}\int dV\ \mathrm{I}_{\gamma_\mathrm{m}}[\varepsilon(\Omega_m)]|\mathbf{E}_m|^2 = 0. \quad (1)$$

Here, the permittivity is an analytic function in the complex frequency plane, evaluated at complex Ω_m, $\mathbf{E}_m$ and $\mathbf{H}_m$ are the electric and magnetic field of the QNM mode, and $\mathrm{R}_{\gamma_\mathrm{m}}[f(\Omega_m)]$ and $\mathrm{I}_{\gamma_\mathrm{m}}[f(\Omega_m)]$ are given by,

$$\mathrm{R}_{\gamma_\mathrm{m}}[f(\Omega_m)] = -\,\mathrm{Im}[\Omega_m f(\Omega_m) - \Omega_m^* f(\Omega_m^*)]\,/(2\gamma_m), \tag{2}$$

$$\mathrm{I}_{\gamma_\mathrm{m}}[f(\Omega_m)] = \mathrm{Im}\,[\Omega_m f(\Omega_m) + \Omega_m^* f(\Omega_m^*)]/(2\omega_m)\,. \tag{3}$$

We show that such definition of operators $\mathrm{R}_{\gamma_\mathrm{m}}[f(\Omega_m)]$ and $\mathrm{I}_{\gamma_\mathrm{m}}[f(\Omega_m)]$ allows to assign a specific physical meaning to the terms in Eq. (1), following the procedure in [5]. The left term corresponds to the total energy decay of the mode, the central term describes the mode energy transfer due to the radiative losses, and the right term represents mode ohmic losses; all terms averaged over the period $2\pi/\omega_m$. This can be confirmed by calculating the Taylor series of Eqs. (2,3) around the real frequency ω_m. The first two terms of expansion are given by,

$$\mathrm{R}_{\gamma_\mathrm{m}}[\varepsilon(\Omega_m)] = \frac{\partial}{\partial\omega_m}(\omega_m \mathrm{Re}\,[\varepsilon(\omega_m)]) - \frac{\gamma_m^2}{6}\frac{\partial^3}{\partial\omega_m^3}(\omega_m \mathrm{Re}\,[\varepsilon(\omega_m)]) + O\left[\left(\frac{\gamma_m}{\omega_m}\right)^4\right], \tag{5}$$

$$\mathrm{I}_{\gamma_\mathrm{m}}[\varepsilon(\Omega_m)] = \mathrm{Im}\,[\varepsilon(\omega_m)] - \frac{\gamma_m^2}{2\omega_m}\frac{\partial^2}{\partial\omega_m^2}(\omega_m \mathrm{Im}\,[\varepsilon(\omega_m)]) + O\left[\left(\frac{\gamma_m}{\omega_m}\right)^4\right]. \tag{6}$$

One can see that $\mathrm{R}_{\gamma_\mathrm{m}}[f]$ and $\mathrm{I}_{\gamma_\mathrm{m}}[f]$ generalize $\mathrm{Re}[f]$ and $\mathrm{Im}[f]$ for dispersive systems.

We apply the developed approach to resonators composed of materials that can be described with the generalized Drude-Lorentz form of permittivity and derive the exact form of $\mathrm{R}_{\gamma_\mathrm{m}}[\varepsilon(\Omega_m)]$ and $\mathrm{I}_{\gamma_\mathrm{m}}[\varepsilon(\Omega_m)]$. For the simplest case of Drude material with $\varepsilon(\omega) = \varepsilon_\infty - \omega_p^2/(w(w + i\gamma_0))$, we obtain the following expressions,

$$\mathrm{R}_{\gamma_\mathrm{m}}[\varepsilon(\Omega_m)] = \varepsilon_\infty + \frac{\omega_p^2(\omega_m^2+\gamma_m^2-\gamma_0^2)}{(\omega_m^2+\gamma_m^2-\gamma_0^2)^2+4\gamma_0^2\omega_m^2}, \tag{7}$$

$$\mathrm{I}_{\gamma_\mathrm{m}}[\varepsilon(\Omega_m)] = \frac{\gamma_0}{\omega_m}\frac{\omega_p^2(\omega_m^2-\gamma_m^2+\gamma_0^2)}{(\omega_m^2+\gamma_m^2-\gamma_0^2)^2+4\gamma_0^2\omega_m^2}. \tag{8}$$

Equations (7,8) show explicitly that only $\mathrm{I}_{\gamma_\mathrm{m}}$ is proportional to the non-radiative damping rate γ_0, as expected.

We further utilize the developed approach to calculate the exact values of radiative and non-radiative losses and their ratio for exactly solvable models, including a one-dimensional slab and three-dimensional spherical resonator. As an example, for the slab we show that in the limit of weak material dispersion and dissipation, the expressions for the radiative and non-radiative Q factor are reduced to $Q_{m,\mathrm{rad}} = (\pi m + \phi_r)/(2\ln[1/|r|])$ and $Q_{m,\mathrm{nrad}} = n/(2k)$, where n and k are the refractive index and extinction coefficient of the slab material, and $|r| = \sqrt{1-(4n)/(k^2+(1+n)^2)}$ is the slab material reflection coefficient with the reflection phase $\phi_r = \mathrm{atan}(-2k/(n^2+k^2-1))$. We believe our approach provides a novel platform for resonant nanophotonics.

Abstract: We develop a general approach for modelling the spontaneous parametric down conversion in both infinite periodic and finite aperiodic metasurfaces via the quasi-normal modes. It is employed to investigate an aperiodic guided-mode-cavity metasurface and a periodic flatband metasurface, both show enhanced photon-pair generation with controllable two-photon states.

Metasurface comprising by artificial planar arrangement of nanostructures has recently drawn an increasing attention for the development of ultrathin quantum light sources through the spontaneous parametric down conversion (SPDC). By leveraging optical resonances in nanostructures, metasurfaces can boost the SPDC efficiency as well as engineer the generated two-photon states. However, modelling the complex and quantum SPDC process in different nanostructures has been a difficulty, preventing the tunability and versatility of metasurface SPDC sources. Recently, coupled mode theory and quasi-normal mode (QNM) theory have been applied for analyzing the SPDC in periodic metasurfaces [1] and single nanoantennaes [2], respectively. Here, we present a general approach to study the SPDC in both infinite periodic and finite aperiodic metasurfaces through the QNMs supported in the metasurfaces. Based on that, an aperiodic guided-mode-cavity metasurface and a periodic flatband metasurface are proposed and analyzed for photon pair generations. The results obtained by the proposed approach show excellent match with the ones obtained by the coupled mode theory.

Figure 1a shows the proposed aperiodic lithium niobate metasurface featuring a guided-mode cavity formed by two distributed Bragg reflectors sandwiching a truncated central grating. By optimizing the dimension of the cavity to match its resonance wavelength with the center grating, we obtained a QNM with a strong field confinement (Fig. 1b) and a high quality factor close to 1000. With the developed QNM approach, we theoretically study the SPDC process in the proposed metasurface, which predicts a SPDC rate up to 157 Hz/mW (Fig. 1c). This represents about 30 times enhancement of SPDC for a focused pump beam when compared to the previous periodic metasurface without a cavity, despite being half the transverse size.

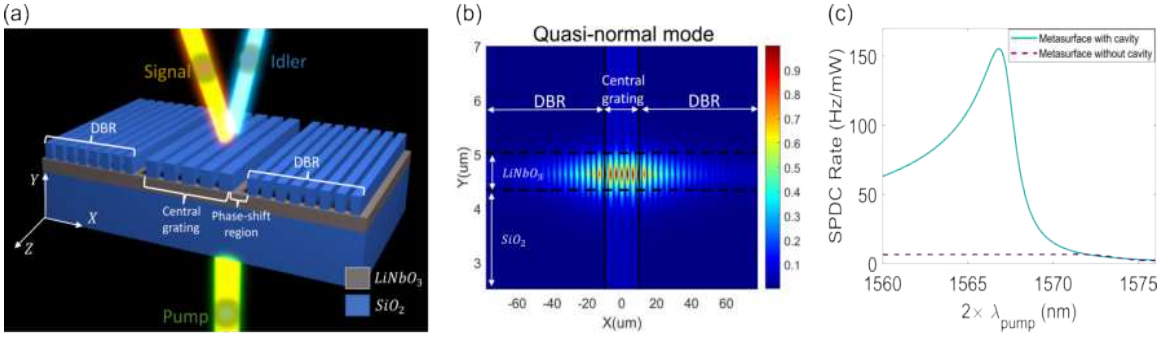

Figure 1. (a) Photon pair generation from a lithium niobate metasurface with a guided-mode cavity. (b) Electric field magnitude distribution of the dominant quasi-normal mode. (c) Simulated SPDC rate as a function of the pump wavelength.

Figure 2a depicts a flatband lithium niobate metasurface for a broad-angle SPDC source. By engineering the coupling between two QNMs with different natures, a nearly flatband dispersion is achieved within the angular range between -0.2 rad/μm and 0.2 rad/μm (Fig. 2b). When pumping for a degenerate SPDC wavelength near this resonant wavelength, the simulation suggests that photon pairs are uniformly emitted within a 6° field of view with a total emission rate up to 539 Hz/mW (Fig. 2c).

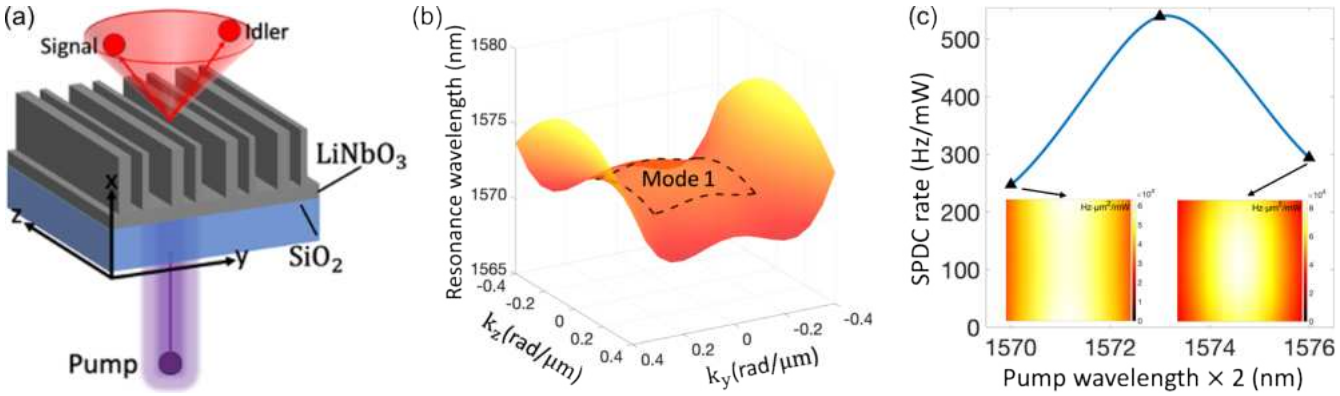

Figure 2. (a) Photon pair generation from a flatband lithium niobate metasurface. (b) Angular dispersion of the dominant quasi-normal mode. (c) Simulated SPDC rate as a function of the pump wavelength. Insets show two broad-angle emission patterns.

It is noteworthy that the QNM approach presented in this work is general to any nonlinear materials and any nanostructures. We anticipate that it will facilitate the investigation of flat-optics photon-pair sources with desired properties.

Anomalous acoustic tunneling effect with non-Hermitian Willis coupling

Danwei Liao[1], **Xinhua Wen**[1], **Xinghong Zhu**[1], **and Jensen Li**[1*]

[1]Department of Physics, The Hong Kong University of Science and Technology, Kowloon, Hong Kong, China.
[*]corresponding author: jensenli@ust.hk

Abstract: We extend anomalous tunneling phenomenon observed in reciprocal electromagnetic metamaterials to acoustic metamaterials via bianisotropy and Willis coupling, covering nonreciprocal regime. Digitally virtualized atoms are employed to generate the required non-Hermitian Willis coupling, which leads to decaying fields for both acoustic pressure and velocity within metamaterial.

Bianisotropy coupling the magnetic and the electric responses in EM wave as a key factor in creating Huygens metasurfaces, chiral metasurfaces, and nonreciprocal metasurfaces [1], has been used to perform optical tunneling due to its potential application value in optical filters, switches, and sensors. Anomalous tunneling effect, consisting of evanescent fields with opposite trends given by bianisotropy among multilayer metamaterials [2], can be extended to acoustics by introducing bianisotropy through coupling between sound pressure and velocity. This concept, also known as the Willis coupling, has been experimentally possible using acoustic metamaterials in airborne sound and elastics [3,4]. To supplement the current mechanism of classical tunneling effect, our work extends the condition of anomalous tunneling to include not only reciprocal but also nonreciprocal bianisotropy. By implementing nonreciprocal Willis coupling using programmable metamaterials through active atoms with a digital feedback circuit [5], anomalous acoustic tunneling effect is realized with both pressure and velocity decay to a minimal value in the middle of the device, while the decay ratio remains exponentially related to the size of bianisotropy and thickness of the effective media.

Here, we implement anomalous acoustic tunneling in a one-dimensional (1D) waveguide as two stacked layers with same length but opposite Willis coupling terms, by adjusting the constitutive matrix to obtain the decayed field in the middle while ideally total transmission for the whole device. The wave equation for the 1D acoustic system in an effective medium representation can be written as the following form under $e^{-i\omega t}$ convention

$$\partial_x \begin{pmatrix} v \\ p \end{pmatrix} = \frac{i\omega}{c} \begin{pmatrix} \beta & i\tau \\ i\tau' & \rho \end{pmatrix} \begin{pmatrix} p \\ v \end{pmatrix}, \tag{1}$$

where p is the pressure, v is the velocity multiplied by the acoustic impedance of the air, c is the sound speed in the air, β and ρ are the dimensionless compressibility and density, $\tau = -\tau_{\mathrm{r}} + \tau_{\mathrm{nr}}$ and $\tau' = \tau_{\mathrm{r}} + \tau_{\mathrm{nr}}$ represent the combination of reciprocal and nonreciprocal Willis couplings, respectively. As indicated in the schematic of the stacked layers in Fig. 1(a), for the left layer (green region) with width L from $x = 0$ to $x = L$, the Wills coupling is set as $\tau = -\tau_{\mathrm{r}} + \tau_{\mathrm{nr}}$, and the right layer (blue region) from $x = L$ to $x = 2L$ shares the same width and effective parameters β and ρ, but with flipped Willis coupling term of $-\tau = \tau_{\mathrm{r}} - \tau_{\mathrm{nr}}$. The pressure (purple lines) and velocity (orange lines) field profiles are obtained using the transfer matrix method, with the reciprocal case ($\tau_{\mathrm{r}} = 0.1$, $\tau_{\mathrm{nr}} = 0$, and $\beta = \rho = 0$) exhibiting a dip in the pressure field and a peak for the velocity field with full transmission. For the purely nonreciprocal case ($\tau_{\mathrm{r}} = 0$, $\tau_{\mathrm{nr}} = 0.1$, and $\beta = \rho = 1$), the pressure and velocity fields tunnel through stacked layers in the same trend, with a dip in the connecting interface of the two layers, acting as a fictitious potential barrier.

Based on analytical analysis of the transmittance diagram demonstrating that the purely nonreciprocal situation indicates superior robustness against the disturbance of effective parameters and Willis coupling term, we implement the experimental verification via active metaatoms realizing purely nonreciprocal Willis coupling. As depicted in Fig. 1(b), the effective medium layers in Fig. 1(a) are substituted by metaatoms positioned at the

top border (blue rectangles) of the waveguide with the detailed schematic presented in Fig. 1(c). Each atom consists of a PCB board with two pairs of microphones and speakers, and a microcontroller that can be programmed to do convolutions Y_{ij} $(i,j = 1,2)$ between the microphones and speakers as $S_i = \sum_{j=1,2} Y_{ij} D_j$ in time domain that behaves as secondary source generating specific scattering waves, allowing the realization of arbitrary constitutive parameters [5]. Four microphones (M_1 to M_4) are utilized to extract the scattering coefficients and additional microphone (D_M) in the middle for detecting the decay ratio of the field. Cascading four atoms with opposite sign of nonreciprocal Willis coupling on each side of the waveguide, the anomalous tunneling effect is achieved as indicated in Fig. 1(d), where the total transmission coefficient is approximately uniform and the decay ratio in the middle of the stacked layers could be minimized to rather small ratio.

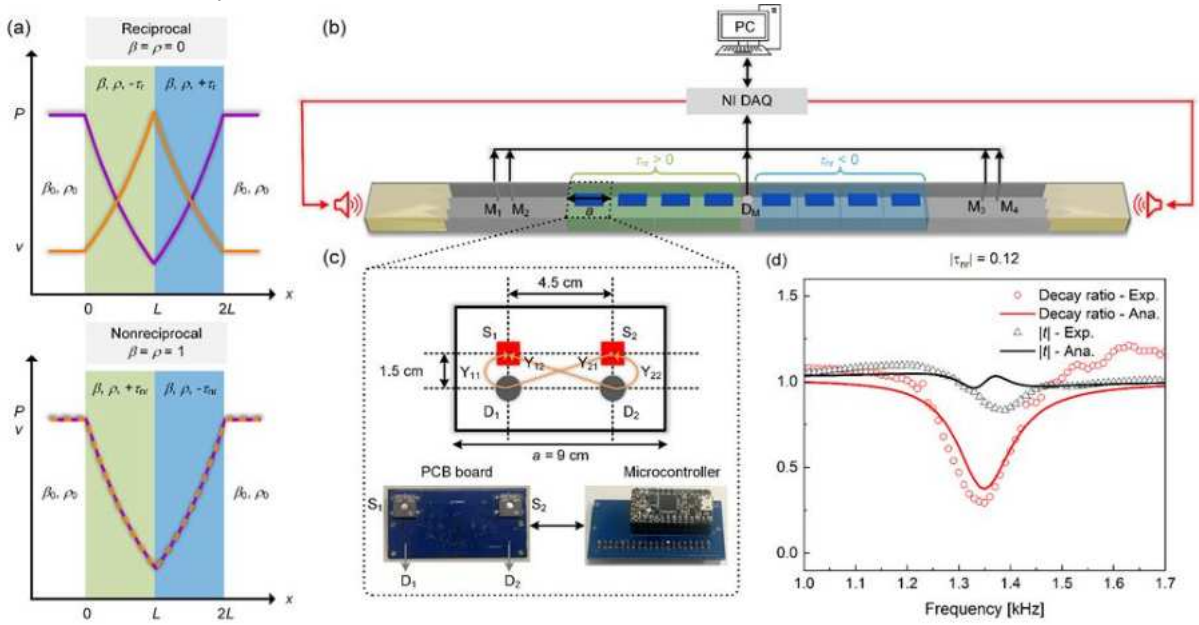

Figure 1. (a) Pressure (purple) and velocity (orange) field profiles for layers with phase elapse $\phi_L = \omega L/c = 8.9$ with purely reciprocal Willis coupling (upper panel) as a comparison to the purely nonreciprocal Willis coupling (lower panel). (b) Experimental setup consists of a 1D waveguide with active atoms. (c) Schematic and photograph of a single atom. (d) Measured (dots) and calculated (lines) results for the transmission coefficient and the decay ratio.

Quasi-normal modes and transmission channels in non-Hermitian disordered media

V. Freilikher

Department of Physics Bar-Ilan University, Israel
freiliv@biu.ac.il

Abstract: A review of quasi-normal modes (QNMs) studies in disordered open systems is presented. The existence of transmission resonances and hidden QNMs in weakly scattering media is demonstrated. The connection between QNMs and diffusive transmission channels is investigated. Algorithms of coherent control of wave transport in randomly scattering media are outlined.

Quasi-normal modes. The notion of QNMs is the natural extension of the classical concept of resonances in impenetrable cavities to open systems, in which stationary states do not exist because of the leakage to the outer space. QNMs can be found as the solutions of the corresponding differential equation with the outgoing boundary conditions. This problem is non-Hermitian, with complex-valued eigenvalues; however the set of the solutions is complete and bi-orthogonal [1], so that any field can be presented as a superposition of the QNMs. This approach is a powerful tool for investigating open systems, that do not conserve energy. QNMs also play an important role in a variety of inverse problems in target identification and non-destructive remote sensing [2]. In "clean" open resonators, quantum dotes and wires, to each QNM there corresponds a peak in the spectrum of the transmission coefficient, so-called transmission resonance (TR), whose frequency is equal to the real part of the QNM's eigenvalue. However, scattering on random fluctuations of material and geometrical parameters, that are ubiquitous in any real medium of propagation, can dramatically change the spectrum and the spatial structures of QNMs. One of the most striking manifestations of disorder is the violation of the one-to-one correspondence between the QNNs and TRs [3]. Due to the interference of multiply scattered fields in weakly disordered systems, some of the QNSs become invisible in transmission (hidden). The averaged ratio N_{res} /N_{mod} of the number of transmission peaks N_{res} to the total amount of QNMs N_{mod}, is a universal quantity, in the sense that it is independent of the physical nature of the random system, and in a given frequency interval is insensitive to the type and degree of disorder. It is close to the value $(2/5)^{1/2}$, which mathematically follows from the general statistical properties of random trigonometric polynomials. In contrast to TRs, the lifetime of a hidden mode (HM) does not rise with increasing fluctuations, rather remains unchanged or even decreases, depending on the strength of the coupling to the leads. The wave functions of HMs are also very unusual. The spatial profiles of their amplitudes are concentrated near one of the edges of the random sample, and exponentially decrease towards the other. As the scattering strength and/or the length of the system increase, HMs eventually become ordinary. Although they appear in the DOS in the same way as the ordinary modes do, HMs are non-conducting, i.e., do not contribute to the total transmission even in the ballistic regime [3].

Transmission channels. During almost a century, the diffusion approach was believed to be an adequate tool sufficient to interpret and explain theoretically the majority of transport phenomena in disordered media.

However, quite recently it became clear that the interference of multiply-scattered fields, which is neglected in the classical diffusion theory, dramatically affects all wave processes in systems with fluctuations. To account for the wave nature of the radiation it is expedient to describe the transport through a given disordered sample by a random transmission matrix (TM), which connects the set of orthogonal modes at the input to that at the output. It turns out that the eigenvectors and eigenvalues of TM, obtained by singular value decomposition bear significant physical meaning: they uniquely determine wave fronts and transmittances of the so-called transmission eigenchannels (TEs). Any incoming wave can be decomposed into a linear superposition of TEs, which propagate independently through the system with the transmittances equal to the corresponding eigenvalues τ. The shape of each channel is given by an eigenvector and is preserved all along the sample, including the output, meaning that signal does not spread in the transverse direction. At the same time, the longitudinal profile of the energy density distribution of TEs is universal [4, 5]. It is given by an analytical formula [4], where the details of the system, such as the geometry and the disorder parameters, enter only into the ratio L/l (L is the distance of propagation, l is the scattering mean free path). The important implication is that TEs can be harnessed to suppress reflection in favor of transmission, and vice versa. This is because the probability distribution of the transmission coefficients is bimodal: it is picked at $\tau = 1$ and $\tau = 0$, corresponding to highly transparent and reflecting channels respectively. The explicit form of this distribution can be the controlled by the reflectivities of the edges [6]. The adaptive wave front shaping technique and the on-chip coupling scheme enable access to all input modes. By selectively coupling the incident wave to the open or closed channels, it is possible not only vary the delivery of energy to the receiver, but also change its spatial density distribution inside the system [7]. Recently, original algorithms of output control by input front shaping in multimode fibers have been developed [8, 9].

Abstract: Exceptional points are singularities of open systems, where eigenvalues and eigenvectors coalesce. They are being intensively studied in photonics, owing to their strong sensitivity to perturbations. However, most works are restricted to wavelength-scale structures. Here, we present rigorous criteria for the design of exceptional points in a single dielectric nanoparticle.

Open optical systems, i.e. systems interacting with an environment, are ubiquitous in nature. One of their most remarkable features is their ability to host spectral singularities where both eigenvalues and eigenvectors coalesce, known as exceptional points (EPs)[1]. While conventional eigenmodes shift linearly with a perturbation ϵ, at an nth-order EP, the shift is proportional to $\epsilon^{1/n}$, where n is the number of coalescing eigenmodes. This peculiarity renders EPs highly attractive for many applications, including biosensing schemes relying on resonance tracking [1]. This has triggered significant efforts for the realization of EPs at smaller scales, aiming at the detection of smaller analyte concentrations. However, the vast majority of studies are restricted to wavelength-scale systems based on waveguides, plasmonic metasurfaces and/or microresonators [1], [2].

Recently, all-dielectric nanoparticles have been shown to be a promising platform for applications in nanophotonics, owing to their negligible ohmic losses [3], [4]. Interestingly, a single dielectric nanoparticle can support a broad class of electric and magnetic resonances, giving rise to several exotic effects [3].

In this contribution, we will derive rigorous rules for the realization of EPs in a single dielectric nanoparticle in the visible range, successfully introducing EP physics to all-dielectric nanophotonics. We demonstrate that EPs are achievable through simple geometry tuning, making them possible in a broad class of dielectric materials, including silicon [5]. To demonstrate their existence, here we consider their formation from the electric (ED) and magnetic dipole (MD) eigenmodes of a nanocylinder with refractive index close to that of silicon (**Fig. 1a**).

Suppose that we perform a small perturbation in the shape of such particle. In particular, the perturbation must break the horizontal mirror symmetry, allowing the even and odd eigenmodes to hybridize (**Fig. 1a**, lower panel). We consider introducing a small conicity. Then, the eigenmodes of the perturbed particle (Modes 1,2 in **Fig.1b**) can be expressed as a linear combination of the original ones. Using the resonant state expansion method [6], this yields a generalized eigenvalue problem for the new eigenmodes. The hybrid magnetoelectric modes can coalesce at a pair of EPs upon changing two selected system parameters, the bottom radius and the conicity (**Fig. 1b**). Owing to the collapse of the eigenspace, the norms of the eigenmodes become the same and tend to zero at the EP (**Fig. 1c**). This poses interesting questions on the completeness of the eigenmode basis, which will be discussed.

We propose to utilize the new EPs to detect small local changes in the refractive index of the surrounding environment (**Fig.1d**). Specifically, we observe a larger spectral sensitivity of the frequency detuning in

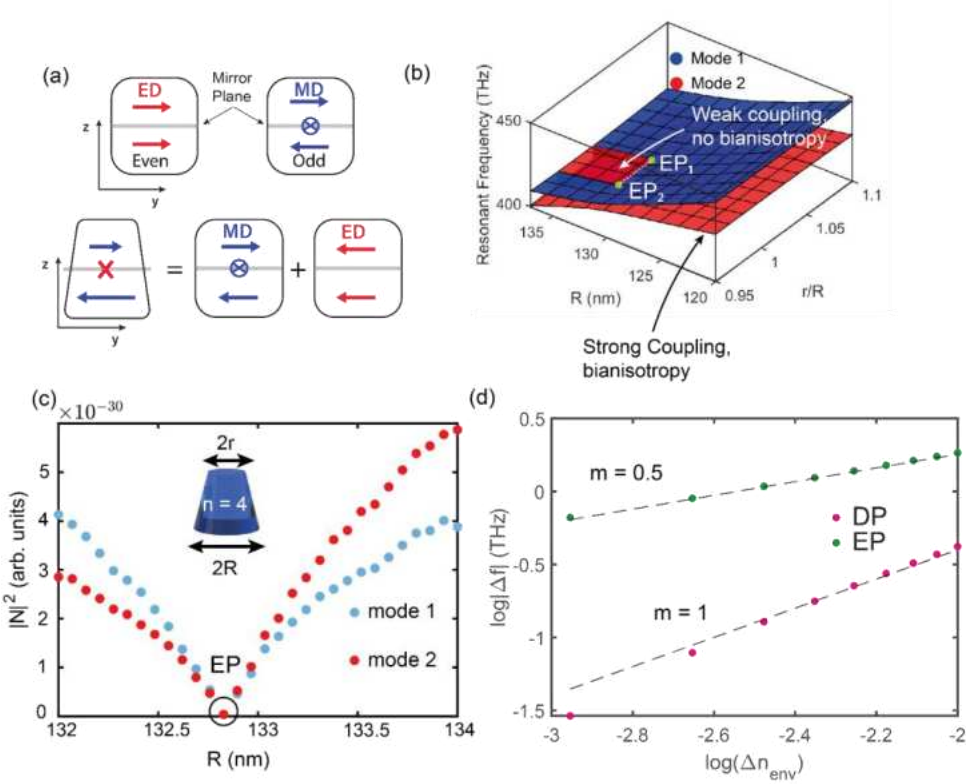

Figure 1. (a) Top: Scheme of the ED and MD modes of a dielectric nanocylinder with respect to a horizontal mirror plane. Bottom: effect of mirror symmetry breaking in the MD mode. (b) Evolution of the resonance frequencies of the single nanoparticle vs. bottom radius and the ratio of top to bottom radius. (c) Norm of the involved resonant states in the vicinity of the EP, for r/R = 0.972. Inset: investigated nanoparticle, with refractive index n=4. (d) Sensitivity of the investigated EP to changes in the environment refractive index, vs the ED and MD modes of the unperturbed nanoparticle (DP). Height: 100 nm.

comparison to the unperturbed eigenmodes of the nanocylinder, owing to the square-root asymptotic near the EP. This is clearly confirmed by a log-log plot of the detuning vs refractive index change, showing a slope of 1/2.

In conclusion, we have demonstrated that EPs can be achieved in single dielectric nanoparticles, paving the way for exciting applications and uncharted effects in all-dielectric nanophotonics.

Photonics of topological transitions Disk - Ring - Split Ring

Abstract: The chain of topological transitions disk – ring – split ring with a gradual change in structural parameters has been studied. We demonstrate that transitions between structures of different topologies are accompanied by impressive photonic effects.

This work consists of two parts connected by a common intermediate structure - a dielectric ring resonator of rectangular cross-section. The first part refers to the topological transition from a dielectric disk to a ring by introducing a coaxial hole. We carried out experimental and theoretical studies of the transformation of resonant scattering spectra, photonic eigenmodes and electromagnetic field distribution patterns with a gradual increase in the coaxial hole in the disk from zero to the ratio of the internal and external radii of 0.5. The hot spot at the center of the resonator flashes brightly immediately after the hole is formed, and then quickly decreases as the hole radius increases.

The hot spot can be explained using 2D Mie theory for an infinite dielectric cylinder with a coaxial hole, followed by a finite length case and numerical analysis using COMSOL Multiphysics. Considering the case of TE polarization for a ring resonator of infinite height, it is possible to express the radial and azimuthal components of the electric field in terms of the azimuthal number *m* and the Lorentz-Mie coefficients, which, in turn, are expressed in terms of Bessel functions. As is known, only the zero-order Bessel function J_0 is equal to unity at the center of coordinates ($r = 0$), and the remaining Bessel functions vanish, so we obtain that only the first azimuthal harmonic (corresponding to the electric dipole) has a local maximum at the center, generating a hot spot when a small hole is formed. Numerical calculations show that the hot spot goes out very quickly and disappears already at the ratio $R_{in}/R_{out} \sim 0.001$. Thus, a hot spot can be considered a hallmark of a dielectric disc $\rightarrow$ dielectric ring topological transition.

The second part of the work concerns the study of the topological transition from a dielectric ring of rectangular cross-section to a split ring [1]. As is known, the scattering spectra of a dielectric ring resonator are determined by a set of doubly degenerate CW and CCW modes and have a pronounced resonant character [2-4]. An important feature of our approach is that during all transformations of the structure we leave its length constant, changing only the curvature. As a result of theoretical and experimental studies, we discovered that at the transition the degeneracy of the CW-CCW ring modes is removed and two families of modes arise. The "ordinary" mode family does not undergo any changes, as do the "curved" strip modes [5,6]. The family of “topological” modes splits off from the “ordinary” modes with a monotonic phase change from 0 to π as the central angle in the split ring increases, reminiscent of the Berry phase in a Möbius strip [5,6]. We were able to establish in detail the unusual mechanism for the emergence of “ordinary” and “topological” modes. It turned out that “ordinary” modes arise when the field zero in the ring is oriented opposite the gap and therefore they practically do not change.

“Topological” modes arise when the antinode of the electric field of the ring mode is oriented towards the gap. In the process of topological transition and “cutting” one antinode into two, an additional phase is gradually added

from 0 to π, and the length of each topological wave monotonically decreases by half a period. Consequently, we obtain a Fabry-Pérot type resonator with an arbitrary resonant wavelength, that is, the resonator length is not a multiple of the resonant wavelength. Moreover, the phase and length of an ordinary wave does not change during the topological transition and can serve as an ideal reference in any research and various applications. Therefore, using a Fabry-Pérot topological resonator with variable curvature and fixed length, it is possible to realize resonant modes with an arbitrary non-integer number of waves, creating a new generation of resonators with unique classical and quantum applications [1].

This work was funded by the Russian Science Foundation (Project No. 23-12-00114).

Response strength of general non-Hermitian systems at exceptional points

Jan Wiersig*

Institut für Physik, Otto-von-Guericke-Universität Magdeburg, D-39016 Magdeburg, Germany
*corresponding author: jan.wiersig@ovgu.de

Abstract: Non-Hermitian systems with exceptional points exhibit a strongly enhanced response to perturbations and excitations. We present the theory of the spectral response strength for the general case where the dimension of the Hilbert space can be larger than the order of the exceptional point.

Exceptional points (EPs) are spectral degeneracies in open wave systems which can produce a number of counterintuitive phenomena with potential applications in particular in optics and photonics [1]. At an EP of order n exactly n eigenvalues (eigenfrequencies) and the related eigenstates (modes) of a non-Hermitian Hamiltonian $\hat{H}_0$ coalesce [2]. When such a Hamiltonian is slightly perturbed, $\hat{H}_0 + \varepsilon\hat{H}_1$, the eigenvalues exhibit a strong spectral response $E_j - E_{\text{EP}} \propto \varepsilon^{1/n}$, where $\varepsilon > 0$ is the perturbation strength. These large splittings can be exploited for sensing applications [3]. For an $m \times m$ Hamiltonian $\hat{H}_0$ it was shown for the special case $m = n$, i.e. the Hilbert-space dimension equals the order of the EP, that the perturbation-induced splitting is bounded from above [4]

$$|E_j - E_{\text{EP}}|^n \le \varepsilon ||\hat{H}_1||_2 \, \xi \, , \tag{1}$$

where $||\cdot||_2$ is the spectral matrix norm, $\xi := ||\hat{N}^{n-1}||_2$ is the spectral response strength, and $\hat{N} := \hat{H}_0 - E_{\text{EP}}\mathbb{1}$ is the traceless part of the unperturbed Hamiltonian. For sensing applications EPs with large ξ are desirable.

For the generic case $m \ge n$ we use the expansion of the $m \times m$ Green's function of the unperturbed Hamiltonian $\hat{H}_0$ [5, 2]

$$\hat{G}(E) = \sum_l \left[\frac{\hat{P}_l}{E - E_l^{(0)}} + \sum_{k=2}^{n_l} \frac{\hat{N}_l^{k-1}}{(E - E_l^{(0)})^k} \right] \, . \tag{2}$$

The integer l labels the considered part of the point spectrum including isolated energy eigenvalues and EPs. The integer k labels additional terms for EPs only. Each operator $\hat{P}_l$ is a projector onto the generalized eigenspace of the eigenvalue $E_l^{(0)}$ with $\hat{P}_j\hat{P}_l = \delta_{jl}\hat{P}_l$ where δ_{jl} is the Kronecker-Delta. The operator $\hat{N}_l$ for a given EP of order n_l is a nilpotent operator of index n_l and defined by

$$\hat{N}_l := \left(\hat{H}_0 - E_l^{(0)}\mathbb{1}\right) \hat{P}_l \, . \tag{3}$$

It holds $\hat{P}_l\hat{N}_l = \hat{N}_l\hat{P}_l = \hat{N}_l$. To describe the situation near an EP of order n_l with eigenvalue $E_l^{(0)} = E_{\text{EP}}$ we consider the leading-order contribution in the Green's function (2)

$$\hat{G}(E) = \frac{\hat{N}_l^{n_l-1}}{(E - E_{\text{EP}})^{n_l}} \, , \tag{4}$$

Our analysis reveals that Eq. (1) is still valid with the spectral response strength

$$\xi = ||\hat{N}_l^{n_l-1}||_2 \, . \tag{5}$$

The right-hand side can be computed by hand in simple cases. In other cases, residue calculus can enable a numerical treatment. From the expansion in Eq. (2) one obtains

$$\hat{N}_l^{n_l-1} = \frac{1}{2\pi i} \oint_C dE \, (E - E_{\text{EP}})^{n_l-1} \hat{G}(E) \, , \tag{6}$$

with C being a simple closed path in the complex energy plane that contains only the eigenvalue E_{EP}. The function $\hat{G}(E)$ is calculated numerically for each energy E by matrix inversion and is integrated in Eq. (6). Finally, the spectral response strength ξ_{num} is numerically determined by Eq. (5).

We demonstrate the efficiency and accuracy of this scheme using the random-matrix approach introduced in Refs. [4, 6]. Consider the $n \times n$ matrix $\hat{H}_0$ having an EP with order n and eigenvalue E_{EP} created via a similarity transformation $\hat{H}_0 =$

$\hat{Q}\hat{J}\hat{Q}^{-1}$, where $\hat{J}$ is an $n \times n$ matrix with an EP of order n in Jordan normal form and $\hat{Q}$ is an $n \times n$ matrix whose elements are complex random numbers with real and imaginary parts being drawn from a uniform distribution on $[-1/2, 1/2]$. We calculate the associated response strength ξ from the former theory [4] for later comparison. Next, we create the $(m-n) \times (m-n)$-matrix $\hat{H}_{\mathrm{a}}$ with its elements to be complex random numbers with real and imaginary parts being drawn from a uniform distribution on $[-1/2, 1/2]$. Finally, we combine these two matrices to obtain the $m \times m$ Hamiltonian

$$\hat{H} = \hat{U} \begin{pmatrix} \hat{H}_0 & 0 \\ 0 & \hat{H}_{\mathrm{a}} \end{pmatrix} \hat{U}^{\dagger} \tag{7}$$

with the random unitary $m \times m$-matrix $\hat{U}$. The resulting Hamiltonian $\hat{H}$ has an EP with the same eigenvalue E_{EP}, the same spectral response strength ξ, and the same order n than the original lower-dimensional Hamiltonian $\hat{H}_0$. The construction of the Hamiltonian $\hat{H}$ in Eq. (7) is illustrated in Fig. 1. Figure 1(a) shows a realization of $\hat{H}$ before the unitary matrix $\hat{U}$ is applied and Fig. 1(b) shows $\hat{H}$ after the unitary transformation. The complex eigenvalues of this Hamiltonian are depicted in Fig. 1(c). It can be seen that the spectrum contains isolated eigenvalues and an EP of order 4.

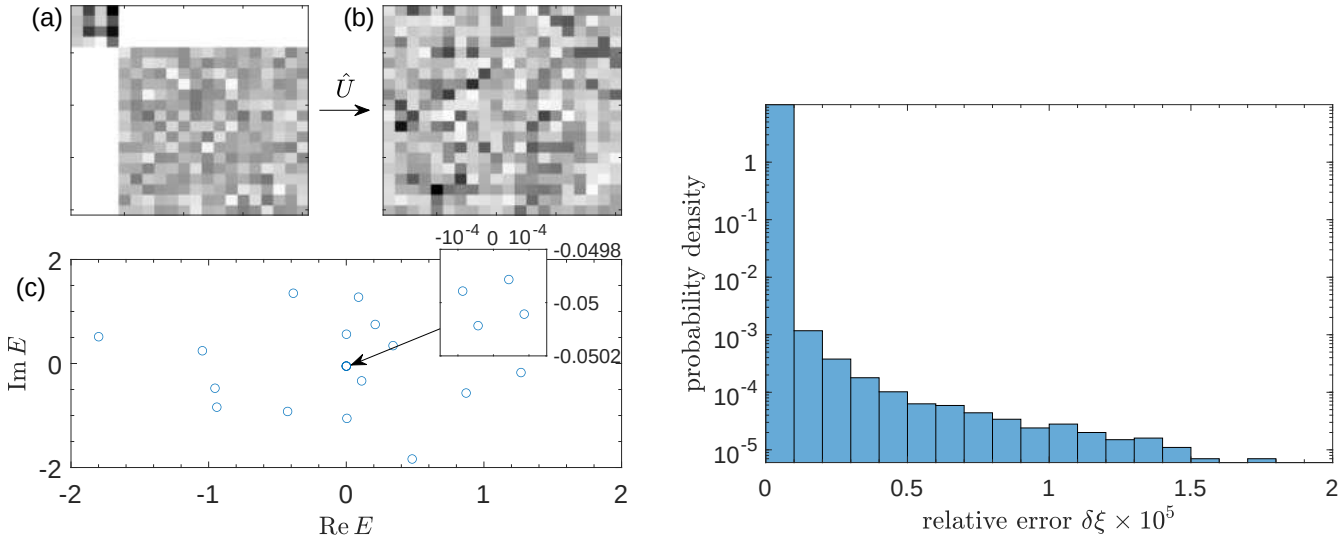

Figure 1: (Left) Illustration of the construction of a random 20×20-Hamiltonian exhibiting an EP of order 4 with eigenvalue $E_{\mathrm{EP}} = -i0.05$. A realization of the Hamiltonian (7) (a) without and (b) with the random unitary matrix $\hat{U}$, respectively. (c) Dimensionless complex eigenvalues of the Hamiltonian. The magnification in the inset reveals that the EP-eigenvalues are slightly split due to tiny rounding errors in the double-precision floating-point arithmetic. (Right) Probability density function of the relative error $\delta\xi := |\xi_{\mathrm{num}} - \xi|/\xi$ calculated from 10^7 realizations of random 20×20-Hamiltonians possessing an EP of order 4. The integration path C in Eq. (6) is a circle of radius 10^{-2} centered at $E_{\mathrm{EP}} = -i0.05$. About 10^{-5} of the data points have $\delta\xi > 2 \times 10^{-5}$ and are not shown.

The Hamiltonians $\hat{H}$ in Eq. (7) constitute a class of exemplary systems for the proposed scheme based on residue calculus in Eq. (6) to compute the spectral response strength ξ_{num} of EPs for the generic situation. The right subfigure of Fig. 1 shows a comparison for 10^7 realizations of 20×20-matrices $\hat{H}$ each with an EP of fourth order. It can be observed that the relative error of the spectral response strength is very small.

To summarize, we have presented the general theory of the spectral response strength for non-Hermitian systems with EPs of arbitrary order and to arbitrary Hilbert-space dimension. A numerical scheme based on residue calculus allows for an efficient and accurate calculation of the response strength. The theory is useful for the design of complex non-Hermitian systems in general but in particular for sensing applications.

Scattering Singularities of Complex Non-Hermitian Systems Probed with Continuously Variable Metasurfaces

Jared Erb[1], **Thomas M. Antonsen**[1], **and Steven M. Anlage**[1*]

[1] Physics Department, University of Maryland, College Park, MD 20742-4111 USA
[*]corresponding author: anlage@umd.edu

Abstract: We utilize continuously tunable metasurfaces to establish coherent perfect absorption and exceptional point scattering singularities in generic microwave resonant systems in 1, 2, and 3-dimensions. We demonstrate CPA through 100% absorption of incident radiation, and examine the topological properties of multiple Exceptional Points in two- and three-dimensional parameter spaces.

We study the wave properties of complex enclosed non-Hermitian scattering systems in the limit where the wavelength is much smaller than the characteristic dimension of the enclosure. In this limit the scattering properties (S-matrix, impedance matrix, etc.) are extremely sensitive to variations in frequency or any property of the interior or perimeter structure of the cavity. We perform two-port S-matrix measurements of a variety of one-dimensional graphs, two-dimensional billiards, and three-dimensional enclosure scattering systems, all of which host two or more electronically tunable metasurfaces. The metasurfaces vary their reflection phase and amplitude as a function of dc voltage, and this has a strong impact on the scattering properties of the entire system. We focus on two scattering singularities generically present in non-Hermitian systems, namely coherent perfect absorption (CPA), and exceptional points (EP), as a function of experimental parameters. Our recent work utilizes multiple nonlinear and continuously tunable metasurfaces to achieve near-perfect absorption over a broad range of frequencies [1]. Placing multiple metasurfaces inside the cavity allows us to engineer desired scattering conditions, such as CPAs and EPs, by actively manipulating the poles and zeros of the scattering matrix through the application of multiple voltage biases [1]. We utilize complex time delay to identify the locations of potential CPA events in parameter space [2,3]. We find that both CPAs and EPs are a generic and common feature of all of the experimental systems studied. Both types of singularity can be created and destroyed through variations in metasurface configuration. This establishes continuous metasurface tuning as a means to exploit CPA and EP scattering singularities for applications.

Abstract: We demonstrate stabilization of solitonic solutions and associated frequency combs in Kerr cavities with non-Hermitian periodic modulations. These potentials hybridize the two mechanisms of soliton formation, yielding new families of stable solitons and molecules and making them accessible. This scenario diversifies frequency combs, allowing real-time reshaping and broadening applications.

Solitonic solutions generated in nonlinear optical cavities and their spectrum, i.e. frequency combs, are a crucial tool for many applications as high precision spectroscopy, atomic clocks or optical communications and their real-time manipulation has been recently explored in different situations [1]. Here, we uncover a mechanism for a controlled reversible switching between different frequency combs corresponding to Localized States with different widths. Such control is based on the tilt of the snaking branch structures associated to different families of such solitonic solutions.

The proposed mechanism is based on the introduction of integrated electro-optical modulators and amplifiers inside dissipative Kerr cavities generating modulations of the refractive index and gain/losses in the form of a non-Hermitian periodic potential. Recently, nonlinear ring fiber or waveguide cavities have emerged as attractive options for generating frequency combs, see Fig. 1 a) [2]. Passive and dispersive cavities including third order Kerr nonlinearities and a complex spatial potential $V(x)$ follows the damped-driven Nonlinear Schrödinger Equation:

$$\frac{\partial A}{\partial t} = h - (1+i\delta)A + 2i|A|^2 A - i\frac{\partial^2 A}{\partial x^2} + V(x)A \qquad \text{with} \quad V(x) = me^{-i\phi}\cos(2\pi nx/L) \tag{1}$$

that includes the external energy injection h and the cavity detuning δ. The complex amplitude of the periodic potential is described m and ϕ, while n is the number of periods along the cavity with length L.

The Kerr nonlinearity induces bistability of homogeneous states and the formation of Pattern States (P) and Localized States (S) in a particular detuning interval. Dissipative Kerr cavities with normal/anomalous Group Velocity Dispersion (GVD) present P and S showing a branch structure with a collapsed/standard snaking shape, both inaccessible to be inside the bistable interval. As an example, Figure 1 b shows pattern branches for the unmodulated case with normal GVD and showing snaking branch structures collapsing to a particular detuning value inside the bistable interval (the Maxwell-Point) [3]. Each colored branch corresponds to a pattern composed by a different number of solitons inside the window. The periodic potential reduces the patterned structures while the number of periods in the cavity, n, determines the possible patterns and corresponding

localized structures, see Fig. 1 c) for n=7.

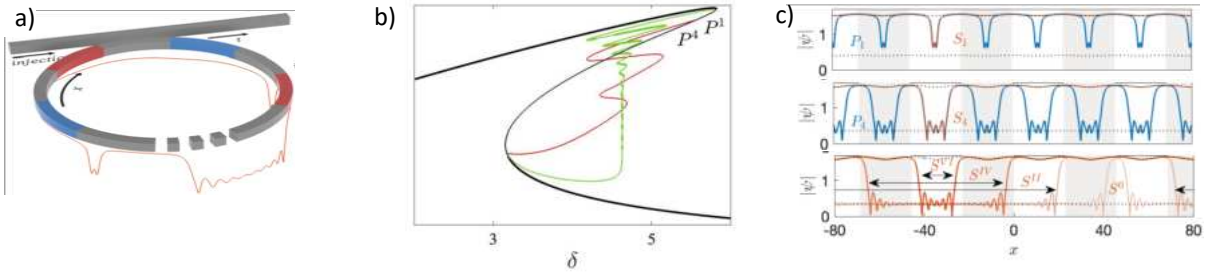

FIG. 1: a) Schematic representation of a modulated Kerr optical ring cavity. b) Homogeneous branches in black and pattern collapsed branches as a function of the detuning for solitons with 1 and 4 oscillations. c) Patterns in blue and corresponding localized states for a cavity with 7 oscillations of the potential.

The non-Hermitian potential hybridizes the two scenarios combining both collapsed and standard snaking branches, see Fig. 2 a). Collapsed branches correspond to solitons confined in one period of the potential modulation and with an increasing number of oscillations around the lower homogeneous state (upper and middle example of Fig. 1 c)), while standard snaking branches correspond to solitons spanning an increasing number of periods of the potential (lower example of Fig. 1 c)). Moreover, the non-Hermitian potential tilts the branch structures to the outside of the bistable interval (shaded in grey color) for a large enough m amplitude, see Fig. 2 b). This turns solitons accessible just scanning de detuning and allowing a controlled switching between different S states and corresponding frequency combs, see Fig. 2 c).

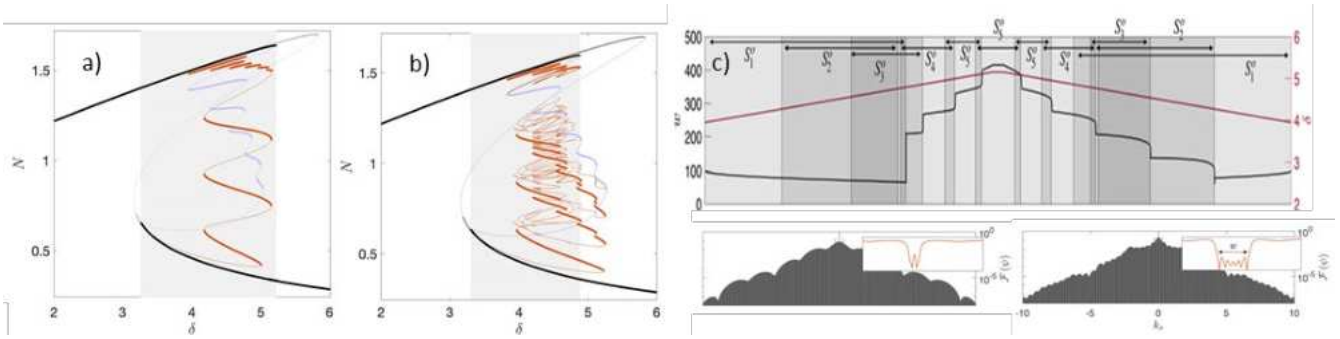

FIG. 2: Hybridised collapsed and standard snaking bifurcation structure of patterns (blue) and solitons and molecules (red) for a) m=0.1 and b) m=0.15. c) Consecutives switching between solitons and two corresponding frequency combs.

Nonperturbative effects in the eigenvalue sensitivity of non-Hermitian systems

H. Schomerus[1]

[1]Department of Physics, Lancaster Unversity, UK
[*]corresponding author: h.schomerus@lancaster.ac.uk

Abstract: Systems with an effectively non-Hermitian Hamiltonian display an enhanced sensitivity that arises from the nonorthogonality of their eigenstates. I derive an exact nonperturbative expression for this sensitivity that applies to arbitrary eigenvalue configurations. This reveals that states can have a sizable effect even if they are spectrally well separated.

Systems governed by an effectively non-Hermitian Hamiltonian exhibit heightened sensitivity to parametric and dynamic perturbations due to the nonorthogonality of their eigenstates [1-13]. This increased sensitivity is quantified by the Petermann factor [2], which originated from quantum noise theory, but turns out to the key characteristic for the general response of any non-Hermitian system. The Petermann factor diverges at exceptional points [3,4,5], which signals non-Hermitian phase transitions and results in significantly altered noise characteristics, such as a squared-Lorentzian line shape [6,7]. This enhanced sensitivity also leads to new design concepts for sensors [8]. Furthermore, in non-reciprocal settings, this effect provides insights into the dramatic difference between the spectral properties with open and periodic boundary conditions and leads to novel design concepts for directed sensing and amplification [9-11]. Because of these features, which are intimately tied to spectral degeneracies, very detailed theoretical descriptions now exist for the quasi-degenerate scenario, even for exceptional points of arbitrary order [12].

I present a precise nonperturbative expression for this sensitivity measure that is applicable across more general (indeed, arbitrary) eigenvalue configurations [13]. The expression disentangles spectral correlations from additional geometric data and maintains a straightforward asymptotic behavior near exceptional points of any order, while elucidating the impact of additional states within the system.

It then becomes evident that such states can significantly influence the system's sensitivity even when they are spectrally well separated. This is illustrated in Fig 1, which depicts how a related sensitivity measure changes when more and more eigenvalues are being incorporated into the description. Typically, a large number of eigenvalues is required before the true sensitivity can be established. The developed formalism reveals the origin and identifies the specific matrix elements responsible for this nonperturbative effect.

The algebraic method I use, which is based on the eigenvectors-from-eigenvalues idea [14], also reveals the shape of the states near an EP. Notably, they obey an equipartition principle governing the contributions from different directions in the quasidegenerate subspace of the system. This is illustrated in Fig 2.

Therefore, the presented formalism provides a systematic tool to determine and examine a key characteristic of non-Hermitian systems, their enhanced sensitivity dynamical and parametric to perturbations.

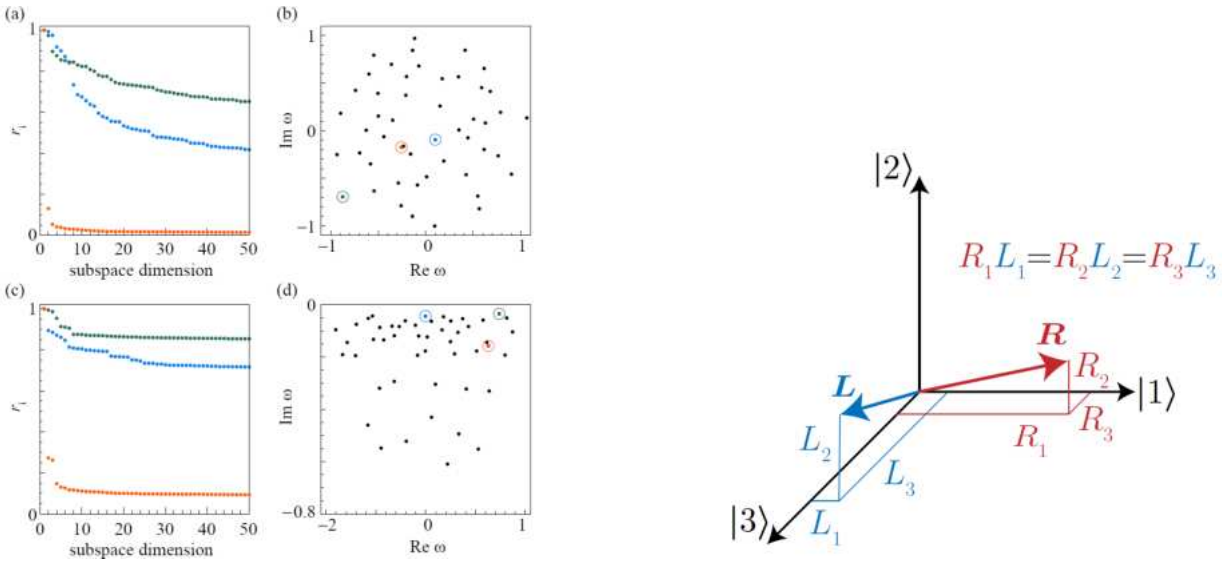

Figure 1 The systematic expansion presented here allows to detect how the spectral sensitivity is affected by well-separated eigenvalues. In the figure this illuminated by a systematic truncation of the system. Typically, the true value of the sensitivity (here represented by the phase rigidity $r \sim K^{-1/2}$) is only established when a large number of states are taken into account.

Figure 2 The formalism also reveals that within the quasidegenerate subspace, the contributions of the different directions are systematically linked to each other.

Non-Hermitian mode-cleaning in linear and nonlinear optical waveguides

M. N. Akhter[1], R. Herrero[1], K. Staliunas[1, 2] and M. Botey[1]

[1] Departament de Física, Universitat Politècnica de Catalunya (UPC), Barcelona, Catalonia, Spain

Abstract: We present a novel all-optical mode-cleaning mechanism in waveguides triggered by an antisymmetric non-Hermitian potential. Unidirectional coupling among transverse modes enables light management, yielding ideally single-mode spatially coherent output. Analytical predictions based on a 1D linear and nonlinear mode coupling expansion are numerically validated.

Non-Hermitian systems in photonics hold unique properties such us controlling the flow of light, controlling stabilizing lasers or control optical turbulence, among others [1-5]. In guided wave optics, considerable efforts have been directed towards creating tailored gain and loss platforms to efficiently realize functionalities such as asymmetric mode transfer [6]. Just recently, non-Hermitian coupling induced by simultaneous longitudinal modulations of the propagation constant and of the gain/loss coefficient along graded was proposed for the control of the modes at the output, in parabolic multimode optical waveguides [7]

In this work, we propose the introduction of non-Hermitian potentials as a mode-cleaning mechanism in graded index waveguides, see Fig. 1a, which may represent an alternative to various attempts to address randomization [8,9,10]. We analytically predict and numerically demonstrate that non-Hermitian modulations lead to and effective control over all transverse modes eventually ideally resulting in single-mode spatially coherent output, irrespectively of the initial field distribution [11].

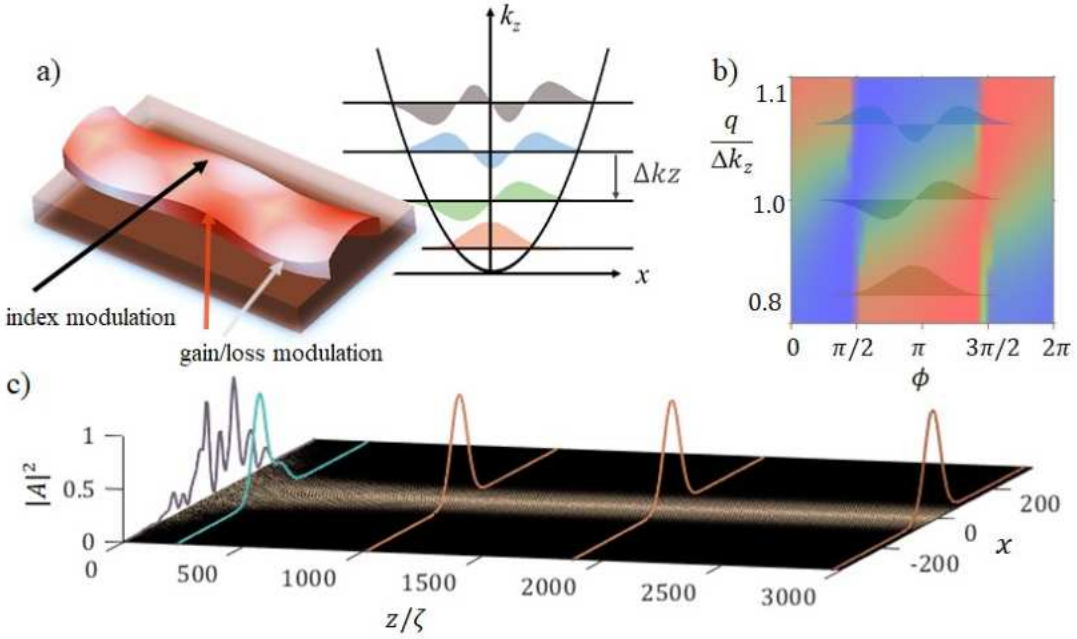

Figure 1. a) Periodically modulated non-Hermitian in a parabolic-index waveguide. Inset: spatial profile of the first equidistant transverse modes of the waveguide, with mode spacing Δk_z. b) Map of the participation of each mode into the final eigenmode of the modulated 1D waveguide, as a function of the gain/loss and index phase ϕ, and the wavenumber q of the non-Hermitian modulation. c) Evolution of a transverse noisy profile along the modulated

waveguide, distance normalized to the self-imaging period of the waveguide $\zeta=2\pi/\Delta k_z$.

The governing equation along linear multimode waveguides is the linear Schrödinger Equation (SE) while active multimode waveguides in quasi-CW regimes may be described by the Complex Ginzburg-Landau Equation (CGLE). We consider a non-Hermitian potential in the longitudinal direction with an antisymmetric transverse profile, which in the simplest from may be taken as:

$$V(x,z) = V(z)V(x) = \left[m_{re} cos(qz) + \mathrm{i} m_{im}\ cos(qz+\phi) \right]\ (x/x_0)\, \mathrm{e}^{-x^2/x_0^2} \tag{1}$$

being m_{re} and m_{im} the amplitude of the modulation, q the longitudinal wavenumber (assumed to be close to the mode spacing of the unmodulated waveguide, $q \approx \Delta k_z$), and ϕ the spatial delay between the index and gain/loss modulations. This potential is expected to stabilize the system while controlling the mode coupling. The analytical approach is based on the analysis of the eigenfunctions of the modulated system. We expect de system to evolve, after sufficient propagation along the wavelength, to an eigenmode of the coupling matrix. This allows mapping the mode cleaning-efficiency in terms of the parameters of the potential, namely the spatial delay between index and gain/loss modulations, ϕ in eq. (1), see Fig. 1b. By tuning the parameters, wide islands of mode cleaning are found indicating the robustness of the proposed mode-cleaning scheme. Finally, the predictions the prediction are numerically proven by direct integration of the SE or CLGE, for linear or nonlinear waveguides, respectively, see Fig 1c. The numerical results show how the resulting beam upon propagation in the non-Hermitian asymmetric waveguide resembles the locked mode state. For particular parameters of the potential a significant mode-cleaning is observed, as the beam acquires a bell-shaped profile in propagation along the waveguide by the non-Hermitian action. The study may be numerically extended to 2D waveguides -with different transverse profiles-, offering broad applicability.

To conclude, we propose and demonstrate an effective mode-cleaning for linear and nonlinear active waveguides, by introducing an asymmetric non-Hermitian potential.

Non-Hermitian Systems with a Real Spectrum and Selective Skin Effect

Li Ge[1, 2*]

[1]Department of Physics and Astronomy, College of Staten Island, CUNY, Staten Island, NY, USA
[2]The Graduate Center, CUNY, New York, NY, USA

Abstract: We show a simple approach to constructing non-Hermitian Hamiltonians with a real spectrum, using the product of a Hermitian Hamiltonian H_0 and a positive semi-definite matrix A. When A is diagonal, we reveal a selective non-Hermitian skin effect where only the zero mode is a skin mode.

In this talk, we first introduce a simple approach that gives non-Hermitian Hamiltonians in their matrix forms with a real spectrum. We start with an arbitrary Hermitian Hamiltonian H_0, and we show that its product with a positive semi-definite matrix A leads to a non-Hermitian Hamiltonian H with a real spectrum. Because A is arbitrary itself and this procedure is not a similar transformation, the same H_0 can lead to an infinite set of H's with different real spectra. Depending on whether A has zero eigenvalue(s), the resulting H can possess an EP at zero energy. When A is only required to be Hermitian instead, the resulting H is pseudo-Hermitian that can have real and complex conjugate energy levels.

In the special case where A is diagonal, we compare our approach to an imaginary gauge transformation, and we show that our approach leads to a selective non-Hermitian skin effect, where only the zero mode is a skin mode and the non-zero modes reside in the bulk. Furthermore, we find that this selective non-Hermitian skin mode has a much lower lasing threshold than its counterpart in the standard non-Hermitian skin effect with the same spatial profile, when we pump at the boundary where they are localized. Finally, we show that the form of our construction can also be found, for example, in non-Hermitian dynamical matrices describing coupled frictionless harmonic oscillators with different masses.

Pseudospectra and non-normality in non-Hermitian photonics

K. G. Makris[1,2]

[1]*ITCP-Physics Department, University of Crete, Heraklion, 71003, Greece*

[2]*Institute of Electronic Structure and Laser (IESL) FORTH, Heraklion, 71110, Greece*

[*]corresponding author: makris@physics.uoc.gr

Abstract: In the context of non-Hermitian photonics we present recent results regarding sensitivity of non-normal optical waveguide lattices. We investigate dissipative optical lattices with gain/loss and asymmetric couplings and study their response in terms of their pseudospectra. The effect of disorder and optical nonlinearity will be also discussed.

Dissipation due to the inherent material losses has been always considered as an obstacle. However, based on the notion of parity-time (PT)-symmetry, that was recently introduced in the context of optical physics [1], such synthetic structures can utilize loss as an advantage in many applications [2,3]. Recently, in the context of non-Hermitian optics, the concept of non-Hermitian power eigenchannels was introduced [4] based on singular value decomposition of the associated propagator [5,6].

The first part of the talk is devoted to dissipative waveguide arrays with sparse gain with symmetric or not coupling coefficients. The sensitive to external perturbations in terms of pseudospectra will be presented in detail. In the second part of the talk, we will present recent results regarding the effect of uncorrelated disorder. Despite the Anderson localization of all eigenstates, the system exhibits counter-intuitive propagation by quantized jumps between states located around distant sites [7, 8]. The relevance of this type of transport to the corresponding asymmetry will be discussed.

Our pseudospectra approach can be applied to any non-Hermitian system that contains complex elements with loss-gain, or exhibits an asymmetry induced non-Hermiticity and thus exploits the meaning of wave transport in complex open systems.

Topological Origin of Surface Maxwell Waves and Surface Acoustic Modes

Franco Nori

Riken (Japan) and University of Michigan (USA)
fnori@riken.jp

Abstract: Interfaces between optical media (including dielectrics, metals, negative-index materials) can support surface electromagnetic waves, which now play crucial roles in plasmonics, metamaterials, and nano-photonics. We have shown [K. Y. Bliokh et al., Nat. Commun. 10, 580 (2019)] that surface Maxwell waves at interfaces between homogeneous isotropic media described by real permittivities and permeabilities have a topological origin explained by the bulk-boundary correspondence. This is explained by the nontrivial topology of the non-Hermitian photon helicity operator in the Weyl-like representation of Maxwell equations. The corresponding topological invariant, which determines the number of surface modes, describes the winding of the complex helicity spectrum across the interface. Our theory provides a new twist and insights for several areas of wave physics: Maxwell electromagnetism, topological quantum states, non-Hermitian wave physics, and metamaterials. We have also analyzed [K. Y. Bliokh et al., Phys. Rev. Lett. (2019)] another type of classical waves: longitudinal acoustic waves corresponding to spinless phonons. We show that surface acoustic waves, which appear at interfaces between media with opposite-sign densities, can be explained by similar topological features and the bulk-boundary correspondence. However, in contrast to photons, the topological properties of sound waves originate from the non-Hermitian four-momentum operator in the Klein-Gordon representation of acoustic fields.

Abstract: This talk covers the detailed information and guidelines on scientific paper preparation and submission, including tips for writing an effective cover letter, an informative abstract, a comprehensive introduction and an attractive paper, and editorial and peer-review processes. You will also get to know how to choose a journal for submission, what editors seek, how your papers are reviewed and how to make an appeal.

DNA nanotechnologies for photonics and sensing

A universal impedance-matching strategy towards ultrathin broadband perfect absorbers enabling efficient hot electron photodetection

C. Zhang,[1,2,*] and X. Li[1,2,*]

[1]Country*School of Optoelectronic Science and Engineering & Collaborative Innovation Center of Suzhou Nano Science and Technology, Soochow University, Suzhou 215006, China*

[2]*Key Lab of Advanced Optical Manufacturing Technologies of Jiangsu Province & Key Lab of Modern Optical Technologies of Education Ministry of China, Soochow University, Suzhou 215006, China*

[*]corresponding author: zhangc@suda.edu.cn; xfli@suda.edu.cn (Prof. Li*)*

Abstract: We derive conditions for achieving impedance matching in ultrathin films with negligible/comparable thickness to the incident wavelength. We design and experimentally demonstrate broadband perfect absorbers operating across various spectral bands, with average absorption exceeding 90%. Integration with p-type silicon enables hot carrier photodetection, promising applications in telecommunication and near-infrared imaging.

Efficient light absorption is of significant importance for applications in optics and optoelectronics, such as structural colors, stray light elimination, optical switches, stealth technologies, photovoltaics and photodetection [1−3]. Optical reflection losses always exist due to the impedance mismatch at interfaces between air and absorbers. Typically, single and multilayer dielectric anti-reflection coatings with thickness of at least a quarter-wavelength of light are used to suppress reflection. The anti-reflection coatings based on destructive interference only works at specific incident wavelengths, angles and polarizations [4−6]. The thicknesses of anti-reflection coatings for the mid- and far-infrared are great, which can be a challenge and limitation for fabrication. Another approach involves the tapered nanostructures to realize the gradient effective refractive index, including nanocones, tapered gratings and nanopyramids, etc [7]. To achieve broadband anti-reflection effects, the lengths of the nanostructures are sufficiently long to eliminate optical resonances, which imposes similar thickness limitations. Another alternative way to achieve broadband optical absorption is to use plasmonic nanostructures, i.e., metamaterials. By precisely controlling the shape, size, and arrangement of the elements, the absorption bandwidth can be broadened by overlapping the multiple resonances, such as in nanocubes, nanodisks, nanocrosses, crossed trapezoids/gratings, multilayer grating stacks, and even resonators integrating the aforementioned nanostructures. Nevertheless, these plasmonic absorbers generally have delicately designed subwavelength nanopatterns that are fabricated through top-down lithography such as e-beam lithography (EBL), focused ion beam milling (FIB), and reactive ion etching (RIE), leading to high equipment cost, low fabrication throughput, and small footprint size that severely restrict the practical large-scale applications [8]. Therefore, there is significant benefit to achieve the ultrathin broadband perfect absorbers based on lithography-free planar multilayer structures.

In this work, we analytically derive the general solutions of film parameters for impedance matching using an absorbing film with thickness negligible or comparable to incident wavelength, or the case using a lossless dielectric film on any substrate. We present a detailed step-by-step process illustrating how to employ the strategy for designing multiple layers to achieve broadband perfect light absorption. We numerically and experimentally demonstrated the broadband and efficient absorbers working in different spectral bands, including the visible (0.4−0.8 μm), visible to short-wave infrared band (SWIR, 0.4−2.5 μm), middle-wave to long-wave infrared (MWIR−LWIR, 3−16 μm), and long to very long infrared (LWIR−VLIR, 16−32 μm and 8−32 μm) bands, respectively. The absorbers exhibit an average absorption ranging from 90% to 99.6% based on

multiple stacks comprising 2 to 9 layers, while also showcasing sustained high performance under large incident angles of up to 50° for unpolarized incidence and displaying excellent tolerance to film thickness errors of up to 30%. Furthermore, we achieve broadband perfect light absorption below the silicon bandgap by employing a planar absorber consisting of ultra-thin silicon (100 nm) and a transition metal film (20 nm), breaking the limitation of poor hot electron generation in thin metal films. The ultra-thin hot carrier photodetector shows a responsivity that is 3.5 to 45 times higher than that observed with a similar structure using a silicon substrate and transition metal film under backward incidence. As a proof of concept, the infrared communication and imaging are demonstrated, showing the great potential of the proposed device. The work presents a general solution for achieving broadband perfect absorption in ultrathin films under a planar configuration, paving the way for lithograph-free and large-area practical applications such as photodetector, photovoltaics, optical sensing, and stealth technology.

Integrating functional inorganic nanomaterials for spatiotemporal modulation of full-polarized light emission

J. Lv[1], J. H. Han[1], and K. T. Nam[1*]

[1]Seoul National University, Republic of Korea
[*]corresponding author: nkitae@snu.ac.kr

Abstract: Here we present a solid-state full-polarized controlling device by integrating the spatiotemporal modulation of the LED device, the precise control and efficient polarization emission through nanomaterial assembly, and the programmable patterning/positioning using 3D printing. We achieved an extremely high degree of polarization for both linearly and circularly polarized emission.

Solid-state polarized light-controlling devices made of (nano)materials without the conventional bulky polarization optics promise simpler device structure, miniaturization, and multi-functionality. While several design routes have been proposed for polarized light-controlling devices using organic or inorganic nanomaterials, they usually suffer from small degrees of polarization, limited polarization states, low light utilization efficiency, and the absence of spatiotemporal control. Herein, to address this challenge, we fabricated a six-polarized-elemental-pixels-based device by integrating the spatial-temporal modulation of LED device, the precise control of polarization by nanomaterial assembly and the programmable patterning/positioning by 3D printing. Our idea is scalable and form-factor-free, making it compatible with the state-of-the-art micro-LED display industry. We achieved a high degree of linearly polarized emission (DoP) over 0.8 through the templated alignment of quantum nanorods with ultrathin inorganic nanowires. Furtherly, by precisely controlling the phase retardation of the printed inorganic nanowire film, circularly polarized luminescence (CPL) with an anisotropic factor (glum) up to 1.1 was obtained. The linear combination of the on-off state of each pixel can generate enormous states of polarization. This concept is indeed a good platform for multiplexing spatiotemporal information with the aid of polarization freedom. As two examples, we demonstrated polarization-based encrypted communication and multichannel display using our device. The encrypted communication was enabled by the further integration of chiral plasmonic assemblies which add physical unclonable encryption on top of our device. As a result, dramatic modulation of the polarization states across the Poincare sphere that is difficult to be hacked by any other devices was achieved, enabling secured visible light communication (VLC). As for the multichannel display, we showed that 3D information can be transferred by one-shot 2D image, indicating the potential of our device in volumetric display and polarization-based hologram.

Abstract: Strongly absorbing materials are needed for nanoscale optoelectronics and strong light-matter coupling applications. Here, we demonstrate that monolayer WS_2 superlattices provide higher absorption than natural monolayers and bilayers while preserving the exciton emission. The use of a molecular spacer allows us to control the interlayer coupling at sub-nanometric distances.

Strong light absorption in ultrathin materials plays a vital role in various applications, including light detection, waveguiding, and modulation. One relatively new class of strongly absorbing materials is that of atomically thin materials. Transition metal dichalcogenides (TMDs), such as tungsten disulfide (WS_2) and molybdenum diselenide ($MoSe_2$) possess unique optical properties. Bulk TMDs consist of weakly bound atomically thin layers, and stable monolayers can be easily prepared through exfoliation. Exfoliation provides the highest exciton quality for the strongest absorption and narrowest linewidth. Monolayer TMDs show an exceptionally strong absorption of light despite being less than one nanometer thick. The combination of strong absorption and the ability to tune the excitonic resonances through doping enables their use in nanoscale optical elements such as atomically thin photodetectors, modulators, and lenses. TMD monolayers can also be used to create atomically thin mirrors that are promising for spatial light modulators, active metasurfaces, and active cavity control. In addition, the high oscillator strengths and sharp resonances of excitons in these materials can enable reaching the regime of strong light-matter coupling and the manipulation of light via surface exciton-polaritons.[1,2]

Here, we create WS_2 monolayer-based structures to approach the fundamental thin-film absorption limit of 50%. We demonstrate three simple methods to obtain stronger absorption than monolayer WS_2. Different superlattice structures of WS_2 monolayers result in an increased light absorption, while also preserving the exciton emission and quality. We characterize these structures using transmission and photoluminescence spectroscopy. Additionally, we employ hyperspectral imaging to gain insight into the spatial variations of exciton properties. We start with simple structures containing two monolayers separated by a spacer to retain the optical properties of the individual monolayers. However, such structures prove to have coupling between layers that is difficult to control reliably and results in absorption reduction. Instead, we demonstrate the use of a molecular spacer to construct stable stacked bilayers. Finally, we fabricate higher-order superlattices with an increased number of layers using Al_2O_3 as a thin dielectric spacer to approach the thin-film absorption limit in a more scalable process.

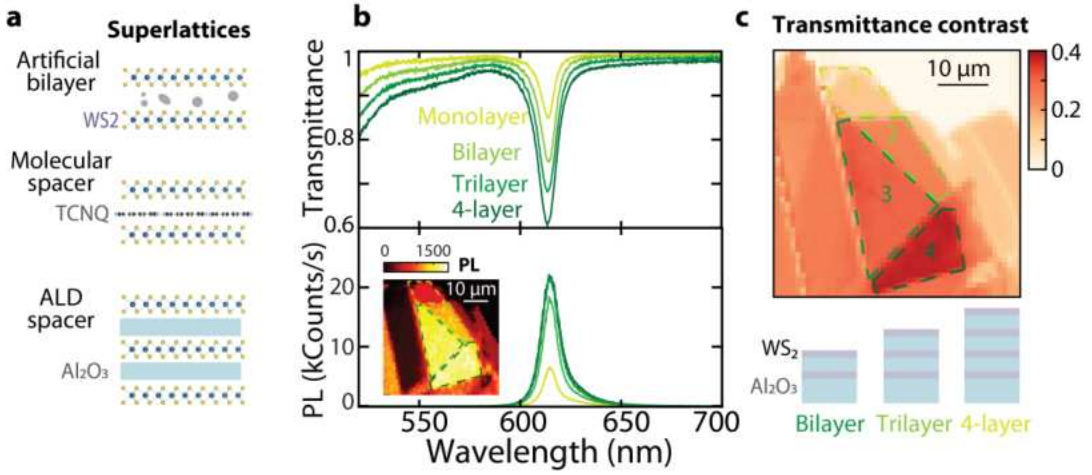

Figure 1. Stacking of WS_2 monolayers into superlattices for high absorption.

We have also investigated in detail the use of organic molecular spacers in WS_2 monolayer stacks to control the exciton properties through interlayer interactions. This approach enables finely tuning the interlayer coupling and modulates the interaction between WS_2 monolayers. Introducing molecular spacers addresses the limitations imposed by traditional spacer materials like hexagonal boron nitride and Al_2O_3 in achieving ultra-thin layers with controlled thickness and large area. The sub-nanometric control over the spacer thickness provides a substantial modulation of photoluminescence intensity and spectral shift. This method enables precise manipulation of the interaction strength between the monolayers, transitioning from strongly coupled layers at lower molecular concentrations to loosely coupled layers at higher concentrations. Additionally, we observe a considerable impact on the valence band splitting, evidenced by a change in the energy difference between A and B excitons.

Our work puts forward the potential of monolayer superlattices as a flexible platform for developing novel two-dimensional nanophotonic devices. As the superlattice fabrication process relies on simple methods, such superabsorbing materials are posed to have an impact on a variety of fields. By engineering the molecular spacers in monolayer stacks, we also unlock the potential to fine-tune excitonic properties and pave the way for nanoscale sensors and sub-nanometric rulers.

Abstract: We have performed the transport and IR-photoresponse measurements in the twisted bilayer graphene. The structure demonstrates enhanced photothermoelectric response compared to the previous works. We demonstrate the gate-tunable biased photovoltage that strongly correlates with the peculiarities in transport measurements. The obtained results can be further used for tunable mid-infrared optoelectronics.

2D layers stacking of van der Waals materials enables various degrees of freedom for properties control [1]. Stacking of two monolayers leads to formation of a metamaterial with effective periodic potential due to the emerging moiré superlattice. Small-angle twisted bilayer graphene (tBLG) has attracted much attention since the breakthrough experimental work [2] due to appearance of low-energy flat bands. Strong electron-electron interactions within the bands lead to correlation-driven phenomena, realization of correlated phases, and result in new devices [3]. In particular, optoelectronic devices such as infrared and THz detectors have been recently demonstrated [4,5,6].

We investigated tBLG with mis-orientation angle close to 1° and lateral size ~3x1.25 μm^2 obtained by standard dry transfer technique. The Fermi level position was ruled by the back gate to the silicon substrate with 280 nm silicon oxide and 15 nm hBN flake as a gate insulator. Transport measurements were made using a standard 2-point scheme and lock-in amplifier at 111 Hz. The resistance dependence on gate voltage is shown in the Fig.1 by blue color. Central peak near -10V corresponds to the charge neutrality point (CNP), whereas side peaks at ±30 V (with respect to CNP) – to the full filling of the superlattice minizones, i.e., 4 electrons per moiré cell. The side peak positions correspond to ~0.95° moiré angle.

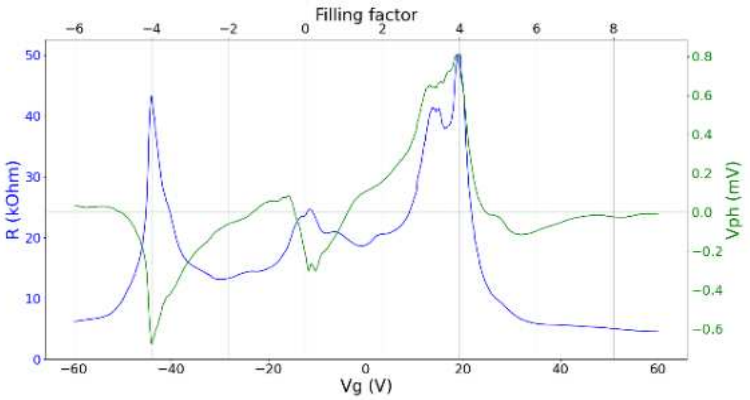

Figure 1. Resistance *R* (blue, left axis) and photovoltage *Vph* (green, right axis) versus the gate voltage *Vg*. T=8.6K, beam power on sample ~5uW

The IR-photoresponse in such structures was shown to have a bolometric nature [4,5] with the highest value ~30 mA/W though with the large bias current > 50μA [4]. We used 6 μm laser excitation in a regime of quasicontinuous wave with the frequency 11 Hz. The beam was focused by the lens on the substrate to the spot with the diameter ~40 μm. The voltage drop was measured by the synchronized lock-in amplifier. The maximum photocurrent observed was ~6 mA/W with no bias applied.

Also we preformed transport and IR-photoresponse measurements with applied bias DC current (see Fig.2). We observe strong *V(I)* non-linearity that has already been seen in graphene-based structures [7]. At current densities high enough Fermi distributions of electron and holes change. It is known as Schwinger mechanism of charge transport and it should affect photoresponse as well. The correlations between lower and upper panels in the Fig.2 are clearly seen. However, photoresponse of our sample has three different mechanisms that makes it difficult to explain the *Vph* behavior. The first one is photothermoelectric effect, i.e. Seeback effect due to the different radiation heating near the metal contacts of the sample. The second one is pure bolometric effect, i.e. the change of the sample resistivity due to radiation heating. Finally, due to nonlinear *V(I)* the rectification effect can lead to the origin of photovoltage.

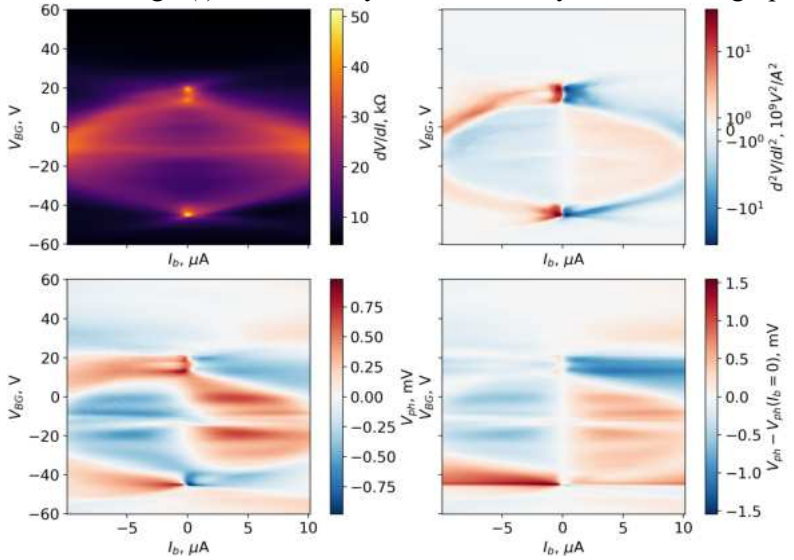

Figure 2. *dV/dI* (upper left), d^2V/dI^2 (upper right), *Vph* (lower left) and *Vph-Vph*(*Ib*=0) (lower right) maps with gate voltage *Vg* and bias current Ib changes. *dV/dI* and *Vph* were directly measured experimentally while d^2V/dI^2 is a numerical derivative of *dV/dI*.

To sum up, we performed transport and IR-photoresponse measurements on the tBLG with the mis-orientation angle 0.95° close to the magic one. We observed the signs of the transition to the Schwinger mechanism of charge carriers transport and measured photovoltage under IR irradiation in this regime. The correlation between photoresponse and transport maps was experimentally detected.

Abstract: Bottom-up synthesis of vanadium dioxide (VO_2) micro- and nanostructures is achieved by focusing an infrared laser beam on a gold film or on gold plasmonic nanoantennas immersed in a precursor solution. Site-selective VO_2 synthesis is demonstrated by controlling the excitation of localized surface plasmon resonances.

Vanadium dioxide (VO_2) has been thoroughly studied for its ultrafast solid-solid phase transition that occurs close to room temperature (about 60 ºC).[1,2] When the material switches from its semiconducting state to its metallic state, dramatic, nonlinear changes are observed not only in its electrical properties but also in its optical properties. For this reason, VO_2 is a material of particular interest for designing new electronic and photonic devices such as nanoscale switching devices with highly tunable electronic and optical responses.

The fabrication of integrated VO_2 micro- and nanostructures typically relies on conventional fabrication processes such as pulsed laser deposition, sputtering, and molecular beam epitaxy, or chemical solution deposition, followed by photo- or electron-beam lithography, and finally etching or lift-off steps.[2] However, those top-down fabrication techniques are costly and drastically limits the range of practically feasible nanostructure designs. On the contrary, cost-effective, bottom-up fabrication techniques often consist in the synthesis and assembly of particles in liquid dispersion. Solvothermal synthesis (including hydrothermal synthesis) of VO_2 nanoparticles, nanowires, and nanosheets has been reported.[2] However, the integration of dispersed nanomaterials in electronic and photonic devices is a quite challenging task.

In this work, we apply the recently demonstrated laser-induced hydrothermal synthesis method to directly grow VO_2 micro- and nanostructures on a substrate.[3,4] A precursor solution was prepared following a reported recipe.[5] After dropping a few microliters of the precursor solution on a sample (glass substrate with gold film/nanostructures), a 1064 nm infrared (IR) laser beam was focused onto the gold film/nanostructures at the surface of the glass substrate.

First, the fabrication of VO_2 microstructures was achieved by locally heating a 30nm-thick gold film covered with a 3nm-thick alumina layer. Figure 1(a) shows a SEM image of a well-crystalized, 1µm-large VO_2 structure with circular shape synthesized using a laser power of 18 mW. Despite the temperature threshold for the VO_2 synthesis reaction to happen and the aqueous environment, the local temperature elevation was large enough to enable the synthesis of crystallized VO_2 structures. The alumina layer was required to promote the adhesion of the synthesized VO_2 structures.

We then investigated the laser-induced hydrothermal synthesis of VO_2 at the surface of plasmonic nanostructures. Following a similar process, VO_2 nanostructures were successfully grown on gold nanodisks and nanorods. The excitation of localized surface plasmon resonances (LSPR) was found to enhance the photothermal heating of the gold nanostructures, enabling efficient VO_2 synthesis by plasmon-assisted

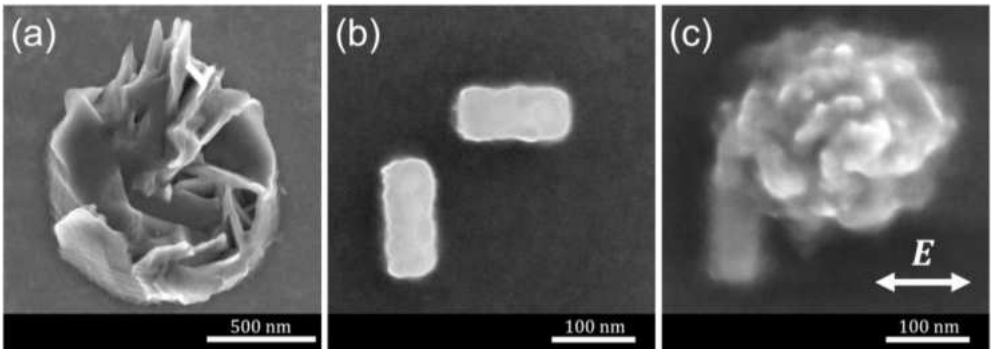

Figure 1. SEM images of (a) a 1µm-large VO_2 structure fabricated by focusing a 18 mW IR laser beam on an alumina-coated gold thin film, (b,c) gold dimer composed of two perpendicularly oriented, resonant plasmonic nanobars (b) before and (c) after irradiation of a 3.7 mW linearly polarized, focused laser beam with horizontal polarization orientation. A VO_2 shell was locally synthesized only on the horizontal nanobar.

hydrothermal synthesis.[4] Moreover, site-selective VO_2 synthesis was achieved by controlling the LSPR excitation of plasmonic nanostructures composed of nanobars with different orientations. As shown in Figure 1(b), by tuning the orientation of the linear polarization of the incident laser beam, VO_2 nanostructures were selectively grown on nanobars with similar orientation.

We believe that laser-induced hydrothermal synthesis and the plasmon-assisted hydrothermal synthesis techniques demonstrated in this work will enable the fabrication of highly tunable, hybrid micro- and nanodevices with novel designs and functionalities.

Circularly polarized photoluminescence from light-emitting metasurfaces

V. E. Ferry[1*]

[1]University of Minnesota, USA
[*]corresponding author: veferry@umn.edu

Abstract: This talk will discuss recent results on semiconductor nanocrystal-based metasurfaces designed for circularly polarized photoluminescence. We will discuss two complementary fabrication routes, direct write electron beam lithography and large-area printing, and the design guidelines for incorporating chiral nanocrystals, chiral semiconductor patterns, and chiral plasmonic patterns to manipulate the optical response.

Chiral metasurfaces allow for the manipulation of circularly polarized light. This talk will discuss metasurfaces comprised of patterned, light-emitting semiconductor nanocrystals, where the light-emitting nanocrystals are patterned deterministically to form part of the metasurface.

This presentation will discuss several different implementations of these patterned, chiral structures. First, we study hybrid systems of plasmonic nanostructures and patterned, light-emitting nanocrystals. By strategically placing these nanopatterns, the polarization state, photoluminescence intensity, and angle of the emitted light can be controlled. The nanocrystal patterns are created using direct-write electron-beam lithography, where the nanocrystals serve as the resist. Exposure to the electron beam cross-links the ligands between the particles. We show how the spatial arrangement of these nanopatterns, shape, and chiral structures of either the quantum dot pattern or the nearby plasmonic structure influences the obsereved response. We will then discuss semiconductor metasurfaces made of chiral materials, and the design rules for amplifying circular dichroism with patterning. Finally, we will discuss an alternative fabrication route for large-area metamaterials that is both additive and roll-to-roll compatible. The method uses UV-based imprint lithography to produce a pattern with spatially modulated surface energy. When a functional ink is dragged over the surface it dewets and fills in the recesses. This method works for a variety of ink materials (metal, dielectric, semiconductor), can create multi-layer patterns, and offers flexibility in creating metamaterials on free-standing and flexible substrates.

Abstract: In this presentation, we demonstrate the implementation of both plasmon-mediated and chemical reduction methods for generating large area arrays of single-crystal gold and silver hexagonal nanoplates, nanotriangles, and helical spirals on substrates.

Noble metal nanoplates represent a remarkable class of nanostructures that provide a highly compatible geometry for integration with wafer-based processing since the combination unites two systems that have an inherently two-dimensional character. In this presentation, we demonstrate the utility of using a crystalline substrate as the primary driver for forming substrate-based gold seeds with the internal defect structures and crystallographic alignment required for nanoplate growth. Using this capability along with other controls that are unique to substrate-based syntheses, we implement both plasmon-mediated and chemical reduction methods for generating arrays of hexagonal nanoplates, nanotriangles, and helical spirals.

Up- and Down-conversion Engineering with Surface Lattice Resonances

S. Murai*

Department of Material Chemistry, Graduate School of Engineering, Kyoto University, Japan
*Corresponding author: murai@dipole7.kuic.kyoto-u.ac.jp

Abstract: We combined a luminescent layer or substrate with metallic or dielectric nanoantennae to harness the photoluminescence into a specific direction predefined by the antenna design. A notable (> 10 times) enhancement in radiation intensity into a designated direction is demonstrated. We describe the mechanism using a simple analytical model. We also fabricated "nanoantenna sticker" where the nanoantenna was embedded in a flexible polymer. The sticker can be stacked on any clean surfaces and act as nanoantenna.

Nanoantenna is a periodic array of scattering elements that can harness light into a specific direction. Combination of nanoantenna with phosphors enables spatial and spectral control over the luminescence (Fig. 1) [1-3]. In this presentation, we use several sets of nanoantennae (metallic or dielectric) and phosphors (organic or inorganic) to demonstrate the luminescence control. Typical nanoantenna consists of aluminum [1], silicon [2], and titanium dioxide [3]. We will discuss the difference of conversion efficiency from blue excitation to yellow-red luminescence for the metallic and dielectric nanoantenna.

We also introduce the nanoantenna stickers, which are the nanoantenna embedded in the flexible polymer [4]. We place this sticker on top of the luminescent layers to modulate their emission directionality. Because of its flexibility, the sticker gives control over luminescent directionality via stretching/compressing it.

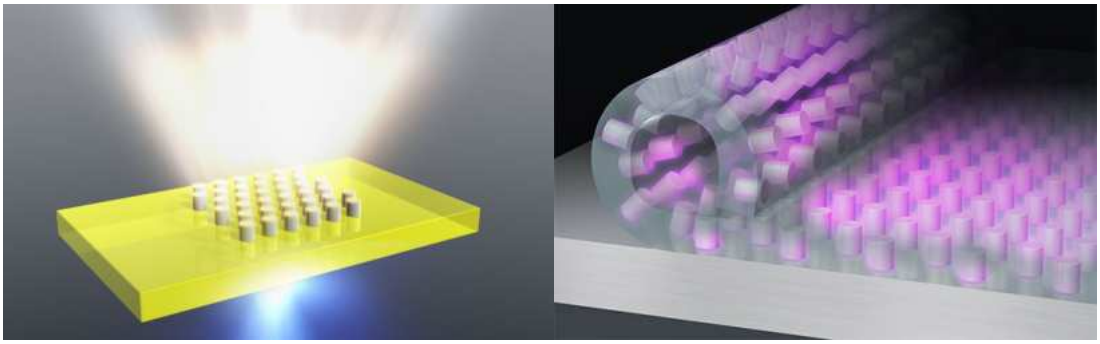

Fig. 1: (left) Sketch of the nanoantenna phosphor, converting a blue light into yellow photoluminescence with a directionality. (right) Sketch if the nanoantenna sticker, which is flexible and can be attached to any clean surfaces.

Abstract: Nanogap waveguides are demonstrated as a promising platform for the routing of Stokes emission in a context of surface-enhanced Raman scattering, or more generally for the decoupling of localised emission. Coupling of waveguides to metalenses provides additional opportunities for the creation of compact sensing devices.

The first part of the presentation introduces the concept of nanogap metallic waveguides and their utilization for the routing of localised emission [1, 2]. Focusing on surface-enhanced Raman scattering events, we demonstrate large coupling efficiencies near unity for Stokes emission, promising a novel avenue towards integrated, on-chip Raman sensors for biospectroscopy. Specifically we introduce the concept of a beta-factor, in analogy to laser physics, in order to quantify the coupling of Stokes scattering to waveguide modes.
The second part of the presentation will present our most recent works on metasurfaces for sensing, energy conversion, and routing of quantum emission [3].

Abstract: Interference between an incident circularly polarized optical field and a scattered field by a plasmonic cuboid particle created a spiral-shaped optical field structure, which was replicated on a polymer relief through photo-polymerization.

Even when a symmetric nanostructure (typically plasmonic nanostructure) is illuminated with a linearly polarized optical field parallel to the symmetry axis, circularly polarized fields appear in the local sites near the nanostructure, and the spatial distribution of the handedness of the field is in an anti-symmetric manner (Figure 1).[1] Conversely, when a symmetric nanostructure is illuminated by circularly polarized light, assymmetric optical field distribution is induced, which has a potential to create materials with chiral assymmetry through photochemical reactions. This idea was actually reported to be achieved with metal nanocuboid, on which photoproduct was deposited at two of diagonal apexes.[2] The result was attributed to the plamonic mode structure induced on the cuboid when excited by circularly polarized light. In the present study, we report experimental results that an additional mechanism of chiral field generation due to interaction between the symmetric nanoparticle and circularly polarized light provides a further complex structure of the photoproduct.[3]

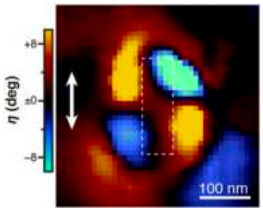

Fig. 1 Near-field ellipticity image (@ 800 nm) of a gold nanorod.[1]

We adopted a chemically synthesized Au@Ag nanocuboid particle as a plasmonic light scattering center to generate chiral optical field. The synthesized cuboid particle has dimensions of 60 × 60 × 120 nm^3, and shows transverse and longitudinal plasmon resonances at 470 and 700 nm, respectively, in a colloidal solution. The nanoparticles were dispersed on a fused-silica substrate using spin-coating of the colloidal solution. We investigated photopolymerization reaction in the periphery of the nanoparticle under circularly polarized illumination. For this purpose, the photopolymerizable mixture composed of the monomer divinylbenzene (DVB, 99 wt%) and the photoinitiator tetraphenylporphyrin (TPP, 1 wt%) was prepared. To start the polymerization reaction, a laser beam with a wavelength of 660 nm was irradiated to the substrate coated with Au@Ag nano-particles, which is immersed in the photopolymerizable mixture. Upon the irradiation, the excited state of TPP can initiate the polymerization reaction and immediately form polymer layers on the substrate.

Figures 2a and b show SEM images of the product on the Au@Ag cuboid nanoparticles after the exposure of a laser beam with left- and right-handed circular polarization (LCP and RCP), respectively. Depending on the handedness of circular polarization of the illumination, the S- or inverted S-shaped polymer layers that were oriented along the longitudinal axis of the nanoparticle were formed. In addition to it, if we look at the long-range area of the photo-treated sample, a spiral-shaped surface pattern was found, as shown in the AFM image (Figure 2c). The polymer structure formed on the surface by the LCP beam was formed in a circular area with a diameter of about 6 μm, which is matched with the area of the laser beam irradiation. The thickness of the polymer layer was about 200 nm in the central part, which corresponds to the thick polymer layer near the nanoparticle surface,

and it gradually decreased toward the outer edges. Radial groove patterns with periodic intervals (440 nm) were developed in the form of a double Archemedean spiral structure.

We discuss the origin of the created spiral photochemical product based on finite-difference time-domain (FDTD) simulation of the electric field near the nanoparticle. Figures 2d-g represent simulated optical field intensity in the periphery of the nanocuboid on the illumination of left- and right-handed circularly polarized light. In the close vicinity of the nanocuboid, assymmetric field distribution depending on the handedness of the circular polarization was generated, which well explains the created chiral polymer structures depicted in Figures 2a and b. In the wider area around the particle, we can find Archemedean-spiral-like structures of the field intensity, which reasonably resemble the created spiral structure observed in Figure 2c. The separated components of incident and scattered (by the particle) fields did not show any chiral feature (Figure 2h and i), which indicate that the double spiral structure might be originated from the interference between the incident (background) circularly polarized field and the scattered field by the plasmonic nanoparticle at the center.

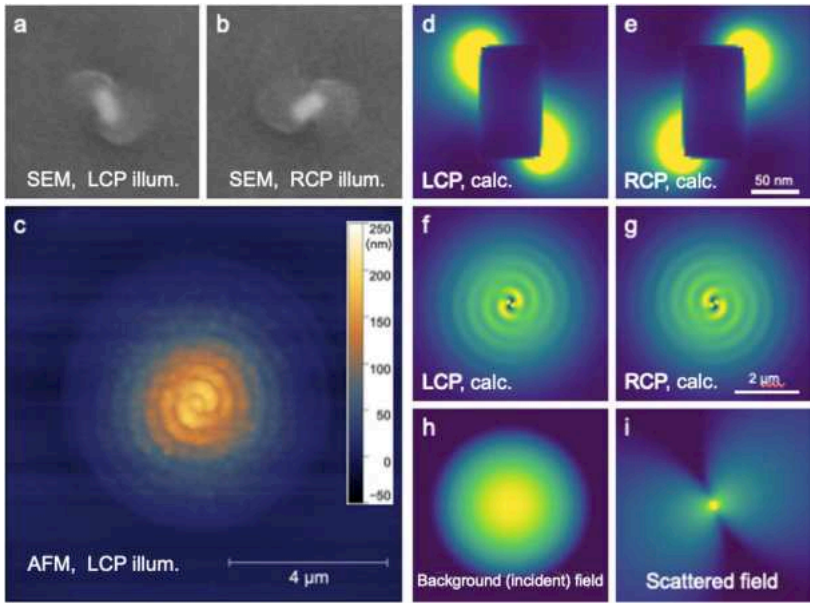

Fig. 2 (a,b) SEM images of photopolymerized structure formed around the cuboid nanoparticle under the (a) LCP and (b) RCP illumination. (c) AFM image of chiral double spiral structure. (d,e) Simulated electric field intensity near the cuboid nanoparticle under (d) LCP and (e) RCP illumination. (f,g) Simulated electric field intensity in several micrometer scales under (f) LCP and (g) RCP illumination. (h,i) Electric field distribution in log-scale of (h) background field of incident beam and (i) scattered field from the nanoparticle.

It is noteworthy that the chiral electromagnetic field scattered from the nanoparticle, although it is much weaker than the incident field in the far-field region, creates spiral-shaped intensity modulation over the several micrometer scale, and photopolymerization reaction condition used in this study is sufficiently sensitive to replicate the intensity profile of the generated interference pattern. We expect that further engineering of the geometry and the resonance of the central nanoparticle can yield the different chiral shapes of the interference patterns and the resulting chiral polymerized structures.

Abstract: Optical Mie resonators based on silicon nanostructures allow tuning of light-matter interaction. Optically active materials such as transition-metal dichalcogenide monolayers or europium ions can be placed in the near-field region of such Mie resonators allowing control of both the excitation and the emission processes trough antenna design and cylindrical vector beams.

Enhancing and controlling the light emission of quantum emitters coupled to optically resonant nanostructures is essential for new light sources at the nanoscale. The photoluminescence (PL) intensity of a quantum emitter at a position r coupled to a nanoantenna is influenced by three parameters, as expressed in the following equation[1]:

$$I(\mathbf{r}, \omega_{exc}, \omega_{em}) = P_{exc}(\mathbf{r}, \omega_{exc}, \omega_{em}) \times \phi_{em}(\mathbf{r}, \omega_{em}) \times C_{coll}(\mathbf{r}, \omega_{em}) \quad (1)$$

where $P_{exc}(r, \omega_{exc})$ is the excitation rate, proportional to the excitation pump, $\phi_{em}(r,\omega_{em})$ is the quantum yield related to the local density of photon states (LDOS) at the emission angular frequency ω_{em}, and $C_{coll}(r,\omega_{em})$ is the collection efficiency, that depends on both the emission directivity and detection geometry.

Here we show that by placing an atomically thin semiconductor (TMD) directly in the near-field of individual dielectric nanoresonators, give us access to $\phi_{em}(\mathbf{r},\omega_{em})$[2, 3] without the use of complex near-field spectroscopy techniques. We compare the near-field resonance energies with far-field resonance energy measurements on the same resonators and observe a clear blue-shift of the near-field energies in our far field results. We show tuning of the optical absorption of the atomically thin semiconductor $MoSe_2$ through the interaction with the nanoresonator near-field.

In a second time, we investigated the photoluminescence mappings of Eu^{3+}-doped cluster-deposited films on Si nanorings using different cylindrical vector beams. We demonstrate that the polarization and shape of the excitation beam can also be used to manipulate light emission, as azimuthally or radially polarized cylindrical vector beam offers to spatially shape the electric and magnetic fields, in addition to the effect of silicon nanorings (Si-NRs) used as nanoantennas[4]. Now, in addition to the photon LDOS, we show that the excitation

beam shape and polarization have an important effect. Radial and azimuthal polarized beams exciting ring shape nanoantennas allow to tune the near-field hot spots, hence the local PL enhancement.

Our results show that it is possible to spatially shape the photoluminescence of quantum emitters coupled to dielectric nanoantennas by both the excitation and emission channels, offering important insights for the design of efficient TMD and Rare earth ions-based nano-devices.

Abstract: Pure or tungsten-doped vanadium dioxide thin films are elaborated by pulsed laser deposition. Gold nanoparticle arrays are then deposited by e-beam lithography. The metasurface ultrafast optical response is determined. The influence of the localized plasmon resonance is analyzed in terms of photothermal conversion and near-field enhancement.

Thermochromic materials such as vanadium dioxide (VO_2) exhibit an insulator-metal phase transition (IMT) when their temperature exceeds a certain value or when they are illuminated by ultrashort light pulses. The phase transition occurs at the temperature T_{IMT}=68 °C for pure VO_2, and T_{IMT}=25 °C for VO_2 doped with tungsten ($W_{2\%}V_{98\%}O_2$). By combining plasmonic nanoparticles (NPs) and thermochromic materials, it is possible to obtain a metasurface with improved optical properties and faster dynamics compared with conventional VO_2.

We produced such metamaterials using various nanofabrication techniques. They consist of a thin layer of tungsten-doped VO_2 supporting, in a 2D lattice arrangement, gold nanodisks or nanorods produced by electron lithography. The temperature and thickness-dependent optical properties of VO_2 thin films were measured by spectroscopic ellipsometry. The results were analyzed alongside structural and electronic characterizations to elucidate the underlying physical origin of VO_2's distinctive properties. In addition, using ultrafast time-resolved pump-probe spectroscopy, we demonstrated a clear improvement in the optical properties of samples combining a doped-VO_2 thin film and gold NPs as compared with a configuration combining VO_2 and NPs, or simply with doped-VO_2 alone. These results highlight the contributions of the plasmonic effect and VO_2 doping on the energy threshold required to induce the phase transition. The mechanisms behind this threshold lowering will be discussed, involving photothermal conversion and amplification of the optical near-field by the NPs.

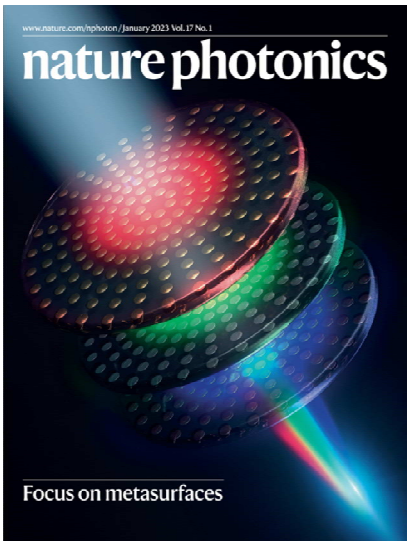
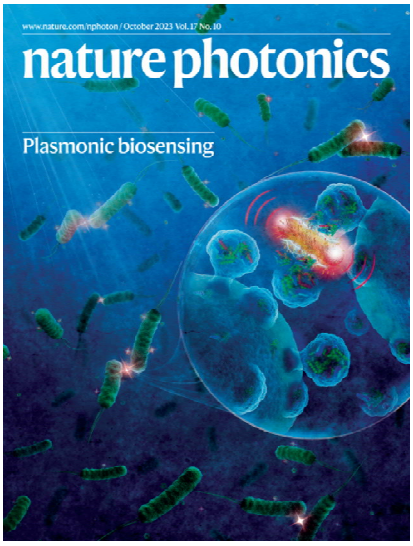
Publishing in *Nature* journals



Rachel Won



Nature Photonics, UK
r.won@nature.com

Abstract: In this talk, Rachel will tell you all you need to know about publishing your work in *Nature* journals, including an introduction to existing and new *Nature* journals, recent trends in publishing, options you have during your submission, and the editorial and peer review processes.

Biography: Rachel Won is an International Editor of *Nature Photonics*. She joined the journal in June 2006 as one of the four Founding Editors. Before that, Rachel worked for Aston University's Business Partnership Unit in Birmingham, UK, as a Medici Fellow, commercializing the research output of the university, particularly that of photonics research. She obtained her PhD in microwave photonics and nonlinear optics as a member of Aston's Photonics Research Group. She worked for Philips Optical Storage in Singapore as an Optics Engineer after completing her Master's degree study in Nanyang Technological University of Singapore doing research in optical fibre sensing. She holds a Bachelor's degree from the National University of Malaysia. She is a Fellow of OPTICA and SPIE (the International Society of Optics and Photonics).

Bound States in the Continuum: Advancements in Photonics from Enhanced Upconversion to Ultra-Sensitive Sensors

Abstract:
Bound states in the continuum (BICs) refer to special electromagnetic modes that exist within the continuum of radiation modes but do not couple with them. Specifically, BICs are resonant states that possess infinitely high Q-factors due to their non-radiative nature [1, 2, 3]. Unlike typical resonant modes that radiate energy into the surrounding medium, BICs are characterized by their inability to couple with external radiation. This results in a divergence of the Q-factor, making them highly desirable for various applications in photonics and optical engineering. Our research group has showcased numerous applications of BICs, including biological and chemical sensing and imaging with the capacity to detect molecules of ultralow weight [4, 5, 6, 7], as well as surface amplification of fluorescence emission and Raman scattering [8].

Herein, we report remarkable recent results regarding two different applications. Firstly, we propose the concept of supercritical coupling in near-field coupled resonances close to the Friedrich–Wintgen condition applied to the giant enhancement of lanthanide nanoparticles upconversion [9]. Secondly, we present a pioneering sensor platform empowering the BIC sensing principle with a molecularly imprinted polymer (MIP) cladding layer suitably engineered for specific binding to transforming growth factor-beta (TGF-β), a multifunctional cytokine involved in regulating various cellular processes, including cell growth, differentiation, migration, apoptosis, and immune responses.

Both results highlight the growing significance of BICs and their role in advanced technologies through innovative coupling mechanisms.

Abstract: We demonstrated the strategies for the synthesis of Gold NanoSpheres (AuNS), NanoRods (AuNR), and NanoWires (AuNW) that are both scalable and affordable. We explored how their properties can be tailored for optimal performance in specific applications. Implementing our approaches enables the realization of the full potential of gold nanoparticles and their assemblies, opening avenues for practical applications across various domains.

The intense light-matter interactions and large optical cross-section of metallic nanoparticles and their assemblies enable efficient focusing of optical fields at nanoscale. This unique capability is highly dependent on the shape and size of the nanoparticles enabling them to be a potential platform for a range of applications, including sensing, photo-detection, spectroscopy, and optical information processing. However, in order to realize the potential of these nanoparticles for practical use, it is crucial to develop scalable, reproducible, and cost-effective manufacturing processes that involve efficient synthesis with tunable structures, robust processing, and integration. Recent advancements, rooted in a deeper understanding of growth mechanisms, have transformed strategies along these lines for Gold NanoSpheres (AuNS), NanoRods (AuNR), and NanoWires (AuNW). Our synthetic strategies are designed to enable independent control of particle volume and dimensions while minimizing impurities and dispersity based on a refined understanding of the growth mechanism that governs the shape evolution of gold nanoparticles grown from single /penta twinned crystalline seeds.

These advancements have boosted production rates more than tenfold, while enhancing precise control over particle volume and dimensions, minimizing impurities, and reducing variation in particle size.1 As a result, solution dispersions exhibit absorption and scattering cross-sections nearing theoretical limits while displaying higher-order multipole plasmon resonances.2 As an example, we demonstrated films featuring voxelated structures

through the utilization of a highly concentrated solution (100+nM) tailored for specific applications.3 This involved combining techniques such as blade and spray coating, along with post-processing methods like laser reshaping. These films serve diverse functions as static and dynamic, multi-band filters, polarizers, and transparent conductors.

Development of new chiroptically active quantum nanostructures

Y. K. Gun'ko*

School of Chemistry and CRANN, Trinity College Dublin, Dublin 2, Ireland
*corresponding author: igounko@tcd.ie

Abstract: This work is to develop new types of nanoparticulate materials possessing optical activity and chirality, study their properties, investigate their nature and explore their applications. Here report a range of new chiral nanomaterials including chiral semiconducting nanoparticles as well as chiral 2D nanostructures for potential enantioselective chemo-sensing applications.

Symmetry and chirality are properties commonly found throughout the natural world. Chirality is one of the most important factors in molecular recognition, with chiral compounds having a major role in chemistry, biology and medicine. Chirality has also been envisaged to play an important role in nanotechnology. Over the last years the area of chiral nanoparticles has received a great deal of attention due to the range of potential applications offered by these materials [1-4].

The main aim of our work is to develop new types of technologically important inorganic nanoparticulate materials possessing optical activity and chirality, study their properties, investigate their nature and explore their applications.

We have developed a range of new chiral nanomaterials including chiral ternary silver indium sulfide and selenide based semiconducting nanoparticles (quantum dots). In addition, we started to explore the properties of new anisotropic chiral 2D nanostructures. The new nanomaterials have shown a very interesting optical activity and unusual chiral morphologies which were confirmed by various instrumental techniques.

Several critical aspects on the nanocrystals growth and chemico-physical characterization, and the optimisation of the surface passivation by the chiral ligand in order to optimize the nanoparticle chirality are thoroughly investigated. Optical spectroscopy as circular dichroism and luminescence as well as nuclear magnetic resonance techniques are exploited to analyze the coordination processes leading to the formation of the ligand-nanocrystal chiral interface. The study highlights the dynamic nature of the interaction between the nanocrystals surface and the chiral ligand, and clarify some fundamental aspects for the transfer and optimization of the chiroptical activity. We have also explored potential applications of chiral quantum dots for chiral recognition and luminescent chemo- and bio- sensing.

Finally, we present an overview of chiral nanomaterials within the framework of synthesis-structure-property-application relationships and provide insights on how to leverage machine learning for the study of these highly complex relationships (see Figure 1 below).

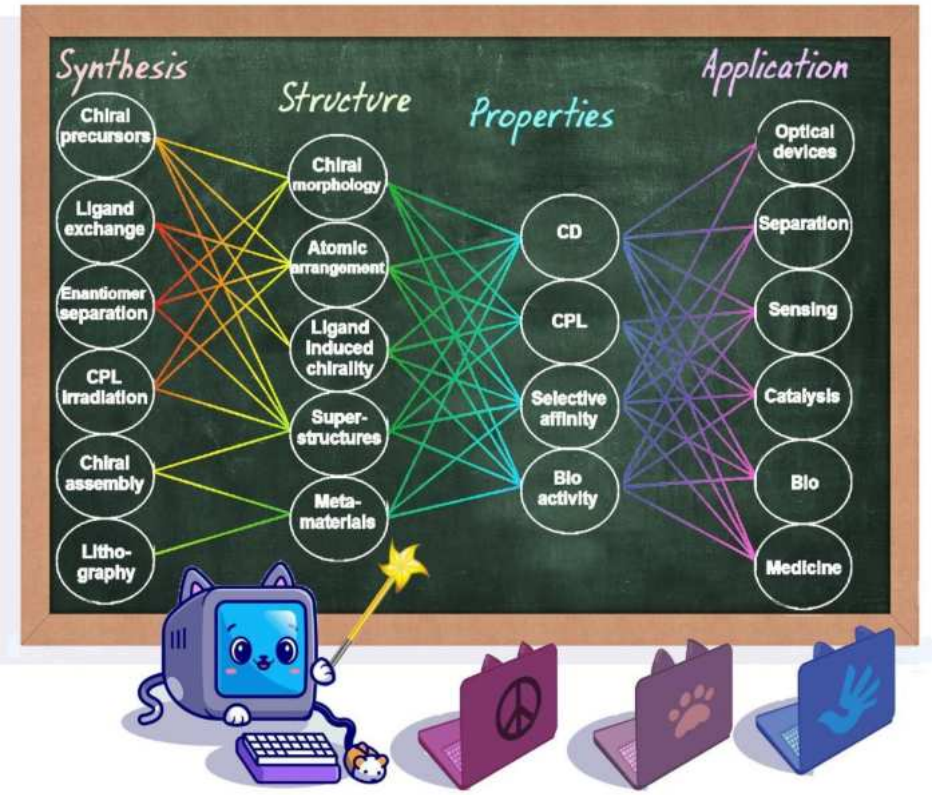

Figure 1. Schematic representation of the connectivity between synthesis, structure, properties, and applications of chiral nanomaterials [5].

Abstract: We self-assemble optical antennas based on silicon nanoparticles using the DNA origami technique. We exploit these structures to manipulate the fluorescence properties of single fluorophores placed in their proximity. We focus on effects on the fluorescence lifetime, intensity and directivity.

Over the last decade, the DNA origami method[1] has established itself as one of the most versatile techniques for the bottom-up synthesis of hybrid species with tailored functionality[2]. This approach, which is based on the self-assembly of DNA strands into arbitrarily designed 3D structures, can be exploited to organize different entities, such as fluorophores, proteins, or NPs with nanometer precision and stoichiometric control. Consequently, it has been widely used to produce a variety of optical antennas for sensing and light manipulation at the single molecule level in controlled geometries. However, to date this approach has been constrained to Au, Ag and QD NPs with no works reported so far on combining DNA origami with high-index dielectric NPs. In this work, we develop a technique to functionalize high-index dielectric colloidal Si NPs[3] with DNA sequences using click-chemistry. To further demonstrate these findings, we self-assemble Si NP dimers using the DNA origami technique. Finally, we also exploit the DNA origami technique to position both Si NPs and organic fluorophores at controlled gaps to study the distance dependance energy transfer, the modification on the fluorescence rates (figure 1b) and the emission directivity. Our results show that in the vicinity of the Si NPs the radiate rate increases more than the non-radiative rate and that the Kerker condition can be exploited to obtain emission unidirectionality (figure 1c).

Nonradiative Cooling

Wakana KUBO*

Tokyo University of Agriculture and Technology, Japan

*corresponding author: w-kubo@cc.tuat.ac.jp

Abstract: We report a nonradiative cooling technology that can reduce the temperature of space surrounded by an opaque container. When a metamaterial-loaded thermoelectric device is placed in an opaque and sealed container, the metamaterial absorber absorbs the thermal radiation inside the container, resulting in a temperature reduction inside the container.

Radiative cooling is a key technology that reduces the temperature of sky-facing objects through radiative energy transfer between the objects and outer space at 3 K. An atmosphere has a transparent window ranging from 8 to 13 μm, which coincides with the thermal radiation of an object at ambient temperature, leading to thermal radiation from the object to the outer space. However, this technology is not applicable when cooling objects and spaces are surrounded by opaque absorbers. Here, we report a nonradiative cooling technology that can reduce the temperature of space surrounded by an opaque container.[1] When a metamaterial-loaded thermoelectric device is placed in an opaque and sealed container, the metamaterial absorber absorbs the thermal radiation inside the container, and the thermoelectric element converts the thermal energy to electric current. The generated current flows to the resister placed outside the container, releasing thermal energy to free space as Joule heating. To the best of our knowledge, there is no literature reporting the cooling technology combined with the thermal gathering acquired by the MA and thermoelectric conversion.[2] In this study, we demonstrate nonradiative cooling realized by metamaterial thermoelectric conversion and examine whether the non-radiative cooing occurs in an opaque and sealed container.

We used an MA consisting of a Ag film and Ag disk sandwiching a thin layer of calcium fluoride (Fig.1(a)). The MA-attached thermoelectric device (Fig.1(a)) was installed in an opaque container as shown in Fig. 1(b). Figure 1(c) shows the absorption spectra of the MA and control electrodes, and the blackbody radiation spectrum calculated at 311 K. The MA exhibited a sharp absorption around 9 μm. This unbalanced absorptivity difference between the MA and control electrodes can induce an additional thermal gradient

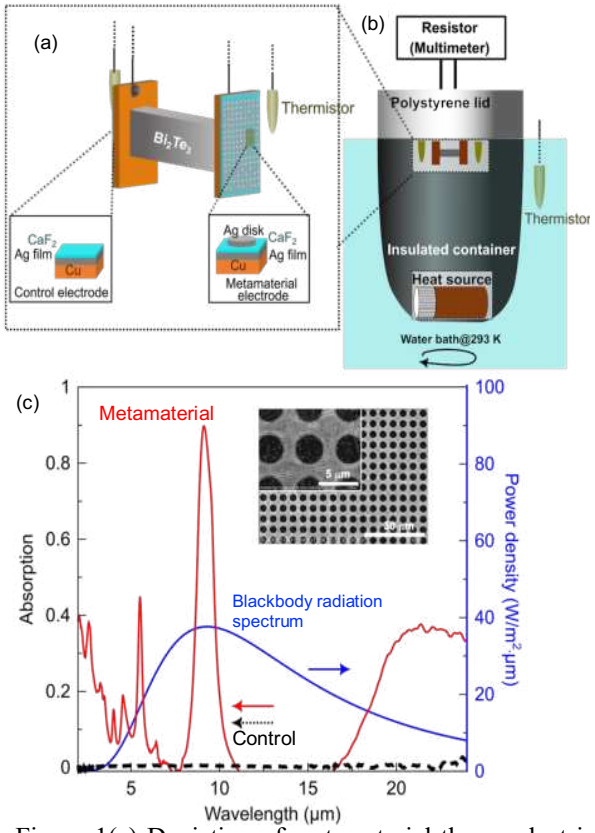

Figure 1(a) Depiction of metamaterial thermoelectric device and (b) schematic of a container soaked in a water bath at 293 K. (c) Comparison of absorption spectra of the metamaterial absorber (red line), a control electrode (dashed black line), and the blackbody radiation calculated at 311 K (blue line). The inset shows SEM images of the metamaterial absorber. The scale bars are 5 and 30 μm, respectively.

across the thermoelectric element, driving the thermoelectric conversion in an environment with uniform thermal radiation.

Figure 2(a) shows the time dependence of the environmental temperature difference of the containers loaded with MA or control devices. The container with the MA device showed a faster reduction in the environmental temperature than the container with the control device, indicating that the nonradiative cooling is demonstrated. The dashed lines in Figure 2(a) represent the effective output voltages generated by the MA and control devices. We repeated these experiments five times. Figure 2(b) shows the comparison of the averaged environmental temperature difference and effective output power generated on the MA and control devices. The environmental temperature difference in the container with the MA device was 6.2 ± 1.2 K (n = 5), while the container with the control device exhibited a difference of 5.9 ± 1.0 K (n = 5), resulting in a 0.4 K difference between the MA and control containers.

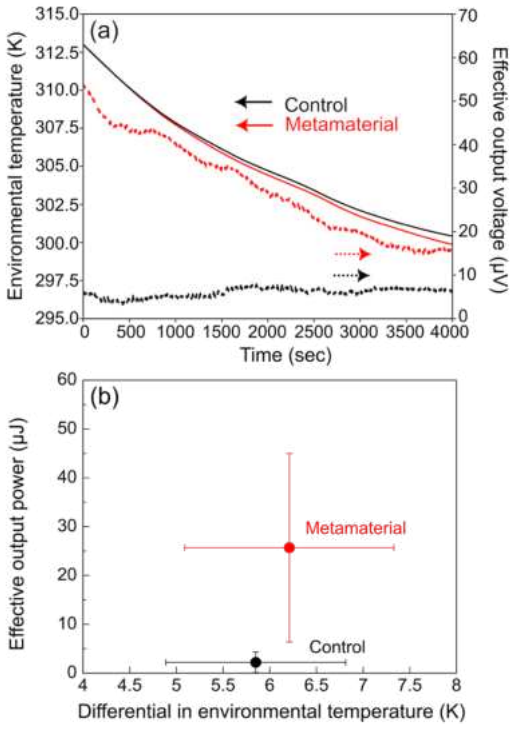

Figure 2(a) Time dependence of the environmental temperature difference within an opaque and sealed container loaded with the MA or control devices (solid lines) and the corresponding effective output voltages (dashed lines). (b) Comparison of the environmental temperature difference and the sum of output power generated on the MA and control devices observed for 1000 sec.

These results indicate that MA absorbs thermal radiation within the container and generates plasmonic local heat, creating a thermal gradient across a thermoelectric element and subsequent thermoelectric conversion. In addition, the electricity, which is a converted form of thermal energy through thermoelectric conversion, is transferred to the outside of the container, owing to the electrical bias generated on the thermoelectric device.

As proof of this concept, we evaluated the heat power extracted from the opaque and sealed container. If our experiment of nonradiative cooling is carried out ideally, the following equation is expected to hold,

$$Q_{cont} \cong Q_{MA} \cong \frac{Q_{TE}}{\eta}, \quad \text{Eq.(1)}$$

where, Q_{cont}, Q_{MA}, Q_{TE}, and η are the heat power extracted from the sealed container, the heat power absorbed by the MA, the heat power released through thermoelectric conversion, and the thermoelectric conversion efficiency, respectively. We evaluated these heat powers by analyzing five sets of measured data for comparison. Consequently, the calculated values of Q_{cont}, Q_{MA}, and Q_{TE} are (0.10 ± 0.05), 0.10, and (0.15 ± 0.05) J, meaning that these values fall within a very cloase range. These results support the fact that the temperature reduction inside the container with the MA is attributed to the thermal radiation absorption by the MA. We concluded that nonradiative cooling was successfully demonstrated. The nonradiative cooling gives an important insight that embedding arrays of metamaterial thermoelectric devices on the surfaces of roads and buildings suggests the potential for simultaneous environmental cooling and power generation through metamaterial thermoelectric conversion.

Proving non-thermal plasmon catalysis mechanism through the overtone vibrational quantum states

Zee Hwan Kim [1*]

[1]Department of Chemistry, Seoul National University, Seoul 08826, Korea
[*]corresponding author: zhkim@snu.ac.kr

Abstract: Employing SERS spectroscopy, we show that the plasmons activate the reactants to vibrational overtone states possessing > 0.5 eV of energy. We use the light intensity and wavelength dependences of the overtone population to quantify the non-thermal contribution to the activation and to validate the indirect hot electron transfer mechanism.

Plasmon-assisted chemical reactions, in which the chemical reactivity of surface-bound reactants is significantly enhanced and altered by the plasmon-excited metallic nanostructure, have attracted tremendous attention as a promising heterogeneous photocatalyst. One hypothesis for the mechanism is the non-thermal vibrational excitation (VE) of surface adsorbed reactants: the energetic electrons called the hot electrons (HEs), that are non-thermally excited during the decay of plasmons, transfer energy as a form of vibrational energy to the reactant. However, such a hypothesis has yet to be validated at the molecular quantum state level.

In this work, we study the steady-state distribution of overtone-excited reactants prepared by plasmon excitation. We find that the anti-Stokes peak of surface-enhanced Raman scattering (SERS) spectra of 4-nitrobenzene (NBT) reactant placed in a plasmon-excited metallic gap, obtained under the illumination of continuous-wave (cw) visible light, is asymmetrically broadened due to the overtone-excited reactants. From the lineshape analysis, we determine that at least 40 % of the vibrationally excited NBTs are in the overtone states under the light illumination of a few hundred kW/cm^2. We use the intensity and wavelength dependences of overtone-state distributions to clarify the thermal and non-thermal contributions to the activation and identify the physical origin of non-thermal activation.

Optoelectronic Physical Reservoir Computing with Digital Delayed Feedback featuring in situ Optimization

Abstract: Reservoir computing (RC) is a neuromorphic approach mimicking biological neural systems by employing randomized and fixed internal connections. This simplifies training and facilitates straightforward implementation. Optoelectronic oscillators are among the most promising material platforms for physical RC, combining optics' high modulation bandwidth with electronics' robustness, flexibility, and tunability. We've developed a physical reservoir achieving state-of-the-art performance in tasks like pattern recognition and time-series prediction using delayed feedback. Notably, a single physical node utilizing FPGA-based delayed feedback, delivers impressive results. Incorporating digital delay provides adequate delay time within the reservoir's operational bandwidth, compatible with generic electronic hardware. This capability allows for tuning and in-situ optimization of delay time, achieving a normalized mean squared error (NMSE) below 0.6 in NARMA10 time series recovery task.

In the heart of reservoir computing (RC) is a nonlinear network of recurrent dynamical nodes called a reservoir featuring fixed rather than trained connections, allowing straightforward physical realizations. One of the most widely explored realizations of RC is in the delay system. The structure of a generic and delay-based RC is schematically shown in Figure 1.

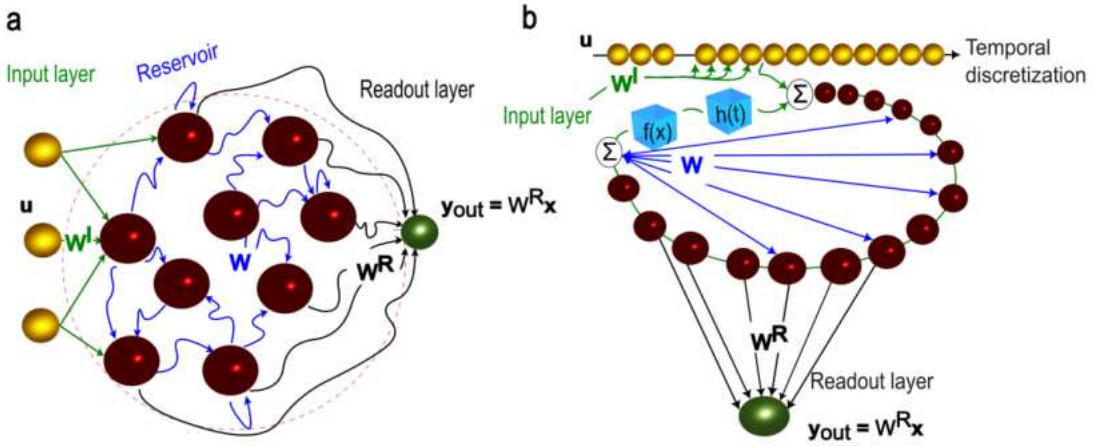

Figure 1: (a) Generic reservoir computing architecture. The depicted layout consists of distinct components: an input layer (bronze spheres) responsible for receiving external data, a reservoir (ruby spheres) featuring randomized fixed connections, and a linear readout layer (green spheres). (b) Delayed feedback-based reservoir

Figure 2 presents the experimental setup implementing RC in optoelectronic platform with delayed feedback.

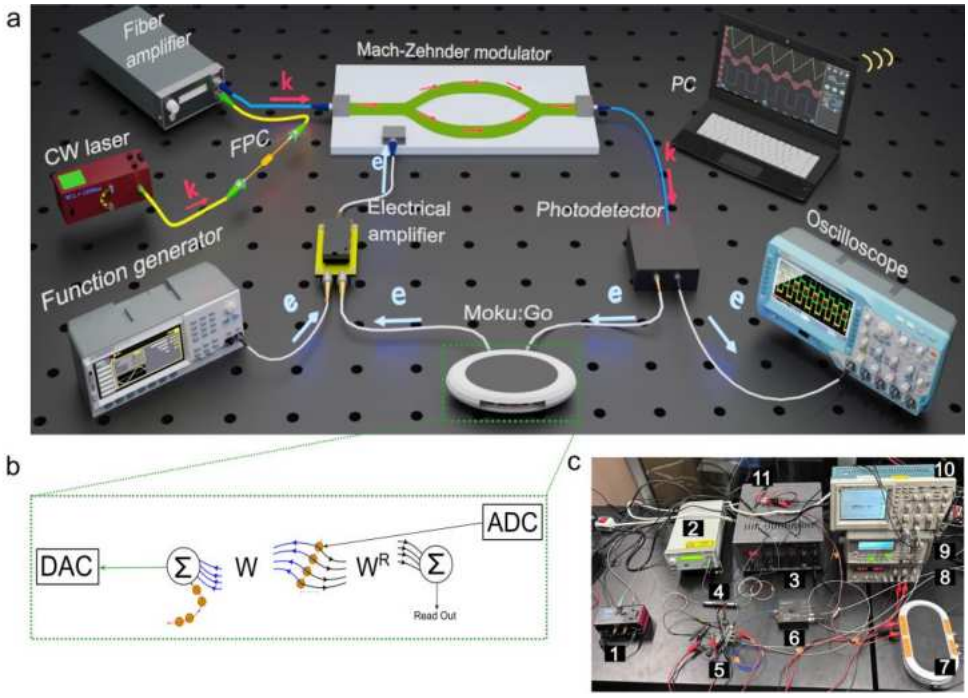

Figure 2: (a) Schematic of the experimental set-up. (b) Schematics of the digital delay and data digitizer combined with data digitizer: delayed feedback implements the reservoir's connectivity matrix W while the digitized reservoir states are weighted with the readout matrix W^R. (c) Photograph of the experimental setup, components are labeled as follows: 1. continuous-wave laser, 2. Erbium-doped fiber amplifier, 3. function generator producing trigger signal. 4. fiber polarization controller, 5. Mach-Zehnder modulator with electrical driver, 6. photodetector, 7. Moku:Go, 8. power supply for the electrical driver, 9. arbitrary waveform generator, 10. oscilloscope, 11. variable optical attenuator.

Figure 3 shows the results of *in-situ* optimization of our RC for NARMA10 time series recovery task.

Innovative Deposition and Oxidation-Coupled Technique for Low-Temperature Fabrication of VO_2 Thin Films and their Application to Photonic Devices

M. Chaker[1*]

[1]Institut National de la Recherche Scientifique, Centre Énergie Matériaux Télécommunications, Varennes, Qc, Canada
[*]corresponding author: mohamed.chaker@inrs.ca

Abstract: Vanadium dioxide is a "smart" material that exhibits a metal-to-insulator transition at a temperature of 68 °C. This property makes it of strong interest for many applications, including advanced photonic devices. An innovative deposition method is presented to achieve VO_2 thin films at low temperature on large area scale.

With the growing trend towards portable and adaptable devices in various fields, the demand for flexible electronics and coatings utilizing phase transition materials like vanadium dioxide (VO_2) as a functional layer is rising. VO_2 possesses a notably low transition temperature (T_c = 68°C) suitable for such applications. However, depositing high-quality crystalline VO_2 films directly onto polymer substrates remains challenging due to the thermosensitivity of such materials being barely compatible with usual VO_2 deposition methods. Two aspects were investigated in the present research. First, we introduced an improved deposition technique called sputtering oxidation coupling (SOC) using VN as intermediate material [1]. VN films are first deposited on quartz by magnetron sputtering. In a second step, a post-annealing process in oxygen is carried out to obtain VO_2. The lowest possible temperature for achieving VO_2 from VN with a significant electrical transition contrast is found to be 400°C, which makes the proposed method promising for growing VO_2 films directly on heat-sensitive polymer substrates such as Kapton. Second, we deposited VO_x films onto a Kapton substrate at room temperature using pulsed laser deposition (PLD) from a vanadium target and subsequently annealed it in an oxygen atmosphere at 390°C [2]. The electrical and optical properties of the VO_2/Kapton samples with different film thicknesses obtained by both techniques were investigated. The 200 nm-thick PLD vanadium dioxide films exhibit the best resistivity contrast with 3.1 orders of magnitude (OOM), while the 50 nm-thick PLD films show the best transmittance change of 54% at 2500 nm. The switching performances are comparable or even superior to those achieved previously using more complicated synthesis processes such as film transfer, introduction of buffer layers, and ink injection. Additionally, by coupling W elemental doping and thin film strain, we successfully tuned the VO_2 transition temperature to room temperature with a dopant concentration of only 1.1 at.% while maintaining a high electrical contrast (2 OOM). The impressive electrical and optical transition performance of the VO_2/Kapton samples, combined with their tunable transition temperature, makes them promising candidates for flexible electronic devices and photonic devices.

Ultrafast Processes and Energy Dissipation in Hybrid Nanomaterials

G. P. Wiederrecht[1]

[1]Center for Nanoscale Materials, Argonne National Laboratory, Lemont, IL, 60126, USA,

[*]corresponding author: wiederrecht@anl.gov

Abstract: Optically induced ultrafast processes are characterized to better understand energy flow and dissipation in nanostructured materials. The potential impacts on hybrid nanomaterials of interest for optoelectronics, energy conversion and sensing are described. Efforts to enhance the range of materials that can be explored by ultrafast spectroscopy are also described.

Nanostructured materials and their interaction with light produce many interesting and potentially useful properties. In many cases, the nanostructure size, shape, composition and local environment enable control of the magnitude of light-matter interactions at the nanoscale. This can produce important opportunities in widely varied fields such as quantum optics, optical energy conversion, nonlinear optics, sensing and many others. For example, in plasmonic materials, nanostructuring is known for producing large evanescent electromagnetic field enhancements near surfaces as compared to the bulk. This process is of strong interest for sensing given the fact that many plasmonic materials can be functionalized to selectively bind a wide range of molecular analytes. Another property of plasmonic nanostructures is that the enhanced electromagnetic fields at their surface can help produce a higher concentration of “hot” or “nonthermal” electrons that in principle can be used to perform work.[1] Hybrid systems, whereby the second material can interact with the enhanced field or enhanced concentration of hot electrons, can be designed to attempt to harness these enhanced photoprocesses for improved application efficiency. Electromagnetic coupling between closely spaced nanostructures, such as in many metamaterials, can also create enhanced and tunable light-matter interactions for varied applications.

These applications are impacted by ultrafast processes that frequently play a key role in the flow of energy and energy dissipation in nanoscale materials. For example, many nanomaterials undergo strong and ultrafast electron-phonon coupling (picoseconds or even faster) following the absorption of a photon, with optically excited electrons dissipating their energy into phonons as heat that can lead to poor optoelectronic performance or even melting. Time-resolved spectroscopy can be applied over varied spectral, temporal and spatial ranges to extract vibrational, electronic and structural changes resulting from photoexcitation and subsequent energy flow.[2] In this talk, ultrafast spectroscopy of novel nanomaterials are described, including high melting point refractory plasmonic metal nanostructures and colloidal nanoplatelets that can produce multi-exciton behavior upon photoexcitation. Hybridization of plasmonic and semiconductor materials, and the impact on ultrafast processes, are also described.

Ultrafast spectroscopy techniques that enable a wider range of materials to be studied are also described. In a nutshell, many interesting materials that are of interest for study cannot withstand ultrafast pulse illumination for a period long enough to characterize via standard spectroscopic techniques. We describe approaches, particularly ultrafast compressive sensing approaches, that can dramatically decrease the length of time needed to determine dynamical responses following optical excitation.[3]

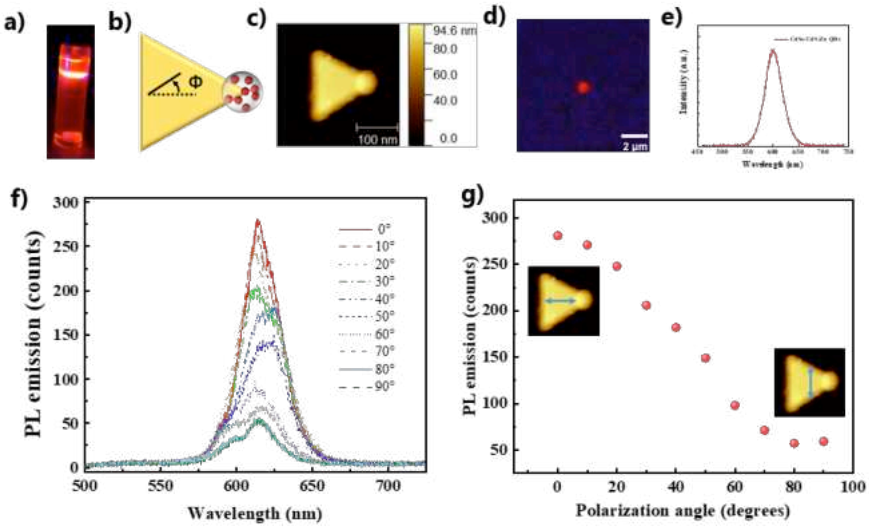
Abstract: The development of hybrid plasmonic nanosources of light require the control of the spatial distribution of the active medium in the vicinity of metallic nanoparticles. An approach used to take up this challenge is based on plasmonic photopolymerization. In particular, the spatial symmetry can be controlled at the nanoscale.

Modern information and communication technologies request higher bandwidth and more efficient energy data communication to solve the challenge of increasing data traffic. In this context, optical data is the key: the fast development of integrated optics and nanophotonics has realized more and more optical functionality in a small chip [1]. Rapid growth of this nanophotonics area requires the development of advanced nanosources of light whose geometry must be scalable with nanophotonic devices and whose tunability must be simple and efficient. Over the past two decades, hybrid plasmonic nanosources based on energy transfer between metal nanoparticles and semiconductor quantum dots/nanocrystals (QDs) or organic dyes have turned out to constitute a promising solution of efficient optical nanosources [2].

We will discuss the different regimes of coupling between an active medium and a metallic nanoparticle that is seen as a nanocavity or a nanoantenna, and will stress the importance to control the nanoscale spatial distribution, and related symmetry, of the active medium.



In microscale optoelectronics, the possibility to precisely control the spatial distribution of the active medium leads to optimization of systems and devices. At the nanoscale, this issue still constitutes a challenge.

We studied and exploited the controlled nanoscale spatial positioning of semiconductor quantum emitters in the close vicinity of metal nanostructures. This control relies on plasmon-assisted nano-polymerization [3,4] of a photosensitive formulation that hosts nano-emitters[5,6,7]. In addition to offering a promising platform for nanochemistry, this approach enables the design of the symmetry of the medium surrounding plasmonic nano-antenna.

Through selected examples, we will show that this approach has opened many new avenues and exciting concepts, such as

- Polarization-sensitive photoluminescence [8] (see Figure below as an illustration)
- Polarization-driven color selection [4]
- Life time engineering [9]
- Control of the local space symmetry group

- Rationalized plasmon-assisted donor-acceptor energy transfer [4]
- Single-photon switch that is driven by polarization [8]

Abstract: We present a direct sampling approach for localized surface plasmons in the petahertz domain, permitting to trace few-fs transient fields in the visible spectral region. The experiment can be accompanied by single-digit femtosecond optical pump-probe spectroscopy to correlate plasmon damping and electron dynamics in the time domain.

Determining the orientation of gold nanorods by means of polarimetric spectroscopy

P. C. Simo[1*], A. Mildner[1], D. P. Kern[1], and M. Fleischer[1*]

[1]Institute for Applied Physics and Center LISA+, 72076 Tübingen, Germany
[*]corresponding authors: christian.simo@uni-tuebingen.de, monika.fleischer@uni-tuebingen.de

Abstract: We present a technique to acquire the azimuthal orientation of gold nanorods of various aspect ratios within just four measurements. Dark-field spectroscopy enables the extraction of the eigenmode line shape and phase shift information, which can be used in tandem with an analytical dipole model to determine the azimuthal orientations.

Applications of chiroptical spectroscopy in biomedical and pharmaceutical research fields heavily depend on the knowledge of the azimuthal orientation of a structure, such as a gold nanorod (GNR), since the information on the polarization state is needed to investigate optically active hybrid compounds.[1] Similarly, angled meta-atom constituents of metasurfaces also need to stay within a low error margin to pass quality control and thus benefit from a reliable non-destructive method to extract their azimuthal orientation. When observing GNRs for simplicity, their azimuthal position naturally coincides with their plasmonic longitudinal resonance (LR) mode and can be determined with conventional excitation polarization sweep measurements.[2] Considering the high number of measurements per GNR, the throughput is limited and prone to errors originating from human precision. High-throughput single-shot methods could be achieved with an advanced optical setup and image analysis with deep-learning algorithms to eliminate the human error; however, the orientation predictions oftentimes depend on the aspect ratio (AR) <1.6 of the GNRs and on reaching standard deviations of below five degrees.[3,4]

In this work, we show an alternative spectroscopic method that gains angular information of a single GNR within four measurements with a regular dark-field setup, two polarizing filters, and a cross-shaped aperture, reaching a standard deviation of ±2.4°. Coherently fitting the measurements with the help of an analytical dipole model, the azimuthal angle of the LR is extracted by varying the planar orientation of the analyzing filter.[5] The additional elements, such as a piezo-electric rotational mount for the positioning of the analyzing polarizer filter, reduce the human error to a minimum while enhancing automation possibilities.

The analytical dipole model describes the intensity of the electric far-field radiation from dipoles excited by a plane wave with an arbitrary polarization angle Φ.[5] Each dipole with individual orientation and magnitude will express a phase shift φ relative to the polarized incident plane wave. If the electric far-field radiation is analyzed with a polarizing filter of angle Θ, the relative phase between the dipoles allows the extraction of the dipolar orientation. The phase shifts φ_1 and φ_2 of two dipoles with magnitudes $p_1(\omega)$ and $p_2(\omega)$ and respective orientations β and γ, which represent the orientations of transverse resonance (TR) and LR modes, can be calculated from a dark-field spectrum of a randomly spin-coated GNR under unpolarized excitation (see Figure 1a)). By keeping the excitation angle fixed at $\Phi = 45°$ and varying the analyzer angle to a set of random angles (here $\Theta = [9°, 106°, 155°]$), one can use the model to fit the data coherently and extract γ_{fit} (Figure 1b)). Comparing γ_{fit} to the SEM-extracted angle γ_{SEM} shows a standard deviation of only ±2.4° (see Figure 1c)). An SEM micrograph with the drawn-in γ_{fit} and γ_{SEM} can be seen in Figure 1d) and shows good concordance. This approach proves to be reliable with a low sensitivity to AR compared to the current state of the art.

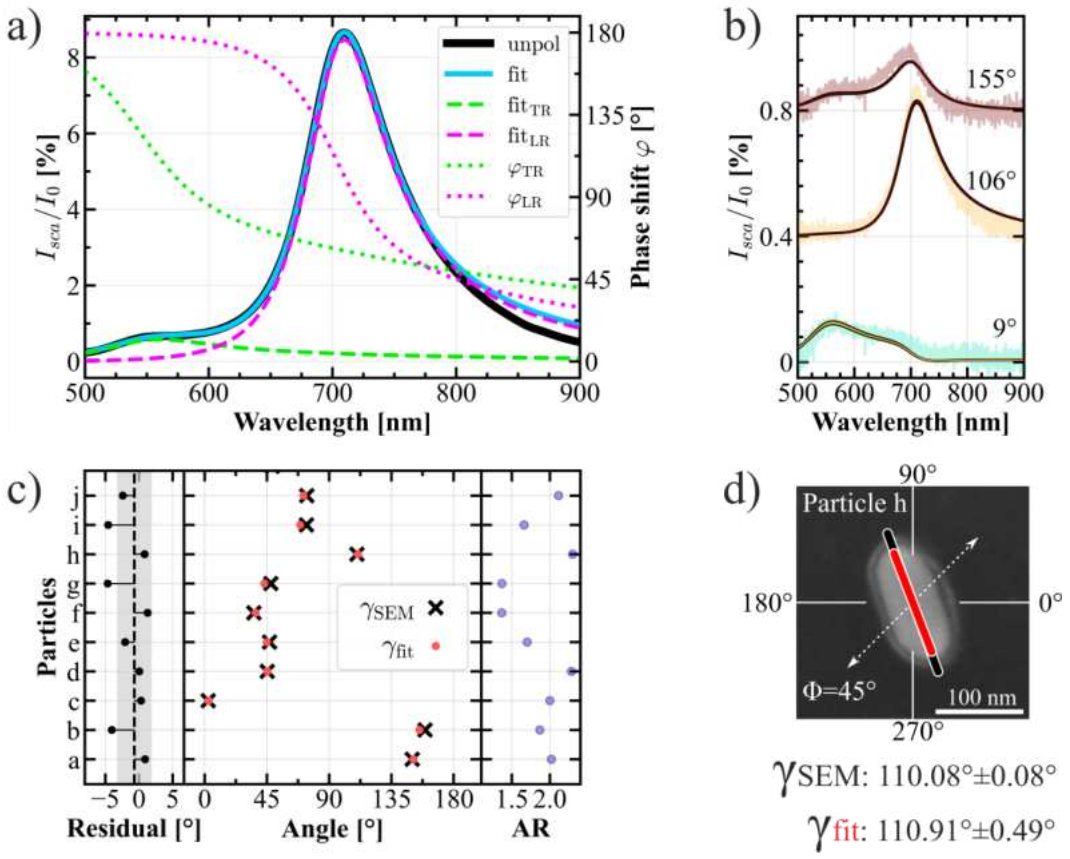

Figure 1. a) Spectrum under unpolarized excitation with fitting curve. The separate TR and LR modes were also plotted with the respective phase shift φ of the mode. **b)** Stacked polarimetric dark-field measurements with fixed excitation polarization and varied analyzer angle fitted coherently with the dipole model to extract the LR orientation γ_{fit}. **c)** Angles γ_{fit} from a collection of GNRs compared to their physical orientation γ_{SEM} extracted from SEM images. Residuals and the AR variation are also displayed to show the low standard deviation (gray band) and broad AR distribution (blue dots). **d)** SEM micrograph of particle "h" with superimposed axes and values of γ_{SEM} (black) and γ_{fit} (red).

Abstract: High volumetric optical cavity is essential for high performance light-emitting devices where absolute absorption is necessary. In this talk, I will present several design concepts of dielectric resonant nanostructures to enhance the fluorescent down-shifting proccess of colloidal quantum dots for applications in high-resolution full-color displays.

In the first design, we propose a resonant nanostructures based on the hybridisation of a waveguide mode within the quantum dot (QD) layer and a resonant “Bloch mode” originating from the high-index contrast grating made of TiO2 stripes on glass substrate as shown in Fig. 1a. The resonant structure has dual resonances at the blue wavelength (emission peak of microLEDs) and green wavelength (emission peak of green QDs) as shown in Fig. 1b,c, which can enhance both in-coupling (i.e., absorption) and out-coupling (i.e., emission) of the device. Most importantly, it has a large mode volume that results in the enhancement of a large number of QDs within the structure. Another design approach is to use a Gires-Tournois etalon cavity (aka the asymmetric Fabry-Perot etalon). This etalon is a standing-wave optical cavity that reflects light of all wavelengths of interest with a strong dispersion of the phase delay. Controlling the phase delay at the resonance wavelength for certain angle(s) allows maximum power transfer to the optical cavity. We modified the cavity by adding a metasurface layer made of SiO_2 and TiO_2 to further improve the optical confinement and thus, absorption in QD layer (Fig. 1d-f).

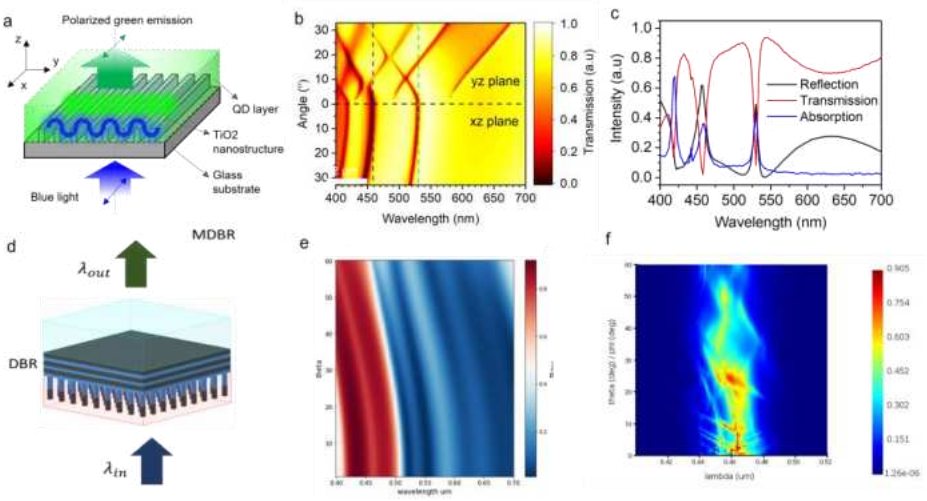

Figure 1. (a) Concept of nanoantenna-enhanced downconversion by high index grating. (b) Simulated angle-resolved transmission spectra. (c) Transmission, reflection and absorption of QDs in the grating cavity. (d) Concept of Gires-Tournois metasurface-DBR (GTMD) to enhance absorption. (e) Angle resolved reflection of the DBR mirror. (f) Absorption of the green QD as a function of angle of incidence and wavelength.

To pattern the QD on top of the pixelated nanostructures, we developed a direct deep-patterning technique for making fluorescent patterns with near-unity pixel yield, well-preserved quantum efficiency, precisely defined lateral sizes as well as uniform and desirable thickness for both green and red emitters with pixel sizes down to 300 nm as shown in Fig. 2a - d. A large mode volume can be created within a thin layer of the quantum dots (i.e., ~ 400 nm) by the interaction of the nanostructure resonances and the optical modes. This allows maximum mode overlapping between the resonance and the quantum dots, resulting in a large absorption and emission enhancement as can be seen in Fig. 2 e,f. We have achieved the maximum enhancement of ~ 141 times and a total emission enhancement of ~ 40 times within 0.55NA. The enhancement encompasses absorption enhancement, Purcell enhancement and directionality enhancement (i.e., outcoupling). We achieved total absorption of 35% for green quantum dots with a remarkably thin layer (i.e., ~ 400 nm).

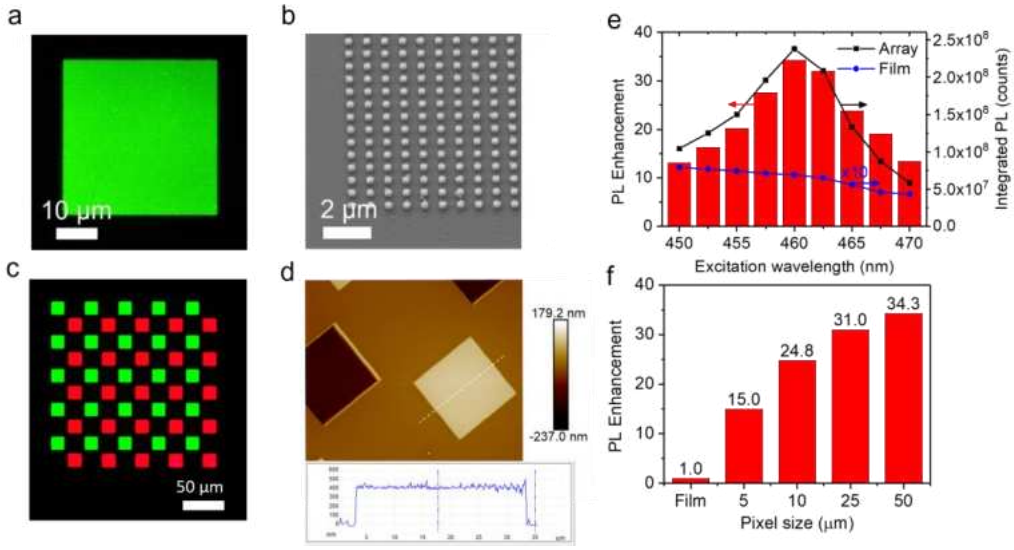

Figure 2. (a-b) Florescent microscopy images (a) and the corresponding SEM (b) of patterned green QDs with pixel size of 300 nm. (c) 2-layer patterning of green and red quantum dots with lateral accuracy of less than 100 nm. (d) AFM measurement of patterned QD layer on top of resonant nanostructure. (e-f) Fluorescence enhancement of QDs within the resonant nanostructure for different excitation wavelengths (e) and pixel sizes (f).

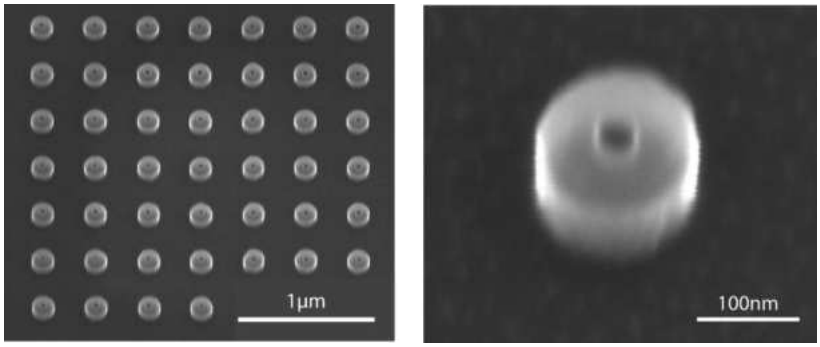
Abstract: Chirality is omnipresent in biochemistry, where molecules with opposite handedness can have markedly different effects. Detecting molecular chirality is however plagued by low sensitivity, limiting it to high concentrations and volumes. We present nanophotonic structures and a polarization-modulation microscope to push the limits of chiral sensing using fluorescence.

Detecting the handedness of chiral molecules is critical in biomedicine, where the functionality of biomolecules such as proteins, amino acids, and carbohydrates can strongly differ between enantiomers. Circular dichroism (CD) is commonly used to distinguish enantiomers based on the differential absorption of right- and left-handed circular polarizations of light by chiral molecules. This transmission-based method requires measuring very small changes in absorption, which is inherently difficult at low concentrations due to the large background caused by the light source itself. As a result, the sensitivity is reduced, requiring a high density of molecules and long measurement times. Conventional methods are thus unsuitable for critical applications like detecting protein aggregates linked to various diseases.



Silicon nanoantennas tailored to boost fluorescence-based chiral sensing.

Fluorescence-based chiral sensing bypasses some of the difficulties of CD by detecting light emitted at a different wavelength than the excitation source, allowing for the complete removal of the source background from the signal. In general, fluorescence-based chiral sensing can be split into two categories. Firstly, fluorescence detected circular dichroism (FDCD), where the differential absorption is measured as a difference in emitted fluorescence intensity. Secondly, circularly polarized luminescence (CPL), where molecules are excited by unpolarized light and the circular polarization of the emitted fluorescence is measured. Nanophotonics offers two routes to enhance the sensitivity of chirality detection [1], [2], [3], [4]. Super-chiral fields, offering a higher

chirality than circularly polarized plane waves, can exist within the near field of nanophotonic structures. Furthermore, nanophotonics can enhance the detected fluorescence intensity through excitation, Purcell, and collection enhancements. Our simulations using silicon nanostructures show a 10-fold polarization enhancement while simultaneously enhancing the fluorescence intensity 1000 times. This combination of enhancement is promising for probing molecular chirality at the single-molecule level, eliminating the impact of ensemble averaging.

We present our experimental progress, including fabrication methods for achieving such nanostructures using crystalline silicon for its high refractive index and lower losses than amorphous silicon. Furthermore, we introduce a custom-built microscope setup for measuring degrees of circular polarization below 1%. We use photoelastic modulation for precise polarization modulation and an avalanche diode for photon counting to enable lock-in detection with suppressed noise.

SEM images of fabricated nanophotonic structures for chiral sensing.

In conclusion, we combine advancements in silicon metasurfaces tailored for fluorescence-based chiral sensing and a novel polarization-resolved microscope to increase the sensitivity toward single-molecule chirality detection.

Abstract: Within this work, we investigate how mid-infrared can excite sub-diffractional, volume-confined hyperbolic modes within nanostructured surfaces of (100)-cut calcite crystals. We find that controlling the relative orientation of these nanostructures and the crystal anisotropy provides unique tuning of the spectral and energy propagation characteristics of these modes.

Calcite is the quintessential birefringent material – possessing different optical properties along its crystal axes. While small differences in the optical permittivity of calcite lead to interesting effects like double refraction in the visible spectral regime – in the infrared, this anisotropy becomes extreme, resulting in simultaneous dielectric and metallic optical behavior along different crystal axes. This extreme anisotropy occurs within the reststrahlen regions of calcite (w=870-888 cm-1 and 1400-1551 cm-1), which is the fundamental property required to support hyperbolic optical modes that are highly directional (depending only on the permittivity) and confined well-beyond the diffraction limit.

While hyperbolic modes have been well-studied in nanostructured materials with high degrees of symmetry – e.g., h-BN and (001)-oriented calcite with cylindrically-symmetric nanostructures and permittivities (isotropic in the sample plane) [1,2] – within this work, we investigate how such modes behave within a low-symmetry calcite system. To accomplish this, we fabricate a series of gratings on (100)-oriented calcite substrates that possess anisotropic optical behavior that lies within the sample plane. To investigate the optical properties of this metamaterial system, we perform polarization-dependent, infrared reflectance microscopy measurements and correlate the results to full-wave electromagnetic simulations performed within COMSOL. Overall, we find that these gratings support high-quality factor hyperbolic modes (Q > 200) that can be tuned throughout the entire reststrahlen region by only changing the relative orientation between the grating and the crystal axes – keeping the grating profile fixed. In addition to experimentally demonstrating this behavior, we have developed a semi-analytical model that predicts how the mode frequency and wave-directionality evolve with grating orientation, eliminating the need to perform full-wave electromagnetic simulations for each grating orientation.

Abstract: Low-loss phonon polariton (PhP) modes are promising for mid-IR applications. Here, PhP eigenmodes in nanostructures of InP and 4H-SiC are spatially mapped using confocal Raman microscopy. We find that the polarizability selection rules surprisingly couple PhPs to bulk phonons, potentially providing a new approach to tune PhPs through phonon interactions.

Phonon polaritons (PhPs) are collective modes that emerge when photons couple with optical phonons in a polar dielectric material. PhPs have been shown to confine electromagnetic fields far below the diffraction limit just like surface plasmon polaritons (SPPs) can, notably without the high losses associated with SPP modes[1]. In addition, PhPs are widely tunable though nanostructure geometry, and coupling to free carriers[2]. These advantages have made PhP modes a promising platform for low-loss mid-infrared (mid-IR) photonics. Attention has also been drawn to the possibility of electrically pumped tunable mid-IR emitters based on PhPs, but efforts to demonstrate the viability of these devices has been frustrated by the presumed weak coupling between PhP and bulk phonon modes[2].

Assessing the promise of PhP modes as mid-IR emitters clearly requires a full investigation of the coupling between electrons, phonons, and PhP modes in dielectric nanostructures. This task is made more complicated by the fact that the coupling between electrons, phonons, and polaritons has high spatial dependence, further demanding a method that can spatially map these interactions. To date, investigating PhP eigenmodes has primarily been accomplished using near-field IR microscopy, such as near-field scanning optical microscopy (NSOM) and Nano-FTIR techniques. Recently, monochromatic electron energy loss spectroscopy (EELS) in scanning transmission electron microscope (STEM) setups has also been employed to visualize SPhP modes in nanostructured materials. In particular, tomographic EELS has enabled 3D measurements of Surface PhP (SPhP) modes in magnesium oxide nanocubes[3], demonstrating that specialized techniques can be employed to visualize the 3D distribution of PhP electromagnetic fields.

Increasingly, these efforts have been augmented with the techniques of Raman spectroscopy, leveraging its ability to provide abundant information on light-matter interactions. Raman techniques have particularly been used to probe PhPs in 2D materials. Initial works demonstrated resonant Raman spectroscopy as a valuable tool to probe PhP modes at Van der Waals (VdW) material interfaces. Furthermore, recent investigations have shown that conventional backscattering Raman can probe PhP modes in 2D GaSe, utilizing the polarizability selection rules[4]. Such techniques are not restricted to 2D materials, micro-Raman investigations of 4H-SiC nanopillars found that spatial dispersion of the permittivity in dielectric nanostructures can play a major role in the spectral behavior of PhPs[5]. This discovery highlights the fact that much of the physics related to the spatially dependent interactions of electrons, phonons, and SPhP modes in nanostructures remains uninvestigated. Therefore, efforts

to understand the physics governing PhPs in nanostructures, demand not only spectral probing of SPhP dispersion but also spatial mapping of light-matter interactions through the nanostructure volume with more sophisticated Raman techniques.

In this work, we report the full 3D mapping of SPhP electromagnetic fields in nanostructures of InP and 4H-SiC. We combined confocal Raman microscopy with an eigenmode reconstruction approach to provide a 3D view of localized polariton fields. Using this technique, we demonstrate that all Raman active bulk phonon modes in both InP and 4H-SiC do couple to the localized surface polariton modes, in contrast to the assumption that the longitudinal polarization field of the LO phonon is non-interacting with the transverse (and thus orthogonal) SPhP modes. Our Raman maps confirm that the polarizability selection rules form the dominant mechanism through which SPhPs couple to Raman phonons. For the specific case of the $A_1(LO)$ and $E_1(TO)$ phonon modes in 4H-SiC, electron-phonon coupling also plays a role, even for low-doped substrates. These results challenge the conventional understanding of SPhP-phonon coupling and indicate that electrically pumped SPhP mid-IR emitters might be achievable with dielectric nanostructures. Furthermore, our work provides a method for real-space mapping of SPhP eigenmodes in a manner analogous to tomographic EELS, but with no destructive sample preparation and not requiring the specialized equipment of highly-monochromatic EELS. Thus, Raman imaging can be a complimentary tool for the visualizing of SPhP modes which also provides a natural platform for investigating the interactions between electrons, phonons, and SPhPs.

Quasi-2D Colloidal Quantum Wells for High Optical Gain and High LED Efficiency

F. Shabani[1], F. Işık[1], S. Delikanlı[1], and H. V. Demir*[1, 2]

Abstract: Colloidal quantum wells (CQWs) are shown to possess exceptionally high performance as the gain medium and active layer in the LEDs. The CQWs exhibit a record-breaking gain coefficient of 140,000 cm^{-1} with a lasing threshold of 8 μJ cm^{-2} and an ultra-high external quantum efficiency of 18.1% for CQWs-LEDs.

Colloidal semiconductor quantum wells (CQWs), also known as nanoplatelets, are among the most attractive groups of solution-processed nanocrystals, which provide a strong and versatile ground to engineer and tune the optical properties. The two-dimensional shape of these CQWs (Figure 1a) results in tight confinement in the vertical direction, which is the basis for many of their superior optical properties. Here, we report the advances in high-performance devices based on engineered CQWs

The CQWs were shown to possess an anisotropic emission behavior, which, by their collective assembly, an extremely high level of in-plane transition dipole moments of 92% was achieved (Figure 1b). The optical properties, including the absorption and PL were tuned by the design of the heterostructure and thickness of the CQWs covering a broad range of the visible spectrum (Figure 1b). We demonstrate that by careful design of the synthesis, complex heterostructures can be realized (Figures 1c and 1d), which possess tunable recombination pathways with a mixture of type-I and type-II natures. These excellent and distinct properties of the CQWs are the basis for fabricating devices with superior properties.

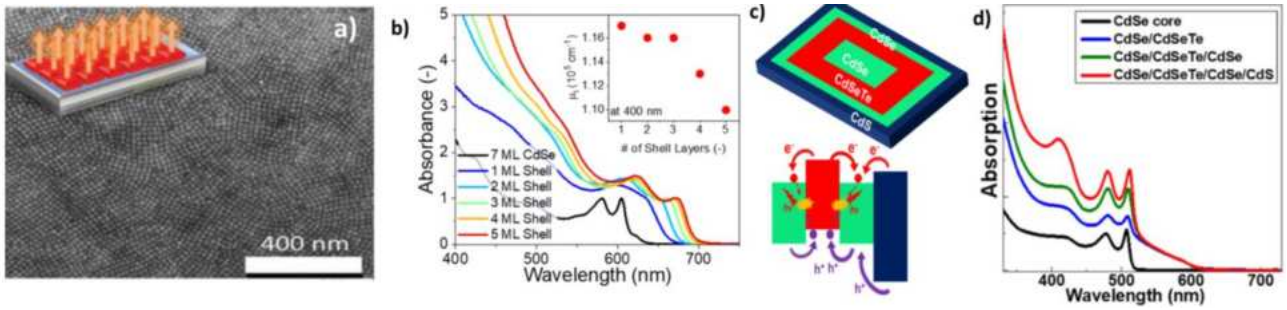

Figure 1. (a) TEM image of self-assembled CdSe/CdZnS core/shell CQWs. (b) Absorption spectra and absorption cross-section of CdSe/1-5 CdS core/shell CQWs. (c) Complex design of multi-crown CQWs and the possible recombination pathways, and (e) the resultant absorption spectra.

CdSe/CdSeTe/CdSe/CdS core/(multi)-crown type-II CQWs benefit from two type-II interfaces, yielding a photoluminescence quantum yield (PLQY) of ca. 90%. The terminating CdS crown layer enhances the in-solution and film stability, which is essential for the electroluminescence application. The LED device with these CQWs as the emissive layer (EML) exhibits an external quantum efficiency of 9.3% and a maximum luminance of 36,612 cd m^{-2}, the highest reported values for type-II CQWs.

CdSe/CdZnS core/alloyed shell CQWs exhibit a direct recombination PL with a near-unity PLQY. The all face-down self-assembled monolayer of these CQWs possesses an extra-high outcoupling efficiency of 34% in LED devices due to the high in-plane transition dipole moments, a step-wise hole transport layer (HTL) and Mg-doped ZnO electron transport layer (ETL), which prevents the exciton quenching (Figure 2a). While

self-assembly of the EML does not change the electroluminescence peak position (Figure 2b), it substantially enhances the EQE of the device from 9.5% for randomly-oriented EML to 16.3% (Figure 2c). The enhancement is due to the light-outcoupling, which can be further improved by exchanging the original bulky ligands with short ligands leading to an EQE of 18.1%.

The core/shell CQWs also provide a very interesting ground for optical gain performance. In a systematic study, giant CdSe/CdS core/shell CQWs with varying thickness demonstrate a gain coefficient of 140,000 cm^{-1} (Figure 2d), two orders of magnitude higher than the best reports for the colloidal nanocrystals, originating in the high density of states and suppressed Auger recombination. The whispering gallery mode (WGM) laser based on these CQWs (Figure 2e) resulted in an ultra-low lasing threshold of ca. 8 μJ cm^{-2} (Figure 2f), and further in-solution amplified spontaneous emission (ASE) was also observed.

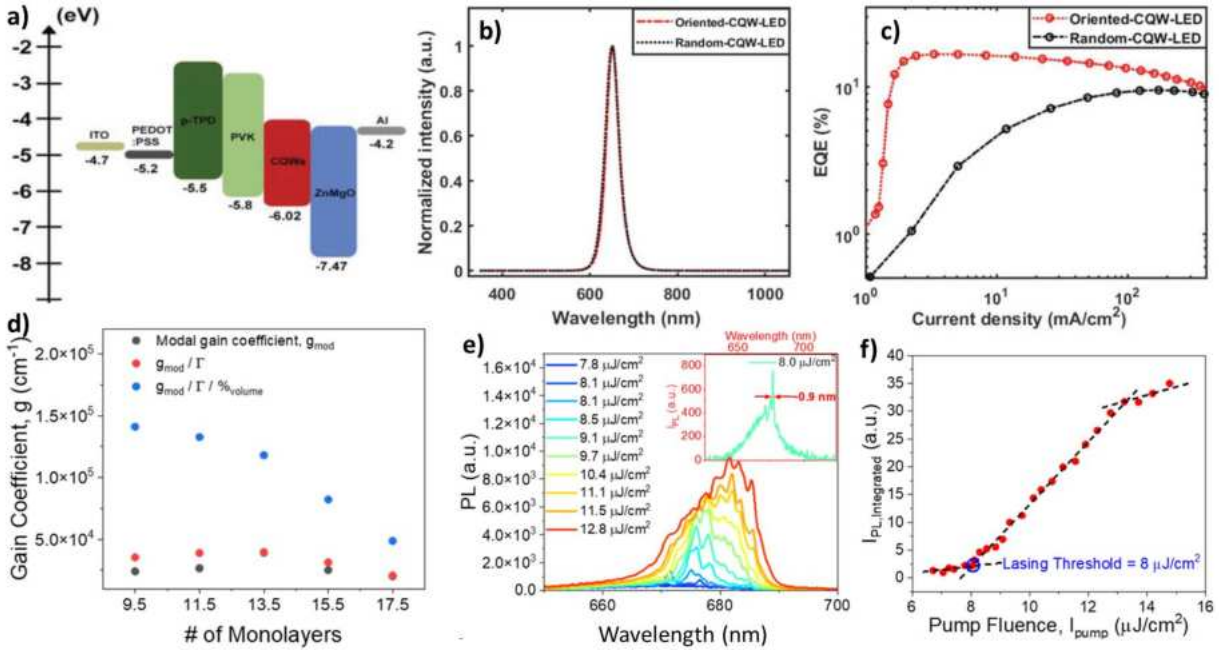

Figure 2. (a) Energy band diagram of the CQW-LEDs. (b) EL and (c) EQE of LEDs with random and self-assembled ELM. (d) Maximum modal gain coefficients with the shell thickness. (e) The lasing spectra of WGM-assisted CQWs. The inset shows the lasing spectrum at the threshold. (f) The lasing threshold measured via integrated PL intensity.

Abstract: Upconversion of infrared light into visible light has wide potential applications, but current efficiency is too low to be practical. Here, we present a variety of dielectric and plasmonic metasurfaces that enhance upconversion efficiency. We show that enhancement of several orders of magnitude may be achieved at low excitation flux.

Photon upconversion is a process that converts two or more low-energy photons into a higher-energy photon. Upconversion of infrared light into visible light is particularly interesting because of its potential to sensitize silicon to sub-bandgap photons, thereby benefiting a wide range of applications including deep-tissue imaging, telecommunications, sensing, and photovoltaics.

In our studies, we explore two types of upconversion, based on excitonic materials (specifically quantum dots and organics) and lanthanide-doped nanocrystals, respectively. Both types of upconversion have low external quantum efficiency in the solid state, owing to weak absorption of the incident infrared light.

Here, to improve infrared absorption, we design and implement a variety of dielectric and plasmonic metasurfaces with resonant wavelength at 980 nm or 1550 nm. For instance, we employ periodic arrays of resonant nanostructures to confine light efficiently in the upconversion nanomaterials. We also explore metasurface-integrated Fabry-Pérot cavities to allow greater tolerance of the cavity modes to fabrication variations.

With efficient integration of nanomaterials and metasurfaces, we show enhancement of upconversion luminescence by several orders of magnitude at low excitation flux, which saturates to about two orders at high excitation flux when the intermediate excited states reach a critically high population.

Finally, we discuss the feasibility, progress, and challenges of combining metasurface-enhanced upconversion with silicon photodetectors for sub-bandgap infrared detection.

Abstract: We established directional quantum dot (QD) emission coupling to a planar TiO_2 waveguide assisted by a Yagi-Uda antenna. Antenna on waveguide is first designed by scaling radio frequency dimensions to nano-optics, taking into account the hybrid plasmonic/photonic platform. The optical characterization shows clear directional coupling originating from antenna effect.

In the past decades, strong efforts have been put towards convergence of integrated photonics and quantum technologies [1]. Recently, several groups have achieved direct on chip integration of single photon. Moreover, since quantum operation requires photons source presenting a long coherence time, Purcell-enhanced single photon sources are generally used so that the emission dephasing rate becomes negligible [2]. Most of on chip quantum circuits rely on single photon sources coupled to a micro-optical cavities of high quality. Another approach is to take benefit from the low mode volume of surface plasmon, pushing further integration capabilities. In this context, optical nano- antennas are promising candidates which provide both Purcell enhanced photon emission and directivity at the same time. Photonic waveguide decorated by optical antenna strongly focus guided mode onto a subwalength area compatible with single photon source excitation [3]. In this work, we investigate a reciprocal configuration, namely nano-antenna assisted quantum dot (QD) emission into high index (TiO_2) planar waveguide.

Design of Yagi-Uda antenna Yagi-Uda antenna consists of five gold nanorods: a reflector, a feed and three directors, as shown in Fig. 1. The lengths of the antenna elements (feed, directors and reflector) govern the antenna resonance whereas their spacing govern the antenna directivity. According to antenna theory, the feed length should be half the effective wavelength of the mode propagating along the rod to support a dipolar resonance. Therefore, we first estimate the effective wavelength $\lambda_{spp}=n_{spp}\ \lambda_0$ of the surface plasmon polariton (SPP) propagating along an infinite nanowire deposited on a TiO_2 planar waveguide at the QD emission wavelength λ_0 = 670 nm. Effective index n_{spp} = 3.64 so that Fabry-Perot like resonances for feed length $L_f \approx \lambda_0/(2n_{spp}) \approx 92$ nm. The length of reflector (L_r) and director (L_d) are deduced as $L_r = 1.25L_f \approx 115$ nm and $L_d = 0.9L_f \approx 83$ nm, respectively. For a directivity into the guided mode along the antenna y-axis spacings of feed to reflector (y_r) and feed to directors (y_d) are estimated from the RF rules as $y_r = \lambda_0/(4.4n_{wg}) = 89$ nm and $y_d = \lambda_0/(4n_{wg}) = 97$ nm where n_{wg} = 1.72 is the effective index of the TE guided mode, calculated for a 80 nm thick TiO_2 planar waveguide lying on a glass substrate. The thickness has been chosen to obtain a single mode waveguide. We completed this semi-analytical analysis with full electromagnetic numerical simulations based on finite element method (FEM).

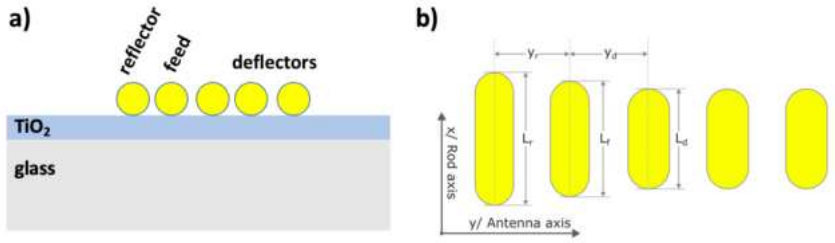

Fig 1: Scheme of the Yagi-Uda antenna on a TiO_2 planar waveguide. a) Side-view detailing of antenna elements. b) Top view with dimensions.

Directional QDs emission into planar waveguide We use 50 µm circular microdisk as planar waveguide so that the optical paths from its center to all directions are the same, see Fig. 2a. Antenna mediated QD emission coupled to TiO_2 waveguide is shown in Fig. 2b). Light coupled to microdisk propagates radially in the waveguide and scatters out at the edge. We observe directional scattering towards the right (0°) in agreement with the antenna effect but also unexpected directionality on the top left side (120°). We experimentally measured 39% coupling efficiency and 60% forward [4]. The efficiency of the device is very sensitive to the location of the quantum emitters. This hybrid platform based on plasmonic antenna assisted directive emission into photonic waveguide could also be used for lab-on-chip applications combining surface enhanced spectroscopies and photonics capabilities.

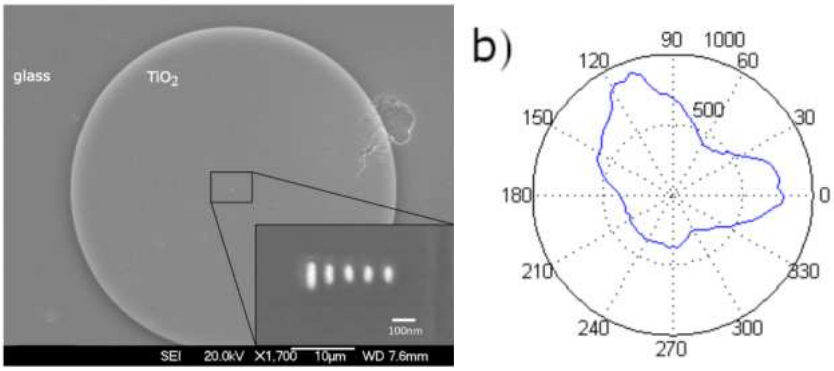

Fig. 2 : a) SEM image of Yagi-Uda gold nanoantenna centered on TiO_2 50 µm diameter microdisk planar waveguide. L_f =90 nm, L_d=85 nm, L_r=100 nm, y_r=85 nm and y_d=90 nm.b) Polar plot of the light scattered along the waveguide periphery with Yagi-Uda antenna assisted QD emission.

Abstract: The effect of localized surface plasmon resonance (LSPR) on chemically synthesized gold nanoparticles is utilized to setup a biosensing platform with the potential for sensitive and specific detection of biomolecules of interest such as biomarkers. This principle is demonstrated both on a single particle level for DNA detection, then extended also to proteins, and to arrays of particles. In order to readout the arrays, imaging spectrometer were developed.

Detection of molecular interaction is an important analytical field with implications ranging from food or drinking water quality control over drug development to medical diagnostics. One approach for label-free detection of molecular targets is based on LSPR on metal nanostructures, which show a spectral change upon binding of molecules.

Imaging spectrometers allow for the spectrally resolved imaging of sample surfaces. In the case of a LSPR array, an array of spotted gold nanoparticles is utilized as sensors, and for specific identification of certain biomolecules, modified with receptor molecules which are specifically binding respective target molecules. In case of binding, the LSPR of the particles in this spot will change, when the refractive index on the surface of the nanosensors is changed. The LSPR shift (located in the visible range of light) is measured as sensor signal, and correlates with the surface concentration (also mass) of bound molecules.

In order to readout these spectral changes, imaging spectrometers are preferred compared to scanning approaches, as the measurement time does not directly scale with the number of spots. Moreover, already for medium integration (numbers of spots), scanning is hampering readout speed. Beside an imaging spectrometer based on Fourier transformation and a Michelson interferometer, less complex and faster approaches are studied, such as one based on Liquid Crystal Tunable Filter (LCTF) using electronically controlled liquid crystal (LC) elements to transmit only a selectable wavelength range of light. Here, the number and wavelength values are freely selectable. A faster but less flexible approach for imaging spectrometry has been realized using various LEDs with different wavelengths. The effect of the number of LEDs on the resulting detection capability of LSPR shift monitoring was studied. Moreover, various algorithms for peak shift detection were compared regarding their stability and reproducibility.

On the receptor side, beside DNA receptors for binding (sequence-complementary) DNA targets, also protein as well as small molecules and even heavy metal ions were studied as potential targets. Hereby the ease and reproducibility of surface functionalization plays an important role in the choice of suitable receptor molecules. Staying with the same class of molecules and an established immobilization chemistry but being able to detect various classes of molecules, such as DNA, proteins, small proteins and even metal ions, would provide an important advantage for LSPR sensing. Therefore, the use of DNA is preferred. DNA can bind by hybridization to complementary single-stranded DNA. However, DNA can also bind proteins, such as observed in cells for e.g. single-strand binding (SSB) proteins, or for transcription factors, which regulate the readout of DNA. Moreover, DNA can form quite defined 3D structures, which can act similarly to antibodies and selectively binding certain target structures. Such structures are called aptamers, which show a huge potential as

receptors in sensing approaches, as they overcome several problems connected with the established antibody receptors, such as reproducibility, ethical concerns (as antibodies are generated in animals), application conditions not limited to physiological conditions, etc.

Abstract: Precise manipulation and discrimination of particles on a scale smaller than the diffraction limit is a topic of enduring interest. This study provides an alternative approach for trapping and identifying dielectric and bioparticles using metamaterial plasmonic tweezers, while paving the way for label-free characterization of biomolecules at single-entity levels.

Summary: We introduce hybrid Fano-resonant metamaterial plasmonic tweezers (MPT) to exhibit stable nano-trapping. Although plasmonic tweezers can achieve manipulation on a scale smaller than the diffraction limit, direct trapping of sub-10 nm dielectric and bio-particles in an aqueous environment without modifications of surrounding mediums remains challenging.[1-3] Here, I will discuss on heat generations from photon-to-phonon conversion of a MPT system, and will review how to transfer this photothermal heating effect to rapidly trap single dielectric nanoparticles and enzymes, and follow the conformational changes of enzymes molecules in real-time. We observe that by analyzing the spatial probability distribution of trap particles under the increase of thermal gradients near the MPT′s surface, we are able to distinguish dielectric particles from biomolecules.[4]

We believe that this photothermal-assisted trapping approach will open a new set of opportunities for the development of ultrasensitive label-free detection and characterization of biomolecules at the single-particle level.

Key words: Metamaterials, plasmonic tweezers, single nanoparticle and enzyme trapping.

Abstract: In this work, we explored the polymerization of diazonium molecules on the surface of gold nanoparticles under CW- and pulsed laser irradiation. Two different polymerization mechanisms of diazonium salts can be induced by gold nanoparticles under irradiation through local heating and hot electron injection resulting in different polymer patterns.

Gold nanoparticles are considered a promising platform for nanochemistry and catalysis because they can boost chemical reactions by generating local heat and hot electrons under irradiation.[1] Nonetheless, the separation of hot electron and heating effects in the experiment is often challenging or even impossible, as these effects occur on the femto- or picosecond scale, whereas the reactions are typically performed within seconds or minutes. In this work, we investigate the polymerization of diazonium salts on the surface of gold nanoparticles, which can pass through two different mechanisms: cationic and radical ones. Diazonium molecules are highly reactive compounds, containing N_2^+-moiety, which can be eliminated under heating or by electron transfer.[2] We show that different excitation wavelengths as well as the regime of the excitation (CW or pulsed laser irradiation) result in different polymer patterns, which we associate with the dominance of heating-induced or hot electron-induced mechanisms of polymerization.

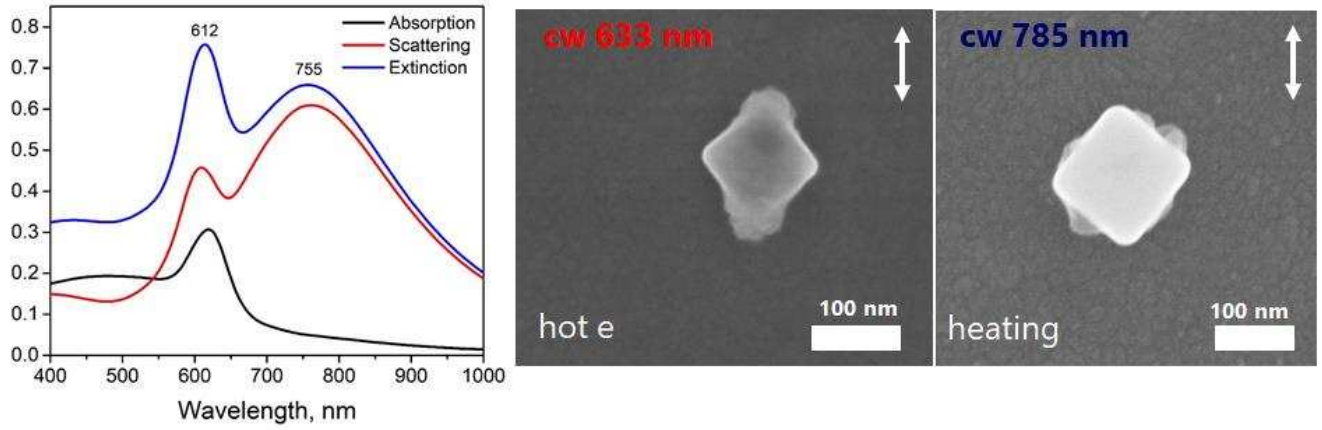

Figure 1. FDTD simulated optical spectra of a gold nanocube and experimental SEM images of gold nanocubes with polymerized diazonium structures under continuous-wave laser excitation.

The CW excitation of the quadrupolar plasmon resonance of gold nanocubes results in polymer growth on

the corners, with respect to the incident light polarization, and therefore can be assigned to a hot electron-induced process. The CW excitation of 785 nm that matches the dipolar mode of the gold nanocube leads to the chaotic polymer distribution, probably, caused by the thermal effects. Intriguingly that the excitation at the same wavelength of 785 nm but at the fs-pulsed regime also results in polarization-dependent polymerization on nanoparticle corners. Thus, by varying the excitation regime we can control the polymer growth and switch between thermal and electron-driven processes.

This study was financially supported by the French Research Agency (ANR) in the frame of the ADVANSPEC and POPCORN projects. Fabrication and characterization were made by the facilities of the Nano'mat platform and the French RENATECH+ network.

Designing lattices and interface modes in valley topological photonics

Abstract: Valley topological photonics allows designing devices whose performances strongly depend on the geometry of both unit cells and interfaces. We compare classical honeycomb crystals and a lattice consisting of three non-equivalent subsets of holes, whose richness brings insights in the relation between the interface geometry and the topological light conduction.

Topological photonics relies on mimicking quantum Hall effects in solid-sate physics to transport an electromagnetic signal in compact and low-loss devices[1]. In valley topological photonics, an interface is created between two mirror-image photonic crystals with broken inversion symmetry. Both are associated with Berry curvature confined close to K and K' high symmetry points and with opposite signs between both crystals. This allows exciting topologically protected edge-modes along the interface, which have been proven to sustain robust unidirectional propagation with low back-scattering at sharp bends and low sensitivity to lattice imperfections[2]. They are considered as choice systems for many applications in optical and terahertz telecommunications.

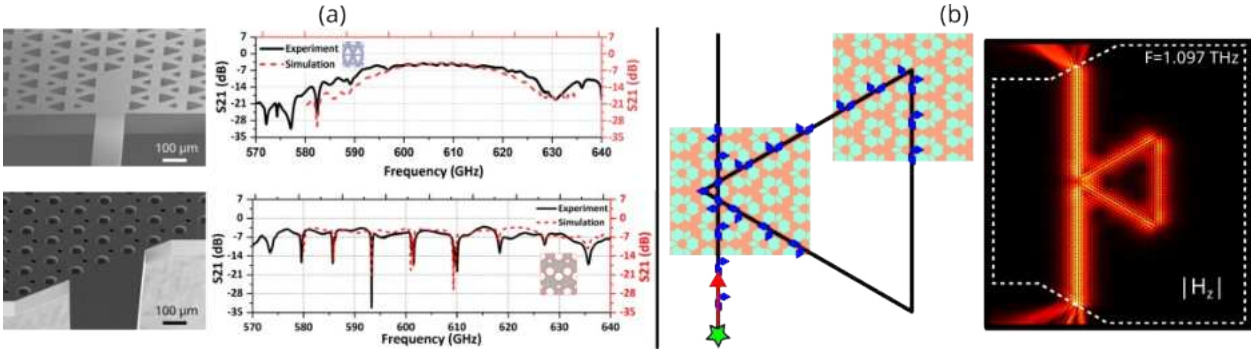

Figure 1: (a) Left: SEM images of triangular- and circular-holes-based topological devices. Right: experimental and numerical transmission through a ring resonator. (b) Left: ring resonator based on a three-diamonds lattice and with displacement interface. Right: typical magnetic field amplitude distribution at F = 1.097 GHz.

In order to build telecommunication devices based on valley topology, a silicon membrane is usually periodically structured with air holes. However, a careful choice of both the shape of holes and the geometry of interfaces between the two mirror-imaged lattices must be made. As illustrated on Fig. 1(a), the transmission through a topological ring cavity shows very different behavior depending on whether the holes are triangular and the interface zigzag (top), or the holes are circular and the interface bearded (bottom). In the former, the transmission is flat as immunity to back-scattering is high, while in the latter the occurrence of several regularly spaced resonances shows that the topological protection is lower[3], but that the device can be used as a filter. This

phenomenon is important to tailor the properties of passive functions for telecommunication technologies.

In order to expand this exploration of the effect the geometry of the interfaces on the waveguiding of light in valley photonic lattices, we propose a photonic crystal based on three non-equivalent subsets of diamond-shaped air holes. A total number of fourteen different bearded interfaces supporting edge modes can be built along a ΓK interface between two image lattices, instead of two bearded interfaces in the standard approach based on a honeycomb lattice with two-holes per unit cell. We show that, among them, six edge-modes can propagate along an interface between two lattices differing only by a translation. An example of such an interface is shown on Fig. 1(b), where the blue diamonds underline the edge. The lattices in contact are not mirror-symmetric, but differ only by a displacement. As a consequence, the two corresponding photonic crystals, despite having non-zero Berry curvature at their respective K and K' points, have strictly identical valley Chern number, which rules out the valley-topological origin of the corresponding edge modes. However, they show robust propagation at sharp corners and through ring resonators as illustrated on the magnetic field distribution of Fig. 1(b), raising new questions about the origin of the protection of the light propagation in circuits with sharp features, generally prohibited in devices based on trivial geometry.

Controlling properties of collective plasmonic–diffractive excitations via dispersion engineering

J. Kelavuori[1], A. Panahpour[1], and M. J. Huttunen[1*]

[1]Tampere University, Finland
[*]corresponding author: mikko.huttunen@tuni.fi

Abstract: We show how strong dispersion can be used to control losses in diffractive–plasmonic resonances. Bragg-reflector waveguides are proposed as highly dispersive media for plasmonic metamaterials, allowing orders of magnitude reduction in array sizes, while still achieving ultra-high quality factors.

Collective plasmonic–diffractive resonances called surface lattice resonances (SLRs) combine the strong light–matter interactions of single particle plasmonics with the low losses of diffractive modes. The combination generates optical excitations with very strong local fields, which scale with diminished resonance losses. The losses are quantified using quality (*Q)* factor, linking energy loss per cycle to the total energy of the resonance. The high *Q*-factors and the strong light–matter interaction in SLRs make them attractive for applications in, for example, nonlinear optics and lasing. While *Q*-factor is one of the most important characteristics of the SLRs, the means to increase and control it are limited to some trivial methods. Namely, the radiative losses can be decreased by increasing array size and the spatial coherence of the light source,[1] and the material losses can be decreased by designing the diffractive mode far away from the single particle plasmonic resonance.[2] Furthermore, there has been research on utilizing out-of-plane resonances[3], and indirect excitation[2] to heighten *Q*-factors in SLRs. Also, active control over the SLR *Q*-factor can be achieved by induced symmetry breaking in the dielectric medium, causing reversible and controllable growth in radiative losses.[4]

Here, we propose a new method for increasing and controlling the *Q*-factors in SLRs. We show how utilizing strong refractive index dispersion in the medium surrounding the plasmonic nanoparticles can significantly decrease resonance losses. Previously, the effect has been demonstrated in microcavities using highly dispersive bulk materials as cavity medium.[5] We propose embedding plasmonic nanoparticles (NPs) to Bragg-reflector waveguides (BRWs), where extreme dispersion can be seen near the cutoff frequencies of the waveguide modes. Equivalently, the waveguide mode has a near flat band near its cutoff frequency, leading to almost divergent density of states. This highly enhanced Purcell factor leads to enhanced coupling between the NP scatterers. We show how the *Q*-factors in such structures are almost linearly dependent on the group index in the waveguide, and how, with the extreme dispersion in BRWs, the radiative losses can be diminished up to a hundred-fold. In plasmonic–diffractive resonances material losses quickly become dominant over radiative losses, lending the overall *Q*-factors less extreme. However, since the usual means for decreasing radiative losses in plasmonic NP arrays includes increasing the array size, this technique can be utilized to decrease array areas very efficiently. For example, a *Q*-factor traditionally achievable with an array size of 600×600 μm^2 can be obtained in just a 50×50 μm^2 area with a ten-fold increase in the group index. Such an increase is easily achievable in BRWs.

Figure 1 shows lattice-sum calculations for an array inside BRW with different dispersion properties. The group indices n_g for the excitations are calculated as:

$$n_g = n_{\mathrm{eff}} + \omega \frac{\mathrm{d}n_{\mathrm{eff}}}{\mathrm{d}\omega} \qquad (1)$$

where n_{eff} is the effective phase refractive index of a waveguide mode and ω is the angular frequency of the light. High group index values stem from extreme dispersion near the cutoff frequency. The frequency of the resonance was changed by varying the array period. The calculations were done for an empty-lattice approximation, and material losses were not included. Radiative losses are shown to decrease with increased number of particles, and with higher group indices. When the number of particles reaches a certain value, the Q-factors no longer grow, but are saturated to values close to 16 000 for our BRW. Further increase is halted by the losses in the BRW-mode inhibiting coupling between the far-away particles. This saturated particle count (N), especially, seems to be highly dependent on the used group index. Resonances at highly dispersive regions therefore need drastically less particles to achieve high Q-factors. The technique has potential to help plasmonic metasurface fabrication, and it allows the usage of SLRs in micrometer-scale pixels.

Nonlinear optical sensing in arrays of plasmonic nanoparticles

Abstract: Second harmonic generation from plasmonic materials, originating mostly from the surface, is a promising platform for sensing applications. In this work, we investigate the performance of a sensor based on periodic and aperiodic metagratings of V-shaped nanoantennas, exploring both the intensity and angular variations of their nonlinear emission.

Second-harmonic generation (SHG), the optical process by which two photons at a fundamental wavelength (FW) are converted into one at twice the frequency, is well known to be forbidden in centrosymmetric crystal lattices,[1] such as those found in plasmonic materials. Thus, in this situation symmetry breaking is required for this phenomenon to be supported, which can be achieved in two ways: field gradients in the bulk of the material, or surface contributions.[2,3] This latter approach has received special attention due to its potential for sensing applications: indeed, a variation in the surface susceptibility tensor, mediated for instance by a biological binding event, could give rise to a large change in the observable SHG.

In a previous work from our group, Ghirardhini et al.[4] showed that using the SH signal in a refractometric experiment could provide a significantly enhanced sensitivity compared to the FW (up to one order of magnitude). However, her configuration was subject to significant damping of the emission due to the dense packing of the array, which suppressed all diffracted beams except the zero-order, and was moreover generating detrimental near-field coupling between the antennas.

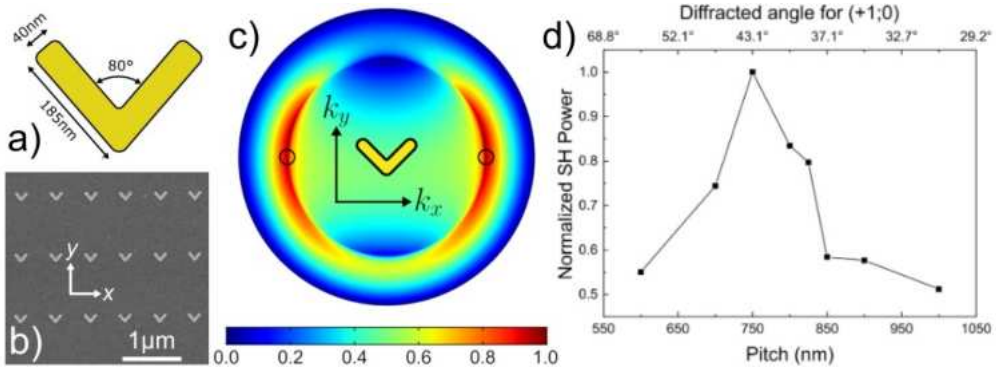

Figure 1: (a) Geometrical parameters of the nanoantennas. (b) Scanning electron microscope image of one of the gratings. The periods in x and y are 800 and 1025 nm, respectively. (c) EP in the Fourier plane of the substrate half-space associated with the antenna design given in (a), the black circles denoting the optimal position of the diffraction orders. (d) Optimization of the lattice parameters for SHG extraction, based on the lattice period in x.

In this context, we are working with a platform constituted by rectangular gratings of V-shaped gold nanoantennas, deposited on a glass substrate (see fig. 1a-b). The sample is pumped at a FW of 1550 nm, the SHG collected in epi configuration, ie. from the substrate side, and its Fourier plane is projected onto a camera, giving us insight into the angular behavior of the emission. Recently[5], we optimized the lattice arrangement to allow optimal extraction of SH signal, in an attempt to improve our signal-to-noise ratio. In particular, we achieved a doubling of the collected signal, by overlapping diffraction orders with the single particle emission

pattern (EP), as shown in fig. 1d. As the period in *x* is changed, so does the direction of the (±1;0) diffraction orders (or, equivalently, their lateral position in the Fourier plane). At 750 nm of pitch, the emission angle coincides with the emission lobes of the EP (see fig. 1c), leading to a significantly increased collected SH signal.

Interestingly, this optimization opens a new alleyway to improve the sensitivity: as the EP depends on the local refractive index (RI), but the diffraction pattern of our grating remains fixed (since we are collecting from the substrate side), the overlap provides a new way of probing the environment of the antennas. To explore this possibility, we first investigate several gratings of varying fixed period (fig. 2a-b), then move to a variably pitched lattice configuration (fig. 2c-d). In the first case, we find a maximum resolution (ie. minimal detectable refractive index variation) of 4×10^{-4} RIU (fig. 2b). In the second case, a broadening of the side (±1;0) diffraction orders is obtained by chirping the period in *x* (fig. 2c), within which we the shift of the angular emission as the RI changes can be observed (fig. 2d).

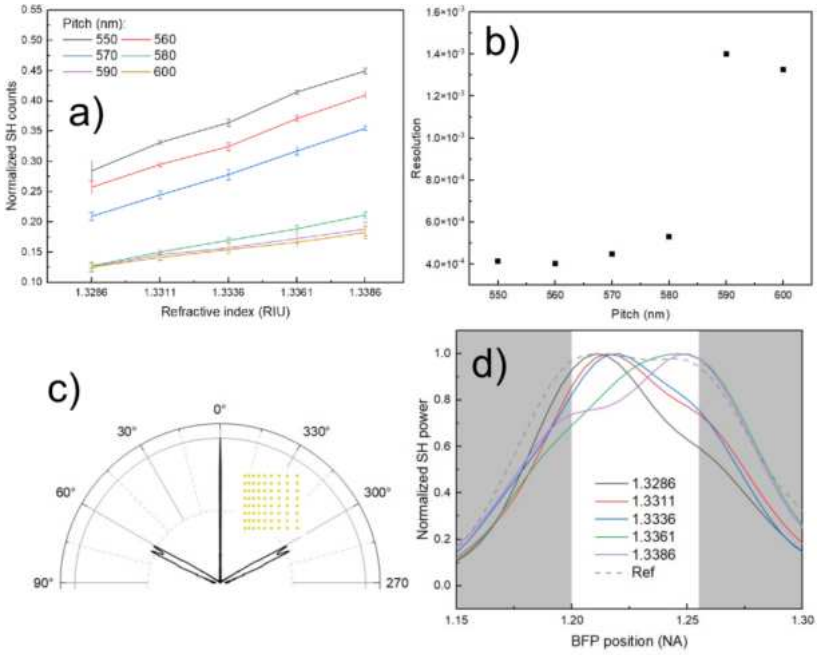

Figure 2: (a) Refractometric sensing experiment for different fixed pitch gratings. (b) The associated refractive index resolution for each configuration. (c) Calculated emission pattern of the variably pitched array (VPA) (inset: schematic of the lattice). (d) Cuts in the back focal plane of the VPA emission at the SH, for different RIs.

Rapid modulation of left- and right-handed optical vortices for precise measurements of helical dichroism

S. Hashiyada[1*], and Y. Y. Tanaka[1]

[1]Hokkaido University, Japan
[*]corresponding author: shun.hashiyada@es.hokudai.ac.jp

Abstract: We propose and experimentally demonstrate rapid modulation of the directions of handedness of optical vortices carrying orbital angular momentum (OAM) at around 50 kHz. This modulation is achieved through the rapid modulation of those of circularly polarized lights carrying spin angular momentum (SAM), coupled with the SAM-OAM conversion techniques.

Understanding chiral light-matter interactions in the context of angular momentum is crucial for both basic science and practical applications, including material chirality sensing and the development of chiral optical devices. An object in helical motion, i.e., a combination of translational and rotational motion, possesses angular momentum and exhibits chirality. A current in a chiral material, a circularly polarized light (CPL) and an optical vortex (OV) are chiral. CPL with spin angular momentum (SAM) of $s\hbar$ ($s = \pm 1$) per photon [1] is commonly employed to study the chiral-optical responses, such as circular dichroism (CD), defined as the difference in optical absorption for the left- and right-handed CPLs. Recent efforts to further understand how chiral matter interacts with the angular momentum of light have focused on exploring the chiral-optical response to an OV with quantized orbital angular momentum (OAM) of $l\hbar$ ($l = 0, \pm 1, \pm 2, \ldots$) [2]. An OV has a complex field characterized by $\exp(il\varphi)$, where φ is the azimuthal around the optical axis, and l is the topological charge (TC). Helical dichroism (HD) extends the concept of CD and denotes the difference in absorption that depends not only on the SAM but also on the OAM. In the previous study of the HD [3], generation of OVs with both positive and negative TC (l) is routinely achieved by using spatial light modulators (SLMs). While SLMs provide significant flexibility, they are limited by a slow response time. The switching of the left- (LH) and right-handed (RH) OVs occurs only below 100 Hz, a frequency comparable to low-frequency noise. This limitation poses a challenge for precise HD measurements.

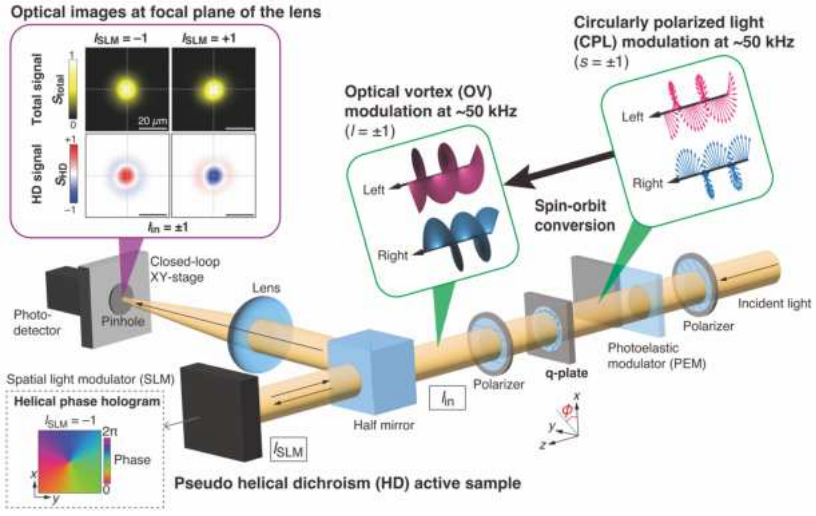

Figure 1. Optical system for the rapid modulation of OVs and the HD measurements using modulated OVs.

Here, we report a novel approach for the rapid modulation of the LH and RH OVs carrying OAM ($l = \pm 1$) at around 50 kHz. This is accomplished by employing a photoelastic modulator (PEM) to modulate the LH and RH CPLs carrying SAM ($s = \pm 1$) at around 50 kHz. Subsequently, these modulated CPLs are inserting into a q-plate [4] for SAM-OAM conversion (see Figure 1). To validate the capability of the proposed optical system for rapid modulation of OVs and HD measurement, we analyzed the light state using the Jones matrix method. The light transmitted through the polarizer and the PEM can be written as $\mathbf{E}_{\text{spin}} = \sqrt{\frac{1+\sin\delta}{2}}\mathbf{E}_{s=+1} + i\sqrt{\frac{1-\sin\delta}{2}}\mathbf{E}_{s=-1}$, where $\mathbf{E}_{s=+1}$ and $\mathbf{E}_{s=-1}$ are the vectors of the LH and RH CPLs, respectively. The parameter $\delta=\delta_0 \sin\Omega t$ describes the phase modulation induced by the PEM, where δ_0 is the amount of phase modulation, and Ω is the modulation frequency (around 50 kHz). This equation indicates sinusoidal modulation of the amplitudes of the left- and right-handed CPLs at Ω. After passing through the q-plate and the polarizer, modulated CPLs can be converted into modulated OVs as follows:

$$\mathbf{E}_{\text{orbit}} = \left(\sqrt{\frac{1+\sin\delta}{2}}\exp(+i\varphi) + i\sqrt{\frac{1-\sin\delta}{2}}\exp(-i\varphi)\right)\mathbf{E}_{\text{LP}}, \quad (1)$$

where $\mathbf{E}_{\text{LP}}$ is the vector of the linearly polarized light. Equation (1) is the main result of this study and indicates sinusoidal modulation of the amplitudes of the LH and RH OVs at Ω (around 50 kHz). When the modulated OVs interacts with a sample exhibiting HD, the complex amplitudes of the LH and RH OVs are further modulated by factors T_+ and T_-, respectively. The detected signal contains a frequency component of $n\Omega$ (where n is an integer). By demodulating the detected signal for the $n\Omega$-components with a lock-in detection technique, information for the total intensity ($S_{\text{sum}} = |T_+|^2 + |T_-|^2$) and the HD ($S_{\text{HD}} = |T_+|^2 - |T_-|^2$) of the sample for the left- and right-handed OVs are simultaneously obtained.

To experimentally demonstrate the proposed OV modulation, we utilized a SLM as a sample showing the HD (Fig. 1). Due to the interactions of the incident light ($l_{\text{in}} = \pm 1$) with SLM ($l_{\text{SLM}} = +1$), TC of the outgoing light should be $l_{\text{out}} = +2, 0$ according to the selection rule; $l_{\text{out}}=l_{\text{SLM}}+l_{\text{in}}$ [5]. For $l_{\text{out}} = +2, 0$, the beam intensity profiles of the focusing field should be donut-shaped and Gaussian, respectively, and the HD signal should have a negative maximum at the center of the beam. As shown in Figure 2(b-c), a negative and a positive HD signal peak were observed at the center of the beam for $l_{\text{SLM}} = +1, -1$, respectively, as expected. Therefore, we have successfully demonstrated the OV modulation. We demonstrated the OV modulation technique based on the rapid CPL modulation with a PEM and the SAM-OAM conversion with a q-plate. The method we have developed in this study is expected to establish the foundation for a high-precision HD measurement method.

Abstract: Polymerization induced by surface plasmon resonance was used to couple functional polymer on metal nanostructures. This approach is a method for investigating nanophotochemistry and opens the door towards new functional nanoobjects for applications in sensors or nanophotonics.

In this study, we describe an approach developed to carry out and characterize polymerization reactions triggered by the excitation of metal nanostructures. Nanoparticles prepared by chemical (colloidal synthesis) or physical (dewetting of gold films) methods are used. The particles are deposited on TEM grids, enabling nano-objects to be characterized at every stage of the experiments. Different configurations are used to irradiate the nanoparticles and induce polymerization reactions, with continuous or pulsed light, in the visible or near infrared, and different polarization states.

After irradiation, polymer patches are observed on the metal nanostructures. These patches are analyzed as a function of irradiation conditions, and compared with numerically calculated field maps.

Various chemistries were applied to this configuration. The main results were obtained by radical photochemistry induced by monophotonic or biphotonic absorption. On the basis of this chemistry, other polymerizations were induced, such as that of living photopolymerization systems, molecularly imprinted polymers or metal salt photoreductions.

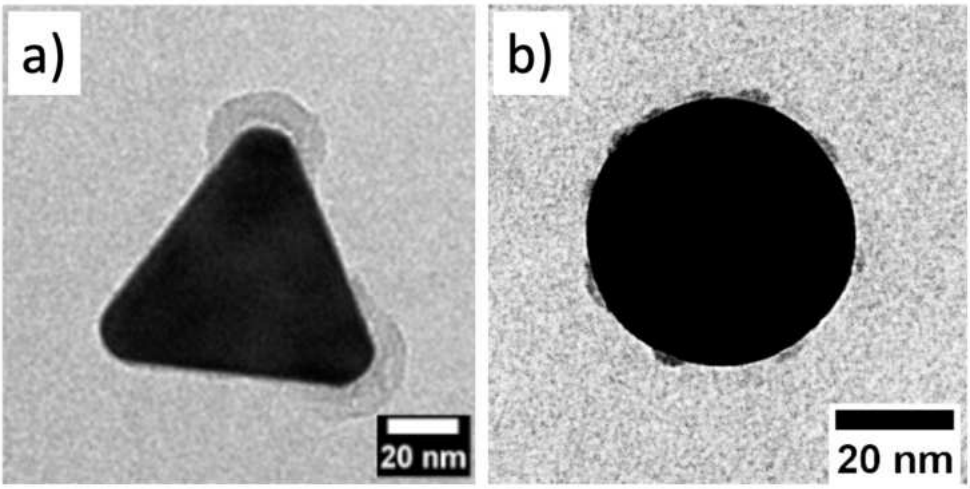

Figure : TEM images of metal nanoparticles with polymer nanopatches prepared by polymerization induced by surface plasmon resonance

This approach provides a platform for studying photopolymerization reactions at the nanoscale, highlighting novel phenomena linked to the confinement of light in nanovolumes and also to the extremely limited number of

reactive species excited in the volume corresponding to the optical near-field. Comparison of the different regimes also enables us to discriminate between the origins of chemical phenomena, between photochemistry, hot carriers and thermal effects. Finally, beyond these fundamental challenges, we demonstrate the interest of this route for the preparation of hybrid nanoparticles coupling functional materials to metallic nanostructures, with applications in the field of sensors and more generally nanophotonics.

Abstract: We present a single-molecule plasmon sensor suitable for continuously monitoring analyte concentrations over time. We analyze the far-field optical properties of the sensor by single-particle spectroscopy. A reversible sandwich assay enables the monitoring of DNA markers a temporal resolution of minutes and a sub-picomolar limit-of-detection.

New biosensor technologies are of great interest for personalized health care, a sustainable food industry, and monitoring of our environment. There is an urgent need for sensing techniques that provide continuous information to enable autonomous sensors that operate at the point-of-interest. Here we present a DNA-assembled nanosensor based on a nanoparticle-on-film construct that is suitable for single-molecule and continuous biosensing. The sensor reports increases and decreases in analyte concentration with a temporal resolution of minutes and a sub-picomolar limit-of-detection.

The sensor operates by optically monitoring the binding and unbinding of single nanoparticles to the metal film. Particle-binding occurs through reversible single-molecule DNA interactions, providing a dynamic switching between bound and unbound states. Single-particle spectroscopy indicates that the far-field scattering spectrum in the bound state is an interplay between the propagating and localized plasmons and results in a strong reshaping of the spectrum. We develop a DNA sandwich assay where the frequency of binding events provides a readout for analyte concentration. The sensor has a sub-picomolar limit-of-detection and enables continuous monitoring of DNA in diluted serum with a temporal resolution of minutes. Analysis of the sensor dynamics further enables kinetic fingerprinting to distinguish mono- and multi-valent interactions. The presented sensor can be generalized to other analytes to serve as a continuous and autonomous biosensor for lowly concentrated analyte.

Anapole modes enabling linear and nonlinear chiral sensing in hybrid metasurfaces

Abstract: In this work, we present how anapole modes can be exploited in hybrid metasurfaces to significantly enhance circular dichroism (CD) up to 5 times. Our results demonstrate that this metasurface offers efficient generation of background-free nonlinear CD signals, up to a 10-fold enhancement, that complements linear CD measurements.

Chirality, denoting the lack of specular symmetry in any plane of an object and the resulting existence of two mirror images (enantiomers), is a key aspect for the understanding of the biological functionality of many molecules in the human body and pharmaceutical compounds [1]. This recognition has sparked a growing industrial interest in discriminating molecular chirality, given its implications for drug efficacy and safety.

One of the key challenges in finding new ways to enhance the intrinsically weak circular dichroism (CD) chiroptical effect, thus enabling an efficient chiral sensing. Over the past decade, the design and development of nanophotonic platforms tailored for this purpose have emerged as a significant area of research and innovation. Fundamentally, the CD effect is proportional to the local Optical Chirality Density (OCD) C [2], defined as

$$C = -\frac{\omega\varepsilon_0}{2}\Im\mathfrak{m}(\boldsymbol{E}^* \cdot \boldsymbol{B}) = -\frac{\omega}{2c^2}|\boldsymbol{E}||\boldsymbol{H}|\cos(\Phi) \quad (1)$$

where ω is the angular frequency, c the speed of light, ε_0 is the vacuum electric permittivity and Φ is the phase angle between $i\boldsymbol{E}$ and $\boldsymbol{H}$. In the case of plane waves in vacuum Φ is maximized when the polarization is circular. The overall nanophotonic enhancement of the CD effect comes from the ratio between the spatial average of this quantity over the sample volume and the OCD of circular light.

As can be seen in equation 1, OCD enhancement at a particular wavelength can be achieved by local field concentration in nanophotonic structures while the phase relation $\cos(\Phi)$ is preserved. Various approaches have been explored to address this challenge. For instance, proposals based on plasmonics have exploited the substantial electric field enhancement generated by Surface Plasmon Resonance (SPR) [3]. On the other hand, the use of High Refractive Index Dielectric (HRID) materials has gained attention due to their low-loss nature and mixed electric and magnetic resonances, which can enhance both fields [4]. Hybrid structures, combining synergistically metallic and dielectric features, have emerged as particularly promising candidates [5].

In particular, HRID structures exhibit the noteworthy capability to sustain anapole resonances, characterized by intense optical field confinement. In the context of chiral sensing, this feature is interesting for background-free OCD enhancement as the phase relation of circularly polarized light is preserved [6]. Complementarily, this field confinement in anapole resonances can be exploited to enhance nonlinear optical effects, notably Third Harmonic Generation (THG). For example, HRID materials, with high third-order susceptibilities, have been combined with metallic materials to enable highly efficient THG in hybrid systems [7].

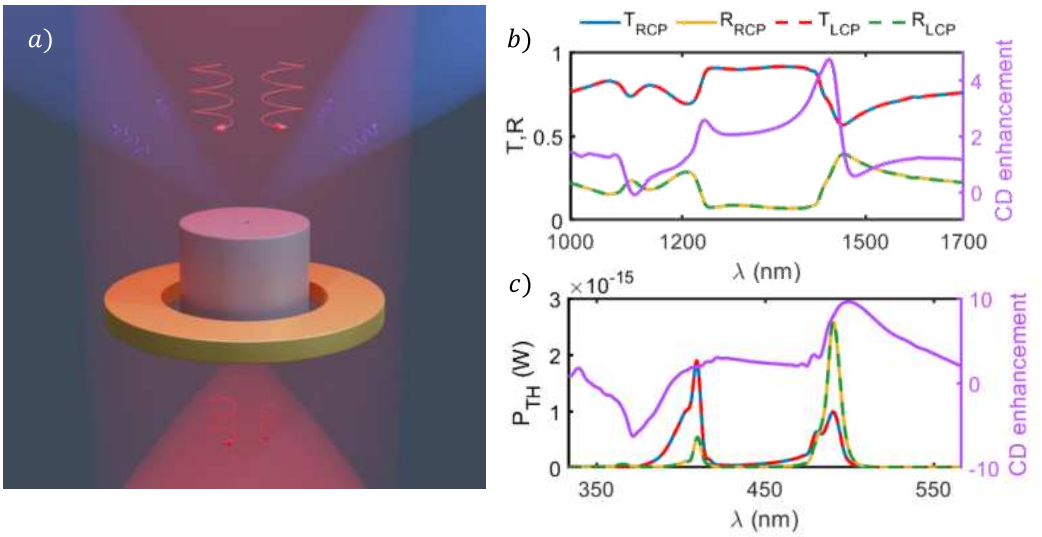

Figure 1. a) Depiction of the unit cell of the proposed metasurface. b) Linear reflectance and transmittance results of the proposed metasurface, together with linear CD enhancement up to 5 times. c) Third Harmonic Generation from the metasurface (reflection and transmission directions), with its associated CD signal, reaching a 10-fold enhancement at 490 nm.

In this study, we demonstrate numerically the efficacy of a hybrid structure (Figure 1a) consisting of a HRID (amorphous silicon) slotted nanodisk coupled to a gold ring as a promising platform for chiral sensing. This configuration yields a broadband, high average OCD value throughout a significant volume due to the confinement of electric and magnetic energy near anapole resonances. Additionally, we leverage these resonances to achieve a background-free, enhanced nonlinear third harmonic CD signal, with theoretical efficiencies up to 0.08%. Our results, summarized in Figure 1, show that CD enhancement can be 5-fold in the linear regime (Figure 1b) and up to 10 times in the third harmonic regime (Figure 1c).

Abstract: DNA origami nanoforks are used to assemble versatile plasmonic nanoantennas optimized for single-molecule surface-enhanced Raman scattering (SERS). Here, we demonstrate the role of molecular orientation within the SERS hot spot on single-molecule spectra as well as a detailed analysis of single protein SERS spectra.

DNA origami nanostructures are ideally suited to arrange both plasmonic nanoparticles as well as receptors for analyte molecules with nanometer precision. In this way they can provide optimized substrates for surface-enhanced Raman scattering (SERS), where the strongest signal enhancement is localized in nanometric hot spots and where the DNA origami can be used to precisely position the molecules of interest. In recent years we have demonstrated the few- and single-molecule SERS detection in different nanoparticle arrangements.[1] We have created a dedicated DNA origami nanoantenna,[2] which was also used to study chemical changes in hemin,[3] and to detect single proteins.[2] Very recently, we have further optimized the plasmonic nanoantennas by comparing the SERS performance of dimers of different nanoparticle species from spherical Au and Ag nanoparticles to anisotropic gold nanoflowers and combinations thereof.[4] We could show that a combination of Au nanoflower and Ag nanosphere allows for a broadband SERS excitation and improved single-molecule detection.

In the present contribution recent unpublished single-molecule SERS results are presented focusing on the following aspects: i) We explore the influence of the orientation of molecules within the hot spot of DNA origami-assembled nanoparticle dimers on the single-molecules SERS spectra. ii) Single proteins are investigated in detail using SERS. Using cytochrome c as an example we demonstrate the occurrence and analysis of the amide III band as a structural marker band in single-molecule SERS spectra. Additionally, we studied the enzymatic activity of horseradish peroxidase (HRP) on the single-molecule level.

Optical Modelling of DNA-Made Janus Nanoheaters

Pablo Albella

Department of Applied Physics (Group of Optics), University of Cantabria, Faculty of Science, Santander, Spain

e-mail: pablo.albella@unican.es

Abstract: Nanostructures manufactured using DNA-based nanotechnology, especially DNA-origami, possess a DNA core that influences their thermoplasmonic performance. In this work, we identify key parameters that optimize its thermoplasmonic response by comparing them with their solid counterparts. We also explore the impact that random rotations have on their thermal performance.

The generation of Localized Surface Plasmon Resonances (LSPRs) is accompanied by a partial reemission of the incident electromagnetic energy (nanoantenna effect) but also by a partial absorption, which usually leads to substantial temperature increase. This behavior effectively converts the nanoparticles into both nanoantennae and miniaturized heat sources, commonly known in thermoplasmonics as nanoheaters [1].

Traditionally, researchers tried to minimize or avoid that absorptive nature of nanoantennae to reach strongly enhanced local fields and clean far field signals containing the information of the local targets [2]. However, plasmonic nanostructures (gold in particular), when acting as nanoheaters, have shown great potential in a wide range of applications such as drug delivery or photothermal therapies (PTTs). Hence, big efforts are being made to either find new nanoheaters or to improve the photoinduced thermal response of the existing metallic nanostructures [3-5].

Three factors are especially important when looking at designing nanoheaters for such applications: the biocompatibility of the nanostructure materials, the photothermal conversion efficiency of the applied agents and their stability under rotations with respect to the radiation source. These limiting factors provide a well-defined path for the design of nanoheaters oriented to PTTs. Firstly, nanoheaters must be made of biocompatible materials capable of providing a strong plasmonic response. Secondly, their geometry must support resonances within the so-called biological windows (NIR-I: 700-900 nm and NIR-II: 1000-1400 nm) where the penetration in the tissue and maximum permissible exposure (MPE) are maximum. Finally, they must present a reasonable tolerance to rotations [6]. It is well-known that anisotropic nanoheaters offer different thermal responses depending on their relative orientation with respect to the polarization of the incident beam [6-8]. This is of extreme importance in areas like PTT, where nanoheaters, either free in blood or attached to cells, present a random orientation distribution.

DNA-based nanotechnology, especially DNA origami techniques, provide feasible route to fabricate the aforementioned nanoheaters [9,10]. However, one of the main consequences of using DNA origami for the synthesis of metallic nanomaterials is that their structure is often not solid but has a core formed by DNA. This Janus-like composition can affect their optical behavior and have an impact in their thermoplasmonic response, which ultimately translates into practical variations of the photothermal efficiency.

Here, we present our most recent numerical results on the photothermal response of Janus nanoheaters based on DNA origami. We identify key parameters that optimize its thermoplasmonic response, comparing them with their solid counterparts, and exploring the impact that partial or complete metallic coatings have on their thermal performance. Finally, we study the behavior of these structures when they undergo random rotations and understand how this affects their averaged thermoplasmonic response.

This work was funded by the MOPHOSYS Project (PID2022-139560NB-I00) from Proyectos de Generación de Conocimiento provided by the Spanish Agencia Estatal de Investigación.

Abstract: In this work, we present a new method to conjugate various nanoparticles with DNA by employing freezing-assisted SPAAC reaction, with a special focus on Si and SiO_2 NPs. Further, the developed method has been used for the fabrication of Si dimers using DNA origami structures.

Nanotechnology has revolutionized the fabrication of hybrid species with tailored functionalities. A milestone in this field is the DNA conjugation of nanoparticles, introduced almost 30 years ago by Mirkin's group via the deposition of thiol-modified DNA strands on Au NPs.[1] Since then, the reaction has been widely used, which has resulted in many modifications of the method. A particularly useful scheme is the freeze-thaw process, which results in both a shorter reaction time and a higher surface density of DNA.[2] In general, using thiolated-DNA provide a reliable way to functionalize only noble and coinage metals. Therefore, it is necessary to develop alternative techniques to address the DNA conjugation of NPs with surface compositions that are inert to thiols, including oxides, core-shell, polymeric NPs, and even NPs composed of active metals (Al, Ga) and metalloids (Si, Ge). Si NPs are an interesting example of such structures that cannot be functionalized using thiol chemistry. These high-index dielectric NPs have received growing attention in recent years, as theoretical and numerical studies have predicted novel properties including low heat losses and overlapping strong magnetic and electric modes in the visible range.[3] These features are key for applications in chiral sensing, unidirectional scattering, and the manipulation of magnetic dipole transitions, making Si NPs a convenient alternative to plasmonic NPs that exhibit relatively high losses and the absence of a magnetic response at optical frequencies.[3] However, in spite of the great potential of Si NPs, their stable conjugation with DNA strands has yet to be achieved.

Inspired by recent developments in the functionalization of Au NPs, we report here an approach to conjugate various nanomaterials with DNA by employing freezing-assisted SPAAC, with a special focus on Si and SiO_2 NPs (see Figure 1a). Impressively, this simple method of functionalization proved to tremendously improve the overall DNA deposition efficiency. When comparing with other approaches used for the DNA functionalization with SPAAC, we found that not only does freezing reduce the reaction time from about two days to only a few hours, but also that our method yields 2-10 times higher DNA density on the surface of the NPs, i.e., up to 0.2

molecules/nm^2 (see Figure 1b). The resultant DNA-Si NPs form highly stable colloids, which we incorporate into DNA origami structures via the formation of self-assembled NP dimers at pre-determined positions with an inter-particle gap of approximately 5-10 nm, as presented in Figure 1c. Our results show up to a 78% yield for the formation of NP dimers (i.e., versus unintended NPs monomers), thus representing the first step towards the synthesis of more complex geometries such as hybrid metal-dielectric antennas and the combination of high-index materials with other species in precise geometries. Finally, we demonstrate the versatility of this method by realizing the DNA functionalization of different NPs: oxide – TiO2, Au@SiO2, polymeric – PMMA and PS, as well as metallic Au NPs.

Optically active substrates through DNA-based lithography

V. Linko[1,2*]

[1] University of Tartu, Institute of Technology, Tartu, Estonia
[2] Aalto University School of Chemical Engineering, Espoo, Finland
[*]corresponding author: veikko.pentti.linko@ut.ee

Abstract: We show that by combining DNA origami with common top-down lithography methods, we can create versatile substrates that show superior properties in surface-enhanced Raman spectroscopy (SERS) applications.

Self-assembling biotemplates such as the versatile and rapidly folding DNA origami [1,2] provide an effective shortcut for fabricating nanoscale assemblies with intricate, sub-nanometer detail. Despite their convenience, then converting these biological constructs into equally accurate and small structures with more favorable physical properties is significantly more challenging. One recent approach attempting to overcome this is DNA-assisted lithography (DALI) [3]. DALI integrates DNA origami nanostructures as templates in negative-pattern lithographic masks and processes these with standard nanofabrication techniques (plasma etching, material evaporation, lift-off) to create metallic replicas of the template. Thus far, DALI has been used to pattern particles with sub-10 nm feature sizes from a limited selection of materials on silicon nitride and sapphire substrates [3].

Here, we present a remarkably more adaptable method that circumvents the material constraints of DALI with the incorporation of a sacrificial polymer layer into the process flow. The new technique, named the Biotemplated Lithography of Inorganic Nanostructures (BLIN) [4], enables the pattern transfer of engineered biotemplates into inorganic structures from a multitude of materials and on less restricted substrates. Due to its versatile and parallel nature, BLIN could provide an attractive alternative for patterning optically active devices and other nanopatterned surfaces. To demonstrate this, we fabricate Ag bowtie nanoantennas on common glass substrates and characterize their response in the near-infrared regime using optical transmission measurements and FDTD simulations. Further, we use the patterned substrates in surface-enhanced Raman spectroscopy (SERS) to augment the detection of Rhodamine 6G [5].

Moreover, we can create even more efficient SERS supporting substrates, which are based on DALI and a layered configuration of materials. In detail, we use DNA origami templates to form hybrid nanostructures consisting of aligned silver bowtie-shaped particles and apertures of similar shape in a silver film. It was shown that this particular geometry facilitated a four-fold advantage in Raman enhancement compared to common particle-based SERS substrates (experiments and FDTD). Our DALI-fabricated hybrid structures suppress the background emission, allow emission predominantly from the areas of high field enhancement, and support additional resonances associated with the nanoscopic apertures. Finally, these nanoapertures also enhance the fields associated with the resonances of the underlying bowtie particles [6,7]. The versatility and parallel nature of our fabrication scheme and all above-mentioned features make our optically resonant substrates attractive for various SERS-based applications.

Abstract: Using Nanoscribe IP-Dip technology on conductive substrates we create a metallic chiral woodpile for circular polarized thermal emission. The heated sample emits broadband circular polarized mid-infrared radiation in the optical transparency window of the atmosphere. Predicted on the basis of the local Kirchhoff law and theoretical studies considering fundamental evanescent Floquet states we show first experimental results.

Sensors and emitters in the mid-infrared (MIR) light regime have grown more popular with the possibility of sensing various distinctive molecules such as polymers, toxic or explosive agents and molecular gases [1] through targeting the fundamental vibrational resonance band of such materials. Furthermore, MIR sources designed in the atmospheric transparency window are useful for telecommunication. A variety of sources, predominantly based on semiconductor lasing, exist at these frequencies ([2–4]). However, some applications, such as chiral molecule detection, require a circularly polarized source, which currently depend on the narrow-banded accuracy of the polarizers. A broadband MIR emitter thus widens the field in which a sensor or telecommunication device can be used for.

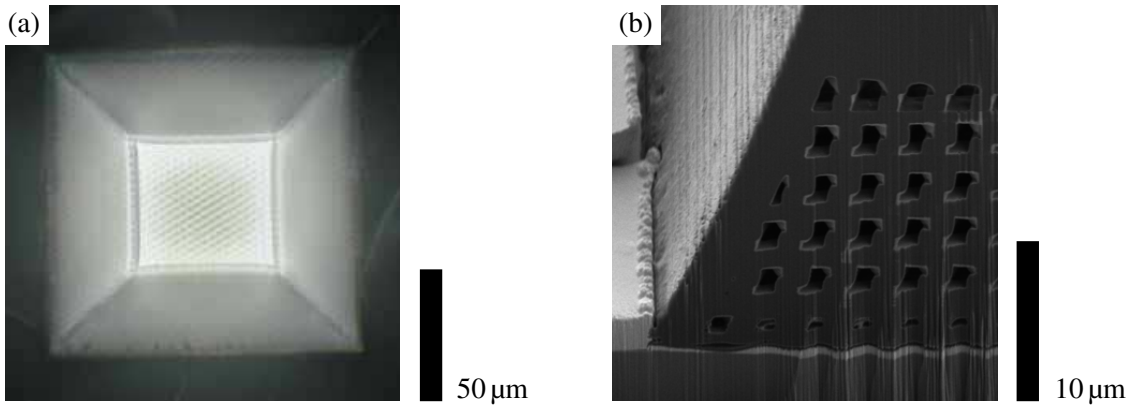

Figure 1: Cross polarization microscopy (a) of a chiral woodpile (100 µm^2) in a surrounding protective layer. The Woodpiles have a truncated pyramid shape to allow adjacent printing. Secondary electron microscopy image (b) of a cross section cut with a focused ion beam allow analysis of the printing quality inside the woodpile.

Here, we present a plasmonic chiral woodpile as a broadband circular polarized thermal emitter in the MIR regime. The chiral woodpile is a relatively simple design that can exhibit strong circular dichroism [5, 6]. According to the local Kirchoff law [7], a chiral woodpile of a lossy, plasmonic material is expected to have a strong, broandband CD between 3 µm and 4 µm insensitive to the precise geometrical details [8].

As two-photon-polymerization is a well-established fabrication technique for 3D MIR structures [9], we use the IP-Dip technology on Nanoscribe to design a pixel array of inverse woodpiles on a Cr/Au coated substrate. The conductive substrate allows the replication of the woodpile through elecrodeposition of platinum. Preliminary absorptivity measurements have been done on a Fourier-transform infrared spectroscopy setup. Step-by-step printing adaptations have been analyzed using a focused ion beam coupled with a secondary electron microscope as you can see in Fig.1.

Abstract: The optical imaging has been demonstrated based on various metasurface devices, such as broadband achromatic metalens, ultracompact spectral light field imaging (SLIM) camera, and pixel-level metasurface-based Bayer-type colour router, etc.

Ideal imaging technique simultaneously requires the three-dimensional (3D) high spatial-resolution and the high spectral-resolution. To date, while compact 3D imaging technique and spectrometer have been individually developed, the combination of these techniques has only been realized in cumbersome systems, significantly limiting their practical applications. A long-standing and critical challenge is how to integrate the 3D spatial-resolution and the spectral-resolution into a single nanophotonic device. Herein, based on the precise wavefront control of metasurface and deep-leaning algorithm, we experimentally demonstrate the first ultracompact spectral light field imaging (SLIM) camera. The SLIM camera consists of TiO2 lens array on a CMOS camera. Owing to the high dispersion of metalens, both the 3D position information and the spectrum can be re-constructed without sacrificing the light throughput. The demonstrated spectral-resolution is as high as 4nm and the spatial-resolution reaches the diffraction limit, enabling the capability of SLIM in precise 3D imaging and material discrimination. By employing an inverse-design method, we demonstrate a pixel-level metasurface-based Bayer-type colour router, with the brightness twice as high as that of a commercial camera.

Abstract: We introduce color arrestor pixels (CAPs), a breakthrough in CMOS sensor technology, offering unparalleled color accuracy and miniaturization. By mimicking human eye response with advanced metasurfaces, CAPs outperform traditional sensors, achieving high efficiency and angular tolerance with a small footprint. This innovation heralds a new era in high-fidelity imaging.

Silicon is the dominant material in complementary metal-oxide-semiconductor (CMOS) imaging devices because of its outstanding electrical and optical properties, well-established fabrication methods, and abundance in nature. However, with the ongoing trend toward electronic miniaturization, which demands smaller pixel sizes in CMOS image sensors, issues, such as crosstalk and reduced optical efficiency have become critical. These problems stem from the intrinsic properties of Si, particularly its low absorption in the long wavelength range of the visible spectrum, which makes it difficult to devise effective solutions unless the material itself is changed. Recent advances in optical metasurfaces have offered new possibilities for solving these problems. In this study, we propose color arrestor pixels (CAPs) as a new class of color image sensors whose composite spectral responses directly mimic those of the human eye. The key idea is to employ linearly independent combinations of standardized color matching functions. These new basis functions allow our device to reproduce colors more accurately than the currently available image sensors with red-green-blue filters or other metasurface-based sensors, demonstrating an average CIEDE2000 color difference value of only 2.88 when evaluating 24 colors from the Gretag-Macbeth chart under standard illuminant D65. Owing to their high fidelity to the human eye response, CAPs consistently exhibit exceptional color reproduction accuracy under various spectral illumination compositions. Simple schematic figure of CAPs is explained in Figure 1. With a small footprint of 855 nm height and 220 nm full-color pixel pitch, the CAPs demonstrated high absorption efficiencies of 80%, 82%, and 63% at wavelengths of 460 nm, 555 nm, and 596 nm, respectively, and good angular tolerance. With such a high density of pixels efficiently capturing accurate colors, CAPs present a new direction for optical image sensor research and their applications.

Abstract-

Designing phase gradient metasurfaces via phase sampling has been extensively investigated, as it enables manipulation of light intuitively. However, it causes unwanted aliasing which reduces the focusing efficiency and degrades imaging quality when the sampling level is insufficient. Here, we investigate aliasing patterns in metasurfaces and how to effectively address them, especially in case of large deflection angles and UV regime.

Metasurfaces have been garnered for several decades with their extraordinary electromagnetic properties by strategic arrangement of meta-atoms. The widely used method to design metasurfaces is phase sampling, mapping the desired phase map and allocating meta-atoms at corresponding phase [1]. This method has been successfully applied to such as lenses, holograms, beam steerers, and waveguides [2-3]. However, at large deflection angles, small periods, and short wavelengths, aliasing severely occurs, reducing efficiency and degrading imaging quality [4].

In this work, we investigate aliasing in gradient metasurfaces. One method to alleviate aliasing is to decreases the periodicity of the unit cell. However, it leads to increase fabrication difficulty and occurs unexpected nonlocal effect. We investigated aliasing in a beam steerer respect to the azimuthal angle of the sampling grid. We also analyzed the aliasing in metalenses with various NA and grid type. Finally, we demonstrate anti-aliasing ultraviolet metalens which has an NA of 0.9. By replacing the outer part of the metalens with an arrangement of asymmetric nanoantennas within a supercell, so-called metagrating, aliasing is effectively eliminated. This anti-aliasing metalens shows higher efficiency than phase sampling metalens. We believe that our findings will shed the light on the systems requiring high NA such as high-resolution imaging system, wide field-of-view in AR/VR devices and LIDAR systems, optical trapping systems and state of the art lithography technology [5].

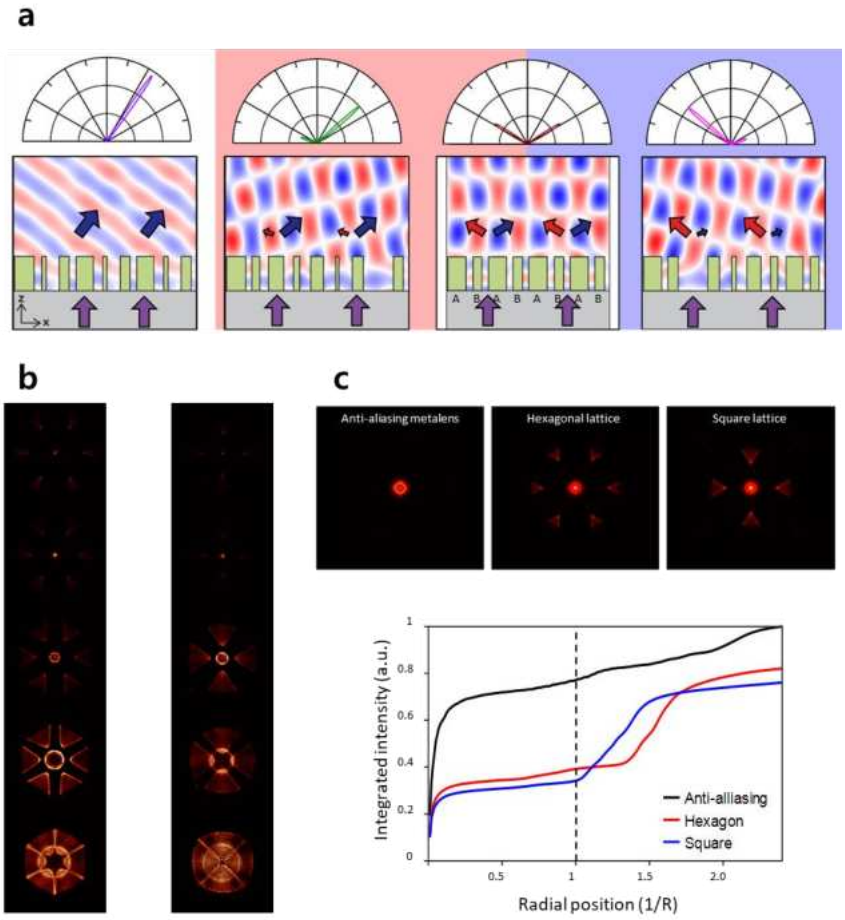

Figure 1. (a) Simulation results of various beam steerer with different deflection angle. Blue arrow represents desire order and red arrow represents aliasing order. (b) Results of Z-scan experiments. Right is hexagonal lattice metalens and square lattice metalens. The NA of both metalens is 0.95. (c) Simulated results of integrated intensity for Anti-alliasing metalens (black), Hexagonal lattice metalens (red), and Square lattice metalens (blue).

Abstract: A commercially viable, portable hydrogen meta-sensor is introduced, integrating gas-responsive liquid crystal cells with two-by-two metasurface arrays. This innovation can identify hydrogen gas concentrations at four levels. Fabricated through cost-effective nanoimprinting methods, the metasurfaces make this gas meta-sensor promising for on-the-go sensing in diverse industrial applications.

Hydrogen has garnered attention as a sustainable alternative to traditional fossil fuels, fueled by the increasing need for long-distance energy transportation and the potential for high-energy storage density [1]. This highlights the necessity for portable and cost-effective concentration monitoring to mitigate potential hydrogen leakage [2]. In this study, we introduce a commercially viable, portable hydrogen meta-sensor achieved through the integration of gas-responsive liquid crystal cells with two-by-two metasurface arrays.

The hydrogen meta-sensor is structured in a sandwich-like arrangement involving an x-polarizer, liquid crystal, y-polarizer, and metasurfaces, incorporating well-defined optical modeling through overlaid holography. Within the hydrogen sensor, liquid crystal cells function as a crucial switch, facilitating real-time visual alarms based on gas concentration. Each metasurface within the arrays is embedded with diverse holographic images, aligning their visual content with the saturation level of metasurface-paired liquid crystals. Through practical experimentation, we showcase the capabilities of the multi-level gas meta-sensor, capable of identifying concentrations of hydrogen gas at four levels (50 ppm, 100 ppm, 150 ppm, and 200 ppm), presenting reconstructed holographic alarms in a visual format. Fabricated using cost-effective nanoimprinting methods, these metasurfaces position the multi-level gas meta-sensor as a promising on-the-go sensing platform for various industrial applications, holding significant potential for mass production.

Control of Electric and Magnetic Dipole Emission by Purcell effect of Mie resonant Silicon nanosphere

H. Kasai[1], H. Sugimoto[1*], and M. Fujii[1]

[1]Electrical and Electronic Engineering, Graduate School of Engineering, Kobe University, Japan

Abstract: The enhancement of magnetic dipole transition is a key factor for controlling light emission of rare-earth ions and facilitating spin-forbidden optical transition. In this study, we employ spherical silicon nanoparticles with magnetic-type Mie resonances for enhancing the magnetic dipole emission of Eu^{3+} ions.

In these days, in addition to the enhancement of electric dipole transition by the nanoantennas, the magnetic dipole transition enhancement have attracted attentions. This is expected to lead to the enhancement of magnetic dipole emission rate of rare earth ions[1,2] and spin-forbidden transition of molecules(e.g. $S_0 \rightarrow T_1$)[3, 4]. Several works have demonstrated the manipulation of magnetic dipole transitions by silicon (Si)-based Mie resonators. However, the observed magnetic emission rate enhancement was marginal. In this work, to achieve substantial magnetic Purcell enhancement, we employ silicon (Si) nanospheres (NSs) and try to enhance the electric and magnetic dipole emission of Eu^{3+} via Purcell effect originated from electric and magnetic Mie resonances.

Prior to the experimental study, we calculated the emission rate enhancement of electric and magnetic dipole emitters by a Si NS. Figure 1(a) shows calculated results of extinction efficiency of Si NP with 275 nm in diameter. The high-order Mie modes such as the magnetic quadrupole (MQ), electric quadrupole (EQ) exist in visible to near-infrared range. Figure 1(b) and (c) show the calculated results of radiative rate enhancement for electric and magnetic dipole emitters, respectively, by Si NS in 275 nm in diameter. At the resonance wavelength of the EQ (MQ), the radiative rate of electric (magnetic) dipole is largely enhanced. In particular, radiative rate for magnetic dipole is enhanced more than 50 times by the MQ resonance. There result indicates that it is possible to enhance electric and magnetic dipole emission of Eu^{3+} by tuning the resonance wavelength, *i.e*, Si NS size control.

Recently, our group have succeeded in producing highly spherical and crystalline Si NSs which have electric and magnetic Mie modes in visible to near-infrared range[4]. We attach Eu^{3+} complexes on the surface of Si NSs (see inset of Figure 2(a,c), Si NS:Eu). Figure 2(a) and (b) show the measured scattering and photoluminescence (PL) spectra of a

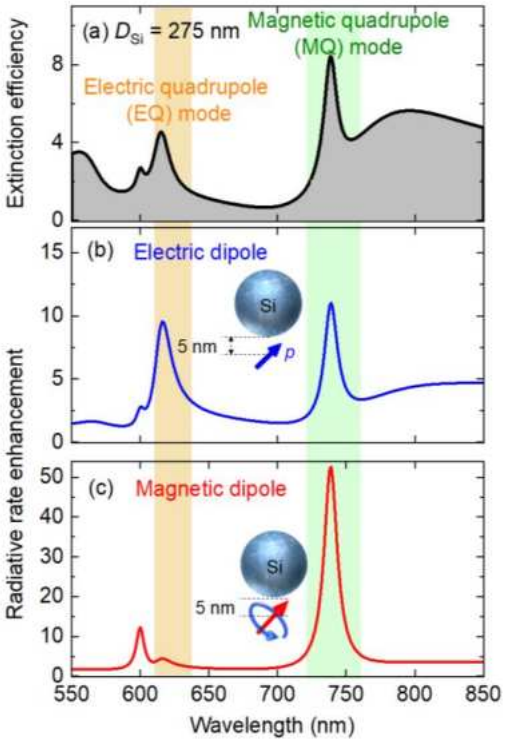

Figure 1: Calculated results of (a) Extinction efficiency and (b,c) radiative rate enhancement spectra for (b) electric and (c) magnetic dipole emitters by Si NS with 275 nm in diameter. Dipole emitters are placed at 5 nm from Si NP surface.

single Si NS: Eu (diameter: 205 nm), respectively. We can observe a MQ resonance at the wavelength of 590 nm in the scattering spectra. In the PL spectra, magnetic dipole emission ($^5D_0 \rightarrow {}^7F_1$) of Eu^{3+} is enhanced compared to reference spectra (blue shade) at the wavelength of 590 nm. As demonstrated in the calculated result, this is due to magnetic Purcell effect by Si NSs. Figure 2(c,d) shows the scattering and PL spectra of Si NS;Eu with 316 nm in diameter. At the wave- length of 690 nm, we can see an EQ resonance of a Si NS and enhancement of electric dipole emission of Eu^{3+}($^5D_0 \rightarrow {}^7F_4$). This is due to electric Purcell effect.

In the poster session, we demonstrate that the branching ratio of the $^5D_0 \rightarrow {}^7F_j$ (j = 0-4) transitions of Eu^{3+} ions can be controlled in a wide range by tuning the resonance wavelength and also discuss the result for selective enhancement of the transition to a specific Stark sublevel by precisely controlling the size of a Si NS.

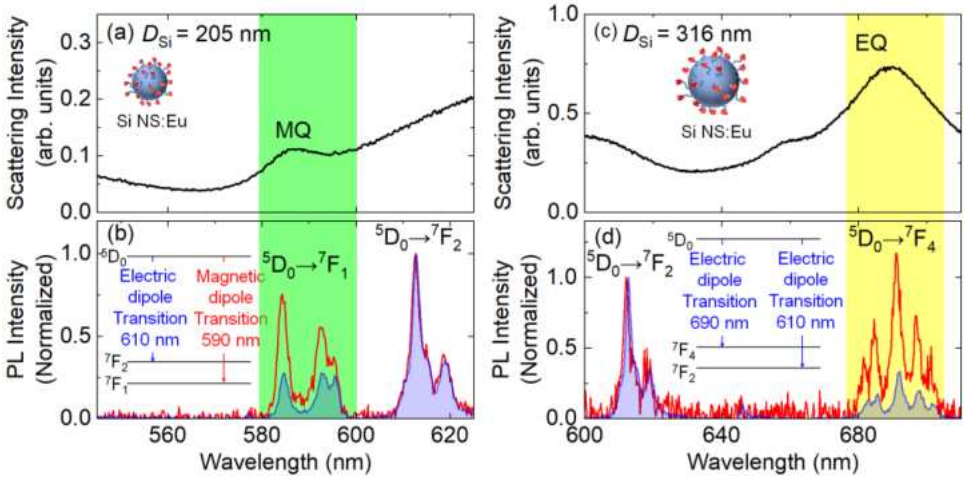

Figure 2: (a,c) Scattering and (b.d) PL spectra of single Si NS:Eu with the diameter of 205 nm(a,b) and 316 nm(c,d) (PL: red curve). PL is also shown as a blue shade.

Exploring Wave Phenomena in Quasicrystal-Based Photonic Structures

M. V. Rybin[1,2]

[1] School of Physics and Engineering, ITMO University, 197101 St. Petersburg, Russia

[2] Ioffe Institute, 194021 St. Petersburg, Russia
*corresponding author: m.rybin@metalab.ifmo.ru

Abstract: Quasicrystal-based photonic structures offer unique design flexibility due to their aperiodic nature, allowing for novel wave phenomena. This article reviews our recent reports on such structures, focusing on intrinsic light localization, photonic bandgap formation, and selective absorption of electromagnetic radiation, showcasing the potential of quasicrystals in photonics.

The recent decades witnessed significant advancements in artificial photonic media, e.g., photonic crystals and metamaterials. Fabrication techniques advanced, adapting theoretical concepts from condensed matter physics to the electromagnetic realm. Traditional treatments rely heavily on translational symmetry, simplifying analyses to single unit cells with Bloch solutions, yet limiting factors like crystallography rules or lack of intrinsic localization persist. Quasicrystals, though non-periodic, offer novel possibilities due to their ordered yet aperiodic nature. These structures hint at sustaining metamaterial properties, local density of photonic states modulation, and other unexplored effects. Our recent reports include intrinsic light wave localization in 3D icosahedral quasicrystals [1], polymer-based photonic structures with complete bandgaps [2], and systems with precise spectral and directional selectivity [3].

Understanding waves in periodic media is aided by the Bloch theorem, relating waves to a periodic function multiplied by a plane wave. Notably, periodic systems offer only localized modes near sample boundaries due to translation symmetry, contrasting quasicrystals where intrinsic wave localization is viable without such constraints. Recent numerical simulations [4] and experiments [1] on icosahedral quasicrystals confirmed this intrinsic wave localization effect, enhancing light-matter interactions and unveiling new possibilities for practical applications.

Aside from 3D structures, interlaced wire media with Penrose tiling patterns exhibit unique properties. These media consist of non-connected wire sublattices on parallel planes, enabling intriguing electromagnetic wave control. By exploiting the C5 rotational symmetry of Penrose tiling, these structures demonstrate diverse wave manipulation abilities, promising further advancements in photonics research and application development [5]. Numerical simulations on interlaced media based on the C5 Penrose tiling showed intrinsic localization of electromagnetic waves in a specific frequency range.

Quasicrystalline structures allow for the reduction of the material's refractive index to create a complete band gap. The overlap of stopbands related to Bragg scattering for all polarizations and directions in a frequency interval is crucial for this. Quasicrystals with a dense distribution of maxima in reciprocal space can have almost spherical Brillouin zones, reducing the requirements for dielectric index contrast for the complete photonic band gap to open up [2].

The modulation of the local density of photonic states was studied concerning translation symmetry. Quasicrystalline structures showed similar frequency modulation of the local density of photonic states as crystal structures, emphasizing the importance of structural ordering over translation symmetry [6]. Also, designing quasicrystalline structures by binarization of sine-type gratings enables manipulation of electromagnetic waves.

Recent designs have shown structures capable of absorbing waves incident at specific angles and frequencies while allowing other waves to pass through with minimal scattering [3].

Overall, quasicrystalline structures offer unique properties for controlling electromagnetic wave behaviors, especially in terms of creating complete photonic bandgaps and managing wave interactions based on specific design parameters.

This work was supported by the Russian Scientific Foundation (grant no. 20-79-10316).

Abstract: Achieving compact varifocal imaging system is significant topic for various practical applications. We introduce a multifocal metalens enabling focal length adjustment through incident polarization variation, targeting AR/VR applications. We analyze multifocal design platform with various lens parameters and explore alternative methods for increasing the focal points.

Metalens, thin and flat lens consisting of nanostructure arrays, have garnered considerable attention due to their potential to reduce the bulkiness of conventional optical imaging system [1]. However, conventional metalenses are limited in functionality, typically offering a single fixed focal length after fabrication. Previous works have aimed to introduce multiple focal lengths or multi-functionality within a single device [2]. Meanwhile, the exploration of varifocal imaging systems has gained prominence due to its applicability in addressing practical challenges, such as resolving the vergence-accommodation conflict (VAC) to enhance the usability of AR/VR systems. In this study, we present a multifocal metalens capable of shifting its focal length by varying the incident polarization and apply it to varifocal imaging system for AR/VR applications.

To achieve the selective imposition of phase profiles corresponding to lenses with two different focal length within a single metalens, we leverage both propagation phase and geometric phase modulation. We utilize the materials with high refractive index and low optical loss, such as SiN (532nm) and a-Si:H (635nm), to obtain enough options for structural parameter candidates. The versatility of fabricated metalens is demonstrated through its integration into varifocal imaging systems, including AR/VR imaging system capable of mitigating the VAC. Additionally, different metalens samples are designed with the various lens parameter and their impacts are analyzed, verified through extreme case of on-off metalens which multiplexed lens profile with zero-phase profile. To enhance the practicality of this platform, we also explore an alternative design method utilizing off-axis elements of Jones matrix to expand the number of focal points.

Abstract: The bandgap properties of chiral metamaterials can be used to inhibit wave modes in physical beams. We use the inverse neural network to get chiral structures that have bandgap requirements by adjusting the range of maximal stress. This approach allows for building metamaterials while adjusting physical characteristics as intended.

With the advances in 3D printing technology, fabricating complex three-dimensional mechanical/elastic structures has become easier. Metamaterials are artificially designed materials with unique physical and mechanical properties not found in nature [1]. They possess distinctive physical features such as negative effective bulk modulus [2] and band gaps [3], making them suitable for use in numerous fields. By utilizing the band gap properties, we can suppress elastic waves in a physical beam, therefore decreasing the vibration of the structure. In particular, complete band gap to block elastic waves of all polarizations has been achieved through chiral mechanical metamaterials [4]. However, previous research lacked analysis regarding the stability of the structures. To design a stable metamaterial, it is essential to take into account both the band gap and stress analysis. However, simultaneously incorporating dynamic properties like as band gaps and static properties like stress creates a broad and intricate design domain, which results in constraints for traditional heuristic-based design approaches.

In this study, we propose a method for producing chiral mechanical metamaterials with desired characteristics through inverse design using artificial intelligence. The tandem architecture is used to address the non-uniqueness problem that could occur in the inverse design process. We develop a forward model for predicting bandgap frequencies and maximum Von Mises stress under compression, which was subsequently utilized for training in the inverse neural network (Fig. 1a). During the training of the inverse neural network, bias was assigned to minimize maximal stress. This makes it possible to design a structure with low stress while maintaining the bandgap distribution (Fig. 1b). Furthermore, the inverse neural network offers flexibility to precisely represent the bandgap criteria and alter the stress values based on the user's desire. Fig. 1c shows that the constructions of each row seem similar in appearance; however, the stress on the rods differs by more than three times. By using artificial intelligence for inverse design, we achieve metamaterial design that enhances stability while maintaining its physical properties.

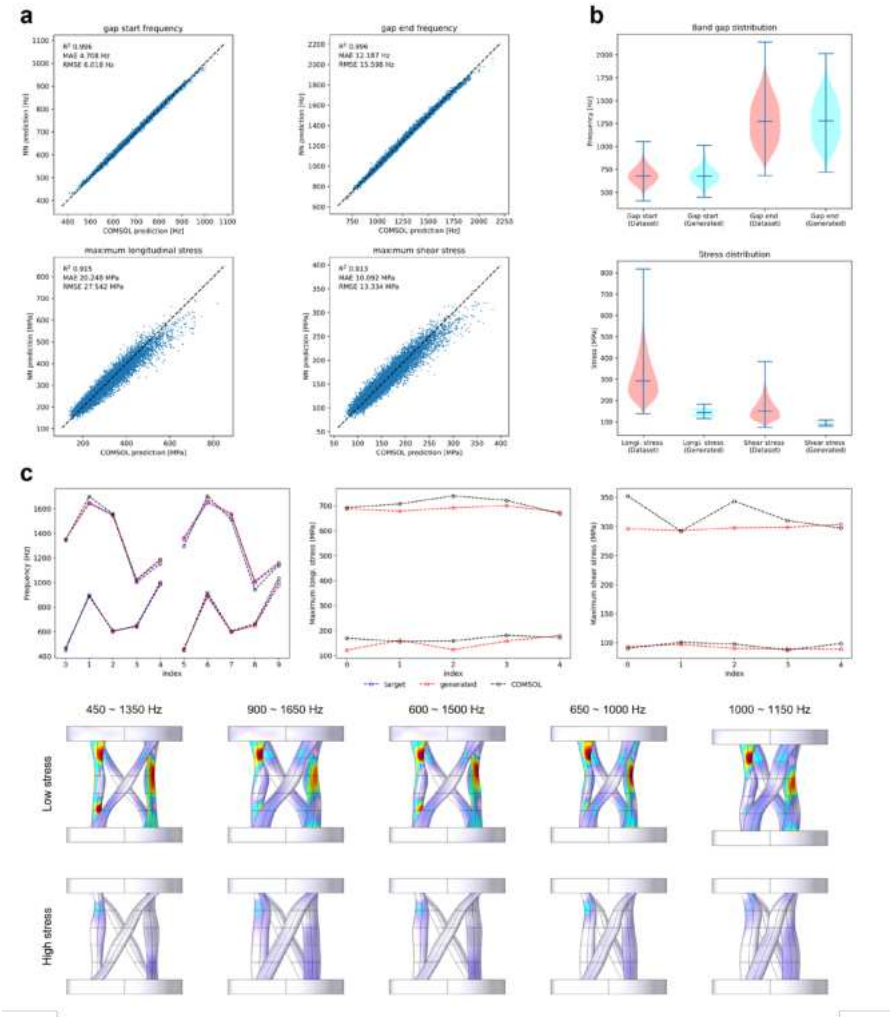

Figure 1. (a) The outputs estimated by neural networks (NN) are compared with the values of COMSOL, and the R-squared (R^2), root mean squared error (RMAE) and root mean squared error (RMSE) are calculated by comparing the NN. (b) Violin plots showing the distributions of the dataset (red) and generated set (blue) for bandgap frequencies and stresses. (c) Chiral metamaterials with low and high stress bias for five pairs of bandgaps. The stress distribution in each structure is analyzed using COMSOL. While the bandgaps are same, the stress on the rods differs by almost three times.

Inverse Design for wavelength and polarization multiplexing in optical metasurfaces

Bo Xiong[1*], and Wei. Ma[1]

[1]Zhejiang University, China
[*]corresponding author: bo.xiong@zju.edu.cn

Abstract: By introducing the engineered noise to the precise solution of Jones matrix elements, we break the fundamental limit of polarization multiplexing capacity of metasurfaces. We experimentally demonstrate up to 11 independent holographic images using a single metasurface illuminated by different polarizations.

Near-infrared multi-spectral and multi-polarization imaging technology enhances target detection and recognition by distinguishing the spectral characteristics of various targets. However, traditional imaging systems heavily rely on complex optical filter designs that are often bulky and mechanically unstable, posing significant challenges for miniaturization and integration challenging. In this talk, we firstly designed a freeform dielectric metasurface with the wavelength-multiplexing focusing effect based on a deep learning model, which can separate the mixed near-infrared light into distinct wavelengths. To effectively modulate the complex amplitude of the transmitted light at three distinct near-infrared wavelengths (1150, 1350, and 1550 nm), high-index silicon freeform nanostructures supporting rich resonant modes were proposed. An inverse design model based on deep learning was utilized to generate individual freeform nanostructures pixel by pixel, satisfying the complex amplitude requirement for a multiplexed metalens design. Finally, a metasurface was employed to realize near-infrared multispectral imaging, which allowed for the distinct detection and decoding of images at the three target wavelengths. Moreover, we also designed a polarization multiplexing metasurfaces based on genetic algorithm, in which noise engineering has been introduced to break the polarization multiplexing capacity of metasurfaces that roots from the dimension constraints of the Jones matrix. Illuminated by the incidence with different linear polarization states, the metasurface can generate up to 11 independent holographic images at the corresponding channels. To the best of our knowledge, it is the highest capacity reported for polarization multiplexing. The proposed technology has a wide range of applications in clinical medicine, biological tissue imaging, and deep-space exploration.

Abstract: This article endeavors to integrate a metasurface with a VCSEL to achieve a perfectly compact and miniaturized perfect vortex beams (PVB) integrated VCSEL chip. This concept is also applied to broaden the functionalities of PVB, including on-chip overlapping PVB and on-chip multi-channel overlapping PVB.

Introduction: Since the proposal of the PVB concept, its extensive application prospects have garnered swift attention, and methods for its generation have proliferated, such as through the application of spatial light modulators, interferometers, or conical lenses[1]. However, these traditional methods of generating PVBs involve a series of bulky optical components. In addition, Minor errors in alignment between individual optical components will affect the quality of the generated PVB. Some researchers utilize the two-dimensional structure of metasurfaces to combine the functions of axicons, vortex phase plates, and Fourier lenses in the same dimension to generate PVB. While this method significantly improves the efficiency of PVB generation, it still requires an independent feed source and imposes high requirements on the quality of the incident beam. Therefore, a more complete collimation system needs to be built, which hinders the further development of PVB. To reveal the full potential of PVB, people are committed to achieving miniaturization and integrated generation of PVB on different platforms. In this article, we present the generation and preparation of a chip that utilizes integrated metasurfaces to directly emit PVB. Unlike the traditional preparation of PVB, our method has the main advantage that we do not require independent feed sources or separate collimation systems[1,2]. We use metasurfaces as intermediaries to directly integrate the collimation function and the control function of vortex beams on the chip, further expanding the control function of the integrated chip on the beam, this provides more opportunities for the application of vortex beams with multiple topological charge value and stable spot diameters. At the same time, the generation of multi-channel overlapping PVB demonstrated here will pave the way for enhancing information capacity and security, as well as improving the number of particle capture and rotating target detection technologies. The proposed method has strong potential in new applications that traditional optics may not be able to achieve.

Results and Discussion: Fig.1a shows the intensity distribution of integrated metasurface PVB along the x-z plane, featuring different topological charge values of l=1, 3, and 5. Three PVBs with different topological charge values exhibit almost the same beam radius and beam divergence. Fig.1b records its intensity distribution at the identical measurement point. Additionally, Figure 1c shows the cross-section of the normalized intensity distribution extracted along the y-direction at a wavelength of 978nm. For three sets of PVB with different topological charge values of l=1, 3, and 5, the measured vortex diameters are 50.1, 50, and 50um, respectively, closely aligning with the theoretical value of 50μm. Besides the variations in topological charge value, the three metasurfaces characterized here share identical design parameters. Specifically, in this section, the period d of the prism is designed to be 39 um. The results suggest that, with the increase in topological charge value, the beam radius remains nearly constant. These findings robustly affirm the effectiveness of our method as a solution for developing PVB laser chips. Fig.2a displays the simulation and test results (left: l_1=2 and l_2=3;

middle:l_1=-2 and l_2=2; right:l_1=2 and l_2=3) of the superposition of PVB with different topological charge values. Fig. 2b illustrates the corresponding normalized intensity distribution.

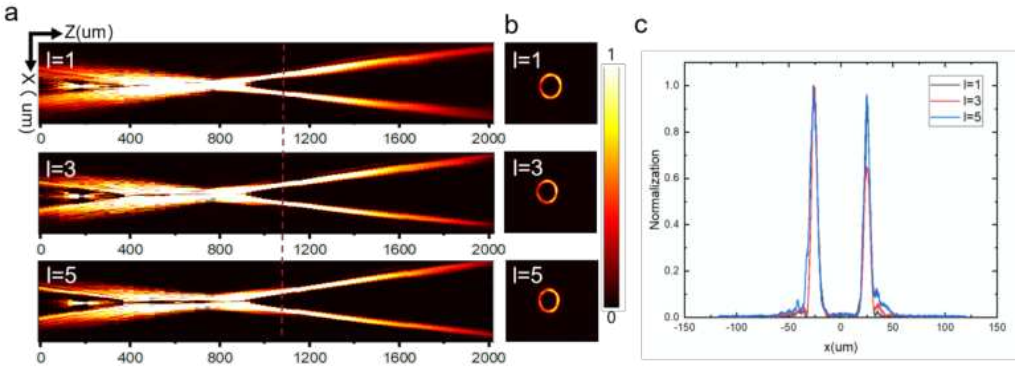

Fig. 1 Generation of the perfect vortex beams. a The measured beam intensity profile along the propagation direction. b The measured annular intensity profiles of the generated PVBs with topological charges of l = 1, 3, 5. c Normalized cross-sections of the annular intensity profiles of the PVBs

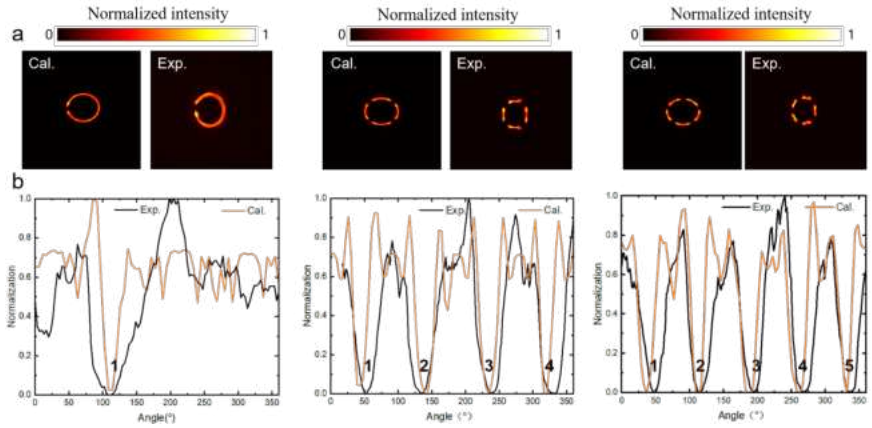

Fig.2 Characterization of overlapping perfect vortex beams. a The simulated and measured intensity distributions of the overlapping PVBs. b The relation between light intensity distribution and the azimuthal angle.

Conclusion: We have designed and demonstrated a series of all-dielectric metasurfaces with PVB, and integrated them on VCSEL chips to construct a complete system for generating structured beams with arbitrary engineering phase profiles on the chip. As a functional demonstration of this design, we further explored the generation of on-chip overlapping PVB and on-chip multi-channel overlapping PVB. Compared with traditional methods for generating and manipulating PVB, our work provides a compact integrated metasurface method to accomplish this complex task, which traditional optical design cannot achieve. This work helps to open up new opportunities for the application of PVB in the field of miniaturization.

Emission properties of plasmonic nanoshell lasers: Symmetric vs. antisymmetric lasing modes and gain-medium detuning effects

K. Caicedo[1*], M. Infusino[1], A. Aradian[2] and A. Veltri[1]

[1]Universidad San Francisco de Quito, Quito, Ecuador

*corresponding author: gcaicedo@asig.com.ec.

Abstract: This research explores the lasing dynamics of gain-doped metallic nanoshells, focusing on frequency pull-out effects and emission linewidth in relation to plasmonic resonances. By analyzing symmetric versus antisymmetric plasmonic modes and the impact of detuning the gain medium with respect to plasmonic resonances, we provide insights into optimizing nanoshell lasers.

Recent advances in nanophotonics have ushered in a new era of miniaturized light sources, leveraging the unique properties of metallic nanoshells (Figure 1). These structures, characterized by their distinct geometric configurations, have shown remarkable potential in enhancing light-matter interactions at the nanoscale. Central to this development is the concept of the gain-doped metallic nanoshells, which integrates optical gain materials in the core, surrounded by the plasmonic metal framework, offering a pathway to overcome intrinsic metallic losses and achieve lasing at the nanoscale (emission of coherent photons from the nanostructure)) [1]. This study delves into the comprehensive modeling and analysis of such gain-enhanced nanoshell systems, focusing on their lasing characteristics and the intricate interplay between their structural attributes and optical behaviors.

We will briefly introduce the theoretical framework we have used to describe the optical behavior of gain-enhanced metallic nanoshells [2-3]. It consists of a state-of-the-art time-dependent model that integrates the principles of optical Bloch equations, to describe the population dynamics in the embedded gain medium, as well as the free-electron motion for the metal, which are coupled together to describe the system behavior both below [21] and above the emission threshold [3]. This approached had already allowed to study the onset of the lasing instability at the threshold in another geometric configuration, i.e. a spherical nanoparticle immersed in gain medium [43]. In the case of the nanoshell geometry, due to fact that the lasing mode remains dipolar above the threshold (for a small enough particle), we were able to further study the lasing state itself [3], and we showed for the first time that unusually strong frequency pull-out effects dominate the dynamics and shape the emission spectrum – in striking contrast with the situation of conventional lasers.

The main goal of this study is to explore two avenues that have not been explored in our previous investigations. The first avenue is related to the fact that plasmonic nanoshells have two natural plasmon resonances (symmetric and antisymmetric), whose respective frequencies depend on the geometric aspect ratio. In the above work [32], as well as more generally in the literature, authors have considered the lasing of one of these resonances in a generic way, without going into the details of the respective benefits or specifics of choosing one or the other. This fact has motivated us to explore the similarities and differences of the lasing performance in both resonances above the gain threshold, starting with comparing and optimizing the amount of gain necessary for the system to start emitting. The optimization depends in particular on the aspect ratio

between the internal and external radii of the nanoshell.

The second avenue that we explored is about the implications of detuning between the gain frequency (transition frequency between the lower and upper energy states of the gain) and the plasmonic resonances of the nanoshell. In our previous work [32] and also in the literature, the gain medium emission spectrum is assumed to be centered exactly on the plasmonic resonance one wishes to bring to lasing. This is both because it simplifies theoretical considerations, and because this is the optimal positioning to minimize the necessary quantity of gain for lasings (since the peak emission is provided to the resonance). There is, however, no physical prerequisite to do so. We will therefore discuss the effect of detuning the gain with respect to the plasmonic resonance, in particular how the gain threshold, the lasing frequency, the emission width, and the above mentioned pull-out effects are affected. In particular, it is known from conventional lasers that gain detuning is a way to shift the laser's emission and hence make tunable lasers. We will discuss how this translates in the case of gain detuning in our nanolaser, making it tunable in a more flexible way than what is possible with centered gain situations.

(I think you can remove the two paragraphs below… this is not a real article, there is no need for a general conclusion, and this will save you some space!!!).

Abstract

This paper proposes a novel approach to achieve robust gesture recognition by employing 26GHz millimeter-wave programmable metasurface. By leveraging beamforming for wavefront manipulation and deep learning for gesture classification, the proposed system aims to enhance accuracy and reliability for gesture recognition.

1. Introduction

Gesture recognition technology has garnered significant attention in recent years due to its potential for human-computer interaction. Among various technologies, radar-based millimeter-wave (mmWave) technology has emerged as a promising avenue for gesture recognition. Leveraging the unique properties of mmWave signals, such as high resolution and penetration capabilities, researchers have been able to develop sophisticated systems capable of accurately detecting hand movements. [1, 2, 3]

However, radar-based gesture recognition systems suffer from expensive prices and clutter interference, which limit the accuracy of recognition, whereas metasurface-based sensing can be a good solution to these problems. In recent years, the advent of programmable metasurfaces has sparked significant interest and exploration across various fields of research, particularly in wireless communication and sensing domains. These metasurfaces, composed of an array of subwavelength meta-atoms, offer unprecedented control over electromagnetic waves at subwavelength scales. Leveraging the concept of metasurfaces, researchers have begun to explore novel paradigms in wireless sensing, facilitated by the ability to dynamically manipulate the propagation and reflection of electromagnetic waves. For gesture recognition tasks, metasurfaces can be utilized to focus the beam on the hand region, thereby minimizing interference from surrounding objects or environmental clutter and enhancing the accuracy and robustness of recognition.

In this paper, we propose a 26 GHz programmable metasurface-based gesture recognition system, presenting the following contributions to enhance recognition robustness: (1)We design a large-scale focusing coding scheme to concentrate the beam on the region of interest, thereby increasing the amount of relevant information and reducing ambient scattering. (2)We implement a high frame rate data acquisition system, enabling the capture of subtle gesture variations with greater temporal resolution. This ensures that even rapid movements are accurately recorded, providing a richer dataset for subsequent analysis. (3)We develop an LSTM-based neural network for data processing. The network enhances the system's ability to distinguish between similar gestures by learning long-term dependencies and context within the gesture sequences.

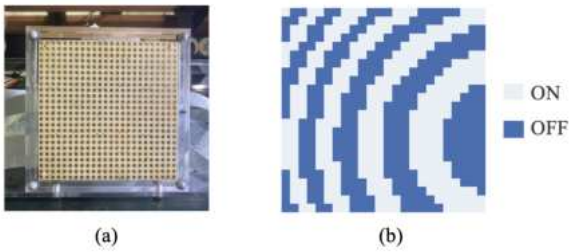

Figure 1: (a) The 26GHz programmable metasurface (b) A typical focusing coding pattern

2. System setup

As shown in Figure 1.(a), the programmable metasurface used in this paper operates at 26 GHz and is composed of an array of programmable metasurface units, each consisting of a PIN diode. By controlling the ON/OFF state of the PIN diode within each unit, the millimeter-wave beam can be focused on any spatial point (x, y, z) within a certain range. We use the so-called modified G-S (Gerchberg-Saxton) algorithm proposed in [4] to calculate the focusing coding pattern. A typical focused coding is illustrated in Figure 1.(b).

By predefined specification, we designate a 15cm × 15cm × 15cm cubic region in front of the metasurface as the gesture recognition area where the user performs gestures, as shown in Figure 2. In this study, we randomly selected 157 points within this area as focal points. Using the modified G-S algorithm, we calculate the corresponding 157 focusing coding patterns.

Our hardware system consists of a metasurface, a transmitting antenna, a receiving antenna, and a 26 GHz millimeter-wave transceiver module. During a single measurement, the transmitting antenna emits a 26 GHz single-frequency wave. The FPGA controls the metasurface to achieve code-switching for beam scanning. The receiving antenna collects the amplitude and phase of the echo signals corresponding to 157 different coding patterns. It is

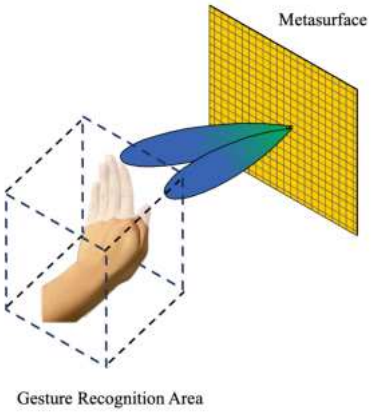

Figure 2: Schematic diagram of gesture recognition area.

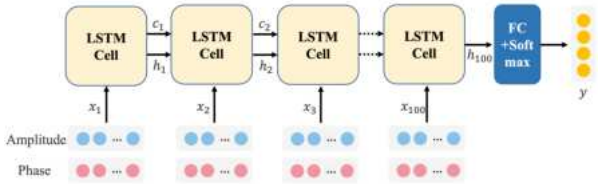

Figure 3: LSTM-based network.

noteworthy that the switching speed of the metasurface can reach 2.5 µs. Consequently, the coding switch time is only $2.5 \times 157 = 392.5$ µs. Including operations such as RF transmission and alignment, a single measurement can be completed in 30 ms, which allows the system to capture subtle gesture changes with higher temporal resolution.

3. Experimental Results

In this paper, we present an LSTM-based network designed for gesture recognition tasks, as depicted in Figure 3. The network processes 100 time samples, each comprising signal amplitudes and phases for 157 coding patterns. The LSTM network consists of 128 hidden units. The input dimension to the LSTM is 2×157, representing the combined amplitude and phase information for each time sample. The final output from the LSTM is fed into a fully connected layer to produce raw predictions across the specified gesture classes. These raw predictions are subsequently normalized using a softmax function to obtain class probabilities.

In this study, we collect data pertaining to four distinct gestures, designated as "fist," "left-to-right wave," "right-to-left wave," and "push." The corresponding microwave data for each gesture is illustrated in Figure 4. Approximately 100 samples are collected for each gesture, partitioned into 70% for training and 30% for validation.

In our implementation, the training is performed in a personal computer with Intel(R) Core (TM) i9-9980XE

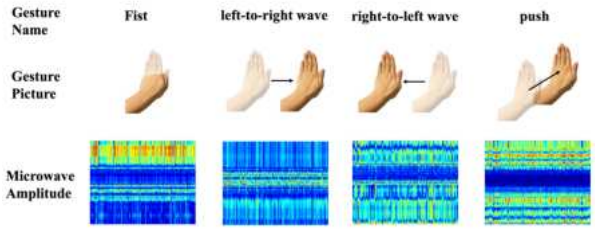

Figure 4: Gestures and corresponding microwave data.

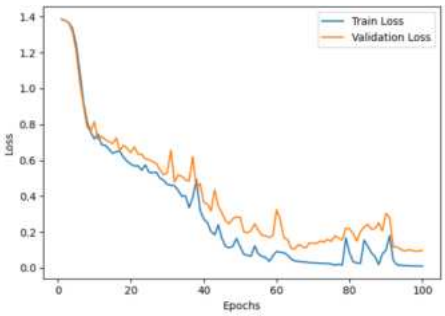

Figure 5: The training and validation losses.

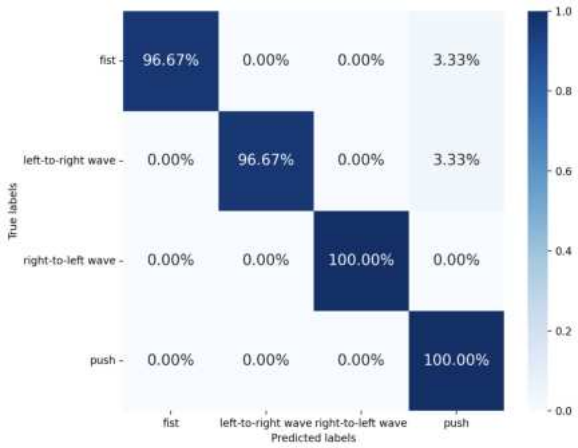

Figure 6: Confusion matrix of gesture classification.

CPU , 128GB RAM and NVIDIA GeForce RTX 2080 Ti GPU. The training is based on the Adam optimizer, with a batch size of 8 and 100 epochs. The learning rate is set to 0.0001. The training and validation losses are depicted in Figure 5.

After training, we collect a set of gesture data for testing, and the confusion matrix is shown in Figure 6. As can be seen, the recognition accuracy for all gestures exceeded 96%, with the "right-to-left wave" and "push" gestures achieving 100%. It is noteworthy that our test dataset includes gestures performed at different speeds, demonstrating the robustness of our method.

4. Conclusions

In conclusion, while radar-based gesture recognition technology has shown promise in recent years, it faces challenges such as high costs and interference. However, the emergence of metasurface-based sensing offers a potential solution to these issues. By leveraging programmable metasurfaces, which enable precise control over electromagnetic waves, we can enhance the accuracy and robustness of gesture recognition systems. In this paper, we propose a 26 GHz programmable metasurface-based system, which incorporates advanced features such as large-scale focusing coding, high frame rate data acquisition, and LSTM-based neural network processing to improve recognition performance. These contributions pave the way for more reliable and efficient human-computer interaction systems based on gesture recognition.

Abstract: Guided Domino Lithography (GDL) presents a novel solution for uniform fabrication of single-digit-nanometer plasmonic nanoantenna arrays. GDL leverages collapsing behavior of unstable photoresist nanostructures to achieve ultra-sharp bowtie masks. Experimental comparison with conventional lithography demonstrates superior yield and uniformity. GDL promises practical manufacturing for diverse quantum nanophotonic devices.

Plasmonic nanoantenna platforms have attracted significant attention for their wide-ranging applications in optical sensors, quantum plasmonics, and beyond. However, achieving uniform and reliable fabrication of nanoantennas at the single-digit-nanometer resolution remains a daunting challenge. In this study, we introduce guided domino lithography (GDL) as a novel solution for producing ultra-sharp nanoantenna arrays with remarkable uniformity [1].

GDL capitalizes on the collapsing behavior of unstable photoresist nanostructures, guided by a supporting structure, to ensure consistent fabrication of ultra-sharp bowtie photoresist masks. Through direct comparisons with conventional lithography methods under optimized electron beam exposure and development conditions (Fig. 1a), our experimental findings underscore GDL's superiority in terms of both yield and uniformity of nanoantenna shape across the fabrication area. Moreover, rigorous analyses are conducted to probe the electric field enhancement effects of ultra-sharp bowtie nanoantennas with diverse geometries (Fig. 1b). These analyses validate the substantial electric field enhancement achieved by the fabricated nanoantennas, further highlighting GDL's potential for practical manufacturing of single-digit-nanometer plasmonic nanoantennas.

In conclusion, GDL emerges as a promising solution for the uniform fabrication of ultra-sharp nanoantenna arrays at the single-digit nanometer scale. Our results not only demonstrate GDL's superior performance in process yield and uniformity compared to conventional lithography techniques but also underscore the significant electric field enhancement achieved by the fabricated nanoantennas. The GDL process thus holds tremendous potential as a practical manufacturing method, opening up new avenues for diverse quantum nanophotonic device applications [2,3].

Abstract: This work presents scalable method for manufacturing near-infrared metalenses. we demonstrate a 1 cm diameter, 0.53 numerical aperture (NA) polarization-independent metalens composed of hydrogenated amorphous silicon. The proposed metalenses exhibit high-resolution imaging capabilities, making significant progress in metalens production and optical technology.

Metalenses are thin, flat surfaces engineered with nanostructures to manipulate light, offering alternatives to traditional bulky optical components[1]. These devices can precisely control the phase, amplitude, and polarization of light, making them highly efficient for various applications such as light-field imaging, augmented/virtual reality, and quantum source[2]. However, conventional metalens fabrication methods, requiring high-resolution nanopatterning techniques like electron beam lithography, are expensive, offer low throughput, and struggle with patterning large areas. In this work, we propose mass-production method for near-infrared metalenses at wafer-scale.

To focus incident light, the phase profile of metalens is expressed by

$$\varphi(r,\lambda) = \frac{2\pi}{\lambda}\left(f - \sqrt{r^2 + f^2}\right) \qquad (1)$$

where λ, f, and r represent wavelength of incident light, focal length, and radial coordinate on the metalens. Eq. (1) means the hyperbolic lens equation. The phase profile of metalens is implemented using cylinder-shape meta-atoms with various diameters.

Metalenses are fabricated using hydrogenated amorphous silicon (a-Si:H) on glass wafers through a direct photolithography process, as shown in Fig. 1(a)[3]. The process involves depositing a layer of a-Si:H, followed by patterning using an argon fluoride (ArF) excimer laser for high-resolution lithography. Fig. 1(b) shows cylindrical meta-atoms composed of a-Si:H. This method produces metalenses with a diameter of 1 cm and a numerical aperture (NA) of 0.53, capable of focusing light close to the diffraction limit (Fig. 1(c)). To evaluate imaging performance of metalenses, a 1951 USAF resolution target is captured by the proposed metalens, as shown in Fig. 1(d). The focusing efficiency of these metalenses at a 940 nm wavelength is measured to be 44%, demonstrating their high performance.

Furthermore, we demonstrate the application of these metalenses in bioimaging, using the example of imaging onion epidermal cells (Fig. 1(e)). The metalens-based imaging system provides superior resolution, which show the potential of metalenses in biological research and medical diagnostics.

In conclusion, we introduce an innovative method for fabricating high-performance, large-scale metalenses, highlighting their potential to revolutionize optical technologies. By offering solutions to the limitations of

traditional optics, such as size, weight, and flexibility in manipulating light, metalenses pave the way for the development of compact, efficient optical devices for a wide range of applications. This advancement is expected to accelerate the industrial adoption of metalens technology and expand its practical applications.

Abstract: Metamaterials are subwavelength structures designed to exhibit extraordinary phenomena such as negative refraction. A multilayer fishnet metamaterial fabricated using colloidal lithography offers large-area production. The material demonstrates negative refraction at 1550nm, promising sub-diffraction imaging, nanolithography and real-time biological imaging.

Metamaterials consist of artificially structured subwavelength components. Light perceives these structures as novel materials, exhibiting unusual optical properties not found in nature. With appropriate design, these subwavelength structures could be tailored to manipulate light. Negative refraction [1,2] is one of the optical phenomena that can be realized with these metamaterials. By controlling the effective permittivity and effective permeability as shown in the equation (1), a negative refractive index can be obtained when both signs are negative. This means that by controlling the nanostructure to have certain permittivity and permeability values, a negative refractive index can be achieved in a specific spectral range.

$$n = \sqrt{\varepsilon_{eff} \cdot \mu_{eff}} \tag{1}$$

Negative permittivity can be achieved by using metals such as gold and silver, or by adjusting the filling ratio of metal and dielectric according to the effective medium theory. Permeability can be negative at specific wavelengths via magnetic resonance. A representative design that satisfies both is a fishnet-structured metamaterial. This structure couples the magnetic strips ($\mu < 0$) with electric strips ($\varepsilon < 0$) in a broad spectral range to achieve negative refractive index. The spectral range may vary depending on the size of the structure. Design of negative index metamaterials faces certain demands such as high-precision, high-throughput and low-cost manufacturing. Although fishnet metamaterial could be fabricated through high-precision fabrications such as e-beam lithography and focused ion beam milling, low-throughput and high-cost are the bottleneck.

In this research, a multilayer fishnet metamaterial is fabricated through colloidal lithography, which can simply create large-area periodic structures (Fig. 1a). This method guarantees high productivity and low costs. The fabricated multilayer fishnet metamaterial (Fig. 1b), exhibits negative refraction near the optical communication wavelength (1550nm) in the NIR region, as confirmed through simulations (Fig. 1c). We expect that this multilayer

fishnet metamaterial will have applications in compact optical systems for sub-diffraction limit imaging, as well as in nanolithography and real-time biological imaging [3].

Abstract: We propose a three-dimensional mechanical metamaterial which can transform its effective elasticity tensor and covers all seven types of extremal metamaterials. By engineering the zero modes in the proposed metamaterial, both the static and dynamic states of the 3D-printed prototype can be reconfigured. Moreover, reprogrammable wave functionalities are also demonstrated.

Mechanical metamaterials[1], comprising rationally designed microstructures, have moved from the stage of acquiring unconventional and programmable properties to the stage of tunability[2]. Generally, the tunable properties of mechanical metamaterials are due to zero modes that cost little to no elastic energy. In fact, the number of zero modes can alter the elasticity tensor among all seven extremal states, also known as extremal metamaterial[3], including null-, uni-, bi-, tri-, quadra-, penta- and hexa-mode, leading to extremal static properties and exotic wave phenomena[4,5]. Two marvelous applications of extremal metamaterials are the design of "invisible" acoustic and elastic cloaks with the penta-mode metamaterial[5,6] and the design of the shear wave polarizer with the quadra-mode metamaterial[7,8]. However, due to the lack of a blueprint for systematically designing the corresponding zero modes, extremal metamaterials with specific number of zero modes or with the ability to transform among all seven extremal states remain unimplemented. Here, we propose a methodology for the design of a mechanical metamaterial that can transform among all seven types of extremal metamaterials (Figure 1), leading to programmable wave functionalities, such as programmable elastic wave splitting and selective filtering. This work sheds lights on the design of new smart metamaterials, and offers the promise for the real-time manipulation of broadband low-frequency elastic waves.

Lighting and displays are integral parts of human activities and economic development. Semiconductor nanocrystals, now offering a market volume exceeding 1B Euros annually, have attracted great interest in quality lighting and displays. Such colloidal semiconductors enable enriched color conversion essential to superior lighting and displays. In this talk, we will introduce the emerging field of semiconductor nanocrystal optoelectronics. Here we will showcase most recent examples of advanced heterostructures of semiconductor nanocrystals along with their photonic structures and device architectures. Optical properties of these solution-processed nanostructures are conveniently controlled by tailoring their size, shape and composition to realize high-performance light generation and lasing. These colloids span different types and heterostructures of semiconductors in the forms of quantum dots and rods, most recently extending to the latest sub-family of nanocrystals, the colloidal quantum wells (CQWs).

In this talk, we will focus on atomically-flat, tightly-confined, quasi-2-dimensional CQWs, also popularly nick-named ‘nanoplatelets’, particularly for use in lighting and displays [1-6]. Also, we will present a powerful, large-area, orientation-controlled self-assembly technique for orienting these colloidal quantum wells either all face down or all edge up [7]. We will demonstrate three-dimensional constructs of their oriented self-assemblies with monolayer precision [8]. Among their extraordinary features important to applications in lighting and displays, we will show record high efficiency from their colloidal LEDs [9] and record high gain coefficients and record low lasing thresholds from their colloidal laser media [1,10-11] using heterostructures [2-6] and/or oriented assemblies [7,8] of the colloidal quantum wells.

Given their current accelerating progress, these solution-processed nanocrystals hold great promise to challenge their epitaxial thin-film counterparts in semiconductor optoelectronics.

Ultrasensitive Portable Surface-Enhanced Raman Spectroscopy for Clinical Applications

D. Wan[1*]

[1]Institute of Biomedical Engineering, National Tsing Hua University, Hsinchu, Taiwan

[*]corresponding author: dhwan@mx.nthu.edu.tw

Abstract: This talk presents a facile, scalable fabrication strategy for developing an ultrasensitive SERS-based detection platform that serves as a rapid, label-free diagnosis device. Highly dense Au nanoparticle arrays with narrow gap distances is formed directly through physical vapor deposition on hydrophobic cellulose fibers to achieve excellent portable SERS performance.

Surface-enhanced Raman spectroscopy (SERS)-based biosensors have garnered significant attention for their label-free detection capabilities, ultrahigh sensitivity, and unique molecular fingerprinting. In this talk, I will illustrate an attractive development in SERS technology: a wafer-scale, ultrasensitive, highly uniform, and portable SERS detection platform (see Figure 1). This innovative platform is constructed on paper, featuring abundant and densely packed gold nanoparticles with narrow inter-particle gaps. These gold nanoparticles are deposited directly onto ultralow-surface-energy fluorosilane-modified cellulose fibers using a straightforward thermal evaporation process, with precise control over atom diffusion behavior.

Our paper-based SERS substrate stands out with an exceptionally high Raman enhancement factor, reaching an astounding 3.9×10^{11}. This platform exhibits remarkable detectability at sub-femtomolar concentrations, even achieving single-molecule-level sensitivity. It boasts excellent signal reproducibility, with a low relative standard deviation of 3.97%, making it highly reliable even when operated with a portable 785-nm Raman spectrometer. One of the most impressive aspects of this technology is its versatility. We employed this system for fingerprinting the identification of 12 diverse analytes, spanning clinical medicines (cefazolin, chloramphenicol, levetiracetam, nicotine), pesticides (thiram, paraquat, carbaryl, chlorpyrifos), environmental carcinogens (benzo[a]pyrene, benzo[g,h,i]perylene), and illegal drugs (methamphetamine, mephedrone). The lowest detection concentrations reached the sub-parts-per-billion (ppb) level, with a remarkable low of 16.2 parts per quadrillion (ppq) achieved for nicotine.

The potential applications of this novel technology are vast and impactful. It holds promise for clinical applications such as therapeutic drug monitoring for individualized medication adjustment and ultra-early diagnosis of pesticide intoxication. In addition, I will also illustrate a microneedle-assisted paper-based sensing platform for rapid, label-free, and ultrasensitive detection of molecules. The platform allows facile recovery of analytes and provides desirable recognition capacities through portable SERS. The sensing platform can be used for pain-free monitoring of drug levels in human interstitial fluid. In summary, the scalability, portability, and ultrasensitive nature of these fibrous SERS substrates open up new avenues for practical on-site detection in biofluid analysis, point-of-care diagnostics, and precision medicine.

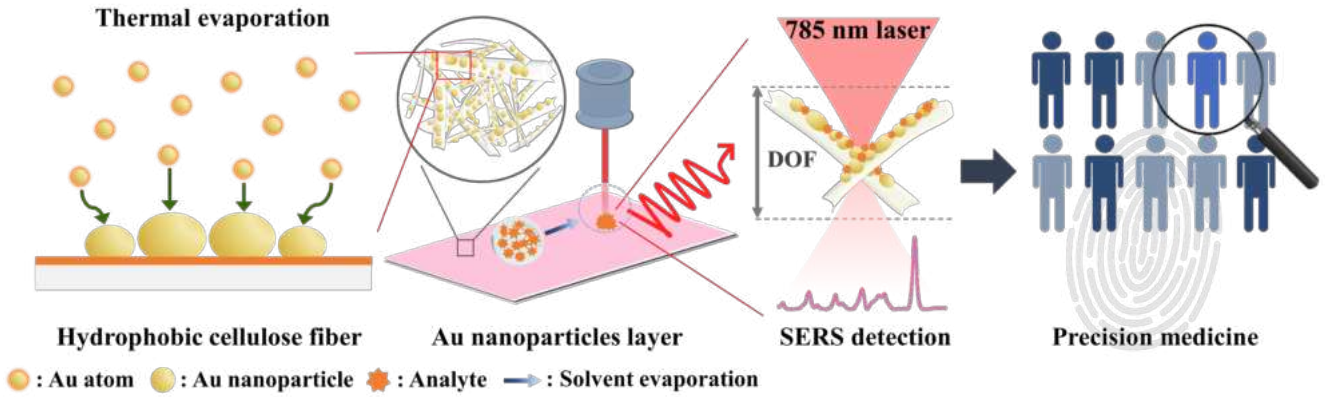

Figure 1. An ultrasensitive paper-based SERS detection platform for precision medicine.

Abstract: Understanding hot electron transport requires identification of diffusive or ballistic regimes. We determine the energy-dependent electron propagation time through Fe(001)-Au(001) heterostructures using femtosecond time-resolved photoelectron spectroscopy, electronic structure theory, and transport simulations. The electron velocity increases with growing Au layer thickness since the propagation aligns with the interface normal direction.

Optically excited processes are used in energy conversion applications. An essential aspect is that optical excitations lead to nonequilibrium phenomena which allow for carrier multiplication by carrier-carrier scattering, but also challenge our understanding of steady-state operation. The spatio-temporal dynamics of carrier-carrier scattering, in which transport of excited carriers and their interaction with other charge carriers proceed simultaneously, is highly relevant for improved energy-related applications. Properties like the ballistic mean free path of optically excited carriers can be measured in thin films by pump-probe experiments when the pump and the probe step are spatially separated [1,2]. A related problem occurs in photoinduced switching of magnetization in spin valves, by femtosecond laser pulses, that aims to reduce energy consumption in data storage technology [3]. The magnetic moment of a ferromagnet can be spatially redistributed in superdiffusive spin transport of optically excited carriers across interfaces inducing a spin-transfer torque [4], which may lead to magnetization reversal [3] at reduced energy compared to thermodynamic magnetization reversal. Furthermore, electronic excitation of layered systems has further potential regarding terahertz (THz) radiation generation [5]. In such systems, electronic excitations, which are induced optically in a ferromagnetic layer, the emitter, are transferred across an interface to another layer, the collector, which is electronically strongly interacting with the initially excited layer. For such phenomena, the energy-dependent scattering rate and length of optically excited carriers in heterosystems are essential because they determine the energy and momentum distribution.

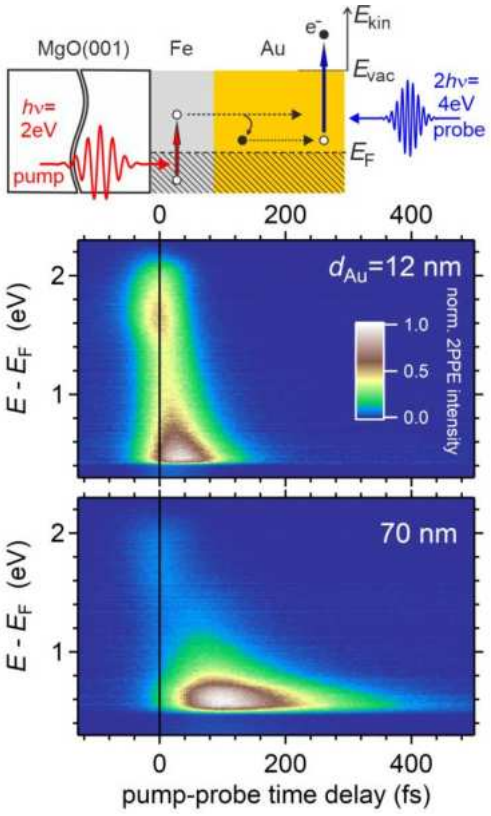

Fig. 1: Scheme of the back-side pump front-side probe geometry in time-resolved 2PPE spectroscopy (top). Time- and energy dependent photoelectron intensity for two thicknesses of the Au layer, as indicated, from [6].

As depicted in Fig. 1, we use a backside pump – frontside probe geometry to excite electron propagation across an epitaxial heterostructure Au/Fe/MgO(001) and detect the transport in a time-of-flight like approach in two-photon photoelectron emission (2PPE) on the Au surface. The photon energies used in femtosecond laser pulses are 2 eV for pumping and 4 eV for probing. With increasing Au layer thickness d_{Au} we observe an intensity drop in the 2PPE spectrum 1.7 eV above the Fermi energy E_F in combination with a shift of a second feature at 0.6 eV to later time delay, see Fig. 1. By real time time-dependent density functional theory calculations we assign the signal at 1.7 eV to electrons at their primary excitation and injection energy while the one at 0.6 eV represents electrons that have scattered inelastically with another electron, see [6] for details. By microscopic electron transport calculations, we quantify the inelastic scattering events occurring during the propagation time t^* through Au as a function of energy and compare it to the measured values, see Fig. 2. This comparison provides a determination of the number of scattering events of 1 to 4 which suggests a superdiffusive transport regime. For the high electron energies the measured t^* are shorter than the simulated ones indicating ballistic transport. With increasing d_{Au} the electron trajectories favor ballistic electron propagation along the interface normal direction which explains an experimentally observed increase in the effective electron propagation velocity with d_{Au}. This phenomenon facilitates electron momentum or energy selection by choice of the propagation layer thickness, as discussed in detail in [6].

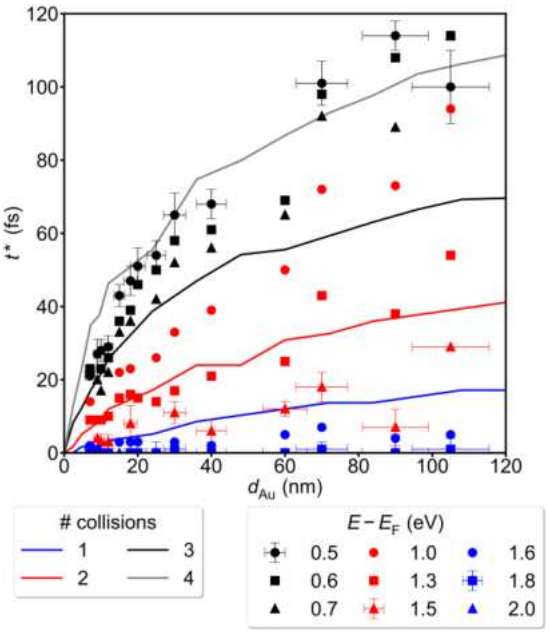

Fig. 2: Comparison of experimental and theoretical electron propagation time through the Au layer as a function of d_{Au}, from [6].

Abstract: Phase change materials in optical switching devices provides with tunable optical responses, ultrafast switching speeds, and low power consumption. In this contribution we will present a novel optical amplitude switch incorporating PCM antimony trisulfide (Sb_2S_3) based on the Brewster angle phenomenon.

The increasing importance of high-speed data processing with minimal energy consumption has spurred the utilization of light for signal transmission and processing. By employing nanostructures, the energy requirements and interaction timescales can be greatly reduced, enabling the integration of multiple devices that possess the ability to control, modulate, and process light signals with high speed and energy efficiency in the same chip [1]. The pursuit of more versatile nanophotonic devices has led to the exploration of phase-change materials (PCMs), offering the potential to create tunable and switchable nanophotonic systems through the modulation of their optical properties via external stimuli [2]. Reconfigurability offers significant advantages over conventional fixed-function devices by allowing dynamic adjustments in real-time, thus meeting the evolving demands of many photonic applications [3].

So far, reported optical switches are based on PCMs rely on $Ge_2Sb_2Te_5$ (GST). This is a consolidated technology for rewritable optical disk storage and non-volatile electronic memories due to its high thermal stability, fast switching speed, and ability to undergo numerous rewriting cycles. Most of GST based switches rely on absorption modulation because of the huge contrast in the extinction coefficient k at 1550 nm between crystalline ($k \simeq 1.49$) and amorphous ($k \simeq 0.12$) phases [4]. However, the high optical losses in GST make this material impractical for large-scale photonic integrated circuits (PICs) where light is guided through numerous phase change photonic routers. Additionally, the optical losses of GST limit its exploitation for applications where phase modulation is required without affecting the amplitude of the signal. Moreover, because of the increasing extinction coefficient k at shorter wavelengths for both phases, the integration of GST in photonic devices such as tunable metasurfaces operating in the visible or near infrared (near IR) becomes impractical [5].

Wide-bandgap PCMs are currently being investigated to overcome this limitation. They provide low-loss or even zero loss operation from the visible to mid IR range. Sb_2S_3 has been recently proposed as low-loss PCM. In its crystalline form, it has a band gap of 1.6 eV, while the amorphous phase 2.2 eV, enabling a low-losses spectra region (extinction coefficient $k = 0$) extending from 1.6 eV to the IR with an optical contrast $\Delta n \approx 0.5$. Sb_2S_3 has already been exploited in the design of reconfigurable structural color platforms, as well as amplitude and phase light modulation in all-dielectric metasurfaces and Mach-Zehnder interferometers (MZIs) operating in the C- and O- communication bands [6].

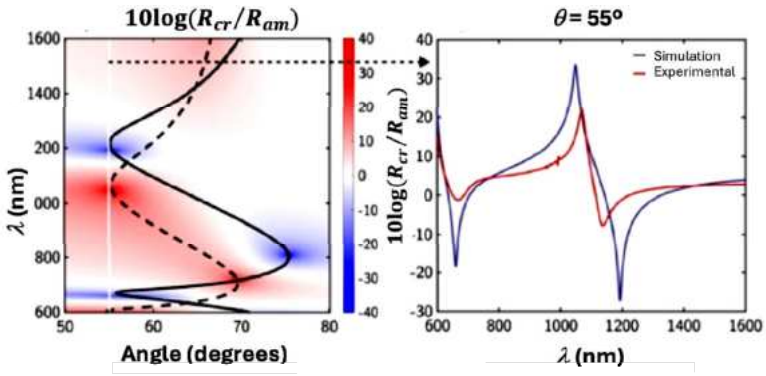

Fig. 1.- (*Left) Simulated optical contrast C in dB (C = 10log$_{10}$(R_{cr}/R_{am})) for p-polarization as a function of the angle of incidence and wavelength λ. (Right) Calculated and experimentally measured C spectra in dB for an incident angle of 55°. R_{cr} and R_{am} are the reflectivities of Sb_2S_3 in its crystalline and amorphous phases, respectively.*

In this work, amorphous and crystalline samples of Sb_2S_3 are optically and structurally characterized to explore their potential in the design of an optical amplitude switch based on the Brewster angle phenomenon [7]. The Brewster angle value depends on the refractive index of both materials at the reflective interface. Thus, the Brewster angle is strongly affected by the phase of the PCM. When the non-reflection condition is met for one of the Sb_2S_3 phases (i.e., at the Brewster angle), upon phase-change the Brewster condition is broken, leading to light reflection at the interface and producing an optical contrast in reflection that can be harnessed for optical switching applications. Sb_2S_3 is the alternative low-loss PCM with larger transparency window. i.e. spectral range beyond which neither of the material's phases experience optical losses. This is important for the optical switch based on Brewster angle, as this phenomenon only takes place if the material is transparent to light (negligeable extinction coefficient, $k \simeq 0$). With this optical switch configuration, we experimentally demonstrate an optical contrast of 22 dB (Fig. 1). Noteworthy, we theoretically predict that this contrast could be further enhanced by tailoring the incident angle and the wavelength of the beam. These findings highlight the potential of using the Brewster angle effect in developing efficient optical switch devices based on low-loss wide band gap PCMs such as Sb_2S_3.

Modeling Photomolecular Effect Using Feibelman Parameters and Generalized Boundary Conditions for Maxwell Equations

Gang Chen

Department of Mechanical Engineering
Massachusetts Institute of Technology
Cambridge, MA 02139, USA
gchen2@mit.edu

Abstract. Here, we re-derive a set of generalized boundary conditions for Maxwell equations using Feibelman parameters to describe the photomolecular effect: photons directly cleaving off water molecular clusters in the visible spectrum where bulk water has negligible absorption. We show that this approach can reasonably explain our experimental data.

Based on a series of experiments, we recently suggested that visible light can directly cleave off water molecular clusters from water-air interfaces, despite that bulk water absorbs very little in the visible spectrum, and we called this process the photomolecular effect(*1*, *2*). Our experimental observations were first made based on water evaporation from porous hydrogel and then from a single air-water interface under sunlight, light-emitting diodes (LEDs), and laser irradiation. The photomolecular effect was introduced to explain the super-thermal evaporation rates observed(*3*, *4*) in some solar interfacial-evaporation experiments: evaporation from porous materials floating on water surface subjected to sunlight irradiation(*5*, *6*). The photomolecular effect is surprising and poses challenges for modeling, from both microscopic and macroscopic perspectives. Microscopically, the details of water cluster cleavage processes remain unclear. Macroscopically, the question is how we can model the process based on the Maxwell equations. This paper focuses on answering the latter question, which is important for simulating absorption of clouds and hydrogels due to the photomolecular effect. We will show that the generalized boundary conditions for the Maxwell equations built on the Feibelman parameters, which were developed to describe responses of metal surfaces to light(*7*, *8*), can be used to capture the trends observed in photomolecular effect, hence lending confidence to the photomolecular effect in addition to establishing a foundation to simulate the effect.

Although all previous discussions of the Feibelman parameters were based on light interactions with electrons at a metal surface, the derivation of the generalized boundary conditions for the Maxwell equations requires no such background. As long as we recognize that the transition of the electrical field between the two sides of the interface occurs over a small distance, rather than change discontinuously, the generalized boundary conditions naturally emerge when one integrates over a spill-box spanning the transition region. (*9*, *10*)

$$[\![\boldsymbol{H}_{\parallel}]\!] = i\omega d_{\parallel}[\![\boldsymbol{D}_{\parallel}]\!] \times \boldsymbol{n} \quad (1)$$

$$[\![\boldsymbol{D}_{\perp}]\!] = d_{\parallel}\nabla_{\parallel} \cdot [\![\boldsymbol{D}_{\parallel}]\!] \quad (2)$$

$$[\![\boldsymbol{E}_{\parallel}]\!] = -d_{\perp}\nabla_{\parallel}[\![\boldsymbol{E}_{\perp}]\!] \quad (3)$$

$$[\![\boldsymbol{B}_{\perp}]\!] = 0 \quad (4)$$

where the operator $[\![\ \ ]\!]$ means the difference across the interface for the quantity inside the bracket, i.e., $[\![D_z]\!] =$

$D_z(0^+) - D_z(0^-)$, with z representing the coordinate perpendicular to the interface. The subscript "$\parallel$" means parallel to the interface (in x or y directions), while "$\perp$ " means in the z-direction. The gradient operator $\nabla_\parallel = \left(\hat{x}\frac{\partial}{\partial x} + \hat{y}\frac{\partial}{\partial y}\right) = \hat{x}ik_x$. The Feibelman parameters $d_\parallel$ and $d_\perp$ are $d_\perp = \frac{\int_{z_1}^{z_2} z\frac{dE_z}{dz}dz}{\int_{z_1}^{z_2}\frac{dE_z}{dz}dz}$ and $d_\parallel = \frac{\int_{z_1}^{z_2} z\frac{dD_x}{dz}dz}{\int_{z_1}^{z_2}\frac{dD_x}{dz}dz}$. The real part of $d_\perp$ measures the spatial deviation of the induced surface charge from z=0, and the real part of $d_\parallel$ is a measure of the location of the gradient of induced polarization parallel to the surface, i.e., the Feibelman parameters are the surface response functions. The imaginary part is related to dissipation, i.e., surface absorption.

Using the above boundary conditions, we can derive expressions for the surface absorptance for TM and TE-polarized incident light as

$$A_p = -\frac{4(n_2^2-n_1^2)}{(n_1\cos\theta_2+n_2\cos\theta_1)^2}\frac{2\pi n_1}{\lambda_o}\cos\theta_1(d_{\parallel i}\cos^2\theta_2 + d_{\perp i}\sin^2\theta_1) \quad (5)$$

$$\mathrm{A_s} \approx \frac{-4(n_2^2-n_1^2)}{[n_1\cos\theta_1+n_2\cos\theta_2]^2}\frac{2\pi n_1}{\lambda_o}\cos\theta_1 \mathrm{d_{\parallel i}} \quad (6)$$

where n_1 =1 is the refractive index of air and n2 the the refractive index water. These two expressions can be used to reasonably explain experimental data we observed in the photomolecular effect. We have used the above expressions to fit experimental data and found that the agreements were reasonable.

Acknowledgements, I would like to thank Dr. Guangxin Lyu for the experiments data used to compare with the model and the support of the MIT Bose Award.

Abstract: Integrated nonlinear optical devices are important in modern optical communications. However, a universal method for designing such devices on chip still lacking. We proposed a general strategy based on transformation optics to design curved accelerating waveguides with spatially gradient curvatures able to achieve broadband nonlinear frequency conversion on chip.

To achieve broadband quality in nonlinear optical devices, many approaches have been proposed, such as group-velocity dispersion engineering, zero-index waveguides, or microcavity [1-2]. However, these approaches strictly depend on material or are not strictly continuous.

Transformation optics (TO) is a novel optical designing method that provides additional degrees of freedom to manipulate electromagnetic waves by engineering the permittivity and permeability across space and time [3, 4]. Specifically, conformal transformation optics (CTO) eliminate the extreme anisotropy that hampers the experimental realization of TO, demonstrating its application in many interesting phenomena. However, most of applications of TO are limited to linear optics.

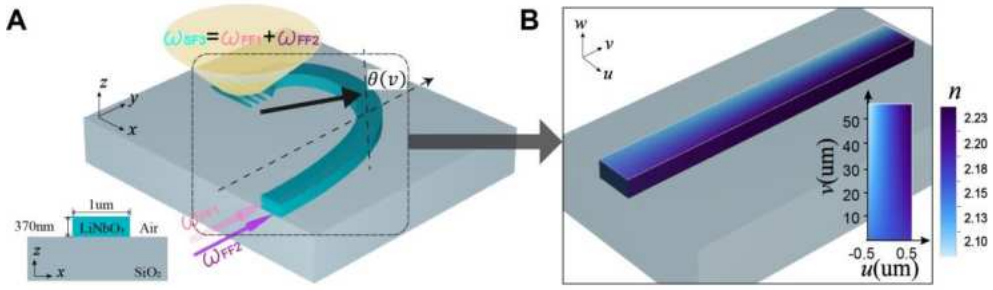

Fig.1 A. Depiction of a CAW of LNOI in the physical space (x, y, z), with the spatially gradient radius $r(v)$. The inset shows the material and the structure of CAWs in out work. **B**. The refractive index distribution of the transformed straight waveguide in the virtual space (u, v, w).

In this work, we present a general strategy utilizing TO to design curved accelerating waveguides (CAWs) with spatially gradient curvatures able to achieve broadband nonlinear frequency conversion on chip (Fig.1A). The CAW's radius is expressed by $r(v)$, where v denotes the imaginary axis after the transformation (Fig.1B). To transform it from the physical space $\xi = x + iy$ to a straight waveguide in virtual space $\zeta = u + iv$, we search a conformal mapping $\xi = f(\zeta)$, requiring the total length remain unchanged under the transformation, i.e. $|d\xi| = r(v)d\theta = dv$, where $\theta(v) = \int_0^v dv'/r(v')$ denotes the angle between the tangential direction of the curved waveguide and the vertical axis of the physical coordinate. The conformal mapping is then obtained through the integration of $\theta(-i\zeta')$ in terms of $\xi = \int_0^{-i\zeta} e^{i\theta(-i\zeta')}\, d\zeta'$. The theory of CTO enables us to calculate the refractive index of the straight waveguide

$$n = n_0 \left|\frac{d\xi}{d\zeta}\right| = n_0 \left|e^{i\theta(-i\zeta)}\right| \tag{1}$$

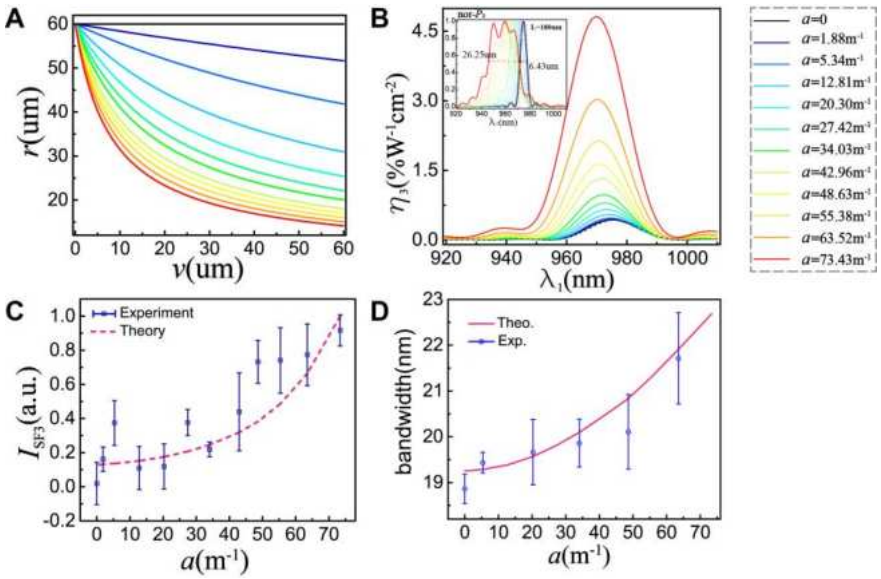

Fig.1 A. The radii of 11 CAWs as functions of v. The legend on the far right gives the exact values of accelerations. **B**. The normalized frequency conversion efficiency $\eta_3 = P_3/(P_1P_2L^2)$ as a function of the fundamental wavelength λ_1. The inset theoretically demonstrate that the normalized bandwidth of a CAW can be 4 times higher than $a = 0$ if the length of the waveguide increased to 180um. **C**. The dependence relation between the SFG output intensity with the acceleration a (for $\lambda_1 = 960nm$). **D**. The experimental results of SFG bandwidth for different CAWs.

To design CAWs in Fig.2A, we consider a spatially gradient radius given by $r(v) = r_0'/\left[\ln\left(n_0'\sqrt{1-av} - n_1'\right)\right]$, where $r_0' = 25.56um$, $n_0' = 1847.7$, and $n_1' = 1849.2$ are constants that will be determined through initial conditions. The mode index in such a CAW then be resulted to a simple function as $n_{\text{eff}}(v,\omega) = n_{\text{eff}}(0,\omega)\sqrt{1-a(\omega)v}$. Hence the wave equation governing the electric field in the CAW is given by,

$$\nabla^2 E - \frac{n_{\text{eff}}^2(0,\omega)(1-av)}{c^2}\frac{\partial^2 E}{\partial t^2} = 0 \tag{2}$$

The propagation solution of equation (2) takes the form of $E \sim (1-av)^{-1/4}\exp[i\phi(v,\omega)]$ since we interested in the case where the refractive index $n_{\text{eff}}(v,\omega)$ varies slowly along v, where the phase is $\phi(v,\omega) = n_{\text{eff}}(0,\omega)k_0(v - av^2/4)$. Then considering the sum-frequency generation (SFG) process $\omega_1 + \omega_2 = \omega_3$, we derive the transformed nonlinear SFG coupling equations by substituting the approximated solution to polarization equation $\boldsymbol{P} = \epsilon_0\chi^{(2)}\boldsymbol{E}^2$. The theoretical and experimental results are shown in Fig.2. We can see that both the conversion efficiency and the nonlinear conversion spectrum are boosted by the acceleration.

In conclusion, this approach offers a universal strategy to design broadband nonlinear optical devices on chip without the limitation of materials and the limitation of $\chi^{(2)}$ or $\chi^{(3)}$, and is applicable to various nonlinear optical processes. The experimental results validate the effectiveness of LNOI chip design, indicating its potential for practical applications.

Fano line shapes generated by excitonic nanoparticles

S. Hayashi[1,2]

[1]Graduate School of Engineering, Kobe University, Japan

Abstract: Based on the Mie theory and its electrostatics approximation, we analyze analytically and numerically optical responses and resonant behaviors of internal fields in spherical excitonic nanoparticles and show that Fano line shapes can easily be generated in the scattering spectra and spectra of internal fields.

Dielectric nanoparticles not showing distinct Mie resonances have been discarded as useful elements of resonant nanophotonics. However, the incorporation of the excitonic transition into such nanoparticles may allow us to generate sharp resonances, in particular, Fano resonances, thereby enhancing the utility of such nanoparticles. As schematically shown in Fig. 1, we consider an excitonic sphere of radius R characterized by a dielectric function $\varepsilon(\omega)$ placed in a surrounding material with a dielectric constant ε_{m}. The dielectric function of the excitonic particle is assumed to take the following form:

$$\varepsilon(\omega) = \varepsilon_{\mathrm{b}} - \frac{f\omega_{\mathrm{exc}}^2}{\omega^2 - \omega_{\mathrm{exc}}^2 + i\gamma_{\mathrm{exc}}\omega_{\mathrm{exc}}},$$

with the background dielectric constant $\varepsilon_{\mathrm{b}} = 2.2$, the energy of exciton transition $\hbar\omega_{\mathrm{exc}} = 2.0664$ eV (600nm), $\hbar\gamma_{\mathrm{exc}} = 103.32$ meV and the oscillator strength $f = 0.13$; the parameter values were chosen to reproduce well optical spectra of the PVA film doped with J-aggregates of TDBC molecules[1,2], which is one of the typical excitonic materials.

The findings of this work are summarized as follows[3]:

I. Small particle limit

For a sufficiently small excitonic nanoparticle (small particle limit), calculations based on the electrostatics approximation show that scattering and extinction spectra exhibit the Fano line shape (external Fano resonances), caused by the interference between a broad background (Rayleigh scattering) and a sharp excitonic response. It is also shown analytically that the line shapes can be expressed by the generalized Fano function with a q factor expressed in terms of the system parameters.

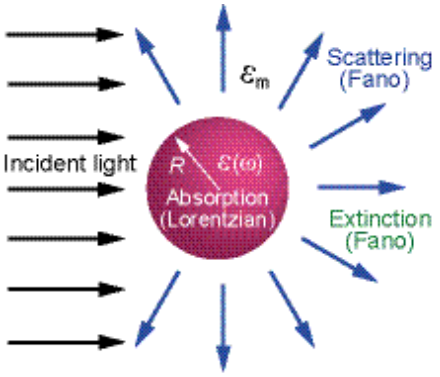

Fig. 1 Excitonic nanoparticle illuminated by incident light.

Figure 2(a) and 2(b) show spectra of efficiencies of scattering Q_{sca} and absorption Q_{abs}, respectively, of a spherical particle of TDBC-doped PVA with R =20 nm. Figure 2(c) shows the scattering efficiency of a pure PVA sphere (f = 0) without excitonic transition, called background scattering Q_{back}, which obeys the $(\hbar\omega)^4$- law of Rayleigh scattering. In Fig. 2(a) we see clearly an asymmetric line shape superposed on the Rayleigh background. As shown in Fig. 2(d), the spectrum of F_{sca} obtained by normalizing Q_{sca} to Q_{back} exhibits Fano line shape which is well reproduced by the generalized Fano function $F_{\mathrm{sca}}^{\mathrm{ap}}$ derived analytically within the electrostatics approximation. On the other hand, the normalized absorption spectrum F_{abs} exhibit the Lorentzian line shape as can be seen in Fig. 2(e).

II. Beyond the small particle limit

Calculations based on the exact Mie theory show that the Fano line shapes are preserved and can be well fitted by the generalized Fano function, provided that R is smaller than an upper bound value (results not shown here).

III. Internal electric fields

Behaviors similar to those of Q_{sca} are found for the enhancement factor FE of the internal fields averaged over the spherical particle (internal Fano resonances).

In Fig. 3(a), a spectrum of FE of the doped sphere is shown together with FE_{back} of undoped sphere, obtained within the electrostatics approximation. The spectrum of F_{int} obtained by normalizing FE to FE_{back} again shows the Fano line shape that can be well reproduced by the generalized Fano function F_{sca}^{ap} derived analytically.

The results of the present work provide a firm basis for discussing the external and internal Fano resonances in excitonic nanoparticles

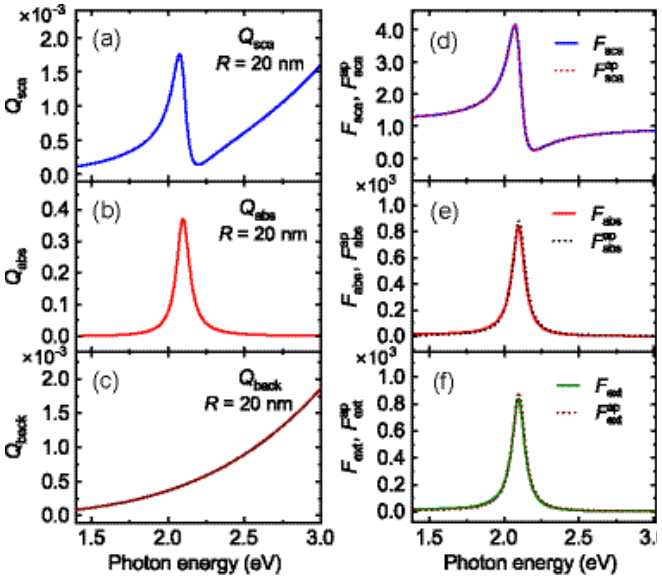

Fig. 2 Spectra of efficiencies of scattering Q_{sca} (a), absorption Q_{abs} (b) and background scattering Q_{back} (c) for an excitonic sphere. Comparison of the scattering (d), absorption (e) and extinction (f) spectra normalized the background scattering with those obtained by analytical expression of the generalized Fano function.

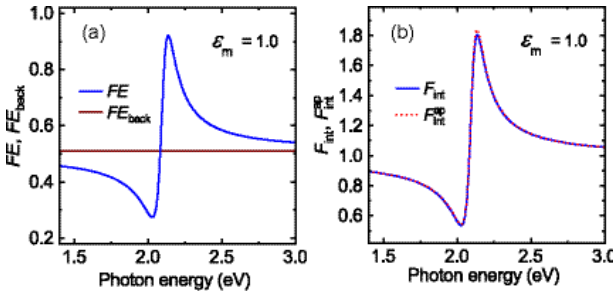

Fig. 3 (a) Spectrum of FE of doped sphere, field enhancement factor averaged over the sphere, and that of FE_{back} of undoped sphere. (b) Spectrum of F_{int} obtained by normalizing FE to FE_{back} and that of F_{sca}^{ap} obtained from the analytical expression of the generalized Fano function.

Abstract: Metasurfaces have demonstrated themselves as a promising platform for enhanced second harmonic generation (SHG) to achieve ultracompact nonlinear light sources. Lithium niobate (LN), particularly the crystalline LN thin film on insulators (LNOI) has emerged recently as a promising platform to manufacture metasurfaces. In this talk, we will present our recent works about tunable SHG from lithium niobate metasurfaces.

Second harmonic generation (SHG), which converts the frequency of a laser ω to twice its frequency 2ω, plays a key role in extending spectral coverage of laser sources to wavelengths that are difficult to access by standard laser gain media. As we enter the Nano-era, the SHG at nanoscales with controllable performance is highly desired. Nonlinear metasurfaces have provided us with a revolutionary concept to engineer nonlinear responses from nanoscale. In addition, it also acts as a new platform to realize novel nanoscale SHG light sources. Recently, crystalline lithium niobate thin film on insulators (LNOI) has emerged as an excellent solution for the novel SHG metasurfaces and nonlinear light sources [1-4]. An SHG conversion efficiency higher than 0.1% has been achieved from LN metasurface framework [5]. How to further tune the SHG performance dynamically has become an urgent problem to address. In this talk, we will present our recent results on the topic of tunable SHG from lithium niobate metasurfaces. Our works offer insights for the development of tunable SHG sources in integrated photonics and nanoscale optical devices.

Chiral emission from perovskite metasurfaces and metacavities

Young Chul Jun[1,*]

[1]Ulsan National Institute of Science and Technology (UNIST), Republic of Korea
[*]corresponding author: ycjun@unist.ac.kr

Abstract: In this talk, we discuss two recent experiments on chiral emission from resonant optical nanostructures. First, maximally chiral emission from perovskite metasurfaces is demonstrated using chiral quasi-bound states in the continuum. Second, chiral electroluminescence is achieved at room temperature with a substantial degree of circular polarization using thin-film-based chiral metacavities.

Chiral optical objects exhibit different optical responses under left circularly polarized (LCP) and right circularly polarized (RCP) light incidences. Chiral responses, such as circular dichroism and optical activity, are present in numerous natural materials; however, they are typically very weak. To overcome these limitations, various optical nanostructures, including three-dimensional chiral structures and two-dimensional planar chiral structures, have been widely studied. Chiral nanophotonic structures can significantly enhance the chiral optical responses and provide unprecedented design flexibility. Because chiral light sources are desirable for various applications, such as displays, optical recording, optical communication, bioimaging, and biomedical diagnosis, chiral emission is also attracting considerable attention. Highly enhanced chiral light–matter interactions are desirable to realize chiral light sources in compact device platforms.

In this invited talk, we introduce our recent experimental demonstrations on chiral emission from perovskite metasurfaces and metacavities [1-5]. Chiral light sources based on perovskite materials are attracting considerable attention to fully exploit their exceptional optoelectronic properties. Recently, there has been extensive research for achieving chiral photoluminescence from perovskite materials. However, it remains challenging to obtain chiral emission with a large degree of circular polarization (DCP) at room temperature. Moreover, there was no demonstration of chiral electroluminescence yet with a substantial DCP, although it represents a critical step toward practical device applications. Here, we mainly discuss two recent experiments from our group: (i) maximally chiral emission from perovskite metasurfaces and (ii) chiral electroluminescence from perovskite metacavities.

First, chiral quasi-bound states in the continuum are realized in the visible range by controlling the etching depths in the substrate and inducing out-of-plane symmetry breaking. An organic-inorganic hybrid perovskite film is spin-coated on a patterned glass substrate. Grayscale lithography is employed to control the etching depths in the substrate and induce out-of-plane symmetry breaking. An extremely high level of chiral emission from the perovskite metasurface is experimentally achieved in the normal direction at room temperature. Chiral emission is maximally enhanced for one helicity via critical coupling while strongly suppressed for the other helicity.

Second, chiral electroluminescence is experimentally achieved at room temperature with a substantial DCP (~0.38) using thin-film-based chiral metacavities. In our design, a periodic lattice of inversion-symmetry-broken polycrystalline silicon (poly-Si) patterns is integrated with an inorganic perovskite electroluminescence device. The bottom dielectric metasurface (poly-Si layer) and top metal layer forms a chiral metacavity, which supports

photonic eigenstates with close-to-maximum chiral response. Chiral Fabry–Pérot modes supported by the metacavity determine asymmetry of electroluminescence, and pairs of LCP and RCP waves of equal powers are generated in the opposite oblique directions. By optimizing the pattern geometry and dimension, we can enhance and tailor the chiral emission from the metacavity. Detailed theoretical analyses based on chiral coupled-mode theory have also been conducted.

Amorphous dielectric materials with complete photonic band-gaps in 3D.

Abraham Aguilar[1*], **Marian Florescu** [2], **and Frank Scheffold** [1]

[1]Department of Physics, University of Fribourg, Switzerland.

[2]Advanced Technology Institute and Department of Physics, University of Surrey, U.K.

[*]corresponding author: abraham.aguilaruribe@unifr.ch

Abstract: In a recent paper, our research group proposed a comprehensive framework that unifies the description of light transmission through three-dimensional amorphous dielectric materials **[1]**. In our model we address the role of both light localization and the photonic bandgap. Here, we present experimental results on light transmission and reflection in amorphous dielectric networks, providing empirical support for the theoretical framework.

Over the past decade, it has been demonstrated that amorphous photonic dielectric materials can exist in two and three dimensions, displaying a complete photonic bandgap that inhibits the propagation of electromagnetic waves within a specific frequency range [1]. These materials show great promise in both fundamental physics and various technological applications.

In a recent paper, our research group proposed a comprehensive framework that unifies the description of light transmission through three-dimensional amorphous dielectric materials. In our model we address the role of both light localization and the photonic bandgap [2]. Here, we present experimental results on light transmission and reflection in amorphous dielectric networks, providing empirical support for the theoretical framework [2].

Our findings include compelling evidence of complete photonic bandgaps in dielectric networks made of silicon. To fabricate these network structures, we employed direct laser writing of polymer templates followed by subsequent thermal shrinkage [3]. The polymer structures were then converted into high refractive index silicon through chemical vapor deposition.

Of particular importance in our investigation is the specific examination of the role of direct coherence reflection or single scattering in the proximity of the photonic bandgap, necessary to interpret the experimental data.

Fundamental studies for new device applications in two-dimensional plasmonic crystals through analytical demonstrations in the submillimeter-wave band

G. Itami[1*] and O. Sakai[1]

[1]The University of Shiga Prefecture, Japan
[*]corresponding author: ot68gitami@ec.usp.ac.jp

Abstract: Plasmonics is attracting renewed attention as the demand for optical integrated circuits increases. In particular, localization and near-field enhancement of light by surface plasmon and plasmonic band design are important for device applications. A control method of plasmonic skin depth and band structures using periodic structures are introduced.

A metal hole array (MHA) is a representative structure of two-dimensional plasmonic crystal [1]. And its complemental structure, metal plate array (MPA) can also be used for surface wave generation, if the conductive part in MPAs is thick enough to act as a boundary [2]. The structures used in this study are MPA and the structure with holes in MPA, which is called a ring dipole array (RDA) shown in Figure 1(a) [3]. By widening holes in the RDA, the propagation state is changed to a differential mode from conventional surface wave modes. In this case, the resonant frequency of extraordinary transmission (EOT) is maintained, but the bandwidth gradually narrows and the Q-factor increases. This is a conversion process to a quasi-BIC mode following the toroidal dipole model. Here, the skin depth on the RDA can be expressed as follows.

$$L = \frac{c}{\sqrt{\omega^2 - {\omega_\mathrm{p}}^2}} \tag{1}$$

Here, ω is the angular frequency and ω_p is the cut-off frequency. As Fig. 1 (b) shows, the skin depth in the RDA can be controlled by using the size of holes (p), because the cut-off frequency is varied in the process while resonant frequency is kept. Next, the band structure in the two-layered model of the RDAs in Fig. 1(c) is discussed [4]. If an equivalent circuit model is used, the ideal propagation modes can be expressed as CRLH transmission lines and the dispersion relation shows a Dirac cone (ω'_r and ω_r: the upper and lower frequencies of Γ point), shown in Fig. 1(d). Varying the interval between the layers changes the resonance frequencies of the upper and lower bands, thus creating a band gap. In practice, the dispersion relation is expected to be similar to that of a Dirac cone due to the inclusion of multi-wave interference effects between surface wave modes, suggesting the possibility of modulating the surface wave propagation in the structure by changing the interval.

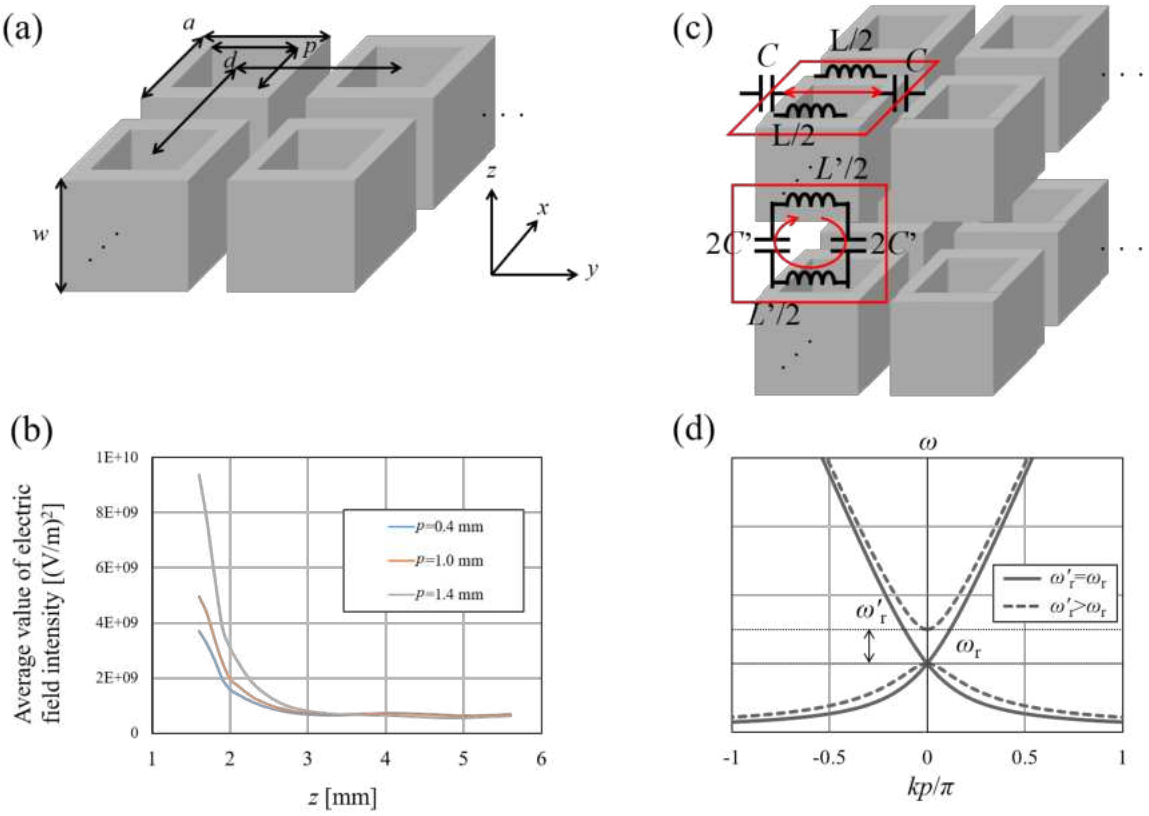

Figure. 1: (a)The structure of the ring dipole arrays, (b)one-dimensional spatial distribution of electric fields on surface modes in the RDA, (c) the structure of the two-layered ring dipole arrays, (d)the dispersion relation of Dirac cone in the two-layered ring dipole arrays.

Full-space Janus Metasurface for Direction-duplex Quad-channel Electromagnetic Wave Manipulation

Weixu Yang, Shufang Dong, Ke Chen and Yijun Feng*
School of Electronic Science and Engineering, Nanjing University, Nanjing, China
*corresponding author: yjfeng@nju.edu.cn

Abstract: This article presents a full-space Janus metasurface that enables asymmetric transmission-reflection-integrated electromagnetic wave functionalities for the right-handed circularly-polarized incidence propagating along opposite directions. As a proof of concept, direction-duplex quad-channel holographic images are demonstrated in microwave region using the fabricated metasurface.

Janus metasurfaces is a category of two-faced devices utilized for achieving distinct functions selectively excited by choosing the propagation directions [1]-[3]. Recently, full-space metasurfaces have gained much attention due to their coverage extension and function integration [4]. Although numerous Janus metasurfaces have been proposed to achieve asymmetric transmission functionalities, their reflection channels still keep unexploited, thus supporting only two channels.

As shown in Figure 1, here we propose a design strategy to extend the function of Janus metasurface from asymmetric transmission channels to direction-duplex full-space channels. As a result, when the metasurface is illuminated by a forward (+z) right-handed circularly-polarized (RCP) incidence, independent images of letters "F" and "R" are generated in the transmission and reflection regions, respectively. While for the backward (−z) RCP incidence, another two distinct images of letters "T" and "B" are achieved, thus yielding asymmetric full-space wave functionalities and integrating four independent channels in a single Janus metasurface.

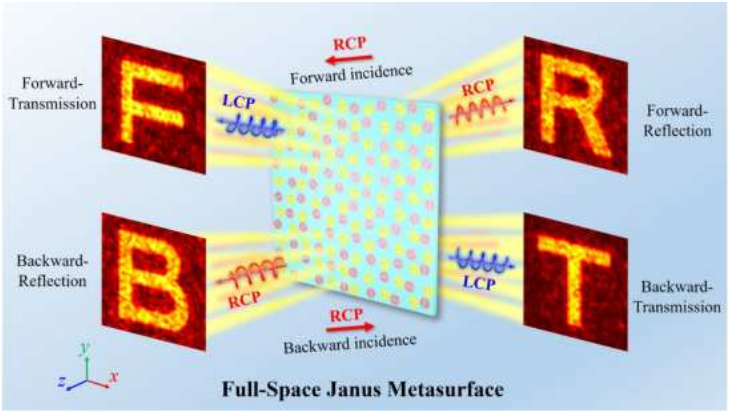

Figure 1. Conceptual illustration of the proposed full-space Janus metasurface.

To achieve this goal, two kinds of meta-atoms with direction-selective scattering properties, respectively denoted as yellow and red cells in Figure 1, are ingeniously designed and then interleaved in the Janus metasurface. The receiver-transmitter structure is adopted in each meta-atom, which is composed of left-handed circularly-polarized (LCP) and RCP patches with opposite chirality. Therefore, when the same incident wave illuminates the metasurface from two sides, the meta-atom will operate in transmission and reflection modes, respectively. By rotating the orientation angles of the receiver and transmitter patches, decoupled phase delays can be generated in such full-space channels. It is worth noting that the two kinds of meta-atoms can be

converted with each other by swapping their constituent receiver and transmitter, thus providing four degrees of freedom to independently manipulate four phase patterns for RCP incidence with opposite directions.

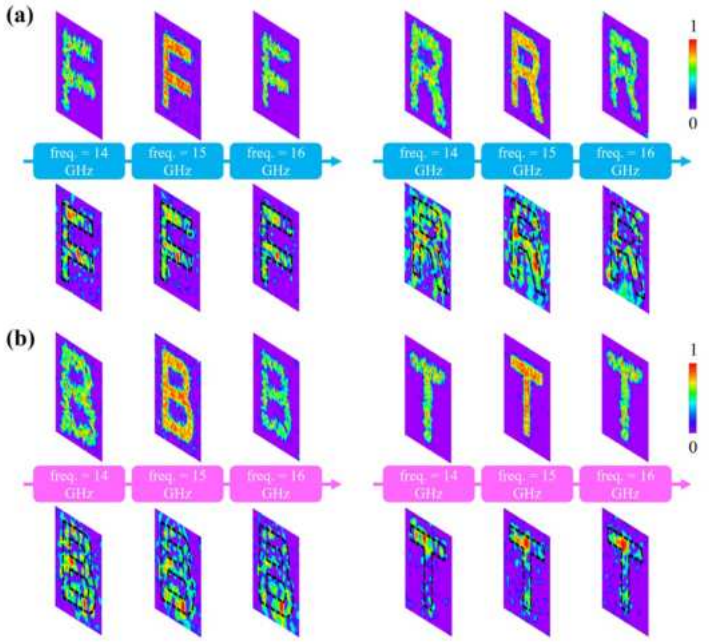

Figure 2. Direction-duplex full-space meta-holography for the (a) forward and (b) backward RCP incidence.

The theoretically calculated and experimentally measured results of direction-duplex full-space holographic images at three distinct frequencies are shown in Figure 2. The center frequency is 15 GHz. The fabricated metasurface consists of 40×40 pixels, occupying a size of 380×380 mm^2. Defining the imaging efficiency as the ratio of the energy concentrated in the holographic pattern to all energies on the imaging plane, the measured imaging efficiencies of four holographic images "F", "R", "B", and "T" are 81.5, 68.8, 70.1, and 78.2%, respectively at 15 GHz. The full-space Janus metasurface proposed here may open new possibilities toward sophisticated multifunctional meta-devices ranging from microwaves to optical systems.

Topological phase-supporting materials for nanophotonic sensing

G. Cruz[1], S. Roy[2], A. Banerjee[1], and P. Bermel[2,*]

[1]Department of Physics, Purdue University, West Lafayette, IN 47907, USA

Abstract: Dimensionality affects topological phases in materials such as bismuth selenide telluride (BST), and applications to nanophotonic sensing. Understanding how to adjust the phase transition point of these materials allows us to put our sensor near the phase transition line, to substantially heighten its sensitivity to the local environment.

Recent papers have shown the potential of BST and related materials to form topological phases [1,2]. In the overarching thesis of our quantum sensing work, understanding how to adjust the phase transition point of these materials between topological insulator (TI) and topologically trivial states allows us to carefully position our sensor near the phase transition line, to substantially heighten its sensitivity to the local environment. Specifically, the abrupt change in an order parameter and topological invariants is highly sensitive to fluctuations which we aim to leverage. Work to date in our project has clearly shown that density functional theory (DFT) methods can be effectively implemented to calculate topological phase material band structures in bulk materials, along with Chern numbers, as well as other signatures of topological phases. They also provide the ability to predict the role of impurity of defect states in topological phase formation [3].

An example of the results obtained are shown in Fig. 1, below. They were calculated using standard Generalized Gradient Approximation (GGA) for the exchange and correlation energy in the parameterization of Perdew, Burke, and Ernzerhof (PBE-96), in the Full Potential Local Orbital Code (FPLO). A K-mesh subdivision of 12 × 12 × 4 was employed for a full 3D electronic band structure calculation.

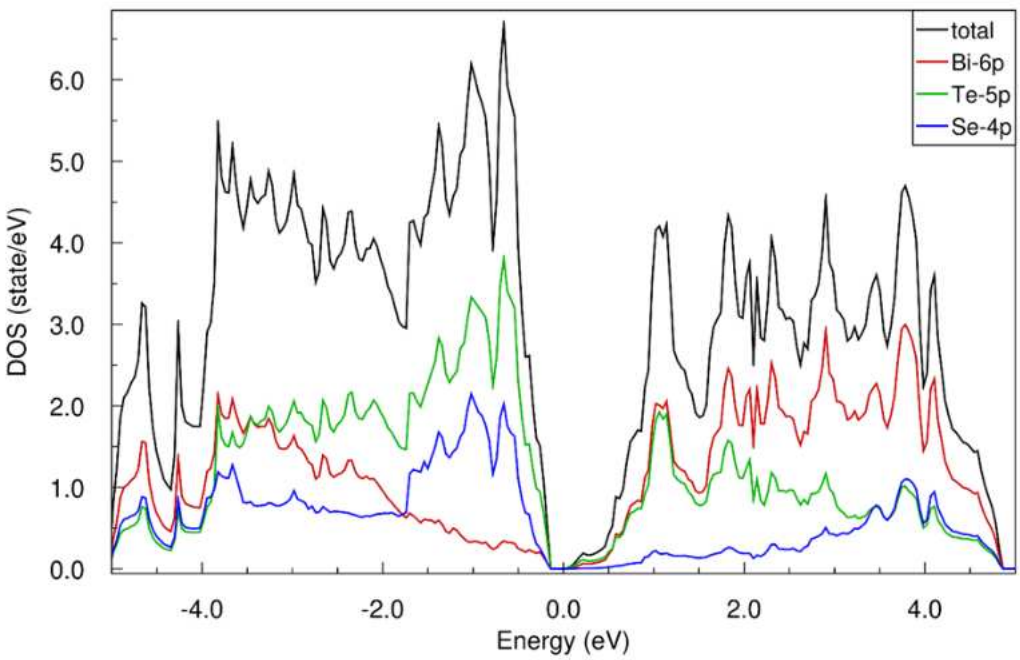

Fig. 1: DFT calculation of the electron density of states in bismuth selenide telluride (BST), including the specific orbitals most relevant to the topological state calculation. The bandgap is found to be approximately 0.14 eV, similar to experiment.

We are also completing analogous calculations for 2D and 1D quantum-confined versions of the same baseline material, to understand the role of reduced dimensionality in the ability to support topological phases.

Planned work in this area that should be completed by the time of this presentation aims to predict the potential of BST materials for enhanced quantum sensing. Using DFT calculations of one or more alloys of bismuth selenide telluride (or related compounds) formed into nanowires and nanosheets, to calculate the response of topological phase to mechanical strain and external electromagnetic fields (for sensing). Also, we will calculate key coupling parameters in a phenomenological Hamiltonian capturing the strength of coupling to strain, electric, and magnetic fields.

It will also be important to characterize BST and BST-like material band structures in reduced-dimensionality samples. In this work, we will perform Angle-Resolved PhotoEmission Spectroscopy (ARPES) on BST samples with reduced dimensionalities, provided by collaborators from Indiana University. This will be compared to both a control 3D bulk sample of BST, along with a measurement of the role that nanosheets and nanotubes play in topological phase in a relaxed state. If instrumentation supports, we will also measure the effects of mechanical strain, external electric fields, and external magnetic fields on the topological phase, and compare to theoretical predictions.

The ultimate goal of this work will be to combine state-of-the-art device and nanowire fabrication informed by prompt inputs from DFT, spin-orbit coupling (SOC), and computational modeling of magneto-chiral anisotropy in TI sensors to build a platform sensitive to amplitudes and phases of tiny electrical and magnetic signals.

We acknowledge support from the Center for Quantum Materials, an I/UCRC funded by a combination of National Science Foundation, industry, and other government sponsors.

A polarization-tunable coloration with wide dynamic range using highly lossy material-based metal/dielectric/metal-subwavelength grating

Y. Takashima[1,2*], K. Nagamatsu[1,2], M. Haraguchi[1,2], and Y. Naoi[1,2]

Abstract: A polarization-tunable coloration with wide dynamic range was demonstrated using the highly lossy metal-based metal/dielectric/metal-subwavelength grating structure. By using the spectrally broadened resonant reflections and phase retardations in the designed structure, we achieved the multi colors generation across entire visible region by simply rotating the polarization of light.

Color generation is important for enormous applications, for example displays, imaging, security, communication. Structural coloration via subwavelength resonant structures is one of the most interesting approaches because its optical characteristics, such as resonant wavelength, efficiency, and spectral shape can be artificially designed by adjusting the structural parameters [1]. In particular, the dynamic controlling of the structural color provides not only one static color but also multi colors, and it is very attractive for the applications mentioned above. Many reports have demonstrated the dynamic control of the structural color using polarization states [2, 3], mechanical stretch [4, 5], electro-chemical deposition [6], phase-change material [7] and metal hydrides [8]. However, the realization of wide tunable range of the coloration still be challenging.

This presentation introduces new strategy for the wide dynamic range color generation by using highly lossy metal-based metal/dielectric/metal-subwavelength grating (SWG) structure. In general, the design of the structural color avoids to the lossy materials because the optical loss causes broad resonant spectral shape and degradants the color performance. In contrast, we positively utilized the spectrally broadened resonant reflection for wide dynamic range of coloration rather than avoiding loss. The designed highly lossy metal/dielectric/SWG shows the relatively broadened resonant reflection spectra in visible region and the independent phase retardation for the orthogonal polarizations. The resonances generate the multi reflection colors across entire visible region by simply rotating polarization of the incident and the reflected lights. Our strategy realizes the wide dynamic range of structural color and opens new design and material selection concept for coloration.

In situ modification of the Quantum Hall effect with cavity vacuum fields

J. Enkner[1], L. Graziotto[1], F. Appugliese[1] , D. Boriçi[3], M. Beck[1], C. Reichl[2], W. Wegscheider[2], G. Scalari[1], C. Ciuti[3], and J. Faist [1*]

Abstract: Cavity vacuum fields can break the topological protection of edge states in the integer Quantum Hall effect. With the ability to in situ tune the light-matter coupling of this system, we observe a reduction of the g-factor and a hardening of the gap of fractional states while increasing the coupling.

Even in the absence of external illumination, a resonator exhibits modes populated with virtual photons, known as cavity vacuum fields. Placing a complementary split ring resonator (CSRR) around a GaAs-based heterostructure Hall bar, effectively immersing it in cavity vacuum fields, introduces a long-range perturbation that manifests itself effectively in opening a scattering channel for electrons in both bulk and edge states. Using this platform, previous investigations have demonstrated a breakdown of the topological protection of edge states within the integer quantum Hall regime [1]. Instead of the expected quantized Hall resistance and associated zero longitudinal resistance, quantization in Hall plateaus is lost paired with a finite longitudinal resistance. The theoretical interpretation of this effect, termed "cavity-mediated electron hopping" by C. Ciuti [2], describes the anti-resonant interaction between cavity vacuum fields and electrons in neighboring Landau levels, enabling electrons to scatter in and out of topologically protected edge states. This anti-resonant effect decays exponentially in magnetic field, with a decay rate associated to the system's Rabi frequency.

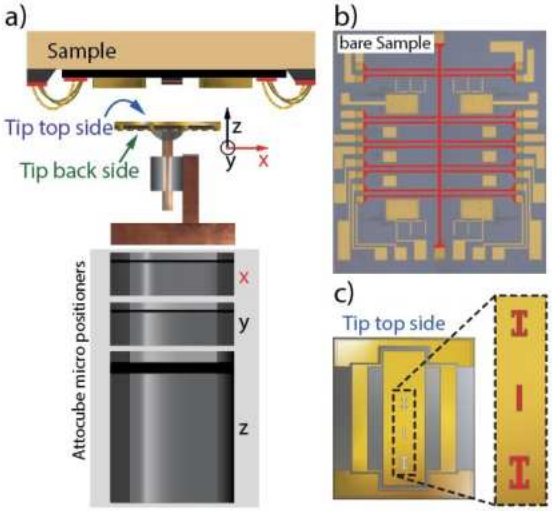

Figure 1: Sketch of the setup: The Atto cubes in 1a) enable the alignment of the cavity relative to the Hall bar, and therefore allows for in situ tuning of the coupling. The z axis can be used to alter the distance between the cavity plane 1c) and the sample with the Hall bar (in red) 1b).

In a recent experiment, we improved the experimental platform by introducing an in situ technique to vary the coupling between the cavity and the electrons inside the Hall bar [Fig. 1]. Utilizing three Atto cube micro-positioners, we can dynamically align and adjust the position of the 2D cavity plane relative to the Hall bar, enabling selective coupling with the extruding fringing fields of the cavity. This configuration allows for real-time tuning of the coupling as a function of the distance between the cavity plane and the Hall bar sample.

As the resonator is brought closer to the Hall bar, thus increasing the coupling, we observe intriguing phenomena such as the reduction of the g factor and the hardening of the gap for fractional Laughlin states 7/5, 5/3, and 4/3 [Fig. 2].

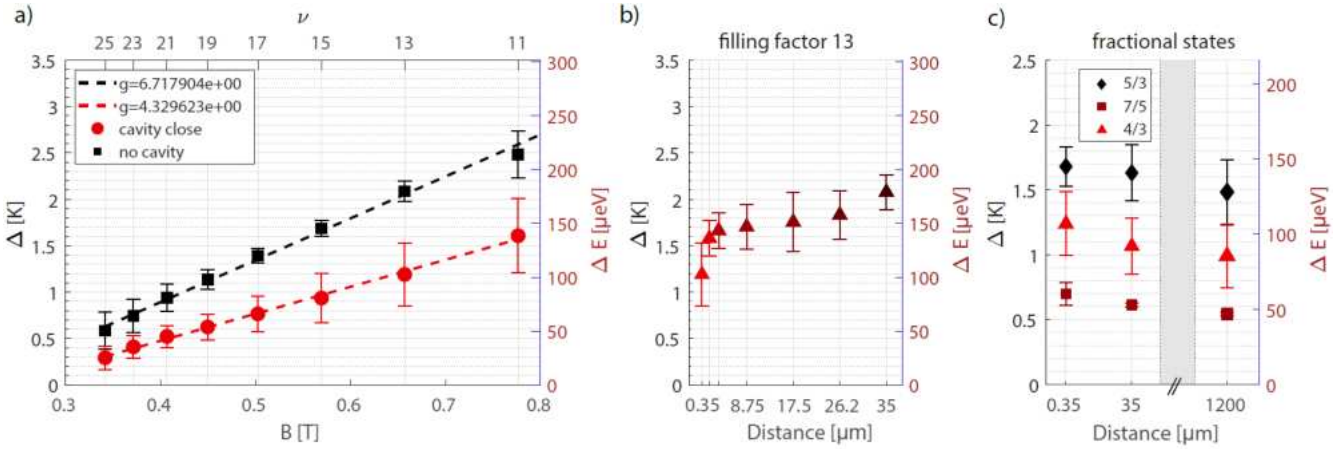

Figure 2: Figure 2a) shows the energy gap of the Zeeman-split states as a function of the magnetic field. From the corresponding linear fit, we infer the g-factor of the system indicated in the legend; 2b) shows the evolution of the activation energy for filling factor 13 as a function of the distance of the cavity from the sample surface; in 2c) we show the activation energy for the fractional states.

The distinct nature of models describing the physics of fractional and integer quantum Hall states necessitates different interpretations of the cavity's effect in these regimes. While the effect on the g-factor in the integer quantum Hall regime aligns with the theoretical framework of "cavity-mediated electron hopping", which can also be seen as an effective renormalization of the Zeeman splitting arising due to a cavity-induced long-range pertubation, for fractional states, the increased energy gap proportional to the coupling instead implies a modification of the short-range interaction between electrons.

These experimental findings offer exciting perspectives and hint at the potential emergence of a novel phenomenon within the field of cavity-engineered quantum materials.

Abstract: Transparent conducting oxides have evolved from an industrial platform to a new playground for photonic scientists. Within this context, I will provide a quick overview of past results while also giving relevance to our most recent achievements and future perspectives around nonlinear integrated photonics and light acceleration in time-varying media.

During the last decade, the optics and photonics community have renewed their interest in transparent conducting oxides (TCOs), a class of materials that for more than two decades has been extensively utilized in the manufacture of transparent electrodes for photovoltaic and touchscreen applications. This resurgence of focus on TCOs is motivated by their potential as low-loss alternative to noble metals in the fabrication of ultra-compact plasmonic devices, and their remarkable optical nonlinearities in proximity to their crossover point — the wavelength at which the real component of the dielectric permittivity transitions in sign [1].

Furthermore, TCOs are epsilon-near-zero (ENZ) materials across an extensive near-infrared window, inclusive of the entire telecommunications bandwidth. Within this operational domain, they allow a host of novel electromagnetic phenomena, including supercoupling, wavefront freezing, photon doping, etc. [2]. A unique property of TCOs, when compared to other ENZ systems, is their extremely low real index ($n<0.2$) near the ENZ wavelength. This feature has been linked to a slow-light effect that significantly amplifies the materials' nonlinear properties [3-7].

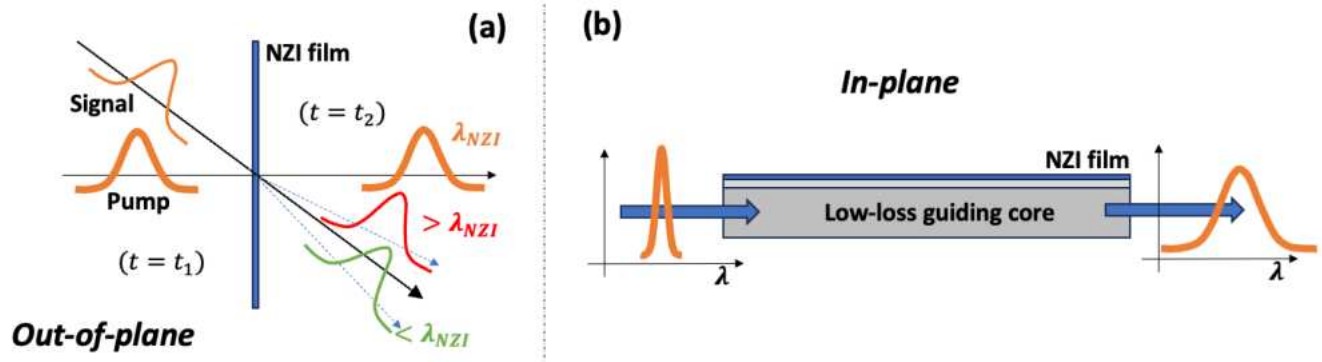

Figure 1 – Extreme nonlinear effects in TCO-based systems. a) Spatio-spectral fission in time-varying films. b) Nonlinear spectral broadening in NZI-coupled silicon nanowires.

The swift advancement of nonlinear optics in conductive oxides is motivated by a plethora of experimental results documenting unprecedented optical effects, such as unitary index change, bandwidth-large frequency shift, efficient on-chip nonlinear frequency conversion, etc. [8-10]. Along this talk, an evolving narrative about TCOs will be provided, from their initial industrial application as transparent electrodes, through their role as a

novel solution for low loss plasmonics, until their most recent connotation as driving force for the development of novel integrated nonlinear systems. More specifically to our most recent research achievements, I will discuss how the extreme optical modulation of the complex index in a low-index thin film can lead to a full spatio-spectral fission of a trespassing pulse (see Fig. 1-a), and also how by exploiting evanescent coupling between a low-loss optical channel and an upper layer of indium tin oxide, it is possible to attain novel nonlinear waveguides with unparallel nonlinear figure of merit over hundreds of microns of propagation length (see Fig. 1-b).

Conclusions:

Over the past thirty years, the perspective of scientists and technologists on transparent conducting oxides (TCOs) has undergone a significant transformation. Initially regarded as industrial materials for the mass production of transparent electrodes, TCOs have evolved into potential substitutes for metals in plasmonic applications and further into low-index nonlinear systems. In their latest role, these compounds have demonstrated unparalleled figures of merit for the creation of ultra-compact nonlinear devices. This trajectory suggests that the forthcoming phase of development for TCOs may well extend into quantum applications [11].

Ceramic metasurfaces for biophotonics applications in the visible range

M. Biabanifard[1], T. Plaskocinski[1], J. Xiao[1], and A. Di Falco[1*]

[1]University of St Andrews, School of Physics and Astronomy, North Haugh, KY16 9SS, St Andrews, UK
[*]corresponding author: adf10@st-andrews.ac.uk

Abstract: We introduce ZrO_2 as a reliable material platform for photonic metasurfaces for on-chip optical trapping and imaging applications in the visible range. We demonstrate devices for optical trapping with a high numerical aperture at a wavelength as low as 488 nm, validating the use of the platform for biophotonics applications.

This work presents a new metasurface platform for the visible light range based on ceramic materials. ZrO2 has recently caught the attention of the nanophotonics community for its extended operational wavelength, and moderately high refractive index, with a flat dispersion across the visible range and negligible optical absorption, down to the UV region [1].

ZrO_2-based metasurfaces have the unique potential to revolutionize lab-on-chip applications in the green and blue regions of the visible spectrum, where light structuring is a pivotal paradigm for imaging and optical manipulation experiments.

To demonstrate this capability, we designed metasurfaces with high NA=1.2 operating at 532 nm and 488 nm and used them to create optical traps with high trap stiffness.

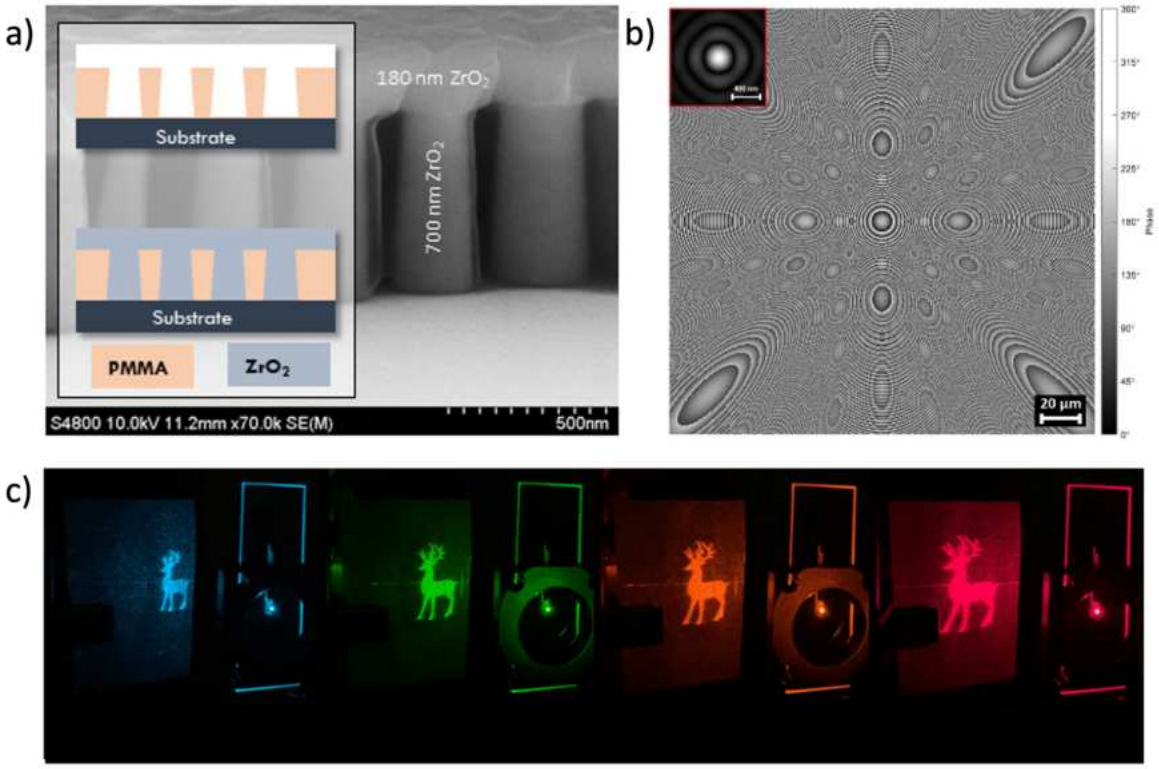

Figure 1 a) Scanning Electron Microscope image of a section of the metasurface (inset: sketch of the

fabrication process). b) Calculated phase profile for a metasurface focusing light with NA=1.2 (inset: experimental image of the focused spot). c) Collection of holographic images created by ceramic metasurfaces, covering the visible range.

The metasurfaces were fabricated (see Figure 1) using via Electron Beam Lithography, using PMMA as a positive-tone resist. After development, the air holes were filled with ZrO_2, using atomic layer deposition, which guarantees a complete filling of the holes. At variance with standard similar fabrication processes, we designed the meta-atoms to include the ZrO2 uniform cap. This choice simplifies the fabrication procedure and creates a natural protection layer which insulates the metasurface from the surrounding environment. This feature is particularly useful in biophotonic applications, where the metasurface is in contact with a not homogeneous medium, with variable refractive index.

For the optical trapping experiments, we used a custom setup. The ceramic metasurfaces were realized on the top slide of a microfluidic chamber, facing the liquid environment. The metasurfaces were illuminated with a collimated trapping beam from the top and a focused spot was formed in the middle of the chamber, at several tens of microns from the metasurface. Systematic trapping experiments with SiO_2 beads with a diameter of 2 μm showed an optical trapping stiffness greater than 200 pN/μm/W, at a wavelength of 488 nm. To the best of our knowledge, this is the first demonstration of on-chip optical trapping at wavelengths below 500 nm [2].

This demonstration unequivocally confirms the quality of the optical landscape created by the metasurfaces and candidates ZrO_2 to become a reference material platform for integrated biophotonics applications, in the visible region and beyond.

The project was supported by the European Research Council (ERC) under the European Union Horizon 2020 Research and Innovation Program (Grant Agreement No. 819346).

Abstract: In this work we present a method to perform magnetic control of electrically uncharged particles based on magneto-optical materials illuminated by a spinning monochromatic light field. We analyze the behavior of these particles under different isotropic optical configurations, and we calculate the value of the induced magnetic charge.

Constant magnetic fields are known to interact with electrically charged particles inducing Lorentz forces that point in a direction perpendicular to the field. However, if the particle is electrically discharged, it is impossible to induce a force using a constant magnetic field. An exotic option is to mimic a magnetic charge on a neutral particle. This false magnetic monopole will interact with the magnetic field just as an electric charge would do with an electric field through the Coulomb interaction. Attempts to generate this magnetic charge have mainly relied on quasiparticles generated using condensed matter spin ice networks [1-3]. In this work we present another option based on neutral magneto-optical particles illuminated by a spinning monochromatic light field [4]. We will analyze the behavior of these particles under different fluctuating isotropic optical configurations [5,6], and we will calculate the value of the induced magnetic charge. We will prove that this is a purely non-reciprocal effect as the reciprocal equivalent (a chiral dipole) despite presenting a dichroic response, does not experience any force when illuminated by the spinning field. The magnetic charge induced by impinging radiation on the magneto-optical dipole is found to depend linearly on the helicity of the field. In addition, this artificial monopole experiences a dichroic permanent optical torque and does not interact with an external electric field.

Abstract: THz time-domain spectroscopy is a widespread technology. It is pump-and-probe-based and delivers a large dynamic range, currently limited by the probe shot noise. Therefore, quantum metrology tools, such as squeezed states, can enhance its sensitivity. We shall present our first attempts in this direction, including discrete and continuous variable approaches.

Time-domain spectroscopy in THz and infrared spectral ranges utilises constant carrier-envelope offset sources and ultrashort probe pulses, shorter than the half period of the highest frequency to be sampled. This method enables recording the electric field, providing spectrum and time-of-flight information. Limited by probe pulse shot noise, quantum metrology can enhance the sensitivity of THz time-domain spectroscopy (THz-TDS) [1]. Here, we discuss ongoing efforts towards developing a quantum-enhanced THz-TDS technique.

Quantum metrology offers potential improvements, like utilising NOON states for Heisenberg-limited phase estimation. We present experiments employing weak squeezed vacuum fields as probes in THz electro-optic sampling, detected with single-photon detectors. Our method achieves sensitivity limited by probe state statistics, using phase-locked single-photon detectors [2], opening avenues for quantum-enhanced THz sensing.

Classical approaches outperform discrete variable quantum enhancements for real-world THz-TDS applications due to the large probe pulse photon numbers. We aim to enhance THz-TDS sensitivity by employing macroscopic squeezed pulses. We explore the generation and detection of <200fs intensity correlated twin beams via parametric down-conversion for ultrafast quantum-enhanced sensing. Our setup involves a 40W, 1030 nm laser with a pulse duration of 245 fs. Quantum-correlated radiation is measured by high-efficiency, low-noise balanced photodetectors. Compared to a coherent source, we observe ~3dB noise reduction below the standard quantum limit with >500 nW average power pulses. This represents the highest noise suppression measured with <200 fs duration twin beams at 1030 nm. We discuss our results and design choices enabling significant noise reduction using sub-shot-noise correlations among ultrafast pulses.

Abstract: We present the design, fabrication, and detection of topological bandgaps and edge modes of photonic crystal slabs fabricated in the top Si layer of SOI wafers. We show their polarization properties in addition to their dispersion relation based on high-resolution angle-resolved reflection measurements.

Topological photonic crystals (PhCs) have been attracting a great interest mainly because they can materialize helical one-way edge modes on the boundary between trivial and non-trivial PhCs (PhC-t and PhC-n). The PhC design for the helical edge modes was given by Wu and Hu[1)] for two-dimensional PhCs. Their recipe was modified by Barik et al.[2)] to apply to PhC slabs.

In this presentation, we would like to introduce our recent sample fabrications to materialize topological bandgaps and edge modes, and their confirmation by high-resolution reflection spectroscopy in the mid infrared range. We fabricated two types of specimens in the top Si layer of SOI (silicon on insulator) wafers with and without mirror symmetry about the mid horizontal plane of the PhC slab.

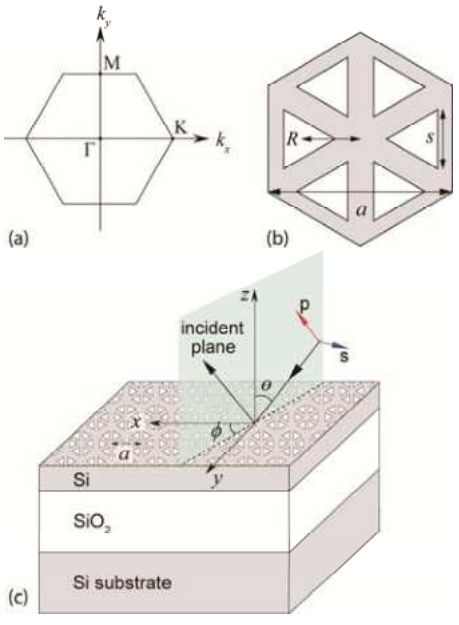

Fig. 1 (a) The first Brillouin zone of the PhC specimens of the C_{6v} symmetry and (b) the top view of the unit cell. (c) Configuration of the incident plane wave for the angle-resolved reflection measurement on the illustration of the asymmetric PhC structure.

Figure 1 shows the sample structure and the configuration of the angle-resolved reflection measurements.[3)] For the symmetric PhC specimens, we further capped the top Si layer with SiO_2 by plasma-enhanced CVD.[4)] Figure 2 shows SEM images of our specimens fabricated by electron-beam lithography.

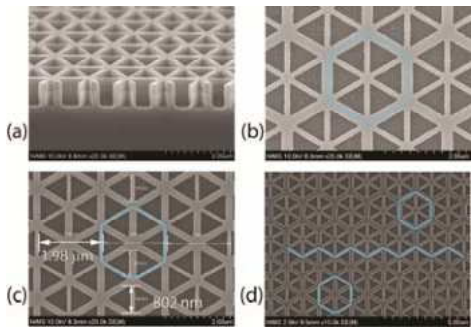

Fig. 2 SEM images of fabricated specimens. (a) Crosssectional view after etching. Top view of (b) PhC-t and (c) PhC-n. (d) Top view of the combination specimen.

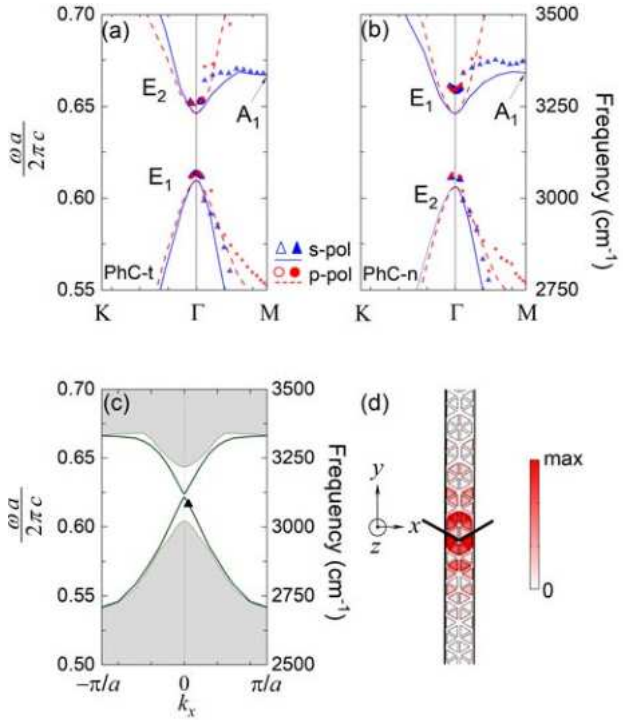

Fig. 3 (a) Dispersion relation of TE-like modes for asymmetric PhC-t and (b) PhC-n. Blue solid line and red broken line show calculated dispersion curves for s- and p-active modes, respectively. Blue open circle and red open triangle show data points measured for s and p polarizations, respectively. (c) The calculated dispersion relation of edge modes (dark green line) and the spectral range of bulk modes (gray color). (d) The time average of the square of the z component of the magnetic field.

By adjusting R in Fig. 2(b), we can materialize PhCs with topologically trivial (PhC-t) and non-trivial (PhC-n) bandgaps. Figure 3(a) and (b) show both the calculated and measured dispersion curves for the asymmetric PhCs. We used COMSOL Multiphysics for the calculation and a home-made high-resolution angle-resolved reflection setup[5] for the measurement around the Γ point. The dispersion relation of the edge mode materialized on the boundary between the PhC-t and PhC-n and its field distribution are shown in Fig. 3(c) and (d).

The dispersion relation of the edge modes was also measured by the angle-resolved reflection. As expected from the numerical calculations, the edge modes at the Γ point are linearly polarized whereas they are basically circularly polarized. The former feature was brought about by the 1:1 mixture of the upper and lower edge-mode branches due the absence of inversion symmetry around the boundary between the two PhCs.

We did the same calculations and measurements for the symmetric PhCs, for which the topological bandgaps are more rigorously defined, and confirmed the presence of the edge modes.

The interplay of gain and loss in room-temperature planar polaritonic systems

Anton K. Samusev[1*]

[1]Experimentelle Physik 2, Technische Universität Dortmund, 44227 Dortmund, Germany
[*]corresponding author: anton.samusev@tu-dortmund.de

Abstract: Strong exciton-photon coupling in systems based on halide perovskites and 2D semiconductors at room temperature is demanded in tunable and nonlinear on-chip photonics. Here, we demonstrate a weak-to-strong coupling transition accompanied by the onset of polariton motional narrowing, polariton lasing enhanced by exceptional points, and an ultrafast high-contrast polariton modulator.

Tunable, highly nonlinear planar optical systems operating at room temperature are of great interest due to their potential applications in on-chip photonics. Contemporary quantum materials, such as perovskites and transition metal dichalcogenides (TMDs), offer stable excitons at ambient conditions. These can form exciton-polaritons by coupling to high-Q optical states in solid and nanostructured slabs with the on-demand design, enabling exceptionally large optical nonlinearity.

In the first part of the talk, I will employ an experimental approach to retrieve the full complex dispersion of both leaky and evanescent waves in arbitrary planar structures [1]. The method is based on back focal plane microspectroscopy combined with a solid immersion lens (SIL) separated from the sample by a precisely controlled nanoscale air gap (Otto geometry). Varying the gap allows for extracting both real and imaginary parts of the wavenumber of surface and guided waves propagating in an arbitrary in-plane direction. Using this approach, we directly probe and control guided exciton–polaritons in a planar TMD-based waveguide [2]. Careful measurement of angle-resolved reflectance maps as a function of the SIL-sample air gap enables reversible control of the waveguide and exciton-polariton dispersions. For a single-layer WS_2 deposited on an unpatterned dielectric slab waveguide, we retrieve the complete set of parameters of the system, which include radiative and nonradiative decay rates of the exciton resonance as well as the dependence of corresponding rates for the optical mode on the SIL-sample distance. Additionally, we demonstrate for the first time control of exciton-polariton coupling strength via SIL-induced rearrangement of the local electromagnetic field in the polaritonic waveguide. Utilizing the transition from weak to strong coupling regime, we experimentally observe the onset of the motional narrowing effect and demonstrate control over the inhomogeneous broadening of polaritons. Using a similar approach for a thin, unpatterned $MAPbBr_3$ perovskite film, we study how in-situ variation of radiative losses enables control over the spectrum and threshold of polariton-driven amplified spontaneous (ASE) and stimulated emission [3].

In the second part of the talk, we will discuss the engineering of polariton dispersion and regimes of polariton lasing in 1D photonic crystal slabs (PCSs) based on halide perovskites [4-6]. For the first time, we employ the mechanical scanning probe lithography (m-SPL) method to realize planar room-temperature exciton-polariton systems based on 2D perovskites [4]. The fabricated PCSs support the long-living polariton modes with a Q-factor up to 100. Thanks to the flexibility of the m-SPL method, it is possible to vary the modulation of the structures with a few tens of nanometers precision. This way, we achieve broad control over the dispersion, optical radiative losses, and the Rabi splitting of the exciton-polariton states in the planar photon

cavity based on (PEA)2PbI4. Our recent studies confirm that the demonstrated method can be introduced for other halide perovskites.

For a 1D PCS realized by nanopatterning of a thin (sub-100-nm) $MAPbBr_3$, we demonstrate room-temperature high-Q (up to Q≈2300) polariton lasing mediated by the exceptional points (EPs) in the exciton-polariton dispersion [5]. We reveal that the ASE in the studied samples originates from the accumulation of polaritons in the spectral region with the excitonic fraction in polariton of around 0.3. With further increase of the carrier concentration, the ASE broadens towards the red region due to the polariton relaxation, and EPs appear when the PCS modes' crossing falls in the gain spectral range. These results explain the fundamental origin of the lasing in lead-bromide perovskite PCSs and open new ways to realize room-temperature planar polariton lasers based on a wide variety of halide perovskites.

Finally, we demonstrate that such a MAPbBr3 perovskite PCS provides strong and ultrafast optical modulation based on the polariton condensation mediated by exceptional points at room temperature [6]. The modulation of transmission filtered spectrally and angularly exceeds 25 times the pristine values thanks to the accumulation of boson exciton-polaritons in a condensed state. The modulation time is 440 fs with a minimum control pump fluence of approximately 40 $\mu J/cm^2$. The combination of the relatively short modulation time and high transmission modulation depth is achieved thanks to the benefit features of EPs. Compared to existing systems, our optical modulator currently sets a record for the highest transmission modulation depth in the visible spectral range while exhibiting comparable time modulation values and control pump power consumption. Crucially, the modulation duration and its delay with respect to the pump pulse can be tailored by adjusting the pulse power and wavelength, providing multiple degrees of freedom for various applications.

Continuous mechanical machining of asymmetric nanogratings with tailored period and shape by azimuthal rotation-controlled nanoinscribing

Jong G. Ok[1*]

[1]Seoul National University of Science and Technology, Seoul, Republic of Korea
[*]corresponding author: jgok@seoultech.ac.kr

Abstract: We demonstrate the high-throughput mechanical patterning of period- and shape-tunable asymmetric nanogratings via azimuthal rotation-controlled nanoinscribing (ARC-DNI) which utilizes continuous inscription of a nanograting tool edge on viscoelastic polymers. ARC-DNI enables scalable fabrication of diverse asymmetric nanogratings with trapezoidal, triangular, and parallelogrammatic profiles for various photonic and diffractive optical elements.

This talk presents an azimuthal rotation-controlled dynamic nanoinscribing (ARC-DNI) process for the continuous and scalable fabrication of asymmetric nanograting structures with tunable periods and shape profiles. A sliced edge of a nanograting mold typically having a rectangular grating profile slides over a polymeric substrate to induce its burr-free plastic deformation into a linear nanopattern (Figure 1). During this continuous nanoinscribing process, the 'azimuth', which is the angle between the inscription stroke direction and the mold's grating line direction, can be rotated to tailor the period, geometrical shape and profile of the resultant nanogratings. By controlling the azimuth along with other important ARC-DNI parameters, specifically the temperature, force, and inscribing speed, we demonstrate that the azimuth-dependent change in the nanograting mold's opening profile and modulation of the temperature- and time-dependent viscoelastic polymer reflow can enable the continuous patterning of asymmetric, blazed, and slanted nanogratings having diverse geometrical profiles, such as trapezoids, triangles, and parallelograms. ARC-DNI can be utilized in many practical applications exemplified by diffractive optical elements and potentially in AR/VR devices.

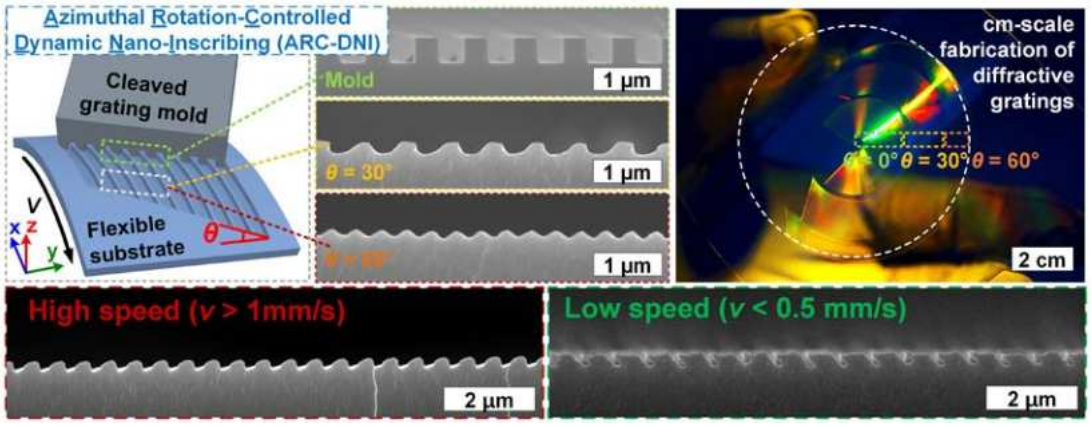

Figure 1. Scheme and components of the ARC-DNI process (left), results of controlled periods and shapes of ARC-DNI-ed asymmetric nanogratings (middle), and diffractive nanograting lens fabricated by performing ARC-DNI along a circular route (right). Inscribing speed-dependent change in the geometric shape of asymmetric nanogratings is demonstrated at the bottom.

Dynamic Thermoplasmonic Control of Colloids, Molecules and Fluids

M. Fränzl[1], D. Quinn[1], D. Paul[1], and F. Cichos[1*]

[1]Molecular Nanophotonics Group, Leipzig University, Linnéstr. 5, 04103 Leipzig, Germany
[*]corresponding author: cichos@physik.uni-leipzig.de

Abstract: Optically pumped plasmonic nanostructures allow a dynamic release of heat for an unprecedented control of objects like colloids and macromolecules in microfluidic environments. We report on experiments that assemble photonic and molecular structures with the help of local hydrodynamic flow and pressure fields that are the result of thermoplasmonic heating.

In microfluidics, the manipulation of liquids and suspended objects in small channels has diverse applications, including triggering chemical reactions, creating new materials, analyzing single cells at high throughput, and simulating organs on a chip [1]. Efficient mass and heat transport at small scales, along with experimental accessibility and control, drive innovation in fields like biology, chemistry, drug design, and medicine. Most microfluid manipulation methods thereby rely on external pressure differentials in complex channel systems where local control is difficult.

In recent years, new techniques have emerged for manipulating nano-objects and flows in a fluidic environment using remote control through light. These methods go beyond the force generation capabilities of optical tweezers and employ plasmonic structures. By generating temperature gradients with plasmonic structures at the boundaries between liquids and solid surfaces in simple fluidic slit pores, local flow patterns can be created to guide, manipulate, and separate suspended objects without the need for external pressure differences [2]. This new field is termed thermofluidics and comprises new rapid developments.

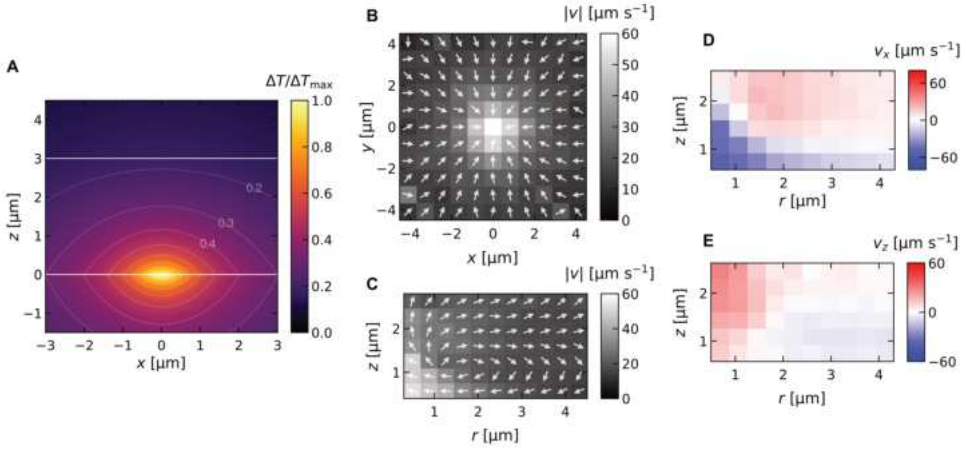

Figure 1. (**A**) Temperature field generated in a thin liquid film above a thin gold film by a focused laser. (**B**) Experimentally measured flow field generated by the temperature field in **A** directly at a gold water interface. (**C**) Flow field measured across the film thickness. (**D-E**) Magnitude of the flow vector components measured as a function of distance from the hot spot.

We show in this contribution how optically heated plasmonic nanostructures can induce complex hydrodynamic flow fields. These flow fields arise from forces generated in an ultrathin boundary layer of a few

nanometer thickness at the liquid-solid interface and are termed thermo-osmotic flows [2]. Such thermo-osmotic flows can be combined with van der Waals and electrostatic forces to dynamically generate controlled plasmonic structures using gold nanoparticles. The large thermal diffusivity at these length scales further ensures that complex temperature fields may be generated by multiplexing in time and space, which allows additional control on the cluster formation. We present the spectroscopic signatures of these clusters that can be formed and reformed on demand and dynamically.

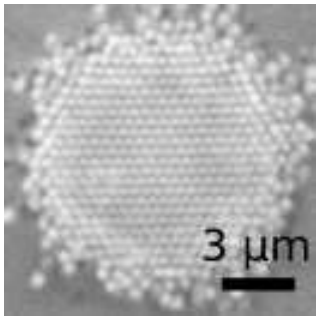

Figure 2. *Photonic crystallite grown from 300 nm polymer beads by thermoplasmonic actions.*

We further show how molecular compounds in the solution allow the non-equilibrium growth of photonic crystallite structures. The colloidal crystals are thereby formed with the help of osmotic pressure gradients that are the results of the interaction of the molecules with the plasmonic temperature fields. These functional photonic crystallites which exhibit clear signs of stop bands do not need any attractive interaction between the colloids to grow but are solely the result of the local pressure fields and hydrodynamic flow fields and cease if these are switched off. The thermal non-equilibrium nature thereby provides new dynamic control to form even mixed crystals which can be combined with real-time spectroscopy of the structures

The applied thermoplasmonic actions that involve thermophoresis, thermo-osmosis, thermo-viscous effects, or other secondary effects can be dynamically modified at high speeds due to fast thermal diffusion on the micrometer scale [2]. In addition to the manipulation of colloids [3], these techniques enable precise control over single and multiple macromolecules [4]. They facilitate the study of protein aggregation [5] and show promise for integration with advanced plasmonic sensing techniques creating feedback loops with the help of machine learning controlled feedback loops [6].

Abstract: We investigated the quantum nature of non-linear processes driven by non-classical light. We studied second-harmonic generation pumped by parametric down-conversion (PDC), and we observed a quantum effect for high-flux PDC, beyond the photon pairs regime.

Recent years have witnessed a renewed focus on exploring quantum effects in nonlinear light-matter interactions, specifically two-photon absorption (TPA) [1,2] and second-harmonic generation (SHG) [3], driven by nonclassical light sources. Ongoing debates surround the nature of the observed enhanced nonlinear signal, with doubts raised about its validity (see e.g. [4]). Additionally, scepticism persists regarding the applicability of quantum effects in two-photon interactions due to the low signals typically generated [5]. To contribute to this topic, our investigation delves into the SHG of parametric down-conversion, spanning both the spontaneous (photon pairs) regime and higher photon fluxes.

A 40 W, 500 kHz, 1030 nm, 245 fs pulsed laser (Light Conversion Carbide) undergoes frequency doubling to a central wavelength of 515 nm, serving as the pump for parametric down-conversion (PDC) in a 2 mm BBO crystal. After appropriate pump filtering, the resulting PDC is imaged onto a second identical crystal using a pair of 90-degree off-axis parabolic mirrors in a 4-f configuration to achieve second harmonic generation (eSHG). The eSHG signal was detected with a photomultiplier tube connected to a time-to-digital converter.

The eSHG signal, measured as a function of PDC energy in the low-gain, spontaneous regime, conforms to the expected linear scaling (inset of Fig. 1). To authenticate this as a genuine quantum effect, losses were introduced to the PDC beam, resulting in a decrease in the eSHG signal, a phenomenon absent in standard SHG driven by a classical beam. Notably,

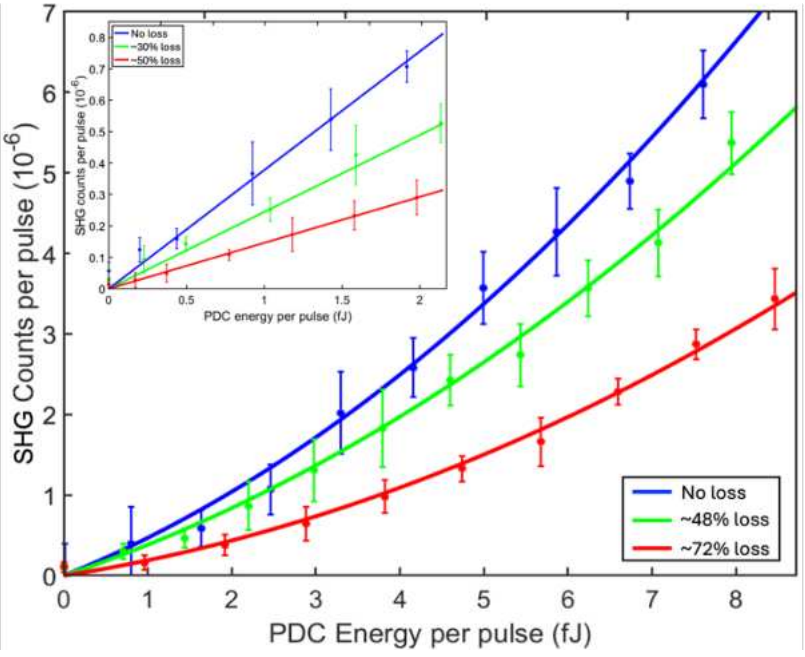

Fig. 1. SFG counts per pulse as a function of the PDC pulse energy in the spontaneous (inset) and stimulated regimes.

this effect persisted at higher PDC fluxes in the stimulated regime (Fig. 1 - main), confirmed by the nonlinear scaling of PDC versus pump energy. The observation of quantum effects beyond conventional quantum advantage regimes in eSHG or eTPA suggests potential avenues for leveraging quantum two-photon interactions in imaging and metrology.

Abstract: Vortex rings are generated by the interference of Gaussian beams and a plane wave. We describe non-trivial topological events controlled by relative amplitude and phase: birth and death of isolated vortex rings as well as reconnections of two or more vortex rings, including transformations which change the number of rings.

Historically, the term vortex ring is associated with the study of smoke rings by Helmholtz [1], while in optics, the first appearance of vortex rings is linked to the study of Airy rings [2,3]. The basic topological reactions associated with the rings include their birth and death at isolated points and reconnection of vortex lines [3,4].

We investigate whether vortex rings can be generated in linear paraxial systems and if asymmetries in the beam shape affect the topological structure. We explore an accessible model that generates vortex rings as a result of the superposition of a Gaussian beam and a co-propagating plane wave, which can be replicated using readily available laboratory equipment. The results are presented in more detail in Refs. [5,6].

Propagation of laser beams in free space is governed by the Schrödinger paraxial wave equation for slowly varying envelope of electric field E:

$$4i\frac{\partial E}{\partial t}+\frac{\partial^2 E}{\partial x^2}+\frac{\partial^2 E}{\partial y^2}=0, \tag{1}$$

here we use dimensionless coordinates x and y, measured in units of beam width w_0, and the "time" t is normalized by the diffraction length $z_R=\pi w_0^2/\lambda$. We use the fundamental solution to Eq. (1), the 1D Gaussian beam:

$$E_1(x,t;w_0,t_0)=\frac{w_0}{\sqrt{w_0^2+i(t-t_0)}}\exp\left(-\frac{x^2}{w_0^2+i(t-t_0)}\right), \tag{2}$$

to construct 2D Gaussian beams with elliptic transverse profile: $E(x,y,t)=E_1(x,t;w_x,d/2)E_1\left(y,t;w_y,-d/2\right)$. We reduce the parameter domain by introducing the ellipticity parameter ϵ, such that $w_x/w_y=\tan\epsilon$, and the beam is astigmatic for $d\neq 0$.

In case of the radially symmetric fundamental Gaussian mode [5] $(\epsilon=\pi/4, d=0)$, we look for the nodal (vortex) lines, $E=0$, of the superposition $E=E_2+Pe^{i\phi}$, here P is the relative intensity of the plane wave and ϕ is the relative phase difference. The vortices lie on the intersection of two surfaces: iso-surfaces for beam envelope intensity $|E(x,y,t)|=P$ and phase level surfaces, $\mathrm{Arg}\,E=\phi+2n\pi$. Two topological mechanisms are identified in this case: the nucleation of a single ring on the optical axis, when the phase ϕ passes through the endpoints of the intensity iso-surfaces, and a nucleation of a pair of counter-propagating rings.

The radial symmetry forces the rings to exhibit a flat configuration, oriented perpendicular to the axis of propagation [5], while in elliptic beam cases $(\epsilon\neq\pi/4)$ the rings deform in 3D space [6]. This introduces two additional topological transformations: nucleation of a pair off-axis rings and ring reconnections. The birth of an off-axis pair is the product of elliptic asymmetry: the rings are no longer flat; thus, they cannot annihilate with each other as it was possible in the radially symmetric beam. The underlying mechanism for the birth of a pair off-axis remains consistent across all three non-radial scenarios, although the nature of reconnections varies.

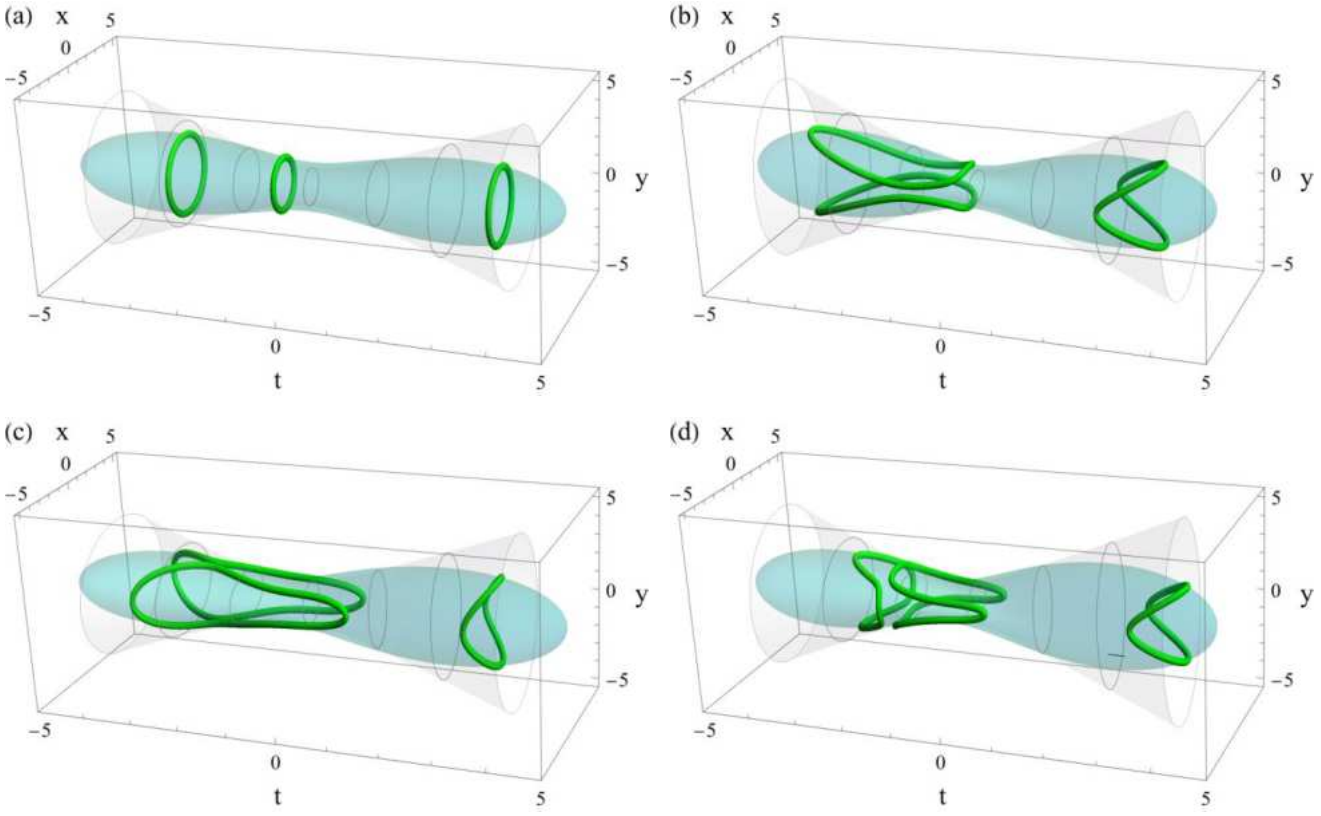

Figure 1. Beam shapes (grey surface), spheroids of intensity $P = 1/5$ (cyan surface), and vortex rings (thick green lines) for: (a) radially symmetric beam $(\phi = -0.1\pi)$, (b) elliptic beam $(\phi = -0.05\pi)$, (c) astigmatic beam $(\phi = -0.05\pi)$ and (d) elliptic-astigmatic beam $(\phi = -0.17\pi)$.

We identified the generic $2 \to 2$ reconnections, where two rings touch on a point and form two separate rings, that is present in all cases. However, at certain cases, i.e. ϕ passing through the point in the beam shape with the round transverse profile, $3 \to 3$ and $2 \to 4$ reconnection cases become possible, which is attributed to the elliptic symmetries and cannot be generic in nature.

Abstract: Integrated photonics advances emerging artificial intelligence and quantum information processing technologies. This work employs on-chip, reconfigurable devices for highly efficient, intelligent, and secure classical and quantum signal processing. We demonstrate simultaneous operations with high speed, low power consumption, and small footprints, paving the way for next generation telecommunication solutions.

Artificial intelligence and quantum information science provide innovative tools for advanced signal processing toward emerging smart technologies in the fields of, e.g., communication and optical computing [1,2]. For instance, software/electronic-based artificial neural networks have been used to optimize telecom data transmission [3]. Yet, current implementations are inefficient to process real-time signals due to high latency and low processing speeds. Similarly, quantum signal processing has been pivotal to implement quantum communication in fiber networks to guarantee unbreakable data security [4]. However, fiber-based quantum communication suffers from limited distances and low transmission speeds, due to photons scattering and losses.

We develop integrated, reconfigurable all-optical neural networks (ONNs) to process and recover nonlinearly distorted telecom signals at ultrafast speeds. In parallel, we use on-chip photonics for the generation and processing of complex entangled photon states toward high-speed quantum key distribution (QKD). These implementations are realized by utilizing a single all-integrated photonic platform, which comprises a nonlinear source (spiral waveguide or microring resonator) [5] and an on-chip programmable interferometry system [6].

Our proposed ONNs feature a recurrent network topology [1], where the encoded information density is enhanced via the use of a microcomb [3] and manipulated by means of wavelength division multiplexing techniques. We apply our ONNs for nonlinear channel equalization to regenerate the temporal waveform of the transmitted signal, which undergoes dispersive and nonlinear impairments due to propagation in the fiber channel. In general, this complex task demands the implementation of rigorous digital signal processing e.g., digital back propagation, requiring extensive computational power and a detailed understanding of the transmission system. Our objective is to develop highly versatile and easily integrable ONN platforms that are capable of processing telecom signals at ultra-high speeds and with reduced latency. Preliminary results suggest that our tunable ONN devices can process and accurately reconstruct nonlinearly distorted telecom waveforms, achieving processing speeds exceeding GHz/s with nanosecond-level latency.

The spiral waveguide and the cascade of on-chip interferometers can also be exploited for the generation of high-dimensional (qudit) time-entangled photon states at telecom wavelengths. The interferometers generate

pulse burst that subsequently induce spontaneous four-wave mixing and thus generate time-entangled photon pairs in the spiral waveguide. The programmable interferometers, combined with external fiber-based GHz speed phase modulation, are used for quantum state processing i.e., for quantum interference and quantum state tomography measurements, as well as telecom-compatible secure QKD. The use of entangled photons provides robustness against eavesdropping attacks, as they allow the exchange of a device-independent secret key. The use of qudits guarantees an increase in the secret key rate, noise resilience, and information capacity. From preliminary tests, we estimate a record high secret key rate of several hundred kbit/s and a quantum bit error rate below 12%. These results show the high robustness of the cryptography key generated via our photonic qudits against eavesdropping attacks.

Adapted from [5]. (c) Schematic representation of the scheme used for photon state generation. OIC: on-chip interferometer cascade; T1, T2: transmission ratios of the interferometers; SW: spiral waveguide; NF: notch filter.

Our platform provides compact and CMOS compatible solutions that enable significant scaling of information through time or frequency multiplexing, establishing it as a highly suitable candidate for signal processing applications. Moreover, the high nonlinearity and low heat dissipation profiles of our devices, will position our research in line with the needs for energy efficiency required by next-generation ONN, while also boosting quantum state processing, and the security of quantum optical signals in fiber telecom networks.

Abstract: Template-assisted self-assembly is a scalable nanofabrication technique in which elastomeric pre-patterned stamps are used to induce long range order from a colloidal dispersion used as ink. Metal colloids or perovskite nanocrystals are used to fabricate high quality and large area 2D photonic crystals supporting narrow lattice resonances and chiroptical properties.

Photonic architectures offer a promising avenue for optimizing the performance of various optoelectronic devices. Nevertheless, the future of optoelectronic devices hinges on cost-effective and large-scale manufacturing techniques that can reduce expenses and boost production efficiency. To harness the remarkable attributes of photonic structures for enhancing these devices, they must undergo a processing approach akin to that of the devices themselves.

Soft nanoimprinting lithography is a versatile, rapid, and cost-efficient method for crafting nanostructures from a diverse variety of materials. In soft nanoimprinting, we make use of pre-patterned elastomeric stamps to corrugate materials such as resists, biopolymers, colloids and nanomaterials in general. In all cases, the resulting photonic architectures can exhibit a resolution below 100 nm while covering areas up to 1 cm^2. During this presentation, I will explain how we use pre-patterned stamps to induce the long-range alignment into 2D lattices of different colloids, including gold and silver colloids and perovskite nanocrystals, to attain distinct optical properties, such as lattice resonances with high Q-factors.[1,2] Moreover, I will showcase how elastomeric molds featuring chiral 2D arrays can lead to chiral metasurfaces[3] exhibiting strong circular dichroism using traditional gold and silver colloids (g-factors of 0.4) and intense circularly polarized photoluminescence (CPL), making them seamlessly applicable in various practical applications.

Dynamically switchable phase contrast imaging with metaoptics

S. B. Sulejman[1], L. Clark[1], H. Wang[1], L. Wesemann[1], and A. Roberts[1*]

Abstract: Metasurfaces can all-optically manipulate images in the object or image plane leading to an orders-of-magnitude reduction in size compared to Fourier plane approaches. Here approaches to dynamically modifying the response of a device, essential for multifunctional imaging, using polarization and phase change materials is discussed.

Although the use of optical systems to perform image processing in the Fourier plane has been well-known since the 1950s, most commonly applied operations (such as edge detection or enhancement) are more widely performed digitally. Information carried in an optical wavefield introduced by, for example, propagation through transparent objects or turbulence is, however, lost on acquisition with a camera. Although sophisticated computational strategies for extracting phase from intensity images exist, these can be relatively slow and computationally demanding. Conventional all-optical approaches for image processing and phase contrast imaging, on the other hand, typically require relatively bulky, and sometimes expensive, optics but the drive for miniaturization of optical components, and advances in nanoscience have underpinned a renewed interest in all-optical image processing.

An optical wavefield carrying an image can be decomposed into a superposition of plane waves each with a characteristic amplitude and phase travelling in a given direction with respect to the optical axis. There is a one-to-one correspondence between the direction of a plane wave contribution and the transverse components of the spatial frequency (k_x,k_y). Traditional spatial frequency filtering involves introducing an amplitude and/or phase mask into the focal plane of a lens taking advantage of its Fourier transforming property. This places constraints on the positioning of the filter as well as requiring bulky lenses and the inclusion of propagation distances from the object to the Fourier plane. It is also possible to directly manipulate the spatial frequency content via a device that has a reflection or transmission that depends on the angle of incidence of a plane wave performing a direct modification of the amplitude and/or phase of a given plane wave component. In addition to providing a more compact all-optical system, there is considerable flexibility in the positioning of the device within an optical system since the angular spectrum is manipulated directly [1]. Concepts from nanophotonics can be used to produce compact devices with a tailored angular dispersion and, hence, expanded capacity to manipulate images and, more generally, perform analogue computing [2,3]. Specifically, there is considerable scope for the development of compact devices that can, all-optically, generate enhanced contrast images of transparent, phase objects. We have previously shown that a commercially available notch filter can performs edge detection in transmission at the bandstop wavelength [4] and that a planar metal-insulator-metal Salisbury screen also can be used to enhance phase variations introduced by biological specimens and microlenses in reflection at the resonant wavelength [5]. We also demonstrated that a resonant waveguide grating in transmission [6] can be used to generate phase contrast images of unstained HeLa cells. A particular focus has been on the necessity of introducing an asymmetry into the system to produce pseudo-3D phase contrast images

similar to those seen using Differential Interference Contrast images [6-9].

Many implementations of phase contrast imaging would benefit from the capacity to switch the modality of the imaging process. For example, being able to simply change from a bright field to a phase contrast image or to extract phase gradient images along different directions in a sample provides a means to, not only visualize additional information, but also to perform quantitative phase imaging and wavefront recovery. This presentation will discuss recent progress in the use of various strategies including polarization, wavelength multiplexing and the use of phase change materials [10] to demonstrate a variety of different phase contrast images using a single, fixed meta-optic.

Coherent Array of Superconducting Qubits as a Sensitive Microwave Antenna

P. Navez[1], A. G. Balanov[2], S. E. Savel'ev[2], and A. M. Zagoskin[2*]

[1]Université de Montpellier, France

Abstract: Progress in the creation of large-scale, artificial quantum coherent structures comprised of superconducting qubits opens new possibilities for their applications. Our analysis shows that such structures, in particular, an array of qubits in a resonator, can serve as sensitive antennas of microwave radiation, and that the signal-to-noise ratio under certain condition can exceed the Standard Quantum Limit and approach the Heisenberg limit of sensitivity.

Superconducting quantum bits keep playing the central role in the progress of quantum technologies due to their versatility of designs, relative facility of fabrication and robustness against decoherence [1]. They can serve as quantum analogues of both nondissipative and dissipative circuit elements, as building blocks of quantum metamaterials, or as artificial atoms; small driven arrays of superconducting qubits are predicted to demonstrate complex (chaotic or hyperchaotic) behaviour [2].

Superconducting qubits operate in the MW frequency range, which makes them attractive as unit elements of MW quantum antennas. Operating in quantum nondemolition regime, such antennas would be able to reach the standard quantum limit of sensitivity [3,4] or exceed it approaching the Heisenberg limit [5], at a single-photon level.

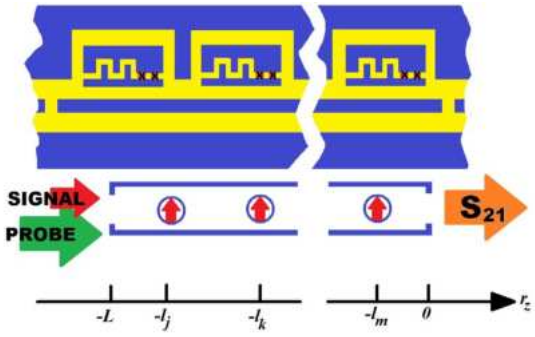

Figure 1. Array of transmon qubits in a cavity resonator (from [4]). The off-resonance interaction of the qubits with the signal in the presence of the probe produces detectable variations of the transmitted sigal.

This opens the road to a number of applications, such as open-air quantum communications in MW range, or an attempt to detect galactic axions [6].

Abstract: This paper reviews recent advances in the research and development of graphene-based 2D plasmonic metamaterials for terahertz detectors and reports on achieving responsivities.

Two-dimensional (2D) plasmons in graphene-channel FETs (GFETs) have attracted increasing attention as a promising mechanism for highly sensitive, fast-response, terahertz (THz) detection operating at room and elevated temperatures [1]. In addition, fast photothermoelectric (PTE) THz detection, as well as sensitive bolometric detection by graphene layer (GL) based van der Waals (vdW) 2D heterostructure devices has been enabled by superior carrier transport properties of graphene [2].

First, we investigated the plasmonic and photothermoelectric detection mechanisms for a single graphene FET (GFET). A few-layered, non-Bernal-stacked epitaxial graphene synthesized by thermal decomposition of a SiC substrate was utilized as the channel layer material. The gate stack included a plasma-enhanced chemical vapor-deposited SiN insulation layer. The Ti/Pd/Au asymmetric dual-grating-gate (ADGG) electrodes were fabricated by e-beam evaporation and lift-off (Fig. 1). The carrier density in the channel was periodically modulated by altering the ADGG bias and formed the plasmonic cavities underneath the highly biased gate fingers. Plasmonic rectification under zero drain bias resulted in fast and sensitive THz detection. The drain bias induced a DC potential slope along the channel heating carriers. The hot carriers absorbed the THz radiation and thermo-diffused towards the cold source and drain electrodes, unequally due to their drift/diffusion induced by the potential slope. This detection mechanism resulted in fast and more sensitive detection supported both by the photothermoelectric (majority) and plasmonic (minority) detection (Fig. 1). Such a detector had a 100-ps class fast detection response with 1-mA/W class modestly high responsivity as a GFET at room temperature (Fig. 1) [3].

Second, we investigated the vertical GL and b-As_xP_{1-x} heterostructures (Fig. 1) which can enhance the GL-based THz photodetector performance [4,5]. The intersubband transitions of graphene Dirac fermions in the GL (with extremely high transport properties) followed by the carrier propagation across the b-As_xP_{1-x} layers with much lower transport properties (Fig. 1) [4,5]. This carrier velocity modulation in a GL-bP-FET (GPFET) mediated the injection of extra carriers from the emitter contact providing the photoconductive gain, which can enable enormously high values of the detector responsivity [4,5]. The bias voltage V_{ds} and the signal voltage δV_{ω} were applied between the GPFET source and drain, whereas the signal voltage was produced by an antenna receiving the impinging THz radiation with frequency ω. The spectral dependences of the responsivity, R_{ω}^{V}, of the GPFET detectors were calculated for different scattering frequencies ν and different parameters of the structure (Fig. 2) [6-8]. An increase in the collision frequency ν smeared the resonant peak. In a wider frequency range, the

responsivity of the detectors under consideration was an oscillatory function of the radiation signal frequency ω with a set of the maxima at the plasmonic resonances $\omega = n\Omega$ (n being the resonance index). The dependences R_ω^V vs. $\omega/2\pi$ exhibit the alternating sharp maxima and relatively deep minima. The device characteristics of GPFETs with relatively low energy barrier layers (BLs) were optimized by choosing the barriers containing a number of the b-As_xP_{1-x} atomic layers. The resulting room temperature responsivities exceeded 5 kV/W and 10^3 A/W (Fig. 2) [8]. Furthermore, we analyzed the effect of the lateral thermal conductivity of the 2DEG and its Peltier cooling on the GPFET responsivity and its characteristics [9]. To confirm the significance of the electron thermal transfer in the GPFETs, we calculated the frequency dependences of the responsivity disregarding the electron thermal conductivity, i.e., neglecting the electron heat transfer to the side contacts [9]. The results indicate that the electron viscosity naturally weakens the plasmonic resonances [9]. The obtained results are an important contribution to terahertz devices in general and especially to plasmonic enhancement of the detector performance.

In summary, graphene-based 2D plasmonic metamaterials for terahertz (THz) detectors are promising for the realization of next-generation 6G and even 7G THz wireless communication services.

Abstract: Bound states in the continuum (BICs), which are localized states above the light, is actively studied due to their high Q-factor and topological nature. In this presentation, we introduce observation of photonic BIC with off-Γ wavenumbers not only in k- but also real spaces using light propagation imaging.

Bound states in the continuum (BICs) in photonics are exotic localized modes that are confined in the structures although they are above the light cone in k-space. Photonic BICs can be observed in various photonic systems including photonic crystals, metamaterials, and so on [1]. Since the BICs have no radiation loss, the Q-factor is infinite in principle, which makes the BICs very useful for application to lasers, and sensors, and so on. The photonic BICs can be categorized into two types: one is at-Γ BICs (symmetry protected BICs), and the other is off-Γ BICs (topologically protected BICs) which are observed at non-symmetric points in k-space. While a study on at-Γ BIC has long history, off-Γ BICs have been found recently and are attracting lot of attentions from researchers due to its intriguing features such as topological protection and steering ability [2,3]. In this presentation, we introduce our resent experimental demonstration about observation of off-Γ BIC in k- and real spaces.

In many papers, the off-Γ BIC was termed as “accidental” BIC because this kind of BIC is observed at a specific parameter of the structure, and we need to systematic parameter sweep to design it. However, recently, we found the “deterministic way” to generate off-Γ BIC by using structural symmetry and its topological nature [3]. This methodology enables us to design off-Γ BIC in any substrate with any thickness, which dramatically expand the capability of the off-Γ BIC. We start from traditional triangular lattice photonic crystal with C6 symmetry. In this structure, the at-Γ BIC with topological charge of 2 is achieved. Important point here is the topo. charge is not 1, but 2, which enables the “splitting” of the charge. When we introduce the perturbation breaking C_6 symmetry, the at-Γ BIC with topological charge of 2 split into two off-Γ BICs with charge of 1. Depending on the perturbation direction, we can control the split direction (k_x or k_y) in k-space. To observe “deterministic BIC,” photonic band was directly measured using Fourier plane imaging spectroscopy. We clearly observe the signal disappearance at off-Γ BIC due to extremely small radiation coupling of BICs. Our clear measurement allows to evaluate the Q-factors precisely and revealed the high Q-factors up to 1000 at around the off-Γ BICs.

Since off-Γ BICs have a finite in-plane wave number (different from the symmetry points), off-Γ BICs have a finite group velocity and thus can propagate in the slab. Although many papers observed off-Γ BIC using photonic band measurement (Fig. 1(a)), long-range propagation of the off- BIC has not been reported so far. To observe the off-Γ BIC propagation in real space, we utilize one-dimensional gratings supporting the off-Γ BIC [4]. The laser was injected from the side of the gratings, and we acquired the light scattering image from the upper side of the structures. At the BIC wavelength, propagation was clearly visualized and long-range propagation in millimeter scale was observed (Fig. 1(b)). The wavelength dependence of transmitted light intensity shows high transmission at around BIC wavelength. Interestingly, we observed unique self-collimation

behavior in the BIC propagation, which can be explained by localized Q-factor in k-space. Due to this feature, even when we tilt the incident angle, the direction of the propagation is unchanged.

In summary, we directly observed the off-Γ BIC in photonic crystals by using the photonic band measurements and propagation imaging. Fourier space imaging spectroscopy is a powerful to visualize the photonic band and observe the BICs. Moreover, light propagation measurements offer complementary information about off-Γ BICs. The observed unique long-range propagation by off-Γ BIC open the new opportunity to design photonic waveguides and integrated circuits.

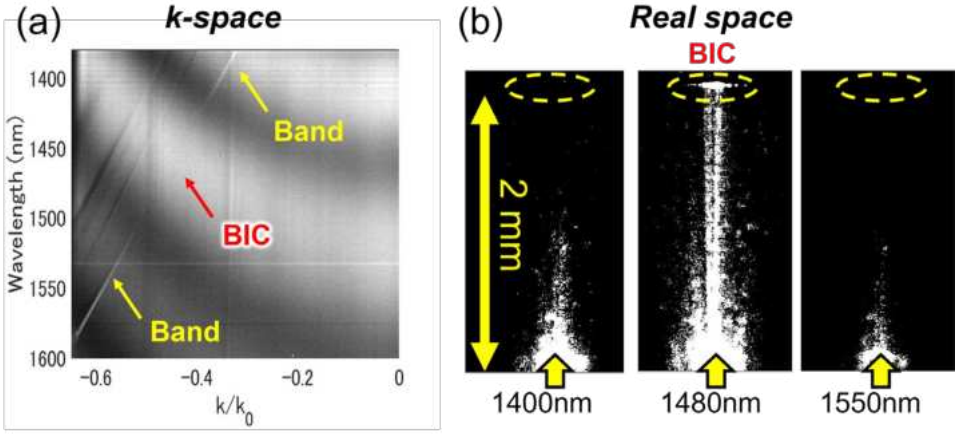

Fig.1 (a) k- and (b) real space observation of off- BICs. The BIC is observed using Fourier plane imaging spectroscopy in (a). The light propagation at the BIC wavelength clearly visualized in light propagation imaging measurements.

Abstract: Conducting polymer nanoantennas with redox tunability form an emerging approach towards dynamic plasmonics. In this talk, the progress and future prospects of active plasmonics based on conducting polymers will be briefly reviewed.

Plasmonics based on conventional metals are broadly used for biosensing and optoelectronic devices, but suffer from limited optical tunability. We recently demonstrated conducting polymers as a new category of plasmonic materials exhibiting excellent optical tunability. In this talk, I will briefly introduce the emergence, current status, and future prospects of using conducting polymers for dynamic plasmonics.

Metal nanostructures are key elements in nano-optics due to their intense resonant interaction with light via plasmonic charge oscillation. However, they suffer from limited tunability due to the fixed optical properties of metals. By contrast, conducting polymers, a new category of organic conductors, exhibit excellent tunability and were recently introduced for dynamic plasmonic antennas. We revealed that nanoantennas based on conducting polymers show clear dipolar plasmonic resonance and sustain reversible tuning via chemical and electrical approaches[1,2]. In this talk, I will present our latest progress of conducting polymer nanoantennas made through colloidal lithography and their applications for dynamic optical systems[3].

Integrated microlasers on a Bloch surface wave platform

Y.-C. Lee[1], Y.-L. Ho[1], B.-W. Lin[1], M.-H. Chen[1], D. Xing[1], H. Daiguji[1], J.-J. Delaunay[1]

Abstract: We report the stimulated emission of a quasi-Bloch surface wave mode guided in a ring made of a gain material. The ring is patterned by UV lithography on a 1D photonic crystal using a dye-doped resist. The reported microlasers exhibit narrow line widths of approximately 0.02 nm.

Integrating coherent light sources on existing surface wave platforms offers tremendous opportunities in the areas of sensing and data processing. Here, we demonstrate a microfabricated coherent light source based on the stimulated emission of a guided Bloch surface wave mode [1].

The proposed Bloch surface wave (BSW) ring laser consists of a thin ring structure made of the gain material on a truncated 1-D photonic crystal. The presented results are shown for a ring (diameter = 100 µm and thickness = 140 nm) made of a SU8 resist doped with the dye rhodamine 6G fabricated by UV lithography on the top of a truncated 1-D photonic crystal consisting of a SiO_2/TiO_2 multilayer. The lasing mode is investigated using mode analysis. Fig 1 (left) shows a typical electric field distribution for a BSW mode (maximum at the layer interfaces between the low and high refractive indices) with an effective refractive index of the mode n_{eff} = 1.38. This structure was optically pumped using a ns pulse laser (532 nm) and lasing was achieved above a pump threshold of 30 µJ/mm^2. Fig 1 (center) exhibits a typical lasing peak series obtained for ring structures sustaining whispering gallery modes. The lasing behavior is confirmed by examining the very narrow full width at half maximum of the emission peaks (0.02 nm) and the pump threshold for lasing. To confirm that this experimental lasing mode corresponds to the simulated BSW mode shown in the left figure, the radiation leaked by the lasing structure is collected from its bottom and analyzed using a back focal plane configuration (Fig. 1 (right) showing both below and above lasing threshold angular distribution). The direction of the light in the mode is analyzed via radiation leakage and corresponds to a numerical aperture 1.32~1.4 (i.e., 1.32 < n_{eff} < 1.4), as seen in the ring position for the case above the lasing threshold. This confirms that the observed lasing mode corresponds to the BSW mode having n_{eff} = 1.38 and validates the presented BSW ring laser principle.

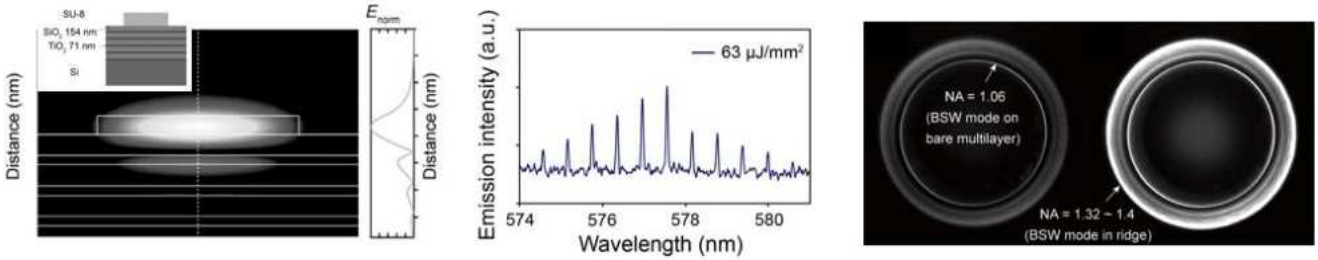

Figure 1 (left) Analysis of the lasing mode. (center) Lasing results exhibiting whispering gallery mode behavior. (right) Leakage radiation pattern in the back focal plane below and above the lasing threshold confirming the effective index of the lasing mode.

Detailed discussion about the quality factor of the employed mode as well as potential applications of these microlasers will be presented.

Abstract: Introducing a novel approach to customize the optical properties of a transparent conductive oxide that exhibits epsilon-near-zero (ENZ) behavior in three dimensions. The combination of 3D photonic crystals with the ENZ material yields a promising 3D device with static optical properties suitable for telecommunication applications.

The emerging photonic materials, have gained significant attention the last decades (i.e., Transparent Conductive Oxides-TCOs), which possess unique properties such as tailorability, large damage thresholds and epsilon-near- zero behavior[1]. In optical device design, tailoring the optical and especially the ENZ behavior by manipulating the properties of such materials plays a crucial role in achieving the desired functionalities. In general, ENZ materials, with their ability to increase light-matter interaction and effectively confine light within sub-wavelength structures, offer substantial advantages for optoelectronic devices[2].

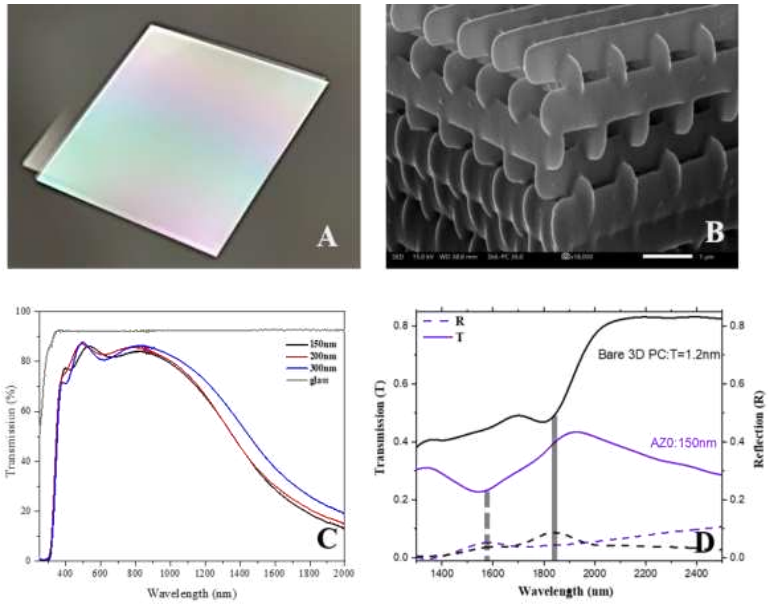

Figure 1 A. AZO thin film, **B**. SEM image of 3D PC coated with AZO thin film, **C**. Transmission spectra of the AZO thin films with 150,200,300nm and **D**. Transmission (solid line) and reflection (dashed line) measurements of the 1.2μμm inlayer periodicity 3D PC without(black) and with 150nm AZO thin film(purple) coating

Aluminum Zinc Oxide (AZO) is one of the preferable TCOs studied for its ENZ behavior, showing promise in nonlinear optics, and tunable nanophotonic devices, among others[3][4]. Until recently, AZO has mainly been studied as thin films or coatings in one- or two-dimensional structures. These studies revealed that altering AZO's thickness, carrier concentration, doping, or substrates can enhance different properties, both linear and nonlinear.

Another widely studied way of light-matter interaction is the photonic crystal environment. Photonic crystals (PCs) are divided in one-, two- and three-dimensional structures. Specifically, PCs are consisting of different dielectrics with different refractive indices that are periodically arranged to provide a photonic bandgap[5].

In this work, a novel approach is introduced to customize the ENZ behavior of AZO in a three-dimensional environment. The method involves developing 3D photonic crystals (PCs), through Multiphoton Lithography (Figure 1B), and subsequently coating them with AZO thin films (Fig. 1B), using the Pulsed Laser Deposition method. The shift observed in the bandgap of the AZO-coated 3D PCs (Fig. 1D) demonstrates the tailored static optical properties of AZO in three dimensions. This successful development of 3D PCs coated with AZO further underscores the synergy between the extraordinary optical properties of well-investigated 3D PCs and the morphological, structural, and optical characteristics of AZO thin films (Fig.1A, C) within the ENZ regime. This outcome is new promising platform for applications in photonics and tunable photonics, especially in the telecommunication band.

A Compact Silicon Photonic Crystal Spectrometer with Unprecedented Resolution

Takasumi Tanabe*, Junnosuke Kokubu, Ryo Sugano, and Jinwei Zhang

Department of Electronics and Electrical Engineering, Faculty of Science and Technology, Keio University, Japan
*corresponding author: takasumi@elec.keio.ac.jp

Abstract: We introduce a compact, cost-effective silicon photonic crystal spectrometer with unparalleled resolution (0.01 nm for single, <0.03 nm for multiple wavelengths), leveraging a chirped waveguide for enhanced precision.

Advancements in photonic nanostructures have led to more efficient devices. We have developed a small (740×9 μm^2) silicon (Si) photonic crystal spectrometer that greatly exceeds traditional resolution limits by employing a chirped waveguide that enhances resolution through light scattering and random localization. The need for such compact, cost-effective, high-resolution spectrometers is growing, particularly in optical communications and smart manufacturing. Traditional, larger spectrometers face a size versus resolution trade-off that our approach overcomes. By capitalizing on nanophotonic technologies and the inherent randomness in photonic crystal structures, we bypass common fabrication precision issues, offering a significantly miniaturized spectrometer without sacrificing performance, thus providing a novel solution to a longstanding challenge in photonics.

The core of our spectrometer design is a chirped Si photonic crystal (PhC) waveguide, which narrows as light moves through it, with a total size of 740×9 μm^2. The PhC has a constant lattice spacing of 420 nm and a hole diameter of 262.3 nm. The Si slab is 220 nm thick and clad by SiO_2. This waveguide begins wider than standard (W1.05) and tapers slightly narrower (W0.99), creating a chirped structure. This design causes light of certain wavelengths to scatter at specific locations, determined by the waveguide's narrowing mode gap frequencies. However, due to fabrication limits, this tapering happens in 2 nm increments, leading to an essential design resolution of 1.6 nm at telecom wavelengths, which may not meet all application needs.

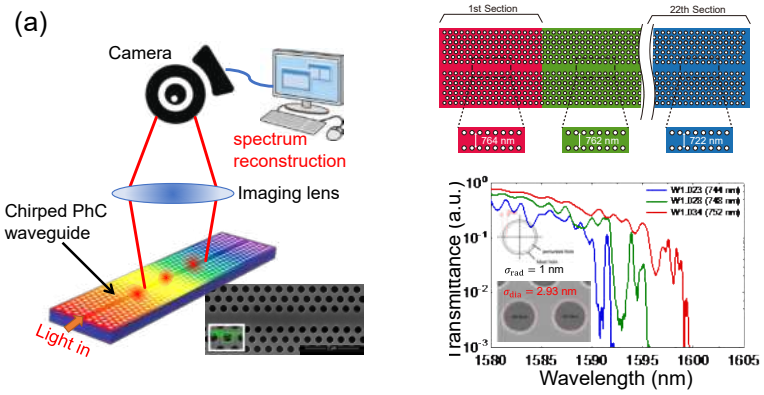

Fig. 1: (a) Experimental setup. (b) Device structure (chirped PhC waveguide). (c) Transmittance spectrum of PhC waveguides with different widths containing randomness.

To overcome this, we leverage natural randomness in the fabrication process, where slight variations in the air holes' positions, diameters, and shapes induce random light trapping (Anderson localization). This randomness produces high-quality (Q) resonances, allowing us to detect slight wavelength differences. We use

this inherent structural variability to enhance resolution beyond the 2 nm design limit, effectively using randomness as a tool rather than a hindrance. Calibration is crucial due to the variability introduced by this randomness, necessitating a detailed database of localization patterns for different wavelengths. This calibration process is similar to that of conventional spectrometers but exploits the unique properties of our design to achieve superior resolution.

Our experimental setup involved designing and fabricating a device using standard Si photonics processes. We first measured the transmittance spectrum across various waveguide widths, confirming the expected mode gap shifts and observing resonant peaks with quality factors ranging from 10^4 to 10^5. We captured light localization patterns at different single wavelengths using an IR camera, showcasing the device's ability to resolve wavelengths with high precision.

We developed a calibration process for single wavelength reconstruction by scanning across a wavelength range and recording IR camera images. It generated a calibration matrix to reconstruct the input spectrum from observed light patterns. Employing a cost minimization algorithm, including the Fast Iterative Shrinkage-Thresholding Algorithm (FISTA), allowed us to achieve a wavelength accuracy of ±0.01 nm, surpassing the design resolution of 1.6 nm. Our results demonstrate high precision over a broad bandwidth, with a significant portion of measurements falling within this narrow error margin.

We also explored multi-wavelength reconstruction, assuming the superposition of intensity patterns for inputs of different wavelengths. We confirmed through experimental and simulation validations that our device and reconstruction algorithms can accurately decipher multi-wavelength information, even distinguishing wavelengths separated by as little as 0.01 nm with a modest error. This capability extends to reconstructing continuous spectra, highlighting the device's versatility and high resolution in practical applications.

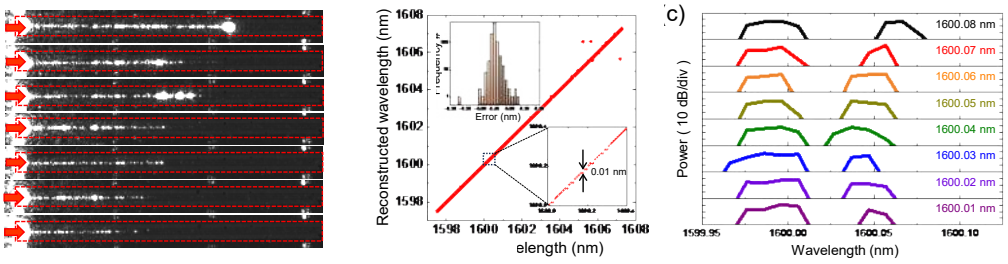

Fig. 2: (a) IR camera image taken from the top of the slab when a single wavelength laser is input from the left. (b) Reconstructed wavelength for single input wavelength with our device. The wavelength accuracy is 0.01 nm. (c) Reconstructed spectra for multi-wavelength input. One wavelength is fixed at 1600.00 nm, and the other is scanned from 1600.01 to 1600.08 nm.

In summary, our compact spectrometer demonstrates exceptional wavelength accuracy of ±0.01 nm for single-wavelength inputs and a resolution of 0.03 nm for multi-wavelength inputs within a minimal footprint. The innovation of leveraging inherent structural randomness and a precisely engineered chirped structure surpasses the anticipated resolution limit of 1.6 nm. This approach challenges the traditional view of fabrication errors as obstacles and showcases a method to exploit these variances to enhance device performance. This breakthrough offers promising directions for advancing nanophotonic devices, suggesting new strategies for improving precision and efficiency in photonics technology.

Controlling the radiation space and wavelength with MIM metasurface in mid infrared wavelength

Abstract: We have realized the thermal radiation control of MIM metasurface using the concept of metalens. The reflection phase was obtained FDTD simulation and fabricated the metasurface by electron beam lithography. The focal spot of thermal radiation can be seen with desired focal point.

1. Introduction

The absorption metasurface, consisting of Metal – Insulator – Metal nanostructures (MIM), has a unique optical property. The bottom metal film layer prohibits light transmission; The incident light is strongly localized in the insulator layer and absorbed by the MIM metasurface. At the same time, due to Kirchhoff's law of thermal radiation, which indicates the equivalence of absorption and emission efficiency, the absorption metasurface became the thermal radiation metasurface. We have developed MIM metasurfaces as mid-infrared light sources and other sensing applications [1-7]. Due to these optical properties, MIM metasurface is focused as the mid-infrared light source for infrared optical sensors. However, the thermal radiation pattern for far-field from the conventional radiative metasurface is spread out over approximately 120 degrees. This will lose the amount of light that is taken into the detectors. To resolve this problem, we tried to realize the thermal radiation control without a lens and the other optical components, based on the metalen technology.

2. Experiments

2-1. FDTD simulations for design of metasurface

The design of the metasurface was optimized using FDTD (Finite differential time domain) simulation with commercial software (Ansys Lumerical FDTD solver). The components of MIM structures were set with gold-SiO2-gold nanodisk; all permittivity was set to Palik's data. The thickness of the gold film was 200 nm, SiO2 was 150 nm, and a gold nanodisk thickness was 50 nm. In addition, The radius of the gold nanodisk was adjusted from 0.5 μm to 1.3 μm, and the period of the simulation region was set to 3 μm with periodic boundary conditions. The phase of optical reflection at the desired wavelength was monitored with a power monitor, which was put above the plane wave light source. There is no way to calculate thermal radiation directly using the FDTD method. Therefore, in this study, we have designed a total metasurface based on the phase of reflection light.

2-2. Fabrication of metasurface

Metasurface fabrication using electron beam lithography was performed as described elsewhere in more detail based on a previous report. In short, 5 nm Cr and 200 nm Au were thermal deposited on a silicon substrate first. After depositing 5 nm Cr, a set of samples with SiO2 layers from 100 nm to 500 nm (with a 100 nm step)
were deposited by electron-beam (EB) evaporation. After, an electron beam lithography (EBL) resist was spin-coated, and EBL exposure was performed to define the top-layer metallic nanostructures. After

development, Cr 5 nm and various metals were deposited, and lift-off followed.

2-3. Experimental setup for thermal radiation pattern

Micro spectroscopy was used for spectral characterization of meta-surface MIM structures, which had a footprint with a 300 mm cross-section. A Fourier transform infrared (FT-IR) spectrometer and a microscope unit (FTIR-6000 and IRT-1000, JASCCO) were used to measure the reflection spectra in the mid-infrared region. Film of Au of 350 nm thickness was used for the reflection reference, with 98% reflectance in the entire mid-infrared area. Thermal radiation was measured using the FTIR system. Compact FTIR (ARCOptix) was connected to collimation mirrors and reflection objective lenses. The sample was set on the piezo heater and in the x, y, and z tri-axial stages.

3. Results and discussions

The metasurface was fabricated with the uniform disk, f = 5 mm, f = 7.5 mm, and f = 10 mm setting with a 5 mm total disk area. From the reflection spectra, absorption peaks have appeared around 5 mm. The uniform metasurface was set to minimize the reflection at 5 mm. Due to the different sizes of disks, the focusing metasurface has lower absorption compared to the uniform disk metasurface. The thermal radiation results show apparently focusing features in the designed focal length except for the uniform wavelength.

4. Conclusions

We first reported controlling the thermal radiation of the MIM metasurface using the metalens concept. The FDTD simulation results successfully controlled the focal spot. This means that the reflection phase should have a high correlation with that of the phase of thermal radiation. The performance of the metasurface is not completely optimized, but the directional control radiation should be applied to the mid-infrared sensors, energy harvesting, radiation cooling, and so on.

Abstract: We investigate transmission properties via sharp bends of various triangular- and square-lattice photonic-crystal waveguides including valley-photonic waveguides, and have found that high transmission appears for some type of bands and interface configurations, irrespective of the inversion symmetry. This phenomenon is governed by bright circularly-polarized singular points around the bending interface.

The bending loss is one of the troublesome issues for nanophotonic integrated circuits, especially for photonic crystal waveguides. Concerning this issue, valley photonics has attracted much attention because many reports showed that one can achieve broad-band high transmission via sharp bends in valley-photonic waveguides without any local modification around the bending corners. Since the back reflection would be suppressed in valley-photonic waveguides when the valley spin is preserved, this property has been regarded as the result of the valley properties. However, it is not clear whether the valley spin could be really preserved at the bending corners.

In this study, we investigate a systematic model structure for 120-degree bends based on a triangular-lattice air-hole photonic crystal slab shown in Fig. 1, which covers various types of interfaces with and without the inversion symmetry by varying the shifting parameter *S* and the hole shape. This model represents various valley-photonic waveguides with broken inversion symmetry and their counter-parts having the inversion symmetry. We confirmed that this model structure shows nontrivial Berry curvature when the inversion symmetry is broken, and thus should have valley properties. As a result of numerical electromagnetic simulations, we found that broad-band high bend transmission appears for a certain value of *S*. An important finding is that the appearance of the high bend transmission is solely determined by the shifting parameter S and does NOT depend on the existence of the inversion symmetry.

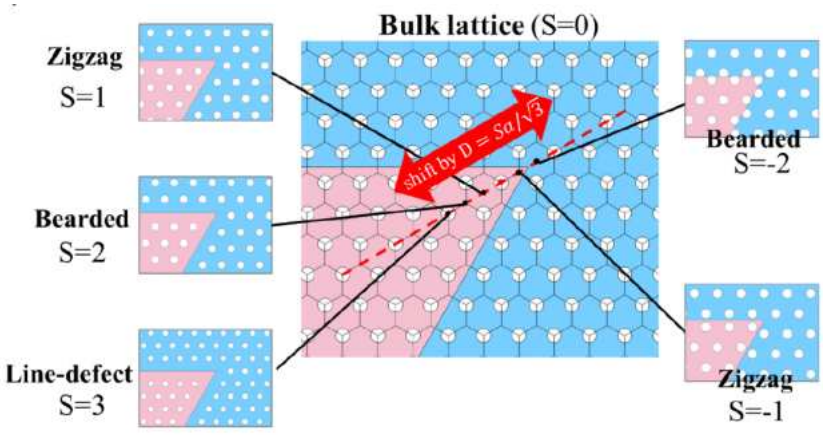

Fig. 1. Structure model for 120-degree bends in triangular-lattice photonic crystal waveguides.

Previously, it has been reported that glide-symmetric valley photonic waveguides show sharp bend transmission contrast across the degeneracy

point at the Brillouin zone boundary, which was argued as the valley property of each band[1]. In our simulation, we have observed similar high transmission contrast in our model structures when the structure has a glide-symmetry. Interestingly, this property also does NOT depend on the existence of the inversion symmetry. Since the essence of the valley properties arises from the existence of the inversion symmetry, the present result indicates that high transmission does not originate from the valley properties. We performed optical transmission measurements for the proposed model with various parameter S fabricated in Si photonic crystal slabs, and confirmed that the experiment shows essentially the same results.

Next, we investigate 90-degree bends of square-lattice photonic crystal waveguides with a glide symmetry shown in Fig. 2. Similar to the cases of glide-symmetric triangular lattices, the existence of the degeneracy point in square lattices is protected by the glide symmetry. Our numerical studies have shown that this structure shows a very similar high bending transmission contrast across the degeneracy point. It would be worth noting that this square-lattice waveguide posses the inversion symmetry and does not have valley properties at all.

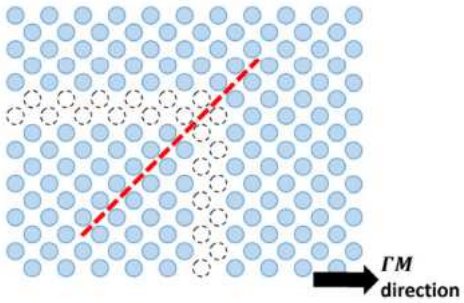

Fig. 2. Structure model for 90-degree bends in square-lattice photonic crystals.

In summary, we have theoretically and experimentally confirmed that broad-band high bend transmission, including interesting transmission contrast across the degeneracy point, appears in a wide range of configurations, irrespective to the existence of the inversion symmetry[2,3]. Concerning the physical mechanism of the high transmission, we found that the bending transmission is highly affected by the circularly-polarized topological singular points. In both cases for triangular- and square-lattice photonic crystal waveguides, we found that high bend transmission appears when the bright circularly-polarized topological singular points exist around the bending interface. We discuss more in detail about the effect of circularly-polarized singular points in the conference.

Abstract: We introduce attosecond transmission electron microscopy as a method to probe the electromagnetic near-fields of nanostructures in space and time.

Introduction. When light strikes a material, the initial interaction involves the reaction of the material's bound or free electrons to the light wave's rapidly changing electric field cycles. This movement is influenced by the material's atomic and nanoscale structure and properties, which act as a restoring force. Consequently, the behavior of materials on extremely small and fast spatial and temporal scales plays a crucial role in determining their macroscopic properties. Gaining insights into and manipulating the motion of electrons at scales smaller than a light cycle period and wavelength—specifically, attoseconds and nanometers—are critical for advancements in modern optics and nanophotonics. However, progress in these areas significantly depends on our capacity to observe and quantify the electromagnetic aspect of material responses over space and time.

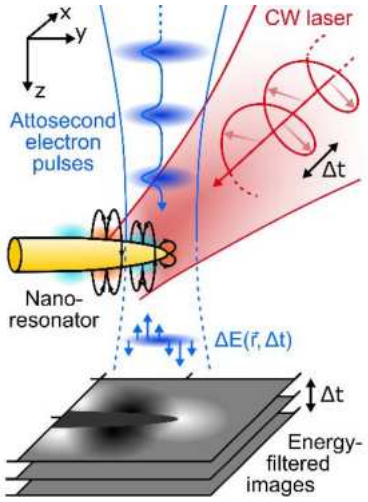

Fig. 1. Attosecond electron microscopy. A continuous-wave laser (red) with tailored polarization excites a nanophotonic material (yellow). Attosecond electron pulses (blue) probe the time-frozen electric fields as a function of space ($\vec{r}$) and delay time (Δt). Light-cycle contrast appears via spatiotemporal electron energy changes $\Delta E(\vec{r}, \Delta t)$.

Methods. Here we present the advancement of transmission electron microscopy to achieve attosecond temporal resolution, thus enabling the visualization of optical field oscillations on their fundamental dimensions [1]. We use a continuous-wave laser with 1064 nm wavelength to periodically speed up and slow down the electron beam in a transmission electron microscope. This process creates high-contrast attosecond pulses (Figure 1, illustrated in blue). The sample under investigation, such as a nanophotonic resonator (depicted in yellow), is excited by the same continuous-wave laser (shown in red). The electron pulses used for probing (blue), which are synchronized with the laser phase and have sub-cycle duration, allow the local electromagnetic fields within and around the sample (shown in orange/cyan) to seem virtually static. Depending on the spatial location $\vec{r}$ and arrival time Δt with respect to the light cycle, the electron wave packets experience a gain or loss of kinetic energy $\Delta E(\vec{r}, t)$ by travelling through the electric fields around the nanoresonator. The energy change is captured by a CMOS-based camera system equipped with a post-column energy filter. By varying the time delay Δt we can create a dynamic, spatio-temporal movie that showcases the near-field response of the sample in both real space and time, at the attosecond and nanometer scale.

Results. We explored using helical light to influence the spatiotemporal chirality of near fields around a plasmonic needle tip, modified with a slit at the apex using a focused ion beam (Fig. 2a). The circularly polarized laser targeted the needle asymmetrically at 45° angles, generating distinct plasmonic field cycles along the needle. As

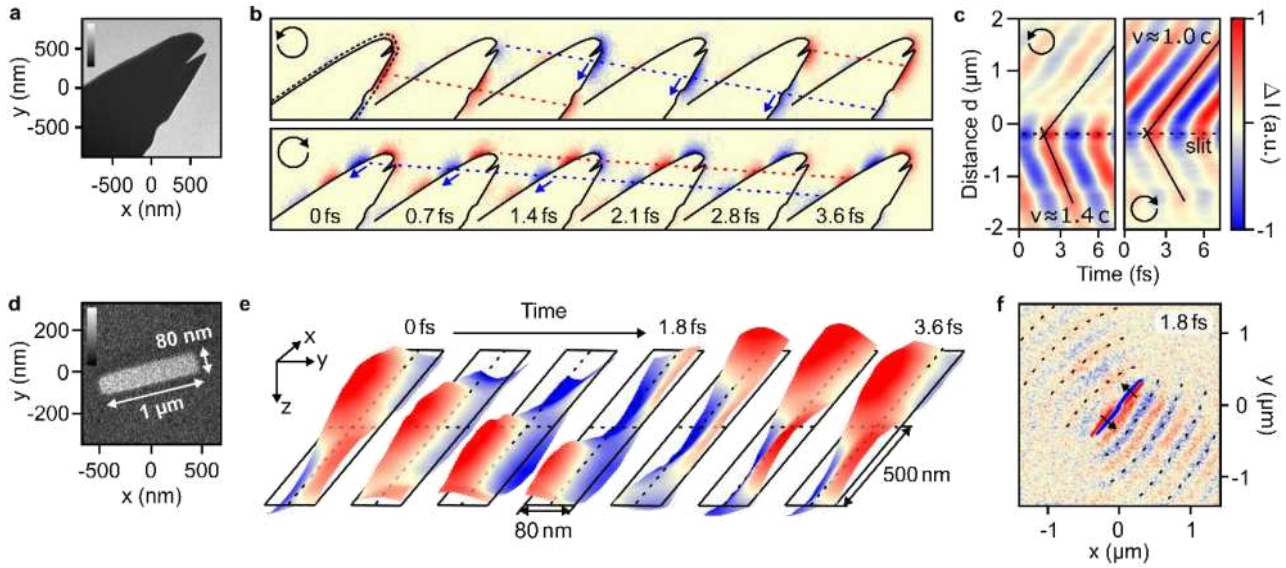

Fig. 2. Dynamics of the electric fields in nanoresonators. a, Image of the modified tungsten nanotip. **b,** Time-resolved electron energy changes for left-circular (upper panel) and right-circular excitation light (lower panel). The dashed lines and arrows visualize the propagation dynamics of the positive (red) and negative (blue) field cycles. **c,** Measured electron energy gain along the surface of the nanotip (dashed black line of Fig. 2b) as a function of time and distance from the tip. Dashed line, location of the nanoslit; black lines, phase velocities. **d,** Image of the slit resonator, milled into a freestanding 200-nm thick silicon membrane. **e,** Measured electron energy changes as a function of space and time. **f,** A snapshot at t = 1.8 fs shows the re-radiation of the nanoresonator into the membrane material. The black dashed lines highlight the propagating wave front of the buried field cycles.

shown in the dynamic snapshots (Fig. 2b), the plasmonic fields move from the needle's cut to its shaft with varying periodicity and phase velocity, depending on the circular polarization direction. The dynamics were directional, favoring the needle's upper side for left-handed polarization and the lower side for right-handed polarization, which we ascribe to a dynamic electron-surfing effect. Analysis of electron energy changes around the needle (Fig. 2c) revealed phase velocities of (1.4±0.1) c on the right/lower side and (1.0±0.1) c on the left/upper side, attributable to the interplay between the needle's plasmon polariton wave and the excitation wave. The interaction creates a superluminal phase velocity on the laser-facing side and a subluminal velocity on the opposite side. In a second experiment, we examined the spatiotemporal behavior of dielectric nanoresonators in a 200-nm thick silicon membrane (Fig. 2d) with dimensions tailored to the laser wavelength, allowing for formation of higher-order modes. The laser's 45° azimuthal angle and parallel polarization to the resonator's short axis allowed us to observe temporal shifts between quadrupolar and dipolar field distributions, indicating the interaction of phase-shifted modes (Fig. 2e). Notably, the guided waves' complex re-radiation pattern, trapped by silicon's high refractive index, was visualized using light-cycle contrast microscopy (Fig. 2f), highlighting its capability to also reveal internal field dynamics within materials.

Summary. In summary, our experiments demonstrate that attosecond transmission electron microscopy offers a powerful and non-invasive technique for capturing the intricate dynamics of light-matter interactions on a fundamental spatial and temporal scale, holding significant promise for pushing the boundaries of modern optics and nanophotonics into new areas of application.

Abstract: Transparent conductive oxides (TCOs) are often exploited as active optical materials in field-effect configuration. Voltage-driven charge accumulation/ depletion in TCOs allows to tune their optical response. We report an in-operando investigation of TCOs under field effect, exploiting spectroscopic ellipsometry and optical modelling to reconstruct the charge-density profile within the materials.

Active photonics materials are capable of changing their optical properties in response to an external stimulus. In this category, transparent conductive oxides (TCOs) are active optical materials often exploited within field-effect devices, where the voltage-induced charge accumulation or depletion is the physical effect leading to the desired modification of the optical response. In order to understand the role of active photonic materials within devices, it is paramount to assess the microscopic characteristics of the charge-injection/depletion spatial profile. This allows, in turn, to reconstruct the spatial gradients of dielectric function and, ultimately, model and predict the optical response of the active photonic devices.

In this contribution we report an in-operando spectroscopic-ellipsometry (SE) investigation of various active photonic devices under variable applied voltage. The devices under scrutiny are in the form of planar capacitors, with the TCO acting as one of the electrodes. Thanks to a careful modelling of the spatial grading of the optical response of the systems under applied bias, we are able to reconstruct the charge injection/depletion profile within the TCO at the TCO/dielectric interface, and model the corresponding spatial gradient of the dielectric functions.

In Figure 1 we report the data relative to a system based on Al-doped ZnO (AZO). AZO films ≈70 nm thick were grown on STO (110) substrates with the aim of obtaining a large charge modulation. AZO thin films were deposited by pulsed laser ablation (PLD) on 110-oriented 500 μm thick STO. The aluminum content was nominally 0.1%. The STO substrate is an insulating centrosymmetric paraelectric material with a perovskite structure. It exhibits a very large DC permittivity constant, reading ~22000 at 4.2 K. An Ag backgate was realized at the back of the STO. Spectroscopic ellipsometry (SE) experiments were conducted by means of a J.A. Woollam V-VASE ellipsometer. The AZO/STO was mounted in a cryostat with optical viewports (Oxford Instruments Optistat CF-V) at a temperature of 4.2 K (spectral range 0.7−3.2 Ev). The variations of the optical response of the AZO films were investigated by applying an electric field of 2 kV/cm across the STO substrate. The top left and bottom left panels report the ellipsometry spectra $\Psi(\lambda)$ and $\Delta(\lambda)$ (lines) and the respective variations upon applied voltage (symbols).

Upon application of the external voltage, charge is accumulated in the TCO, with areal density:

$$\sigma_e = \frac{\varepsilon_r \varepsilon_0 V_g}{d} \qquad (1)$$

and decay constant λ_D. Here ε_r is the DC dielectric constant of STO, V_g is the applied voltage and d is the STO thickness. In the bottom right panel of Figure 1, we show the experimental data related to the voltage-induced Ψ variation (symbols), along with theoretically-calculated spectra (lines). The theoretical values correspond to different values of spatial decay constants λ_D for the injected/depleted charge inside the TCO, starting from the TCO/dielectric interface. The black line corresponds to uniform charge distribution within the TCO, and clearly does not agree with the experimental data. Varying λ_D (coloured lines) it is possible to optimize the agreement with the experimental data, finding the best value for λ_D =2 nm (green line), that corresponds to the physical decay constant of the injected/depleted charge profile within the TCO [1].

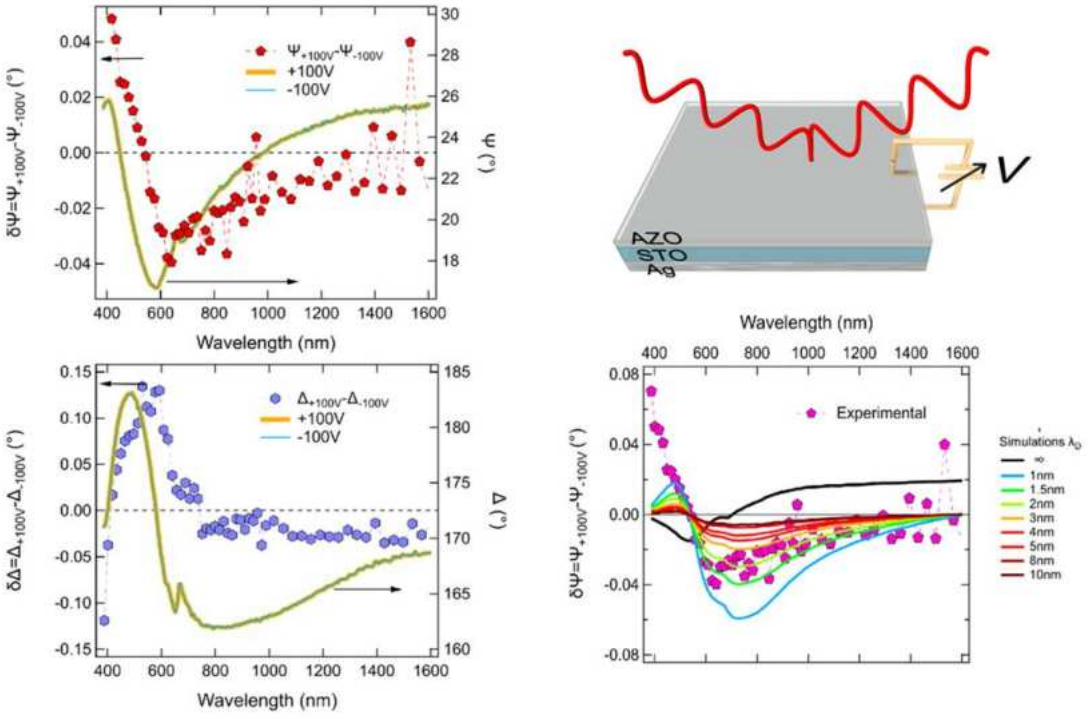

Figure 1: spectroscopic ellipsometry characterization of the AZO/STO/Ag system.

This analysis shows that it is possible to reconstruct the spatial charge profile at buried TCO/dielectric interfaces within active-photonic devices modulated by field effect. This result paves the way for the optimization of the optical response of TCOs in active materials and metamaterials.

Ge-Sb-Te material for applications in photonics

M. V. Rybin[1,2]

Abstract: Phase change materials including Ge-Sb-Te (GST) are under extensive studies for applications in photonics. Here is a brief review of recent works reported by our team in this topic: modification of radiation properties, fabrication of GST samples by lithography and other techniques, and study of single GST particle resonators.

During the last decades an intensive research was focused to artificial photonic media, starting from photonic crystals to metamaterial and metasurface-based structures. Advanced photonics exhibited many novel phenomena and photonic-based devices that promise application of the unique properties. One of the important functionality is a reversible post-fabrication modification of the optical response. To this end, nonlinear techniques allow going to the ultrafast but tiny modification of the refractive index [1]. Stronger effects can be achieved by using thermal heating of materials with a phase transition for example vanadium dioxide. However for both of these approaches, the photonic structure retreats to its initial state right almost after the external treatment ceasing.

Recently non-volatile phase change materials (PCM) attracted a remarkable attention of photonic community, because PCM have two metastable phases, which coexist at the normal conditions, but their optical and electric properties are dramatically changed [2]. The three-component Ge, Sb, Te material (GST) is one of the most studied PCM in the context of its application regarding to the electronic devices such as the solid-state memory. The integration of novel materials into photonic structures demands a bunch of conceptual, technological and engineering problems to be solved, i.e. we have to deliver answers to the questions including: Where to place PCM in the photonic structure? How to fabricate the samples? Which additional opportunities do provide the using of PCM? Here I report on our recent research on reversible non-volatile switched photonic based on GST material.

The stoichiometric composition $Ge_2Sb_2Te_5$ has a notably high dielectric index, which is about 15 in visible range and over 35 in the near-infrared telecommunication bands for the crystalline state. The phase change leads to modification of dielectric environment of an emitting center located nearby. So the GST provides unique opportunity to change the photoluminescent properties of a quantum emitter through Purcell effect. We studied the modification of halide perovskite photoluminescence affected by a sublayer of GST, which state was changed by optical means [3]. Another interesting point is the generation of the high-order harmonics by GST itself and its peculiarities on the crystalline and amorphous state [4]. The physics of high-harmonics is completely different from the second and third harmonic generation one. Unlike the latter appearing due to non-harmonic perturbation of the atomic potential, the former is caused by the Bloch currents of carriers in the conductive bands. The fundamental question whether high-harmonics are possible in GST had no evident answer in general and our experimental studies shed the light on it.

Next problem was to fabricate metasurfaces made of GST by a lithography method. We designed an array of

GST rods with rectangular cross-section supporting magnetic dipole mode. This structure has a strong reflection modulation in the telecommunication bands. Then we fabricated the metasurface and examined its properties in experiment, which shows a good agreement with the prediction of the numerical simulation [5].

2.5D metasurfaces has additional degree of freedom in the third dimension. They provide more flexibility for design and adjusting resonance spectral positions. However, they are hardly to be produce by lithography. We used two-photon polymerization to fabricate two lattices of low-index posts with different height. On the second step GST was electro dispersed onto the polymer matrix forming 2.5D metasurface comprising GST nanoparticles at the top of the posts. We examined the response of the metasurface in dependence on GST state by varying the post height difference. In the amorphous GST state, a Mie-type resonance in nanoparticles was tuned to the lattice resonance leading to the electromagnetically induced transparency effect. For the crystalline state of GST, the lattice resonance position was kept, while the Mie resonances were detuned. As a result, we observed an on/off switching in the response of the 2.5D metasurface [6].

Photonic systems including optical antennas require single elements. So we aimed to fabricate and study single GST nanoparticle. We used laser-induced forward transfer technique to produce GST nanospheres by an ablation from the GST thin film on the donor substrate and the nanoparticles were received on the acceptor substrate. The properties of GST nanoparticle were examined by TEM imaging, Raman spectroscopy, and second harmonic generation methods. Also we demonstrated several cycles of reversible GST state switching in single nanoparticles by optical means. The response was controlled by dark-field scattering measurements [7].

To sum up, the integration of GST into meta-optical structures has a great potential for discovering novel fundamental effects. Also, GST has many interesting applications in photonics.

Abstract: We present the systematic design of cylindrical metasurfaces that provide the designer wavefront for the ultrahigh field brain MRI. We achieve substantially improved B_1^+ whole brain homogeneity, implying the solution for the issue which has persisted in the past 20 years.

The ultrahigh field (UHF) brain MRI with static magnetic field B_0 over 7T is widely used in the diagnostics of Alzheimer, Parkinson disease, and multiple sclerosis lesions [1]. However, in the UHF MRI regime, the wavelength of the B_1^+ field in the tissue becomes smaller than the human head, leading to the B_1^+ inhomogeneity arising from the modal interference. As B_1^+ field homogenization is essential for high signal-to-noise ratio and uniform imaging contrast, the active parallel RF transmission approach [2] and the passive method based on high permittivity materials [3] have been suggested for the mitigation of B_1^+ inhomogeneity. However, the mesoscopic nature of the participating elements in UHF MRI hindered sufficient *volume* homogenization so far [2-4]. Here, we tackle this problem by systematically controlling the scattering patterns. The solution is confirmed with the full-wave analysis utilizing realistic human models. Our technique constitutes the successful solid approach for the homogenization problem, which has been persistent in the past 20 years. In the talk, the application of metasurfaces will be discussed.

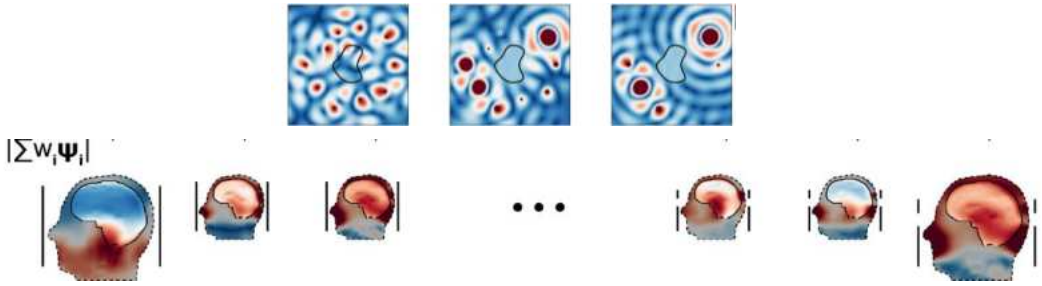

Figure 1. Top. The proposed concept, showing the evolution of scatterer-based field homogenization. Bottom: The B_1^+ field evolution in the brain, obtained from the optimization process.

Abstract: Spatial control of atoms with subwavelength accuracy is a crucial tool for quantum computing and quantum simulations. Using superoscillatory structured light we plan on extending the recent work on single atom subwavelength trapping to few atoms superoscillatory tweezer arrays, where trap sizes and interdistances is dynamically tuned below diffraction limit.

Tweezer arrays of neutral atoms are a strong candidate for making a viable quantum computer. They however require the loading and rearrangement of individual atoms in the register at the beginning of each computing cycle. After rearranging the atoms in the array, the individual qubits -encoded into the atom electronic state- can be addressed selectively via shining a laser onto them to perform the different gates required. The duration of a single computing cycle is then limited by 1) the initial random loading, 2) the rearrangement and 3) the sequence of quantum gates. State-of-the art neutral atoms arrays use high numerical aperture lenses in vacuum to minimize the lattice parameter [1], effectively reducing the time for rearranging and increasing the qubit-qubit coupling, i.e. reducing the laser power and duration required for the gates. It is thus important to continue looking for smaller lattice parameters to relief constraints on the laser system during the rearrangement and computing steps. This idea is also present in quantum simulation with neutral atoms, where one wishes to control the relative strength between tunneling and interaction in a generic Hamiltonian. Having a dynamically tunable lattice parameter for such a system is also very exciting and promise to reveal more of the phase diagram.

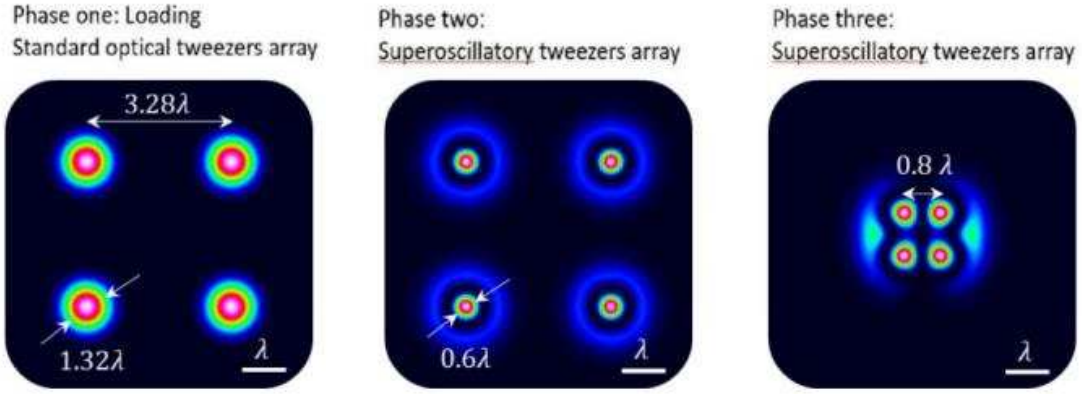

Figure 1 Three-steps loading of four site tweezer array and subsequent transfer to subwavelength trap size and interdistances. Steps are quasi-adiabatically connected using spatial light modulators.

We have previously demonstrated the trapping of a single atom in a sub-wavelength superoscillatory tweezer [2]. Our next objective is to extend this concept to few atoms (2 to 4) and demonstrate the loading and deterministic rearrangement of a superoscillatory tweezer array of a few sub-Doppler cooled thermal atoms. Fig.1 shows such the loading sequence, where initially 4 atoms are loaded in a standard tweezer array then transferred *in situ* in the superoscillatory array and finally brought closer to each other at subwavelength distances. By controlling the relative intensity of the tweezers and lowering the central potential barrier, we can classically, *i.e.* thermally rearrange the atoms.

Another level of control is eventually attainable by cooling the atoms to the fundamental state of the tweezer potential and control dynamically the tunneling between tweezers. This requires a precise control of the relative intensity and relative distance between individual sites to fulfil the resonant tunneling condition.

Epsilon-Near-Zero Regime in the Infrared for Ultrafast Switching

C. S. Davies[1*] and A. Kirilyuk[1]

[1] HFML-FELIX, Radboud University, Nijmegen, The Netherlands
[*]corresponding author: carl.davies@ru.nl

Abstract: Using narrow-band infrared pulses tailored to entirely fit the epsilon-near-zero regime, we experimentally find that the magnetization in iron-garnet films and the polarization in ferroelectric barium titanate can be permanently reversed. This offers a novel strategy for the ultrafast switching of spontaneous magnetization and polarization.

Ultrashort pulses of light can serve as fascinating multi-faceted instruments for the coherent and efficient manipulation of spontaneous order parameters. By sculpting the many attributes of light-wave pulses, such as their frequency, polarization, duration, peak amplitude and so on, and also the optical properties of the irradiated medium, it is possible to substantially strengthen the coupling between light and matter. Groundbreaking works in the research field of non-linear phononics have, across the last two decades, powerfully demonstrated that high-frequency lattice vibrations, when driven to high amplitude by mid- to far-infrared (IR) optical pulses, can temporarily modify a variety of spontaneous orderings [1]. This approach revolves around the excitation of IR-active transverse optical (TO) phonon modes, which are marked by poles in the imaginary part of the permittivity.

Here, we discuss an alternative strategy in which the optical pulses are instead tailored to match the frequency of longitudinal optical (LO) phonons, i.e., the frequency at which the real part of the medium's permittivity goes to zero. Specifically, using narrow-band IR optical pulses delivered by the free-electron laser facility FELIX with frequency ranging between 6 THz and 30 THz (wavelength 10-50 μm) [2], we irradiate ferrimagnetic iron-garnet films [3], antiferromagnetic nickel-oxide films [4] and ferroelectric crystals of barium titanate [5]. We consistently find that the strongest impact is obtained when the frequency of the optical pulse matches not that of the strongly-absorbing TO phonon modes but rather that of the LO phonon modes (Fig. 1). We note that these materials have very dissimilar crystal symmetries, causing the phonon modes in all these systems to have very different character. Moreover, the LO phonon modes are equivalent to longitudinal electromagnetic waves, so they cannot even be directly excited by the impinging light.

To therefore explain these results, we draw attention to the fact that the spectral position of the LO phonon mode actually corresponds to the frequency at which the material's permittivity goes to zero [6]-[7]. In this so-called epsilon-near-zero (ENZ) regime, the attributes of light-matter interaction become highly counter-intuitive. For example, in barium titanate, we estimate that the wavelength of the penetrating optical pulse stretches by a factor of two, and its group velocity diminishes by almost a factor of forty. Moreover, the light-matter interaction becomes strongly amplified. Our results highlight the importance of the ENZ regime for ultrafast switching of spontaneous order parameters [8]. Moreover, the fact that ENZ conditions often organically emerge in the infrared spectral range suggests that the demonstrated mechanism could be truly universal, capable of strengthening light-matter interaction and permanently switching order parameters in a wide variety of systems.

Abstract: We propose two novel designs of high contrast gratings (HCGs) composed of silicon grating bars: pedestal and half-buried HCG designs, and demonstrate that these designs exhibit improved bulk refractive index sensitivity and limit of detection (LoD) for myoglobin, in a concentration range relevant for clinical diagnostic applications.

Refractometric sensing has been used widely among other optical read-outs schemes for biosensing applications. High contrast gratings (HCGs) [1] or non-local metasurfaces [2,3] are grating structures made of high refractive index material like Si surrounded by a low refractive index matrix and they support guided-mode resonances localized around grating bars. HCGs have been used for biosensing applications by detecting resonance shifts induced by local refractive index change, which in turn is caused by the presence of the analyte in solution and by the binding of analyte molecules to the sensor surface [1].

Here, we report two novel HCG designs and their realization for biosensing applications, named ”pedestal” and ”half-buried” HCGs (Fig. 1(a)-(c)) [4-6]. The two HCG designs aim at increasing the overlap between hot spots of electric fields and analyte around the Si gratings as means to increase the wavelength shift of resonance. These HCG structures were fabricated by the combination of deep ultraviolet lithography and dry etch techniques. Pedestal HCGs were realized by controlled etching of silicon dioxide substrate below silicon grating bars with hydrogen fluoride in the vapor phase [5]. Half-buried HCGs were fabricated with a benzocyclobutene (BCB) polymer layer that partially fills the gaps between the silicon grating bars [6]. We performed optical characterization of sensing performance of the two designs to compare them to conventional HCG structures.

The bulk refractive index sensitivity of each type of grating is 409 nm/RIU, 482 nm/RIU, and 536 nm/RIU for the half-buried, conventional, and pedestal HCGs, respectively (Fig. 1(d)). To examine surface sensitivity, the conventional and pedestal HCGs were utilized for detection of the model analyte avidin with a limit of detection (LoD) of 3.2 ng/ml and 2.1 ng/ml. Finally, half-buried and pedestal HCGs were tested for myoglobin detection, yielding LoDs of 34.6 ng/ml and 37.3 ng/ml, respectively. This shows that the half-buried and pedestal HCGs exhibit gives enhanced sensitivity over conventional ones, being a potential platform for biosensing applications.

(d) Sensing platform	Q-factor	FOM [RIU^{-1}]	BRIS [nm/RIU]	Avidin detection LoD [ng/mL]	Avidin detection LoQ [ng/mL]	Myoglobin detection LoD [ng/mL]	Myoglobin detection LoQ [ng/mL]
Conventional HCG	1.3×10^3	438	482	3.2	213	-	-
Pedestal HCG	1.5×10^3	564	536	2.1	85	37.3	138
Half-buried HCG	1.1×10^3	293	409	-	-	34.6	102

Abstract: We explore strategies to harness the polariton-assisted nonlinear response and optoelectronic tunability of graphene to actively control quantum light emission and manipulate the quantum states of atomic systems.

Coherent control of light and atomic systems enables fundamental explorations of quantum physics while promising disruptive applications in diverse fields, ranging from information and communications technologies to optical sensing and metrology. In this context, the intrinsically strong and actively tunable light-matter interactions available in atomically thin materials such as graphene offer unique opportunities to trigger nonlinear and quantum optical phenomena on the nanoscale by invoking their supported polaritons and near field interaction with proximal quantum light emitters [1,2]. Here we propose to harness the optoelectronic properties of graphene to electrically control the coupling of light to nearby atoms. In particular, we investigate optically-driven two-level atomic systems exhibiting controllable bistability due to the self-interaction mediated by the graphene sheet. Our results indicate that the electro-optical bistability and hysteresis exhibited by the atom manifest in the intensity, spectrum, and quantum statistics of the light emitted by the atomic system. The optically-driven atom-graphene system thus constitutes a platform for active and *in situ* control over driven quantum optical systems for explorations in coherent quantum control and atomic physics.

Abstract: We study a microcavity-based photonic crystal formed by self-assembled uniformly lying helices of the embedded cholesteric liquid crystal. Applying an external voltage breaks the system's mirror symmetry inducing optical activity due to the inter-band interaction. This suggests a dynamically tunable way of controlling light polarization at the nanoscale.

Intrinsic properties of soft matter provide an accessible and versatile toolkit for photonic systems engineering [1]. In particular, tunability, self-assembly and remarkable optical characteristics of liquid crystals enriched the functionality of such optical devices as microcavities [2], giving rise to tunable photonic spin-orbit coupling [3], photonic persistent spin helix [4] and topological transitions [5].

Here, we study a planar optical microcavity filled with a cholesteric liquid crystal twisted around the axis parallel to the microcavity planes forming the so-called uniform lying helix (ULH) [6]. The ULH formation relies on the self-organization of liquid crystal molecules, which can be easily tuned by applying an external voltage. The cavity transforms photons into effective 2D free massive quasi-particles [7, 8]. In turn, the embedded ULH creates a polarization-dependent periodic potential felt by these quasi-particles resulting in the emergence of band gaps in the dispersion relation for one of the two possible linear polarizations. In this regime, the strong optical activity due to the cholesteric liquid crystal twist is suppressed inside the microcavity because of the mirrors restoring the inversion symmetry. However, if the molecules are tilted by applying an external voltage, the modes of different linear polarization couple, resulting in the emergence of optical activity. Strong anisotropy of liquid crystals promotes remarkable dynamic control over multiple parameters of the band structures, including the optical activity strength, band energies, and the width of the photonic band gap. Such tunability is challenging to achieve by alternative methods. Additionally, by introducing a dye within the microcavity, we demonstrate the capability of our platform to achieve the spin-polarized lasing. This level of control over band structure and spin-orbit coupling opens new avenues for light-matter interactions.

Lasing of gain-doped plasmonic nanoshells: Threshold, emission linewidth and giant pull-out effects

A. Aradian[1*], A. Cathey[2], K. Caicedo[3], M. Mora[3], M. Infusino[3], and A. Veltri[3]

Abstract: We present a model describing the lasing / spasing properties of a nanoshell made of a plasmonic metal, whose core is filled with a gain medium. We calculate the nonlinear lasing state above the threshold, demonstrating that the emission linewidth is dictated by unusually strong frequency pull-out effects.

Nanoscale structures combining together optical gain with plasmonic (or other) resonators have formed a thriving topic of research over the last two decades, starting with the 2003 hallmark article by Bergman and Stockman [1] on spasers. In particular, when the provided gain exceeds loss sources in the structure, a coupled phenomenon of "spasing" (coherent generation of plasmons) and "nanolasing" (emission of coherent photons from the nanostructure) emerges. Numerous experimental and theoretical works have followed on all flavors of nanolasers based on combinations of metals, semi-conductors, doped dielectrics made into various geometries (see for example the following review of the literature [2]).

One promising class of nanolasers are hybrid spherical nanoparticles, e.g. core-shell particles where the core is made of a metal and the shell is made of a gain medium, or nanoshell particles where, oppositely, the gain medium is in the core and the metal in the outside shell. We studied the optical response of both geometries using a simplified approach based on the quasi-static polarizability of the nanoparticle [3]. This allowed us to describe in a compact manner the behavior of the nanolaser under the lasing threshold (where it behaves like an optical amplifier of the probe field), and also to obtain the value of the lasing threshold. However, the lasing behavior itself could not be described using this approach, since it was a static one, hence intrinsically unable to treat the nonlinear time dynamics at play above the threshold. (This is, by the way, true as well for many spaser-related works in the literature, which rely on static dielectric permittivities).

In a different work [4], we studied the situation of a homogeneous metal nanosphere plunged into an unbounded gain medium (like a dye solution), this time using a much more realistic model, allowing both for temporal and spatial variations of the fields, where the population dynamics within the levels of the gain medium was described and coupled to the fields in the nanoparticle. This allowed to demonstrate analytically that when the gain in the system (provided by some external pumping) was sufficiently increased, the system underwent a *self-oscillation instability*, i.e., the nanoparticle would produce a non-zero field even if it was not excited by any probe field – which is one way to define the lasing threshold. We also showed that, as the instability grows, the system in this geometry inevitably triggers a cascade of multiple lasing modes. This cascade dramatically complexified the theoretical description and made the detailed study of the long-term lasing state of the system out of reach.

In the present work, we aimed at bridging these gaps by applying the same time-dependent model to the nanoshell geometry shown in Fig. 1(a). We show that the nanoshell system does *not* enter into a mode cascade

above the threshold, so that the dipolar lasing mode is the only one active above the threshold. We use optical Bloch equations to describe the dynamics of the gain medium within a two-level effective framework. This provides differential equations for the population inversion and the polarization inside the gain medium. The metal is described using a free-electron equation of motion. Taking into account the single-mode operation of the lasing state, boundary conditions are implemented accordingly at interfaces, with the caution that electrical permittivities cannot be used above the threshold due to the dynamical nature of the lasing state.

Similarly to the previously studied geometry of a homogeneous particle in a gain medium, we find the condition for the lasing threshold within our model as a self-oscillation, and show that it exactly matches the more intuitive approach used in [3]. Then, we solve the model equations above the threshold and find that, after a transient, the nanolaser reaches a steady state of emission where the intensity of the emitted field is kept constant, but the complex field amplitude is submitted to slow rotations in time, as shown in Figure 1(b). Such behavior is commonly known as a "frequency pull-out" effect in the field of classical lasers.

However, while pull-out effects are responsible for delicate shifts of laser frequencies in macroscopic lasers, we find that in the nanoshell laser, these effects are comparatively huge, so much so that they reshape the spectrum of emission [see Fig. 1(c)] and are ultimately responsible for defining the emission linewidth of the nanolaser. This novel finding is a strikingly different paradigm as compared to standard laser physics.

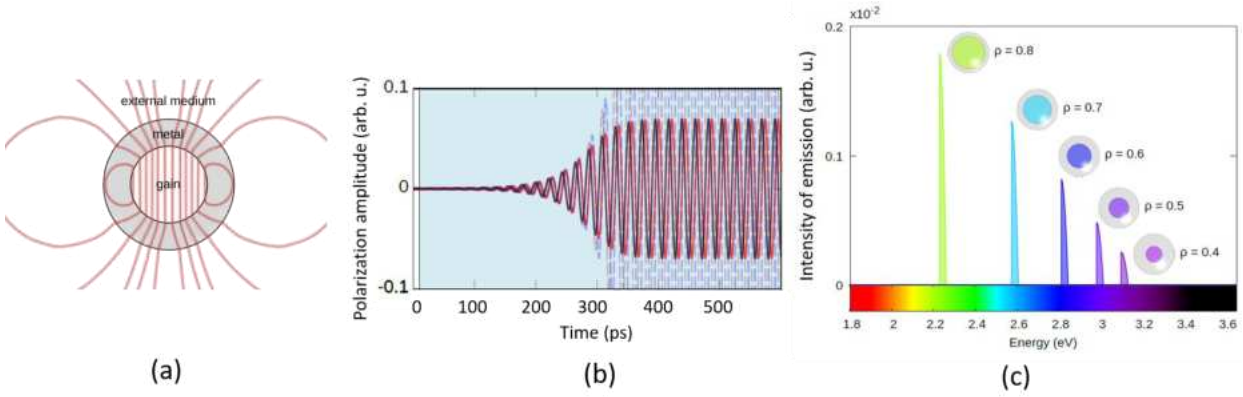

Figure 1. (a) Nanoshell schematics. (b) Transient growth and steady state (lasing) of a component of the polarization inside the gain medium. (c) Nanolaser emission spectrum for various aspect ratios of the nanoshell (left to right, from thinner to thicker shell).

Manipulating the Exotic Quasi-Particles of van der Waals Correlated Antiferromagnet

Han Htoon

Center for Integrated Nanotechnologies, Materials Physics and Applications Division,
Los Alamos National Laboratory, Los Alamos, NM 87547, USA
htoon@lanl.gov

Abstract: We report influences of material composition and lateral dimension on spin-correlated exciton and magnons of van der Waal correlated antiferromagnets MPX_3 (M = Mn, Fe, Ni; X = S, Se)

A Van der Waals correlated antiferromagnet, metal phosphorus trichalcogenides (MPX_3, M = Mn, Fe, Ni; X = S, Se), have emerged as promising candidates for next generation spintronics, and quantum information technologies. Nickel phosphorus trisulfide ($NiPS_3$) is a most notable member of this family and has been extensively studied for its unique properties, including the emergence of an ultra-sharp photoluminescence (PL) peak at ~1.476 eV below Néel temperature of 150 Kelvin. While the highly anisotropic, linearly polarized emission of this PL peak has been shown to be directly correlated to the long-range spin order of $NiPS_3$, its ultra-narrow linewidth of a few hundred μeV has led to the speculation that it is originated from a coherent many-body exciton state. Observations of multiple phonon bounds states and formation of exciton-polaritons also creates more excitement as they present new possibilities for design and control of correlated electron systems.

Aiming to achieve understanding and control of this spin-correlated exciton, we first conduct temperature dependent, polarization resolved, PL and Raman spectroscopy studies on compounds of $NiPS_3$ doped with different concentration of Mn ($Ni_{1-x}Mn_xPS_3$). We observed systematic variation in characteristics of the spin-correlated exciton revealing their sensitive dependence on disturbance in the magnetic order of $NiPS_3$. Notably, the sharp peak disappeared beyond x of 0.2 (Fig. 1a). Furthermore, we analyzed the polarization-resolved PL of $Ni_{1-x}Mn_xPS_3$ alloys. At 5 K, increase of Mn concentration leads to decrease in degree linear polarization. In parallel, Raman spectroscopy of $Ni_{1-x}Mn_xPS_3$ revealed the two magnon scattering peak, a key indicator of correlated antiferromagnetism in $NiPS_3$, exhibited a shift towards lower energies and suppression when x is increased from 0 to 0.2 (Fig. 1b). This correlates with our findings in the PL spectrum further underscores the pivotal role of Mn impurities in disrupting the AFM order of $NiPS_3$ system. This study unveils the interplay between impurity-induced disruption in spin structures and PL and Raman characteristics in $NiPS_3$, shedding light on their potential for future application.

Next to understand how the reduction in lateral size influence the spin-correlated exciton, we conducted single nano-flake PL spectroscopy on individual crystalline nanoflakes (NFs) of $NiPS_3$ that prepared by wet-chemical synthesis. Our study revealed that by reducing the lateral dimension of correlated antiferromagnet $NiPS_3$ flakes to tens of nanometers and thickness (Fig. 2a) to less than ten nanometers, we can switch-off the bulk spin-correlated exciton in at 1.47 eV and activate new, ultra sharp optical transition in visible-range (1.8 – 2.2 eV) (Fig.2 c). These ultra-sharp lines display resolution limited lineweidth of <120 μeV at 4.2 K share the spin-correlated nature of the bulk exciton by displaying a strong linear polarization below Néel temperature. Furthermore, exciton photoluminescence lineshape analysis reveals a polaronic character via coupling with at-least 3 phonon

modes and a comb-like Stark effect through discretization of charges in each layer. These findings augment the knowledge on the many-body nature of excitonic quasi-particles in correlated antiferromagnets and also establish the nanoscale correlated antiferromagnets as a promising platform for integrated magneto-optic devices.

Advanced Terahertz-Wave Phase and Polarization Control Devices Powered by Metasurfaces

Yuehong Xu[1*], **Hiroaki Minamide**[1]

[1]RIKEN Centre for Advanced Photonics, RIKEN, Japan

[*]corresponding author: yuehong.xu@riken.jp

Abstract: This work introduces several advanced terahertz-wave phase and polarization control devices powered by metasurfaces, integrating dynamic and geometric phase control. This spin-decoupled phase control method offers robust and flexible solutions for beam steering and polarization multiplexing.

Terahertz (THz) waves, nestled between microwaves and infrared, are prized for their unique electromagnetic properties, offering deep penetration and safe application across various fields such as non-destructive testing and communications. However, traditional THz phase and polarization control devices are bulky and limited in function, driving the need for innovative, lightweight, and versatile solutions. Advances in metasurface technology, particularly through the Pancharatnam-Berry (PB) phase control for circular polarization, have significantly improved phase modulation. Federico Capasso's team further revolutionized this field in 2017 by introducing a spin-decoupled phase modulation technique into metasurface in optical regime, enabling separate phase control for different circular polarizations and paving the way for more sophisticated meta-devices. Subsequent THz domain research has built upon this spin-decoupled phase modulation approach, spearheading a series of developments.

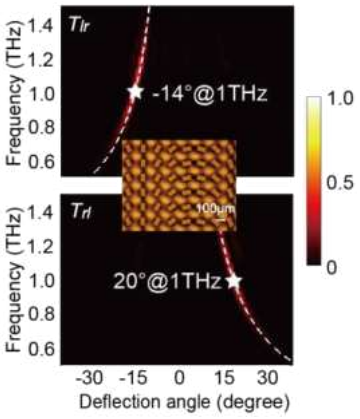

Figure 1. Experimental results of the THz asymmetric angle anomalous deflection device.

In 2019, Yuehong Xu et al leveraged the high efficiency and adaptable phase tuning of all-dielectric metasurfaces, in conjunction with the PB phase and dynamic phase, to unveil a spin-decoupled phase modulation technique in THz regime. The design method skillfully integrates both dynamic phase (φ_f) and PB phase ($\pm 2\alpha$) into a single structure, which consists of a high-resistance silicon pillar with half-wave plate property. This spin-decoupled phase control method enables independent control of the phase of left-handed (LCP) ($\varphi_{lr}=\varphi_f-2\alpha$) and right-handed (RCP) ($\varphi_{rl}=\varphi_f+2\alpha$) circularly polarized THz waves. Both the PB phase control and dynamic phase control can be achieved by rotating the pillar and altering its geometric parameters, respectively. This method breakouts the spin phase lock limitations inherent in PB phase-only control, facilitating the creation of several spin-dependent asymmetric angle anomalous deflection devices as shown in figure 1, as well as a suite of linear polarization (LP) -dependent dual-channel polarization converters. This design methodology offers insights for the generation of polarization beams and systems for polarization multiplexing in THz regime.

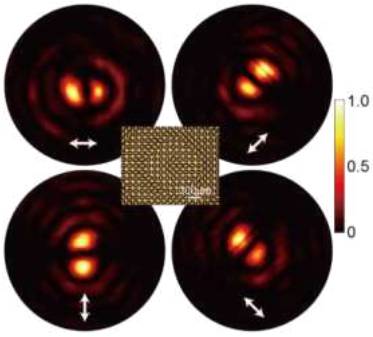

Figure 2. Experimental results of the radial polarization Bessel beam generator: Under *x*-linearly polarized incidence, the electric field distribution maps are detected in four linearly polarization directions.

In 2020, leveraging the same phase control strategy, Yuehong Xu et al achieved development in independently manipulating the emission phase distributions of THz waves for two circular polarization channels. By harmonizing with the principles of polarization superposition, they pioneered a method for generating LP-related THz vector beams, successfully realizing

generators for LP-related THz vector vortex and Bessel beams in experiments, as shown in figure 2. This achievement enabled the acquisition of radial and azimuthal THz vector polarization distributions under orthogonal linear polarizations, facilitating advancements in THz multi-channel communication and super-resolution imaging.

Recently, we focused on exploring and developing THz multi-beam polarization control meta-devices based on spin-decoupled phase control strategy. Leveraging the principle of phase discontinuities, by integrating two rows (columns) of meta-gratings with opposing phase gradients along the *x* (*y*) direction and adeptly managing the initial phase difference between these two rows (columns) of meta-gratings, it is feasible to generate four beams from a single incident light beam, as shown in the formulas.

$$\Psi^x_{rl_odd} = \frac{2\pi x}{nP},\ \Psi^x_{rl_even} = -\frac{2\pi x}{nP} + \Psi^x_{rl},\ \Psi^y_{rl_odd} = \frac{2\pi y}{nP},\ \Psi^y_{rl_even} = -\frac{2\pi y}{nP} + \Psi^y_{rl} \quad (1)$$

$$\Psi^x_{lr_odd} = \frac{2\pi x}{nP},\ \Psi^x_{lr_even} = -\frac{2\pi x}{nP} + \Psi^x_{lr},\ \Psi^y_{lr_odd} = \frac{2\pi y}{nP},\ \Psi^y_{lr_even} = -\frac{2\pi y}{nP} + \Psi^y_{lr} \quad (2)$$

Moreover, this approach enables the manipulation of the polarization states of the four emitted beams. Specifically, with $\Psi^x_{rl} = \pi,\ \Psi^y_{rl} = \pi/2,\ \Psi^x_{lr} = 0,\ \Psi^y_{lr} = 0$, a THz four-beam polarization rotator is designed. In this case, when the incident wave is a 0° LP wave, the orientation angles of the LP output for the four beams are respectively 0°, 45°, 90° and -45 °, as shown in figure 3. This device will increase the versatility of THz wave manipulation, contributing to advancements in THz communication, multi-polarization imaging, biomedical sensing, and more.

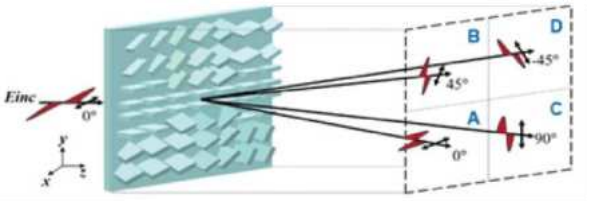

Figure 3. Function diagram of the THz four-beam polarization rotator

In summary, this work primarily focuses on the wavefront control of THz waves through orthogonal polarization (circular polarization) parameter multiplexing. Utilizing all-dielectric metasurfaces, we introduce several advanced multifunctional THz wavefront control devices developed via the spin-decoupled phase control method. These include asymmetric THz anomalous deflection devices with unique deflection angles, THz vector vortex and Bessel beam generators, and THz multi-beam polarization control devices. These contributions are poised to offer novel solutions for THz applications, potentially propelling further advancements in the field of THz technology and its interdisciplinary applications.

Manipulating Chemical Reactions with Light

Z. Fusco[1], A. Edirisooriya[1], N. Lyu[1,2], C. David[2], F. J. Beck[1]

Abstract: Light-matter coupling mediated by plasmonic resonances could allow the manipulation of chemical reactions. Resonant energy transfer between plasmonic modes and molecular energy levels can activate molecular bonds, inducing bond breaking or triggering transformation which can enhance or suppress a particular chemical reaction pathway, and ultimately determine the final product distribution.

While there have been extensive reports of using plasmons to enhance photocatalytic (PC) and photo-electrochemical (PEC) reactions over the last decades [1], the concept of *controlling chemical reaction pathways with resonant light-matter coupling* has only recently been explored [2]. Plasmons allow efficient light-matter coupling via optically-driven, collective oscillations of the conduction electrons in metals. They can be induced and sensitively controlled by modifying the geometry of metal nanostructures. At energies around the resonance, plasmons produce strong, optical near-fields confined to sub-wavelength volumes, and can excite electrons to energy levels well above the Fermi level, leading to a population of energetic 'hot' carriers. Nearby molecules can then resonantly couple with plasmonic modes, through either electron or photon transfer. Resonant transfer of electrons between plasmonic metal structures and molecular energy levels can produce transient negative ions, accessing new potential energy surfaces and changing preferred reaction pathways. Additionally, reversible exchange of either electrons or photons can leave the metal–adsorbate molecule complex in a vibrationally excited state, which can activate chemical bonds, triggering dissociation or transformation reactions. Experimental demonstrations are only just beginning to provide indirect evidence of these mechanisms [1, 3]. As the final product distribution depends on the reaction pathway, selectively activating particular intermediate reaction steps by plasmonic light-matter coupling could be used to target high value products. Seminal work by Prof Jain's group in 2018 confirmed that plasmonic nanoparticles can photoreduce CO_2 to C_{2+} products [4].

In this talk, I will give an overview of our investigations into plasmonic light-matter coupling, and how this can be used to modify photocatalytic (PC) and photo-electrochemical (PEC) reactions. Our approach is to combine insights from a combination of time dependent density functional theory simulations (TD-DFT) (Fig. 1b and c), nano-scale characterization and modelling (BEM, FEM) of plasmonic resonances, and in-situ monitoring of chemical reactions using surface enhanced Raman spectroscopy (Fig. 2) to probe underlying mechanisms [5, 6]. In addition, I will discuss how insights from atomistic studies and model molecule-nanoparticle systems can be leveraged to design practical photoelectrodes and photocatalysts for large scale CO_2 reduction based on self-assembled dendritic structures [7],[8].

Soft Metamaterials for Innovative Medical Devices

Jianfeng Zang[1,*], Hanchang Tang[1], Ye Tian[1], Zhangqi Pan[1]

[1] School of Integrated Circuits and Wuhan National Laboratory for Optoelectronics, Huazhong University of Science and Technology, Wuhan 430074, China

Abstract: Soft metamaterials can generate mechanical deformation when subjected to external stimuli like optics, acoustics, mechanics, electric field, magnetic field, etc., resulting in new properties or functions. This talk will summarize our recent works on soft acoustics metamaterials [1-3], and their medical applications including bioinspired cochlear [4], implantable sensors.

Soft metamaterials have the advantages of flexibility, ductility, and biocompatibility, and can be designed on-demand to precisely regulate the physical field and endow with exotic characteristics, which can realize great innovations in complex medical scenarios, difficult medical tasks and better functionality compared with traditional medical devices. A fundamental starting point for the design of soft metamaterials lies in the fact that the very small modulus and low density of the soft substrate need to be considered as this is both an excellent medium for elastic wave transmission and a key parameter affecting elastic wave transmission. Thus, the structural primitives and ordering modes of the soft metamaterials are the basis for the functional design. Based on the principle of local resonance and the translational acoustic method, the structural paradigms of soft metamaterials, including skeletonized hypersurfaces, topological arrangement, disordered hyperuniform distribution, gradient index, and periodical arrangement, are investigated holistically.

First, we have fabricated a porous network metasurface of soft polymer fiber/rigid beads that are physically equivalent to crosslinked spring-mass resonators based on the electrostatic spinning process. And the traditional paper-cutting art to carve the ultrathin metasurface into hollow-out patterns is incorporated, resulting in a variety of remarkable functions, including acoustic vortex, focusing, and super-resolution.

The above mentioned metasurfaces fall under the category of 2D materials, while soft material takes on a more pronounced role in 3D devices. We study topological states in soft metamaterials. The on-demand reversible switch in topological phase has been achieved by changing filling ratio, tension, and/or compression of the elastic metamaterials with the topological arrangement based on hexagonal lattice. By combining two elastic metamaterials with distinct topological invariants, we further demonstrate the formation and dynamic tunability of topological interface states by mechanical deformation, and the manipulation of elastic wave propagation. Our approaches to dynamically control interface states in soft materials paves the way for the precise regulation and utilization of acoustic waves on the surface of the human body.

Soft metamaterials are capable of not only controlling the fundamental properties of waves, but also the energy concentration of waves. Based on the disordered hyperuniform distribution, we constructed an acoustic black hole achieving a remarkable concentration of vibrations in broad frequency bands by a maximum enhancement factor of ~4000 at 1930 Hz. The disordered hyperuniform elastic metamaterials (DHEM), with

rational sizes from ~1 cm to ~1000 cm, covers a broad range of frequencies from ~10 Hz to ~10 kHz. Moreover, the soft DHEM enabling conformal attachments on uneven object. This demonstrates the promise of the application of elastic waves in the human body, such as elastic wave lithotripsy, surgery, and signal transmission.

The acoustic rainbow trap effect is realized by gradient index metamaterials, deduced by transformation acoustic theory. Based on this, a bioinspired soft elastic metamaterial that reproduces the shape and key functions of the human cochlea is reported. Inspired by human cochlea, the metamaterials are designed to possess graded microstructures with high effective refractive index distributed on a spiral shape to implement position-related frequency demultiplexing, passive sound enhancements of 10 times, and high-speed parallel processing of 168-channel sound/piezoelectric signals. Besides, it is demonstrated that natural hearing artificial cochlea has fine frequency resolution up to 30 Hz, a wide audible range from 150–12 000 Hz, and a considerable output voltage that can activate the auditory pathway in mice. This work blazes a promising trail for reconstruction of natural hearing in patients with severe hearing loss.

The phononic crystal is the most fundamental acoustic metamaterial and have been extensively and intensively studied. When it is combined with soft materials, such as hydrogels, additional advantages will be integrated. We present an implantable, bioresorbable, and wireless metastructured hydrogel (metagel) sensor for continuously monitoring of in vivo signals. The metagel sensors are encompassing biodegradable and stimulus-responsive hydrogels as well as periodically aligned air columns with a specific acoustic reflection spectrum. Implanted into animal bodies (rat, pig), the metagel can sensitively detect physiological environment signals including strain, pressure, temperature, and pH. The metagel sensor provides promising multiparametric sensing performances on par with conventional non-resorbable wired clinical benchmarks.

In summary, we have revealed new applications for different structural paradigms, especially in the biomedical field, which greatly expand the idea and direction of novel medical device design and are expected to play a disruptive role in the diagnosis and treatment of difficult and complicated diseases.

Design of Thin Film Metamaterial Absorber for IoT Application

T. Matsui[1*], T. Narita, S. Yoshikawa

[1] Department of Electrical and Electronic Engineering, Graduate School of Engineering, Mie University, Japan
*corresponding author: matsui@elec.mie-u.ac.jp

Abstract: We show numerical designs of the thin film metamaterial absorber. We designed a subwavelength-thick ground plane-less and reflection-less metamaterial absorber that shows frequency-selective narrow-band near-perfect absorption, and also designed polymer thin film metamaterial absorber that can be fabricated by printing technology, both work at 2.4 GHz for IoT application.

With the advent of metamaterials, a rich variety of novel concepts such as negative index, super- and hyper-lens, and optical cloaks that cannot be obtained from natural materials have been demonstrated in recent years. Many studies have been devoted to invent metamaterials with optical effects for more practical device applications, and among these, metamaterial perfect absorbers (MPAs) [1–4] are promising. We have so far developed metamaterial absorber that shows frequency-selective absorption working at the Wi-Fi band of 2.4 GHz and low reflection in a wide spectral range [5]. The absorber does not have a ground plane and is constructed with a square array of pairs of C-shaped split-ring resonators (SRRs) orthogonally arranged in such a way that induced electric and magnetic dipoles destructively interfere and no reradiation of electromagnetic (EM) waves is observed. The SRRs are made of nichrome with high ohmic loss so that EM energy dissipates as heat. In the optimum design, absorption of 97% is achieved at 2.4 GHz. The thickness of the absorber is 20 mm, which correspond to 1/6 of the wavelength of the EM field [5]. We are aiming at developing more thinner, plate or film type of metamaterial absorber, and here, we demonstrate (1) subwavelength-thick ground plane-less and reflection-less metamaterial absorber that shows frequency-selective narrow-band near-perfect absorption and (2) polymer thin film metamaterial absorber that can be fabricated by printing technology. In this study, the design of the devices and analysis of their microwave responses were performed using 3D EM field

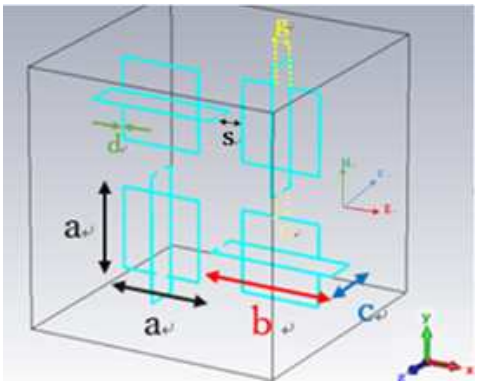

Figure 1. The schematic of the designed reflection-less frequency-selective metamaterial absorber consist of square and rectangular shaped SRRs. The supporting PDMS matrix is omitted for clarity.

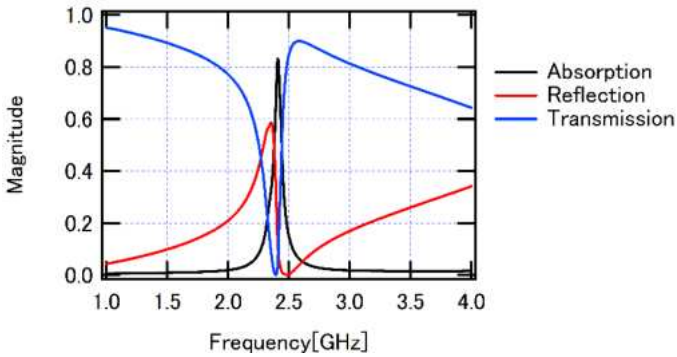

Figure 2. Absorption, reflection, and transmission spectra of the designed metamaterial absorber.

analysis software, CST Studio.

In the first approach, we tried to compress C-shaped SRRs into rectangular shape to make the device thinner as schematically shown in Fig. 1. We assumed to use cupper ($\sigma = 5.8\times10^7$ S/m) for SRRs and PDMS as a supporting material and achieved high absorption of 83% at 2.41 GHz as shown in Fig. 2. The thickness was made down to 7 mm, which correspond to 1/18 of the wavelength of the EM field. In the second approach, we assumed to use one of the most promising π-conjugated polymers, poly(3,4-ethylenedioxythiophene):poly(styrene sulfonate) (PEDOT:PSS) [6] as a ink and fabricate the absorber by screen printing [7]. Details will be presented at the conference. Our basic concept can be extended to higher frequency ranges and may be utilized for next-generation wireless communications, the IoT, and so forth.

Abstract: Explore recent developments in metamirrors, utilizing sub-wavelength micro- and nanostructures. These mirrors offer advantages such as high reflectivity and focusing in a single, thin layer. This talk reviews low-noise meta mirrors for precision applications, tracking progress from infrared to visible spectra, providing insights into the ongoing advancements in this field.

Optical frequency stabilization is integral to modern experiments, essential for applications like interferometric gravitational wave detectors in the infrared [1] and optical atomic clocks in the visible spectrum [2]. Existing laser frequency stabilization systems, relying on Bragg mirrors within optical cavities, face limitations from thermal noise [3]. An innovative solution lies in metamirrors—micro- or nanostructured layers of highly refractive material on a low-refractive substrate (see Fig. 1) [4]. Calculations indicate their potential to reduce thermal noise by over an order of magnitude [5,6]. Recent experiments at 1550 nm demonstrate promising results with cavity finesses reaching 12,000 [4].

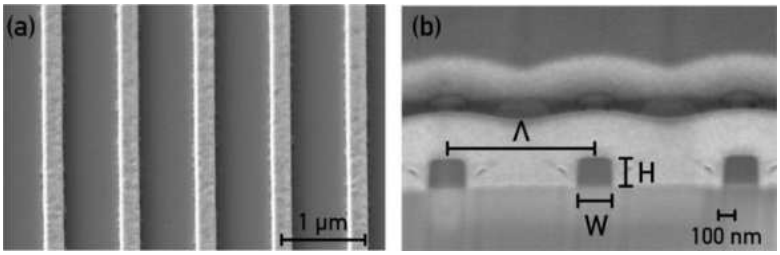

Figure 1: Scanning electron microscope images of a fabricated low-noise meta mirror for a working wavelength of 1550 nm consisting of a structured silicon layer on top of a silica substrate. (a) top view, (b) side view. [4]

Future research aims to explore alternative materials for metamirror fabrication, extending their application wavelength to the visible spectrum. Figure 2 illustrates thermal noise calculations for various metamirror materials such as silicon, diamond, titania, and gallium nitride (GaN), along with their respective working wavelengths. Diamond, with its high Young's modulus, stands out for superior noise performance, surpassing silicon and competitors at the application wavelength. Although titania and GaN exhibit slightly inferior noise performance, likely due to higher mechanical losses, these metamirrors theoretically reduce Bragg mirror thermal noise by over an order of magnitude, translating to a more than 100-fold reduction in noise power density. Moreover, the application wavelength ranges of titania and GaN extend seamlessly into the visible spectrum. With AlGaN, the application wavelengths can even be shifted into the UV, down to 250 nm.

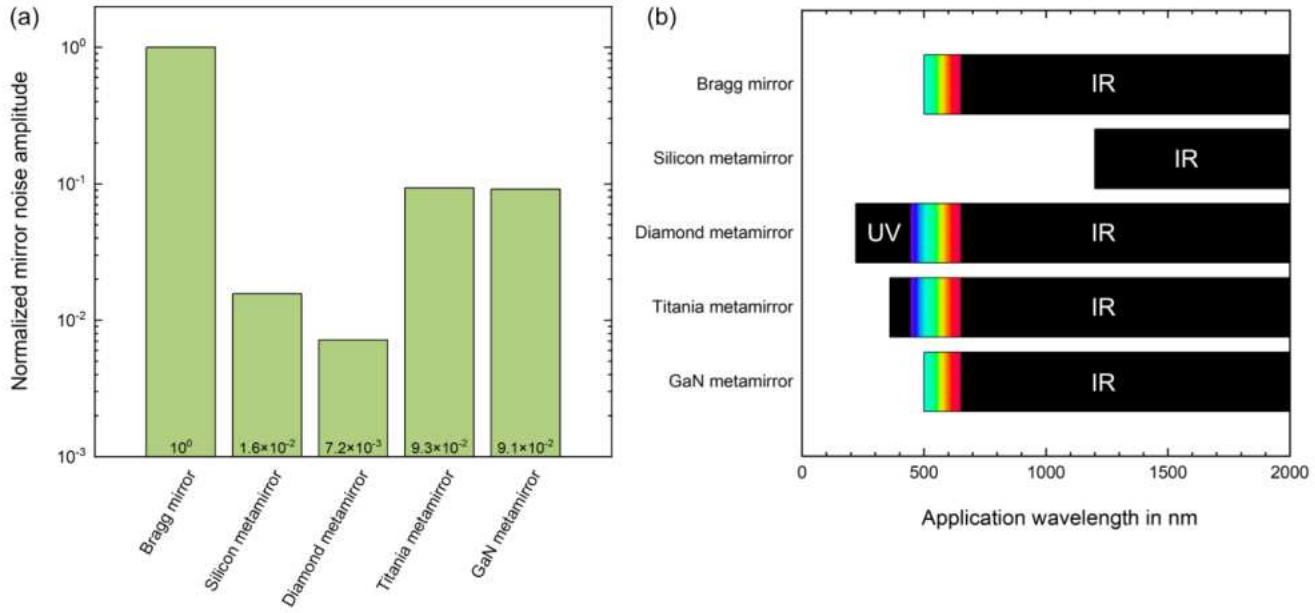

Figure 2: (a) Calculated thermal noise of metamirrors based on different materials, normalized to the thermal noise of a dielectric Bragg mirror consisting of 52 layers made from silica and tantala (wavelength 1.55 µm). (b) Application wavelengths of the different mirrors based on the absorption coefficient (IR – infrared, UV – ultraviolet).

In this talk, we will delve into the latest advancements in low-noise metamirrors, specifically focusing on their applications in the visible spectral range.

Metamaterials based Pixelated Thermal Signature Control

Zhuo Li[1], Xiu Liu[1], Yibai Zhong[1], Lin Wang[2], Tak Sing Wong[2], Han Wang[3], Jing Kong[4], Xu Zhang[1] and Sheng Shen[1*]

Abstract: We will present two examples about metamaterials based pixelated thermal signature control. Inspired by leafhopper-generated brochosomes, we designed binary metastructures functioning as pixel twins to achieve pixelated thermal signature control at the microscale. We also experimentally demonstrated dynamic, pixelated modulation of coherent emission based on an electrically programmable plasmonic metasurface.

Inspired by leafhopper-produced brochosomes, here we introduce an infrared signature management solution by pixelating surfaces with a spatial resolution down to the micrometer level with a pair of micro-sized pixel twins [1]. Brochosomes are hollow spherical structures with distributed open pores interconnected by a hollow cavity. Based on the brochosome-inspired pixel twins, we demonstrate a dual effect of concealing binary information/images in the visible range but displaying them in the infrared range via thermal excitation, without relying on external light sources such as lasers. To mimic the binary states in digital electronics, these brochosome-like pixel (BLP) twins are engineered with either open pores (op-BLPs) or closed pores (cp-BLPs) and perform as the building blocks for spatial emissivity manipulation. BLP twins show distinct emissivities when thermally excited, which form infrared counterparts of the binary states 0 and 1. Therefore, images can be encoded using a 'bitmap' consisting of the pixel twins, which can then be visualized using infrared imaging systems. This pixel-by-pixel approach employs unique brochosome geometries, instead of specific material property for emissivity control, and thus is compatible with different substrates. Remarkably, the two types of BLPs share similar appearances when observed under visible imaging systems. This similarity allows the stored patterns formed by one type of BLPs to blend with the background formed by the other. This effect resembles 'background matching', a common camouflage strategy in nature. To the best of our knowledge, this is the first time that a pair of microscopic structures has been designed to be distinguishable in the infrared range, while remaining indistinguishable in the shorter visible range, despite the fact that the shorter wavelength typically provides a finer spatial resolution, according to the Rayleigh criterion.

To date, various methods have been employed to actively excite thermal infrared metasurfaces, such as thermal hot plate, mechanical actuation, and optical laser pulse. However, the realization of electrically programmable on-chip integration for large-area pixelated 2D arrays remains a significant challenge. Single-pixel active metasurfaces, by electrically modulated refractive indices of materials like graphene and transparent conductive oxides, typically yields limited infrared emissivity contrast. Joule heating in an incandescent metasurface with a fixed resistance restricts the pixel modulation to binary on/off states and imposes constraints on the available design parameters for coherent characteristics due to the overlap of electrodes with the optically active region. Although state-of-the-art research has predominantly featured with

in-plane fan-out writing designs for 1D arrays, the electrically driven 2D pixelated metasurfaces have rarely been demonstrated due to the complexities of electrical addressing.

In this work, we experimentally demonstrate the pixelated modulation of coherent thermal emission from an electrical-programmable plasmonic metasurface integrated with a graphene field effect transistor (Gr-FET) [2]. The exceptionally broadband transparency of single-layer graphene enables the free-form control over plasmonic meta-atoms fulfilling the design space for controlling mid-infrared coherent states across a wide range of wavelengths and polarizations. The spatial temperature modulation generated by the Gr-FET is effectively synergized with the emissivity control by the localized surface plasmon polaritons (LSPPs) from gold nanoantennas. This integrated temperature-emissivity modulation is systematically extended to form a pixelated 2D array, signifying a new approach toward scalable 2D electrical wiring for densely packed, individually addressable pixels. Specifically, a 3×3 sweeping pixel array demonstrates diverse alphanumeric displays, supported by an explicit analytical model detailing the control mechanism. Our method offers superior potential in large-area scalability: to independently control N×N pixel arrays, but only 2N+1 electrical pins rather than N^2 pins are required. The extremely small thermal mass from the ultrathin graphene film further enables rapid modulation, achieving a 3-dB bandwidth of 146 kHz in a total 95 μm×95 μm device. In conjunction with the CMOS-compatible fabrication and outstanding high-temperature resilience of the large-area chemical vapor deposited (CVD) graphene, our device represents a significant stride in the development of next-generation mid-infrared active metadevices.

Abstract: A general concept of multipole coupling is discussed to explain the control of light propagation and trapping in dielectric and hybrid metasurfaces. Several examples with important application perspectives are presented.

We demonstrate and discuss multipole mechanisms for controlling light propagation and the trapping effect in structures composed of dielectric nanoparticles supporting electric and magnetic multipole resonances. First, the concept of multipole coupling is introduced to explain what type of multipoles can be coupled and why in periodic nanoparticle structures (metasurfaces). Then, a realization of such coupling for light trapping, which does not require special conditions of irradiation with incident light or geometric distortion of the symmetry of periodic structures, is presented. It is shown that the trapping effect can arise due to energy exchange between multipole moments of the same parity symmetry excited in different nanoparticles of a symmetrical structure. As an example, we consider how multipole coupling in a metasurface consisting of particles with high refractive index leads to the excitation of a dark electric octupole mode with strong energy storage in the plane of the metasurface [1]. The realization of a multiresonance response [2] and accidental quasi bound states in the continuum (BICs) associated with multipole interactions in symmetric metasurfaces is demonstrated. We further demonstrate the effects of magneto-electric multipole coupling in metasurfaces and individual structures consisting of particles with bianisotropic electromagnetic response. A general strategy for the realization of the resonant absorption band in metasurfaces consisting of bianisotropic hybrid (dielectric/metal) particles is also discussed [3]. The presented mechanisms have a general character and can be realized in many structures, which opens new perspectives for their application.

Abstract: Nanoporous gold (npAu), known for its adjustable large surface-to-volume ratio and broadband light absorption, exhibits potential for advanced optical applications. Our study investigates the npAu structural properties and its impact on absorption, electron collision frequency and photoemission efficiency. Optimizing npAu feature sizes enhanced performance in photocatalysis processes is demonstrated.

In this study, we investigate the fabrication of high quality npAu thin film with adjustable feature sizes, and apply it as model material for a comprehensive study of surface effects on absorption, photoemission efficiency and electron collision frequency. Electrochemical dealloying was employed to provide a precise control of the selective dissolution of the less noble metal (Ag) from a AuAg leaf precursor to produce npAu thin film (around 140 nm thick). NpAu gold thin film with small ligament sizes can be obtained from dealloying at high potentials, which induce a fast removal of Ag atom and less diffusion of Au atom to coarsen. The smallest ligament can reach down to about 6.5 nm, as shown in Fig 1, and the overall average ligament size is around 8 nm.

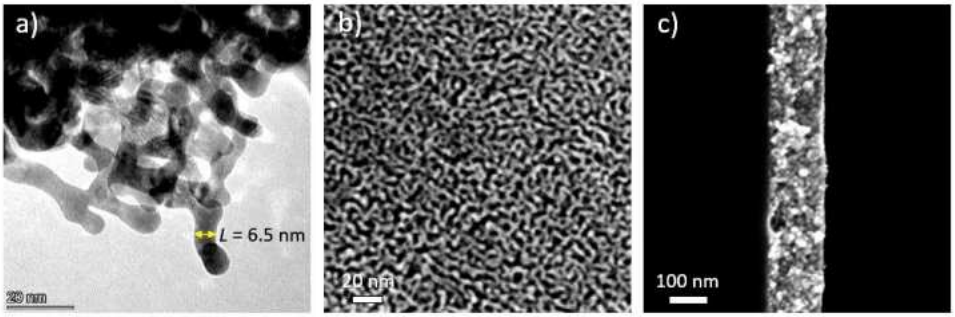

Figure 1. a) the microstructure of top view from Transmission Electron Microscope, b) microstructure of top view from Scanning Electron Microscope, c) the microstructure of side view from Scanning Electron Microscope

Then we conducted photoelectron injection from npAu into the electrolyte under UV illumination to investigate electron transfer processes. Simultaneously, cyclic voltammetry scans from a potentiostat were applied to coarsen npAu thin films from a small initial ligament sizes (below 10nm), allowing for an *in-situ* study of the influence of npAu ligament size on photocurrent. The resulting variations in ligament size were verified using Scanning Electron Microscopy (SEM). By strategically limiting the upper scan potential, subtle changes in ligament size were obtained, providing a means to modify the surface-to-volume ratio of npAu at the lower limit of the nanoscale.

Our results, as shown in Fig 2, demonstrate that the internal quantum efficiency of the npAu network photoelectrode is significantly influenced by ligaments of npAu thin film. We observed a notable trend: as the ligament size increased from ~8 to ~16 nm, the quantum efficiency exhibited a corresponding decrease, following with high precision the inverse square relationship to the ligament size. In contrast to prior findings [1] that suggested efficiency would level

off with decreasing ligament size, we did not find any saturation effect within this range of ligament sizes. The parabolic dependence on the inverse ligament size shows the dominant role of surface photoemission in the observed photocurrent with a smaller contribution of volume photoemission.

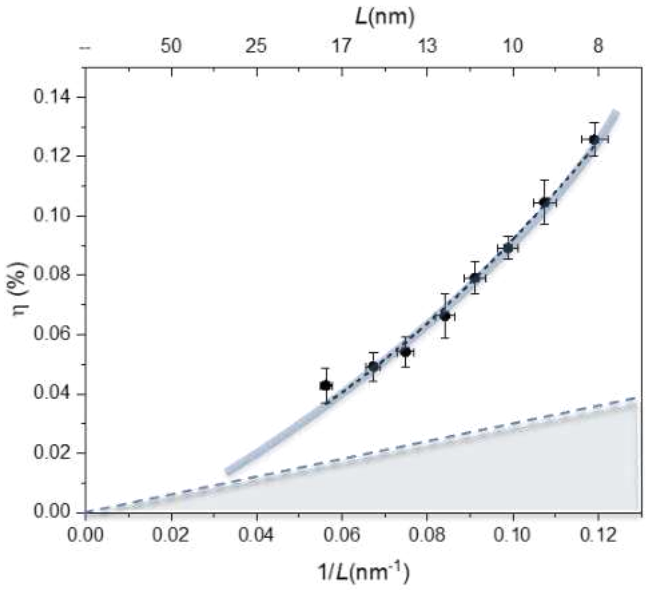

Figure 2. Size dependence of the internal quantum efficiency η of photoemission at a wavelength λ = 291 nm measured at 0.33 V vs. RHE. The dashed line represents a parabolic fit with linear and quadratic terms versus inverse ligament size L^{-1}. The shaded area under dashed curve shows the volume contribution.

In the study of absorption of npAu, we integrated an electrochemical cell on a spectroscopic ellipsometer, enabling in-situ measurements of optical properties during electrochemical processes, such as surface oxidation and reduction. The oxidized surface with large surface to volume ratio is believed to cause an enhanced effective electron collision frequency of metal [2,3]. Previous research on gold nanoparticles demonstrated an increased damping rate at the plasmon resonance [4]. Our results on flat gold also exhibited a similar effect, holding promise for observing more pronounced effects on npAu gold with a much larger surface area.

Abstract: We investigate the influence of nanoparticle structure and excitation condition on the rate of plasmon-induced chemical reactions using surface-enhanced Raman scattering (SERS). In particular, we focus on the size of Au and Ag nanoparticles, as well as chiral Au nanocubes using excitation with circularly polarized light.

One of the most intriguing applications of plasmonic nanoparticles is based on their ability to transform the energy of light into chemical energy. A broad range of chemical transformations have been demonstrated already to be triggered directly by excitation of the nanoparticle's surface plasmon resonance. It is still debated whether hot electrons or heat are driving the plasmon-induced chemical reactions, but the details depend on the respective chemical systems and the nanoparticle species. We have recently established the plasmon-induced transformation of 8-bromoadenine into adenine as a model system, in which the carbon-bromine bond is cleaved by an irreversible transfer of a hot electron from the light-excited nanoparticle to the 8-bromoadenine molecule.[1,2] We have characterized the kinetics of the plasmon-induced dissociation of 8-bromoadenine by surface-enhanced Raman scattering (SERS) on Au and Ag nanoparticles, and with 8-bromoadenine incorporated into DNA. [1,2]

The plasmon-induced molecular transformations can be controlled by the choice of nanoparticle species. In this contribution we systematically explore two aspects of nanoparticle structure: i) The influence of nanoparticle size on the rate of bromoadenine decomposition is studied using SERS. ii) The possibility to control the reactivity of molecular transformations by polarization is explored using chiral Au nanocubes, which are excited with either left- or right-handed circularly polarized light. We demonstrate that reaction rates are increasing with the size of nanoparticles within nanoparticle clusters. With chiral Au nanocubes the reaction rates depend on the polarization of the excitation light and the photochemical g factor can exceed the optical g factor and can be boosted by choosing proper excitation conditions. This allows for precise control of plasmonic reactivity by the choice of nanostructure and excitation condition.

Abstract: We present plasmon-enhanced nanospectroscopy using a sharp metallic tip which enables us to demonstrate not only nanoscale sensing but also nanoscale control of molecular reactions.

We have been developing a variety of laser-based nanospectroscopic methods in combination with plasmonics and metamaterials where optical nanostructures play a crucial role in enhancing various optical signals (visible absorption/reflection, Raman scattering, fluorescence, infrared absorption) from targeting molecules. Here in this talk, we focus on active plasmon-enhanced Raman microscopy using a plasmonic tip which enables us to demonstrate not only nanoscale observation but also nanoscale control of molecular reactions.

Tip-enhanced Raman scattering (TERS) microscopy is a powerful surface analytical tool with single molecule sensitivity and nanoscale spatial resolution. A sharp metallic probe tip plays important roles in plasmonically enhancing Raman scattering from sample molecules in the vicinity of tip. We demonstrated TERS spectroscopy of a single gold-binding peptides (GBP) which exhibit specific binding affinity to gold surface, as schematically shown in Fig. 1(a). The time-dependent TERS spectra in Fig. 1(b) show temporal fluctuations of both TERS intensity and frequency, enabling us to spectroscopically elucidate the binding sites and mechanisms.

Recently, we have developed a new type of TERS microscopy in combination with local application of external stimuli such as pressure and voltage to sample molecules through the tip apex (Fig. 2), enabling us to induce various chemical reactions in the vicinity of the tip. The chemical reactions were spectroscopically probed by detecting tip-enhanced Raman scattering in response to the external stimuli.

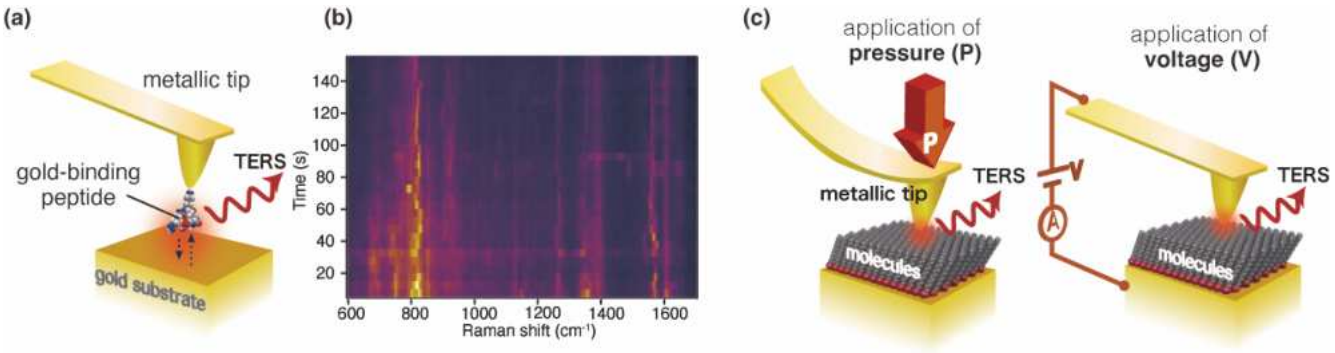

Figure 1 (a) Schematic of TERS measurement of a single gold-binding peptide (GBP) adsorbed on the gold substrate. (b) Time-dependent TERS spectra of GPB. (c) Advanced TERS microscopies in combination with tip-applied external stimuli.

Ultrabroadband polarization-independent directional thermal emission

Abstract: By leveraging non-imaging optical principles, a pixelated micro-emitter is experimentally demonstrated for ultrabroadband, polarization-independent directional control of thermal radiation. This design enables high emissivity contrasts at different view angles. By exploiting the tunable angular range of the pixelated micro-emitter, we create an infrared display with directionally encoded information.

The intrinsic quasi-isotropy of thermal radiation hinders potential advancements in radiative cooling, thermal sensing, thermal photovoltaic and incandescent infrared lighting. Thus, directional thermal radiation is highly sought after and has been realized within narrow spectral ranges with phonon polariton gratings[1], plasmonic metasurfaces[2], nanoantenna[3], and bull's eye structures[4]. However, these works only realized directional control of thermal emission over a narrow wavelength range with reduced radiative efficiency. Recent efforts have been made to remove the bandwidth limitation by utilizing the Brewster effect[5], impedance engineering[6], and gradient epsilon-near-zero (ENZ) metamaterials[7]. Nevertheless, these approaches only controlled p-polarized thermal emission over an insufficiently wide spectral range. A novel design with polarization-independence and ultrabroad bandwidth is therefore desired.

Here we design a three-dimensional (3D) pixelated directional micro-emitter (PDME) whose pixel structure is composed of parabolic reflectors on a thermal emitter. Our design centers on the concept of etendue conservation, where etendue is proportional to both areal and angular spread of light. By mapping thermal emission from a small area A_0 to a large area A_1 (Figure 1a), the angular range of thermal emission will be reduced at A_1 owing to the conservation of etendue. Figure 1b inset shows an SEM image of the fabricated PDME with 15° acceptance angle (15°-PDME), demonstrating high structural quality. We characterize the angular-resolved thermal emissivity of the 15°-PDME through radiometric measurements over the range of 7.5 – 14 μm. In Figure 1b, an angular width of ±16° is identified, with the maximal emissivity over 0.8, well matching the design and simulated results. The emissivity for different polarizations matches each other, proving the polarization-independent feature of the PDME. Spectral characterization was performed with a Fourier-transform infrared spectrometer (FTIR), showing abrupt emissivity drop over a large spectral range (5-20 μm) when the angle increases (Figure 1c).

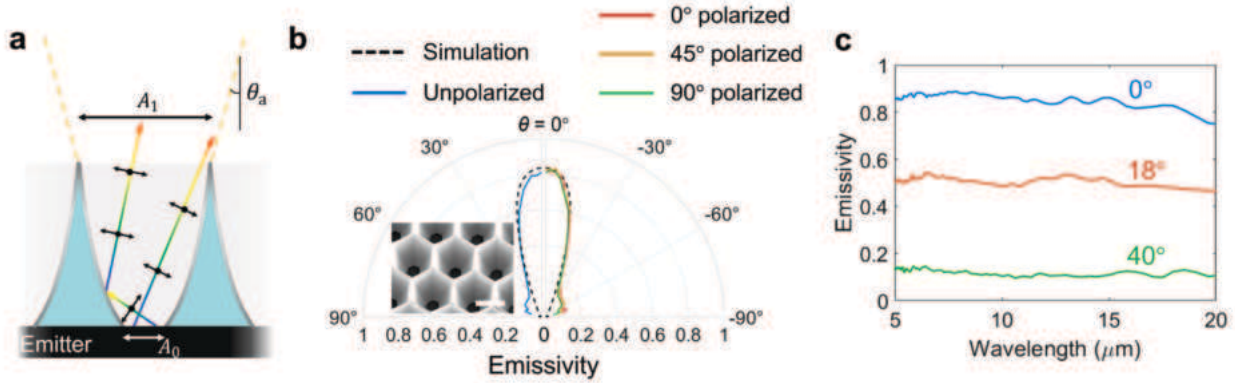

Figure 1 | a, 2D illustration of the PDME. **b**, Angular-resolved thermal emissivity for unpolarized and polarized thermal emission from the 15°-PDME. The inset shows an SEM image of the 3D hexagonal pixels, scale bar: 50 μm. **c**, Measured emissivity spectra of the 15°-PDME from different angles.

Next, we explore the tunability of our directional micro-emitter to create a pixelated display that directionally encodes infrared information and achieves thermal camouflage. By integrating pixels with varying acceptance angles (Figure 2a), we produce IR messages visible only from certain directions, effectively camouflaging them in the background. For example, the "TAMU" pattern was visible at approximately 30°, but obscured at other angles (Figure 2b).

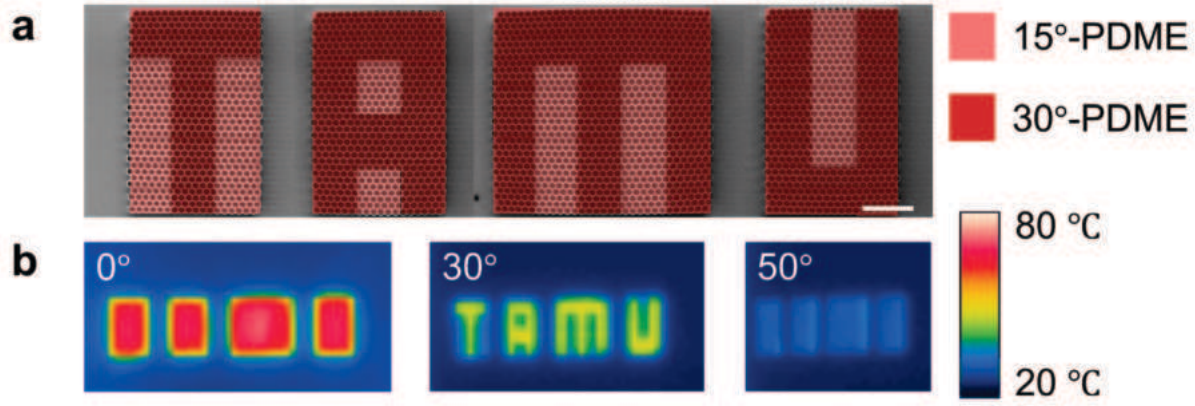

Figure 2 | a, SEM image (scale bar: 500 μm) and **b,** thermal images of a pixelated PDME camouflage composed of 30° and 15°-PDME pixels.

In summary, we have created a compact pixelated directional micro-emitter exhibiting performance superior to previous works, including polarization-independence, high emissivity (> 0.8), narrow angular range (down to ±16°) and an ultrabroad spectral range (5 – 20 μm). We further demonstrate the PDME's ability to encode information into the viewing angle of infrared displays.

Förster resonance energy transfer in absorbing environment

L. S. Petrosyan[1], M. N. Noginov[2], and T. V. Shahbazyan[1*]

Abstract: We present an analytical model for Förster resonance energy transfer between donors and acceptors in the presence of a metal surface. We find that energy transfer to the metal results in a reduction of the Förster radius, leading to a suppression of concentration quenching for high molecule concentrations.

In this paper, we develop an analytical theory to Förster resonance energy transfer (FRET) between donor and acceptor molecules in the presence of an inhomogeneous absorbing environment such as metallic structures characterized by a complex dielectric function. Specifically, we show that energy transfer to the environment, which accompanies FRET, results in a reduction of the Förster radius R_F characterizing FRET efficiency between the molecules. For large concentration of molecules situated near a metal surface, this leads to a suppression of fluorescence concentration quenching for small average molecule separations from the metal and to a reduction of the effective fluorescence decay rate relative to that in homogeneous environment. Our numerical calculations of the effective fluorescence decay rate for molecules embedded in a dielectric slab on top of a metal surface reveal a characteristic minimum at intermediate slab thicknesses for high molecule concentrations, consistent with the experiment [1-2].

We start with the probability rate of acceptor excitation by the donor's electric field [3]

$$W_a(R_{ad},t)=\frac{3c\kappa_{ad}^2}{2\pi\hbar\omega R_{ad}^6}\sigma_a(\omega)|\boldsymbol{p}_d(t)|^2$$

where $\sigma_a(\omega)$ is acceptor's absorption cross-section at the transition frequency ω, R_{ad} is the donor-acceptor separation, $\boldsymbol{p}_d$ is the excited donor's dipole moment causing the transition, and κ_{ad}^2 characterizes molecules' mutual polarization. In the presence of metal surface, the donor's dipole moment is time dependent, $\boldsymbol{p}_d(t)=\boldsymbol{p}_d e^{-\Gamma_d t/2}$, where $\Gamma_d=\gamma_d+\gamma_s$ is the donor's full decay rate comprised of the fluorescence rate γ_d and the energy transfer rate to the metal $\gamma_s \gg \gamma_d$. In this case, to properly define the Förster radius, the FRET probability rate should be averaged over the fluorescence time as

$$W_a'=\tau_d^{-1}\int W_a(t)dt=\left(\frac{\gamma_d}{\Gamma_d}\right)W_a$$

The modified Förster radius R_F' is determined from the condition $\tau_d W_a'(R_{ad})=1$, where τ_d is the free donor's fluorescence decay time, and we obtain

$$\frac{R_F'^6}{R_F^6}=\frac{\gamma_d}{\Gamma_d}$$

indicating that in an absorbing environment the effective Förster radius is reduced.

The emission kinetics is obtained in a standard way by averaging out over random position of the acceptors [3] and we obtain the time-dependent fluorescence intensity as

$$I_d(t)\sim e^{-\Gamma_d t-N_A'\sqrt{\pi\gamma_d t}}$$

where $N_A'=n_A V_F'$ is the acceptor number within modified Förster volume $V'_F=4\pi R_F'^3/3$ and n_A is the acceptor concentration. Thus, in the absorbing environment, the number of acceptors that can be efficiently

excited by the donor is effectively reduced by the factor $\sqrt{\gamma_d/\Gamma_d}$, leading to an interplay between the metal quenching and concentration quenching at intermediate distances to the metal surface.

In Fig. 1a, we show the calculated effective fluorescence decay rate from dielectric film doped by HITS:PMMA die molecules on top of Ag surface versus the film thickness at various die concentrations. These calculations are compared with the experimental data taken on a similar system shown in Fig. 1b [2]. A clear minimum of the effective decay rate is observed for high molecule concentrations indicating that, for intermediate average molecule distances to the metal surface, the metal quenching is weakened while the concentration quenching is still suppressed. The mechanism of this suppression is a reduction of the effective Förster radius in an absorbing environment due to competition between two energy transfer channels.

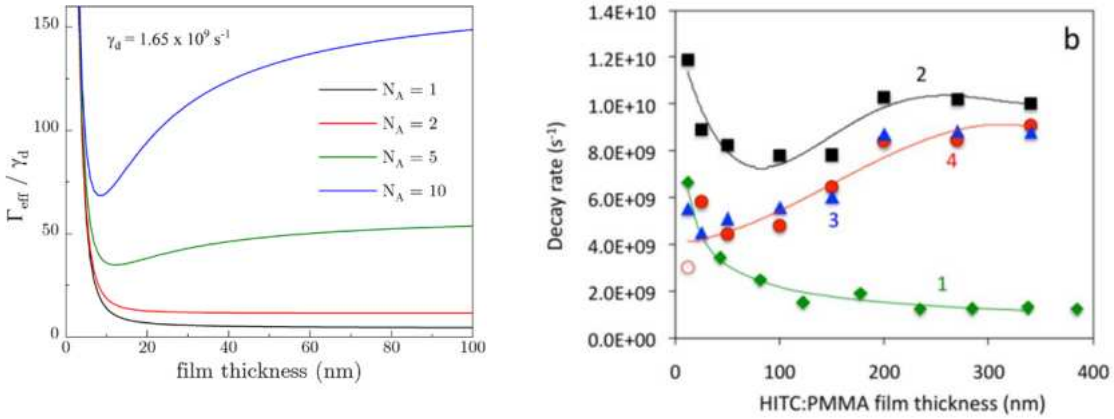

Figure 1. (a) Calculated effective decay rate from dielectric film doped by HITS:PMMA die molecules on top of Ag surface vs. film thickness for various molecule concentrations. (b) Experimental data for the effective decay rate taken on a similar system [2].

Resonances in doubly anisotropic, high-index nanoplatelets

Bingying You[1,2], Tom T. C. Sistermans[1,2*], and Alberto G. Curto[1,2*]

[1] Photonics Research Group, Ghent University-imec, Ghent, Belgium

Abstract: Optical anisotropy plays a crucial role in the manipulation of light. Its strength is, however, limited to low values in conventional materials. Transition metal dichalcogenides possess both high refractive index and high birefringence. Here, we investigate optical resonances in nanoplatelets with both geometrical and refractive index anisotropies to control light scattering and emission.

Anisotropy plays a crucial role in manipulating light as the basis for optical components such as polarizers, waveplates, or modulators and phenomena like phase matching in nonlinear optics. The functionality of these devices hinges primarily on the retardance between two orthogonal linear polarizations, which is proportional to both the thickness and the birefringence (Δn) of the material. A large birefringence is thus beneficial for the performance and compactness of such components. Birefringence is a tuning degree of freedom for nanophotonics, for example, in electro-optic modulators, waveguides with reduced cross-talk, and electro-optic polarization conversion. Beyond natural materials, metasurfaces and metamaterials can be constructed to achieve high anisotropy but suffer from losses and fabrication challenges. As a result, natural materials with higher anisotropy than conventional dielectrics or metals are in demand.

Transition metal dichalcogenides are promising birefringent materials due to their layered van der Waals structure, which naturally leads to a large intrinsic birefringence above unity. In particular, molybdenum disulfide (MoS_2) possesses the highest birefringence of all natural materials in the near infrared. Such a high birefringence is possible thanks to the presence of strong excitons. They endow MoS_2 with a high in-plane refractive index above 4.5 while making it possible to have higher out-of-plane index contrast than lower index dielectrics. A high refractive index also enables the existence of Mie-type resonances in MoS_2 nanostructures for enhancing and controlling light-matter interaction.

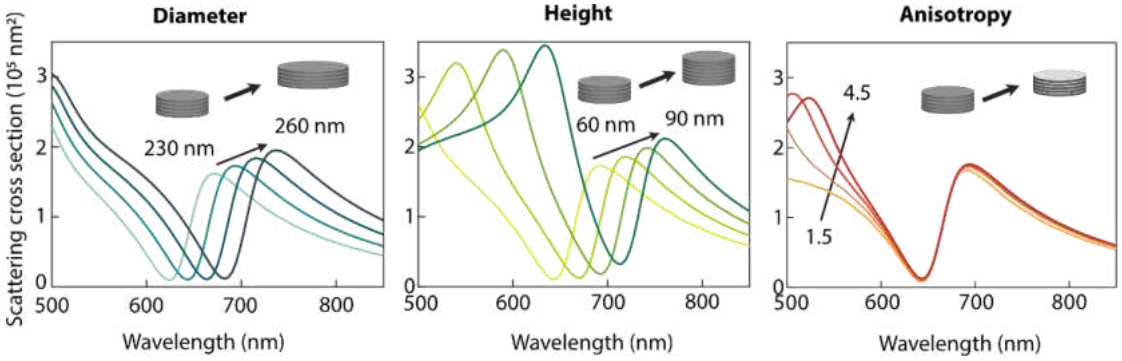

Figure 1. Different dependence of electric and magnetic dipole resonances on geometrical and optical anisotropy.

Here, we study the optical resonances sustained by nanoplatelets made of high refractive index material with high optical anisotropy. Nanoplatelets have both geometrical and refractive index anisotropies. Their high refractive index enables them to sustain electric and magnetic resonances. We find a distinct impact of changing geometric and birefringence on the tunability of electric and magnetic resonances, which we explain using multipolar expansion. Due to their double anisotropy, the optical response of nanoplatelets strongly depends on the direction of illumination, as different illumination conditions can lead to in-plane or out-of plane electric and magnetic multipoles. We also show that nanoplatelets can control the polarization and directionality of the scattering radiation patterns. Finally, we show preliminary experimental results using MoS_2 nanoplatelets.

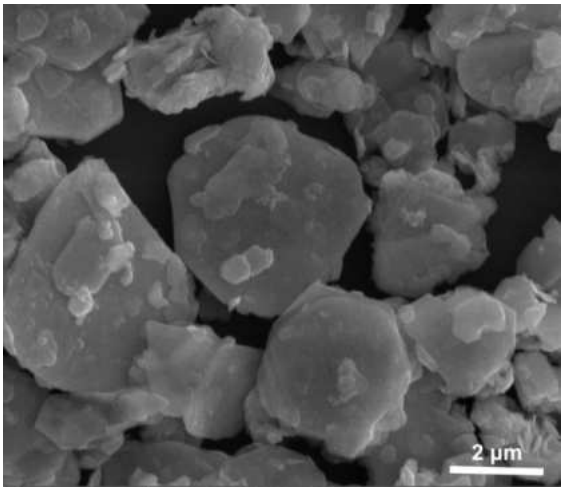

Figure 2. SEM image of MoS_2 nanoplatelets.

In summary, high-refractive-index nanoplatelets with intrinsic out-of-plane anisotropy and large birefringence exhibit a wealth of electric and magnetic multipolar resonances that are sensitive to geometry and anisotropy in distinct manners. We envision that nanoplatelets could be used to enhance and direct light scattering and light emission, with applications in light-emitting devices and lasers.

Electromagnetic enhancement induced by subradiant plasmon resonance demonstrated using single plasmonic systems

T. Itoh[1*], and Y. S. Yamamoto[2]

[1] National Institute of Advanced Industrial Science and Technology (AIST), Japan
[2] Japan Advanced Institute of Science and Technology (JAIST), Japan

Abstract: Plasmon resonance has been used for exploring the mechanism of surface enhanced Raman scattering (SERS) of single plasmonic systems. We here investigated the relationships between SERS, electromagnetic enhancement factor, and plasmon resonance Rayleigh scattering spectra of single nanoparticle dimers. The numerical analysis revealed that the SERS is mainly caused by dipole-quadrupole coupled resonance, which is subradiant, for asymmetric dimers.

Surface enhanced Raman scattering (SERS) has opened a variety of exciting research fields [1]. Plasmon resonance is a key for the large Raman enhancement based on electromagnetic (EM) mechanism [2]. Dipole-dipole (DD) coupled plasmon resonance coupled with molecular exciton resonance have been focused for reproducing surface enhanced Raman scattering (SERS) with SEF spectra using single plasmonic dimers [3]. However, when the sizes of the NPs of a dimer differ significantly, the largest EM enhancement factor F_R is not generated by the DD-coupled plasmon but by dipole–quadrupole (DQ)-coupled plasmon, which is a subradiant mode [4-6]. In such a situation, the DD-coupled plasmon contributes to transfer the excitation light energy to the DQ-coupled plasmon, and emits SERS with SEF by receiving energy from the DQ-coupled plasmon through near-field interactions. In this case, the DD-coupled plasmon resonance Rayleigh scattering $C_{sca}(\omega)$ spectra obtained by dark-field spectroscopy are not identical to the F_R spectra. This contribution of DQ-coupled plasmon resonance may look the breakdown of EM mechanism; thus, is needed to be carefully examined.

The relationships between SERS with SEF spectra and DD-coupled plasmon resonance $C_{sca}(\omega)$ are systematically

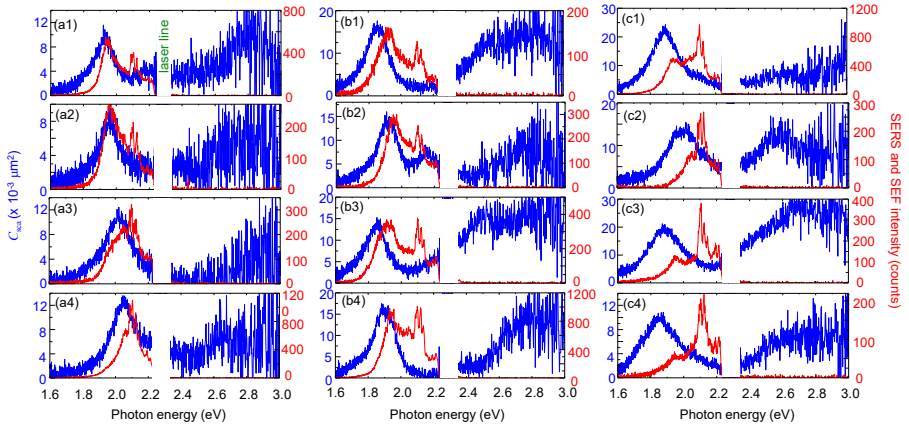

Fig. 1 (a1)–(a4) $C_{sca}(\omega)$ spectra (blue lines) and spectra of SERS and SEF (red lines) of single dimers exhibiting similar spectral shapes (Type I). (b1)–(b4) $C_{sca}(\omega)$ spectra and spectra of SERS and SEF for single dimers exhibiting spectral deviation with respect to each other (intermediate type). (c1)–(c4) $C_{sca}(\omega)$ spectra and spectra of SERS and SEF with maxima that are close to spectral dips in the $C_{sca}(\omega)$ (Type II).

examined for single silver NP dimers to clarify the contribution of DQ-coupled plasmon resonance to SERS with SEF as shown in Fig. 1. The spectral envelopes of the SERS with SEF were mostly similar to those of the plasmon resonance spectra. However, some dimers showed their spectral envelopes that shifted to higher-energy regions from the DD-coupled plasmon resonance maxima. In short, there are two types of relationships: Type I, in which the envelopes of the SERS with SEF are similar to the plasmon resonance maxima, and Type II, in which the envelopes shift to the higher-energy side from the maxima. The relationships indicated that the SERS with SEF, which spectral envelope is similar to the plasmon resonance $C_{sca}(\omega)$ spectra, is mainly caused by DD coupled plasmon resonance in symmetric dimers. The SERS with SEF, which spectral envelopes shift to higher energies, may be mainly caused by DQ-coupled plasmon resonance in asymmetric dimers. The experimental spectra for both $C_{sca}(\omega)$ and SERS with SEF were successfully reproduced in FDTD calculation by changing the degree of morphological asymmetry in the dimers. This analysis of the calculations revealed that Types I and II are caused by DD and DQ coupled resonance, respectively. DQ coupled resonance is subradiant; thus, The DQ coupled resonance receives excitation light and emits SERS and SEF light through near-field interaction with DD-coupled resonance. Furthermore, $F_R(\omega)$ obtained by absorption spectroscopy showed the spectral correlation between $F_R(\omega)$ and plasmon resonance absorption, because both origins are common in quantum optics, namely, AP term [6]. The absorption spectroscopic method of single dimers are described elsewhere [8]. This analysis method has applied to plasmonic nanowire dimers and successfully exhibit the contribution of DQ coupled resonance to SERS and SEF [7].

Abstract: Recent studies have unveiled the capability of van der Waals (vdW) two-dimensional atomic crystals and their nanostructures to sustain diverse polaritonic modes across the mid-infrared to THz spectral range. In this presentation, we will share our latest research progress in the exploration of polaritons within nanostructures of vdW crystals. Additionally, we will delve into the optoelectronic and photonic applications that emerge from these investigations.

Polaritons are hybrid modes formed through the coupling of the electromagnetic field with the charged collective excitations in materials[1]. They exhibit a remarkable ability to confine the electromagnetic field within or at the surface of a material, thereby significantly enhancing the interaction between electromagnetic fields and matter at the nanoscale. This unique property positions polaritons as highly advantageous for the development of nanophotonic and optoelectronic devices. Noble metals, doped semiconductors, and their nanostructures excel at supporting polaritons in the visible and near-infrared regime. However, their field confinement capabilities degrade significantly as the operational frequency shifts into the mid-infrared and terahertz region. This limitation makes them unsuitable for developing high-performance and miniaturized photonic and optoelectronic devices in the specified frequency domain. Recent studies have uncovered the remarkable capability of van der Waals (vdW) two-dimensional atomic crystals and their nanostructures to sustain diverse polaritonic modes across the mid-infrared to terahertz spectral range[2,3]. In this presentation, we will briefly review the roadmap of polaritonic van der Waals crystals. Subsequently, we will introduce our recent work on the plasmon polariton properties of graphene and its nanostructures. Following that, we will share our discovery of hyperbolic phonon polaritons in a type of semiconducting van der Waals crystal, specifically, the α-MoO_3[4,5]. We will demonstrate that, owing to the in-plane anisotropic dielectric function of α-MoO_3, phonon polaritons can propagate within the basal plane with a hyperbolic wavefront, leading to strong electromagnetic field confinement in the mid-infrared region. Exploiting this exotic characteristic, we have developed a type of polariton tuners with frequency and polarization selection capabilities in the far-field. Furthermore, we utilize these tuners to create polarization notch filters, showcasing distinctive features including high-Q (300) resonance and extinction ratios up to 6.5 dB at a remarkably thin sub-wavelength thickness of 200 nm[6].

Abstract: Photonic Crystal Surface Emitting Lasers (PCSELs) have emerged as a third-generation diode laser technology for high power high brightness high speed lasers with applications in LiDAR and 3D sensing, datacom and lasercom, photonic and quantum integrated circuits. In this talk, we report PCSEL performance trade-offs and challenges in power scaling, modal competition, and charge injection control. We will report the impact of charge injection control, the design towards high speed high power lasers, and coherent coupled PCSEL arrays. Perspectives on the future directions will also be discussed.

[*]corresponding author: renxf@ustc.edu.cn

Abstract: I will introduce our recent works about quantum photonic sources based on nanophotonic structures, such as 2D materials, metalens array, microcavity, nanowaveguide, etc.

Integrated quantum photonics has attracted intensive attention due to the compactness, scalability, and stability. Quantum photonic source, especially an on-chip entangled photon source, is a basic device for realizing quantum photonic integrated circuits (QPICs). I will introduce our recent works about quantum photonic sources based on nanophotonic structures and materials, such as 2D materials [1], metalens array [2], microcavity [3], nanowaveguide, etc.

Intracavity metasurfaces in fiber lasers for linear and nonlinear applications

Lili Gui[1*], Chuanshuo Wang[1], Hao Chen[1], Chao Meng[2], Xianglong Mei[1], Hailun Xie[1], Zhijin Chen[1], Fengbin Lin[1], Fei Ding[2], Sergey I. Bozhevolnyi[2], and Kun Xu[1]

Abstract: Intracavity metasurfaces are explored for spatially or temporally modulating light wave inside fiber lasers. First we harness static and dynamic metasurfaces for building orbital-angular-momentum (OAM) laser sources. Secondly, resonant metasurfaces are used for Q-switched or mode-locked fiber lasers. They open new perspectives in structured optics, ultrafast optics and neuromorphic photonics.

Ultrathin plasmonic and dielectric metasurfaces enable flexible manipulation of the interacted optical wave in magnitude, phase, polarization etc. in both linear and nonlinear regime. Here we show applications of metasurfaces integrated in fiber lasers. In comparison with single-pass strategies, our strategies making use of combination with fiber lasers could provide efficient gain together with filtering mechanisms that ensure desired light-matter interactions with high efficiency and high purity. For this purpose we demonstrate two examples. The first example is to utilize the phase-control degree of freedom of metasurfaces in order to generate structured beams directly from a laser [1-4]. With this strategy loss issues of metasurfaces can be compensated and relaxed. We will show how to design both linear, V-shaped and circular fiber cavities in order to fully exploit the phase manipulation capabilities of both metallic and dielectric metasurfaces, including both static and dynamic functionality. The second example is to employ the nonlinear absorption properties of metasurfaces by virtue of local-field enhancement (the magnitude-control degree of freedom) [5-8] in order to tailor and enhance the pulsing building processes in fiber lasers, the typical nonlinear operation ranges in lasers. In this case the design principles of nonlinear metasurfaces for optical frequency generation that have been extensively studied before can be easily extended to investigations of intracavity nonlinear dynamics, and hence it provides exciting and versatile avenues for designing new saturable absorbers and reaching related applications such as optical neuromorphic computing, spiking neural networks, and so on. All these trials open new doors for integrated laser technologies, structured beam generation, ultrafast nonlinear nanophotonics, and intelligent optical information processing, etc.

High Q-factor coupled Fabry-Perot plasmonic nanoresonator

B. Fix[1*]

[1] DOTA,ONERA,Université Paris Saclay F-91123 Palaiseau - France

[*]corresponding author: baptiste.fix@onera.fr

Abstract: Multi Fabry-Perot (FP) nanoresonators have been widely described as independent cavities. However, we evidence the coupling of FP nano-cavities leading to perfectly absorbing high quality factor plasmonic resonators through an analytical model and experimental demonstration on several architecture. Applications for nonlinear optics and infrared photodetection will be presented.

The Fabry-Perot (FP) interferometer was invented in 1899, and consisted of two parallel highly reflecting mirrors, the resonance behavior being characterized by peaks or dips in the transmission and reflection spectra [1]. It has been used in a variety of devices among which optical cavities for lasers or filters [2]. In the past two decades, the development of nanophotonics has given birth to FP-like resonators [3], in which a guided mode in a metallic cavity has a behavior that is well described by the FP formalism. The advantages of these nanoresonators are their compactness, and the possibility to combine them to design broadband or multiband resonances. It is well accepted that, since these metallic cavities are the siege of localized resonances, they have negligible influences on each other when they are combined [7]–[6]. The two most common plasmonic nanostructures with a FP behavior are the metal-insulator-metal patch nanoantennas (horizontal resonance), and the high aspect ratio nanogrooves (vertical resonance). Both of these resonators are promising for applications ranging from thermal emission [7], or infrared detection [8] to biosensing [9]. Yet, they suffer from their low quality factor.

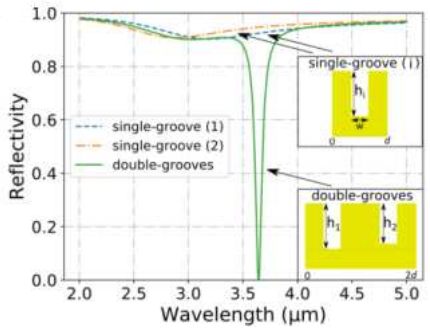

Figure 1 Comparison between the reflectivity of two under-coupled single-nanogroove resonators and the reflectivity of a critically coupled resonator composed of the two aforementioned cavities. The geometrical parameters of the

In this letter, we introduce double cavity Fabry-Perot like nanoresonator in both vertical and horizontal configurations. It departs from the previous work on multimirror FP resonators, as the mirrors are in an hybrid configuration between series and parallel. It gives birth to a spectacular effect where critical coupling (a zero of reflectivity) is obtained while, independently, each of the two cavities is loosely-coupled to free space. Moreover, the quality factor of the double cavity resonators is increased from 11 to 50, well beyond the limit for FP plasmonic nanoresonator [4]. We developed an analytical model that confirms the multimirror FP behavior Then we experimentally demonstrate the coupled Fabry-Perot resonance on a horizontal nanoresonator.

First, we study a periodic double-groove resonator whose period contains two grooves of different heights. While the reflectivity of the periodic single-groove resonators does not go below 85%, the resonance of the double-groove presents a zero of reflectivity and a quality factor of 50 (See Figure 1). We demonstrate thanks to a simple analytical

model that this coupling can be ascribed to a double FP cavity resonance, with the unique feature that the cavities are coupled to one another through a common mirror.

For the experimental demonstration, we consider horizontal nano FP cavities which are analogue to the nanogrooves providing a simple geometry transformation. The resulting horizontal coupled FP nanostructures studied in this letter are made of three layers as illustrated in the inset of the figure 4.b. A top periodic nanostructure composed of one or several gold ribbons of the same height (t=50 nm) but different width denoted by capital letters (W_A= 400 nm and W_B= 495 nm) is deposed on two continuous layers, a SiC insulating layer of 280 nm thickness and a gold mirror.

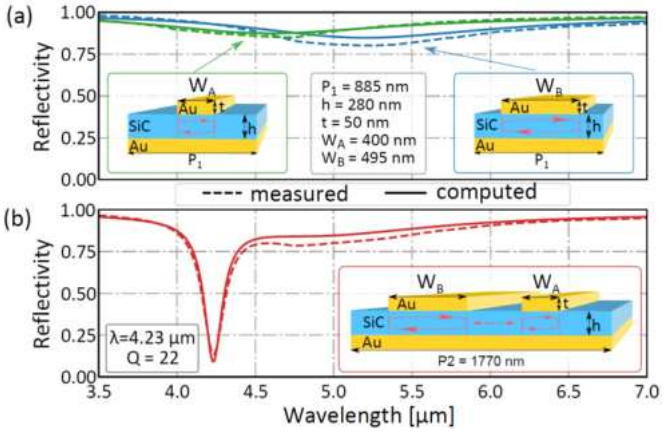

Figure 2: *Measured (dotted) and computed (plain) reflection spectra of (a) single-FP structures and (b) the coupled nano FP structure. Due to the thickness of the SiC layer, the two single FP resonators are under-coupled and their reflectivities do not go below 80%. Due to the coupling between the two FP, the new coupled FP resonance is visible at λ= 4.23 µm with a minimum of reflectivity of 14% and a high Q-factor of 22. The insets represent the different structures*

Finaly, we discuss how the new properties of this coupled FP resonator can be used in multiple domain such as the non-linear optics [11] or infrared photodetection [12]

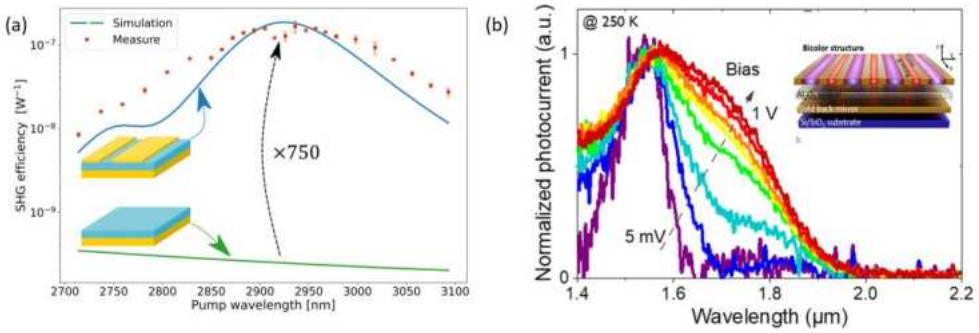

Figure 3: (a) Efficiency of the second harmonic generation enhanced in an horizontal coupled nano-FP structure.[11]

(b) Evidence of the bias reconfigural photoresponse of a quantum-dot on vertical coupled nano-FP structure. [12]

In conclusion, the description of the double-groove resonator paves the way to the manipulation and the engineering of the equivalent mirror coupling the two nanocavities, in order to reach multimirror interferences predictions. This structure is also very promising for many practical applications such as non-linear optics, infrared photodetection, gaz sensing, etc.

Abstract: Optical metasurfaces are two-dimensional assemblies of optical nanoresonators and could constitute next generation ultrathin optical components. We propose an emulsion-based scalable fabrication approach both for the fabrication of colloidal resonators, presenting a strong interaction with light with simultaneous magnetic and electric modes of resonance, and for their deposition in homogeneous films.

The emergence of optical metamaterials is intertwined with that of artificial materials designed to present a significant degree of magnetic polarization under light. Self-assembly methods have typically contributed to this endeavor by fabricating subwavelength structured particles and materials that harbor strong optical magnetism [1]. This specific property can give access to so-called Huygens scatterers. For Huygens scatterers under plane wave illumination, the scattering is dominated by a mode of even parity (such as the electric dipolar mode with Mie coefficient a_1) and a mode of odd parity (such as the magnetic dipolar mode of Mie coefficient b_1) having equal magnitudes and phases, so that they interfere constructively in the forward direction and destructively in the backward direction, leading to forward scattering. Strong forward scattering is important for metasurface applications because it ensures that backscattering is canceled, or minimized, which results in high transmissivity for low-loss all-dielectric metasurfaces and potential near perfect absorption for lossy Huygens scatterers.

Densely-packed spherical colloidal clusters of metallic nanoparticles (NPs) have been proposed theoretically as efficient Huygens scatterers [2]. More generally, they have garnered a lot of interest recently, because they involve localized resonant inclusions that are assembled into a Mie resonator and present structural degrees of freedom as required for resonance engineering. We have used an emulsion route to assemble plasmonic clusters with Au NPs [3] and Ag NPs [4], and have studied their optical properties in liquid suspensions. Furthermore, we have proposed a new method to directly assemble metasurfaces covered with such clusters. This method implements a two-in-one hierarchical process: the fabrication of the clusters and their simultaneous deposition on a surface.

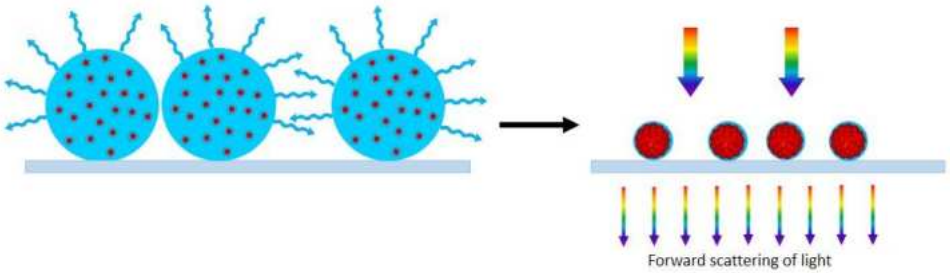

Figure 1. Schematics of emulsion route for simultaneous fabrication and deposition of the Huygens nanoresonators on a surface

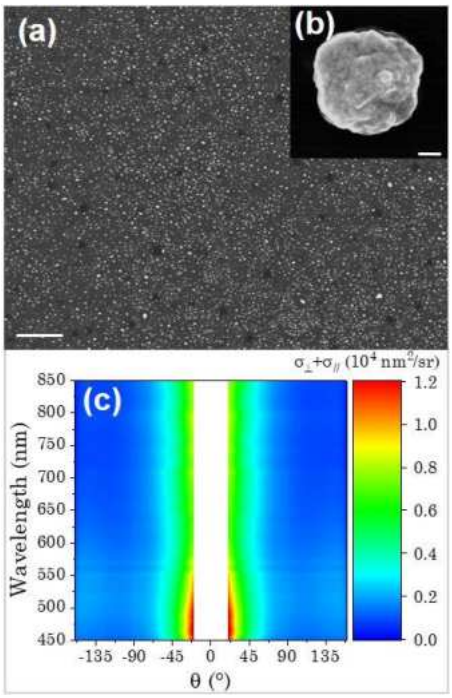

Figure2. Metasurface and meta-atoms. Scanning electron microscopy image of (a) a metasurface (bar = 10 µm), (b) a meta-atom (bar = 100 nm), (c) wavelength- and angle-resolved measurement of the differential scattering cross-section (in nm²/steradian) for a suspension of meta-atoms in a solvent.

Clusters of controlled sizes (in the range 80-200 nm) and metal fraction (between 15 and 55 vol%) with gold NPs (r = 6.7 nm) [3] or silver NPs (r = 11.2 nm) [4] were produced and deposited on a glass substrate. We measured the reflection and transmission spectra of the metasurface as well as the spectral and angular polarization-resolved differential scattering cross-section of the nanoresonators after re-dispersion in a solvent. The clusters exhibit different resonant modes, with strong electric and magnetic dipolar resonances as well as quadrupolar electric resonances, and present strong forward scattering. Comparing our measurements with numerical results reveal that this forward scattering is the result of multipolar interferences and highlight the role of the electric quadrupole in the blue-end of the spectrum and that of the magnetic dipole at the red-end. The scattering cross sections reach values as large as 4 times the geometrical cross section of the clusters, and we show that this figure is an increasing function of the volume fraction of silver NPs inside the clusters. The measured surface absorbances are as high as 50%, while the layer of adsorbed objects is only 100−200 nm thick. This demonstrates the strong interaction of the deposited resonators with incoming light.

Here, we demonstrate that an emulsion drying route can provide control of the structure, and therefore properties, of colloidal clusters both in the volume of a continuous phase or at the surface of a substrate. This “two-in-one” process opens a new route for the fabrication of metasurfaces with enhanced and targeted optical properties that is both simple and scalable.

Rayleigh surface waves of extremal elastic materials

Y. Wei[1], Y. Chen[1], W. Cheng[1], X. N. Liu[1], G. K. Hu[1*]

[1]School of Aerospace Engineering, Beijing Institute of Technology, Beijing 100081, China
[*]corresponding author: hugeng@bit.edu.cn

Abstract: We theoretically investigate the propagation of Rayleigh waves in extremal materials based on continuum theory and verify our findings with designed metamaterials. Dispersion relations and polarizations of Rayleigh waves in extremal materials are derived, and the impact of higher order gradient effects is also investigated using strain gradient theory.

The characteristics of Rayleigh waves (as shown in Fig. 1) in traditional elastic solids are well known, while their natures in extremal elastic materials have largely remained unexplored. Extremal elastic materials can exhibit highly different bulk wave properties compared to classical elastic materials [1-2]. Mathematically, they are defined as elastic materials whose 6×6 elastic matrixes have $N \geqslant 1$ zero eigenvalue [3]. Depending on N, we refer them as unimode materials ($N = 1$), bimode materials ($N = 2$), trimode materials ($N = 3$), quadramode materials ($N = 4$), or pentamode materials ($N = 5$) [3]. Each of the zero eigenvalues is attributed to a soft deformation mode of the material in the sense that the deformation requires conceptually zero energy. Classical elastic solids correspond to $N = 0$ with no soft modes. The presence of soft modes in extremal elastic materials can drastically change their bulk wave properties, allowing to design interesting wave devices. For example, pentamode-based acoustic cloak [4], metasurface [5], quadramode-based phonon polarizer [6-7], triplemode-based zero-refractive-index [1], just name a few. However, investigations on Rayleigh surface waves, closely linked to bulk wave properties, in extremal elastic materials have been relatively scarce.

In this talk, we focus on the study of Rayleigh surface waves of two-dimensional (2D) extremal elastic materials, whose elasticity matrixes are 3×3. In such case, we have two types of extremal elastic materials, i.e., the unimode material ($N = 1$) and the bimode material ($N = 2$). By directly solving the constraint equations [8],

$$\mathbf{u} = \left(A_1 \begin{bmatrix} 1 \\ \chi_1 \end{bmatrix} e^{k\xi_1 x_2} + A_2 \begin{bmatrix} 1 \\ \chi_2 \end{bmatrix} e^{k\xi_2 x_2} + A_3 \begin{bmatrix} 1 \\ \chi_3 \end{bmatrix} e^{k\xi_3 x_2} + A_4 \begin{bmatrix} 1 \\ \chi_4 \end{bmatrix} e^{k\xi_4 x_2} \right) e^{\mathrm{i}k(x_1 - ct)}, \tag{1.1}$$

as well as governing equations for Cauchy elasticity and second gradient elasticity

$$\begin{aligned} &\left(\sigma_{ij} - M_{ijk,k}\right)_{,j} = \rho \frac{\partial^2 u_i}{\partial t^2}, \\ &\sigma_{ij} = C_{ijkl} u_{k,l} + E_{ijklp} u_{k,lp}, \\ &M_{ijk} = E_{lpijk} u_{l,p} + D_{ijklpq} u_{l,pq}, \\ &f_i = \left[C_{ijkl} u_{k,l} - \left(2\delta_{pr} - m_p m_r\right) D_{ijpklq} u_{k,lqr} \right] m_j = 0, \\ &R_i = D_{ijpklq} m_j m_p u_{k,lq} = 0, \end{aligned} \tag{1.2}$$

(A_3, A_4, E_{ijklp} and D_{ijpklq} simultaneous equal to 0 for Cauchy elasticity, otherwise for second gradient elasticity) it is demonstrated that Rayleigh wave cannot propagate in 2D extremal Cauchy elastic materials when the principal axes of materials are parallel to the free planar surface, including the well-known fact that water (an isotropic 2D bimode extremal material) are not able to support Rayleigh waves as a special case. In Eq. (1.1), c denotes phase velocity, k is the wave number and the imaginary unit i. The ξ = b/k , and the real part of b is

supposed to be positive so that the displacements tend to zero when x_2 decreases from the free surface. The amplitude A and ratio χ are independent of x_i and t. In Eq. (1.2), M_{ijk} is the hyperstress tensor, C_{ijkl} is the fourth-order Cauchy elasticity tensor, D_{ijklpq} and E_{ijklp} respectively denotes the sixth-order elasticity tensor and the fifth-order coupling elasticity tensor. The f_i and R_i are respectively the surface force and surface double-force.

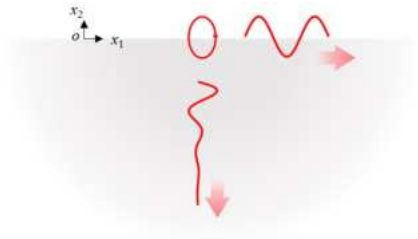

Fig. 1. Scheme of Rayleigh wave.

However, when the microstructural effect is pronounced, we showed that Rayleigh waves can propagate at finite frequencies if second gradient terms of displacement are properly introduced, i.e., the Rayleigh waves can propagate with a dispersive nature when second gradient effects are considered. The characteristics of Rayleigh waves of some isotropic second gradient elasticity have been analyzed in detail. To validate our findings obtained from continuum perspectives, we propose to construct the corresponding discrete models with pantographic microstructures, and to examine their band structures. It is found that for certain isotropic pure second gradient elasticity, the polarization of particles on surface can be either linearly or elliptically polarized, and the Rayleigh waves may not be unique. The results predicted by the discrete models agree quite well with their continuum counterparts. This work provides the first systematic study on Rayleigh waves in extremal elastic materials, and pure second gradient materials as well, and offers a new prospective to control Rayleigh waves in extremal elastic metamaterials.

Abstract: Highly damped plasmonic and ferromagnetic metamaterials exhibit highly efficient broadband light absorption, minimal scattering and strong magnetic actuation capabilities. Here we show how this combination can be applied to develop: (i) wirelessly soft opto-magnetic actuators and detectors and (ii) locally amplified nanotherapies enabling tumor eradication at ultra-low drug concentrations.

Nanostructures of typical plasmonic materials (e.g., Au, Ag) exhibit vivid colors and narrow band resonances, resulting from their negative real part of the dielectric constant and low values of the imaginary part. In contrast, highly damped plasmonic (HDP) materials show negative real part of the dielectric constant, but they present large values of the imaginary part, thus drastically changing their optical response. As a result, HDP nanostructures exhibit deeper light penetration, intense broadband absorption and highly reduced scattering. These features are ideal for generating highly efficient photothermal actuation. Typical HDP materials include many transition metals, such as Cr, Mn, Fe, Ni, or Co. Therefore, in several of these transition metals it is possible to combine strong ferromagnetism at room temperature and HDP behavior. Here, we show how this combination can be exploited, in the case of metallic iron, as multifunctional metamaterials to develop: (i) soft opto-magnetic actuators and detectors, and (ii) locally amplified nanotherapies enabling tumor eradication at ultra-low drug concentrations (Figure 1).

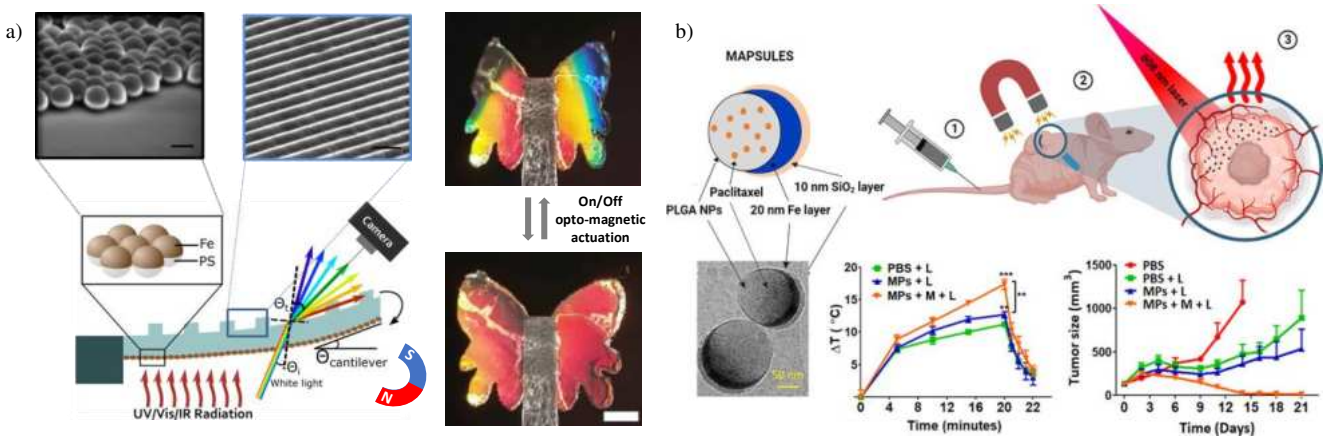

Figure 1: a) Pictures and schematic of the wireless soft opto-magnetic actuators and detectors. b) Schematic representation of the efficient tumor eradication at ultralow drug concentration via externally magnetic concentration and photothermal actuation.

In the first application, we show soft dual opto-magnetic actuators with integrated mechanochromic self-sensing, supporting synergistic untethered optical and magnetic actuation, and self-report of the mechanical state by changing its structural coloration with the bending curvature [1-4]. The actuators are composed of an iron metamaterial layer that is mechanically coupled to thin free-standing soft silicone films whose back-side is periodically corrugated, to act as a light bendable diffraction grating. The opto-magnetic actuator exhibits light absorption in an ultrabroadband spectral range (at least from 0.3 μm to 18 μm), and powerful multimode magnetic actuation by torque or magnetophoretic force. An imaging algorithm accurately quantifies and 2D-maps in real-time the colour changes with a conventional RGB camera, such as a smartphone camera, thereby enabling simple and cost-effective wireless control of the actuation strength.

In the second application, we demonstrate metallic iron-based and drug loaded magnetoplasmonic nanocapsules (MAPSULES) for wirelessly controlled cancer nanotherapies [5,7]. The MAPSULES are composed of a magnetoplasmonic Fe/SiO_2 semishell deposited on 100-200 nm diameter Poly(lactic-co-glycolic acid) (PLGA) beads loaded with paclitaxel. The intense broadband absorption of the MAPSULES in the near-infrared is used for local optical heating, with efficiency similar to the best plasmonic nanoheaters. The MAPSULES exhibit a magnetic vortex configuration, which due to its vanishing remanent magnetization results in virtually no dipolar interactions between particles, leading to an outstanding colloidal stability despite their magnetic strength. Importantly, the strong magnetic character allows remote manipulation of the MAPSULES to easily concentrate them at the site of action and to amplify the photothermal effects. The MAPSULES have enabled complete eradication of the tumors in vivo in mice by combining magnetic concentration in the tumor and local photothermal actuation, using a drug concentration between 200 and 500-fold lower than the therapeutic window of the free drug.

The HDP metamaterial concept can be extended to other metals, polymers with different size, shape, stiffness, and for other drugs. The cost-effective fabrication of the multifunctional HDP metamaterials and their wireless actuation can be applied to a wide range of biomedical, sensing and thermal applications.

Organic epsilon-near-zero and hyperbolic dispersion optical films

Jeong Weon Wu

Department of Physics, Ewha Womans University, Seoul 03760, South Korea
jwwu@ewha.ac.kr

Abstract— Organic thin films presenting a lamellar structure exhibit a hyperbolic dispersion with epsilon-near-zero (ENZ) crossing taking place. Polymethine character of excited-state of donor-acceptor-donor structure is associated with the ENZ behavior of organic molecular films. Linear optical properties such as directive emission and photoluminescence lifetime of fluorescent polymer are controlled by organic ENZ film. Both nonlinear refractive index and nonlinear absorption coefficient of a polymethine thin film are strongly enhanced in the ENZ spectral region, as an example of a third-order nonlinear optical process in organic ENZ films.

Epsilon-near-zero (ENZ) takes place when the real part of dielectric permittivity crosses the zero-point in the spectrum of dielectric permittivity. Owing to the dielectric permittivity being near zero, there are a variety of important linear optical applications such as directive emissions, electric field enhancement in ENZ mode, perfect absorption, and a deep direct writing lithography, to name a few. Furthermore, the nonlinear optical processes, both quadratic and cubic, have been found to be enhanced in ENZ spectral range.

Regarding organic thin film, an organic monolithic $QQT(CN)_4$ molecular film showed a transverse negative hyperbolic dispersion possessing a transverse ENZ. [1,2] Furthermore, regioregular poly (3-alkylthiophenes) (rr-P3AT) organic film is reported to show a similar transverse negative hyperbolic dispersion possessing a transverse epsilon-near-pole (ENP). [3] That is, $QQT(CN)_4$ and rr-P3AT films possess ENZ and ENP, respectively, at the parallel component of dielectric constant, i.e., $\epsilon_{\|}$. Hyperbolic dispersion of these organic thin films is attributed to a spontaneously aligned lamellar alternating-sublayers structure. Polymethine character of excited-state of donor-acceptor-donor structure is associated with the ENZ behavior of organic molecular films. [4]

Using [2,4-bis[8-hydroxy-1,1,7,7-tetramethyljulolidin-9-yl] squaraine] organic thin films, ENZ responses between 450 and 620 nm are demonstrated. Both nonlinear refractive index and nonlinear absorption coefficient are enhanced by more than two orders of magnitude in the ENZ spectral region. These optical effects in the visible spectral range come from the strongly dispersive permittivity of molecular aggregates resulting from the coupling of excitonic transition dipoles. [5]

We introduced an organic ENZ film placed on top of a polymeric fluorophore film to demonstrate a directive emission. By taking advantage of the structural coherence in the P3HT film and the ENZ

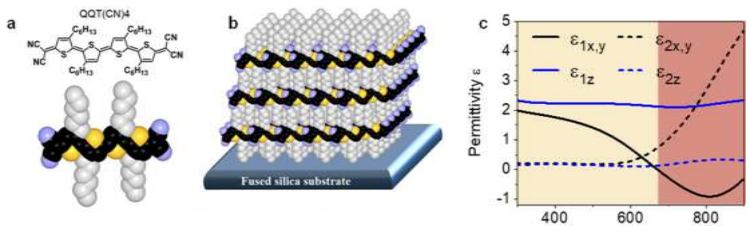

Figure 1: (a) Molecular structure and space-filling representation of $QQT(CN)_4$ (insulating alkyl side chains are represented in gray). (b) Schematic representation of the layered molecular packing structure in spin-coated polycrystalline $QQT(CN)_4$ thin films. (c) x,y component and z component of the real and imaginary parts of the complex permittivity of $QQT(CN)_4$. [1]

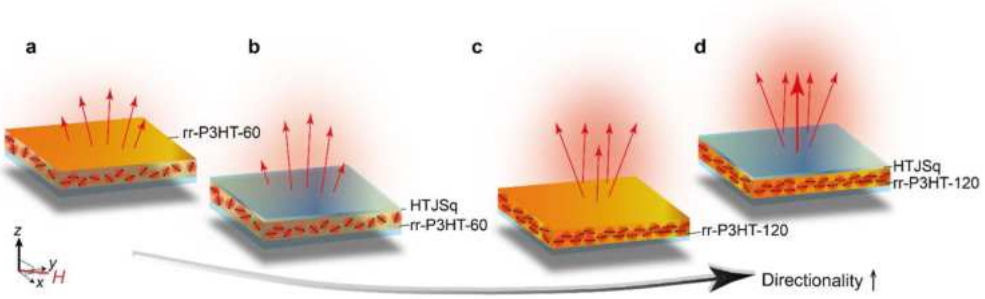

Figure 2: Schematics of directional emission from (a) rr-P3HT-60 bare film, (b) rr-P3HT-60 film with HTJSq film on top, (c) rr-P3HT-120 bare film, and (d) rr-P3HT-120 film with HTJSq film on top. [6]

response in the squaraine molecular film, 42% increase in directive emission is achieved. Spatial coherence of optical wave originating from the ENZ response in squaraine film is responsible for the directive emission of photoluminescence. Notably, HTJSq ENZ film offers wavelength tunability for controlling the directive emission at optical frequency. Based on purely organic compositions, the emission directionality is increased at visible wavelength spectral range by taking advantage of the spatial coherence in squaraine film and structural coherence in polymeric fluorophore film. Capability to control directive emission with organic ENZ films is highly useful in applications requiring bio-compatibility of a fluorophore-embedding medium. [6]

Also, we demonstrated a simple approach to achieve a wavelength-dependent photoluminescence (PL) lifetime modification using monolithic organic molecular aggregates films. These single monolithic organic films are designed to have a Lorentzian dispersion, including epsilon-near-zero (ENZ) and epsilon-near-pole (ENP) spectral regions with increased and decreased photonic density of states, respectively. This dispersion leads to enhanced and depressed PL decay rates at different wavelengths. [7]

Abstract: We demonstrated a crystalline silicon (c-Si) metasurface simultaneously exciting bound states in the continuum (BICs) resonance at the near-infrared wavelength and a plasmonic resonance at the DUV regime to enhance third harmonic generation (THG). We achieved a THG power of 14.5 nW under a peak power density of 15 GW/cm^2.

1. Introduction

Recently, bound states in the continuum (BIC) have emerged to get extremely high Q-factor cavity that theoretically reaches infinity [1]. Ultracompact deep ultraviolet (DUV) coherent light sources can find applications in bioimaging [2], nanolithography [3], and medical inspection [4]. Although conventional nonlinear crystals exhibit relatively high conversion efficiency, their optical losses in DUV hinder their operating regime. Metasurfaces consisting of low-loss nonlinear materials, such as crystal silicon (-Si), would enhance the nonlinear conversion efficiency [5].

2. Results and discussion

We have demonstrated a BIC resonance inside the c-Si metasurface and its unit cell consists of two resonators as shown in Fig. 1a. The structural parameters for the metasurface include the width of top and bottom sides denoted by L_1 and L_2, respectively. The cross-section of the two resonators is a right trapezoid. In the case of L_1=L_2, the BIC resonance is confined so that it cannot be coupled to the radiation spectrum. We only observed a BIC resonance after inducing lattice symmetry breaking by reducing the top side width L_1 of both right trapezoids as shown in Fig. 1b. The theoretical Q-factor was up to 900 for $\Delta L = L_2 - L1 = 20$ nm.

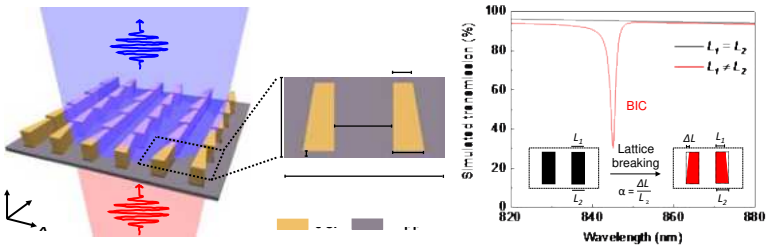

Figure. 1 Metasurface design of c-Si metasurface supporting BIC resonance. (a) 3D schematic of c-Si metasurface on sapphire with a pump fs-laser at wavelength 840 nm, denoted by E_ω, and the collected THG in DUV range at a wavelength 280 nm, denoted by $E_{3\omega}$. (b) Simulated transmission before and after lattice symmetry breaking showing BIC near 840 nm.

The fabrication steps of our metasurface started with electron beam lithography using a negative e-beam resist

hydrogen silsesquioxane (HSQ) of thickness 100 nm. Then, we performed a reactive ion etching using chlorine gas to transfer the HSQ pattern to c-Si, as shown in the inset of Fig. 2a. The experimental Q-factor obtained was more than 180. We pumped the fabricated c-Si metasurface using a linearly polarized fs-laser with the polarization in the horizontal direction. The DUV-THG was measured by using a photomultiplier tube (PMT) after filtering the pump laser.

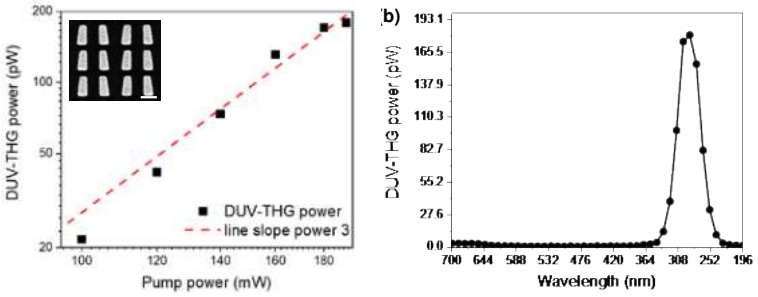

Figure. 2 DUV-THG measurement of c-Si BIC metasurface. (a) The measured DUV-THG versus pump power at a wavelength around 280 nm. (inset) the SEM image of the fabricated c-Si metasurface, with a scale bar of 200 nm. (b) The measured DUV-THG spectrum versus wavelength.

We plotted the DUV-THG power as a function of the pump power in Fig. 2a. The maximum DUV-THG power was up to 200 pW at a pump power of 200 mW. In addition, we measured the DUV-THG spectrum by rotating the resolving prism before the PMT and the results are plotted in Fig. 2b. Our finding will help in obtaining efficient silicon photonic devices operating in the DUV regime.

Tailoring THz radiation pattern through intrapulse and interpulse difference-frequency generation at the nanoscale: modeling and perspectives

Abstract: All-dielectric nanoantennas and metasurfaces unlock the possibility to engineer the directionality of electromagnetic fields owing to the interference between multipolar resonances. We exploit this concept in the framework of NIR-to-THz conversion from flat-optics elements and analyze the role of pump's degrees of freedom in the intrapulse and interpulse schemes for difference-frequency generation.

The terahertz (THz) region of the electromagnetic spectrum (1 – 30 THz) enables to address physical mechanisms that are of great interest not only for fundamental research (e.g. materials science, optics...) but also for applications in telecommunications, biology and industry [1]. Such a variety of disciplines, in which powerful and compact THz devices are required, fairly explains the wide range of methods that have been developed for THz generation: photoconduction, spintronics, laser-induced plasma, or wave-mixing in $\chi^{(2)}$ media [2]. Each of these processes invokes different characteristics of the generated light in terms of bandwidth, efficiency or tunability. Among all, difference-frequency generation (DFG) mediated by the effective $\chi^{(2)}$ of nanophotonic platforms has gained attention owing to the breakthrough in their modeling and fabrication techniques. Particularly, all-dielectric nanoantennas have been proved to be a competitive alternative to plasmonic structures in the near-infrared (NIR) [3] as well as in the THz regime [4], owing to their ability to harness Mie resonances, exploit bulk nonlinearities and circumvent intrinsic ohmic losses in metals. In this work, we present their potential to tailor the emission pattern of THz radiation generated from AlGaAs and $LiNbO_3$ nanocylinders, paving the way to functionalities such as nonlinear routing and sensing.

The concept for rectifying a femtosecond pulse to a THz signal is presented in Figure 1(a) below. A laser pulse polarized along the *x* axis of the laboratory frame excites a magnetic dipolar mode, thereby localizing and enhancing the fields at the laser fundamental within the nanostructure. Considering the NIR fields at an angular frequency ω_1 and at $\omega_2 = \omega_1 - \omega_{THz}$ that fall within the bandwidth of the resonance, the local $\chi^{(2)}(\omega_{THz}, \omega_1, -\omega_2)$ will induce a nonlinear/DFG polarization current density (left panels in Figs. 1(b)-(e)) operating as a sub-wavelength THz source.

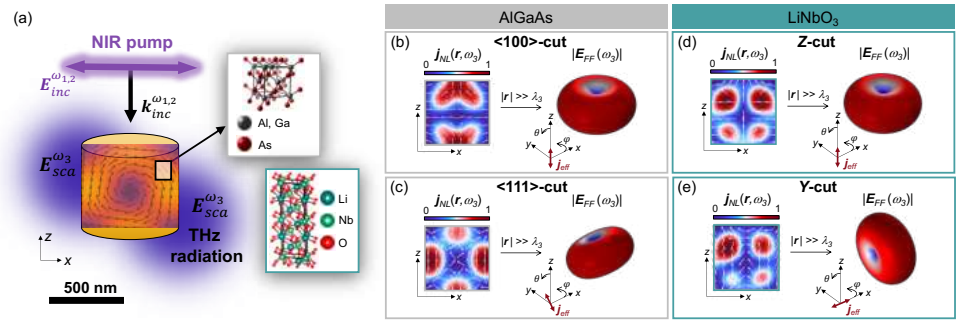

Figure 1. (a) Intrapulse DFG (optical rectification) in high-index dielectric nanopillars, pumped at the magnetic dipole resonance. Nonlinear THz radiation is shown in (b)-(c) for AlGaAs and in (d)-(e) for $LiNbO_3$ nanoantennas [4].

Interestingly, the possibility to grow the nanopillars along different crystallographic directions of the medium results in a reconfiguration of the spatial distribution of nonlinear currents, since the projection of the NIR internal fields on the crystallographic frame (in which $\chi^{(2)}(\omega_{THz}, \omega_1, -\omega_2)$ is defined) will correspondingly change. Figures 1(b)-(e) show that both AlGaAs and $LiNbO_3$ nanoantennas can be designed to remove the radiation null from the forward/backward directions [4].

The same strategy can be followed in the presence of not one but two NIR pulses: the DFG process takes now place between two different pump spectra separated by a THz distance. Such a two-beam scheme, despite the increased set-up complexity, might be preferred for spectroscopy applications requiring high-power, narrowband and tunable THz waves [1]. Figure 2(a) shows the optical-to-THz conversion efficiency obtained with the interpulse DFG in the $LiNbO_3$ nanopillar, when the linearly polarized pumps are mutually orthogonal. The decomposition of the nonlinear THz fields into a spherical multipolar basis elucidates the transition from a purely *z*-directed electric dipole emission (intrapulse case, with degenerate pump polarization) to a superposition of in-quadrature electric dipoles and a magnetic dipole moment. In this spirit, the angle between the two pumps can be used as a knob to control all-optically the THz emission characteristics at an almost constant efficiency (Fig. 2(b)).

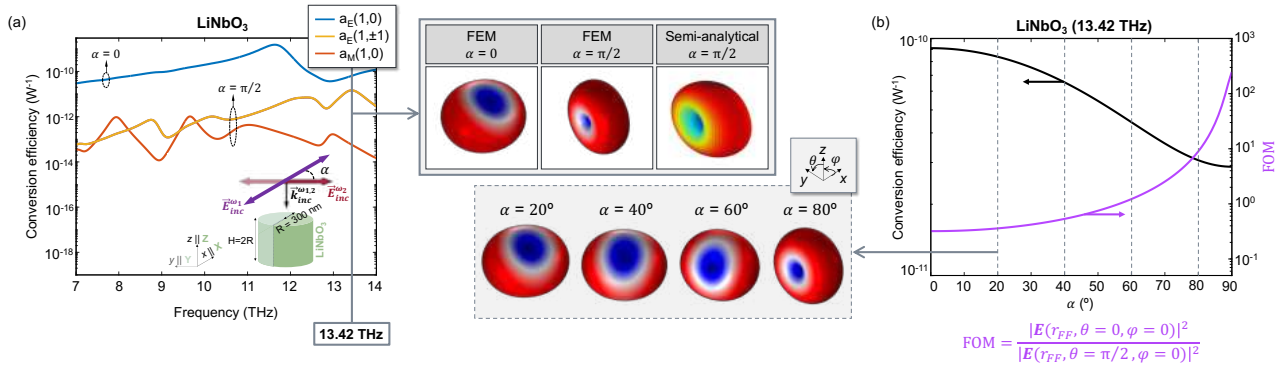

Figure 2. (a) Contribution of electric, $a_E(l,m)$, and magnetic, $a_M(l,m)$, multipolar coefficients to the conversion efficiency of the $LiNbO_3$ nanopillar. (b) Evolution of the efficiency and emission pattern for a varying interpulse polarization angle (α).

These degrees of freedom (crystal orientation, pump configuration and polarization) can be exploited even better in a metasurface configuration, constituted by a two-dimensional periodic arrangement of the proposed nanopillars. Actually, the metasurface could exhibit unprecedented flexibility to steer the THz generated beam analogous to the case of negative index media, but in the nonlinear regime of optical rectification.

This work is part of the METAFAST project (no. 899673) funded by the EU H2020 programme.

Abstract: Here, we design and experimentally demonstrate surface-relief plasmonic metasurfaces that realize high-performance colors and high-density data storage. The plasmonic resonances could be engineered to provide extraordinary capabilities in realizing ultra-high saturated colors or encode various information states into a single subwavelength pixel.

The ever-growing interest of developing modern digital displays and color printing industries drives the urgent need for advanced structural color techniques to realize remarkable color performances. Currently, metasurface-based structural coloration shows unprecedented advantages in chiaroscuro presentation, wide-gamut palette, high-saturation and dynamic tunability. However, most previous approaches are incapable of simultaneously achieving all the above merits [1]. Here, we design and experimentally demonstrate a surface-relief plasmonic metasurface that combines those advantages in one [2]. The color pixel consists of ultra-shallow nanoapertures placed at the centers of hexagonal unit cells, enabling independent manipulation of color hue, saturation and brightness by individually varying geometric dimensions and orientation of the nanoapertures. The plasmonic resonances provide extraordinary capabilities in realizing ultra-high saturated colors and the resonant positions of individual pixels are linearly varied with the lateral size of the nanoapertures, establishing a one-to-one relationship between spectral and spatial information. By uniting differently oriented nanoapertures to modulate color properties and mimicking the conventional sketch drawing & oil-painting techniques, the experimentally photographed microscale images vividly showcase photorealistic and stereoscopic impressions as depicted in Fig. 1a. The reproduced artworks present strikingly clear and subtle renderings of texture details of the original paintings. Moreover, another all-aluminum metasurface is proposed to enhance data-storage density [3]. Localized surface plasmon resonance ensures small unit size approaching diffraction limit with at least 8 different color states encoded in each individual pixel. Distinct information states can be encoded and revealed from the patterned metasurface when the unique polarizer-analyzer combination is provided, thus exhibiting significant potentials in steganography and anticounterfeiting techniques as shown in Fig. 1b. We believe our findings open up avenues for high-fidelity color printing, novel display technique, high-density data storage as well as advanced optical steganography.

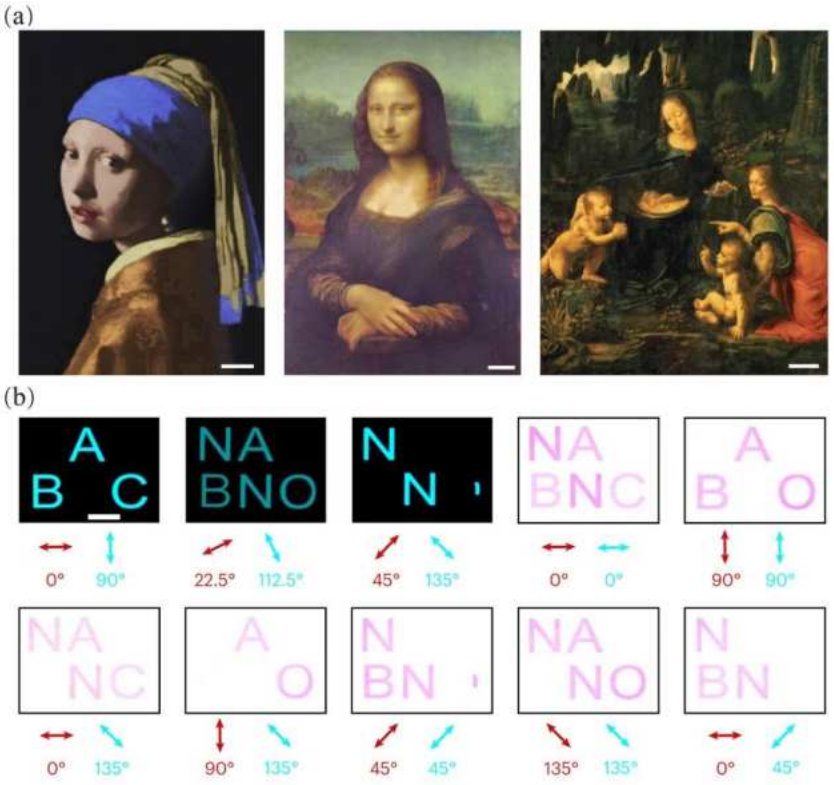

Figure 1 (a) Experimentally captured optical photographs of the metasurface based artworks. The images show ultra-smooth transitions between the different color hues and brightness by using our plasmonic coloring approach. All the white scale bars represent 200 μm. (b) Experimentally captured optical micrographs of the steganographic information display. Different information states can be clearly decrypted under special combinations of polarizer and analyzer angles. Scale bar: 40 μm.

Abstract: We present a novel approach to designing high-quality bound states in the continuum (BIC) in dielectric metasurfaces using magnetic dipole resonances coupled to a mirror, enabling strong light–matter interaction without the need for asymmetric geometry or polarization dependence. This simplifies fabrication and enhances practical applications, demonstrated by a record-breaking third harmonic generation efficiency. Additionally, we showcase superior modulation characteristics with a pulsewidth-limited switching time of 100 fs and a remarkably low energy consumption, facilitated by the narrow photonic resonance of our metasurface. Our findings offer significant potential for optical sensing, quantum photonics, and nonlinear devices.

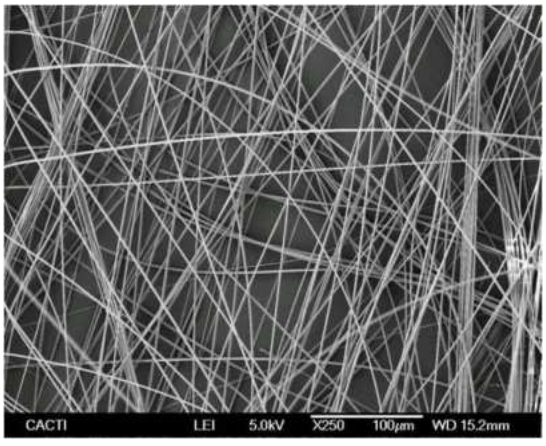
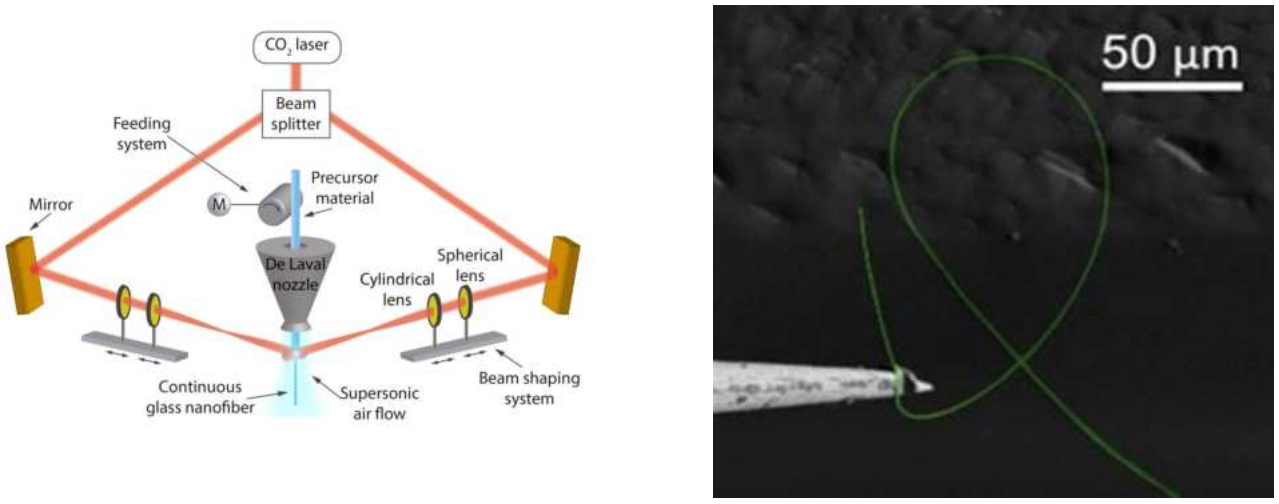
Abstract: Nanofibers are novel materials with very special properties, different from their bulk counterparts, due to the very reduced size and consequent microstructural differences. In this presentation two novel laser-assisted technologies, specific developed for the production of nanofibers, will be introduced: Laser Spinning and COFIBLAS.



Introduction & main results

The search for materials with improved mechanical properties and functionalities has boost the development of advanced continuous nanofibers. The development of nanofibers and nanotubes predicted the production of new nano-composites with exceptional mechanical properties. However, the breakthrough predictions haven't been achieved yet, in part due to the reduced length of the nanofibers or nanotubes, which restrained the mechanical reinforcement and manufacturing. Consequently, there is an enormous interest in the development of advanced continuous nanofibers, but conventional methods for fiber spinning cannot produce fibers thinner than some micrometers robustly. Here, we present two laser-assisted methods to produce glass nanofibers.

On one hand we have Laser Spinning. This technique involves melting and elongation of a precursor material with tailored composition using a high power laser and a supersonic gas jet. Laser Spinning can quickly produce a big quantity of glass nanofibers. Figure 1a shows the schematic idea of this technique. The type of product obtained by this technique is shown in figure 1b.



a)

b)

Figure 1. *a) Schematic illustration of the Laser Spinning technique. b) Example of the nanofibers produced by Laser Spinning. [1].*

On the other hand, Continuous Fiberizing by Laser melting and Supersonic dragging (Cofiblas) is a new process that basically consists on irradiating the precursor material uniformly, therefore heating it extremely fast using a high power laser while, at the same time, the molten material is rapidly drawn and cooled by the action of a supersonic air jet. A laser beam shaping system was specifically developed for this method. This beam shaping system allows a precise control of the temperature distribution in the filament. A de Laval nozzle was designed to provide a coaxial gas jet that exerts a high tension localized at the molten segment of the to-be-formed nanofiber.

a) b)

Figure 2. *a) Schematic illustration of the COFIBLAS technique. b) Example of the extraordinary flexibility of the nanofibers produced by COFIBLAS [2].*

Figure 2a shows the schematic configuration of the COFIBLAS experimental system. Figure 2b shows an image taken by scanning electron microscopy of one nanofiber produced by the COFIBLAS process. It is quite remarkable its extraordinary flexibility.

This innovative method produces glass nanofibers with lengths that are, effectively, unlimited by the process. This method enabled the production of virtually unlimited long, solid, and nonporous glass nanofibers that display outstanding flexibility and could be separately arranged and weaved.

Both techniques will be explained as well as the potential applications of the nanofibers so produced in the biomedical field, textile field, composite manufacturing, etc.

Abstract: We present our work for producing high quality silicon nitride films for integrated quantum optics and quantum phononics. Our main findings are related to refractive index and its dependence on the film stress and surface roughness. Furthermore, photon and phonon dispersion relations, particle group velocities and the nonlinear index depends very much on the material quality. Here we show how we can use fabrication steps and tools to ensure the reliable realization of next-generation devices targeting applications in quantum technologies.

Thermochromic thermal radiator based on angle selective thermal radiation applicable under direct solar irradiance

M. Shimizu[1*], R. Onozaki[1], R. Benlyas[1], Z. Liu[1], and H. Yugami[1]

[1]Graduate School of Engineering, Tohoku University, Japan
[*]corresponding author: makoto.shimizu.a3@tohoku.ac.jp

Abstract: In this study, a thermochromic thermal radiator is proposed that can dissipate heat at high temperature but insulate heat at low temperature. In addition, thanks to the angular selective thermal radiation property at high temperature, it is applicable under solar irradiance due to its angular selective emission (absorption) property.

In this study, a novel heat dissipating device based on radiative heat transfer with the ability to release heat at high temperatures and insulate it at low temperatures is realized, thus realizing a device whose thermal radiation properties change with ambient temperature. This property is realized by using vanadium dioxide, which undergoes a temperature-dependent metal-insulator phase transition, in a metamaterial structure as shown in Fig. 1. We have previously reported that by reducing the thickness of the dielectric layer in a metal-dielectric-metal metamaterial structure, angle-selective thermal radiation at a grazing angle can be achieved[1]. It is also seen when thin films of polaritonic material are formed on a reflective substrate and is called Berreman mode[2]. This device is applicable to realize a device that can dissipate heat based on radiative heat transfer even in an environment where direct sunlight is incident from the vertical direction.

These characteristics would be applied to spacecraft heat dissipation control. For example, in an environment with direct sunlight, the device can reflect sunlight and promote thermal radiation from the spacecraft, while in an environment without sunlight, the device can suppress radiation as much as possible and insulate heat. In this way, the heat dissipation characteristics can be passively controlled according to the environment to reduce the temperature difference. More detail will be explained in the presentation.

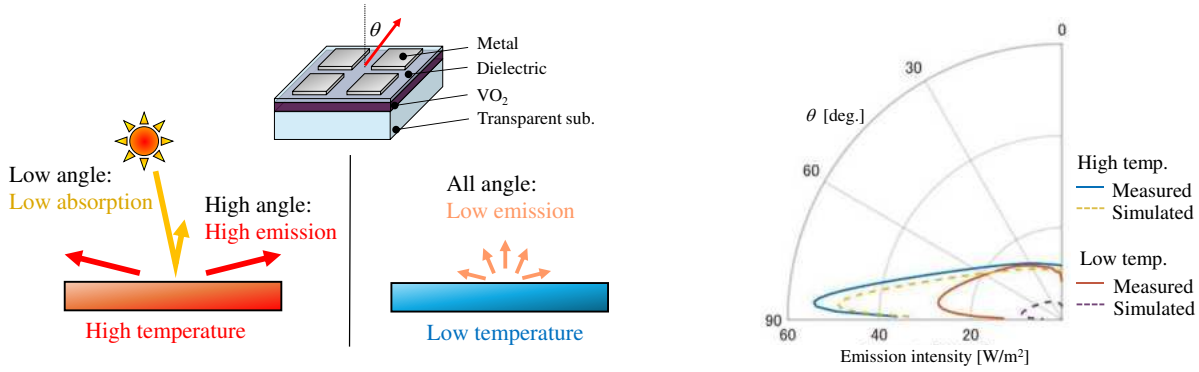

Fig. 1 Schematic image of the proposed thermochromic device and its emission property changing with surrounding temperature (Left). Angle dependence of emission property of the device is shown where the solid lines are the measured ones and dashed lines are the simulated ones (Right).

High-performance Ultraviolet Metasurfaces based on Wide bandgap Dielectrics

Cheng Zhang

School of Optical and Electronic Information & Wuhan National Laboratory for Optoelectronics, Huazhong University of Science and Technology, Wuhan, Hubei 430074, China

cheng.zhang@hust.edu.cn

Abstract: I will present our recent work on employing wide bandgap dielectrics to implement an array of high-performance metasurface optics in the ultraviolet, including down to the deep-ultraviolet region.

In this talk, I will show how low-loss, all-dielectric metasurfaces operating at ultraviolet (UV) wavelengths down to the deep-UV range can be implemented using wide-bandgap dielectric materials[1,2]. The exploited materials in this study include Tantalum Pentoxide (Ta_2O_5) and Hafnium Oxide (HfO_2). For the Ta_2O_5-based metasurfaces, we develop a reactive sputtering process which produces loss-less Ta_2O_5 films for the entire near-UV region, and a fluorine-based reactive ion etching (RIE) process which produces Ta_2O_5 nanostructures with decent sidewall profiles. We demonstrate high-NA metalenses and broadband metaholograms operating across the near-UV regime. For the HfO_2-based metasurfaces, we develop a unique Damascene fabrication process, involving both low-temperature atomic layer deposition (ALD) of HfO_2 onto patterned resist and back etching with Argon (Ar) ion milling, to achieve high-aspect-ratio HfO_2 nanostructures with straight and smooth sidewall profiles. We demonstrate a variety of polarization-independent and polarization-multiplexed UV metasurface devices having representative wave-front shaping functionalities, namely diffraction-limited focusing, hologram projection and self-accelerating beam generation, operating at distinct UV wavelengths down to the deep-UV region.

Abstract: We present a new numerical finite difference numerical package capable of handling periodic driven or eigenvalue linear problems in an arbitrary number of dimensions and with user-defined physical laws (e.g. Maxwell's or Schrodinger's equations). We then illustrate the applications to experimental nanophotonic devices and highly confined polaritons in 2D materials.

This project has received funding from the European Research Council (ERC) under the European Union's Horizon 2020 research and innovation programme (Grant agreement No. 948250).

Strong Coupling with Different Photonic Modes within Single GaN Microstructure

Yong-Hoon Cho
Department of Physics and KI for the NanoCentury,
Korea Advanced Institute of Science and Technology (KAIST), Daejeon, Republic of Korea
*corresponding author: yhc@kaist.ac.kr

Abstract:
Exciton-polaritons are quasi-particles that are half-light and half-matter, which can form single-ground-state polariton condensates in microcavities. In particular, since GaN has large exciton binding energy and high oscillator strength, a GaN hexagonal microrod has been utilized for the generation and condensation of exciton-polaritons at room temperature. Firstly, we observed whispering gallery polariton condensation in GaN hexagonal microrod structures at room temperature [1, 2]. When it is excited by a laser, various photonic and polariton modes such as whispering gallery modes (WGMs) and Fabry-Perot modes can be generated. Optical properties of the WGMs and the Fabry-Perot modes generated in a hexagonal GaN microrod are systematically compared and an experimental technique for selecting a specific mode is investigated among the various photonic modes in the microrod. In particular, angle-resolved micro-photoluminescence (μPL) experiments are performed with varying excitation beam spot sizes to study the tendency of photonic and polaritonic modes. The emission and interference characteristics are analyzed and compared in both real and momentum spaces. Second, we successfully fabricated triangular GaN structures by using the selective area growth method with metal-organic chemical vapor deposition and could observe polariton condensation coupled with WGMs and superscar modes (SSM). The SSM is an optical cavity mode found in polygonal structures that has a longer optical path and higher quality factors compared to the WGM. We could adjust the dominant mode between WGM and SSM for the condensation by changing the opening shape on the GaN template for the selective area growth. To elucidate the processes of polariton formation and condensation in a triangular structure, angle-resolved μPL experiments are carried out with varying excitation power.

Howardhw.lee@uci.edu

Abstract: Optical fiber is a well-established and efficient light-guiding medium. Although optical fiber is efficient for transmitting light, its functionality is limited by the dielectric material of the core, which has poor optoelectronic, magneto-optical, and nonlinear-optical responses and has a dielectric diffraction limit. Therefore, the optical properties of the optical fiber such as phase, amplitude, polarization, and mode profile, cannot be altered after the fiber drawing fabrication, thus limiting the development of novel in-fiber devices. Integration of new materials and nanostructures into fiber will enhance processing/transmission capabilities and novel functionalities.

In this talk, I will present our recent development of "Meta"-optical fiber, an advanced optical fiber integrated with emerging nanophotonic concepts such as optical metasurfaces, plasmonic nanowires, and zero-index photonics. I will present the development of ultrathin optical metalens which is cascaded on the facet of a photonic crystal fiber that enables light focusing. I will also discuss the ability to develop tunable meta-optical fiber for advanced beam steering and dynamic focusing. These advanced "meta"-optical fibers open a pathway to revolutionary in-fiber optical imaging/endoscopy, lasers/spectroscopies, and optical communication devices.

Tuning Nanoscale Photocurrent Direction and Terahertz Polarization State via Incident Light Polarization in Optoelectronic Metasurfaces

Hou-Tong Chen[1*], Jacob Pettine[1], Yunseok Choi[1] and Chun-Chieh Chang[1]

[1] Center for Integrated Nanotechnologies, Los Alamos National Laboratory, Los Alamos, NM 87545, USA

[*]corresponding author: chenht@lanl.gov

Abstract: Nanoscale vectorial photocurrents were observed in symmetry-broken optoelectronic metasurfaces. Nanoantennas with three-fold rotation symmetry enable the continuous rotation of the photocurrent direction and the linear polarization of the emitted terahertz radiation by 360°, and the switching of terahertz vector beams between radial and azimuthal directions, via the incident light polarization.

Control of non-hermitian degeneracy using intersubband polaritonic metasurfaces

Hyeongju Chung[1], Beomjoon Kim[1], Gerhard Boehm[2], Mikhail A. Belkin[2] and Jongwon Lee[1*]

[1] Department of Electrical Engineering, Ulsan National Institute of Science and Technology (UNIST), Ulsan 44919, Korea

Abstract: We suggest the control of non-Hermitian degeneracies in the mid-infrared spectrum using two electrically tunable plasmonic split-ring resonators. These resonators interface with intersubband transitions within multiple-quantum-wells and can be independently manipulated via two bias voltages. At a wavelength of 8.97μm, we achieve the convergence of eigen polarization states.

In the past decade, metasurfaces have garnered significant attention for their ability to manipulate the phase, amplitude, and polarization of scattered light locally. Moreover, ongoing research has focused on developing reconfigurable metasurfaces capable of dynamically adjusting their functionalities. Recent efforts in the mid-infrared spectrum have showcased reflection and phase modulation using electrically reconfigurable polaritonic metasurfaces. These metasurfaces integrate plasmonic ridge-resonators with the remarkable electro-optic properties of Stark-tunable intersubband transitions (IST) in multiple quantum wells (MQWs) [1].

From a foundational standpoint, a metasurface functions as an open system, engaged in continual interaction with the incident field and resonant nanostructures, either absorbing or exchanging energy. These open systems undergo parity-time symmetry breaking at exceptional points (EPs), leading to intricate scattering phenomena linked with optical singularities. While EPs have primarily been observed experimentally in passive settings, they are profoundly sensitive to structural fabrication and prone to fabrication errors, necessitating repetitive manufacturing. To tackle these challenges, a recent study employed a graphene-based device, showcasing EP emergence in an electrically modulated interaction between light and a cluster of organic molecules in the terahertz range [2]. Additionally, an experimental demonstration revealing a missing dimension within a reduced polarization eigenspace at a chiral EP has been achieved using a graphene-metal hybrid metasurface [3].

In this study, we propose the creation of non-Hermitian degeneracies, specifically EPs, employing an electrically reconfigurable intersubband polaritonic metasurface. This metasurface is engineered to merge the electromagnetic modes of two orthogonal plasmonic split-ring resonators and Stark tuning of intersubband transitions by applying bias voltages independently to the MQW layer for each split-ring resonator.

We devised a 300nm-thick MQW layer comprising 16 repetitions of double quantum wells, constructed with $In_{0.52}Al_{0.48}As$ and $In_{0.53}Ga_{0.47}As$ materials, as depicted in Fig. 1(a). The absorption energy of IST between the 1st and 2nd states in the conduction band of the MQW is 122 meV at 0V bias. By applying bias voltages ranging from +1.5V to -1.5V, the IST energy can be adjusted from 105meV to 141meV, respectively. In the presence of IST absorption, the dielectric constant of the MQW layer undergoes modification, albeit solely in the surface normal direction (z-direction). Figure 1(b) displays the calculated imaginary part of the dielectric constant for bias voltages ranging from -1.5V to +1.5V. The unit cell structure depicted in Figure 1(c) comprises left x-directional and right y-directional split-ring resonators, along with two vertical load lines featuring bridges for independent bias voltage application. Each x- and y-split ring resonator can initiate plasmonic resonances for x- (left) and y- (right) polarized incident light, respectively, thereby generating enhanced E_z fields within the MQW layer that can interact with the IST. The coupled mode with the IST can be manipulated by applying bias voltage to each split-ring resonator independently, leading to spectral and phase modulation of x- and

y-polarized reflected light. Figure 1(d) illustrates the reflection spectra of r_{xx}, r_{xy}, r_{yx}, and r_{yy} (where the subscript [yx] denotes reflected linear polarization conversion from x- to y-linear polarization) at a constant V_x of +0.9V while V_y varies from -1.5V to +1.5V in increments of 0.3V. By applying bias voltages to the unit cell structure, several EPs are discovered. One of these EPs is depicted in Figure 2. To attain EPs (non-Hermitian degeneracy), the magnitude and phase of eigenvalues are extracted from the reflection matrix of Figure 1(d) around the wavelength of 8.97μm, as illustrated in Figures 2(a) and 2(b). Specifically, the EP is achieved when both V_x and V_y are set to +0.9V, indicated by the yellow sphere in Figures 2(a) and (b), respectively. Furthermore, the eigenpolarization states are derived from the reflection matrix of Figure 1(d) and plotted on the Poincaré sphere as depicted in Figure 2(c), spanning the wavelength range from 8.75μm to 9.55μm. When V_x is held constant at +0.9V and V_y varies from -1.5V to +0.9V, the eigenpolarization states transition from vertical and horizontal linear polarization to left circularly polarized (LCP) states. Beyond V_y = +1.5V, the eigenpolarization states segregate once more. Figure 2(d) illustrates the eigenpolarization states of the EP, with the LCP states converging at the wavelength of 8.97μm and applied voltages of V_x and V_y set to +0.9V.

Active layer morphology of organic and perovskite photovoltaics – a study based on grazing-incidence X-ray and neutron scattering

Xinhui Lu[1*]

[1] Department of Physics, The Chinese University of Hong Kong, Shatin, Hong Kong, 999077, China,

[*]corresponding author: xinhui.lu@cuhk.edu.hk

Abstract: Nowadays, solar industry becomes the fastest growing industry due to the rising demands to solve the energy crisis and environmental problems. Third-generation solar cells, especially organic and perovskite solar cells are all relying on a semiconducting thin-film active layer to harvest the solar energy. The bulk morphology of the active layer in terms of crystal structure, orientation and nanophase separation behaviors is known to be critical to the organic solar cell device performance. Here, we will present our recent studies on the process-structure-device correlation of organic and perovskite solar cells. In these studies, state-of-art grazing incidence scattering techniques using X-rays and neutrons were employed for various purposes, such as grazing incidence wide-angle/small-angle X-ray scattering (GIWAXS/GISAXS), grazing incidence transmission small-angle X-ray scattering (GTSAXS), grazing incidence neutron scattering (GISANS). These techniques can also be applied in material science, chemistry, biology and condensed matter physics studies. By modifying the wavelength of the probing beam and the experimental geometry, a variety of sample types, such as solutions, powders, surfaces and thin films, can be studied, covering wide length scales as well as versatile dynamic and kinetic behaviors.

Optical Spin Waves

V. Karakhanyan[1], R. Salut[1], M. A. Suarez[1], N. Martin[1], and T. Grosjean[1*]

[1]Optics department, FEMTO-ST Institute UMR 6174, University of Franche-Comté, CNRS, France
[*]corresponding author: thierry.grosjean@univ-fcomte.fr

Abstract: The precession of the magnetic moments in magnetic materials, forming spin waves, has many applications in magnetism and spintronics. We show that an optical analog of spin waves (OSW) can be generated in arrays of plasmonic nanohelices.

The concept of chirality is ubiquitous, impacting fields from biology and medicine to physics and materials science [1,2]. In optics, chiral effects is usually linked to helical waves carrying angular momentum. Recent research has explored the concept of photonic skyrmions by analogy to skyrmions in magnetic material [3,4]. Similarly, we investigate the possibility of generating a photonic counterpart to the spin waves propagating in ferromagnets.

Utilizing gold-coated carbon helices, we demonstrate that near-field coupling between adjacent homochiral helices results in optical waves with intrinsic angular momentum tied to the nanostructures' handedness. These waves propagate independently of the helix direction and are reflected at interfaces between enantiomeric nanohelices, forming heterochiral arrays (see Figure 1). Such a property mirrors the reflection of spin waves between two magnetic materials of opposite magnetization (i.e., of oppostite precession handedness). We fabricated chains of helical nanoantennas and observed energy transport indicative of optical spin waves. The ability of these waves to be guided and reflected within the nanoantenna arrays highlights their potential for integrated photonic applications. The experimental results confirm our theoretical predictions [5].

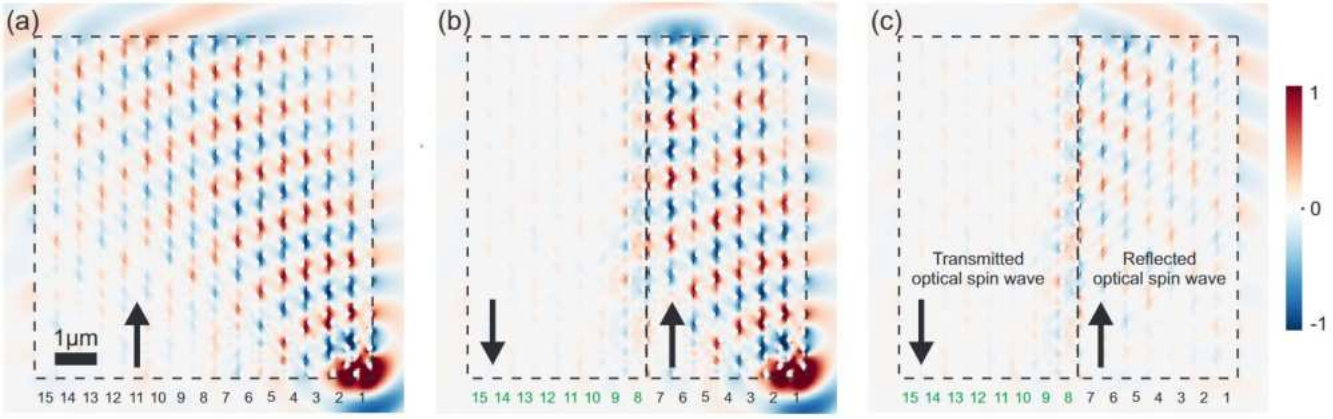

Figure 1: Reflection of a spin-wave at the interface between two homochiral helix chains of opposite handedness. (**a**) Real part of the x-component of the electric field in a homochiral array of fifteen 19-pitch helices. The array is excited with a y-polarized dipole source positioned at the bottom end of the rightmost helix

(λ = 1.55μm). (**b**) The handedness of 8-15 helices is inverted, leading to 2 helix arrays of opposite handedness. In (**a**) and (**b**), the homochiral helix arrays are delimited with dashed lines. The helix handedness in each domain is represented with an arrow. (**c**) Transmitted and reflected optical spin waves on either side of the interface.

The ability of OSW to be guided in a chain of subwavelength chiral structures and to be reflected at the interface between enantiomeric elements holds promise for angular momentum transfer and manipulation in compact integrated platforms. Spin-optical functionalities may arise from the combination of diverse operations on OSW including waveguiding, focusing, interference, steering and modulation, within metamaterials and metasurfaces possibly merging positive and negative refractive indices.

Abstract: We demonstrate ultra-low loss alumina waveguides for visible and UV photonics with sub-dB/cm loss at 450 nm through optimization of film deposition and lithography. Using this technology, we demonstrate the first octave spanning supercontinuum generation in dispersion engineered alumina waveguides spanning a range from the UV to near-IR.

Non-equilibrium light-matter interactions in photonic temporal crystals

Bumki Min[1]

[1]Department of Physics, KAIST, Republic of Korea
[*]corresponding author: bmin@kaist.ac.kr

Abstract: Using classical light-matter interaction theory and Floquet analysis, we demonstrate a significant increase in spontaneous emission decay rates at momentum gap frequencies in photonic temporal crystals. These crystals also facilitate the excitation of atoms from ground to excited states with photon emission.

Over the past several decades, the principal strategies for controlling spontaneous emission have primarily involved the utilization of resonant or space-periodic photonic structures. Initially proposed by Purcell [1] and subsequently elaborated by Yablonovitch [2] in relation to photonic crystals, this method capitalizes on the influence of spatial environments to control the spontaneous emission decay rates of atoms or quantum emitters. Recently, the emergence of time-varying photonics has necessitated a thorough reexamination of the spontaneous emission processes within dynamically evolving environments. This is particularly relevant in the photonic temporal crystals, where optical properties are subject to time-periodic modulations [3-5].

In this work, we employ classical light-matter interaction theory combined with Floquet analysis to uncover a significant enhancement in the spontaneous emission decay rate at the momentum gap frequency within photonic temporal crystals. This remarkable increase is primarily due to mechanisms of loss and gain induced by time-periodicity, along with the inherent non-orthogonality of Floquet eigenstates. Furthermore, our findings reveal that photonic temporal crystals not only enhance spontaneous emission decay rates but also facilitate the excitation of an atom from its ground state to an excited state. This transition is notably accompanied by the spontaneous emission of a photon, adding a new layer of functionality to these time-varying photonic structures.

Ultra-large Area Coherent Lasing Action through Hermitian/non-Hermitian Control in Photonic Crystals

Susumu Noda*

Department of Electronic Science and Engineering, Kyoto University, Kyoto 615-8510, Japan

*corresponding author: snoda@kuee.kyoto-u.ac.jp

Abstract: Realizing large-scale high-power and high-beam-quality semiconductor lasers, which rival (or even replace) bulky gas and solid-state lasers, is one of the ultimate goals of photonics and laser physics. Conventional high-power semiconductor lasers, however, inevitably suffer from poor beam quality owing to the onset of oscillation in many modes, and moreover, the oscillation is destabilized by disruptive thermal effects under continuous-wave (CW) operation. Here, we surmount these challenges by scaling photonic-crystal surface-emitting lasers (PCSELs) [1-5] up to as large as 3mm in diameter while controlling Hermitian and non-Hermitian couplings [6] inside a double-lattice photonic crystal [4] and maintaining these couplings even under CW conditions. The obtained CW brightness, a figure of merit that encapsulates both the output power and the beam quality, reaches ~1 $GWcm^{-2}sr^{-1}$, [6] which rivals those of existing bulky lasers. Our work is an important milestone toward the advent of high-beam quality 1-kW-class semiconductor lasers and toward innovation in a wide variety of industrial applications, from smart material processing to even aerospace applications.

Enhanced Optical Interactions in Nonlinear Topological Photonic Nanostructures

N. C. Panoiu[1*]

[1]Department of Electronic and Electrical Engineering, University College London, Torrington Place, London WC1E 7JE, United Kingdom

[*]corresponding author: n.panoiu@ucl.ac.uk

Abstract: In this talk, I will review some recent results regarding nonlinear optical interactions in certain topological photonic systems. In particular, I will present a detailed analysis of the band topology of 2D photonic crystals (PhCs) with hexagonal symmetry and demonstrate that nonlinear optical processes can be readily implemented via one-way edge modes of this setup. In the second part of my talk, I will illustrate how bound states in the continuum (BICs) of certain PhC slabs, engineered to possess sharp resonances with high quality factors at both the fundamental frequency and second-harmonic, can be used to achieve an orders-of-magnitude enhancement of the SHG. This double-resonance phenomenon is used to significantly enhance the SHG from the PhC slabs.

"EM-Flow": A Conditional Reversible Flow-Based Deep Learning Model for Electromagnetic Inverse Problems

Hongrui Zhang[1], Yanjin Chen[1], Mingyi Li[1], Hengxin Ruan[1] and Lianlin Li[1*]

[1]School of Electronics, Peking University, Beijing 100871, China

Abstract

Deep learning (DL) is playing an increasingly important role in dealing with nonlinear electromagnetic (EM) problems. However, it is a fundamental but unresolved challenge that many DL predictions lack the reliability assessment and physical laws. Here, We present "EM-Flow", a novel deep learning approach for solving EM inverse problems employing a conditional flow-model-based reversible network architecture. The proposed model can learn EM scattering and inverse scattering processes simultaneously, and thus the physical constraint on DL solutions can be automatically imposed. Moreover, owing to the employment of the renormalization group, the interpretability of DL solutions can be ensured in the process of transformation between the target and its scattered field. Selected results have been provided to demonstrate the state-of-art performance of the proposed method in terms of its reconstruction quality and robustness. The proposed method could reveal a new perspective for solving the EM inverse problems including EM inverse scattering and EM imaging based on programmable metasurface with the reliability, interpretability and physical constraints.

1. Introduction

Deep learning (DL) has emerged as a powerful tool extensively utilized in electromagnetic (EM) applications such as EM inverse scattering and EM sensing based on the programmable metamaterial, particularly for dealing with the troublesome yet prevalent EM inverse problems. Compared with the traditional deterministic or stochastic methods such as the Born iteration method (BIM) [1] and the contrast source inversion (CSI) [2] which suffer from the problems of excessive computational complexity and low inversion efficiency. In order to promote its utilization in practical scenes, DL-based methods have obvious advantages in computational efficiency and imaging effect.

Recently, many excellent efforts have been made in this emerging direction in order to learn the mapping between the scattered fields and the scatterer model parameters. To introduce the physical constraints on the artificial networks thereby expect the improvement on the reconstruction quality, more and more hybrid inversion approaches have been proposed aiming at the combination of the conventional noniterative approaches and artificial neural networks [3]. Nonetheless, the current EM inversion methods based on deep learning are usually unidirectional mapping and regard the deep learning as a black box, which is obviously out of the physical law. What's more, most of the DL solutions are deterministic, and they are lack of the uncertainty. But it is usually not true in practical applications because of the unknown ground truth and the uncertainties in measurements and the inverse model.

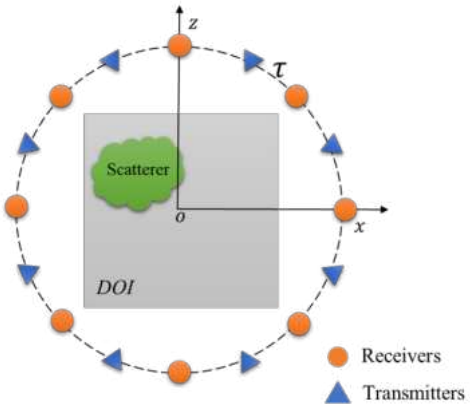

Figure 1: Full-wave 2D forward and inverse scattering model configuration.

In order to resolve above difficulties, here we propose a probabilistic reversible hierarchical deep neural network (DNN) called "EM-Flow", which is inspired by the idea of renormalization group (RG) [4] in physics and the flow-based model in generation model. As an important concept from theoretical physics, RG can help investigate the changes in physical systems at different scales and retrieve the targets on the small scale from that on the large scale through coarse-graining in a hierarchical structure. The random latent variables z in different level separated during this process allow us to quantify the uncertainty and statistical properties. Meanwhile, we introduce the flow-based generation model [5] to make the network reversible and realize the bidirectional mapping between the scattered field and the permittivity. Characterized by the conditional renormalization and generation-flow mechanism with a reversible hierarchical structure, EM-Flow excels in resolving both 2D and 3D EM imaging challenges.

2. Methods

2.1. Forward and inverse models

Taking the 2D numerical experiment as an example, we show our experimental configuration in Fig. 1 for 2D full-wave forward and inverse scattering problems. The forward scattering and inverse scattering which are defined by the state and data equation can be respectively expressed as

$$E_y^{inc}(\boldsymbol{r}) = E_y^{tot}(\boldsymbol{r}) + \frac{jk_0^2}{4}\int_{DOI}\chi_\epsilon(\boldsymbol{r}')E_y^{tot}(\boldsymbol{r}')H_0^{(2)}(k_0|\boldsymbol{r}-\boldsymbol{r}'|)d\boldsymbol{r}', \tag{1}$$

$$E_y^{sct}(\boldsymbol{r}) = -\frac{jk_0^2}{4}\int_{DOI}\chi_\epsilon(\boldsymbol{r}')E_y^{tot}(\boldsymbol{r}')H_0^{(2)}(k_0|\boldsymbol{r}-\boldsymbol{r}'|)d\boldsymbol{r}', \tag{2}$$

where $\boldsymbol{r} \in domain\ of\ interest\ (DOI)$ in (1) and $\boldsymbol{r} \in \Gamma$ (receiving area) in (2), $\boldsymbol{r}'$ are the position vectors, k_0 is the wavenumber in free space and $H_0^{(2)}$ is the 0th-order Hankel function of the second kind. E_y^{inc} and E_y^{tot} are the incident electric and the total electric field, and $E_y^{sct} = E_y^{tot} - E_y^{inc}$ represents the scattered field. What's more, here we assume that the background medium in the DOI is air, so the contrast function χ_ϵ can be expressed as $\chi_\epsilon(\boldsymbol{r}) = \epsilon_r(\boldsymbol{r}) - 1$, where $\epsilon_r = \varepsilon_r + \frac{\sigma}{j\omega}$ is the complex relative permittivity. Here θ is the weights of this end-to-end reversible DNN.

2.2. Architecture of EM-Flow

The overall architecture of EM-Flow is shown in Fig. 2(a), which is an extension of the well-known RG-Flow [6]. It establishes the connection between the relative permittivity distribution $\boldsymbol{x}$ and the scattered fields $\boldsymbol{y}$ through a bidirectional hierarchical network structure, where we assume that $\boldsymbol{x}^h$ is the input of the hth layer of the EM-Flow and in particular $\boldsymbol{x}^1 = \boldsymbol{x}$ is the relative permittivity ϵ_r.

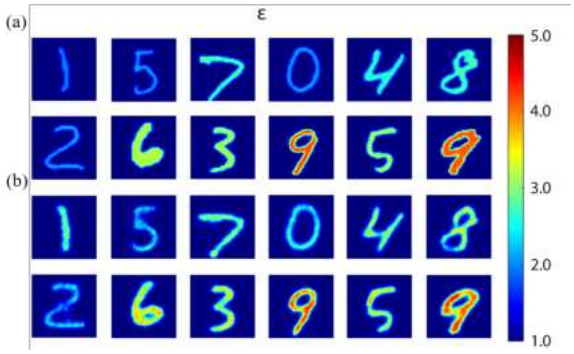

Figure 3: Some examples for the lossy targets. (a) Ground truths of ϵ. (b) Inversion results ϵ by EM-Flow.

The pipeline from left to right in Fig. 2(a) is defined as renormalization $(\boldsymbol{y}, \boldsymbol{z}) = R_\theta(\boldsymbol{x})$, which corresponds to the EM forward scattering process of calculating the scattered fields through dielectric parameters. And its inverse process $\boldsymbol{x} = R_\theta^{-1}(\boldsymbol{y}, \boldsymbol{z}) = G_\theta(\boldsymbol{y}, \boldsymbol{z})$ is called generation, which means the EM inverse scattering process of reconstructing dielectric parameters through scattered fields from right to left. The parameter θ is the weights of this end-to-end reversible DNN.

As a probabilistic DL model for the EM problems, our EM-Flow is a three-port network. To quantify the uncertainty of an output $\boldsymbol{x}$ given the input $\boldsymbol{y}$, we introduce a random latent variable $\boldsymbol{z}$ and $\boldsymbol{z}^h$ is the latent variable of the hth layer of EM-Flow, which represents the disturbance noise and incorporates uncertainty quantification into EM-Flow. In order to minimize the mutual information between the hidden variables and force the variables in each layer to be independent of each other, we choose independent and identically distributed (i.i.d) Gaussian random distributions for all $\boldsymbol{z}$. According to the change of variables theorem,

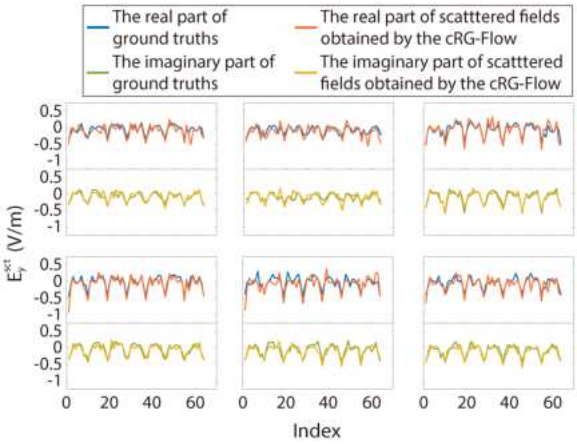

Figure 4: Test of EM-Flow for solving the scattering problems on lossy dataset.

we can model the conditional distribution $p(\boldsymbol{x}|\boldsymbol{y})$ through marginalization over all possible $\boldsymbol{z}$ as

$$\begin{aligned} p_\theta(\boldsymbol{x}|\boldsymbol{y}) &= \int p(\boldsymbol{x}|\boldsymbol{y},\boldsymbol{z})p(\boldsymbol{z})d\boldsymbol{z} \\ &= p(\boldsymbol{z})\left|\det\left(\frac{\partial(\boldsymbol{y},\boldsymbol{z})}{\partial G_\theta(\boldsymbol{y},\boldsymbol{z})}\right)\right|, \end{aligned} \tag{3}$$

where the prior distribution $p(\boldsymbol{z})$ describes the uncertainty of the DL model.

The EM-Flow extracts features layer by layer through a number of bijective cascaded flow blocks with the same internal structure built from the coupling layer [5] as illustrated in Fig. 2(b). Either $s(\cdot)$ or $t(\cdot)$ is just a completely symmetrical multi-layer perceptron (MLP) with a residual structure, composed of fully connected operations and nonlinear activation functions. According to the derivative chain rule, $\ln\left|\det\left(\frac{\partial R_\theta(\boldsymbol{x})}{\partial \boldsymbol{x}}\right)\right|$ in (3) can be easily calculated by the following formula

$$\ln\left|\det\left(\frac{\partial R_\theta(\boldsymbol{x})}{\partial \boldsymbol{x}}\right)\right| = \sum_{l=1}^{L}\left[s_2(\boldsymbol{x}_2') + s_1(\boldsymbol{x}_1)\right]_l, \tag{4}$$

where l indicates the lth flow block, and L is the total number of flow blocks in the network. Each step of the renormalization includes extracting coarse-scale information from $\boldsymbol{x}$ and then inputting it to the next layer, and splitting the remaining fine-grained information into the latent variable $\boldsymbol{z}$ until getting the coarse-grained variable $\boldsymbol{y}$ in the last layer. These separated eigenvectors can be regarded as potential variables at different scales. Conversely, we can directly generate fine-scale $\boldsymbol{x}$ from coarse-scale $\boldsymbol{y}$ in the reverse network. Once the potential variables $\boldsymbol{z}$ of all layers are given, we can recursively generate the fine-scale observation variable $\boldsymbol{x}$ from the input $\boldsymbol{y}$.

According to the maximum likelihood method, the total loss function contains three terms: flow-based model, renormalization and generation. They are defined as follows:

$$\begin{aligned} \mathcal{L}_{total} &= \mathcal{L}_{flow} + \mathcal{L}_{renormalization} + \mathcal{L}_{generation} \\ &= -\mathbb{E}_{\boldsymbol{x},\boldsymbol{y}}\left[\ln p_\theta(\boldsymbol{x}|\boldsymbol{y}) + \ln p_\theta(\boldsymbol{y}|\boldsymbol{x}) + \ln p_\theta(\boldsymbol{x}|\boldsymbol{y},\boldsymbol{z})\right] \\ &= \frac{1}{N}\sum_{n=1}^{N}\left(-\ln p(R_\theta^{\boldsymbol{z}}(\boldsymbol{x}_n)) - \ln\left|\det\left(\frac{\partial R_\theta(\boldsymbol{x}_n)}{\partial \boldsymbol{x}_n}\right)\right|\right) \\ &+ \frac{1}{N}\sum_{n=1}^{N}\left(\alpha\left\|\boldsymbol{y}_n - R_\theta^{\boldsymbol{y}}(\boldsymbol{x}_n)\right\|^2\right) \\ &+ \frac{1}{N}\sum_{n=1}^{N}\left(\beta\left\|\boldsymbol{x}_n - G_\theta(\boldsymbol{y}_n,\boldsymbol{z})\right\|^2\right), \end{aligned} \tag{5}$$

where N is the total number of the samples, and $\boldsymbol{y}_n$ and $\boldsymbol{x}_n$ are the nth scattered field and relative permittivity distribution, respectively. The parameters α and β which are heuristically set to be 1.0 in our experiments determine the variance of $p_\theta(\boldsymbol{y}|\boldsymbol{x})$ and $p_\theta(\boldsymbol{x}|\boldsymbol{y},\boldsymbol{z})$, respectively. $\mathcal{L}_{flow}$ grants the uncertainty to $\boldsymbol{x}$, while $\mathcal{L}_{renormalization}$ and $\mathcal{L}_{generation}$ encourage the certainty of $\boldsymbol{y}$ and $\boldsymbol{x}$.

2.3. Architecture adjustment for 3D objects

Here, we emphasize that the proposed EM-Flow is a highly versatile and flexible model, meaning its internal module structure can be freely adjusted according to our requirements and data formats. Based on the mesh-free modeling method for 3D objects based on the 3D point cloud [7], we adapt EM-Flow to the structure suitable for 3D targets. Compared to the model handling 2D EM inverse scattering above, we replace the primary operational units with 1D convolutional networks, and all operations such as masking, hierarchical extraction and separation are applied to different channels rather than pixels. This means that all points entirely share the same convolutional kernel and masking operations. The modified schematic structure and more details could be found in [7].

3. Results

3.1. 2D numerical results

3.1.1. Lossy handwritten digits

Considering that in practical imaging scenarios targets are generally lossy, we go straight to the lossy handwritten digits which will obviously make it more difficult. The relative permittivity of all the targets is randomly chosen in the range of [2.0, 5.0]. Fig. 3 demonstrates the good inversion performance of our trained network on lossy targets. Reversibility is another significant advantage of EM-Flow, so we directly test its performance in solving forward scattering problem by the network trained above. Fig. 4 shows the scattering results using the scatter shown in the first row of Fig. 3 as the input. It can be seen that although EM-Flow can solve EM scattering problem with a satisfactory accuracy, the results is not as good as its inversion performance. The reason is that we pay more attention to its inversion performance in training phase, so we can give a larger value of α in (5) to balance the two results.

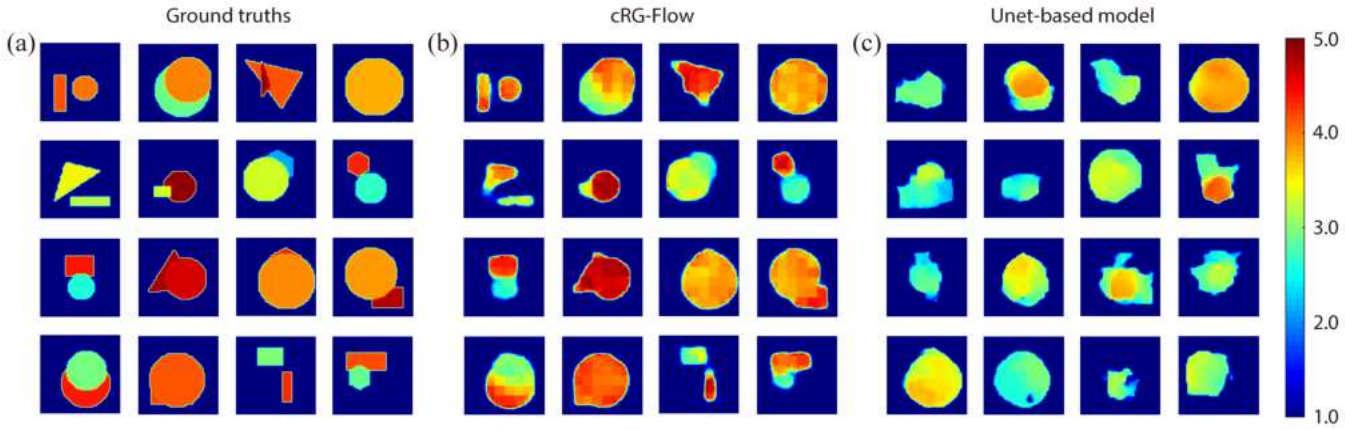

Figure 5: Sixteen representative examples over the nested polygons/circles dataset. (a) Ground truths of ϵ. (b) Inversion results ϵ by EM-Flow. (c) Inversion results ϵ by Unet-based model.

3.1.2. Nested geometries

In order to further verify the capability of our network, we selected targets with more complex shapes which increase the difficulty of inversion during the training and testing stage. At the same time, we used a common network with the U-net sturcture [8] to conduct the same experiment. For fair comparison, the EM-Flow has the almost same the number of trainable parameters as that of U-net.

A set of experiments are conducted over the nested polygon/circle dataset; where the scatterers are random combinations of triangles, circles, rectangles and hexagons, and the relative permittivity is randomly chosen in the range of [2.0, 5.0]. Corresponding results reported in Fig. 5 show that the EM-Flow significantly outperforms the U-net network. Moreover, the average SSIM of the inversion results of EM-Flow is around 0.91, while that of the inversion results of the U-net network is about 0.46. We also find that the U-net suffers from the severe overfitting, but the EM-Flow have not the overfitting. Two possible reasons are: (1) the EM-Flow learns the bidirectional mapping of the scattering fields and relative permittivity; (2) the introduction of a random variable z in EM-Flow makes the less prone to overfitting.

3.2. 3D numerical results

Using the EM-Flow designed for the 3D object based on the point cloud, we train and test the performance of the proposed model with the 3D-MNIST dataset and 3D-object dataset respectively. Fig. 6 show the ground truths of scatterer point clouds and the reconstructed results for the two datasets. We can see that both datasets yield good reconstruction results. Additionally, it is evident that the inversion results for 3D objects are slightly worse than those for digits. The reason for this is that the shapes of 3D objects are more complex than those of handwritten digits. More results could be found in [7], which proved that the proposed model performs very well in addressing the formidable challenge of 3D EM compressing imaging while substantially curtailing data and computational overhead compared to conventional 3D mesh-based models.

3.3. 2D EM compressing imaging

In this section, we validate the performance of our proposed model through challenging 2D EM compressive imaging experiments. Intelligent metasurfaces have been proven to be powerful tools for addressing EM inverse problems such as EM compressing imaging [9, 10, 11]. Based on the metasurface-empowered system described in [9], we demonstrate that our model can achieve high-precision 2D EM imaging and real-time indoor human activity sensing. Fig. 7 shows some results. As can be seen, the imaging accuracy is lower compared to 2D EM inverse scattering simulation experiments due to the significant noise and other interferences present in practical experiments.

4. Conclusions

In this paper, we propose a probabilistic reversible hierarchical neural network named EM-Flow to solve both EM forward and inverse scattering problems at the same time. We choose the representative 2D and 3D numerical examples together with the 2D EM compressing imaging experiment to verify the excellent performance of EM-Flow in reconstruction quality, feasibility, and robustness and show its advantages compared with the traditional DL inversion method. We believe that the proposed methodology holds promise for advancing EM imaging and sensing, with potential applications spanning smart homes, elderly care detection, security check and beyond.

Abstract: We present a bio-inspired metalens array designed to perform directional detection in a 3D light detection and ranging (LiDAR) experiment. Thanks to the high compactness of metasurfaces, our component can be easily integrated in front of any sensing device.

Over the last two decades, many optical components have been largely inspired by biological systems, and some of them are based on the operating principle of arthropod faceted eyes [1, 2, 3]. Each facet of the eye is an optical subsystem, named ommatidium. The curvature of the eye has specifically evolved so that each subsystem forming this compound imaging system can capture light originating from a very specific direction only. In order to mimic arthropod vision, some works show examples of microlens arrays fabricated on a thin flat layer of polymer [1, 2]. This polymer is bent into curved geometries by applying a stress, with the objective of obtaining shapes that are as close as possible of that of the arthropod eyes [1, 2, 3]. From our side, to imitate the eye of an arthropod, we designed a flat component consisting of an array of metalenses and a detection surface made up of a set of photosensitive pixels. Each pixel is associated with an off-axis metalens featuring a unique phase profile. By adjusting the phase profile of all the lenses, we reproduce the curvature of the eye while retaining a planar component. As a result, all the metalenses focus light at the same distance, facilitating on-chip integration.

This component can be used in various imaging systems, such as the plenoptic cameras, based on a lens assembly. As a proof of concept, we experimentally demonstrated the imaging capability of our metasurface in a scanning LiDAR experiment. We proved that by combining a laser source and this metasurface, we can perform angular time-of-flight detection of the objects making up a scene.

The aim of this presentation is to explain how this metasurface was conceived, how we characterized it and to present the results of the LiDAR experiment.

Abstract: Natural networks such as lichen show intriguing properties for light absorption. Inspired by such natural networks, using energy electron loss spectroscopy, we analyze the plasmonic modes of different 2D aluminum networks. We resolve a multitude of different plasmonic modes and show the influence of size, connectivity, and symmetry.

Our daily lives are intertwined with a plethora of networks, ranging from urban transportation and social networks to power grids. Amidst, natural networks such as lichen, coral or algae are especially interesting as they have been optimized by natural selection to fulfill specific functions, e. g. the transport of nutrients or the absorption of light. This is especially evident in the brown algae, which use photonic structures for a dynamic color change. This dynamic color change in response to varying light conditions enables the manipulation of photosynthesis beyond the photochemical process [1].

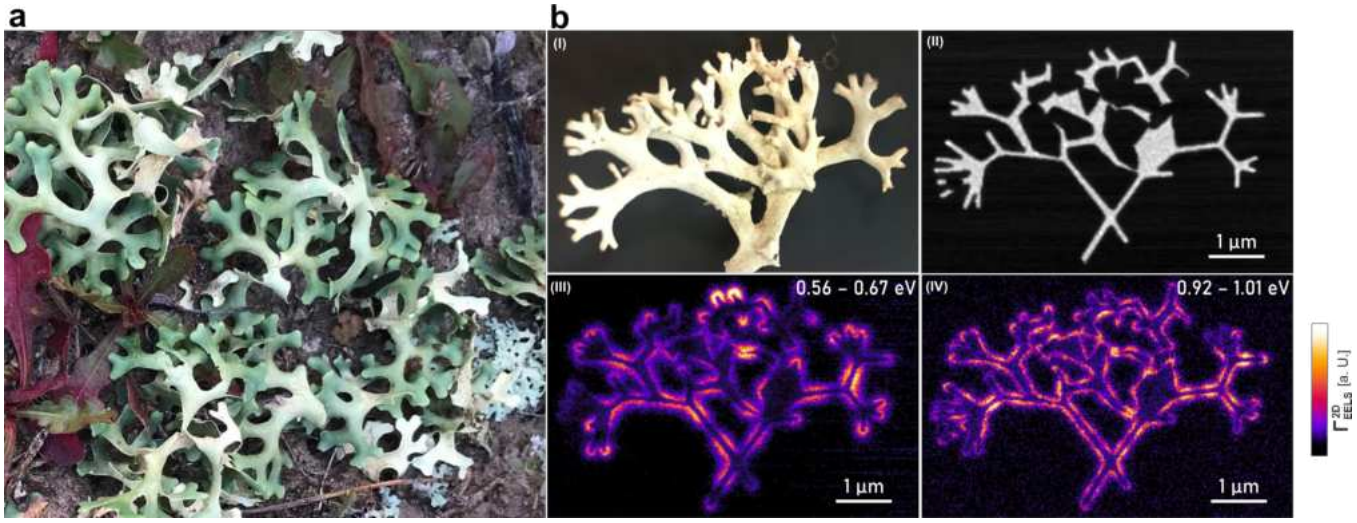

Figure 1: Plasmonic Modes in Lichen networks (a) Image of a common Lichen (b) HAADF image showing a nanoscale reproduction of the lichen network out of aluminum (c) Energy-filtered EELS images corresponding to different maxima in the EELS spectrum showing the excitation of multiple plasmonic resonances in the lichen network.

Inspired by such natural networks, we explore different 2D network metamaterials by electron energy loss spectroscopy (EELS). The different aluminum network nanostructures, ranging from nature inspired lichen and Voronoi networks to Cayley trees and random binomial graphs were fabricated by electron beam lithography and followed by electron beam evaporation. EELS allows to probe the local photonic local density of states (LDOS) with sub-nanometer resolution (Figure 1 and 2). Additionally, EELS spectra and maps of the network nanostructures were

simulated using a boundary element method (Figure 2 a & b). EELS analysis revealed plasmon resonances in the near-IR and visible regions of the electromagnetic spectrum, in good accordance with simulations of aluminum structures of comparable size.

Furthermore, we explore the influence of broken symmetries on the plasmonic modes of the 2D networks. Asymmetrical plasmonic nanostructures have shown extraordinary properties for sensing and biosensing applications [3]. By leveraging the effects of symmetry breaking, we find that it enables us to locally engineer the plasmonic resonances of the networks and thereby facilitates the precise tuning of the local field enhancements. This capability holds great promise for improving the sensitivity and selectivity of plasmonic sensors and opens up new avenues for the detection and characterization of analytes at the nanoscale.

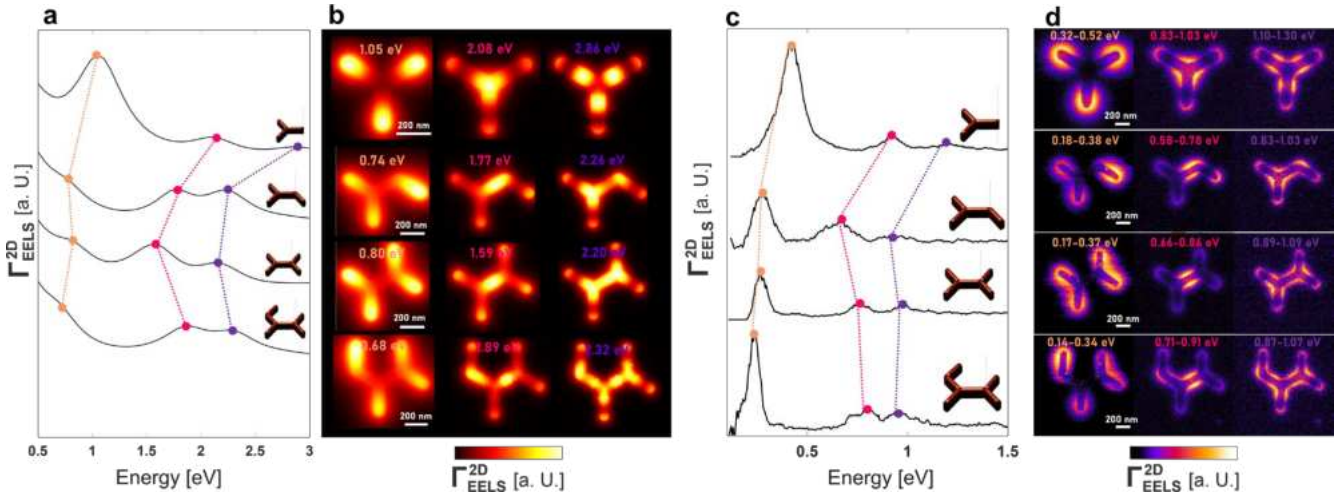

Figure 2: Symmetry breaking in 2D aluminum Cayley trees. (a) Simulated EEL spectra for different Cayley trees, computed in the point shown in the schematics and (b) the corresponding EELS maps at the energies highlighted in (a) [2]. (c) Experimental EEL spectra of different Caylee trees and (d) the corresponding EELS maps at the energies highlighted in (c). Similar modes profiles are observed in both the experimental and the simulated maps. Deviations in absolute energy values stem from the difference in size (smaller for the simulated ones) due to computational reasons.

Our work demonstrates the relation between topology, size and symmetry and plasmonic resonances of 2D network nanostructures. Thereby, EELS gives us direct insight into the LDOS, enabling us to analyze the local field enhancement and mapping the plasmonic resonances of the aluminum networks with ultra-high spatial resolution. The introduced symmetry breaking, along with subsequent mode engineering, holds great potential for site-specific sensing with our 2D network metamaterials.

Investigating disorder in synthetic and biological 3D photonic structures with volume imaging

Abstract: Disorder in photonic structures often alters their optical signal. Complex photonic structures with varying extents of disorder have been found in many animals. In vitro, such structures are often achieved via self-assembly processes. Using volume imaging, we work towards a quantitative understanding of disorder in three-dimensional photonic structures.

Nanostructures on the length scale of visible light are the origin of many brilliant structural colors in nature (1). Complex three-dimensional nanostructures are commonly found in many vibrantly colored insect scales and bird feathers. The dimensions and extent of order in these structures govern the spectral profile and scattering behavior of the optical signal, which may be further altered by absorbing pigments.

Nanostructures smaller than the length scale of visible light are becoming increasingly popular due to their interesting optical properties as they can be exploited as metamaterials for optical computing, or as optical filters or medical devices (2). Our group obtains blueprints for complex nanostructures through block copolymer self-assembly. The fabrication steps induce network distortions, which may diminish the material's desired optical properties. Performing accurate ultrastructural analysis is thus an essential asset for block copolymer-based metamaterials.

The mechanisms governing the transport of electromagnetic waves through ordered three-dimensional structures are well described, but our understanding of how disorder influences optical signals is still limited. To relate optical signals to varying extents of disorder in photonic structures, a quantification of disorder is needed which often requires a volumetric description of the three-dimensional structure. Photonic structures with elements as small as 30 nm and total dimensions on the micrometer scale make high demands on the experimental techniques to obtain volumetric data. Furthermore, many photonic structures are porous, thus achieving high refractive index contrast and often good scattering contrast in scattering experiments (3). Porosity, however, poses another challenge for volume imaging in a slice-and-view approach because it comes with a finite depth of view.

We advanced the quantification of disorder in porous three-dimensional photonic structures and developed an efficient technique for contrast-enhanced volumetric imaging using focused ion beam tomography (4,5,6). Volumetric reconstructions allowed us to extract quantitative network characteristics from complex synthetic copolymer networks with diamond symmetry and biological structures in insect scales of various symmetry classes (Figure 1). Full-wave optical simulations provided simultaneous insight into the optical properties of the photonic structures. Upon comparison with optical measurements, we obtained a comprehensive understanding of the interplay of order and disorder in photonic structures.

Controlling light and heat with Conducting Polymers and Cellulose

Magnus Jonsson

Organic Photonics and Nanooptics group, Laboratory of Organic Electronics, Department of Science and Technology, Linköping University, Sweden

E-mail: magnus.jonsson@liu.se

My group studies novel ways to control light and heat using organic materials like redox-tunable conducting polymers and cellulose. Applications ranges from bioinspired reflective color displays[1,2] and radiative cooling[3-5] to dynamically tunable metasurfaces[6-9] and adaptive camouflage[10]. I plan to present our most recent work on those topics, including nanoantennas based on anisotropic conducting polymers[11] and switchable THz cellulose aerogels.[12]

Structural colors: toward AI-enabled design & solution-based fabrication

Weijie Feng[4], Anwesha Saha[2], Taigao Ma[3], Haozhu Wang[1] and L. Jay Guo[1,4*]

Abstract: Structural colors in the form of layered structures can be mass-produced and have been applied in industrial applications. Such structures can now be designed by using machine learning algorithms. Environmental-friendly chrome-like coating can be designed this way and made by PVD process. Solution process was explored as low-cost alternative to make layered structures.

Structural colors made of inorganic elements contrasts the natural dye pigments, and they are environmental-friendly and offers long-term stability[1]. However, a large class of structural colors relies on precision patterning techniques, which limits their large-scale applications. Another category that is based on multilayer thin film structures are more scalable, but currently depends on vacuum deposition processes[1]. The design of such layered structures requires accumulated experience, thus creates high entry barriers to many. This talk will describe our efforts to address the above challenges.

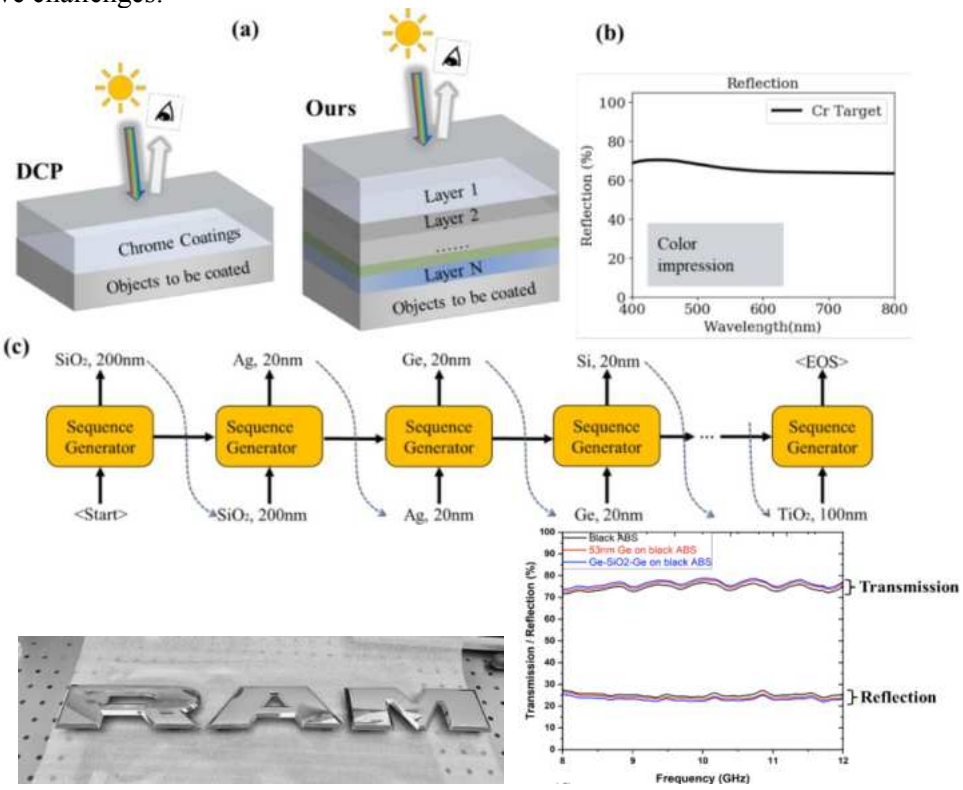

Figure 1. (a) Layered structure to mimic the Chrome reflection spectrum and excluding Cr from the material selection. (b) Reflection spectrum and visual appearance of a Cr layer. (c) Sequential design process used by Reinforcement learning algorithms. Photo of fabricated sample showing chrome-finishing appearance, which shows RF transparency measured in 8-12 GHz range.

To design a thin film structure that can produce the desired color, we formulate the task as an inverse design problem, *i.e.,* design multilayer structures to achieve a certain optical response, such as reflection spectrum of a target color. However, the design process can be non-trivial because for each layer both material selection and thickness need to be considered. To make this easier, many

optimization-based methods have been devised. But these methods are usually based on heuristic searching, which can lead to suboptimal performance. We applied Reinforcement Learning algorithm to treat the multilayer structures as a sequence generation process, and can automatically design the structures to satisfy the targe optical spectrum[2].

To illustrate, we design a structure to mimic the chrome-appearance. Decorative chrome plating is ubiquitous in creating highly appealing chrome-finish. However, the fabrication uses hazardous process with adverse health effects for the workers and causes significant environmental impact. To overcome these challenges, we employ reinforcement learning to generate multilayer structures to mimic chrome's reflection spectrum, which are then fabricated entirely with environmentally benign materials and deposited using PVD process on a variety of substrates. Furthermore, we show another unique functionality by making a chrome-look coating transparent to RF waves, which is not possible at all with traditional chrome coatings. This is achieved by removing metals from consideration during the design process using reinforcement learning algorithm[3].

To reduce the cost of making layered structural colors, we develop a full solution-based method to fabricate multilayer thin film structures, which contrasts with the conventional vacuum-based physical vapor deposition process. We chose copper/dioxide/copper as a model system due to its simple structure and wide color tunability, and carried out systematic investigation for each layer to ensure good film quality as well as its compatibility with all previous layers[4].

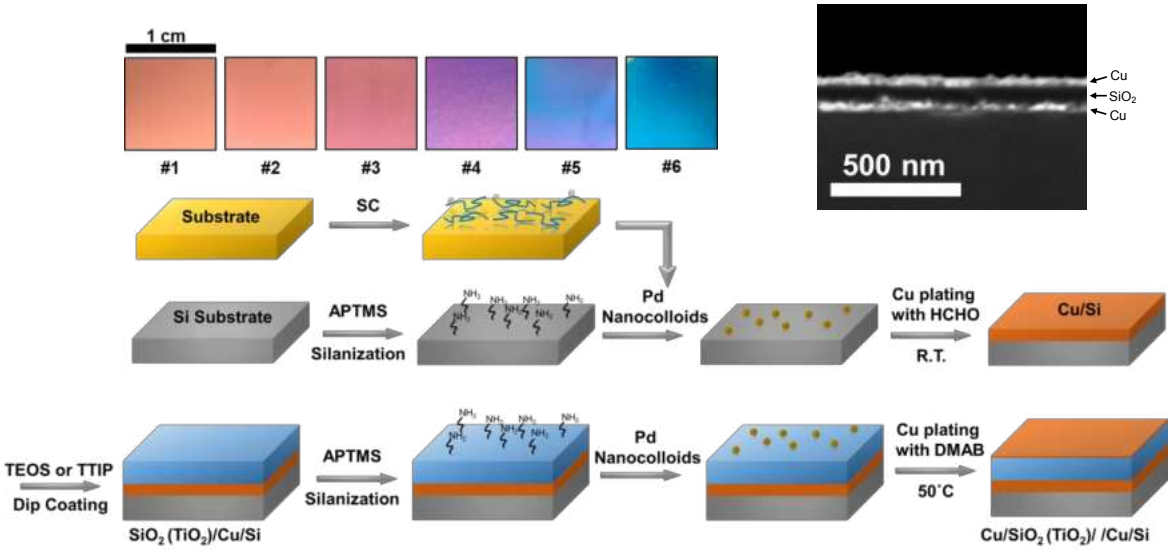

Figure 2. Pictures of solution processed colored samples and cross-section SEM of the cooper/SiO_2/cooper layer. Schematic of steps used in all-solution process to fabricate the individual layers, each compatible with the previous layer.

Abstract: We present a self-assembly platform for low-cost, scalable nanoplasmonic colorimetric sensors, overcoming limitations of traditional fabrication methods. This versatile platform enables real-time detection of chemicals, biomarkers, and environmental conditions, integrating seamlessly with smartphones for portable, power-free diagnostic and sensing applications.

Summary: Colorimetric sensors provide real-time, cost-effective, and high-resolution detection, and are thus a crucial diagnostic tool in various fields. These sensors, which change color in response to specific physical or chemical conditions, offer versatility and adaptability. The interaction of light with the sensor material, which can be fine-tuned to respond to specific stimuli, facilitates this color change. The potential for miniaturization and integration with portable devices, along with their simplicity, makes colorimetric sensors a promising technology for the future. In particular, nanosensors, operating on the nanoscale, have received great attention in recent decades for their remarkable performance. Indeed, their small size allows for high sensitivity and specificity, enabling the detection of minute changes in the environment. These sensors exploit the unique properties of nanomaterials, such as their large surface area to volume ratio and quantum effects, to achieve superior performance. However, the complex and costly processes often involved in the fabrication of nanosensors can limit their widespread adoption.

Here, we present a self-assembly platform for the fabrication of nanoplasmonic colorimetric sensors, providing a solution for large-scale and low-cost nanosensors. This platform simplifies the fabrication process and reduces costs by leveraging the self-assembly of aluminium nanoparticles evaporated through a temperature and pressure-controlled process, making it compatible with current industrial standards[1,2]. Our approach to structural coloration exploits the plasmonic resonances arising naturally from the interaction of light with a random array of self-assembled metallic nanoislands. These nanoislands, grown using conventional thin film techniques, are placed near a mirror, creating a strong hybridization of localized plasmon and subwavelength cavity modes. This results in a single resonance with minimal angular and polarization dispersion and over 90% reflectance at certain wavelengths. The optical response of these nanostructures can be easily adjusted across the entire visible spectrum through simple changes in geometrical parameters, achieving a full color range. Through large-scale fabrication techniques, we produce stand-alone paints that are ready to be transferred onto any substrate. By fabricating the structures through large-scale techniques we produce stand-alone paints that are ready to be transferred onto any substrate.

Importantly, changes in the geometrical parameters or material properties of the structure, triggered by an external stimulus, directly impact its color[3]. We demonstrate how alterations in the morphology of the nanoparticles, resulting from the interaction of the self-assembled layer with an analyte, can be correlated to the

concentration of the target chemical for direct detection of ammonia in water. Alternatively, functionalizing the structure with a carefully selected array of ligands, aptamers, or antibodies, the color can selectively respond to the presence of targeted relevant biomarkers, such as IgG concentrations in blood. Furthermore, the hybridization of an active polymer layer provides readily available solutions for environmental sensing. This approach also allows for the creation of reusable, powerless tags for monitoring environmental conditions such as humidity or temperature, as well as tamper-proof labels for condensation. we demonstrate how a straightforward algorithm leveraging a smartphone camera and image recognition technology can replace traditional bulky and costly spectroscopic systems, streamlining the color-reading procedure. This makes the sensor viable for applications demanding affordability and portability.

Towards a machine learning approach for print parameter prediction in three-dimensional multiphoton laser lithography

S. Enns[1], N. Lang[1], J. Hering-Stratemeier[1], and G. von Freymann[1,2*]

[1]Physics Department and Research Center OPTIMAS, RPTU Kaiserslautern-Landau, Kaiserslautern, Germany

[*]corresponding author: georg.freymann@rptu.de

Abstract: Reducing deviations between design and 3D micro-printed samples without several test prints is difficult since important material properties depend on the process parameters. We present first results towards a detailed prediction of 3D printed structures based on a modeling approach combined with machine learning to adjust the corresponding process parameters.

3D micro-printing using multiphoton laser lithography is an established additive manufacturing technique for the fabrication of, e.g., bio-inspired photonic structures. Recently we could clarify the underlying mechanism of the brilliant whiteness of the cyphochilus beetles using a 3D printed model system [1]. However, deviations between the programmed target structure and the printed samples are inherent, as the material behavior strongly depends on the resulting cross-linking density, which influences the diffusion of the radicals, the overall stability during development and the shrinkage of the structure. Predictions of these interdependent parameters are in principle possible via solving the underlying coupled differential equations describing the photo-chemistry [2]. For extended samples this approach fails due to the numerical costs. Machine learning (ML) has proven to be able to predict parameters in complicated situations in which simulations based on physical models are not practical. The challenge is to provide enough meaningful training data to build the neuronal network.

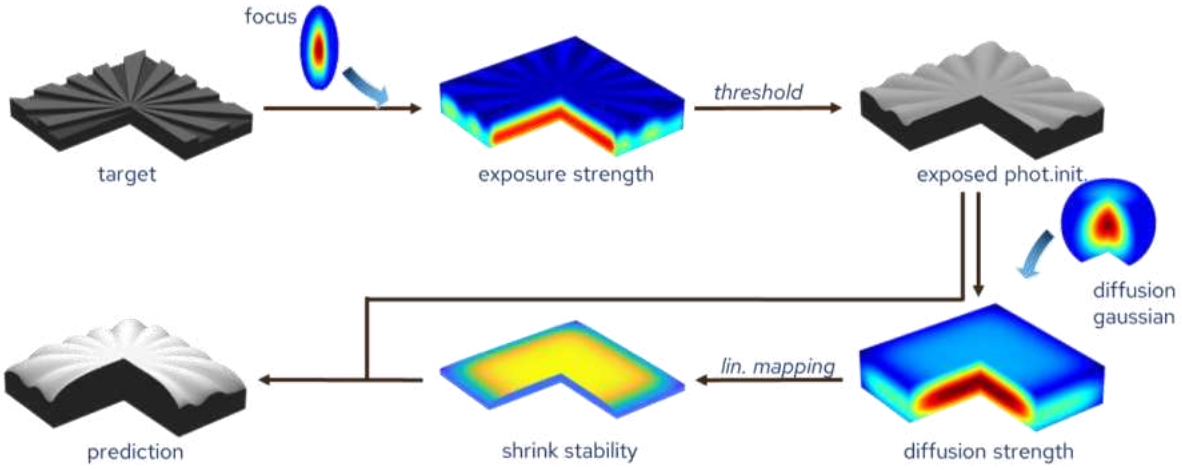

Fig. 1: Schematic representation of the print prediction algorithm: Starting with the target data, exposure dose, radical diffusion, shrinkage and final exposure threshold are calculated to predict the print result.

We use a print prediction algorithm (see Fig. 1) recently developed by us [3] to generate large training data sets, which allow in a first step to generate reliable prediction of the printed structure base solely on the desired target values used for programming the 3D micro-printing device. For ease of characterization, we limit our study

to 2.5D structures as their topography can be easily measured using confocal microscope techniques. Based on this prediction a set of corrected print parameters is calculated, which allows for printing structures which are very close to the designed structure. Fig. 2 presents one example: The target topography is shown on the left-hand side. The center picture shows the measured data if the original design is printed. Huge deviations are obvious. The target data are fed into the trained neuronal network to calculate the print outcome and to derive from these values a corrected set of print parameters. With this set of parameters, the structure has been printed whose measured topography is shown on the right-hand side. Fig. 2 (b) depicts the measured topography values for the cross-sections marked in Fig. 2 (a) showing very nice correspondence between the target structure (red) and the ML-corrected structure (blue). The strong deviations at the edges are due to the difficulty to measure steep edges with the confocal microscope.

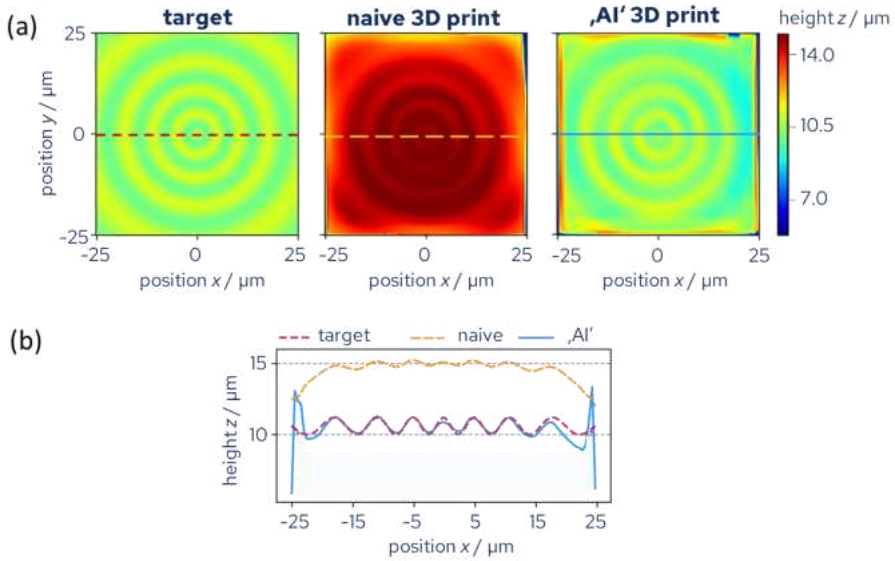

Fig. 2: (a) From left to right: Comparison between the target topography, the measured topography after the printing and the measured topography after printing with the machine-learning corrected parameter set. (b) Cross-section values along the lines in (a) showing the improvement after machine-learning correction.

In conclusion we present first steps towards a machine-learning based approach to predict a set of corrected print parameters allowing to reduce the amount of parameter sweeps in 3D micro-printing.

High-performance optical diffuser inspired by *Morpho* butterfly's optical properties

A. Saito[1,2*], K. Yamashita[1], K. Taniguchi[1], S. Sakamoto[1], T. Hattori[1,2], and Y. Kuwahara[1,2]

[1] Department of Precision Engineering, Osaka University, Suita, Osaka 565-0871, Japan

[*]corresponding author: saito@prec.eng.osaka-u.ac.jp

Abstract: A novel type of diffraction-based optical diffuser was developed inspired by *Morpho* butterfly's optical properties and specific nanostructures. This diffuser can give simultaneously high transmittance, wide angular spread, low color dispersion, diffused-shape controllability, and anti-fouling. Such multi-functional property has been impossible by conventional diffusers that are based on scattering or refraction.

Optical diffusers are essential optical device because it can spread the incident light and create a uniform illumination. This function serves to various application such as daylight window, liquid crystal display, organic light emitting diodes (OLEDs), laser optics, photography lighting, medicine, etc. For these applications, optical diffusers are required to have multi-functions such as i) high transmittance, ii) wide-angle diffusion, iii) low color dispersion (Fig. 1). However, conventional diffusers can hardly achieve these conditions simultaneously. This is because their principles to diffuse the incident light are based on "multiple scattering" or "refraction", which makes the above properties fall into trade-off relationship. Then, we were inspired by the optical properties of *Morpho* butterflies [1].

Morpho butterfly's metallic blue is known as a representative of interferential structural colors, whereas its single color in wide angular range contradicts the interference. This mystery is attributed to specific nanostructures on their wing having both narrow width to produce the wide spread and disorder to prevent the color dispersion [1] (Fig. 2). To simultaneously satisfy the above-mentioned three conditions, we used these *Morpho*-principles, i.e. narrow width and nano-disorder. Also, the limited number of diffraction event that occurs only at an incident interface without multiple scattering can give high transmittance [2,3](Fig. 3). Although our first proposed nanostructure was difficult to fabricate (Fig. 3), we designed a feasible nanostructure using 2D-3D conversion principle obtained from our reflection studies [4].

Finally, a novel *Morpho*-type diffuser was successfully fabricated using nanoimprint technique, which was verified [5] in comparison with the articles on the market [6,7] (Fig. 4). Moreover, our diffuser could provide additional functions to control the diffused light-shape and anti-fouling [8].

Abstract: We present a cross-reactive nanoplasmonic sensor system capable of identifying and classifying almost any complex liquid mixture. Analogous to biological tastebuds, our commercially available plasmonic sensor shows promise in a variety of industrial applications as a simple, rapid quality control measure.

There are a variety of analytical tools that are used in the beverage industry for quality control. Typically, these tools are large, expensive, and are not compatible with real-time, in-line monitoring (e.g. gas chromatography mass spectrometry). On the other end of the scale are human tasters who can be trained to recognize impurities within batches of product, but who, due to the nature of human taste, are prone to giving inconsistent scores. As such, there is the need for simple, real-time sensory tools that can be deployed within production facilities as quality control systems; tools designed specifically to be *non-specific* sensors that can analyse almost any complex liquid, and which, ideally, could also provide "taste" scores analogous to those provided by human testers. Here, we present a nano-scale optical tastebud system that fits these requirements. Our tool can be deployed as a small foot-print benchtop device, or in-line, for applications in industrial mixture production, counterfeit goods detection, quality testing at drinking water treatment sites, and environmental monitoring.

Light-matter interaction on a chip

Deep Neural Networks for Prediction of Structure Parameters and Far-field Radiation Patterns of Nano-antenna

Yi-Chiang Chang and Yung-Chiang Lan*

[1]Department of Photonics, National Cheng Kung University, Taiwan
*corresponding author: lanyc@mail.ncku.edu.tw

Abstract: The inverse neural network (INN) and forward neural network (FNN) are established for bi-directional prediction of structure parameters and far-field radiation patterns of nano-antennas. The INN with pre-trained VGG16 model has better predictive performance. The FNN can capture the main features of predicted radiation patterns.

Optical nano-antennas have tremendous potential in applications of optical communications. Traditionally, the nano-antennas are designed by simulation methods such as finite-difference time-domain (FDTD) method or finite element method (FEM). However, these simulations generally take a lot of time. Recently, deep neural network provides a new and effective scheme to design the nano-antennas. In this work, the inverse neural network (INN) and forward neural network (FNN) are established for bi-directional prediction of structure parameters and far-field radiation patterns of nano-antennas [1].

The INN model uses convolution layers and max pooling layers for feature extraction from radiation patterns and employs a fully connected layer for the classification prediction of structural parameters. Conversely, the FNN model takes structural parameters as input and utilizes transposed convolution layers to effectively reconstruct far-field radiation patterns (Fig. 1). Furthermore, in INN, the transfer learning scheme is used to enhance the accuracy of the model's predictions by employing pre-trained VGG16 model [2]. The studied structure of the nano-antenna is plotted in Fig. 2 with the structure parameters listed in Table 1. A total of 8,000 data (provided by FDTD simulations [3]) are used in INN and FNN for training (70 %), validating (15 %) and testing (15 %) (and adopting the random shuffle method). The INN model is evaluated using two different error assessment metrics which are relative error (Δy_{re}) and R^2 value. For FNN, root mean square error (RMSE) and mean absolute error (MAE) are utilized for evaluating the performance of the FNN model.

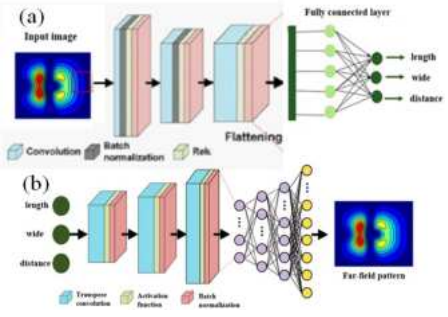

Fig. 1 Schematic diagrams of (a) INN model and (b) FNN model.

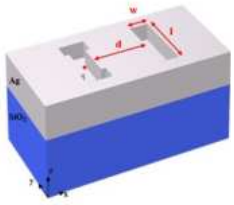

Fig. 2 Schematic diagram of nano-antenna structure. The x-polarized dipole source is placed in the middle of the I-shaped antenna with wavelength of 650 nm.

Table 1. Structural parameters

Structure	Minimum	Maximum	Increment
L	80 nm	270 nm	10 nm
W	20 nm	210 nm	10 nm
D	110 nm	300 nm	10 nm

The training results of the INN model are shown in Table 2. It can be observed that in the predictions of test

set, the INN model's predictions for the structural parameters of length and distance are more precise compared to its predictions for width. The lower predictive ability for structural parameters of width compared to other parameters may be due to the issue of “one-to-many mapping”. In deep learning, it means that the model is handling complex non-linear relationships between multiple outputs predicted from a single input. When the input features are not strongly associated with certain output labels it can lead to decreased predictive performance for the label. The training results of INN using VGG16 pre-trained model are shown in Table 3. Compared to the Table 2, it is evident that the VGG16 model improves predictive performance over the original INN model, particularly in predicting the structural parameters of length and width. This indicates that the VGG16 model is capable of capturing more complex and subtle features. Figure 3 plots the label and prediction with the smallest error in the test datasets of the FNN. Figure 3 shows that, despite of the predicted images being notably blurrier than the label images, FNN still captures the main features of radiation patterns.

Abstract: We have innovated a unique dry etching method for producing lithium niobate nanostructures with side-wall angles exceeding 85 degrees. Utilizing this technique, we have successfully created a second harmonic metalens boasting a remarkable numerical aperture of up to 0.7.

Lithium niobate (LN) has a large second-order nonlinear coefficients (d33=27 pm/V) and wide transparent window spanning from the ultraviolet to the mid-infrared spectral region (350nm-5 μm) [4]. These excellent properties of LN material make it as one of the most outstanding nonlinear optical material. Bulk LN crystals has long been used as intense terahertz or mid-infrared sources and optical modulators. However, optical devices made of high-quality nanostructured LN are still difficult to fabricate due to its strong physical and chemical stability [1,2], which has been a huge obstacle for the more advanced applications of LN.

We developed a novel dry etching method for LN metasurface, and successfully achieve high-quality LN nanostructures with sidewall angle close to 85° at the depth of 300 nm and the selection ratio as high as 8: 1. In our process technique, we choose inductively coupled plasma etching to ensure processing efficiency while achieving fine processing. We find that gas composition and flow rate are two most important parameters determining etching results. Figure 1 shows the fabricated LN nanostructures with various shapes: nanopillars (a), concentric cylinder (b), and nanoholes (c). We believe this etching process is accurate enough to improve LN-based optical devices.

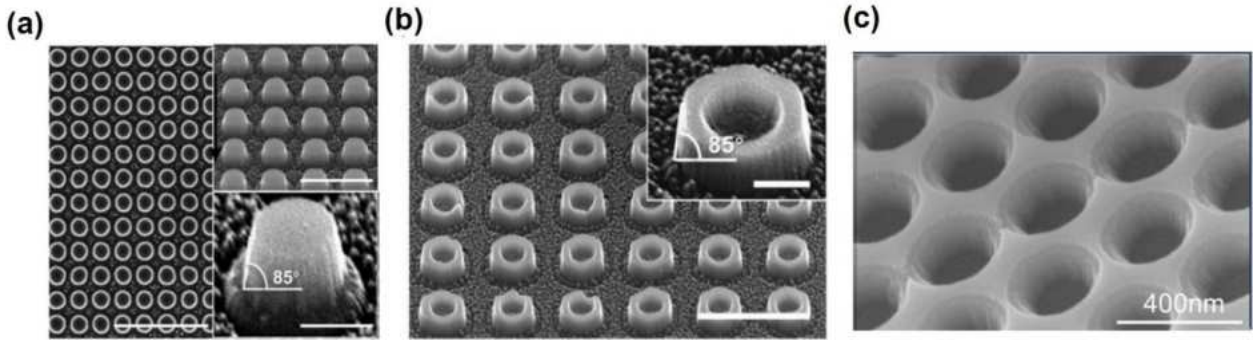

Figure 1: SEM image of various patterned LN nanostructure arrays by nanofabrication process.

We design and fabricate a second harmonic metalens to show the nonlinear wavefront control [3] captivity. The meta-atoms are elliptical holes. Figure 2(a) shows the arrangement of the elliptical holes. The local phase of the emitted second harmonic waves is controlled by tailoring the major and minor axis of the elliptical holes. Figure 2(b)

shows the fabricated LN metalens. Figure 2(c) and 2(d) shows the intensity distributions of the second harmonic waves in the focal plane and a line cross section through the focus, respectively. We observed symmetric focusing of the second harmonic waves with high quality and negligible stray light in the focal plane. The focus lens are 100 μ m and the numerical aperture is up to 0.7, which is among the most high value of nonlinear metalens.

This work was supported by the National Natural Science Foundation of China (1230446, 12074420 and U21A20140,)

Abstract: Immersion metalenses are important to numerous applications. We report an ultrathin water-immersion metalens for the visible range. The metalens consists of GaP meta-atoms of various shapes that enable Huygens' resonance for wavefront control. This work provides a striking platform to realize nanophotonic components for bioimaging, sensing, and many other applications.

Immersion lenses play a critical role in many applications, including biomedical imaging, spectroscopy, and lithography. It is of great importance to realize miniaturized immersion lenses for further advancing these technological applications. Metasurfaces have attracted significant attention due to their great ability to manipulate light at nanoscale. To date, realizing efficient water-immersion metasurface-based lenses (metalenses [1]) in the visible range remains unsolved. Here, we report an ultrathin water-immersion metalens by combining a high-index material GaP(fig. 1b) and a group of well-tailored unit cells (meta-atoms). To design and analyze the optical properties of the meta-atoms and the metalens, we used commercial FDTD software ANASYS Lumerical with a combination of an optimization algorithm in the simulations. To design a group of meta-atoms that are feasible for their nanofabrication and show efficient wave control capability, we tuned the geometry of nanoparticles with different shapes We successfully designed eight meta-atoms of different shapes with a thickness of 85 nm, which is less than one-sixth of the operation wavelength (532 nm). The shapes of meta-atoms include disks, squares, and crosses. Overall, the meta-atoms show high transmittance (>80%) and cover complete 2π phase control (fig. 1c).

To gain further insight into the resonance of the meta-atoms, in figure 1d and 1e, we calculated multiple expansion [2], generalized Kerker coefficient [3], and the field distribution of the meta-atoms. The calculations show that the meta-atoms' unique properties are associated with Huygens' resonance[4], which results from the interference between electric and magnetic dipole modes in our meta-atoms. To showcase the utility of the meta-atoms for water-immersion meta-optics, we designed a metalens with a diameter of 14.4 μm and a focal length of 55 μm. Figure 1f shows the required phase distribution for realizing such a water-immersion metalens, which was encoded by carefully arranging the meta-atoms along the surface. The resulting metalens light focusing, with a focal width (FWHM) close to the diffraction limit (0.53λ/NA), is shown in Figure 1g. According to the results in this work, we expect that the reported water-immersion metasurface will lead to novel nanophotonic systems and foster innovative applications in the foreseeable future.

Lithium-plasmon-based low-powered dynamic color display

Jie Liang[1], Yan Jin[1], Jia Zhu[1] and Lin Zhou[1*]

[1]College of Engineering and Applied Sciences, Nanjing University, China
[*]corresponding author: linzhou@nju.edu.cn

Abstract: In modern electronics, displays and power supplies stand as pivotal yet independent pillars. This report introduces a novel dual-function lithium-plasmon dynamic display, seamlessly blending dynamic color features with energy recycling to achieve both low energy consumption and high resolution.

Alkali metals are attracting significant attention at the intersection of plasmonics and energy storage. On the one hand, alkali metal is emerging as a low-loss and active plasmonic material. On the other hand, lithium (Li), as the lightest metal, has long been regarded as the holy grail of high-energy-density anode materials, with a high specific capacity (3860 mAh/g) and the lowest electrochemical potential (-3.04 V versus the standard hydrogen electrode).

Here, for the first time, we demonstrates a Li metal-based low-powered dynamic plasmonic color display, which is simultaneously a nanostructured anode of a Li metal battery, with the inherited advantages of dynamic tunability and extremely low energy consumption. During the charging process, Li metal nucleates and grows on a pre-patterned substrate, resulting in the generation and tuning of plasmonic colors. During the discharging process, Li metal strips off from the substrate, thus leading to the erasure of the color (as shown in Figure 1).

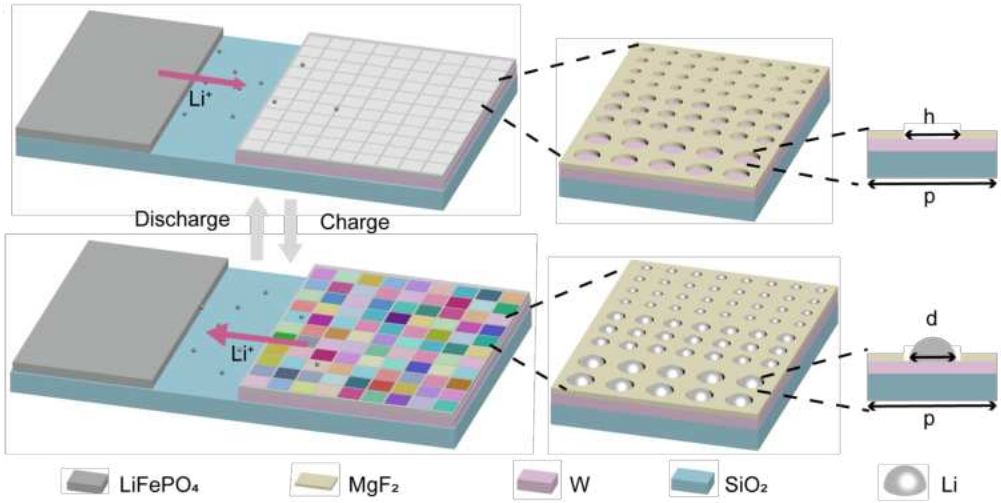

Figure 1. Schematic and illustration of the low-powered dynamic plasmonic color display. The display panel, which serves as the anode of the battery, is composed of silica (SiO_2) substrate, tungsten (W) conductive film (100 nm thick) and a magnesium fluoride (MgF_2) insulating layer (30 nm thick) with periodic holes under the colorless 'off' state. Each pixel is composed of periodic holes with a given lateral period (p) and diameter (h). During the charging (electrodeposition) process, Li nanoparticles with diameter (d) generate colors as the 'on' state. These colors can be erased during the discharging process once Li nanoparticles are stripped off.

The energy storage characteristics of lithium metal can effectively realize energy recovery and reuse during the charging and discharging process. Because of the dual functionality (plasmonic display and energy storage) of Li metal, each pixel is a micro-lithium battery in a display device, in which one charged pixel can power another one to release its energy, and vice versa, during repeated cycling. The energy storage feature of Li metal enables effective energy recycling and reduces the overall energy consumption to 0.390 mW cm^{-2} for the active coloration state and 0.105 mW cm^{-2} for the static coloration state of a proof-of-concept display/battery device, which is much lower than the energy consumption of LCD, LED, EPD display devices, vital for energy-efficient display technologies in the future.

In summary, benefiting from the light field manipulation beyond the diffraction limit and the energy storage battery of Li metals, this work shows much lower energy consumption, much higher spatial resolution, higher compactness, considerable modulation speed and good eye protection for the full-color display. Thus, this Li-metal-based plasmonic color display shows the best overall performance, opening up a promising direction for future high-performance display technology. Their results may offer a unique opportunity to develop a nano-scaled integrated platform for energy storage and information display.

Abstract: We demonstrate highly polarization-sensitive plasmonic phototransistors using a monolayer MoS_2 on an HfN-gated structure and integrated with plasmonic Au nanorod arrays. Through finite-difference time-domain (FDTD) calculations, we achieved a strong linear polarization selectivity of up to 90 % under illumination at 660 nm.

Accurate detection of polarized light is crucial for fields such as quantum communication and quantum information processing. However, the current technology indispensably requires multiple optical components, inevitably resulting in substantial losses and diminished efficiency in polarized light detection. In this study, we introduce polarization-sensitive phototransistors built upon a scalable monolayer of MoS_2 [1,2], utilizing a HfN back gate, and integrated with plasmonic gold (Au) nanorod arrays. The strength of the interaction between excitons and surface plasmon resonances is finely tuned using plasmonic nanostructures, as confirmed by Finite-difference time-domain (FDTD) simulations. Our simulations show that phototransistors with Au nanorod arrays (550 nm in length, 55 nm in width, and 30 nm in height) with periodicity of 620 nm/200 nm, demonstrate pronounced linear polarization selectivity when illuminated at 660 nm. These plasmonic devices exhibit a polarization-dependent absorption spectrum with a linear polarization ratio of 90.5%. This enhanced polarization sensitivity provided by the plasmonic nanostructures opens avenues for further exploration of efficient polarized-light sensitive phototransistors. Finally, we will explore the promising applications of these ultra-thin, high polarization-sensitive phototransistors.

Fig.1 shows the material properties of HfN film. Fig. 1(a) presents the AFM image of HfN film with rms of 0.5 nm. Fig. 1(b) reveals the Raman spectrum of the monolayer MoS_2 on the HfN-based gated structure (30 nm Al2O3 / 100 nm HfN). Fig. 1(c) shows the comparison of PL intensity from monolayer MoS_2 with and without the HfN plasmonic substrate. The results indicate that the PL intensity significantly increases around 660 nm for the one with the HfN back reflector. Fig.2 shows the simulation result of plasmonic Au nanorod arrays. Fig. 2(a) reveals the electric field distribution under illumination with an *x*-polarized light at 660 nm. A strong localized field can be observed. Fig. 2(b) illustrates the electric field distribution under illumination with a *y*-polarized light of 660 nm. It discloses barely any optical field confinement. Fig. 2(c) shows the effective absorbance in monolayer MoS_2 on a different substrate.

Active Multitasking Metasurfaces: Simultaneous and Independent Steering of Frequency-Shifted Beams

P. Thureja[1], J. Sisler[1], M. D. Kelzenberg[1], R. Sokhoyan[1] and H. A. Atwater[1*]

[1]Thomas J. Watson Laboratories of Applied Physics, California Institute of Technology, CA 91125 Pasadena, USA
[*]corresponding author: haa@caltech.edu

Abstract: We experimentally steer frequency-shifted light using an electrically tunable ITO-based metasurface operating at near-infrared wavelengths. By independently addressing metasurface elements, we superimpose MHz driving frequencies with nonresonant spatial phase offsets. This configuration creates a chip-scale platform for simultaneous and independent control of the frequency and wave vector of light.

Active metasurfaces comprising arrays of programmable nanoantennas have gained widespread interest due to their potential for versatile wavefront shaping. Until now, researchers have primarily focused on using active metasurfaces to dynamically control the amplitude, phase, and polarization of light at a fixed wavelength. Recently, there has been growing interest in high-frequency temporal modulation to generate beams at new output wavelengths using a single excitation wavelength. While experimental demonstrations at radio frequencies exhibited large modulations with intuitive antenna designs and fast response times [1], optical frequency demonstrations thus far have faced constraints in real-world applications with most demonstrations relying on all-optical pump-probe schemes [2, 3]. Addressing this gap, our group recently introduced an electrically tunable space-time metasurface operating at 1530 nm by modulating an indium tin oxide (ITO)-based metasurface with two interdigitated electrodes at MHz frequencies [4].

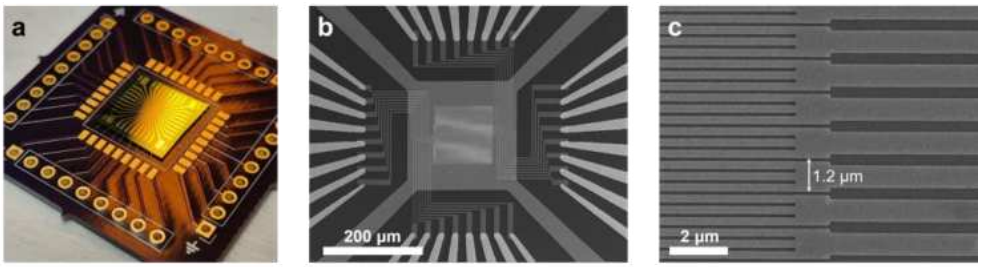

Figure 1. (a) 32-electrode metasurface wire bonded into PCB. (b) SEM of metasurface. (c) Each metasurface electrode is connected to three nanoantennas, corresponding to an effective period of 1.2 µm.

In this work, we build upon our previous proof-of-concept demonstration [4] and incorporate 32 independently addressable metasurface electrodes for versatile wavefront engineering (Fig. 1). The current ITO-based active metasurface exhibits a modulation in the amplitude and phase > 200° at ~1510 nm. In a first step, we collectively modulate all metasurface elements at frequencies up to 10 MHz and frequency-shift the reflected light by multiples of the driving frequency. The measured frequency spectrum is determined by the applied waveform and corresponds to a time-domain Fourier transform of the reflected field in space and time. We then introduce incremental phase offsets between the driving waveforms applied to each electrode to superimpose the temporally varying waveform with a spatially varying phase front. The traveling-wave-like modulation created through this configuration simultaneously shifts the frequency and tangential momentum of

the reflected light, enabling steering of frequency-shifted light up to angles of +/- 20°. Since the spatial variation of phase leverages nonresonant phase offsets that are introduced through an arbitrary waveform generator, we achieve highly directive steering of frequency-shifted light to target angles.

In a next step, we discuss the potential of the proposed space-time metasurface for multi-channel communication, achieved through spatial multiplexing of two subarrays with two distinct driving waveforms at different frequencies (Fig. 2a, 2b). A comparison of the frequency spectra obtained while only modulating one subarray in time *vs.* modulating both subarrays simultaneously shows that there is negligible crosstalk between the two driving frequencies (Fig. 2c). Independent control of phase offsets within each subarray enables simultaneous, independent, and deterministic steering of two frequency-shifted beams. We further discuss the incorporation of this control scheme into free-space laser communication systems, specifically in the realm of intersatellite optical communication. Here, we examine the potential impact of space-time modulation on the overall performance of the system. The methods outlined in this work lay the groundwork for active multitasking metasurfaces, promising increased channel capacity in next-generation optical technologies.

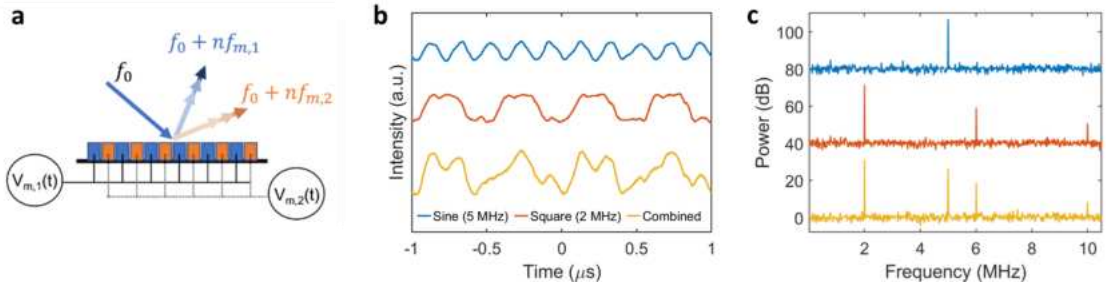

Figure 2. (a) Schematic of multi-frequency multi-beam steering with two independently modulated subarrays indicated in orange and blue, respectively [5]. (b) Time-domain reflection intensity and (c) frequency spectra for modulation of an individual subarray with a 5 MHz sine wave (blue), a 2 MHz square wave (orange) and both subarrays simultaneously with a 5 MHz sine wave and a 2 MHz square wave, respectively (yellow). The time-domain intensity and power spectra are offset for clarity. The incident laser wavelength was 1530 nm.

Abstract: We present a combination of grayscale electron beam lithography (g-EBL) and direct forming methodology to fabricate free-form antimony sulfide structures. 4-level Fresnel Zone Plates (FZP) and metalenses were produced and characterized. The method can be used for the fabrication of 3D micro-optical elements in a single step manner.

The refractive index n=n+ik, is the most important parameter for the design and fabrication of diffractive optical elements (DOEs) and metasurfaces [1]. Recently, antimony trisulfide (Sb_2S_3) has attracted much attention as it is a promising candidate for the fabrication of micro-optical devices. Sb_2S_3 has high refractive index (n~2.5 and 4.5 at 633 nm vacuum wavelength for amorphous and crystalline Sb_2S_3, respectively) while still maintaining low losses, which renders Sb_2S_3 an ideal candidate for the fabrication of high performance DOEs and metasurfaces.

In the previous study [2], Wei Wang et al. demonstrated for the first time that the antimony-butyldithiocarbamic-complex can be used for the direct patterning of Sb_2S_3 nanostructures via various lithography methods, including EBL. In our recent [3] study, Sb_2S_3 nanostructures with controlled lateral and vertical profile were obtained through a single step g-EBL direct patterning scheme (Fig. 1(a)) for the first time. The refractive index of the electron beam patterned structure was calculated based on an optimization algorithm that is combined with genetic algorithm and transfer matrix method. Fig. 1(b) and 1(c) illustrate the schematic of as fabricated 4-level Sb_2S_3 FZP and metalens, respectively. Both FZP's and metalenses satisfy the 4-level approximated spatial variation of the phase as a parabolic lens:

$$\varphi(x,y) = \left[-\frac{2\pi n}{\lambda_0}\left(\sqrt{x^2+y^2+f_0^2}-f_0\right)\right]_{2\pi} \quad (1)$$

FZP is functionalized via height induced propagation phase modulation (delay) composed of a concentric ring staircase structure (Fig. 1(d)). The metalens is based on the phase delay imposed by meta-atoms arranged on 2D lattices (Fig. 1(e)). Both micro-lens exhibit diffraction limited performance and can be used for optical imaging [3].

Full-Stokes metasurface polarimetry based on multidimensional polarization conversion

Chenglong Zheng[1], Huaping Zang[1], Peinan Ni[1,*]

[1]Zhengzhou University, China
[*]corresponding author: nipeinan@zzu.edu.cn

Abstract: We demonstrate a multi-focus metalens for terahertz polarization detection that requires only a single measurement to obtain complete polarization parameters and reconstruct the polarization state of the incident field. The proposed metasurface polarimetry may find applications in the fields of real-time terahertz detection and integrated optics.

Polarization, as important information carried by electromagnetic waves, is crucial in imaging, encryption, image processing, and other fields. How to generate specific polarization states and how to identify the polarization state of electromagnetic waves are both research hotspots. Combined with the wavefront modulation properties of metasurfaces, some polarization detection schemes based on polarization filtering and polarization splitting have been developed. However, existing polarization detection schemes in the terahertz band still face challenges such as narrow operating bandwidth and the requirement for multiple measurements.

Recently, we proposed a multi-focus metalens for polarization detection in the terahertz band. Unlike previously reported two-focus or six-focus metalenses used for polarization detection, or some other polarization detection schemes, the proposed metasurface converted all polarization components used to characterize Stokes parameters into the same polarization state, ensuring that only a single measurement is needed to obtain complete polarization parameters and reconstruct the polarization state of the incident field. This provided a new option for real-time polarization detection in the terahertz band and could be extended to visible light and other electromagnetic bands.

The proposed metasurface consisted of six subarrays (Fig. 1); each subarray sequentially focused x-polarized, y-polarized, 45°-polarized, 135°-polarized, left-handed circularly polarized (LCP), and right-handed circularly polarized (RCP) components in the incident wave and converted them into x-polarization. These subarrays only focused their corresponding polarization components onto the focal plane, excluding their orthogonal polarization states. The polarization state of the incident wave could be reconstructed using the intensities of the six foci.

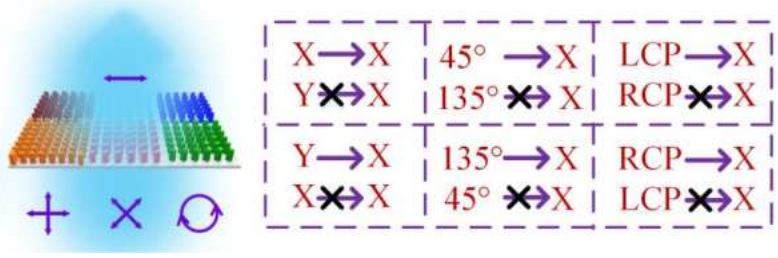

Fig. 1. Schematic of the proposed multi-focus metalens for polarization detection. For arbitrarily polarized wave incidence, this metalens converted each of the six polarized components of the incident wave into x polarization and focused them individually at six positions on the same focal plane.

Figures 2(a-f) illustrated the measured intensity distributions of the transmitted field when the incident waves

were x-polarized, y-polarized, 45°-polarized, 135°-polarized, LCP, and RCP, respectively. For x- and y-polarized wave incidence, the incident polarization states can be inferred from the large contrast between the first and second foci. The calculated parameters S_1 were close to 1 and −1, respectively. For the 45° and 135° polarizations, the parameter S_2 close to 1 and −1, respectively. When the incident waves were circularly polarized, the intensity differences were mainly reflected in the fifth and sixth foci. We compared the experimentally detected polarization states with the incident ones on the same Poincaré sphere, and these six polarization states were in each of the six directions of the three coordinate axes.

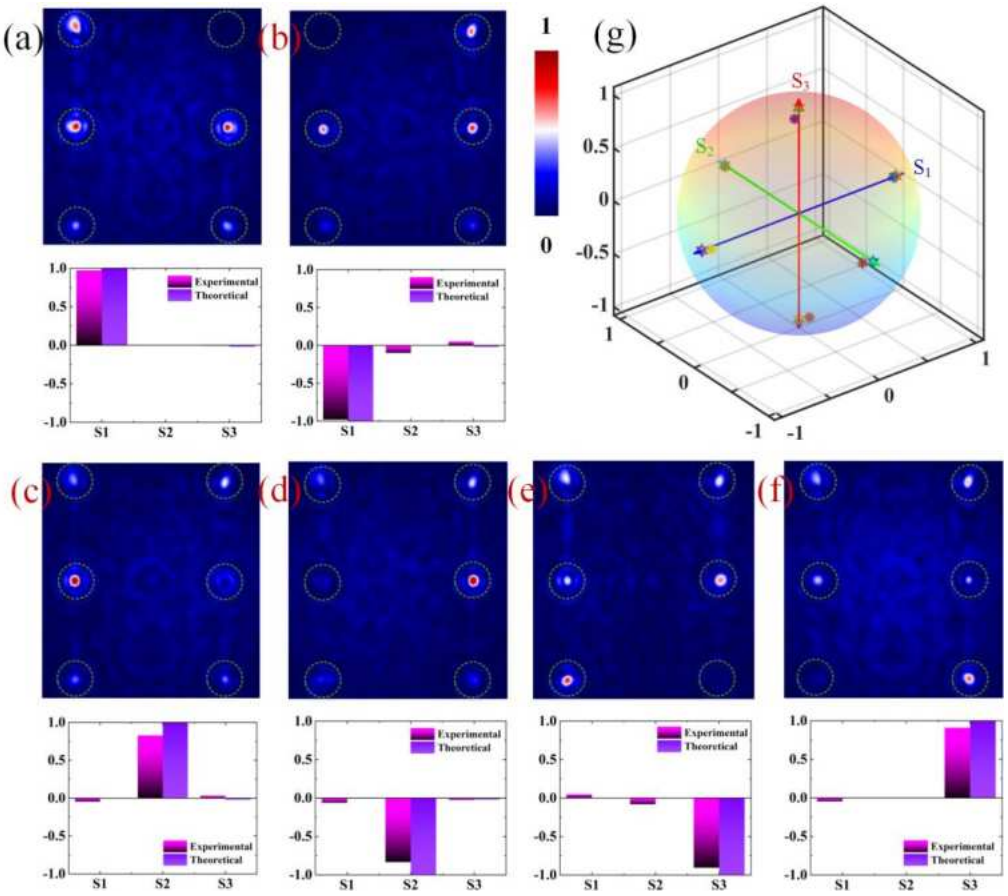

Fig. 2. Experimental characterization of the proposed multi-focus metalens for polarization detection. (a-f) measured intensity distributions of the transmitted x-polarized component, and full-Stokes parameters of the measured polarization states and the incident ones. (g) representation as points on the Poincaré sphere of the measured polarizations (*) and the incident ones (hexagrams).

In conclusion, we demonstrated a polarization detection scheme that requires only a single measurement. The implementation of the scheme was based on a six-focus metalens, which converted six polarization states used to characterize Stokes parameters into x polarization and focused them. Thus, the complete polarization parameters can be obtained by measuring only the transmitted x-polarized response. This efficient polarization detection scheme may find applications in fields such as integrated optics and polarized optics.

Impedance-matched zero-index metamaterials: from waveguide to antenna

Y. Li[1*]

[1] State Key Laboratory of Precision Measurement Technology and Instruments, Department of Precision Instrument, Tsinghua University, Beijing 100084, China
[*]corresponding author: yli9003@mail.tsinghua.edu.cn

Abstract: Photonic-crystal-based zero-index metamaterials feature a uniform spatial phase distribution. Coupling between zero-index modes and plane wave induces in-plane and out-of-plane radiations. We close these radiation channels by forming zero-index modes with BICs, leading low propagation-loss zero-index waveguides. Alternatively, we also leverage out-of-plane radiations to achieve high-directivity small-aperture antennas.

Zero-refractive-index metamaterials show the unique feature of uniform spatial phase distributions, enabling the interaction of single optical mode with matter over an infinite area in an arbitrary shape[1]. This feature brings many novel optical physics and devices, such as cloak, supercoupler, large-area single-mode laser, and extended superradiance. Additionally, zero-index metamaterials have appealing applications in generation of entangled photon pairs via spontaneous four-wave mixing according to the phase-mismatch free characteristic.

Photonic crystal-based zero-index metamaterials realize zero-index behavior via the degeneracy of a transverse magnetic (TM) monopole mode and two TM dipole modes. The monopole mode and the transverse dipole mode correspond to the zero effective permittivity and permeability, respectively, leading to an impedance-matched zero index. The monopole mode and transverse dipole mode can induce in-plane and out-of-plane radiations, respectively.

When we use zero-index metamaterial as a waveguide, such radiations will induce a high propagation loss. To reduce this propagation loss, metals were utilized to hinder radiations by constructing a mirror reflector for the radiation channels. But metals result in high ohmic losses, leading to an overall loss up to 1000dB/mm. In dielectric materials, bound state in the continuum (BIC) has been applied to decrease the radiation losses via destructive interference between several radiation channels. Despite the effective suppression of radiations, the present BIC-based zero-index dielectric metamaterials are typically in a slab configuration which is boundless along the in-plane directions. Such a bulky structure has no lateral radiation by nature, but it is inflexible in realizing various integrated photonic devices such as mirroring and Mach-Zehra interferometer.

We achieved a 1D metawaveguide with zero refractive index along the propagation direction, featuring phase-advance free, high flexibility, and low propagation loss. This zero-index metawaveguide consists of several silicon bow-tie units arranged in a single row, leading to a corrugated metawaveguide. With the fine-tuned structure, a monopole mode and a transverse dipole mode are degenerated at the center of the Brillouin zone. This degeneracy state forms a Dirac-like cone at Γ point and 1550 nm. Simulation results show that effective permittivity and permeability linearly cross zero at 1550 nm. In measurement, on-chip interferometry is used to measure the effective refractive index, in which two counter-propagating coherent continuous waves are incident into the metawaveguide. We extracted the effective index according to the interference patterns via $n_{\mathrm{eff}} = \lambda_0/(2d)$, where λ_0 is the vacuum wavelength and d is the distance between two adjacent nodes or anti-nodes. The experimentally extracted absolute value of refractive index is consistent with the simulation results, both reaching zero near 1550 nm.

We canceled the in-plane radiation of monopole mode and out-of-plane radiation of transverse dipole mode via a quasi-BIC. This quasi-BIC leads to a measured propagation loss down to ~10 dB/mm in the metawaveguide without any extra confining structures such as photonic band gap structures, leading to a compact footprint and high flexibility [2].

By leveraging the out-of-plane radiations of zero-index metamaterials, we achieved a high-directivity small-aperture zero-index antenna. To achieve a zero-index metamaterial with deep-sub-wavelength unit cell, we synthesized a ceramic — $SrTiO_3$ — with a microwave relative permittivity as high as 290. Based on this ceramic, we fabricated a square array of $SrTiO_3$ pillars in a $BaTiO_3$ background matrix, leading to a highly homogeneous zero-index metamaterial whose lattice constant is one tenth of the free-space wavelength. By incorporating this metamaterial into an open rectangular metallic waveguide, we achieved a zero-index antenna[3]. When this antenna's aperture size varies from $0.5\lambda_0 \times 0.5\lambda_0$ to $1.2\lambda_0 \times 1.2\lambda_0$, this antenna can always approach the fundamental limit in the antenna directivity. Compared with dielectric antennas, our zero-index antenna shows comparable directivities with a better scalability.

Reconfigurable Acoustic Metasurfaces for Controlling Disordered Sound Fields

Guancong Ma

Department of Physics, Hong Kong Baptist University, Kowloon Tong, Hong Kong, China

phgcma@hkbu.edu.hk

Abstract: Disordered sound fields are ubiquitous in our daily life – the sound in a room undergoes multiple scattering form such a sound field. Here, we show that reconfigurable acoustic metasurfaces can control the disordered sound for various advanced functionalities, including the generation of quiet zones, and the elimination of cross-talks.

Wavefield shaping in disordered systems has attracted significant interest in recent years. Reverberant environments are examples of such systems in acoustics that we experience every day. These sound fields are essentially random fields that are difficult to control. Here, we show that reconfigurable acoustic metasurfaces can effectively control reverberating sound fields by actively altering the reflective phases, thereby re-scaping the sound field. The acoustic metasurface we employed has 200 units of electrically adjustable Helmholtz resonator, each capable of producing reflected waves with two different choices of phase factors across a broad frequency range of 1000-1700 Hz. They are individually controlled by e a variety of feedback-driven optimization schemes. We will also discuss the limitations and possible paths for further improving the performance of metasurfaces. Our works show that acoustic metasurfaces can bring new solutions to room acoustics and open new directions for acoustic engineering.

Abstract

Monolayer transition metal dichalcogenides (TMDs) are promising materials for electronics and photonics at highly scaled lateral dimensions. Despite extensive research efforts, optimizing scalable monolayer devices has been an ongoing challenge. Their low photon absorption poses a challenge for high-performance optoelectronic devices. We present plasmonic phototransistors (photoFETs) that integrate monolayer molybdenum disulfide (MoS_2) with plasmonic metasurfaces [1-2], such as Ag, Bi, HfN, and TiN. These plasmonic photoFETs exhibit a significant enhancement in photocurrent compared to pristine 2D photoFETs, enabling high-performance devices with ultrahigh photoresponsivity. The enhancement is achieved through plasmonic nanostructures that enhance light absorption [1-4], photo-carrier generation, photo-gating, and hot-carrier transfer rates. Here, we introduce a novel demonstration of utilizing scalable nitride-based resonant plasmonic metasurfaces, with a work function of 4.7 eV, to dramatically augment the light-matter interaction in wafer-scale monolayer single-crystal MoS_2 photodetectors. Our pioneering approach has achieved not only excellent responsivity but also an impressive detectivity of 2.58×10^{12} Jones *via* the *plasmon-enhanced photogating effect*.

A salient feature of this work is the introduction of a novel concept: the giant photocurrent enhancement propelled by the local-electromagnetic-field enhanced photogating effect. This leads to a substantial 190-fold photocurrent boost compared to conventional MoS_2 photodetectors. Moreover, our uniquely designed plasmonic photodetectors consistently retain their performance with minimal degradation. Complementing our experimental results, we have incorporated comprehensive theoretical simulations that elucidate the foundational mechanisms behind scalable 2D plasmonic photodetectors. Perhaps most exciting is the broad applicability of our findings. The integration of 2D semiconductors with HfN plasmonic platforms is not only fully compatible with existing Si CMOS processes but is also scalable across wafer dimensions. This paves the way for an expansive range of applications, spanning imaging, sensing, and optical communications, heralding a new era for photodetection technology.

Monocular metasurface camera for single-shot multi-dimensional imaging

Yuanmu Yang[1*]

[1] Department of Precision Instrument, Tsinghua University, China
[*]corresponding author: ymyang@tsinghua.edu.cn

Abstract: I will present our group's recent effort to replace conventional camera lenses with metalenses. We aim to build compact camera systems that can capture multi-dimensional light field information of a target scene in a single shot under ambient illumination conditions.

Conventional camera systems can only detect light intensity while losing important information about the target scene, including depth, polarization, and spectrum. In order to further obtain the multi-dimensional light-field information of the target object, it is often required to use bulky and expensive instruments. Metasurface is composed of an array of optical antennas that can manipulate the amplitude, phase, polarization, and spectrum of light at the subwavelength scale. By replacing conventional diffractive of refractive elements with metasurfaces in imaging systems, one may be able to build optical sensors for single-shot multi-dimensional imaging with low size, weight, power, and cost. Here, I will present our group's recent effort to replace conventional camera lenses with metalenses. By leveraging the unique capability of metasurface to tailor the vectorial field of light, in combination with an advanced image retrieval algorithm, we aim to build compact camera systems that can capture multi-dimensional light field information of a target scene in a single shot under ambient illumination conditions. Specifically, I will show how we use a polarization-multiplexed metalens for imaging through turbid water. Recently, we further extended such a concept to build a monocular camera that can capture a 4D image, including 2D all-in-focus intensity, depth, and polarization of a target scene in a single shot. The miniaturized 3D camera module may be seamlessly integrated with smartphones, AR/VR headsets, and robots for a variety of applications, including face and gesture recognition, spatial localization and mapping, and collision avoidance.

Active and Nonlinear Metasurfaces with the Generation and Relaxation of Plasmonically Induced Hot Carriers

W. Cai[1*]

[1]School of Electrical and Computer Engineering, Georgia Institute of Technology, 777 Atlantic Drive NW, Atlanta, GA 30332-0250, USA

[*]corresponding author: wcai@gatech.edu

Abstract: The generation, transport, and relaxation of hot electrons in plasmonic metasurfaces provide a novel route to active and nonlinear optical effects with ultrafast responses. Here, we present the exploitation of hot carrier dynamics for diverse applications in all-optical modulation, nonlinear optical signal generation, and photoinduced optical chirality.

Plasmonic metasurfaces consisting of nanostructured metals and electron-accepting materials serve as an enormously fruitful arena for the investigation and utilization of optically excited energetic carriers. The coherent coupling of electromagnetic radiations to plasmons creates a nonequilibrium distribution of electrons at an elevated temperature, known as hot electrons. The dynamics of such hot carriers has been wide employed for various applications, ranging from the detection of sub-bandgap photons in semiconductors to the production of hydrogen gas via photocatalytic processes.

The generation, transfer, and relaxation of hot carriers also provide a novel route to active nonlinear optical effects. For example, the optical Kerr nonlinearity of plasmonic metals provides enticing prospects for developing reconfigurable and ultracompact all-optical modulators. Although enhanced nonlinear responses of metals are known to enable the optical control of light, the intrinsically slow relaxation dynamics of photoexcited carriers, primarily governed by electron-phonon interactions, impedes sub-picosecond modulation speeds. In this talk, we present femtosecond all-optical modulation in plasmonic systems via the activation of relaxation pathways for hot-electrons at the interface of metals and electron acceptor materials. We show that the relaxation kinetics and the optical nonlinearity can be tuned by leveraging the spectral response of the plasmonic system in the linear regime. Our findings introduce a generic scheme for achieving sub-picosecond modulation speeds in plasmonic systems, suitable for the ultrafast control of the intensity, polarization, and phase of light upon exchange of energetic hot carriers.

The dynamics of hot carriers in plasmonic system is further exploited for the creation of optically induced second-order nonlinear materials. Second-order optical processes are pivotal to the active modulation and wave mixing of light waves. The inversion symmetry in most materials, however, prevents achieving a bulk chi-2 effect, thereby limiting the portfolio of second-order nonlinear materials. We propose and demonstrate ultrafast conversion of a statically-passive dielectric to a transient second-order nonlinear medium upon the generation and transfer of plasmonically induced hot electrons. Triggered by an optical switching signal, the amorphous dielectric with vanishing intrinsic chi-2 develops dynamically tunable second-order nonlinear responses, which can be leveraged to address the critical need for all-optical control of second-order nonlinearities in nanophotonic systems.

Ultrafast optical switching in plasmonic platforms relies on the third-order Kerr nonlinearity, which is tightly linked to the dynamics of hot carriers in nanostructured metals. Although extensively utilized, a fundamental understanding on the dependence of the switching dynamics upon optical resonances has often been overlooked. We employ all-optical control of resonance bands in a hybrid photonic-plasmonic crystal as an empowering technique for probing the resonance-dependent switching dynamics upon hot carrier formation. Differential optical spectral measurements reveal an enhanced switching performance near the anti-crossing point arising from strong coupling between local and nonlocal resonance modes. Furthermore, entangled with hot-carrier dynamics, the nonlinear correspondence between optical resonances and refractive index change results in tailorable dispersion of recovery speeds which can notably deviate from the characteristic lifetime of hot carriers.

We further exploit hot-carrier dynamics to facilitate the creation of handedness-selectable transient chirality in achiral optical metasurfaces. As much as chiral metasurfaces are significant in stereochemistry and polarization control, tunable chiroptical response is important for their dynamic counterparts. A single metasurface device with invertible chiral states can selectively harness or manipulate both handedness of circularly polarized light upon demand, where in fact chiral inversion in molecules is an active research field. Tactics for chirality switching can be classified into geometry modification and refractive index tuning. However, these generally confront slow modulation speed or restrained refractive index tuning effects in the visible regime with forbidden 'true' inversion. Here, we reconfigure the 'optical' geometry through inhomogeneous spatiotemporal distribution of hot carriers as a breakthrough, transforming a plasmonic achiral metasurface into an ultrafast transient chiral medium with near-perfectly-invertible handedness in the visible. The photoinduced chirality relaxes through the fast spatial diffusion process of electron temperature compared to electron-phonon relaxation, empowering hot-carrier-based devices to be particularly suitable for ultrafast chiroptics. Our comprehensive understanding provides new protocols for optically characterizing hot-carrier dynamics and optimizing all-optical light modulation and chirality manipulation for operations across the visible spectrum.

Dirac Mass Gap Induced by Optical Gain and Loss

Abstract: We introduce a non-Hermitian lattice model whose quasiparticle excitations are governed by the Dirac equation. Unusually, this non-Hermitian system has bands with real energies and orthogonal eigenstates. The physical implications of the gain/loss induced Dirac mass gap are explored using a synthetic lattice in a coupled fiber loop experiment.

The Dirac equation, which first formulated to describe relativistic quantum mechanical electrons, also governs quasiparticle excitations in certain periodic lattices[1]. Synthetic metamaterials are useful for exploring this area of physics, as they can be flexibly engineered with a variety of properties. For example, they can deliberately incorporate gain and/or loss in order to violate the Hermitian symmetry of the Hamiltonian, leading to interesting situations such as unbroken parity/time reversal (PT) symmetry, which allows for the existence of stable non-Hermitian quasiparticles that do not blow up or decay in time.[2]

In the context of the Dirac equation, non-Hermitian perturbations usually create exceptional points (EPs) or rings of EPs,[3] rather than opening a mass gap. Quasiparticles governed by EPs typically behave very differently from Dirac particles; for instance, the dynamics is usually unstable since the band energies are not real everywhere in the vicinity of an EP.

Recently, we have formulated a non-Hermitian lattice symmetry we call “semi-Hermiticity”, which allows non-Hermitian systems to retain key features of Dirac quasiparticles.[4] A semi-Hermitian Hamiltonian can host bands with real energies, with eigenstates that are pairwise orthogonal. Hence, the non-Hermitian bandstructure can be described by an effective Dirac Hamiltonian, with a *real* mass gap that can be tuned via gain/loss.

To explore this, we implemented a looped optical fiber experiment[5] (Fig. 1**a**) hosting a synthetic lattice with the semi-Hermitian symmetry (Fig. 1**b**). As the gain and loss are adjusted, the non-Hermitian quasiparticles acquire a Dirac mass (Fig. 1**c**), which is observed as a transition from conical to non-conical diffraction (Fig. 1**d**).

In Hermitian systems, it is well known that the sign of the Dirac mass affects the Chern topology of the participating bands. We show that the Dirac mass in our semi-Hermitian lattice plays a similar role, through the observation of a gain/loss-induced topological boundary state (Fig. 1**e**). We have also performed experiments to explore other aspects of these non-Hermtian Dirac quasiparticles. For instance, they can exhibit an anomalous variant of Klein tunneling,[6] whereby a quasiparticle incident on a potential step is strongly transmitted (as in conventional Klein tunneling), but with the transmitted flux amplified or damped by the interface itself (Fig. 1**d**).

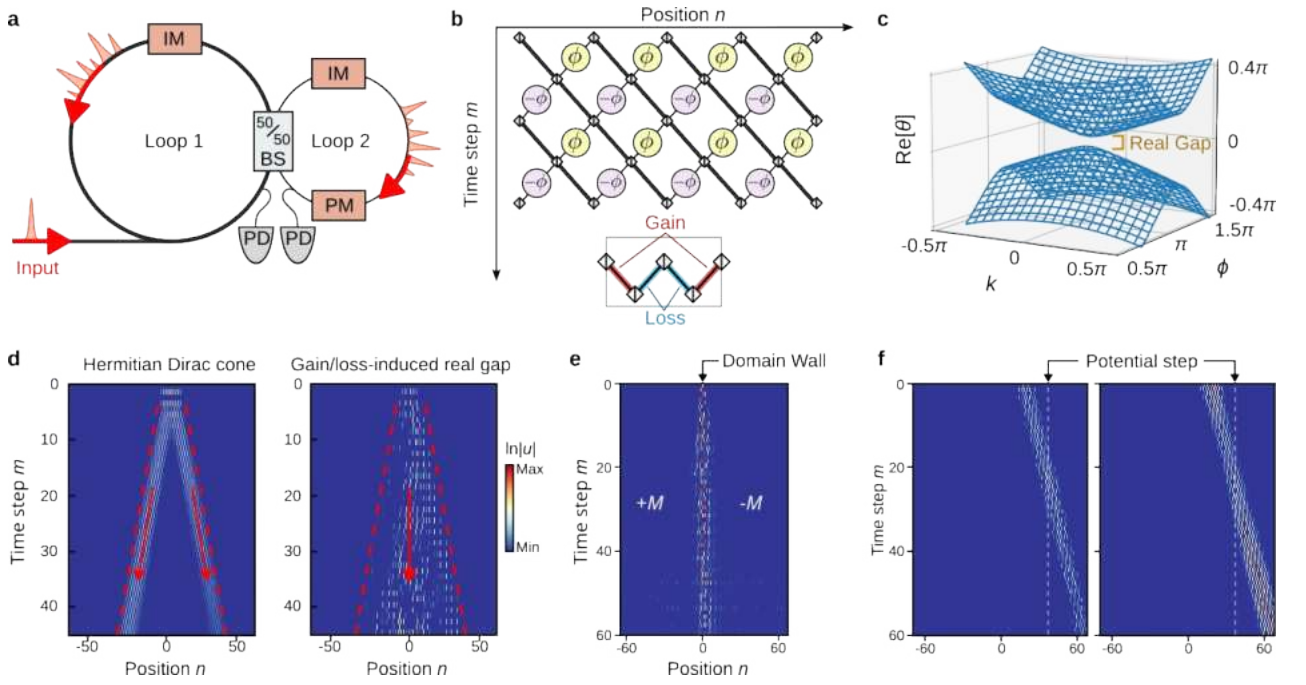

Figure 1. **a**, Schematic of the experiment. Two optical fiber loops are coupled by a 50/50 beamsplitter (BS). Each loop has an intensity modulator (IM), and the short loop also has a phase modulator (PM). The pulses are measured by photodetectors (PD). **b**, In the synthetic lattice, the index *n* in each pulse train maps to position, and the round trip number *m* maps to time. The pulses are modulated by a phase shift $\pm\phi$ and gain/loss. **c**, Floquet bandstructure featuring a real Dirac mass *M*. **d**, Observation of conical diffraction (left), and its disappearance when the gain/loss and hence the Dirac mass are nonzero (right). **e**, Observation of a topological boundary state between domains of opposite *M*. **f**, Observation of Klein tunneling at a potential step (left), and an anomalous variant that does not conserve flux at the boundary.

Abstract: We theoretically model third-harmonic generation produced by collision-driven nonlinear electron dynamics in near-zero index heterogeneous nanostructures. We focus on a sodium-aluminum bilayer and model the harmonic generation process to explore its potential for the development of compact extreme ultraviolet radiation sources and for integrated spectroscopy schemes.

Nonlinear (NL) radiation-matter interactions give rise to many physical phenomena particularly relevant to quantum mechanical processes and offer a promising platform to devise compact ultraviolet (UV) radiation sources [1]. Harmonic generation (HG) is one of the main nonlinear effects amplified by photonic materials with low dielectric permittivity, also known as epsilon near zero (ENZ) media. These materials enhance coherent NL radiation-matter interactions thanks to their natural ability to bypass phase-matching requirements, thus playing a crucial role in several NL phenomena, e.g., optical switching [2]. Currently, ENZ media are adopted to enhance NL optical effects, particularly in the near-infrared part of the spectrum, where doped semiconductors, oxides, and nitrides display this behavior. Poor materials show marked ENZ features in the UV that are promising for guidance [3] and for resonant third-harmonic generation (THG) in thin films, and for manipulation and guidance of extreme-UV (XUV) radiation.

Here, we investigate the potential of two different setups: the first one involves a sodium (Na) – based thin films [4], and the second one a sodium-aluminum (Na-Al) bilayer, both with nanometer-size thicknesses. We focus our discussion mainly on the latter configuration, studying THG produced by out-of-equilibrium (OOE) electron dynamics. To model NL electron dynamics in such heterogeneous nanostructures, we consider the Fokker-Planck-Landau (FPL) theoretical framework, obtaining a set of hydrodynamical equations (HDEs) by solving analytically the Landau collisional integral in the weak coupling limit [5]. Thanks to a perturbative approach, we derive an analytical expression for the dependence over the pump field angular frequency ω of the collision-driven THG NL-susceptibility $\chi_{\mathrm{coll}}^{(3\omega)}$. Moreover, by modelling the THG radiation process accounting multiple reflections of forward (FW) and backward (BW) waves, we obtain the pump field distribution within the thin films in the undepleted pump approximation. In Fig. 1a, where we depict the dependence of the FW intensity of the THG signal over the pump wavelength λ and incidence angle θ, one can see that the THG process exhibits a double resonance for transverse magnetic (TM) pump excitation $\lambda_{\mathrm{THG}} = \lambda/3$ in the ENZ regime due to the coupling of the pump field enhancement and the radiation of the microscopic dipoles. Conversely, for transverse electric (TE) pump excitation, see Fig. 1e, we observe THG enhancement due to the excitation of Fabry-Perot resonances. Finally, we note that for specific angle conditions, it is possible to excite surface plasmon polatitons (SPPs) at the Na-Al interface thanks to attenuated total internal reflection (ATIR), see Fig. 1a, obtaining a THG enhancement factor of 7 orders to magnitude, suggesting the potential of NZI heterogeneous nanostructure devices in the development of integrated XUV source.

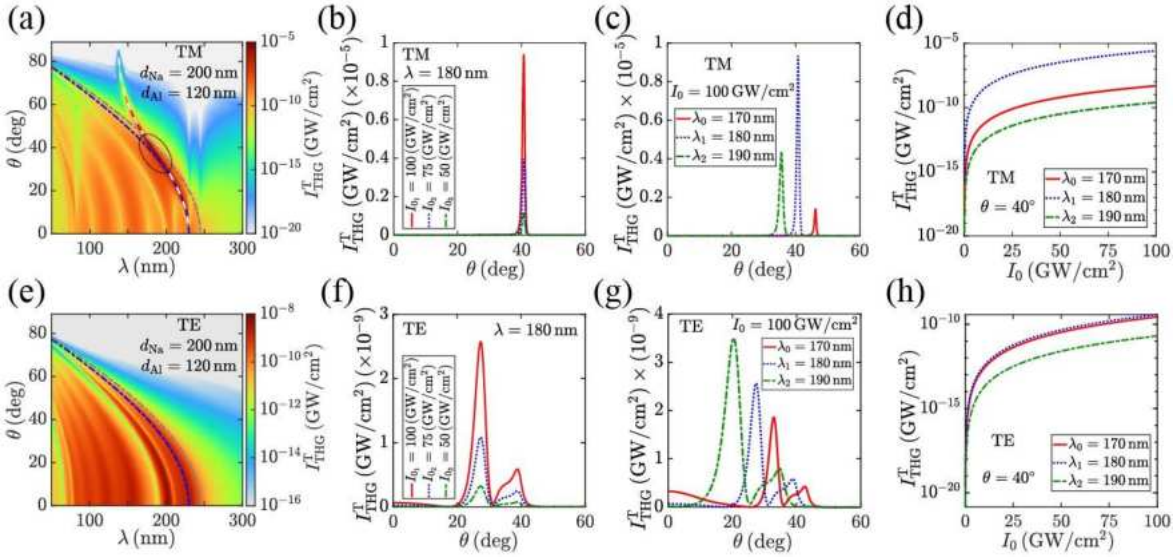

Fig. 1. **(a,e)** Dependence of the FW intensitiy of the THG signal I^T_{THG} over the pump wavelength λ and incidence angle θ for fixed pump intensity $I_0 = 100$ GW/cm^2. The dashed white curve in **(a)** indicates the SPP dispersion curve, while the dot-dashed grey and blue curves indicate the Al and Na NZI dispersion curves, respectively for λ_{THG} and λ. **(b,c,f,g)** Dependence of I^T_{THG} over the pump incidence angle for **(b,f)** fixed pump wavelength λ =180 nm and several intensities $I_0 = 50$, 75, 100 GW/cm^2, and **(c,g)** fixed pump intensities $I_0 = 100$ GW/cm^2 and several wavelengths λ = 170, 180, 190 nm [highlighted by the black circled area in (a)]. **(d,h)** Dependence of I^T_{THG} over the pump intensity I_0 for fixed incidence angle and several wavelengths λ = 170, 180, 190 nm. All plots are obtained for $d_{Na} = 200$ nm and $d_{Al} = 120$ nm and refer to either **(a-d)** TM or **(e-h)** TE polarisation of the impinging pump field.

Manipulation of Electron Beams by Laguerre-Gaussian Modes

Yung-Chiang Lan[1,*] and Ming-Chieh Lin[2]

[1] *Department of Photonics, National Cheng Kung University, Taiwan*
[2] *Department of Electrical and Biomedical Engineering, Hanyang University, Korea*
[*]corresponding author: lanyc@mail.ncku.edu.tw

Abstract: Manipulation of electron beam by Laguerre-Gaussian (LG) modes is investigated using finite-difference time-domain particle-in-cell (FDTD-PIC) simulations. The collective and individual behaviors of macro-electrons are examined. Dependence of electron beam size and current on electric field amplitude and gradient of LG modes are also explored.

Light can have spin angular momentum (SAM) and orbital angular momentum (OAM) [1]. SAM is associated with right- and left-circularly polarized lights. The light with OAM indicates that it has an azimuthal phase dependence of exp(-imφ) and independent of the polarized state (m is an integer number and its sign indicates the handedness with respect to light's propagation direction). The cylindrical Laguerre-Gaussian (LG) laser modes have an azimuthal phase dependence and carry OAM. Recently, microwave OAM beams are generated by using dielectric and metasurface antenna [2]. On the other hand, the electron pulse can obtain OAM to form electron vortices through OAM transfer from photons to electrons [3].

Acceleration of an electron pulse by an LG laser pulse was also proposed and investigated very recently [4]. In this work, modulation of electron beam by LG modes is investigated by particle-in-cell finite-difference time-domain simulations (PIC-FDTD) [5]. An electron beam is irradiated by focused circular-polarized LG modes with different OAMs at microwave regime (12 GHz). The collective and individual behaviors of macro-electrons will be investigated. Dependence of electron beam size and current on electric field amplitude and gradient of LG modes are also explored.

Figures 1(a) and 1(b) show the simulated E_z-field phase profiles of focused circular-polarized LG modes with OAM (m) equal to = +1 and +2, respectively. Here the handedness is defined along the direction of wave propagation (i.e. +x direction). Both Figs.1(a) and 1(b) agree with the typical phase patterns of LG modes in the literature. Furthermore, they have a phase singularity on the beam axis with zero field intensities.

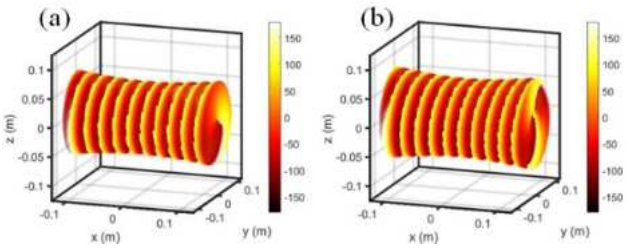

Fig. 1: Simulated E_z-field phase profiles of focused circular-polarized LG modes with m = +1 and +2.

The simulated azimuthal velocity profiles of macro-particles display 3-D spiral patterns with the number of strands equal to sum of state number of SAM (s) and OAM (m) of LG modes. These spiral patterns move with

the electron beams like a wave. The macro-particles also exhibit both orbit revolution and small rotation motion (Figs.2). The former is very similar to the gyromotion of electrons with applying an external magnetic field. The rotation motion has the same frequency as the LG mode while the orbit revolution frequency is far lower. Both the size and current of electron beams at the focal plane decrease with the increase of the electric field amplitude and gradient. This work can provide a new type of electron beams manipulated by LG waves only.

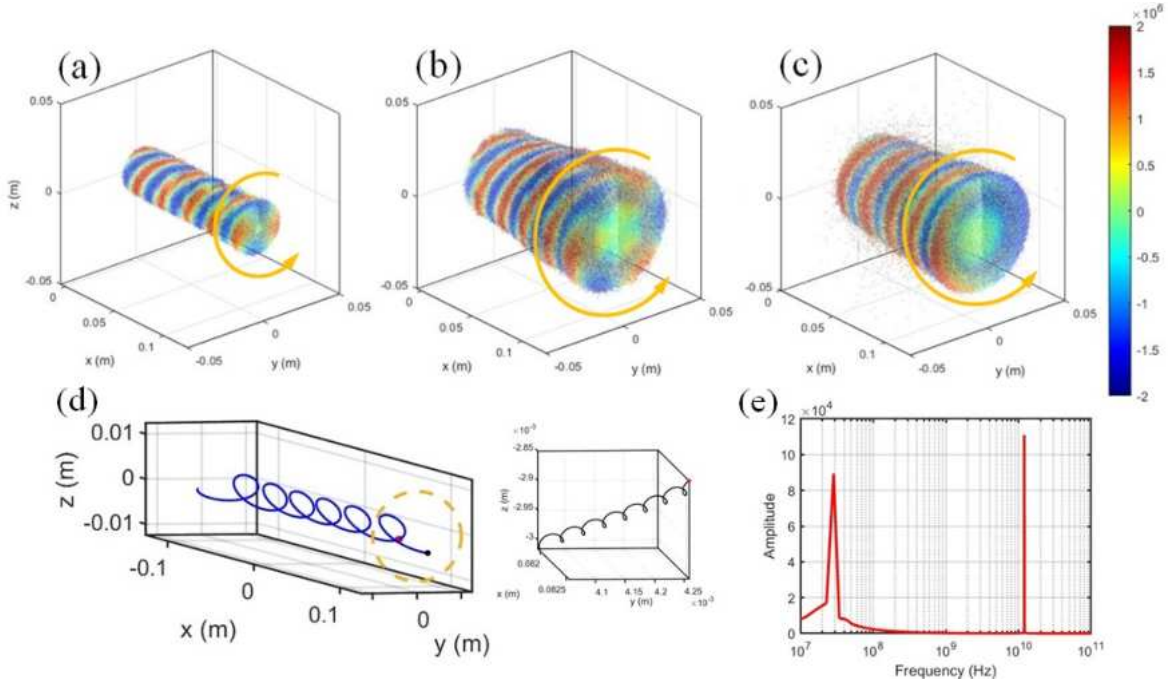

Fig. 2: (a)-(c) Simulated instant azimuthal-velocity profiles of macro-particles for LG modes with (*s*, *m*) equal to (1, 1), (1,2), and (-1, 2), respectively. (d) Simulated trajectory of a macro-particle. (e) FFT spectrum of velocity of the macro-particle.

Methods for characterization of wafer scale SERS substrates

M. Singer[1*], R. Priore[2], and L. Ye[2]

[1]Thorlabs Inc, USA
[2]Thorlabs Spectral Works, USA
[*]Corresponding author: msinger@thorlabs.com

Abstract: *In this work, we demonstrate a textured SiO_2 substrate with Au plasmonic layer that can be fabricated on a standard 4" wafer. The resulting SERS substrate is characterized at the wafer scale using automated tools, paving the way for mass produced and consistent SERS chips.*

Surface enhanced Raman spectroscopy (SERS) is an established method for biosensing of low concentration or fragile materials. However, some challenges remain with implementing SERS devices in commercial applications, such as chip-to-chip variability, batch-to-batch variability, and limited shelf life to name a few [1]. While some commercial SERS chips show promising attributes, such as low limit of detection (LOD) and ease of fabrication [2], we have yet to find a commercial SERS substrate that can simultaneously meet all requirements for a high performing commercial SERS substrate. Furthermore, the careful and automated characterization of the prerequisite specifications is an important step towards commercialization and widespread adoption of this technology.

In this work, we demonstrate the fabrication of a SERS substrate that simultaneously meets many of the aforementioned requirements for a high performing SERS chip. Importantly, we detail the characterization performed to provide this chip to the public. To achieve this result, we employ a lithography free, wafer-scale fabrication method designed to create nanopillars coated in Au (Fig 1a). The Au-coated pillars act like a metal insulator metal (MIM) absorbing structure in the vertical direction [3]. In this case, the incident light is absorbed by the Au and a surface plasmon polariton (SPP) propagates along the height of the pillar (Fig 1b). The varying width of the pillar allows for light trapping over a broad wavelength range. Specifically, at the Raman excitation wavelength of 785 nm, the field enhancement of trapped light is approximately 10^4. While this field enhancement value is modest and other architectures are capable of higher values [4], we believe that our low-cost batch fabrication process, and wafer-scale-compatible Relative Standard Deviation (RSD) characterization technique yields an acceptable tradeoff against ultimate performance.

To characterize our SERS substrates, we developed an automated system consisting of the Thorlabs laser driver, RSBR1 Raman spectrometer, and automated XY stage as shown in Fig 1c. This spectrometer uses a 785 nm excitation wavelength and a defocused beam of 1 mm diameter paired with a coded input aperture to increase throughput while maintaining spectral resolution [5]. For Raman measurements, we drop cast twelve, 2.5 µL droplets of 1,2-Di(4-pyridyl) ethylene (BPE) with a 100 mM concentration evenly across the 4" wafer. The automated stage acquires a measurement at 2 mm intervals across the entire wafer. Due to uneven drying effects, we see clear signs of overlapped droplets and coffee rings. However, these imperfections have a minor impact on the overall Raman signal as shown in Fig 1d. Additionally, upon comparing the brightfield image (Fig 1e) with the mapped Raman signature (Fig 1f), a correlation is evident between intensity of the Raman signature and the overlapping droplets. The measured RSD across the entire wafer is 16.7%. Further test results to be reported in the full publication include five wafers fabricated and tested for batch-to-batch RSD. Additionally, wafers were

fabricated and kept in an inert N_2 environment for six months and compared against wafers stored under ambient conditions. We observe minimal degradation in performance between the two sample sets. Finally, the limit of detection for the SERS substrate was found to be in the 100 nM range for an excitation intensity of 10 mW with a 5 s integration time. The presented research satisfies numerous requirements for a high performing SERS substrate including low cost, low RSD in chip-to-chip and batch-to-batch comparisons, long shelf life, and low LOD. Additionally, we demonstrate an automated and wafer-scale testing protocol, allowing for the consistent characterization of batch-fabricated SERS chips. This method will pave the way for commercial integration of low-cost elements for biosensing, security, and pharmaceutical applications.

Abstract: We demonstrate plasmonic metasurfaces made of Si for DUV spectroscopy. Due to the photon-doping effect arising from the interband transition in the DUV, Si nanostructures show significant plasmonic resonance. The metasurface shows field enhancement at 266nm due to Fano-type resonance. Applications for enhancing fluorescence and Raman scattering will be discussed.

DUV light has been recently found to be very useful for advancing many critical techniques[1,2], including molecular spectroscopy, clinical imaging, and advanced nanolithography. Metasurfaces[3] can further improve those DUV applications by leveraging their capability to enhance electromagnetic fields at the nanoscale. Here, we demonstrate that Si can be used as a promising material platform for DUV plasmonics and metasurfaces. Under DUV illumination, a photon doping effect occurs in Si, inducing the transition of electrons into conduction bands and resulting in free electrons within the conduction band. This phenomenon enables plasmonic resonances in Si nanostructures. The transition of the Si's property from optically dielectric to optically metal can be observed in the spectrum of its dielectric constant. Figure la displays the real and imaginary parts of the dielectric constant (ε) of Si in the UV range. The real part of the dielectric constant turns to be negative below ~ 280nm, confirming its metal-like properties in the DUV. We introduced a tadpole-like unit cell in the metasurface design to enable strong field enhancement in Si metasurfaces. The field enhancement of the metasurface can be effectively tuned by tuning the expanding angle of the unit cell's tail. As a result, the metasurface shows a strong field enhancement up to 700-fold at 266 nm. To experimentally realize the metasurface, we performed electron beam lithography on Si chips. A 50-nm-thick resist PMMA layer coated on the Si chip was exposed by using an electron beam writer with an acceleration voltage of 50 keV. After development in MIBK/PA solvent, the pattern of the metasurface was transferred into the PMMA layer. The pattern was subsequently transferred into the Si chips by performing ICP-RIE to etch uncovered Si. Figure le shows the SEM image of the resulting sample. To characterize the sample's DUV properties, we built a micro-spectrometer consisting of a broadband UV-Vis light source for excitation and achromatic DUV objectives. Figure 1f shows the simulation and experimental spectra of the sample. The polarization direction Is shown in Figure Ic. The experimental spectrum shows a good agreement with the simulation sample. The discrepancy can be associated with the sample imperfection. The sample's robustness in various solvents commonly used in bioassays. The results confirm the metasurface's stability in those solvents. The possibility for using the reported metasurfaces for DUV Raman and fluorescence spectroscopy will be discussed.

In conclusion, we demonstrate a novel class of plasmonic metasurface in the DUV by leveraging the photo-doping effect of Si. The metasurface shows an ideal field enhancement in the DUV and proper robustness. This work paves a novel route toward novel nanophotonic devices and sensing chips in this critical range.

Compact depth sensing and facial recognition from integration of metasurface and photonic-crystal surface-emitting laser

Yao-Wei Huang[1*]

[1] National Yang Ming Chiao Tung University, Taiwan
[*]corresponding author: ywh@nycu.edu.tw

Abstract: Our depth sensing and facial recognition technology leverages the innovative integration of metasurfaces and photonic-crystal surface-emitting lasers with structured light and monocular depth-sensing. Compared to existing approaches, our method projects a higher density of infrared dots across a wider field of view, offering substantial benefits for future spatial computing systems.

Structured light depth sensing technology employs dot projectors to generate pre-encoded spots onto objects. However, dot projectors based on vertical-cavity surface-emitting laser (VCSEL) arrays have several issues such as complex optical system, bulky diffractive optical elements (DOE) and collimator optics, and high-power consumption.

In this talk, I will report on our recent developments of novel depth sensing system that utilizes metasurface and photonic crystal surface-emitting laser (PCSEL), realizing facial recognition in monocular depth sensing [1,2]. Our single-shot system projects approximately 47,500 infrared spots from a compact 297-μm-dimention metasurface, which is lens-free and has an area 233 times smaller than the commercial DOE-based dot projector used in the Face ID on the iPhone. Our proposed system provides a measured field-of-view of 158°. Furthermore, the system reduces 5-10 times the amount of power compared to VCSEL-array based dot projectors.

Furthermore, we realize depth information and 3D point cloud by projecting light dots on statue *David* and calculating its depth map with the block matching algorithm. Our depth-sensing capabilities operate in real-time at approximately 15 frames per second. To quantitatively recognize the face is *David*, we train a facial recognition classifier by using OpenCV. As results, both of our approach and dop projection from iPhone yield accurate results in categorizing the facial features of *David* with similar score [2]. This demonstrates the potential of our approach for commercial applications, offering substantial benefits for future spatial computing systems.

Subradiant Plasmonic Cavities Facilitate Novel Polariton States for Vibrational Strong Coupling

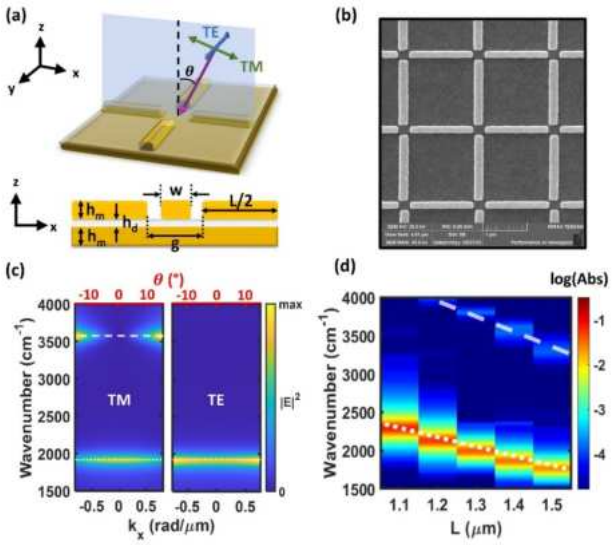
J. E. Yim[1], Z. T. Brawley[1], and M. T. Sheldon[2*]

[1]Texas A&M University, College Station, Texas, USA
[2]University of California, Irvine, USA
[*]corresponding author: m.sheldon@uci.edu

Abstract: This study examines vibrational strong coupling (VSC) in subradiant plasmonic cavities, using polymethyl methacrylate to reveal unique spectral characteristics that contrast with the typical modal behavior. The findings demonstrate the manipulation of dark and bright states, enhancing understanding of polaritons.

Introduction- Vibrational strong coupling (VSC) involves the resonant exchange of energy between molecular vibrational modes and electromagnetic cavity modes, creating hybrid states known as polaritons. Traditional studies utilize bright cavities, which limit observation of non-radiative states [1,2]. We explore the use of subradiant, or "dark," plasmonic cavities which facilitate unique interactions due to their high quality factors and minimal interaction with free-space radiation.

Experimental Setup- Our experimental design employs nanostructured plasmonic surfaces capable of supporting subradiant modes, specifically designed to target the carbonyl stretch in polymethyl methacrylate (PMMA) films. The unique geometry of these surfaces allows for detailed study of both subradiant and radiant modes under varying conditions (Figure 1).



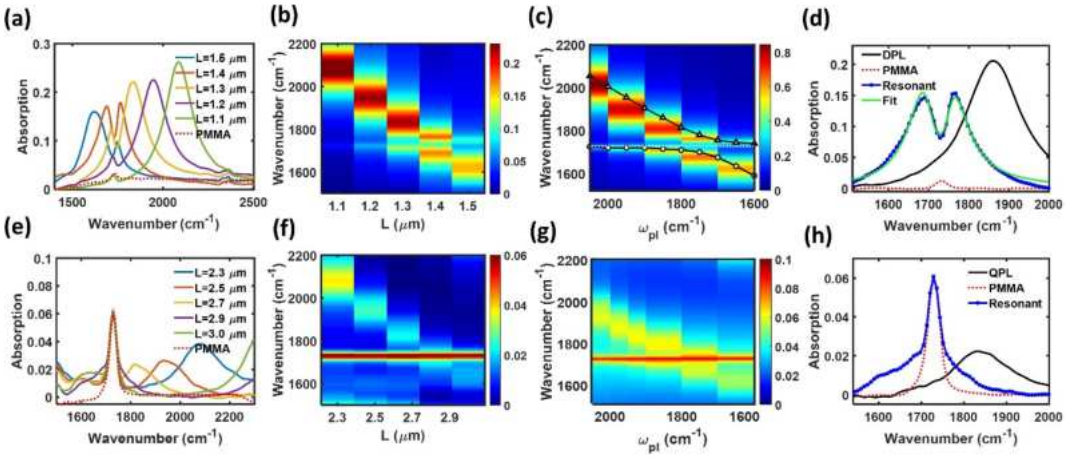


Fig. 1: Far-field behavior of Au nanorod arrays. (a) Schematic unit cell of the array composed of Au nanorods arranged with fourfold rotational symmetry. The electric field polarization of TE- and TM-polarized planewave as well as the corresponding wavevector are shown with blue, green, and pink arrows, respectively. The zenith angle (θ) of a non-normal planewave is also shown. The xz-cross section of the unit cell denoting the width (w), length (L), and height of Au rod (hm) is depicted below. The height of dielectric layer (hd) and gap width (g) are denoted. (b) Scanning Electron Microscope (SEM) image of an L = 1.4 μm array. (c) The calculated dispersion of the same array as a function of in-plane wavevector (kx) or angle of incidence (θ). The electric field intensity (|E|2) is normalized to the maximum value in the x- and y-axis range shown. (d) Experimental absorption with different lengths (L) of the rods. The absorption intensity is plotted on a log scale.

Results and Discussion - *Far-Field Observations* - Figure 1 illustrates the far-field properties of our designed Au nanorod arrays, showing the dispersion characteristics of dipolar and quadrupolar modes and their interaction with incident light. The subradiant modes display distinct behavior by remaining "dark" at normal incidence but gaining radiant character at oblique angles, which is pivotal for accessing and studying these

states.

Fig. 2: Far-field VSC behavior. (a, b) Experimental absorption measured when dipolar plasmons (DPL) were tuned pthrough the C=O stretching mode of PMMA. The red dotted trace is a control PMMA spectrum. (e, f) Experimental absorption measured when quadrupolar plasmons (QPL) were tuned to the molecular vibration frequency. (c, g) Simulated dispersion reproducing (b, f). In simulation, the quadrupolar resonances were excited off-axis (θ=17.5°). The fitted dispersion of the upper (triangle) and lower (circle) polariton branches and the uncoupled molecular vibration (white dotted) are also plotted on (c). (d, h) Experimental spectra for resonant cases (blue dots). For the DPL-molecular system, the experimental spectrum was fit to the two-coupled oscillator model (green). The substrate before deposition of PMMA (black), and the control PMMA spectrum (red dash) are also plotted.

Vibrational Strong Coupling Analysis - Significant findings were observed when these modes were tuned through the PMMA vibrational frequencies. In the case of dipolar modes, expected anti-crossing behavior was observed, indicative of strong coupling. However, the quadrupolar modes, due to their subradiant nature, did not exhibit typical VSC behavior in far-field measurements until probed at specific angles (Figure 2). This demonstrates the crucial role of mode symmetry in the emergence of polariton states. *Near-Field and Computational Insights* - Further computational analysis and near-field probing confirm the presence of dark polariton states under normal incidence, challenging conventional understanding of polariton visibility in spectroscopic measurements. These results are critical as they show the potential of subradiant cavities to control the visibility and properties of polariton states, offering a new tool for the experimental probing of molecular interactions within these states.

Conclusion - Our study confirms that subradiant plasmonic cavities can significantly alter the landscape of vibrational strong coupling. By manipulating the symmetry and radiative properties of cavity modes, we can selectively influence the visibility and behavior of polariton states. This insight opens new avenues for the study of polariton chemistry and the development of advanced materials and devices based on strong light-matter interactions.

Dynamic optical MEMS metasurfaces

F. Ding

Centre for Nano Optics, University of Southern Denmark, Campusvej 55, DK-5230 Odense, Denmark
*corresponding author: feid@mci.sdu.dk

Abstract: We have demonstrated a micro-electro-mechanical (MEMS) mirror-integrated dynamic optical metasurface platform for dynamic wavefront control with high modulation efficiencies and fast speed by electrically controlling the air gap between the plasmonic metasurface and MEMS mirror.

Plasmonic metasurfaces have attracted increasing attention due to their unprecedented capabilities of manipulating optical fields at subwavelength spatial resolutions [1]. Despite significant progress, most metadevices demonstrated to date are passive and lack dynamic modulation post-fabrication. Therefore, it is highly desirable to realize tunable metasurfaces with functionalities actively controlled by external stimuli. In this talk, I will discuss a MEMS-integrated tunable metasurface platform for active wavefront shaping by integrating MEMS mirrors and optical metasurfaces (OMSs) with the mirror-OMS separation being electrically controlled. Recent experimental demonstrations of electrically controlled full-range phase retarders [2] and polarizers [3,4] are presented.

Gap plasmon structures constructed by oligonucleotides and integrated with fluorophores

W.-P. Chan[1], Y.-L. Lin[1], S.-Y. Chen[1*]

[1]Department of Photonics, National Cheng Kung University, Tainan City, Taiwan
[*]sychen72@ncku.edu.tw

Abstract: Structures supporting gap plasmon modes have been widely utilized in metasurfaces. Here, we show that the gap plasmon structures constructed by oligonucleotides (short DNA strands) and their interaction with embedded fluorophores. This configuration may extend the capability of active metasurfaces.

Gap plasmon supported by truncated MIM (metal-insulator-metal) structures is commonly used in the metasurface for modulating phase, amplitude, and polarization of electromagnetic waves. These structures mainly consist of a metal film and patterned metal disks separated by a dielectric gap which is normally optically passive. In this work, we use oligonucleotides (short DNA strands) to efficiently construct structures supporting gap plasmon and simultaneously integrate fluorophores into the structures.

The MIM configuration is composed of gold nanoparticles (NP) and a gold film which are glued by oligonucleotides. The surface of citrate stabilized gold nanoparticles are modified by oligonucleotides through salt aging method[1], Fig.1(A). These oligonucleotide-loaded gold nanoparticles are adsorbed on an ultra-flat gold film through the intrinsic affinity between DNA bases and gold atoms. The adsorption of oligonucleotide-modified gold NP to the gold film is efficient, which only takes 30s while the original gold NP cannot be attached to the gold film, Fig. 1(C)(D). The various gap modes[2] can be observed between this particle-on-film configuration, Fig. 1(B). Since this oligonucleotide driven method is highly efficient, it can be combined with e-beam lithography to generate periodic patterns, as shown in Fig. 1(E).

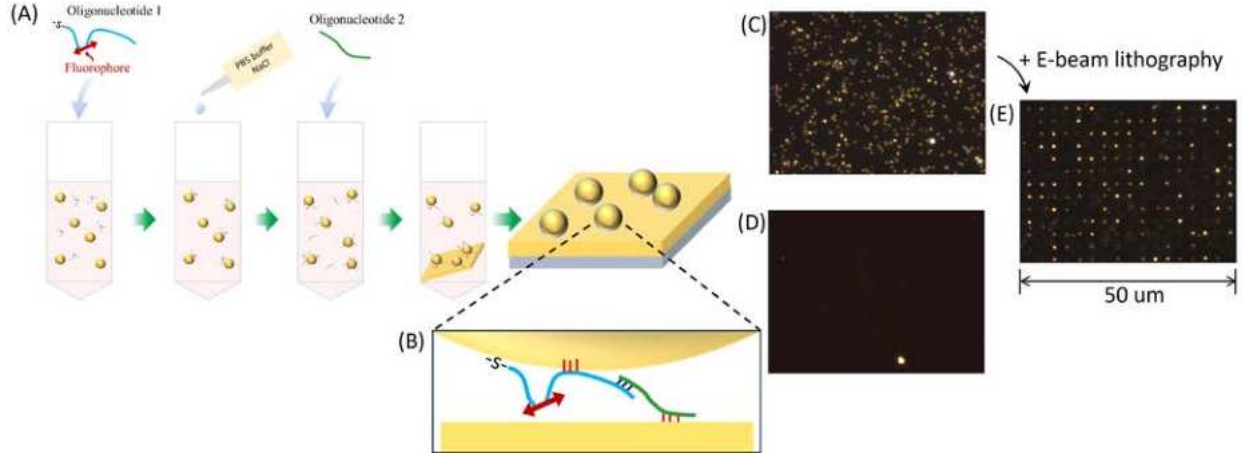

Fig. 1. (A) Salt aging method for modifying gold NP surface with oligonucleotides. (B) The gap region of particle-on-film configurations. Dark-field scattering images of oligonucletoide-modified gold NP (C) and Unmodified NP (D) on gold films. (E) Dark-field scattering image of periodic particle-on-film structures.

In a conventional structure supporting gap plasmon for the metasurface, the gap layer is usually an optically

passive material such as silica, aluminum oxide, etc. Here, the gap plasmon structure can further be integrated with fluorophores through fluorophore-modified oligonucleotides. The exciton of fluorophores can strongly interact with gap plasmon to form polariton at room temperature. We find that the polariton can be perturbed by laser illuminations. As shown in Fig. 2(A), the photoluminescence (PL) spectra under successive illuminations are changed probably because of the alternation of the coupling strength. On the other hand, the PL spectra of the configuration without fluorophores are stable, Fig 2(B).

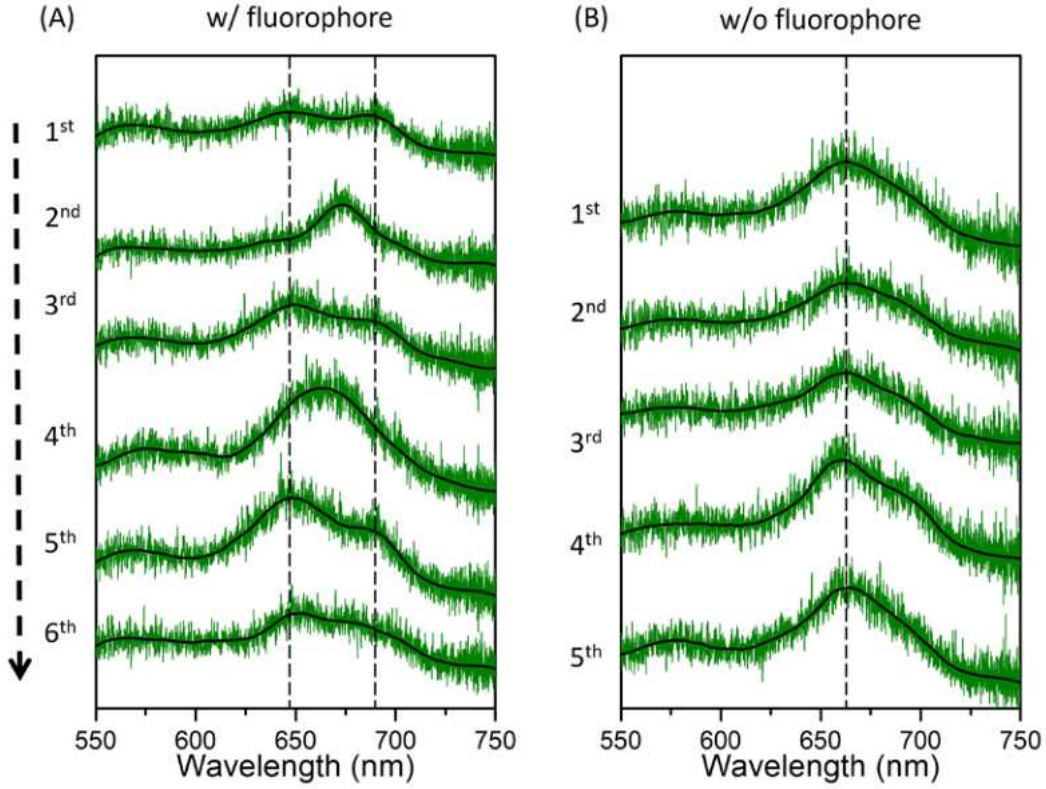

Fig. 2 PL spectra of NP-on-film structures with fluorophores (A) and without fluorophores (B).

Our oligonucleotide driven method can construct NP-on-film structures supporting gap plasmon which can interact with the exciton of the embedded fluorophores. This may provide tunability of the metasurfaces.

Three-dimensional co-axial double cylinder metasurface for high-sensitive gas molecular sensing

Takuo Tanaka[1,2,3]

[1]RIKEN Center for Advanced Photonics, Japan

[3] Institute of Post-LED Photonics, Tokushima University, Japan
[*]corresponding author: t-tanaka@riken.jp

Abstract: An ultra-sensitive infrared spectroscopic gas detection technique enhanced by a three-dimensional (3D) metasurface is proposed. A 3D co-axial double-cylinder structure is introduced as the unit structure of the metasurface. Owing to its strong resonant absorption, unwanted background in IR spectroscopy are suppressed, and the signal-to-background ratios has been improved.

Highly sensitive sensing techniques for biological and chemical materials are becoming imperative in our daily lives. Among the wide range of techniques available, infrared (IR) absorption spectroscopy stands out as one of the most promising analysis methods due to its intrinsic label-free and noninvasive detection characteristics. However, its practical applications are limited by weak signals caused by the inherently low IR absorption of natural substances and strong background noise from the surrounding environment.

Recently, we introduced metallic metasurface absorbers to enhance infrared spectroscopy, aiming to suppress unwanted background signals and improve sensitivity. By leveraging plasmonic enhanced electromagnetic fields and plasmon-molecular coupling in metasurface absorbers, we achieved attomolar (10^{-18} mol) level molecular sensitivity. This was demonstrated using self-organized molecular monolayers of 16-Mercaptohexadecanoic acid as solid samples covering the device's surface [1]. For liquid samples, we developed a metal-insulator-metal (MIM) metasurface absorber consisting of a nanofluidic channel with a depth of several tens of nanometers as an insulator layer [2]. For gas samples, we proposed the use of 3D vertically aligned MIM structures (Fig. 1(a)) [3]. In this paper, we propose a three-dimensional co-axial double cylinder metasurface shown in Fig.1 (b) for physically durable and optically effective enhancement of IR spectroscopic signals. Experimental result of the butane signal taken by this device is shown in Fig. 1(c).

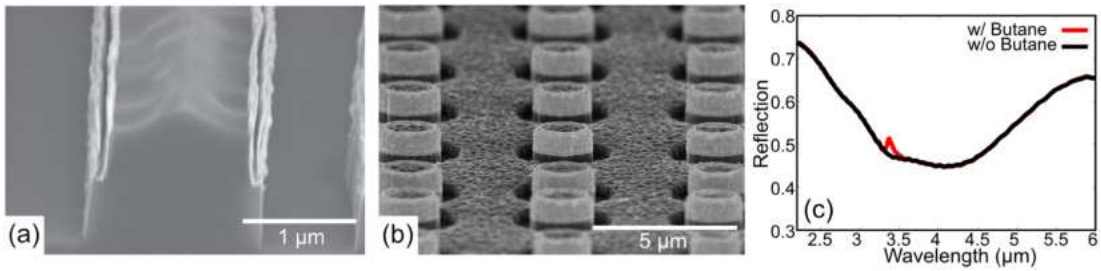

Figure 1 (a) and (b) metasurface absorbers, and (c) detected butane spectrum.

Photoluminescent gratings and metasurfaces

Pierre Berini

School of Electrical Engineering and Computer Science, University of Ottawa, Canada
Department of Physics, University of Ottawa, Canada
Nexus for Quantum Technologies Institute, University of Ottawa, Canada
pberini@uottawa.ca

Abstract: Carbonaceous residue is transformed into carbon quantum emitters on Ag gratings by hot carriers excited through surface plasmon decay thereon. Yellow photoluminescence emerges *in situ* as the carbon dots form in an O_2 depleted environment. The ability to form photoluminescent carbon dots through plasmonic excitation opens a novel pathway to photoluminescent metasurfaces.

SPPs propagating on metal waveguides or resonating on metal nanoparticles, nanoantennas or gratings are generally strongly absorbed by the metal, leading to the effective creation of energetic carriers - “hot electrons” and/or “hot holes” - also localized along the surface. These energetic carriers can be harvested and used for a broad range of applications, *e.g.*, to enhance the performance of optoelectronic and photovoltaic devices, or to open new reaction pathways in chemistry and electrochemistry [1].

Here we report the transformation of carbonaceous residue on Ag gratings into carbon quantum emitters when the gratings are excited by surface plasmons and placed in an O_2 depleted environment [2]. The carbonaceous residue originates from PMMA used in a He+ lithography process applied to create the gratings [3,4]. The surface plasmons excited on the Ag gratings at 532 nm decay partly by exciting hot carriers therein which then act to transform the residue into light-emitting carbon dots in the absence of O_2. Plasmon decay also serves to pump the carbon dots such that bright yellow photoluminescence (~575 nm) emerges *in situ* and in real-time.

The top panel of Fig. 1 shows a series of surface enhanced Raman scattering (SERS) spectra captured over time from a Ag grating supporting SPP excited at 532 nm and exposed to CO_2 in a gas flow cell [2]. The spectra indicate growth of photoluminescent graphitic carbon on the surface, as indicated by clear D and G peaks superimposed on a broad and intense photoluminescent band. The observed luminescence consists of yellow light and persists as long as CO_2 exposure is maintained (Fig. 1, bottom panel). Exposure to O_2 then reverses the process leading to the disappearance of photoluminescence. In some cases, the emission was also accompanied by carbon deposits on the gratings, observable under helium ion microscopy (Fig. 1, right panel), which may be formed by the decomposition of CO_2 [5].

The ability to form photoluminescent carbon dots through plasmonic excitation opens an exciting new pathway to photoluminescent structures and metasurfaces.

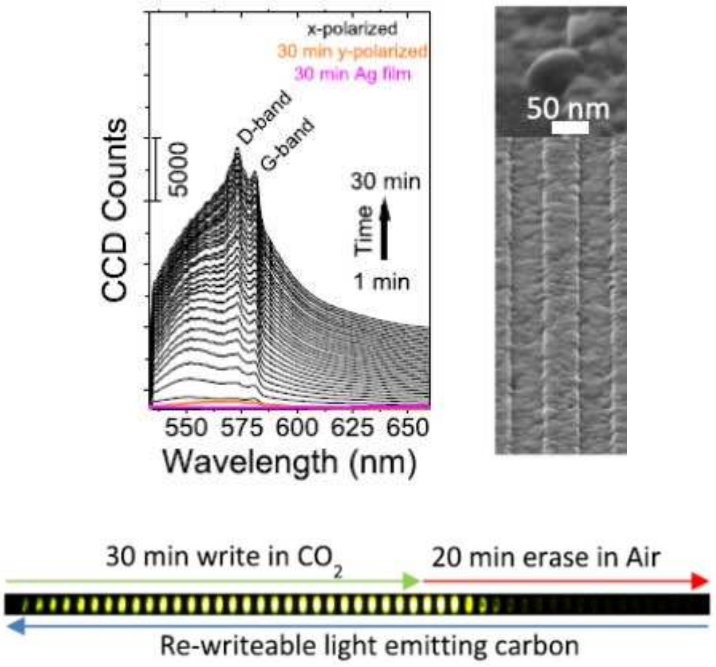

Fig. 1. Top left panel: SERS spectra evolving over time showing the emergence of photoluminescence (broad peak) and the formation of carbon dots (narrow D and G bands). Bottom panel: emergence and disappearance of yellow photoluminescence as carbon dots form in CO_2 then disappear in Air, as captured by a visible camera mounted to an optical microscope. Top right panel: helium ion microscope image of carbon deposits on a Ag grating.

Electrochemically-tunable oxide materials for metasurfaces and large-area, additive patterning

V. E. Ferry[1*]

[1]University of Minnesota, USA
[*]corresponding author: veferry@umn.edu

Abstract: This talk will discuss two strategies for new, tunable metasurfaces. The first part of the talk will discuss the use of electrolyte gating to control the optical properties of materials, focusing on $La_{1-x}Sr_xCoO_{3-d}$ as an exemplary case. The second part will discuss large-area fabrication methods for multilayer, flexible devices.

Alternative materials for metasurfaces enable new properties and lay the foundation for advanced applications. Phase-change materials that change optical properties in response to an applied stimulus, such as voltage, are highly attractive for the development of tunable and switchable metamaterials. The first part of this talk will focus on new electrochemical materials that exhibit significant modulation in optical response under applied voltage.

$Sr_xCoO_{3-\delta}$ (SCO) has attracted considerable attention recently as a voltage-tunable materials system. $La_{1-x}Sr_xCoO_{3-\delta}$ (LSCO) offers similar advantages, but with additional advantages in stability. As deposited, LSCO has a perovskite structure. We focus here on ion-gated systems. Application of a positive gate voltage facilitates the formation and migration of oxygen vacancies. This is accompanied by substantial change in magnetic, electrical, thermal, and optical properties.

We fabricate electric double layer transistors consisting of thin-films of LSCO and an ion gel. We use spectroscopic ellipsometry to map the complex refractive index across the phase diagram of LSCO before and after gating. At $x < 0.18$, as-grown LSCO has a perovskite crystal structure and high refractive index. Upon application of a gate voltage, the LSCO films change to another lower-index, lower-loss insulating perovskite state with $\Delta n > 0.6$. At $x > 0.18$, as-grown LSCO has a perovskite structure and is a lossy metal. Application of the gate voltage transforms LSCO to an oxygen-vacancy-ordered brownmillerite crystal structure with high-index ($n > 2.5$) and low-loss. LSCO is therefore an interesting platform material for switchable metasurface applications, and can be used in either optical applications that require on-off switching (at $x > 0.18$) or resonance modulation (at $x < 0.18$).

The second part of the talk will discuss a new fabrication method for very large-area metasurfaces, which is both additive and roll-to-roll compatible. The method uses UV-based imprint lithography to produce a pattern with spatially modulated surface energy. When a functional ink is dragged over the surface it dewets and fills in the recesses. This method works for a variety of ink materials (metal, dielectric, semiconductor), can create multi-layer patterns, and offers flexibility in creating metamaterials on free-standing and flexible substrates.

Nonlinear all-dielectric metasurfaces driven by multipolar resonances and quasi-bound states in the continuum

Hui-Hsin Hsiao[1*]

[1] Department of Engineering Science and Ocean Engineering, National Taiwan University, Taipei, Taiwan 11677

[*]corresponding author: hhhsiao@ntu.edu.tw

Abstract: The interaction of multipolar resonances in all-dielectric metasurfaces provides a unique platform for confining strong near-field enhancement inside nanocavities as well as tailoring far-field scattering properties. Here, we investigated third-harmonic generation of all-dielectric metasurfaces driven by the generalized Kerker condition and quasi-bound states in the continuum, respectively.

Recently, high-index dielectric metasurfaces that support Mie resonances have been extensively studied for efficient second- and third-harmonic generation (THG) owing to their advantages for a higher laser damage threshold and intrinsic low dissipative loss [1, 2]. In this study, we designed an amorphous silicon (*a*-Si) nanopillar array that sustains toroidal dipole (TD), electric dipole (ED), and magnetic dipole (MD) resonances in the near-infrared region (Figure 1a). By varying the diameter of nanopillars (*D*), the spectral positions of the MD and TD modes can be effectively tuned as shown in Figure 1b. A pronounced THG enhancement is observed when these two modes become spectrally overlapped, corresponding to the generalized Kerker condition where the constructive interference of the total electric dipole (TED, referring to the summation of ED and TD scattered field) and the MD mode takes place [3]. This leads to the suppression of backward scattering as well as the strong field enhancement inside the nanocavities. Our simulation (experimental) results show a 214-fold (17-fold) THG enhancement in the vicinity of the generalized Kerker condition compared with the THG signal of the TD resonance (Figures 1d and e).

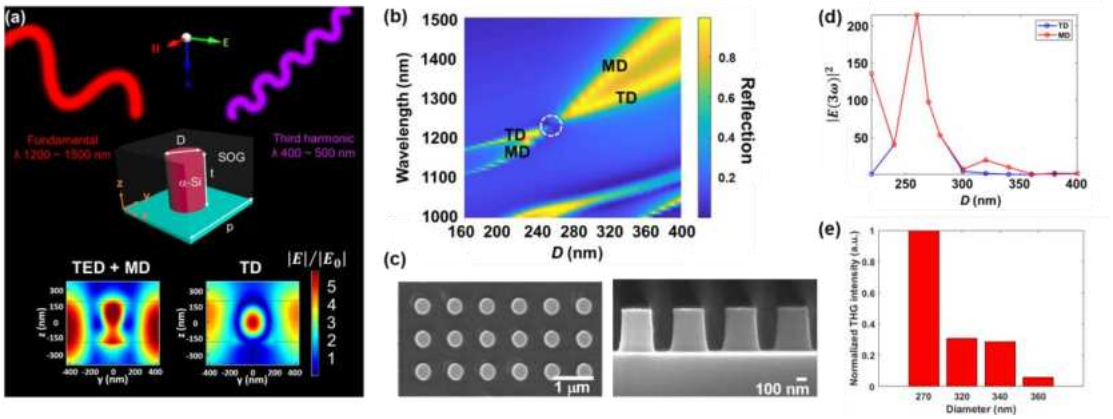

Figure 1. (a) Schematic view of nanopillar arrays. Insets: The electric field distributions at the reflection dip of *D* = 260 nm (left) and at the TD mode of *D* = 360 nm (right). (b) Simulated reflection spectra of nanopillar arrays as a function of *D*. The SEM images of the fabricated samples (d) at the top (left) and lateral (right) views, respectively. (d) Calculated and (e) measured THG peak intensities for samples with different diameters.

In addition, symmetry-protected quasi-bound states in the continuum (quasi-BIC) controlled by

metasurfaces with broken in-plane symmetry can generate sharp resonance with strong light concentration within the nanostructures [4]. Here, we developed a simple approach for designing high quality-factor (Q-factor) quasi-BICs using asymmetry kite-shaped *a*-Si nanopillar arrays and investigated their THG signals (Figure 2a). By breaking the in-plane symmetry of the kite-shaped nanopillars with different axial length difference (Δx) defined in Figure 2b, a quasi-BIC resonance was excited in the transmission spectra around the wavelength of 1325 nm for Δx = 15 nm (Figure 2d). The Q-factors of quasi-BICs exhibit the quadratic dependence on the geometry asymmetry (Figure 2e). In addition, the resonant spectral profile of quasi-BICs can be readily tuned between Fano and Lorentzian-lineshapes through the interplay between quasi-BIC resonances and the broadband MD mode. The high-Q quasi-BIC resonance exhibits an extremely intensive field enhancement confined within the nanocavities, thus resulting in four order of magnitude THG enhancement in calculation and 46.4-fold THG in experiment as shown in Figure 2f. These Si-based designs are compatible with the state-of-art complementary metal-oxide-semiconductor (CMOS) technology and provide a new platform to enhance the nonlinear conversion.

Metamaterial assisted super-resolution microscopy

Zhaowei Liu*
Department of Electrical and Computer Engineering, University of California, San Diego
9500 Gilman Drive, La Jolla, California, USA
*Corresponding author: zhaowei@ucsd.edu

Abstract: Metamaterial assisted illumination nanoscopy (MAIN) has recently been proved to be a promising approach for linear super-resolution microscopy with unprecedented resolution capability. In this talk, I will summarize some of our recent progresses in the field and showing biological imaging examples with resolution down to 20nm scales.

Super-resolution microscopy (SRM) techniques (STED, PALM, STORM, SIM) have been extensively explored in the last two decades with improved resolution beyond the diffraction limit. Especially, structured illumination microscopy (SIM) has attracted great attention due to its advantages to perform high spatial-temporal imaging with low photo-toxicity and wide field of view. However, traditional SIM can only improve the resolution by two-fold because both the illumination and detection optics are diffraction limited.

We developed a speckle metamaterial-assisted illumination nanoscopy (speckle-MAIN) technique, which extends the attainable resolution of SIM to deep subwavelength scales by utilizing high-resolution illumination patterns enabled by metamaterials. Our initial experiment has shown a >7-fold improvement in imaging resolution. With a recently developed stat-of-the-art optical hyperbolic metamaterials, including an Ag/MgO metamaterials at a nominal thickness of 2.5nm and a P3HT based organic hyperbolic material, we demonstrated speckle-MAIN with a >14-fold resolution improvement and achieving image at 20nm scale. We will showcase this recent advancement by showing some 2D and 3D bioimaging examples and also discuss future possibilities to improve imaging speed by more efficient deep-learning based image reconstruction algorithms. Similar SRM idea can be extended to label-free imaging with greatly improved resolution as well.

The MAIN represents a simple super-resolution imaging approach that offers distinct benefits such as low illumination power, high photostability, low cost, and a broad spectrum of selectable probes (or label-free), making it an appealing candidate for dynamic imaging of life science samples.

Abstract: On-chip multiparameter infrared photodetectors are highly desirable for the next-generation ultra-compact optical and optoelectronic systems[1,2]. Here, we proposed the on-chip infrared photodetectors to realize multiparameter detection such as intensity, polarization, chirality, and orbital angular momentum enabled by using the metasurface integrated with two-dimensional materials[3-5].

Real-Time Multidimensional Imaging with an Encoding Metasurface

Lidan Zhang, Chen Zhou, Hyunju Ahn, Shengyuan Chang, Md Tarek Rahman, Tunan Xia, Zhiwen Liu, and Xingjie Ni*

Department of Electrical Engineering, The Pennsylvania State University, University Park, PA, USA

*corresponding author: xingjie@psu.edu

Abstract: We present a metasurface capable of encoding light information across multiple dimensions – polarization, frequency, and time – via the distinct optical responses of its constituent meta-atoms, and consequently, the complete properties of the light field can be captured by a single snapshot. A deep learning-based recovery algorithm is employed to facilitate real-time retrieval of multidimensional images.

Light fields carry comprehensive channels of information, including intensity, spectrum, and polarization. Traditional cameras, however, are limited to capturing merely the intensity distribution, thus neglecting a wealth of additional valuable data. While specialized imaging systems exist – such as hyperspectral for spectral information and polarimetric for polarization data – these alternatives often suffer from drawbacks, being bulky, slow, and expensive. Addressing these limitations, we introduce an all-dielectric encoding metasurface designed to enable the acquisition of comprehensive hyperspectro-polarimetric imagery through a singular, efficient snapshot.

Our metasurface is engineered with unique spectral and polarization responses inherent in its constituent meta-atoms. Such design allows for the encoding of spectral and polarization information into an intensity pattern, which can be readily captured by conventional camera technology. In addition, we integrated a custom-tailored deep learning network, specifically developed to support real-time image recovery. This synergy empowers our system to precisely decode full-Stokes polarization information over an extensive spectral range (700 nm to 1150 nm), directly from a single captured snapshot. Notably, our system achieves a spectral resolution up to 0.23 nm.

Beyond static imagery, our system excels in dynamic capture, successfully recording full-Stokes hyperspectro-polarimetric video in real time, at a commendable rate of 28 frames per second. This performance metric is predominantly constrained only by the inherent readout rate of the camera used.

In summary, our development of the metasurface encoder, in concert with the deep learning-based decoder, presents a compact, rapid, and cost-effective solution for multidimensional imaging. This approach ensures the maximal exploitation of the rich information embedded within light fields. The technology developed could mark a significant leap forward in imaging capabilities and pave the way for diverse applications across various fields, from scientific research to commercial photography and beyond.

Introducing Circular Dichroism with Chiral Bound State in the Continuum

Cheng-An Mao, Wen-Hui (Sophia) Cheng*
National Cheng Kung University, Taiwan
*corresponding author: wcheng@gs.ncku.edu.tw

Abstract: A structure of all-dielectric metasurface with the concept of chiral BIC is introduced and studied. By break both in-plane and out-of-plane symmetry, intrinsic chiral metasurfaces with strong circular dichroism of around 0.9 at normal incidence can be realized.

Chirality is a property observed in natural molecules, which refers to the geometric nature of molecules that cannot overlap with their mirror-symmetric image without rotation. The strong optical chirality induced by artificial metamaterials has drawn much attention. Most of the proposed metamaterials exhibiting strong circular dichroism (CD) are three-dimensional chiral metamaterials, while their two-dimensional counterparts, known as chiral metasurfaces, need to be operated with oblique incident light (extrinsic chirality). However, three-dimensional metamaterials require a more sophisticated fabrication process. Here, we propose a tilted dielectric structure to overcome the weak chiro-optical responses of intrinsic chiral metasurfaces by inducing chiral bound states in the continuum. Our design strategy aims to break both in-plane and out-of-plane symmetry using two deformation parameters. Strong circular dichroism (∼0.9) and large polarization rotation (∼200,000°/mm) at normal incidence in the near-IR region are demonstrated with FDTD simulation. From multipole decomposition, we further interpret the results and reveal that higher-order multipoles play an important role in the observed large circular dichroism. We expect that this work could be applicable to future applications for chiral sensing, polarization optics, quantum optics, asymmetric photocatalysis and chiral light sources and detectors.

Spherulite based metasurfaces

J. Sun[1]*, Y. Liu[1], L. Zhou[1], Y. Shen[1], J. Zhou[1]

[1]State Key Laboratory of New Ceramics and Fine Processing, School of Materials Science and Engineering, Tsinghua University, Beijing 100084, China
*corresponding author: jingbosun@tsinghua.edu.cn

Abstract: Spherulites are crystals with cylindrical crystalline structures and thus exhibit anisotropic optical properties with cylindrical symmetry. Here we proposed several way of generating and modulating cylindrical vector optical vortex beams by using spherulites. This strategy provides promising opportunities for the spherulite applications in structured light fields.

Usually, structured light beams refer to vector beams with cylindrical polarization states or optical vortex with spiral phase distribution or even cylindrical vector optical vortex, and thus provides more degrees of freedom in modern optical applications [1]. These types of beams with circular symmetry are seen as "inhomogeneity" in the frame of Cartesian coordinate (x, y, z). However, they are "homogeneous" and regular in a cylindrical coordinate (r, θ, z). Artificially engineered materials, known as metamaterials or metasurfaces are preferred in the generations or modulations of the structured light [2]. The structures of these metamaterials or metasurfaces are usually designed to be in circular symmetry, which can produce the desired cylindrical optical properties, but are always troubled by strong scattering, limited working bandwidth and the challenging fabrication for the unit cell sizes or numbers are not uniform and decrease along the radial direction towards the center [1-4]. On the other hand, spherulites are radially polycrystalline aggregates where needle-like crystals are aligned radially from the center of the spherulite to provide a perfectly central symmetrical shape and thus natural cylindrical anisotropy [5]. Here, by designing and constructing spherulite crystals with certain circular anisotropy in both linear and nonlinear levels, we demonstrate several spherulite based devices including a spin-orbital angular momentum convertor, a cylindrical vector beams splitter and a nonlinear vortex modulator.

The spin-orbital angular momentum convertor is based on a spherulite composed by a radially distributed structure, which is formed by the self-assembly of disk-like aromatic molecules, i.e., electron-rich "donor" and electron-poor "acceptor", in a condensational crystallization process [6]. The "donor" and "acceptor" molecules are alternatively packed at the radial direction to form a face-centered columnar structure. The charge-transfer absorbance effect occurs between the donor and the acceptor, which significantly enhances the absorption along the normal of the disks and finally enables a cylindrically anisotropic extinction between the radial and azimuthal directions of the assembled spherulite. A beam of circular polarization can be treated as a linear combination of a radially polarized optical vortex and an azimuthally polarized optical vortex with a topological charge of 1 while $\pi/2$ out of phase between each other. In our design, when a left circularly polarized beam transmits through the spherulite, the radially polarized component is filtered due to the strong absorption and the remained part is azimuthally polarized optical vortex with topological charge of 1, which realizes the generation of the orbital angular momentum (OAM) transformed from the spin angular momentum of the incidence.

The cylindrical vector beams splitter is based on the spherulite with cylindrically anisotropic refraction indices while with a wedge-shaped prism by using the nematic LC (4'-Pentyl[1,1'-biphenyl]-4-carbonitrile, 5CB). The

5CB molecule is intrinsically anisotropic with its refractive index (n_e) along the longer axis larger than that (n_o) along the short axis [7]. Once these molecules are constructed into a spherulite with the longitudinal axis along the azimuthal direction of the material, the formed spherulite may show cylindrically anisotropic indices with $n_A=n_e$ and $n_R=n_o$, which is mimicking the metamaterials consisted of concentric multi-layered structure. If such a spherulite is cut into a prism, cylindrical vector beams passing through the prism experience the cylindrical anisotropy and are thus refracted to two different directions. A left or right circularly polarized beam can be decomposed into radial and azimuthal components. After passing through the spherulite prism, the output beams contain topological charge of either +1 or -1 depending on the chirality of the input circular polarization.

The nonlinear optical vortex modulator is based on a spherulite with a ferroelectric nematic phase. The polar molecules are arranged in an azimuthal array, showing a vortex polarity. Such a vortex polarity exhibits anisotropic indices, second harmonic generation and a sum frequency effect, which can manifold vortex generation at different wavelengths, topological charges and polarization states.

Dispersion engineering of mid-IR polaritons in van der Waals crystals

S. G. Menabde[1] **and M. S. Jang**[1*]

[1]School of Electrical Engineering, Korea Advanced Institute of Science and Technology (KAIST), Korea
[*]corresponding author: jang.minseok@kaist.ac.kr

Abstract: In this talk, I discuss several experimental approaches that can be used to manipulate the dispersion of mid-IR polaritons and significantly reduce their damping at the same time: monocrystalline gold, ultra-high-index and low-loss topological insulators, and harmonically corrugated gold substrate.

Polaritons – hybrid light–matter waves emerging from the coupling of light to collective oscillations of charges – promise a deeply subdiffractional light manipulation. In particular, polaritons in low-dimensional van der Waals crystals boast extremely high field confinement. However, tightly confined polaritons are prone to severe scattering loss, making it challenging to fully exploit wave phenomena at the nanoscale. In this talk, I discuss several experimental approaches that can be used to manipulate the dispersion of mid-IR polaritons and significantly reduce their damping at the same time. First, I will highlight the effects of the monocrystalline gold substrate on the polaritonic dispersion. Second, I will introduce bismuth and antimony chalcogenides, which are topological insulators, as a new family of ultra-high-index and low-loss van der Waals dielectrics for polaritonic applications in mid-IR. Finally, dispersion engineering with a harmonically corrugated gold substrate will be discussed.

Experimental demonstration of ENZ-enhanced optical nonlinearity in ultrathin TiN epilayers

F.-T. Tseng[1], I-H. Ho[1], S. Gwo[2], and H. Ahn[1*]

[1]Department of Photonics, College of Electrical and Computer Engineering, National Yang Ming Chiao Tung University, Hsinchu 30010, Taiwan.

Abstract: Epsilon-near-zero (ENZ) effect for metals can be observed in the visible range, but only for ultrathin layers with nanoscale thickness. We report the first experimental realization of ENZ-enhanced ultrafast optical nonlinearity from refractory TiN ultrathin epilayers grown by MBE via the thickness and incidence-angle dependent z-scan and transient absorption measurements.

Recent advances of the epsilon-near-zero (ENZ) materials, whose real part of the permittivity vanishes in certain spectral ranges, offer a new route to achieve the subwavelength confinement and immense enhancement of field and optical nonlinearity.[1-3] The ENZ mode is a confined mode existing only for a given range of thickness (L) satisfying $L \lesssim \lambda_p/50$, where λ_p is the plasma wavelength of materials.[3] Therefore, the commonly used ENZ materials including transparent conductive oxides (TCOs) show their ENZ wavelengths (λ_{ENZ}) in the near-infrared band. Meanwhile, the ENZ wavelengths of metals are in the visible range and the ENZ effect for metals can be realized only for ultrathin films with nanoscale thickness. Typically, the ideal enhancement of field intensity due to the ENZ properties of the materials is known to follow an inverse-square dependence on L,[1] but the percolation threshold (for example, $\gtrsim$6 nm for gold) of metal layers limits the reduction of thickness to achieve an observable enhancement of nonlinearity.[4] Moreover, most metal ENZ materials show relatively high optical losses which causes significant optical attenuation. Therefore, the realization of ENZ effect from metals has been limitedly reported and it is important to search for ENZ materials with low optical losses and high ENZ effect operating in the visible spectral region. In addition, to be utilized in nonlinear optoelectronic devices, nonlinear optical materials need to be not only thermally stables, but also defect-free and high quality to avoid the local heating under intense optical excitation.

Titanium nitride (TiN) is a transition metal nitride possessing many excellent characteristics comparable or superior to noble metals. TiN is highly conductive and chemically stable, and moreover its bulk melting temperature is as high as 3000 ℃, allowing for large nonlinear responses under high intensity excitation and a good candidate for robust and low-cost metallic material that is compatible with complementary metal–oxide–semiconductor (CMOS) fabrication technologies. Besides, high quality ultrathin TiN epilayers exhibing <2 nm percolation threshold thickness could be successfully grown by molecular-beam epitaxy technique.

In this work, we report the ENZ-assisted enhancement of nonlinear optical properties of MBE-grown ultrathin TiN films ranging in thickness from 2 to 50 nm. Dielectric properties are investigated by spectroscopic ellipsometry[5] and the nonlinear optical responses of ultrathin TiN films are explored using nonlinear transmission z-scan technique and transient reflection spectroscopy. It is found that the third-order nonlinearity and carrier dynamics can be tuned by the thickness-dependent ENZ properties. Figure 1a exhibits a significant enhancement of nonlinear responses as the film thickness is reduced below approximately 10 nm and at wavelengths around λ_{ENZ} determined by ellipsometry. Further enhancement is observed for p-polarized beam incident at a specific

angle controlled by the film thickness. (Figure 1b) Additionally, Figure 1c shows that ultrathin TiN films have a sub-picosecond carrier response time, which is long enough to accumulate the nonlinear change and subsequent enhancement.[6]

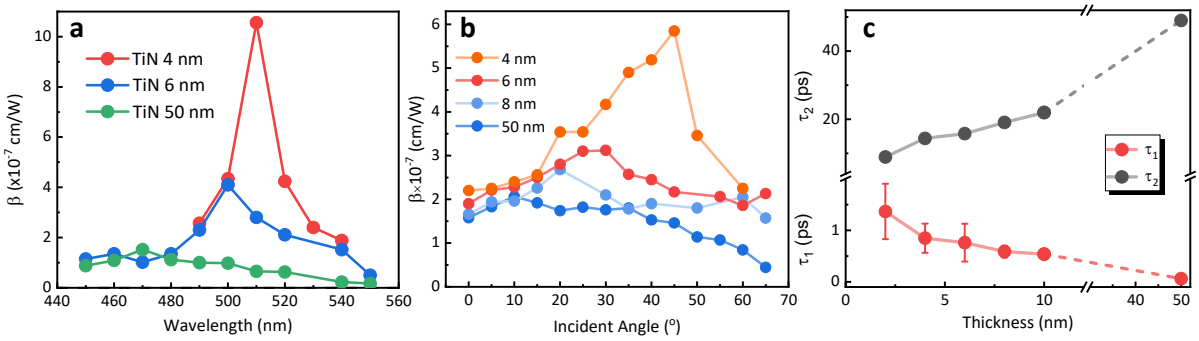

Figure1. (a)(b) Wavelength- and incidence angle-dependence of nonlinear absorption coefficient (β) for ultrathin and thick TiN films. (c) Thickness dependence of carrier lifetimes (τ_1, ultrashort, τ_2, long electron-phonon interaction time) of ultrathin and thick films.

Our results demonstrate that the significant ENZ-enhanced nonlinearity can be realized in ultrathin metal films which have been challenged by optical losses and ultrathin thickness. Combined with its refractory property, ultrathin TiN films can provide an ideal platform in applications of nonlinear ENZ nanodevices operating in the visible spectral range.

Absorption-Based Nanophotonic Quantum Sensing on Resonant Metasurfaces

Laura Kim[1*]

[1]University of California Los Angeles, USA
[*]lbkim@ucla.edu

Abstract: Optically addressable nitrogen vacancy (NV) centers in diamond have emerged as one of the leading quantum sensing platforms but suffer from suboptimal readout due to the inefficient spin-photon interface. I will discuss spin-coupled resonant metasurfaces that offer opportunities for near-unity readout fidelity within a nanoscopic sensing volume for wide-field sensing applications.

Nitrogen-vacancy (NV) centers in diamonds have become a leading solid-state quantum system for wide-field sensing applications, owing to their ability to optically measure quantities such as electric field, magnetic field, and temperature. Atom-sized quantum sensors constructed from this spin-based qubit system can, in principle, achieve a remarkable sensitivity on the order of nT for one-second integration, comparable to the size of a magnetic field generated by a single electron approximately 50 nm away. However, the inefficient transduction process of mapping spin information onto optical fields creates a suboptimal readout of the spin population. The conventional optical readout is done by collecting visible fluorescence. This method is significantly limited due to poor photon collection efficiency and slow radiative transition; as a result, the sensors relying on the conventional fluorescence method remain nearly 1000 times less sensitive than the spin-projection-noise-limited sensitivity. Efforts to gain photonic control of the visible transition have been made; still, the challenge, especially for ensemble-based sensing at ambient conditions, is that an improved rate of fluorescence comes at the cost of diminishing spin contrast [1]. I will discuss nanophotonic strategies for enhancing spin-optic coupling for the *infrared* (IR) metastable transition of NV centers, which allows for *absorption*-based spin readout [2]. Unlike florescence-based detection, this approach offers a straightforward path to significant sensitivity improvements.

First, I will report on a spin-coupled plasmonic metasurface, which relies on the Rayleigh-Wood anomaly mode. This resonant mode strikes the right balance of maximizing the spatial overlap with a given near-surface sub-micron-scale NV layer and enhancing the rate of spin-dependent IR optical transition. This resonant surface is designed to readily couple with external radiation, allowing for shot-noise-limited sensing with a standard camera and eliminating the need of single-photon detectors [3,4]. I theoretically predict that the diamond-spin plasmonic metasurface for IR absorption readout reaches a volume-normalized magnetic field sensitivity of 10 pT $Hz^{-½}$ $um^{3/2}$ with the present-day NV diamond samples and fabrication techniques, which is about three orders of magnitude improvement over what has been previously realized [3]. I highlight that plasmonic metasurfaces have a particular advantage: the metallic structures with a subwavelength spacing can create desired magnetic field or electric field gradients to address NV spin transitions site-specifically. This capability can be leveraged to achieve deep sub-pixel imaging capabilities, paving the way for a new type of quantum micro(nano)scopy. Additionally, I will discuss all-dielectric structures, including q-BIC spin-diamond metasurfaces and slow-light waveguides, as an alternative platform. They offer high-quality factors with no optical losses and are excellent candidates for phase-sensitive dispersive readout schemes. I will report on both recent theoretical and experimental progress concerning such spin-coupled resonant metasurfaces. I will demonstrate that the spin-coupled resonant metasurfaces coherently encode information about the local magnetic field on spin-dependent phase and amplitude

changes of near-telecom light.

The reported spin-coupled resonant metasurfaces are projected to bridge the significant gap between the best demonstrated ensemble-based bulk NV sensors and the inherent spin-projection-noise-limited sensitivity [5]. The projected performance makes these studied metasurfaces attractive for addressing long-standing questions about electromagnetic phenomena and dynamics in quantum materials that remained elusive with classical sensors. Ensemble sensors operating at room temperature hold particular significance for probing biological samples and devices under natural operating conditions. We anticipate targeting the most demanding applications, such as chip-scale spatially-resolved chemical shift NMR and MRI of individual cells and molecules, noninvasive imaging of the magnetic signals from neuronal circuits in animals, and imaging of integrated circuits.

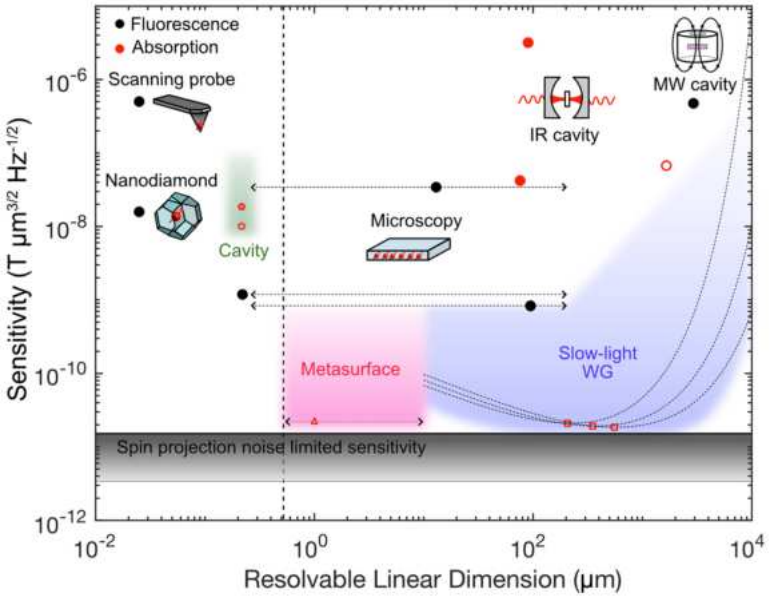

Figure 1. Resonantly enhanced nanophotonic quantum sensing based on absorption-based readout is projected to bridge the gap between the spin-projection-noise-limited sensitivity and the performances of current sensors [5].

Local high quality factor metasurfaces for extremely low threshold nonlinear image filtering and efficient programmable wave shaping

Mark Lawrence, Lin Lin, Bo Zhao, and Samuel Ameyaw

Department of Electrical and Systems Engineering, Washington University in St. Louis, St. Louis, Missouri 63130, USA

Email: markl@wustl.edu

Abstract: The key benefits that metasurfaces offer image processing originate from the ability to almost arbitrarily manipulate light fields on a subwavelength scale. Unfortunately, the latest frontiers of efficient nonlinear and dynamic light shaping are at odds with the traditional metasurface paradigm as the demand for dramatically amplified light-matter coupling typically constrains dielectric meta-atoms to be much bigger than the wavelength. Here, we present a solution to this problem in the form of metasurfaces composed of dipolar guided mode resonators. Achieving meta-atom quality factors of over 1000 while maintaining subwavelength pixel pitch, we demonstrate nonlinear all-optical image processing with $<200\mu W/\mu m^2$, as well as fast, high contrast, spatial light modulation with sub-wavelength resolution driven by volt-level electrical biasing.

Nonlinear Mid-infrared Metasurfaces for Harmonic Generation and Deep-Subwavelength Nanomachining

Abstract: We perform shot-controlled fifth harmonic generation measurements from a SiC meta-membrane with resonances in the mid-infrared. Back focal plane imaging reveals more than two orders of magnitude enhancement of the FHG from the meta-membrane, compared to the unstructured SiC film of the same thickness, along with an unusual Kerr-induced spectral behavior.

Nonlinear light-matter interactions can be strongly enhanced in photonic nanostructures [1] and metasurfaces [2], where the subwavelength thicknesses lifts the phase-matching requirement via resonant excitation. Free-standing metasurfaces–or meta-membranes–represent an attractive alternative to metasurfaces on substrates. In meta-membranes, the active layer of the device is its only layer. Exceptional linear-optical characteristics of free-standing metallic, dielectric and phonon-polaritonic metasurfaces, such as resonant reflectance, transmittance, absorbance, diffraction and polarization sensitivity, have been revealed. However, poor thermal dissipation has made the studies of freestanding metasurfaces under strong laser excitation challenging.

In this paper, we report on the nonlinear optical responses of meta-membranes. A SiC-based holey metasurface exhibits collective resonances in the mid-infrared frequency range (4000 nm) and produces bright fifth harmonic generation (FHG; 800 nm) in the back focal plane (BFP) of the imaging system. The sample of a meta-membrane was fabricated from a SiC free-standing film starting with a monocrystalline 4H-SiC on insulator (SiCOI) substrate fabricated as described in [3]. A typical SEM image of the membrane and its schematic is given in Fig. 1a. The unpatterned parts of the membrane were used for control measurements. The transmittance of the patterned membrane depends on location, with a typical example shown in Fig. 1b. For the design polarization of the sample (V, along the short sides of the rectangular holes), there are pronounced resonances with the Q-factor in the range of 22-31 across the membrane in the desired spectral region.

FHG BFP images show several orders of diffraction at 800 nm, as selected with a bandpass filter (see Figure 1c). The presence of the diffraction orders and the absence of incoherent emission filling the whole objective aperture signifies the absence of parasitic emission such as multiphoton photoluminescence. The FHG nature of the detected signal is additionally proven with single-shot measurements performed while increasing the pump intensity. Fitted with $y = ax^b$, the resulting slopes are $b_V = 5.0 \pm 0.4$ and $b_H = 4.9 \pm 0.7$, signifying the perturbative regime of harmonic generation. No single-shot FHG was observed for any pump intensity used in the experiment from an unstructured membrane. To estimate the maximum FHG enhancement enabled by nanostructuring, we have captured a single-shot FHG frame from the metasurface and an accumulated FHG signal from 1,000 shots measured at the unstructured part of the membrane, both at the same intensity of 300 GW/cm2. The resulting FHG counts are 16±2 for the metasurface using a single V-polarized shot and 40±2 for the unstructured membrane collected over 1,000 shots, signifying around FHG 400-fold enhancement in the metasurface.

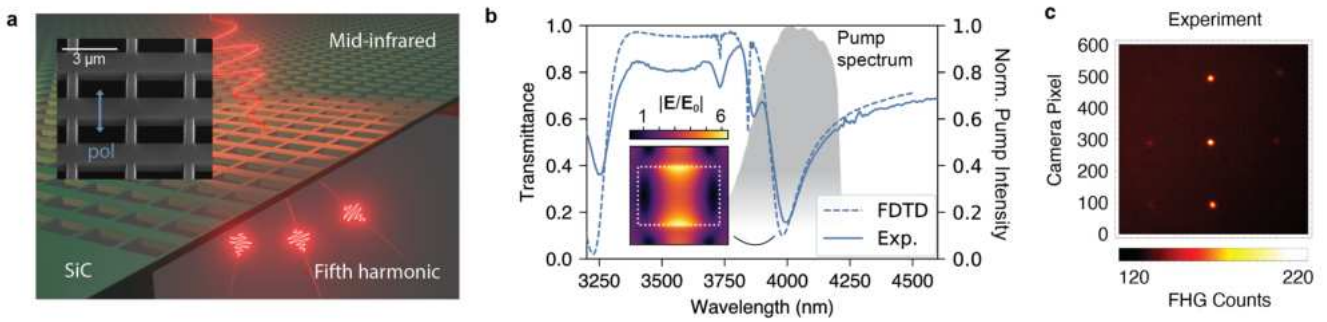

Figure 1. (a) SEM micrograph (left) and schematic (right) of the sample. (b) An experimental mid-IR transmittance spectrum of the sample for the design polarization (solid line) and the corresponding FDTD calculation (dashed line). The spectrum of the pump laser is superimposed (gray shaded area). The calculated local field distribution at a wavelength of 4000 nm in the middle section of the meta-membrane is shown to provide a substantial field enhancement at the pump wavelength. (c) Single-shot FHG from the free-standing SiC meta-membrane: BFP of the FHG emission from the metasurface for the horizontal (V, design) polarization.

We observed that several shots in the same position would permanently damage the metasurface, as the long-term laser damage tends to accumulate in resonant nanostructures [4]. To study the resonance-dependent behavior of FHG, sequences of single-shot measurements, each on a fresh spot of the sample, were performed going across it in places with differing thicknesses for the design polarization (V). The position of each shot was recorded, and its thickness derived by using a thickness map of the membrane obtained before it was. From the thickness, the resonance wavelength of the patterned membrane at each point can be reconstructed by comparison with numerical simulations. The FHG counts for the single-shot measurements are obtained for resonances with different wavelengths across the sample. The difference in the peak position for the FHG as a function of the resonance wavelength is attributed to the dynamic resonance red shift that we successfully explain in the context of a coupled-mode theory with a time-varying resonance frequency.

Near-field manipulation of angular momentum of light

Haoran Ren[1]

[1]School of Physics and Astronomy, Faculty of Science, Monash University, Australia

[*]corresponding author: Haoran.ren@monash.edu

Abstract: Nanophotonics opens the possibility of realising subwavelength optical vortices through coupling optical beams into subwavelength surface polaritons. I will highlight our recent work on hybrid nanophotonic circuits and nano-lasers used for angular-momentum-selective on-chip applications, as well as on dispersion control and multiplication of low-loss polaritonic vortices at mid-infrared frequencies.

Selective control of light is essential for optical science and technology with numerous applications. Nanophotonic waveguides and integrated couplers have been developed to achieve selective coupling and spatial control of multiple degrees of freedom of light [1-10]. Plasmonic nanostructures can enable compact multiplexing of the orbital angular momentum (OAM) of light [11-13]; however, strong dissipation of the highly localised OAM-distinct plasmonic fields in the near-field region hinders on-chip OAM transmission and processing. We demonstrated that incident OAM beams can selectively excite single-crystalline cadmium sulfide nanowires through coupling OAM-distinct plasmonic fields into nanowire waveguides for long-distance transportation [14]. This allowed us to build an OAM-controlled hybrid nanowire circuit for optical logic operations including AND and OR gates.

In addition to the demonstration of passive hybrid circuit, we recently demonstrated an active hybrid nanophotonic circuit that enables nonlinear optical selectivity based on the spin and OAM of light [15]. We designed active nanolaser circuits consisting of plasmonic metasurfaces and individual perovskite nanowires, allowing selective coupling of spin and OAM-distinctive plasmonic fields into nanowires that exhibit single-mode lasing. The optically selected nanolaser with nonlinear increase of light emission greatly enhances the baseline optical selectivity offered by the metasurface from about 0.4 up to near unity. Our demonstrated nonlinear optical selectivity may find important applications in all optical logic gates and nanowire networks, ultrafast optical switches, nanophotonic detectors, and on-chip optical and quantum information processing.

Optical vortices (OVs) with defined topological features are a ubiquitous phenomenon in optics. Owing to the diffraction limit of light, the minimum size of free-space OVs is fundamentally limited to the wavelength scale, while reduction of the physical size of OVs is required for photonic integration, on-chip information processing, and unveiling of new structured light-matter interactions. Nanophotonics opens the possibility of realizing subwavelength OVs via coupling optical beams into subwavelength confined surface states, such as surface plasmon polaritons [16-19] and surface phonon polaritons (SPhPs) [20-22]. However, the topological charge offered by the surface structure used for launching polaritonic OVs is always a fixed quantity. Here, we overcome this limitation via dispersion-driven topological charge multiplication [23]. We switch the topological charge of polaritonic OVs within a small ~3% frequency range by leveraging the strong sublinear dispersion of low-loss SPhPs on silicon carbide membranes. Our work paves the way for all-optical ultrafast switching of OVs and the exploration of OAM-based light-matter interactions at mid-infrared frequencies.

Controlling Far-Field Radiation with Photoluminescent and Incandescent Metasurfaces

A. Nguyen[1], E. Bailly[1], J.-P. Hugonin[1], J.-J. Greffet[1] and B. Vest[1]

[1]Université Paris-Saclay, Institut d'Optique Graduate School, CNRS, Laboratoire Charles Fabry, 91127, Palaiseau, France.

Abstract: Intrinsically incoherent thermal or luminescent emitters can be coupled to metasurfaces to establish some coherence in emission and therefore to enable structuration of the emitted field. We present here light-emitting metasurfaces designed using a Kirchhoff's law approach demonstrating a controlled of the polarization state and angular radiation pattern.

Designing a light-emitting system means shaping light emission so that it matches requirements in terms of radiation pattern, polarization, or spectrum. However, non-lasing sources rely on spontaneous emission processes: the intrinsic randomness of emission prevents the structuration of a light beam by interference effects and most often results in isotropic and unpolarized emission. This has a straightforward solution: optical components. Lenses, irises, diaphragms, mirrors shape the angular spectrum; filters shape the temporal spectrum; Polarizers and waveplates can convert the polarization state, etc… Hence, the current optical engineering workflow is to first use a light emitting material matching a minimal number of requirements, and to eventually shape the emitted light with additional components external to the light source itself, mostly by filtering and rejecting some part of the energy. The addition of external components increases the bulkiness of light-emitting devices, affecting their total energy footprint and limiting integration, miniaturization and introducing losses.

Our work exploits the concept of **Light-Emitting Metasurfaces (LEMs):** devices that do integrate luminescent emitters consisting typically of a substrate covered with arrays of nanoresonators in interaction with luminescent emitters, distributed over the surface of the device. The LEM supports extended electromagnetic modes which play the role of a resonator. Although emitters are incoherent, their decay into the surface modes establishes a non-zero degree of coherence at long range. Besides, the surface modes can be coupled to the far-field (using grating effects for instance).

Light emission engineering is achieved by tailoring the properties of this leaky mode. At this end, we use a **Kirchhoff's approach**, extensively in the context of thermal emission. Here, the power emitted for a polarization (l) in a solid angle dΩ around the direction u at wavelength λ is given by [1]:

$$\mathrm{d}^2P_e^{(l)}(\mathbf{u},\lambda,\mu) = d\lambda d\Omega \int_V d^3\mathbf{r}'\alpha^{(l)}(-\mathbf{u},\mathbf{r}',\lambda,\mu)\frac{hc^2}{\lambda^5}\frac{1}{\exp(\frac{hc}{\lambda k_BT}-\frac{\mu}{k_BT})-1} \quad (1)$$

α is the local absorption rate within the resonator. The second factor is the blackbody radiance evaluated at $hc/\lambda - \mu$, where μ is the photon chemical potential which accounts for the pumping of the system. This relation shows that the local absorption rate α is the key to tailor quantitatively the spectral, angular, and polarization dependence of the emission. The integral is performed over the volume V of emitting material. This formulation

shows that emission in a mode is connected to emitting material placed in regions of high local absorption rate.

We use the Kirchhoff's approach to design and fabricate several LEMs. First, an **incandescent LEM** providing chiral emission in the MWIR (see Fig. 1) [2]. It consists of an array of thin metallic wires, heated by Joule effect on top of a transparent substrate. While the whole wire is heated at once, only the central fraction of the pattern, where inversion symmetry is broken, contributes to dichroism.

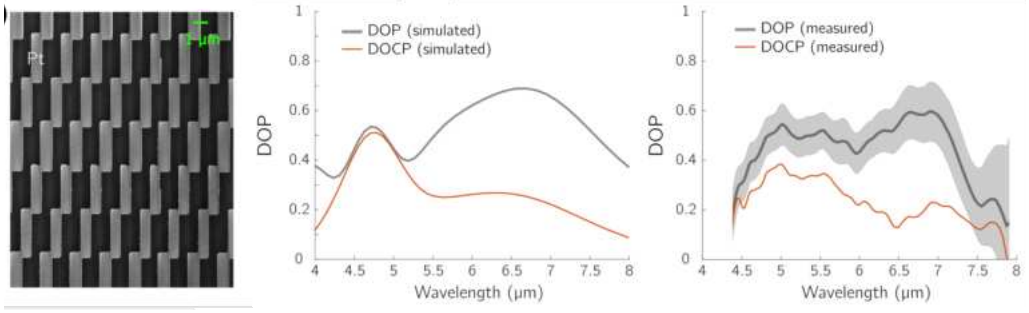

Fig. 1 Incandescent LEM for chiral emission [2] (a) SEM picture of the fabricated device. (b) Simulated and measured degree of polarization (DOP) and degree of circular polarization (DOCP). Shaded areas represent one-sigma error bars.

Second, **photoluminescent LEMs** consisting of metallic gratings covered with nanoplatelets provided by the LPEM [58]. Light occurs around 610 nm, within a 20° wide angular range (Fig. 2) [3], therefore establishing directional emission out of an ensemble of incoherent emitters.

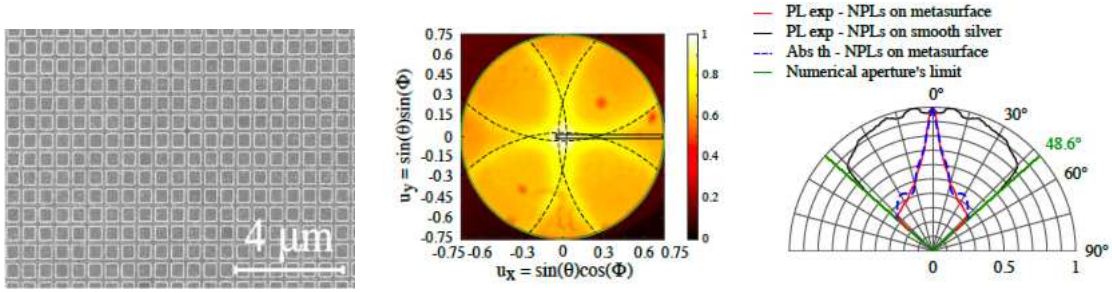

Fig. 2 2D Photoluminescent LEM for directional emission [3]. (Ledt) SEM image of the 2D silver grating forming the base of the LEM (Center) Fourier plane image of the photoluminescent emission **(**Right) Experimental angular radiation pattern (solid red) compared to simulated absorption using the Kirchhoff's formalism (blue dotted). Emission occurs within a 20° FWDH angular cone. Emission from unstructured emitter layer is isotropic (solid black)

Abstract: Chirality is essential in physical, chemical, and biological processes, playing a critical role in disease formation and drug synthesis. While metasurfaces enhance chirality detection, they often introduce significant background. This talk will address these challenges and introduce new design principles to improve the signal-to-noise ratio for more effective chirality detection.

Chirality describes molecules or structures that are not superimposable with their mirror counterparts, namely, enantiomers. Enantiomers may exhibit different biological, physical, or chemical properties, and therefore, have been widely studied. Enantioselective light-matter interactions such as absorption[1], fluorescence[2], and optical forces[3] have been applied to detect and separate enantiomers. Macroscopically, these interactions result in different responses to left- and right-handed circularly polarized light, which can be analyzed using circular dichroism (CD) spectroscopy. However, CD signals are typically weak at low molecule concentrations. To measure trace amounts of chiral molecules, high-quality factor dielectric nano-resonators or metamaterials have been used to detect the enantioselective shift of the resonance frequency[4]. Additionally, plasmonic nanostructures have been employed to enhance chiral absorption through an increased local optical chirality density[5]. Traditionally, such enhancement is modeled through an electric dipole-magnetic dipole (ED-MD) interaction, where the surface plasmon resonance enhances the local optical chirality, thus increasing the differential chiral absorption. However, this overlooks chiral absorption components that are from higher-order multipolar absorption, especially in the presence of plasmon-induced spatial non-homogeneity of the fields[6].

Macroscopic chiral molecules may support non-zero quadrupole moments if the molecules are not completely randomized. In a general gradient field, such an interaction can lead to chiral absorption. However, little is known about how this interaction contributes to the overall chiral absorption in spatially varying gradient fields, for example, those induced by resonant nanostructures. The molecular ED-EQ interaction is sensitive to the field gradient created by localized surface plasmon resonance, which could result in additional chiral absorption, while such an enhancement mechanism and the spectral features are expected to be distinct from the well-known ED-MD interaction[7].

We assume that the chiral medium facilitates an electric dipole-electric quadrupole (ED-EQ) interaction[8] characterized by $Q_{i,j}^{\pm} = \sum_k \gamma_{i,j,k} P_k^{\pm}$, where ± denotes the left- and right- handedness of light; $\gamma_{i,j,k}$ is the ED-EQ coupling coefficient [9]; i, j, k represent the Cartesian coordinates; and P is the polarization vector. For simplicity, we assume the chiral medium has a scalar ED-EQ coefficient, and Q has only non-zero diagonal terms. The polarization vector is associated with the ED-MD interaction through $P_k^{\pm} = \varepsilon_0 \chi E_k^{\pm} - i\frac{\kappa}{c} H_k^{\pm}$, where

χ is the linear susceptibility, κ is the Pasteur parameter that describes the ED-MD interaction, and c is the speed of light. Our analysis focuses on the absorptions associated with the electric dipole, magnetic dipole, and electric quadrupole. Notably, the absorption involving electric quadrupole contains a term analogous to the optical chirality density, $C = \mathrm{Im}\left(E^* \cdot B\right)$, as $C_k^{\ e} = \frac{\partial E_k^{\ *}}{\partial k} B_k$, which is main discussion of this presentation.

In this talk, we show that a chiral medium supporting both ED-MD and ED-EQ interactions can exhibit the extended chirality beyond the traditionally defined optical chirality density. We demonstrate numerically that the overall chiral absorption is associated with the ED-EQ interactions induced by the resonance of metal-insulator-metal nano-resonator. The resonator not only enhances the molecule's chiral absorption through an increased optical chirality density but also through an enhanced ED-EQ interaction via the field gradient.

Electrochemically Active Metasurface and Multispectral Light and Heat Management

P. -C. Hsu[1*]

[1]Pritzker School of Molecular Engineering, University of Chicago, USA
[*]corresponding author: pochunhsu@uchicago.edu

Abstract: Electrochemistry is a powerful tool with gigantic refractive index changes. This talk includes three subjects: (i) Conjugated polymers for near-perfect dynamic thermal meta-emitter. (ii) Reversible metal electrodeposition for multispectral solar and mid-infrared control and dynamic beam steering. (iii) Spectrally selective hierarchical fabric for practical radiative cooling for the human body.

Electrochemistry is a powerful tuning knob for inducing drastic optical property changes. By applying an electrical bias while using counterions to maintain charge neutrality, electrochemistry can vary the carrier density or even trigger a phase transformation in an electrically addressable manner, which is particularly desirable in many applications where tunable range, scalability, or non-volatility is crucial. Meanwhile, metamaterials provide additional degrees of freedom to boost performance and achieve multifunctional control. However, electrochemically active metasurfaces are still largely underexplored, partly due to the lack of intrinsic property databases for newly developed materials. More co-development is needed among fundamental materials science, metasurface design, and electrochemical device engineering. In this talk, I will present two types of electrochemically active materials and one work dedicated to radiative cooling textiles: (i) Conducting polymers for near-perfect dynamic thermal emitter. We conducted infrared ellipsometry to measure the potential-dependent optical property and designed a tunable metal-dielectric-metal near-perfect absorber for wearable variable emittance (WeaVE) devices for personal thermoregulation. (ii) Reversible metal electrodeposition for multispectral solar and mid-infrared control. The potential, electrolyte, and interfacial properties dictate the metal morphology, allowing reversible switching between a solar adsorber and a radiative cooler for all-year-round renewable thermoregulation for net-zero-energy buildings. (iii) Spectrally selective hierarchical fabric for practical personal radiative cooling against urban heat island effect and surrounding thermal radiation. We use vibrational spectroscopy to down-select the textile material that has high and selective emissivity in the atmospheric transmission window. This special spectral property effectively blocks the radiative heat gain from the thermal radiation from the buildings and grounds, resulting in higher radiative cooling power than a broadband-emitting fabric. These research outcomes can lead toward energy-efficient thermoregulation for the human-energy-building nexus for net-zero goals.

Building Uncooled Infrared Camera based on One Atom Thick Graphene

Debashis Chanda

CREOL, College of Optics and Photonics, University of Central Florida, Florida, USA
*corresponding author: Debashis.Chanda@ucf.edu

Abstract: The talk will outline a novel strategy for uncooled, tunable, multispectral infrared detection. Due to the low photon energy, detection of infrared photons is challenging at room temperature. One atom thick graphene offers an alternative mechanism bypassing material bandgap restriction. Further, the ability of carrier concentration modulation on graphene via external voltage offers dynamic spectral selectivity for “color” night vision/sensing. The performance of preliminary demonstration compares favorably even with present cryogenically cooled detection schemes paving the path for commercial development of many applications from space exploration to healthcare.

Palladium Nanorods Overlayer Induced Electrostatic Contribution to Silicon Rib Waveguide Sensitivity

A. Novikova[1*], A. Katiyi[1] and A. Karabchevsky[1]

[1]School of Electrical and Computer Engineering, Ben-Gurion University of the Negev, Beer-Sheva 8410501, Israel
[*]corresponding author: novikoan@post.bgu.ac.il

Abstract: The methods to identifying fast-evaporating substances must be fast, easy to use and sensitive [1,2]. In our work, we modified the surface of rib waveguides with gold nanorods coated with palladium to adsorb the hexane and N-Methylaniline molecules to the waveguide surface. This led to the increased overlap of the evanescent fields with molecules under investigation. Our results on mixtures of hexane and N-methylaniline show absorption of 7.6 dB (amine group) and 6.8 dB (CH group). The absorption of hexane bonds in water is 5.5 dB, which is 100 times higher than those predicted by the numerical simulation.

We investigated the absorption spectrum of the N-methylaniline (NMA) in a hexane mixture and pure hexane on modified waveguides. The IR spectra of the mixtures are presented in Figure 1.

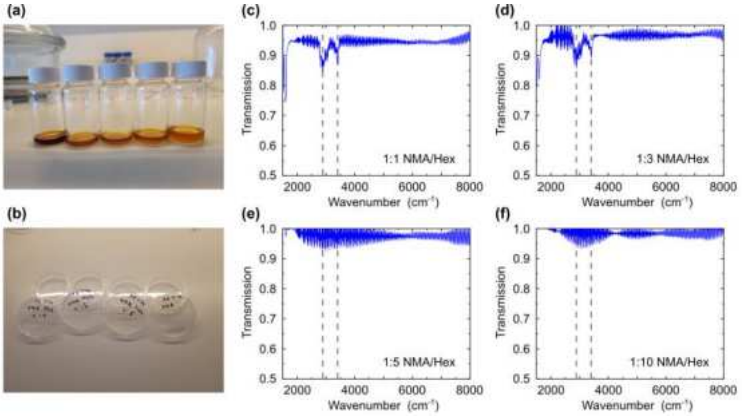

Figure 1. FTIR spectroscopy results. (a) Samples with different concentrations of NMA in hexane and (b) glass slides with palladium layer (concentration of 10 μg/ml in water) with the samples deposited on them. FTIR spectra of glass samples with a concentration of (c) 1:1 NMA to hexane, (d) 1:3 NMA to hexane, (e) 1:5 NMA hexane and (f) 1:10 NMA hexane.

The peaks appear at 3490 cm^{-1} and are associated with CH, methyl group. The peaks associated with N-methyl bond are located at 2812, 2801 cm^{-1} and 2855.65, 2879.45 cm^{-1}. Next, we characterized the gold nanorods with palladium and rib waveguides by means of optical spectroscopy. The clean surface of the waveguide shows strips with varying widths where the wider strip is 20 μm wide and the smaller is 9.9 μm wide, a strip height of 400 nm. The top of the waveguide has a layer of Ta_2O_5. We determined the concentration of palladium in water does not form conglomerates on the surface, but separate areas and amounted to 10 μg/ml.

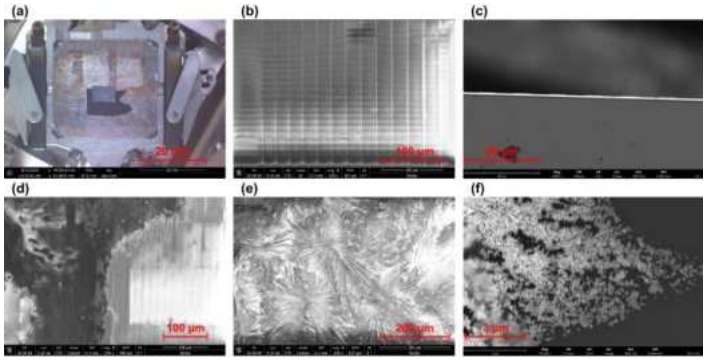

Figure 2. Scanning electron microscope (SEM) images. (a) a photograph of a rib waveguide with palladium positioned on the scanning electron microscope holder. (b) Top view and (c) side view of the surface of a clean rib waveguide. (d) Rib waveguide with palladium nanorods deposited on the top of the waveguide while the palladium nanorods in water had a 100 μg/ml concentration. (e) Zoomed-in image of rib waveguide with palladium. (f) Rib waveguide with palladium nanorods deposited on the top of the waveguide while the palladium nanorods in water had a concentration of 10 μg/ml.

To assess the performance of the modified rib waveguide in a molecular environment, we designed an experimental setup as shown in Fig. 3a. The transmittance of pure and nanorod-coated rib waveguides in air was measured to obtain a reference spectrum. Figure 3e shows the transmission of a pure rib waveguide (blue graph) and a modified rib waveguide with N-methylaniline with hexane (red curve) at a wavelength range of 1300-1600 nm. Absorption bands appear at wavelengths of 1379 nm, 1448 nm, and 1589 nm. The first two peaks are attributed to C-H bones and the last to N-H bonds. Figure 5f shows that in hexane in water, the absorption appears at a wavelength (red curve) of 1379 nm (CH_3) with a drop of 5.5 dB and the blue-shifted peak. There is a peak at 1448 nm (CH_2) with a drop of 1.5 dB. Both peaks are attributed to the C-H bonds of hexane.

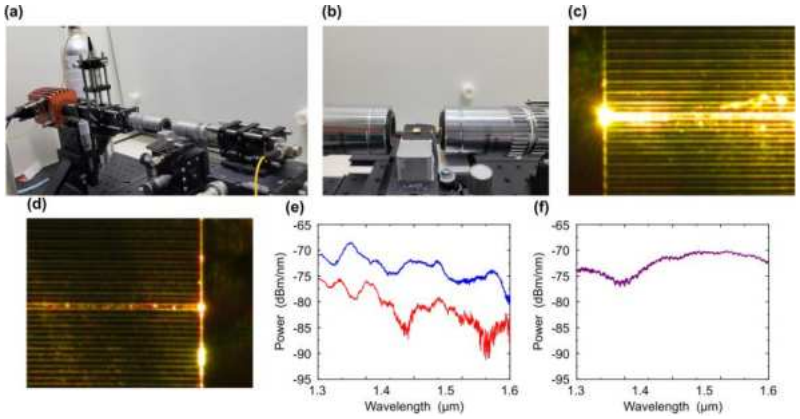

Figure 3. (a) The experimental setup and (b) zoom in on the modified rib waveguide with palladium nanorods. Microscope top view images of (c) the input and (d) output facets. (e) Measured transmission spectra at a wavelengths range of 1.3-1.6 μm modified rib waveguides with palladium nanorods with a mixture of N-methylaniline in hexane (red curve) with a concentration of 1:3 (NMA/hexane) and clean rib waveguide (blue curve). (f) Normalized transmission spectra at a wavelength range of 1.3-1.6μm of modified rib waveguide with hexane in water 1:1.

Abstract: We discuss multiresonant features of symmetric metasurfaces and the physical mechanism behind them, i.e., the lattice induced coupling between high-order Mie-type multipoles. Our analytical and numerical results provide important possibilities in the design of simple metasurfaces for structural color generation, optical sensing, and nonlinear processes.

Simple resonant nanostructures serve as a physical basis for many technological advances in modern nanophotonics. For instance, on the basis of dielectric metasurfaces [1] many optical effects have been realized and proposed [2]. In this context, the study of the relation between resonances and the structural parameters of such systems is important for pushing the limits of current technologies as well as for new applications.

To partially address this big issue, we have investigated a multiresonant response of symmetric metasurfaces. Because multiresonant metasurfaces can be used to have a compact device that operates in multiband regime and is desired for various applications e.g., in sensing, nonlinear optics, structural color generation. Based on our analytical and numerical calculations, we have designed multiresonant metasurfaces by exploiting lattice-induced electromagnetic coupling effect within the same parity multipoles [3]. The proposed metasurface that consists of a regularly arranged (i.e., periodic lattice) array of symmetric dielectric nanoparticles, has potential application in structural color generation (pixel) since it exhibits simultaneous resonances at almost red, green, and blue wavelengths.

Another important aspect of our investigation is that our results provide important possibilities in the design of simple and symmetric metasurfaces with high quality factor resonances that are crucial for optical sensing, lasing and nonlinear processes. Details of this case will be presented at the conference.

We acknowledge support from DFG (German Research Foundation) under Germany's Excellence Strategy within the Cluster of Excellence PhoenixD (EXC 2122, Project ID 390833453).

Vibrational Strong Coupling for Cavity Catalysis of an Enantioselective Reaction

J. Singh[1], P. Garg[1], R.V. Anand[1] and J. George[1*]

[1]Indian Institute of Science Education and Research Mohali, India
[*]Corresponding author: jgeorge@iisermohali.ac.in

Abstract: Vibrational strong coupling is applied, and Fabry-Perot cavity mode is coupled to the reactant vibration in an asymmetric aldol reaction. Increase in product formation is observed by NMR, but negligible changes in enantioselectivity are observed by chiral HPLC. Control experiments suggest the minimum involvement of enantioselectivity in the rate-determining step.

Summary: In the 1960s, when the laser was first invented, scientists tried to modify reactions by shining lasers, and they were partially successful, but the large dissipation in the molecular system hindered its vast applicability. In the last decade, strong light-matter interaction and its applications in the form of a new field, namely Vibrational Strong Coupling (VSC), have also proved to achieve the same goal even more fascinatingly. Since the latter does not require any outside photon but utilizes vacuum energy to induce the changes. In VSC, a molecular vibration of the interest is coupled to the cavity mode of the resonant frequency, forming the new and exotic hybrid polaritonic states separated by vacuum rabi splitting energy. It measures the strength of the interaction between light and matter. Mathematically, Rabi splitting depends on the following equation.

$$\hbar\Omega_R = 2V_n = 2\boldsymbol{d}\cdot\boldsymbol{E} = 2d\cdot\sqrt{\frac{\hbar\omega_c}{2\varepsilon_0\upsilon}}\times\sqrt{n_{ph}+1} \quad (1)$$

Here, V_n is the interaction energy in the absence of any type of dissipation, and it is the scalar product of the transition dipole moment (d) and the electric field strength (E). ω_c is the resonant frequency, E_0 is the vacuum permittivity, υ is the mode volume, and n_{ph} is the number of photons involved. Even if n_{ph} is zero, some splitting will still exist; therefore, it is called vacuum Rabi splitting energy.[1] VSC can modify the ground state chemical reactions,[2,3] crystallization process,[4], etc. It has also been proposed that chiral cavities can modify the enantioselective outcome of the ground-state chemical reaction.[5] But as of now, no experimental reports are presently dealing with an enantioselective reaction inside an achiral FP cavity.

For our experiment, we chose an asymmetric aldol reaction in which two reactants, namely 4-nitro benzaldehyde and acetone, react together in the presence of *L*-proline to form an enantioselective product. The reaction mixture was injected into a microfluidic cell, acting as a Fabry-Pérot cavity. Both the reactants contain a carbonyl vibration, which is coupled to the cavity mode of the resonant cavity. Coupling of the vibrational band of the reactants results in the formation of the polaritonic states with their own exotic properties and leads the system into the strong coupling. This reaction was allowed for a fixed amount of time before quenching and taking out the products for further analysis. The amount of the product in the reaction mixture is estimated by the ^{1}H Nuclear Magnetic Resonance (NMR) spectroscopy. The product formation is roughly 48(±5) % in the experiment without VSC.

On the other hand, in the VSC experiment, this product formation was boosted to a great extent and increased up to 90% at ON-resonance. This shows the reaction progress is greatly enhanced under VSC with the vacuum photon (Figure 1A). Next, we tested the enantioselectivity of the product using chiral High-Performance Liquid Chromatography (HPLC). The enantioselectivity calculated from the six measurements was 62 (±4) % of the R-enantiomer for the non-VSC experiment. For the VSC experiments, the enantioselectivity of the product at ON-

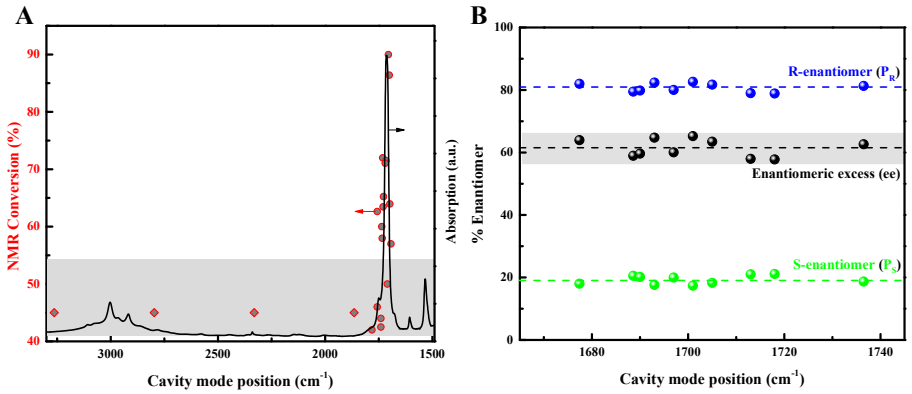

Figure.1 Effect of VSC on reaction yield and enantioselectivity. Variation in **(A)** %NMR conversion and **(B)** enantiomeric excess upon varying the cavity mode position (Gray shaded region shows the variation in enantiomeric excess in the non-cavity experiments).

resonance conditions were largely unaffected (Figure 1B). To investigate further, temperature-dependent experiments were carried out without the cavity since, in much of the literature, it is reported that VSC can modify the reaction rate similarly to temperature increase. Therefore, in non-cavity, if the rise in the temperature can cause an increase in the rate of product formation, enantioselectivity should vary. But, for the current system, negligible change in the enantioselectivity was observed with increased temperature.

Additionally, the literature suggests that this reaction proceeds in two major steps: (1) formation of the intermediate and (2) formation of the product by enantioselective attack of the aldehyde on the intermediate. The slowest step is the first step, where the intermediate is being formed, and therefore, we proposed that VSC can modify the reaction yield but not the product enantioselectivity in this system because the chiral step is not the slowest. Hence, systems with rate-determining and enantioselective steps that are more closely interlinked can be tested under VSC, and the product's enantioselectivity can be modified.[6]

Abstract: In this work, we use nano-optomechanical disk resonators for environmental monitoring. We show that simultaneous tracking of both optical and mechanical modes enables to discriminate between temperature and humidity effects. We demonstrate that actively tracking the optical mode allows to directly obtain reliable mechanical signals, avoiding previous calibration and extra post-processing.

Optical and mechanical resonators have each been abundantly employed in sensing applications. Here we show that bringing together optical and mechanical resonances in a unique sensing platform significantly improves the sensor performance [1]. We employ nanoscale optomechanical disk resonators (Fig. 1.a) fabricated out of GaAs. They simultaneously support high quality optical and mechanical modes, which provide extraordinary sensitivities. Figure 1.b shows the relevance of actively tracking the optical mode when operating optomechanical sensors. It enables the obtention of direct reliable mechanical signals, which avoids previous calibrations and extra post-treatment. In addition, actively tracking the optical mode enlarges the sensing range and prevents degradation of the device sensitivity during the experiment.

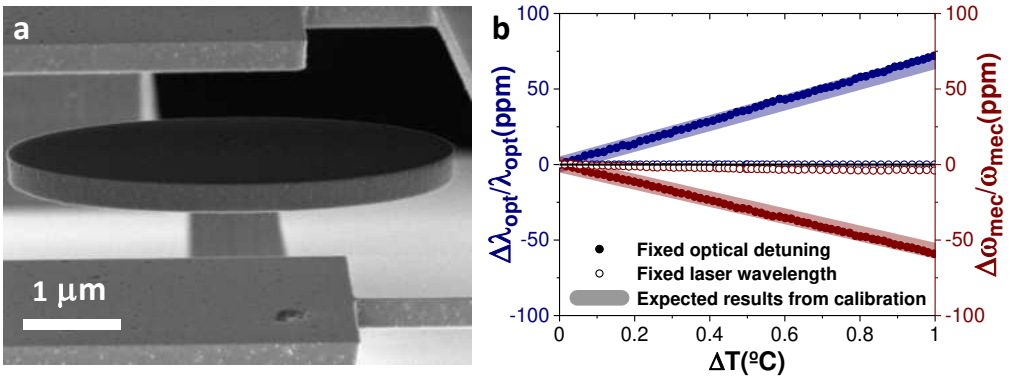

Figure 1. *(a) Scanning electron microscopy image of a GaAs optomechanical disk (r=2.5 um, t=320 nm) resting on an AlGaAs pedestal. (b) Optical (blue) and mechanical (red) resonance shifts as a function of temperature change, fixing the optical wavelength (open circles) and the optical detuning (full circles). Solid lines represent the expected responses.*

To demonstrate the capabilities of simultaneously tracking optical and mechanical signals, we perform environmental monitoring experiments (Fig. 2), in which we vary the temperature and the relative humidity and study the response of our device. By analyzing optical and mechanical signals, we are able to discern in between both temperature and relative humidity effects with a resolution of 1 mK and 0.1%, respectively, and, importantly, when both parameters change at the same time.

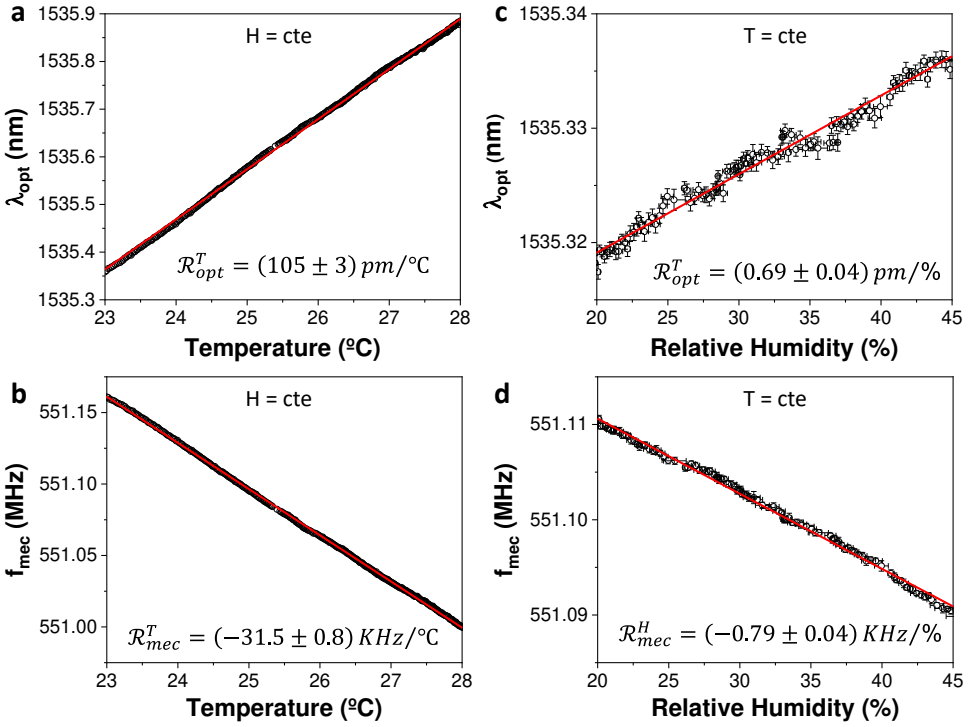

Figure 2. *Optical and mechanical responsivity to temperature and relative humidity changes. (a) Evolution of the disk WGM resonant wavelength and (b) the disk 1st RBM resonant frequency as a function of temperature, at constant relative humidity. (c) Evolution of the disk WGM resonant wavelength and (d) the disk 1st RBM resonant frequency as a function of the relative humidity, at a constant temperature.*

Although we perform environmental sensing, the conclusions of this work extend to other sensing applications. This work sets the basis for multi-mode sensing based on optomechanical disk resonators [2].

Abstract: We investigate theoretically the generation of spatial and spatio-temporal rogue waves in a multimode Q-switched Nd:YAG laser as a result of spontaneous transverse mode-locking. The statistics and temporal dynamics of rogue waves are defined by the frequency separation between the modes and spatial anisotropy of the mode configuration.

Spatial and spatio-temporal rogue waves (RWs) represent “hot spots” with extreme intensities that can emerge spontaneously in complex multimode optical systems. Their formation in lasers can be governed by different factors including nonlinearity, dispersion, gain, and spatial effects [1]. In the case of negligible nonlinear effects in the laser cavity, spatial rogue waves can be onset by spontaneous phase synchronization of transverse modes with close frequencies and assisted by spatially anisotropic mode configuration [2].

To investigate the spatio-temporal dynamics of a multimode laser, we represent the total field inside the cavity through the superposition of individual mode fields [3]:

$$E(x,y,z,t) = \sum_{q,m,n} A_{qmn}(t) U_{mn}(x,y,z) e^{2\pi i \nu_{qmn} t + i\varphi_{qmn}}, \quad (1)$$

where $A_{qmn}(t)$, ν_{qmn}, and φ_{qmn} describe the slowly varying amplitude, frequency, and phase of the mode with a longitudinal index q and transverse indices m,n; $U_{mn}(x,y,z)$ is the spatial field distribution of the mode.

Under the absence of nonlinear effects, the mode frequencies ν_{qmn} and field distributions $U_{mn}(x,y,z)$ are defined by the laser cavity configuration [4]. Typically, the transverse modes can be approximated by Laguerre-Gaussian (LG) or Hermite-Gaussian (HG) modes in the case of a cylindrical or rectangular geometry. The mode phases φ_{qmn} are assumed to be uncorrelated and randomly distributed in the range $[0, 2\pi]$. The time dependence of the mode field amplitudes $A_{qmn}(t)$ is defined by the laser generation regime. Here, we consider the actively Q-switched Nd:YAG laser with up to 15 transverse LG modes and one longitudinal mode (q=0) with parameters described in [2].

Two main factors defining the statistical properties and temporal dynamics of spatial rogue waves are the frequency difference between the transverse modes and spatial anisotropy in the laser mode configuration. The frequency spacing between modes, which corresponds to the inverse period of beating, determines the period of intensity oscillations in the transverse cross-section of the beam. In the case of small frequency separation between the modes (large period of beating), the beam spatial profile is almost unchanged during the entire Q-switched pulse duration, and spatial RWs can be formed for certain realization of initial mode phases φ_{qmn} as a result of the spontaneous mode-locking effect. For increased frequency spacing between modes (smaller period of beating), intensity over the beam profile exhibits periodic behavior during the Q-switched pulse length. At certain time moments, spatio-temporal RWs can be generated [2]. An example of the simulated spatio-temporal dynamics of the output laser beam is shown in Figure 1 for the frequency separation between modes equal to 5

MHz, which represents the limiting case of spatio-temporal RWs formation when the period of beating is comparable to the Q-switched pulse duration (200 ns). The generated spatio-temporal rogue wave with peak intensity larger than 20 mean intensity values is illustrated in Figure 1c.

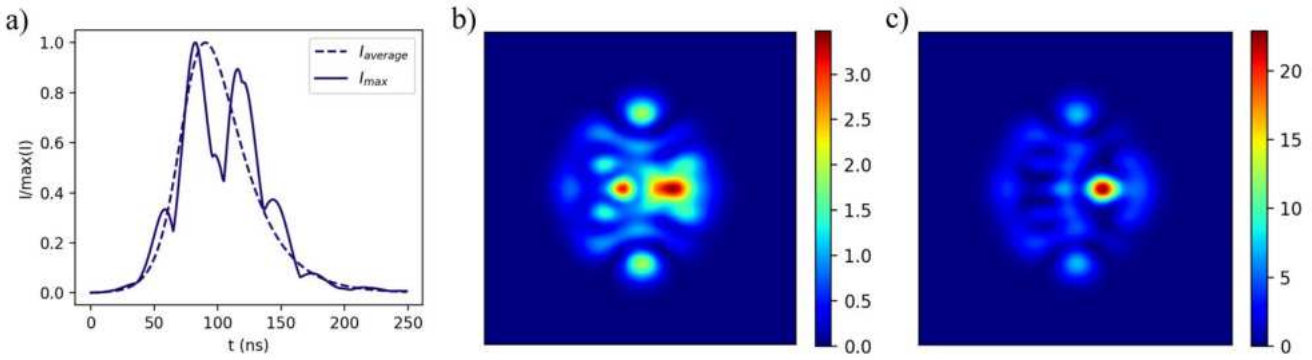

Figure 1. Example of the simulated spatio-temporal dynamics of the output laser beam: (a) temporal profiles of peak and spatially averaged intensity normalized to their maximal values; (b) transverse intensity profile averaged over the Q-switched pulse duration; (c) instantaneous transverse intensity profile corresponding to maximal peak intensity (t = 82 ns). The beam profiles in (b) and (c) are normalized to the same value of mean intensity.

Another important factor assisting the RWs generation is the spatial anisotropy of the mode configuration. This can be achieved by exciting a specific subset of transverse laser modes with close positions of the mode lobes in space, which leads to the increased probability of obtaining non-symmetrical beam patterns with intense "hot spots" formed as a result of the mode superposition. In the absence of nonlinear effects in the laser cavity, this effect is responsible for the L-shaped intensity statistics of spatial RWs, which was shown both theoretically [2] and experimentally [5].

Novel Plasma Treatments for Al:ZnO Local Modulation and its Application on Fabrication of Planar Infrared Metasurfaces

K. Sun[1*], T. Howe[1,2], C. H. de Groot[2], and O. L. Muskens[1]

Abstract: Al:ZnO (AZO) is very popular as a plasmonic infrared material. Here, we demonstrate a novel technique using O_2/H_2 plasma to modulate AZO optical responses and can be used to form AZO metasurfaces. Through s-NOM nearfield scanning, we demonstrate local optical property modulation in the AZO metasurface with sub-10 nm roughness.

In the past decade, optical metasurfaces have been researched for their potentials to tailor optical responses at different wavelength ranges. By defining sub-wavelength feature arrays, optical properties can be engineered to strongly enhance light-matter interactions and achieve electromagnetic control over amplitude, phase and polarization. To achieve infrared spectrum control, Al-doped ZnO (AZO) have been widely investigated in epsilon-near-zero (ENZ) response in infrared band and various optical metasurface applications [1].

Conventionally, the AZO metasurfaces are formed as sub-wavelength nanostructures through plasma etching, which selectively removes AZO and create property contrast. However, this non-planar structured surface provides further challenges when integrating with further functional coatings or another metasurface [2]. This work investigates a novel technique to locally and selectively modulate AZO optical property, and further demonstrates its implementation for planar optical metasurfaces. Figure 1a shows the schematic of the O_2/H_2 plasma treatment on AZO films at a lifted temperature. After the O_2 plasma treatment, refractive index can be significantly changed, and the AZO film becomes dielectric with a low k over the whole range from 0.2 to 40 µm from the metallic response in infrared (Figure 1b). For different Al:ZnO cycle ratios, the carrier density is seen to decrease with O_2 plasma to around 3×10^{19} cm^{-3} (the limit of optical response) and slightly increase with H_2 plasma. It is also noted that the pure ZnO is etched by the 20 min H_2 plasma but not AZO.

The AZO metasurface can be formed through a patterned SiN sacrificial layer for selective O_2 plasma exposure and the SiN can be selectively removed after the plasma treatment, leaving an AZO film with property contrast. Figure 1d shows topological mapping of the sample and square array can be clearly identified with unexposed (high carrier, H-AZO) and exposed (low carrier, L-AZO) in dimension of 1100 nm and 200 nm, respectively. However, the step height between exposed and unexposed AZO regions is less than 10 nm and therefore considered as topologically flat. The dot-like features are believed to be polymer or residue during the removal of masking layer, SiN and could be eliminated in further process optimization.

Figure 1e shows optical amplitude mapping of nearfield measurement at 8 µm wavelength. Unlike the little variation in topological mapping, the amplitude contrast unambiguously follows the AZO arrays made of exposed and unexposed regions as bright squares surrounded by dark frame. A higher amplitude is seen for the unexposed AZO whilst a lower amplitude is seen for the exposed AZO region. From the literature, the higher IR amplitude corresponds to high carrier concentration of zinc oxide, which is more metallic. Thus, the local AZO carrier reduction by O_2 plasma can be evidenced by the nearfield mapping. Figure 1f shows optical phase mapping at 8 µm wavelength. Higher phase rings are seen to surround the square-like unexposed AZO regions. Unlike optical amplitude corresponding to carrier density, the optical phase of ZnO peaks at carrier density

~10^{19} cm^{-3}, which well agrees with the locations as the interface between high carrier and low carrier AZO.

In summary, we present a novel O_2/H_2 plasma treatment technique to effectively modulate AZO optical property. Through an O_2 plasma diffusion barrier (SiN), AZO carrier density can be selectively and locally modulated and a planar AZO metasurface can be formed through the material optical contrast without physically removing AZO. The near-field mapping technique confirms the metasurface's flatness of sub-10 nm in roughness/step and further visualizes the local optical property modulation in term of magnitude and phase, with a spatial dimension of few ten nanometers. The formed planar AZO metasurface shows consistent response of AZO metasurface manufactured by selective etching and this technique offers broad potentials for new functional optical structures and devices.

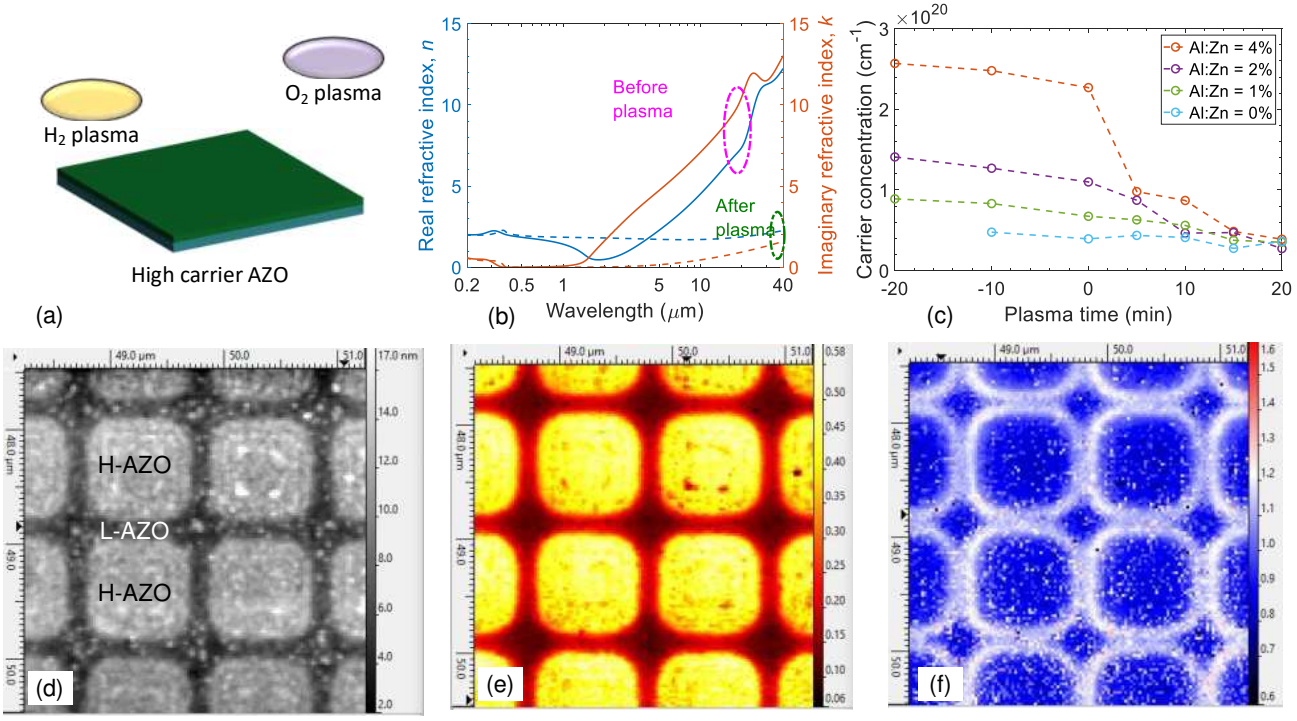

Figure 1 (a) schematic of H_2 and O_2 plasma on AZO film, (b) Ellipsometry extracted refractie index of AZO film before and after O_2 plasma treatment, (c) extracted carrier density of AZO films after different plasma treatments (O_2 plasma as positive and H_2 plasma as negative), (d) schematic of the AZO with features unexposed to O_2 plasma and gap exposed to O_2 plasma, (b) AFM image of the nearfield scanned region, (e) optical magnitude mapping of the AZO arrays and (f) optical phase mapping of the AZO arrays. The wavelength of laser for nearfield measurement is 8 μm.

Abstract: We focus on time-domain topology optimization techniques for the inverse design of materials with arbitrary optical dispersion and anisotropy. This method enables 3D free-form nanostructures with broadband performance. We also present the frequency-domain inverse design of integrated beam splitters with desired phase at the output ports for quantum information processing.

Nanophotonics design is traditionally obtained by direct methods. In direct design, we start from a geometry suggested by prior knowledge or intuition and optimize a set of parameters until a satisfactory performance is achieved. In recent years, inverse design techniques have emerged as promising alternatives to direct design methods. In inverse design, the desired objective is predefined and algorithms based on numerical simulations and optimization methods are developed to find non-intuitive solutions. Topology optimization based on the adjoint method is a powerful technique for nanophotonics inverse design due to its computational efficiency. The method has already enabled devices with superior performance compared to traditional design approaches, along with unlocking new functionalities. Despite the tremendous progress in this field, there are still plenty of opportunities to advance the technique to handle, e.g., advanced optical materials and novel objective functions.

In this talk, I will present our recent works on the use of inverse design methods combined with parallel computing for applications in scattering engineering for broadband field confinement, and integrated nanophotonics. I will focus on the inverse design techniques we developed in-house to optimize media with any arbitrary optical dispersion and anisotropy, where the time-domain nature of the method allows us to achieve broadband performance with one run of the solver [1]. Inspired by the research interest on fundamental limits in electromagnetics, I will also present the inverse design of integrated beam splitters with arbitrary phase [2]. The phase of the signals at the output ports of a beam splitter is responsible, e.g., for the quantum interference between two photons, known as the Hong–Ou–Mandel effect. Therefore, we believe the inverse design of unconventional integrated optical devices may lead to novel experiments in quantum information processing.

Title: Photonics based non-invasive wearable devices for health monitoring.

Prof E.U. Rafailov

Optoelectronics and Biomedical Photonics Group, Aston Institute of Photonic Technologies, Aston University, Birmingham, B4 7ET, UK

Continuous monitoring of human health and activity using wearable devices will be a key technology in the sensor network society for years to come. Recent advances in the development of the miniaturised optoelectronics components with low energy consumption have opened a new perspective for the implementation of non-invasive wearable sensors for health monitoring and personalised medicine. In this paper we will review our recent development of wearable sensors based on Laser Doppler flowmetry and Fluorescence spectroscopy and demonstrate potential applications for such devices.

Meta-optics for multi-dimensional manipulation of light

Crystallization of Induce Optical Vortex by Bessel Beams

Sahil Sahoo and Yuri Gorodetski*
Electrical and Electronic Engineering department,
Ariel University, 407000, Ariel, Israel
* corresponding author: yurig@ariel.ac.il

Abstract

The process of optical vortex formation through interference patterns culminates in the creation of an optical vortex lattice. Our study illustrates the gradual emergence of optical vortices and their crystallization within the array, resulting in the formation of an optical vortex lattice. This phenomenon is exemplified through the implementation of a Bessel beams array on the plasmonic metasurface.

1 Introduction

Optically driven vortex lattices have opened up new and interesting applications in optics. These lattices have a pivotal function in the construction of the pseudo vortex structures in the ultra-cold atomic Bose-einstein condensates gas.[1] Furthermore, they are important in the creation process of photonic crystal fabrication.[2] The generation of these lattices is achieved through beam interference. Researchers have propelled the field forward by employing multi-beam interference techniques. This involves utilizing circularly polarized illumination through the metasurfaces with orthogonal nano-slit pairs, combined with spiral segments, contributing to the generation of optical vortex lattice fields.[3] These fields result from the combination of geometric and dynamic phases, creating intricate lattice patterns.[2,3]

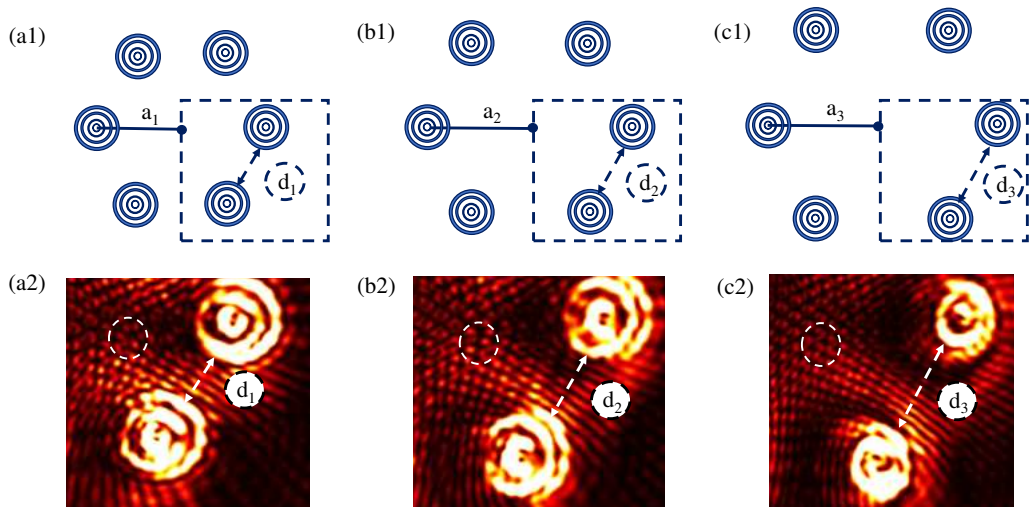

Figure 1: In Figures (a1), (b1), and (c1), we depict the hexagonal arrangement of Bessel beams with hexagonal radii of $8\lambda_{spp}$, $9\lambda_{spp}$, and $11\lambda_{spp}$ respectively. Consequently, the separation distance between the Bessel beams increases, as indicated by $d_1 < d_2 < d_3$. In Figures (a2), (b2), and (c2), we illustrate the evolution of vortices for different array sizes. As the intensity changes, these vortices eventually converge towards the center to form a crystalline structure of vortex lattice.

Advanced techniques, including spin-based plasmonic effects with different geometries, further enhance the formation of optical lattice structures by directing plasmonic waves towards the centre of the geometry, enabling superposition and intricate pattern creation.[4] Plasmonic waves arise from the interaction of an electromagnetic (EM) wave with a metallic subwavelength structure. This interaction entails coupling EM waves with confined electronic oscillations which are known as surface plasmon polaritons (SPPs). The near-field intensity distribution of SPPs is influenced by the polarization state of the incident beam. By designing a plasmonic cavity with a polarization-dependent geometric phase, a plasmonic vortex Bessel beam can be produced.[5] We have demonstrated how the core region of a hexagonal array of Bessel beams at each corner may exhibit intricate interference patterns caused by plasmonic waves. The emergence of an optical vortex lattice is governed by the intrinsic topological characteristics of this configuration and the modifications made to the hexagonal array size. The interference of plasmonic waves leads to the formation of vortices, and as the array size increases, these vortices appear to merge successively, ultimately forming the complete lattice of vortices as shown in Figure 1. The gradual formation of the vortex lattice mirrors offering an intriguing analogy to crystallization process. While researchers have studied vortices crystallization in the rotation of atomic-molecular Bose-Einstein by thermal quenching,[6,7] there is still a knowledge gap concerning the formation of vortex crystals through plasmonic wave interference, which we are studying by gradually increasing the array size. The sequential addition of vortices suggests that the vortex formation occurs during interference, however, it appears that changing the array size causes the initially generated vortices to move toward more stable energy state. Eventually, the energy reaches a point of maximum stability, culminating in the formation of a vortex crystal. Moreover, the vortex lattice demonstrates remarkable topological stability, it appears to be able to preserve its structure regardless of disturbances such as the blocking of a single Bessel beam from the array. This shows the lattice exhibits remarkable topological stability, making it resilient to the disturbance.

Magnetoelectric effect in magnetic toroidal metal HoAgGe

A. Kirikoshi[1*] and S. Hayami[1]

[1]Department of Physics, Hokkaido University, Japan
[*]corresponding author: ak3@phys.sci.hokudai.ac.jp

Abstract: We theoretically study the magnetic states in HoAgGe. The two distinct ordered phases accompany the magnetic toroidal moment with a finite magnetic ordering wave vector. We construct a tight-binding model and discuss the differences in magnetoelectric effects under these phases based on the microscopic electronic degrees of freedom.

In a geometrically frustrated spin system, exotic magnetic phases such as a quantum spin liquid and a spin ice state are expected. In recent years, it has been reported that the two distinct kagome spin ice states are realized in the rare-earth compound HoAgGe at low temperatures, and its transport property has been investigated [1,2]. Meanwhile, the concept of augmented multipoles has been developed, and the complex magnetic structure can be classified by the multipole degrees of freedom [3,4]. In terms of the site-cluster type multipoles, the kagome spin ice states in HoAgGe are the ferri/antiferrotoroidal ordered phases with magnetic ordering wave vector (1/3,1/3,0). Since both spatial inversion and time-reversal symmetry are broken in the magnetic toroidal order, cross-correlated responses such as the linear magnetoelectric effect are expected, as found in the antiferromagnetic metal $UNiB_4$ with a ferrotoroidal moment [5,6]. However, the difference between the response phenomena and transport properties in the ferrotoroidal order and those in the toroidal ordered phase with a finite magnetic ordering wave vector has yet to be fully clarified.

Our research aims to show the differences in response phenomena and transport properties between these ordered phases. To achieve this, we have constructed a minimal tight-binding model consisting of multiorbital on a nine-sublattice distorted kagome structure. We found that different spin ice-ordered phases are characterized by the distribution of local imaginary orbital hybridization between orbitals with different parities, which can be examined through the magnitude of the magnetoelectric effect at each site. We will also discuss the contribution of electron hopping and lattice distortion to the magnetoelectric effect.

Ultrafast Switching of Magnetization using Chiral Optical Phonons

Abstract: Using chiral optical phonons that are driven at resonance within a paramagnetic substrate, we demonstrate that magnetization can be non-locally switched in a magnetic overlayer. This application of the ultrafast Barnett effect offers a novel and potentially universal pathway for the ultrafast switching of magnetization.

Very recently, a series of pioneering experiments have revealed how ultrafast photo-induced demagnetization transfers angular momentum from the spins to the lattice via the Einstein-de Haas effect [1]-[2]. Here, we explore whether the ultrafast Barnett effect – by which mechanical rotations create magnetization [3] - can reciprocally channel angular momentum from rotating lattice vibrations to spins (Fig. 1a). Using ultrashort optical pulses delivered by the free-electron-laser facility FELIX [4], we coherently excite optical phonons at resonance in a paramagnetic substrate (Fig. 1b). Importantly, the optical pulses are circularly-polarized, thus enabling specific optical phonons to become similarly circularly-polarized. The orbital angular momentum of the phonons give rise to a magnetization $\mathbf{M}_{BE}$, pointing either parallel or antiparallel to the substrate's normal. This then switches the magnetization in the nearby magnetic GdFeCo nanolayer.

Typical results proving the feasibility of this switching approach are shown in Fig. 1c. In our experiments, we sweep 3.3-ps-long circularly-polarized pulses, with central wavelength $\lambda = 21$ μm, across the multilayered stack. Using magneto-optical imaging in equilibrium, we assess the impact on the magnetic domains of GdFeCo mounted on a sapphire substrate. We clearly see, depending on the combination of initial magnetic polarity and optical helicity, the switching (or lack thereof) of switched magnetization. By adjusting the duration of the pulses, we are able to distinguish this effect from exchange-driven switching of magnetization observed previously [5].

By tuning the central wavelength of the pumping pulses, we identify that the switching efficiency scales with the strength of the transverse optical phonons found in the sapphire substrate (Fig. 1d). Additional measurements of the same GdFeCo mounted on a fused-silica substrate reveals a different spectral dependence of switching efficiency, that again correlates with the transverse optical phonons in the fused-silica substrate. A control measurement, repeated for the same magnetic overlayer mounted instead on silicon, showed no helicity-dependent switching. The latter is explained by the lack of infrared-active optical phonons present in silicon.

We therefore conclude that we have discovered the ultrafast Barnett effect [6], which can be used to switch magnetization non-locally using coherent lattice vibrations excited within an underlying substrate. Our results represent a breakthrough that could potentially be used to switch magnetic order on a universal scale, since rotational vibrations of ions are found in a multitude of paramagnetic substrates.

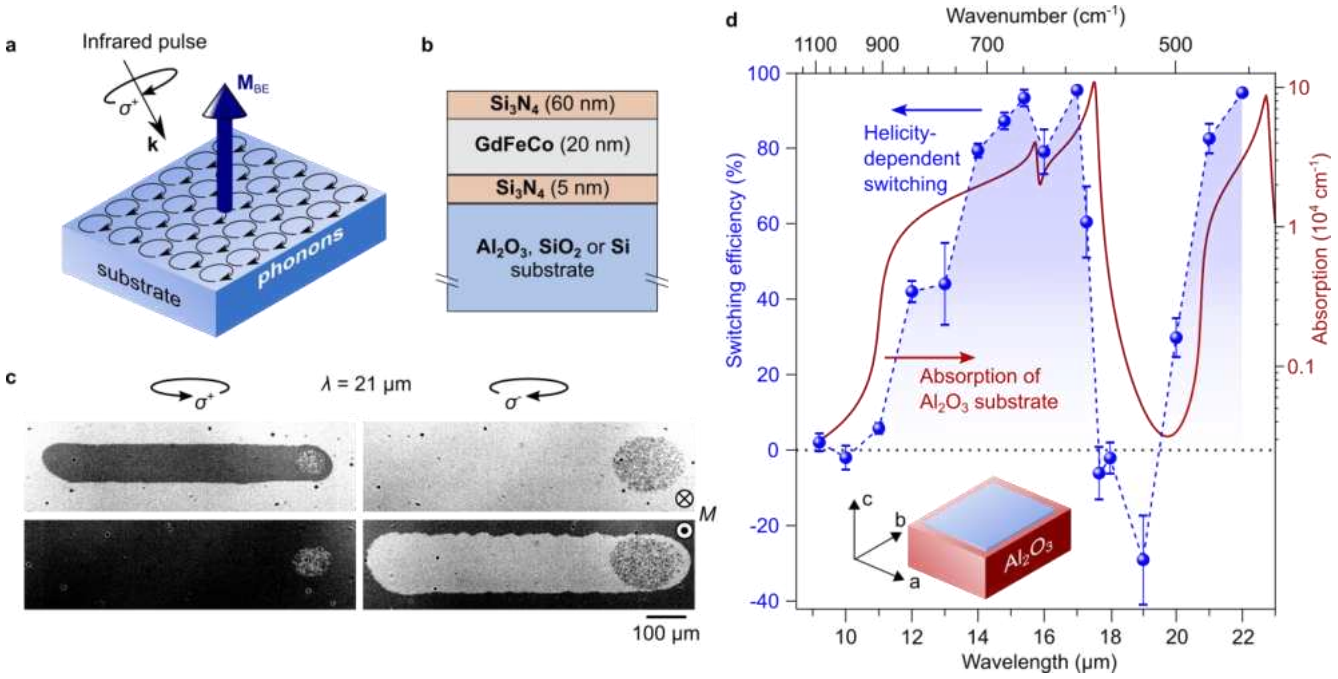

Figure I a Sketch of how circularly-polarized phonons vibrating in a paramagnetic substrate, coherently excited at resonance by circularly-polarized light with helicity $\sigma^{\pm}$, give rise to a magnetization $\mathbf{M}_{BE}$. **b** nanolayer structure used in our experiments. **c** Magneto-optical images of GdFeCo, mounted on a sapphire substrate, taken before and after exposure to circularly-polarized pulses (wavelength λ = 21 μm, duration τ ~3.3 ps) that are scanned from left to right. **d** Spectral dependence of the efficiency of helicity-dependent switching (blue dashed line) and the population of transverse optical phonons in the substrate (red solid line).

Abstract: We realize the Wilson fermions (WFs) in momentum space with electrical circuits and find the structure of WFs manifest as topological spin textures analogous to the half skyrmion, half-skyrmion pair, and Néel skyrmion structures, depending on their mass. We further confirm their topological features in lattice space.

The Wilson fermion (WF) is a fundamental particle in the theory of quantum chromodynamics. Theoretical calculations have shown that the WF with a half skyrmion profile represents a quantum anomalous semimetal phase supporting a chiral edge current, but the experimental evidence is still lacking. We experimentally observed WFs in circuit systems. In addition, we mapped WFs with different masses or configurations to magnetic solitons with different skyrmion charges, which will enable us to study the properties of skyrmions, half skyrmions, and half-skyrmion pairs in electrical circuit platforms. We showed that the nontrivial spin-texture of WFs in momentum space is fully characterized by Chern numbers and winding number in 2D and 3D systems, respectively. The chiral edge current associated with the QASM state dictated by a fractional Chern number was directly detected. Our work presents the first circuit realization of WFs, which sets a paradigm for other platforms, such as cold atoms, photonic, and phononic metamaterials, to further explore these fascinating phenomena.

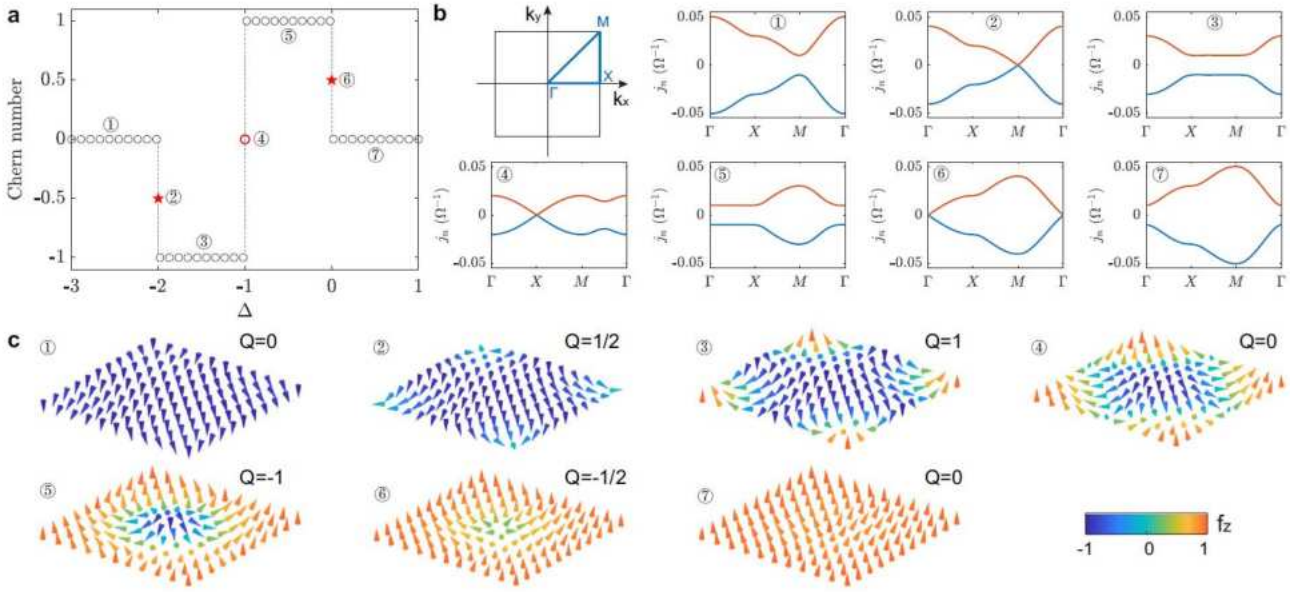

Figure 1 Topological indexes and Wilson fermions. **a**, The Chern number C steps as a function of the dispersionless mass Δ. The red stars and circle represent C=±1/2 and C= 0, corresponding to quantum anomalous semimetal and normal semimetal phases, respectively. **b**, The first Brillouin zone and the typical band structures for Δ = -2.5, -2, -1.5, 0, -0.5, 0, 0.5 respectively, corresponding to different parameter intervals in (a). Abstract: We propose a way to quantitatively evaluate chirality in terms of the electric toroidal monopole, a time-reversal-even pseudo(parity-odd) scalar at the quantum-mechanical level. Applying the method to a twisted chiral methane molecule, we analyze the important model parameter for chirality beyond the symmetry analysis.

Chirality ubiquitously appears in condensed matter physics, chemistry, biochemistry, and so on. In terms of symmetry, a chiral object has neither spatial inversion symmetry nor mirror symmetry, while the time-reversal symmetry is preserved [1]. Barron defined the chirality as a "time-reversal-even pseudoscalar" object from the symmetry point of view [2]. Owing to the lack of the spatial inversion and mirror symmetries, the chiral object exhibits various chirality-induced phenomena, such as chirality-induced spin selectivity [3] and non-degenerate phonon excitations [4]. Nevertheless, the quantitative analysis has not been fully established because of the lack of the microscopic description. Thus, it remains unclear what microscopic key ingredients are important to induce the above chirality-induced phenomena.

Recently, the symmetry-adapted multipole basis (SAMB) has been established, which enables us to express arbitrary electronic degrees of freedom in the physical Hilbert space by a linear combination of four types of multipole basis with distinct spatial inversion and time-reversal parities [5, 6, 7]: electric, magnetic, magnetic toroidal, and electric toroidal multipoles. In the framework of the SAMB, the chirality is microscopically described by the electric toroidal monopole (ETM) [8]. We propose such an ETM as a quantitative indicator of the chirality at the quantum mechanical level [9]. We demonstrate our scenario in the simplest situation by exemplifying the achiral methane molecule model. First, we construct an effective tight-binding model based on the SAMB with the use of a symmetry-adapted Wannier method (SymClosestWannier [10]). Then, we consider a symmetry lowering of the methane molecule by twisting the hydrogen atoms around a two-fold rotational axis so that the molecular object acquires the chiral property. We clarify that the expectation values of the ETM become nonzero when the methane molecule is twisted. Furthermore, we clarify that the handedness of chirality corresponds to the sign of the expectation value of the ETM. We also show that the modulation of spin-dependent imaginary hopping between the hydrogen atoms is essential, while the relativistic spin-orbit coupling in the carbon atom has less effect on chirality.

Abstract: We expand the scope of conventional double-zero-index media by introducing non-reciprocity and experimentally realizing gyromagnetic double-zero-index metamaterials (GDZIMs). A homogeneous GDZIM slab displays an ultra-robust reflection phase vortex, unaffected by slab thickness adjustments. This discovery reveals a novel mechanism for generating robust optical spatiotemporal vortices by breaking time-reversal symmetry.

Electromagnetic zero-refractive-index (ZRI) media are an exemplary family of extreme parameter metamaterials, which exhibit extraordinary optical properties and have wide-ranging applications in wave manipulation and nonlinear optics. In this family of metamaterials, a special member is the media with both zero permittivity and permeability, $\epsilon = \mu = 0$, known as double-zero-index metamaterials (DZIMs). DZIMs are unique in that they not only present a ZRI but also show a conical band intersection at the double-zero-index frequency. This property unlocks a myriad of exclusive optical characteristics and functionalities, such as universal impedance matching and perfect transmission on-chip ZRI materials with ultralow loss, ZRI bound states in the continuum, and large-area single-mode lasing.

While an ordinary DZIM requires its scalar permittivity and permeability to be zero, our work show that by introducing non-reciprocity, the realm of ZRI metamaterials can be substantially expanded. In this work, we experimentally realize, for the first time, such a generalized DZIM, called gyromagnetic double-zero-index metamaterials (GDZIMs) and a nonzero gyromagnetic permeability tensor $\overleftrightarrow{\mu} = \begin{pmatrix} \mu_r & i\alpha \\ -i\alpha & \mu_r \end{pmatrix}$ with a determinant of zero $\det(\overleftrightarrow{\mu}) = \mu_r^2 - \alpha^2 = 0$. We theoretically and experimentally reveal that the GDZIMs not only carry the prominent features of conventional DZIMs, but also gain exotic nonreciprocal characteristics that allow us to observe new wave phenomena in ZRI photonics. In particular, we found that the GDZIMs can be realized by a photonic crystal composed of ferrite rods in the presence of an external magnetic field. By tuning the parameters of the photonic crystal to attain an accidental twofold Dirac cone degeneracy at the center of the Brillouin zone (as opposed to the triple Dirac-like cone degeneracy in ordinary DZIMs), we have observed that the effective permittivity and the determinant of the effective permeability of the homogenized medium both approach zero at the Dirac-point frequency ω_D, whereas the components of the permeability tensor maintain finite values.

The GDZIMs inherit the capability as usual DZIMs to match impedance with any medium, but they differ from the traditional DZIMs by virtue of the nonreciprocity that arises from the breaking of time reversal symmetry. The nonreciprocal nature of GDZIMs is primarily manifested in their extraordinary property of reflection and transmission. At the Dirac-point frequency ω_D, the impedance-matching guarantees that normally incident waves upon a GDZIM slab are perfectly transmitted, while the nonreciprocity causes the reflection phase of oblique incidence waves to be asymmetric about the $k_{\parallel} = 0$ axis. Taken together, these two properties result in the deterministic formation of a vortex singularity in the reflection phase of a GDZIM slab, which is fixed at the point of $(\omega, k_{\parallel}) = (\omega_D, 0)$ in the frequency-momentum plane. This further ensures that when a Gaussian pulse

normally impinges upon the slab, the reflected pulse carries a spatiotemporal (ST) vortex.

Optical ST vortices, which carry transverse orbital angular momentum (OAM), have attracted considerable attention due to their potential applications in optical tweezers, superresolution imaging, and optical information processing. The GDZIM offers a novel approach to generate ST vortices. Compared to other methods of synthesizing ST vortices, such as using a customized spatial light modulator, the current approach stems from the intrinsic Dirac cone band topology of a homogenous GDZIM and boasts exceptional robustness in that the central frequency of the generated spatiotemporal vortices is independent of both the thickness of the GDZIM slab and the refractive index of the background medium.

In summary, by constructing topological metamaterials at the critical transition point of photonic Chern insulator phases, we have experimentally materialized GDZIMs. Such materials represent a conceptual advancement over conventional DZIMs by integrating nonreciprocal and tensor-valued constitutive indices of null determinants. The realization of GDZIMs not only lays the foundation for achieving highly functional devices, such as unidirectional ZRI waveguides and scalable chiral single-mode lasers. It also builds a bridge that connects ZRI photonics, topological photonics, and singular optics, shedding new light on each domain and paving the way for unexplored interdisciplinary research directions.

Control of Circularly Polarized Light Using Electron Beam

T. Sannomiya[1*]

[1]Tokyo Institute of Technology, Japan
[*]corresponding author: sannomiya.t.aa@m.titech.ac.jp

Abstract: This study explores novel approaches to control circular polarization using electron beam excitation. Scanning transmission electron microscopy based cathodoluminescence technique reveals possibilities of circularly polarization light control by electron beam. The demonstrations include manipulating polarization in symmetric structures such as spherical nanoantennas and circular holes in a metal film.

Circular polarization of light is typically controlled using structures with geometric chirality. However, by breaking the symmetry of the entire observation system, including excitation and detection, "chiral" responses can also be obtained from achiral structures. We here demonstrate the control of circular polarization generation using fast electrons even from structures considered to be perfectly symmetric (without chirality), such as spheres or circular holes.[1,2] For the sphere, the circular polarization of light can be controlled by the phase difference between two orthogonal electric dipoles excited within the sphere by the fast electron beam.[1] This phase difference can be controlled by appropriately selecting the excitation position of the electron beam on the sphere, thus breaking the geometric symmetry of the system. In other words, the irradiation (excitation) position of the electron beam enables control of the rotation direction of the electric dipoles, i.e., the selection of right-handed or left-handed circular polarizations. Such achiral antennas allow obtaining equivalent responses of right-handed and left-handed circular polarization from a single antenna, and the ultra-fast switching by electron beams proves to be advantageous.

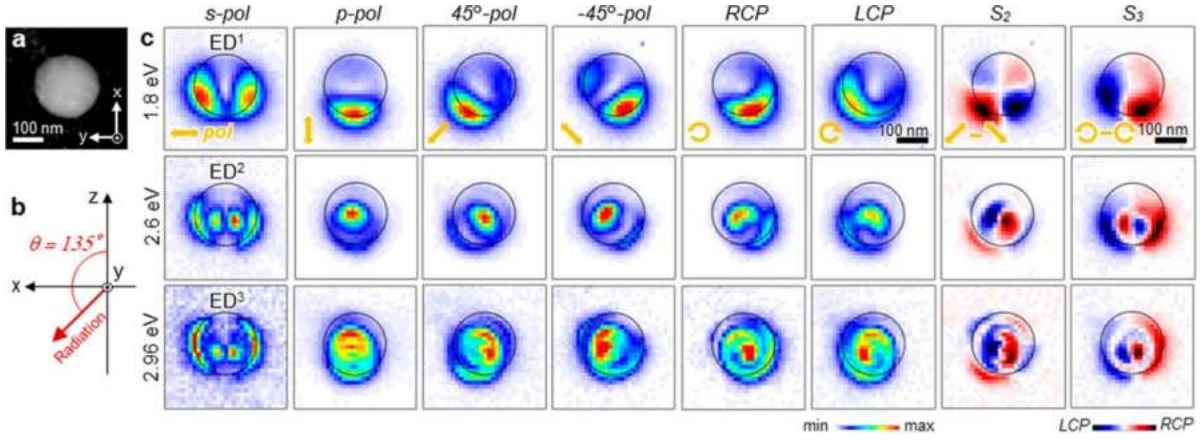

Figure 1. Circularly polarized light emission from a 250 nm Si sphere. [1] (a) STEM dark-field image of the probed Si nanosphere with a diameter of 250 nm (same particle as in Figure 2c). (b) Schematic illustration of the cathodoluminescence detection configuration. (c) Cathodoluminescence (CL) maps with different polarizations as well as representative Stokes maps at different energies. The CL signal is integrated over photon energy within a ± 0.1 eV interval at a detection angle θ = 135°. The edge of the Si nanosphere is indicated by black circles.

In addition to spheres, control of circular polarization in metallic films with circular apertures possessing surface plasmon polaritons (SPPs) — another achiral structure — is achievable using electron beam excitation via a different mechanism.[2] In this case, circular polarization is controlled by the interference of transition radiation (TR) emitted as high-speed electrons pass through the metallic film and the scattered waves from the apertures mediated by surface plasmon polaritons (SPPs).[3] When the electron beam is irradiated away from the aperture, SPPs are excited simultaneously with TR, propagating and exciting local modes of the metallic aperture to scatter light. As all processes of scattering via TR and SPPs are coherent, TR and scattered waves interfere. The polarization and phase difference of these waves can be controlled by the excitation position of the electron beam and the distance between the holes.

This presentation discusses these two approaches of circular polarization generation. The experiments are conducted using a scanning transmission electron microscope (STEM) to detect electron-beam-excited luminescence (cathodoluminescence, CL). An acceleration voltage of 80 kV and a current of 1 nA are utilized, forming an electron probe of approximately 1 nm. This STEM-CL instrument allows angle-resolved spectrum acquisition at each electron beam position. By scanning the electron beam, 4D data sets consisting of 1D angle, 1D wavelength, and 2D space are obtained, which allows analyzing interference of light from multiple coherent emission sources. To fully evaluate the polarization, Stokes parameters are calculated from polarimetric light measurements of six different polarizations.

Classifying Topology in Open Photonic Systems

A. Cerjan[1*]

[1]Center for Integrated Nanotechnologies, Sandia National Laboratories, Albuquerque, New Mexico 87185, USA
[*]corresponding author: awcerja@sandia.gov

Abstract: We develop a mathematical framework for determining the topology and associated measure of protection for photonic structures embedded in free space. This framework is both applicable to 2D systems with radiative environments along their edges, as well as 2.5D slab systems that radiate into free space from their surfaces.

Photonic topological insulators exhibit bulk-boundary correspondence, which requires that boundary-localized states appear at the interface formed between topologically distinct insulating materials. However, many topological photonic devices share a boundary with free space, either on their sides or their surfaces, which raises a subtle but critical problem as free space is gapless for photons above the light line. Thus, traditional definitions of topological invariants cannot be rigorously applied – in the absence of a global bulk bandgap common to all of the materials in the system, there is no clear definition of topological protection, nor can one calculate invariants based on integrating over completely occupied bands. Here, we use a local theory of topological materials to resolve bulk-boundary correspondence in heterostructures containing gapless materials and in radiative environments. In particular, we construct the heterostructure's spectral localizer, a composite operator based on the system's real-space description that provides a local marker for the system's topology and a corresponding local measure of its topological protection; both quantities are independent of the material's bulk band gap (or lack thereof). Using this framework, we demonstrate how to rigorously classify topology both in photonic systems whose edges are surrounded by air, as well as photonic crystal slabs whose surfaces radiate into the surrounding free space environment. Moreover, we show that approximating radiative outcoupling as material absorption overestimates a heterostructure's topological protection.

Chiral and non-chiral magnetic texturing in antiferromagnetic Cr_2O_3

O. V. Pylypovskyi[1*]

[1]Helmholtz-Zentrum Dresden-Rossendorf e.V., Institute of Ion Beam Physics and Materials Research, 01328 Dresden, Germany
[*]corresponding author: o.pylypovskyi@hzdr.de

Abstract: The spontaneous appearance of magnetic textures in the easy-axis antiferromagnets can be related to the grain boundaries and crystal interfaces. Here, we discuss the properties of domain walls in thin films and the surface-symmetry-driven Dzyaloshinskii-Moriya interaction using Cr_2O_3 as the case study.

The physics of antiferromagnetic (AFM) materials offers unique features for fundamental research and applications because of their reach material properties, high eigenfrequencies and robustness to external magnetic fields [1-3]. Challenging access to their magnetic state is facilitated by the development of surface-sensitive techniques, which include magnetotransport [4,5], magnetic circular dichroism [6], Nitrogen vacancy (NV) magnetometry [7,8] and others. The AFM Cr_2O_3 (chromia) with the easy axis of magnetic anisotropy and four spins in the unit cell is a special example of a room temperature magnetoelectric medium [2,9]. While the Dzyaloshinskii-Moriya interaction (DMI) is symmetry-allowed in bulk chromia, it links two AFM vectors and vanishes in the collinear ground state. This enables a search for chiral properties of chromia at textures and interfaces.

In contrast to the single crystals [8], the thin-film chromia samples usually possess the multidomain magnetic state associated with their granular structure, leading to the domain wall pinning. In particular, the NV magnetometry reveals the complex maze-like AFM domain pattern over large areas, which spontaneously appears during (zero) field-cooling procedure and can be quantified by means of the Minkovsky-Boulingand fractal dimension d_c. We model the grain boundaries by the modification of exchange bonds and anisotropy as a Gaussian distribution with the given mean and standard deviation σ. While the spatial variation of anisotropy has a very low influence on the magnetic texture, the experimentally observed d_c is reproduced when the average inter-grain exchange coupling is about 10-15% of its bulk value J_0. The standard deviation influences the distribution of domains by size, allowing us to conclude that for the samples under investigation $\sigma \gtrsim 0.2J_0$ which includes a small portion of ferromagnetic coupling between grains. We found that the domain walls mainly follow the grain boundaries, possessing a narrow width determined by the inter-grain coupling parameters, in contrast to the domain walls in single crystals, where it is determined by the competition between exchange and anisotropies [10].

The surface properties of AFMs are often interpolated from the behavior of their bulk, which may hide a broad range of phenomena. The magnetic symmetry group $\bar{3}'m'$ of bulk chromia determines two high-symmetry and thermodynamically stable crystallographic cuts with the in-plane easy axis of anisotropy, which renders them nominally compensated ones. These so-called *m*- and *a*-plane cuts have the magnetic symmetries of m' and 2, respectively. Therefore, both allow out-of-plane magnetic moment [11]. A change of the magnetic symmetry group from the sample's interior to the surface can be a reason for the change in magnetic ordering. Namely, the m' group allows the canted ferrimagnetic state, while for the *a* plane the rotation axis makes two pairs of magnetic

sublattices independent of each other. This is revealed in the surface-symmetry-driven DMI, which enables terms linking the magnetization and the Neel vector in the surface energy density [12].

The density functional theory (DFT) analysis of *m* and *a* planes shows that the minimal energy configuration corresponds to the canted spin state, with the canting angle to be about $0.5°$. The canting direction is determined by the Neel vector and is opposite for these surface cuts for the same bulk magnetic ordering. The specific feature of the *m*-plane cut is that the magnetic sublattices become inequivalent as in ferrimagnet and there is an additional uncompensated magnetization along the *c* axis of chromia. The theoretically predicted behavior of *m* and *a* planes is confirmed by magnetotransport measurements [12].

To summarize, while there is no clear evidence of chiral magnetic textures in bulk Cr_2O_3, the picture can be substantially different at the interfaces. The grain boundaries act as the strong pinning sites for the domain walls in chromia thin films. This leads to the complex maze-like domain patterns and stimulates further research of granular AFMs to determine the properties of these domain walls. The properties of single crystal boundaries depend on their magnetic symmetry. Certain symmetries, available at the nominally compensated chromia surfaces, enable the Dzyaloshinskii-Moria interaction and lead to the dependence of the surface magnetization on the antiferromagnetic order parameter. The emergent chiral properties of the crystal defects in AFMs open a possibility to explore the defect-driven physics and utilize it for spintronic applications.

Planar resonant metasurfaces with 3D intrinsic chirality

Zi-Lan Deng*, Meng-Xia Hu, Xin Li, Qian-Mei Deng, Feng-Jun Li, Xiangping Li

Abstract: This talk presents our recent studies on the chiral resonant metasurfaces with planar structures embedded in an asymmetric environment, 3D intrinsic chirality could be achieved with simultaneous tunable quality factor and emission circular dichroism, enabling new possibilities for circularly polarized light sources, chiral molecule detection, and chiral nonlinear optics.

Chirality refers to the property of an object that cannot coincide with its mirror image after rotation or translation. The study of chiral properties is significant in multiple disciplines. Particularly in the field of optics, the interaction between light and certain chiral geometric structures can stimulate chiroptical response that is manifested by the amplitude or phase differences between left-handed circular polarization (LCP) and right-handed circular polarization (RCP). On the other hand, resonant metasurfaces with high quality factor (Q factor), possessing excellent capabilities for strong light-matter interactions, have been extensively applied in cutting-edge areas like light emission(*1*), sensing(*2*), nonlinear optics(*3*), and quantum optics(*4*).

Recently, resonant metasurfaces with bound state of continuum (BIC) have been exploited to boost the optical chirality to its maximum(*5, 6*). Usually, three-dimensional (3D) geometries with broken symmetries in both in-plane and out-of-plane are required to achieve the 3D intrinsic optical chirality without polarization conversion under normal incidence. However, the precise manufacturing of such 3D chiral nano-structures are usually challenging, and existing technologies lack flexibility in adjusting chirality and Q factors simultaneously. Here, we introduce an effective strategy to achieve 3D intrinsic optical chirality by merely planarized structures using all-dielectric BIC metasurfaces. This structure, by design, breaks in-plane symmetry to achieve 3D intrinsic chirality within a planar structure in an asymmetric environment. Additionally, it allows flexible tuning of its chirality in terms of the degree of circular polarization and Q factors.

It is worth mentioning that this structure exhibits extremely high chiral emission capability. The circular dichroism of emission (CD) reaches unitary, suggesting that when the chiral metasurfaces is combined with active materials, various strong chiral emission devices with pure circular polarization generation could be constructed. This discovery opens new possibilities for applications requiring ultra-high Q factors and precise chirality control, such as circularly polarized light sources, chiral molecule detection, and chiral nonlinear optics.

In summary, our research paves a new path for controlling chirality and optimizing Q factors in the field of optics, expanding the application scope of optical metasurfaces.

Key words: metasurface, chirality, bound state in the continuum

Abstract: With photonic spin-orbit interactions, efficient generation of ultra-compact optical vortices (OVs) in meta-devices are reported, which have a minimum radius of 1 μm and a signal-to-noise ratio larger than 6 dB. A spin-selective and phase-resolved scanning near-field optical microscopy (SSPR-SNOM) is established to probe and visualize the OV generation process.

The mutual interplay between different angular momenta of light, i.e., the so-called photonic spin-orbit interaction (SOI), has attracted much attention in recent years. Nanoscale optical vortices (OVs) carrying orbital angular momenta can be generated via photonic SOI in nanostructures and have important applications in many emerging fields such as quantum communication and optical manipulations.

In this talk, we first report our recent advances in the efficient generation of ultra-compact optical vortices (OVs) in meta-devices, including a geometric-phase metasurface and an achiral plasmonic annular nanoaperture (PAN).[1, 2] Especially, the PAN is shown to be the simplest nanostructure to generate the most compact OV with a radius down to only 1 μm and possesses a signal-to-noise ratio larger than 6 dB. With this method, the generation of a 3×3 OV array within a small area of 6×6 μm^2 is demonstrated experimentally. Then, we establish and employ a spin-selective and phase-resolved scanning near-field optical microscope (SNOM) to super-resolution image the photonic SOI and OV generation process in the spin basis. The dynamic evolution of the wavefront of the generated OV is directly probed from the near field to the intermediate field and to the far field with subwavelength resolution, which intuitively reveals the SOI process. The findings provide a simple and effective solution for large-scale, low-cost OV beam generation and offer a powerful tool for experimental exploration of the nanoscale photonic SOI.

Abstract: We demonstrate the fabrication of chiral structured materials by utilizing structured light possessing orbital angular momentum (OAM), that is an optical vortex. Such chiral structures pave the way towards a myriad of innovative technologies: for instance, an optical vortex induced self-written helical fiber acts as a mode-convertor for OAM states.

Structured light with an orbital angular momentum (OAM), that is an optical vortex and its related family, possesses a ring-shaped spatial intensity profile arising from its helical wavefront with an on-axis phase singularity [1,2]. In recent years, it has been discovered that the OAM of optical vortex twists the irradiated materials, such as metals, semiconductors, polymers, and even crystals, thus resulting in the fabrication of nano/micro-scale chiral structured materials [3,4]. Optical vortex induced chiral structures will open the way towards exotic chiral engineered materials with physical properties beyond natural materials. Such chiral materials have never been fabricated with the illumination of a circular polarized planer light field only with a spin angular momentum (SAM).

In this presentation, we review the demonstration of optical vortex induced chiral structures. Also, we report on the optical vortex induced helical fiber, which enables the mode conversion between Gaussian and optical vortex modes [5,6]. This demonstration will offer advanced OAM communication devices, and it will give us new fundamental insights.

Also, today, beyond conventional optical vortices, particle-like structured light with topologically protected polarization textures, herein referred optical skyrmions [7], have been demonstrated. We also address advanced photo-induced topological engineered materials with optical skyrmions via exotic light matter interactions.

Thermally Induced Dynamics of Magnetic Skyrmions and Their Device Functions

Masahito Mochizuki[1*], Xichao Zhang[1], and Junnosuke Matsuki[2]

[1]Department of Applied Physics, Waseda University, Okubo, Shinjuku-ku, Tokyo 169-8555, Japan

Abstract: Thermally induced dynamics of magnetic topology in magnets has turned out to host rich physical phenomena and device functions, which are subjects to intensive studies in the research of spintronics recently. Here we discuss two phenomena of magnetic skyrmions related with their thermal motion, i.e., the thermoelectric effect with DC-voltage generation and the active-matter like behavior called chiral swimmer, which were revealed in the recent theoretical studies.

We first discuss the heat-electricity conversion with skyrmions in the presence of thermal gradient [1,2]. A confined skyrmion crystal exhibits rotational motion when a radial temperature gradient is present due to an inverse effect of the topological magnon Hall effect [2]. We discuss that this thermally induced rotational motion of skyrmions can be exploited for the DC-voltage generation. A moving skyrmion texture generates a spinmotive force perpendicular to its moving direction. Consequently, the rotational motion of skyrmions confined in a circular disk generates DC electric voltage in the radial direction. The proposed phenomenon can be exploited as spintronic thermoelectric devices to realize the heat-electricity conversion.

(a) Schematics of the thermoelectric effect of magnetic skyrmions (b) Chiral Brownian motion of skyrmions as a source of active-matter-like behaviors.

Then we discuss the active-matter-like behaviors of magnetic skyrmions due to the chiral Brownian motion [3]. Skyrmions as chiral objects show chiral nature in interactions with nanostructures, which can lead to intriguing

phenomena. We discuss that the Brownian dynamics of skyrmions interacting with a chiral flower-like obstacle in a ferromagnet exhibits topology-dependent outcomes, which can be regarded as a spontaneous mesoscopic order-from-disorder phenomenon driven by thermal fluctuations. This phenomenon can be utilized to control the skyrmion position and distribution without any external driving force and can be exploited as a new way to design topology-sorting devices.

Abstract: We show the magneto-optical Kerr effect (MOKE) induced by the skyrmion formation, i.e., topological MOKE, in Gd_2PdSi_3. The magneto-optical rotation is significantly enhanced in the skyrmion phase, which demonstrates the topological MOKE ranging up to the sub-eV region. This finding exemplifies the light-skyrmion interaction arising from the emergent gauge field.

Magnetic skyrmions are nanometric whirlpools of spins, where the directions of the constituent spins wrap the unit sphere [1], attracting enormous attention as potential information carriers in next-generation memory/logic devices. Due to their non-coplanar spin arrangement, the resultant scalar spin chirality gives rise to the fictious magnetic field (emergent magnetic field) acting on the conduction electrons, which leads to unique transport phenomena through the coupling to low-energy quasi-particles, such as the topological Hall effect. However, the high-frequency or optical response of skyrmions has remained elusive so far.

In this presentation, we show the novel magneto-optical effect induced by the gauge field from skyrmion lattice in the centrosymmetric magnet Gd_2PdSi_3 [2,3]. Although it has been long believed that the magneto-optical Kerr effect (MOKE) is proportional to the magnetization, we reveal that the skyrmion lattice phase exhibits the marked enhancement of MOKE. This previously unobserved optical response directly manifests the emergence of the topological MOKE induced by the gauge field generated from skyrmions, which never requires the strong spin-orbit interaction in stark contrast to the conventional magnetization-induced MOKE. The topological MOKE is observed even up to sub-eV region in photon energy, which demonstrates the significant change in electronic structure even far from Fermi level. Such the change is also found to cause the topological Hall effect as a transport response through its accompanying Berry curvature, establishing the comprehensive understanding of the emergent electrodynamics ranging from DC to optical region. Our findings exemplify the existence of strong light-skyrmion interaction mediated by the gauge field in the optical region, potentially enabling the functional operation of skyrmion-based devices integrated with the versatile laser technology.

Abstract: Colloidal gold@silver nanocuboids were illuminated with circularly polarized light during partial galvanic replacement reaction of the silver shell with gold ions. This resulted in a small symmetry breaking manifested through appearance of circular dichroism, in spite of the random rotational averaging of the nanocuboids with respect to the illumination direction.

Illumination of elongated cuboidal gold@silver core-shell nanoparticles with circularly polarized light within the range of their plasmon resonance wavelengths during partial galvanic replacement reaction (GRR) with gold ions resulted in symmetry breaking of their shape and appearance of significant circular dichroism (CD) signals. This chiral symmetry breaking is probably related to asymmetric localized plasmonic “hot-spots” excited at opposite corners of the nanocuboids (NCs), which lead to oxidation and dissolution of surface silver atoms, followed by some silver re-deposition in parallel to deposition of gold atoms at corners of the nanocuboids. The shape changes of the nanocuboids post GRR under circularly polarized light illumination, analyzed by electron microscopy and electron tomography, were different from those occurring through GRR in dark or under linearly polarized light illumination. The slight chiral symmetry breaking occurs in spite of significant averaging of the effect due to the free rotation of the NCs with respect to the illumination direction, as predicted previously by Govorov and coworkers [1]. The effect becomes smaller in more symmetric geometrical shapes of silver nanoparticles such as triangular nanoprisms and nanocubes, down to zero CD in spherical Au@Ag nanoparticles, as predicted theoretically.

Abstract: Superradiance is a phenomenon of multiple facets that occurs in classical and quantum physics under the extreme conditions. A notion of supermirror made of energy-source powered medium with an inverted spectrum is proposed. Supermirrors resemble the Hawking radiation or the Dicke superradiance. The principle is demonstrated for spin waves.

Wave amplification is an important subject in wave physics. In wave applications, an indispensable component is to amplify a wave which will surely decay or attenuate during its propagation and transportation. Some waves have many efficient and effective ways of amplification. For example, electromagnetic waves in the visible light range can be amplified by the gain medium with population inversion. However, spin wave amplification is still an unsolved problem in magnonics.

Spin waves, the collective excitations of strongly correlated spins, have attracted much attention in the spintronic community due to their rich physics [1-3] and potential applications [4-7]. One challenge in spin-wave based applications is the strong spin wave damping such that it can only propagate a relatively short distance, order of millimeters even for the lowest known damping material of yttrium iron garnet [8,9]. Thus, an effective method for amplifying an arbitrary spin wave is demanded in order to realize the power of spin waves.

Many efforts have been made on spin wave amplification. The anti-damping nature of current-induced Slonczewski spin transfer torque (STT) [10-13] and spin orbit torque [14-16] was considered first. A straightforward analysis of the Landau-Lifshitz-Gilbert (LLG) equation suggests that STTs can exponentially amplify all spin waves. Unfortunately, experiments and micromagnetic simulations observed only the increase of spin wave propagation distance in a proper current, but no spin wave amplification despite many attempts [10-16]. People have also used parametric pumping to amplify spin waves. The idea is to resonate spin waves with external oscillating fields such as an electromagnetic or mechanic wave [18-23]. At resonance, energy from external fields can be transformed into the energy of a spin wave. However, parametric pumping requires specific resonant conditions that are only applicable to a particular wave frequency. The Klein paradox [24,25] has been proposed to amplify spin waves. The concept involves using STT to create a spin wave analogue of black and white holes [25] such that positive-energy and negative-energy spin wave modes can be coupled together in an inhomogeneous FM film. Experimental evidence of this proposal is yet to be provided. Nonlinear 3-magnon and 4-magnon process have also been proposed to amplify spin waves and to create spin wave combs [26]. This approach often requires stringent conditions and for a specific mode.

Reflection and refraction are general wave phenomena occurring at the interface of two homogeneous media. A general rule is that the intensities of both reflected and refracted waves are smaller than the in-coming

wave intensity due to the energy conservation law. A wave in normal media has a normal spectrum whose long wave frequency (energy) is a local minimum (at zero wave number) such that the group and phase velocities are in the same directions (for isotropic media). Under certain circumstances, the spectrum minimum could be away from zero wave number. The group and phase velocities in certain frequency window could be in the opposite directions. We term it as a pumped medium and corresponding spectrum to be inverted because it can only occur with an external energy source. In this talk, I will present a notion of super-mirrors which manifests superradiances under an easily realized condition. We show that an interface separating a normal medium from a pumped medium. The wave frequency in the normal medium increases with the wavenumber and is minimal at zero wavenumber while the wave frequency in the pumped medium is minimal at a negative wavenumber. There is a frequency window in which the phase velocity and group velocity are opposite. To demonstrate the working principle for spin waves, we show that the interface of a current-free (normal) ferromagnet (FM) and a current-flow (pumped) FM is such a supermirror. Surprisingly and interestingly, the reflection coefficient of a wave at the interface between a normal medium and a pumped medium can be greater than 1. The super-reflection is the consequence of current-induced spectrum inversion where spin wave hase and group velocities are in the opposite directions. The physics is that incident spin wave is refracted and activates a backward propagating spin wave inside pumped FM region. The refracted spin wave re-enter the normal FM region to constructively interfere with the reflected wave. It appears that the pumped FM region coherently emits reflected waves, leading to a super-reflection. The process resembles superradiance of a spinning black hole through the Hawking radiation, or the Dicke superradiance of cavity photons inside population inverted media. The physics is clearly revealed in a generic FM model and is confirmed by micromagnetic simulations.

Algebra of Optical Phase Dislocations

Gorodetski Yuri*
Electrical and Electronic Engineering department,
Ariel University, 407000, Ariel, Israel
* corresponding author: yurig@ariel.ac.il

Abstract

We demonstrate that by combining a physical lattice dislocation with the Berry phase dislocation in one structure the manipulation with the topological charge of the emerging vortex beams can be controlled in an intriguing way. As a result, the plasmonic field in the near-field can be modified and selectively excited.

1 Introduction

The study of physical nature of electromagnetic fields often involves topological concepts and mathematical tools that are equivalently suitable for crystal lattice, especially when the dislocation is an object of investigation. Crystal lattice structures exhibit topological defects as line dislocations, disrupting atomic arrangements and affecting material properties.[1] The topological parameter defining the dislocation "strength" - the Burgers vector, has a global effect on a stress distribution in the material.[2] In analogy with solids, a dislocation in a diffractive optical element or a photonic crystal leads to phase singularities in electromagnetic fields. Around the phase singularity the wavefront forms a helical surface of the

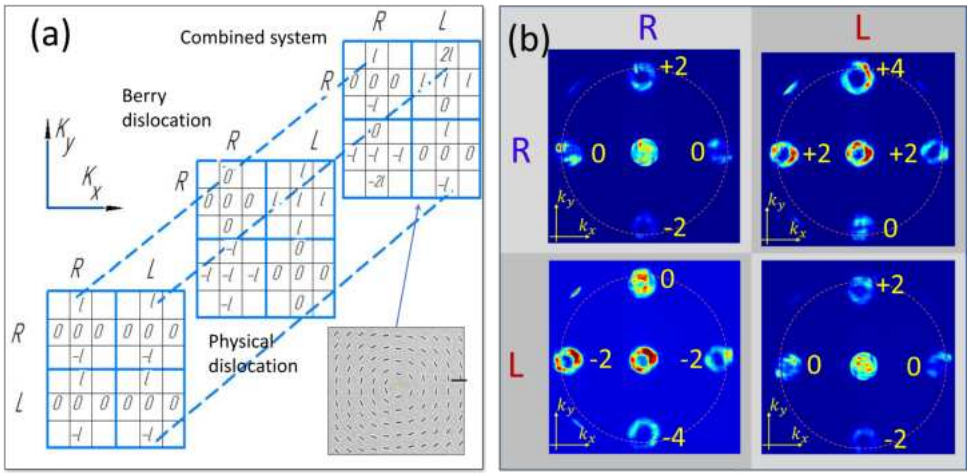

Figure 1: Algebra of dislocations. (a) – dislocation summation rules. Inset shows the combined structure with $l = 2$. The scale bar length is 1 μm. (b) – k - space patterns for all the possible combinations of the polarization states.

form $E \propto \exp(il\varphi)$ (with φ being an azimuthal angle), resulting in a phase shift of $l \times 2\pi$ upon circumvention. Such a wavefront dislocation – an optical vortex – is a unique phenomenon in optical fields widely investigated due to its intriguing topological properties, and a variety of technological applications. The singularity itself is a point of phase discontinuity where the modulus of the complex field

amplitude E vanishes.[3] Optical vortices are characterized by a topological charge - l denoting orbital angular momentum (OAM) per photon in units of $\overline{h}$.[4]

Regular optical waves containing a single screw dislocation or an array of dislocations were experimentally generated using diverse techniques. These methods included transmission or diffraction of laser beams from specially synthesized holographic phase masks, liquid crystal optics and helical transmission phase plates. Phase defects became evident in laser light scattered by a random phase diffuser or transmitted through a multi-mode fiber.[5] The experimental observation of optical vortices has been reported in the oscillation of ring cavities that housed a photo-refractive crystal as a gain medium, as well as in a linear cavity featuring a photo refractive phase-reversal mirror.[6] Recently, the phenomenon of the geometric Pancharatnam-Berry phase (PBPh) has attracted much interest as a means of manipulating the optical field in a polarization dependent manner.[7] The effect has been induced by a local manipulation with the field polarization, that leaded to a distinctive phase of circular states. In the following years the PBPh-based systems have been implemented in surface plasmons (SP) to excite polarization-dependent and unidirectional distributions in the near-field and in the far-field.[8] Moreover, it has been shown that the geometric phase could be algebraically added to the dynamic phase cused by the plasmon propagation and result in strongly asymmetric polarization-based behaviour. In particular, we have shown that in a periodic bi-structure comprising of periodically rotated nanoslits arranged in a square or hexagonal array the plasmon acquires a combined momentum addition due to the grating periodicity and the nanoslit rotation.[9]

In this work we examine the concept of "algebra of optical dislocations". We form a plasmonic structure with physical (fork-type) dislocation and a structure inducing helical Berry phase. We demonstrate the effects of these two types of dislocations alone and finally combine them into one system. The experimental investigation of these combined structures reveals a polarization and position-dependent vortex formation in the k-space. We derive the summation rules for the two types of the optical dislocations and verify them experimentally. The combined system extends the ability to control light matter interaction in the nanoscale and suggests a novel degree of freedom in nanophotonics and optics communication.

Peltier effect of phonons driven by electromagnetic waves

Hiroaki Ishizuka[1,*] **and Masahiro Sato**[2]

[1]Tokyo Institute of Technology, Japan
[2]Chiba University, Japan
[*]corresponding author: ishizuka@phys.titech.ac.jp

Abstract: We show that a phenomenon analogous to the Peltier effect occurs by phonon photocurrent in a material subject to a linearly polarized light. We derive a general formula for the nonlinear Peltier coefficient. An order-of-magnitude estimate using this theory predicts an experimentally observable energy current using available THz-infrared light sources.

In semiconductors, a steady electric current in material causes a temperature gradient, a phenomenon known as Peltier effect [Fig. 1(a)]. As the Peltier effect is caused by the energy carried by carriers in semiconductors, an analogous phenomenon can occur by a flow of other quasi-particles, such as magnons and phonons. A possible route to realize the Peltier effect of magnons and phonons is to use a nonlinear response. For instance, optical generation of spin current by controlling magnon [1-3] and spinon [4] flows using a nonlinear response similar to the bulk photovoltaic effect has been proposed recently. As magnons and spinons also carry energy, a flow of magnons and other low-energy excitations may induce a phenomenon similar to the Peltier effect. Among various candidates, phonons might be an interesting candidate for the optical control of heat flow, as the thermal properties of insulators are often dominated by phonons.

In this work, we show that a Peltier effect analog of phonons occurs in a material subject to linearly polarized light [5] [Fig. 1(b)]. Under light illumination, an energy current of phonons occurs through a nonlinear optical effect, similarly to the bulk photovoltaic effect [6]. We formulate the generic formula for the nonlinear Peltier coefficient of this nonlinear energy current carried by phonons using nonlinear response theory. Using the general formula, we show that the photogalvanic energy current occurs only in a non-centrosymmetric system with two or more optical phonon bands (three or more bands, including the acoustic mode). This is in contrast to the bulk photovoltaic effect and the nonlinear spin current, which occurs in two band models. We also find that the nonlinear Peltier effect is related to the shift vector of phonons, similar to that of shift current [7]. However, reflecting the difference in mechanism, the nonlinear Peltier effect is related to the position of a single phonon

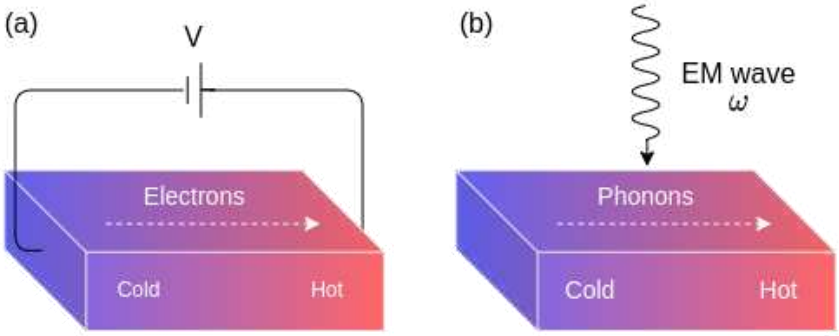

Fig. 1: Schematics of (a) the Peltier effect and (b) nonlinear Peltier effect of phonons.

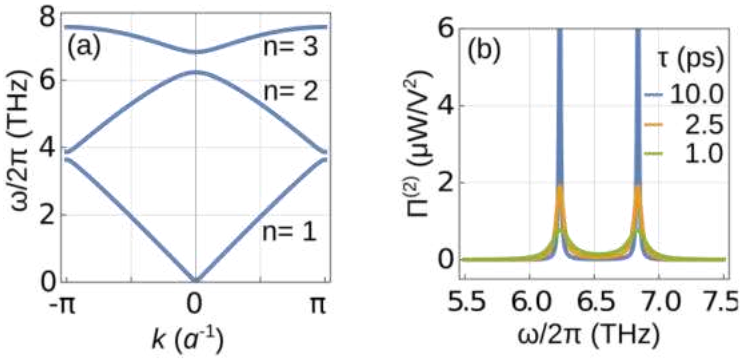

Fig. 2: Nonlinear Peltier effect of phonons in a simple three-band model. (a) The phonon dispersion of three sublattice model, and (b) the calculated nonlinear Peltier coefficient.

excited during the rectification process, whereas the shift current is related to the difference of valence and conduction electrons.

We demonstrate the generation of the photogalvanic energy current using a one-dimensional ion chain with three ions in a unit cell (Fig. 2), which predicts the generation of an experimentally observable energy current using THz-infrared light sources with $E \sim 10^5$ V/m. Recently, thermal imaging techniques have enabled spatial resolution of temperature in small devices [8]. As the nonlinear Peltier effect induces a temperature gradient in an isolated device, it should be observable using the thermal imaging method.

Abstract: We show to coherently control both the spatial and temporal characteristics of laser beams by using a Fourier space-time shaper based on an axicon grating to disperse the frequencies of a pulsed beam into colinear rings which are then individually tailored with an azimuthal phase via a digital modulator.

We present a novel approach to tailor the OAM dependence of the spectrum of a pulsed laser to generate space-time wave packets that exhibit a unique spiralling trajectory through space-time. Our technique leverages a Fourier space-time shaper, innovatively designed around an axicon grating with circular geometry. This design choice is instrumental in mirroring the cylindrical symmetry inherent in vortex beams, enabling the separation of frequencies into co-linear radial rings that can be independently modulated with an azimuthal phase.
We demonstrate unprecedented control over the properties of the wave packet.

Orbital angular momentum of magnons in confined magnetodielectrics

E. O. Kamenetskii

School of Electrical and Computer Engineering, Ben Gurion University of the Negev, Israel

Corresponding author: kmntsk@bgu.ac.il

Abstract: Can magnon excitations have both spin and orbital angular momentum (OAM)? Whereas a single spin flip of magnon is $S = \pm\hbar$, the OAM L of such a magnon is unknown. An analysis of quantum confinement of magnetostatic magnons observed in a quasi-2D ferrite disk shows that an OAM in such a sample is a half-integer internal angular momentum related to a circulating flow of energy. Unique properties of quantum atmosphere in a vacuum vicinity zone of a ferrite disk are associated with symmetry broken patterns and magnetoelectric characteristics.

==========

Can magnon excitations have both spin and orbital angular momentum (OAM)? This question arises for more than a century, since the experiments of Einstein and de Hass [1] and the measurements of Barnett [2]. Whereas a single spin flip of magnon is $S = \pm\hbar$, the OAM L of such a magnon is unknown. Since the total angular momentum $J = S + L$ should be conserved, magnons in a confined magnetodielectric will be sensitive to external fields. In recent studies [3], quantum confinement of magnons has been observed in a quasi-2D ferrite disk placed inside a microwave structure. An analysis shows that an OAM of magnetostatic modes in a ferrite disk is a half-integer internal angular momentum related to a circulating flow of energy. The effect is associated with magnetoelectric characteristics. The symmetry broken patterns are observed by unique properties of quantum atmosphere in a vacuum vicinity zone of a ferrite disk. It is worth noting that we are talking about pseudoangular OAM. While the conservation of angular momentum follows from invariance under rotations of all the constituents of a solid, the conservation of pseudoangular momentum follows from invariance under rotations of fields while keeping the solid fixed [4].

Exploring Strategies for Enhancing the Sensitivity of Chiroptical Spectroscopy with Aluminum Nanoplasmonics

B.M. Reinhard[1]

[1]Department of Chemistry and The Photonics Center, Boston University, Boston, MA 02215, United States

*corresponding author: bmr@bu.edu

Abstract: A scalable nanofabrication strategy for the generation of chiral or achiral aluminum nanoantennas that support plasmon resonances in the UV is evaluated, and design criteria for UV-resonant surfaces that enhance the sensitivity of molecular circular dichroism (CD) spectroscopy are discussed.

Circular dichroism (CD) is a spectroscopy that allows a rapid structural characterization of biomolecules and pharmaceutic compounds. It is of particular interest as an assay to characterize the chirality of molecules in solution or embedded in thin films. Fundamentally, the CD signal is determined by the difference in absorption of a sample under left and right circularly polarized light (r/l-CPL), $\Delta A = A_{\text{l-cpl}} - A_{\text{r-cpl}}$. The absorption rate for any molecule under l/r-CPL excitation is:[1,2]

$$A_{\text{l-CPL/r-CPL}} = \frac{\omega}{2}\alpha''|\mathbf{E}|^2 + \frac{\omega}{2}\mu_0^2\chi''|\mathbf{H}|^2 \pm \frac{\omega}{c^2\varepsilon_0}G''\text{Im}(\mathbf{E}^* \cdot \mathbf{H}) \quad (1)$$

In this expression α'', χ'', and G'' define the imaginary parts of the electric polarizability, the magnetic susceptibility and the chiral polarizability of the target molecule. The first two terms do not depend on the chirality of the molecule and do not contribute to the molecular CD signal, which only depends on the third G''-containing term.

As chiral light-matter interactions are generally weak, CD spectroscopy requires high concentrations and long acquisition times, and there is significant interest in implementing strategies that can boost molecular CD signals. G'' is a molecular constant that cannot be enhanced, so that the $\text{Im}(\mathbf{E}^* \cdot \mathbf{H})$ factor, which is directly related to the optical chirality density,[1,3,4] remains as only parameter to increase the difference in absorption rate for r/l-CPL according to equation 1. Enhancing CD through increased optical chirality density requires correct alignment of electric and magnetic fields in the UV for most molecules of interest. Another mechanism that can potentially enhance molecular CD signals is based on chirality transfer, which generates a chiral response at the plasmon resonance when chiral molecules are in contact with a plasmonic antenna.[5,6] In the case of conventional, discrete plasmonic antennas made of gold or silver, the weak overlap between plasmonic and molecular resonances is one factor that limits chirality transfer.

Plasmonic nanostructures fabricated from gold or silver provide strong electromagnetic field localization throughout the visible and into the near-infrared, which has been exploited for enhancing light-matter interactions and boosting signal intensities in surface-enhanced spectroscopies. Surface enhanced Raman spectroscopy (SERS) is one prominent example.[7] Conventional gold and silver nanostructures face, however, significant challenges to increase the sensitivity of molecular CD spectroscopy, especially, for those molecules whose resonances lie in the UV (which is the case for most biomolecules of interest). Aluminum nanostructures can support plasmon resonances in the UV spectral range,[8–10] and are thus of potential interest as building blocks for antennas that enhance the sensitivity of molecular CD spectroscopy. In this presentation, design criteria of plasmonic antennas that can increase the sensitivity of CD spectroscopy through enhanced optical chirality density[11] or chirality transfer[5] are outlined and evaluated.

A second challenge in addition to the design of appropriate antennas that can increase CD sensitivity in the UV is the need for a scalable fabrication of the antennas, ideally on a scale that makes them compatible with widely available CD spectrometers. In this presentation, a scalable nanofabrication strategy will be introduced that allows the fabrication of extended random arrays of aluminum nanoparticles with tunable plasmon resonances throughout the wavelength range between 180 – 500 nm. The fabrication strategy provides access to both chiral and achiral aluminum nanostructures depending on the details of the fabrication. The aluminum nanoparticle arrays, and their spectral response will be characterized and first applications to increase the sensitivity of molecular CD spectroscopy will be presented and discussed.

A Scalar Product for Computing Fundamental Quantities in Matter

I. Fernandez-Corbaton[1] **and Maxim Vavilin**[2]

[1]Karlsruhe Institute of Technology, Institute of Nanotechnology, Germany
[2]Karlsruhe Institute of Technology, Institute of Theoretical Solid State Physics, Germany
ivan.fernandez-corbaton@kit.edu

Abstract: We introduce a systematic way to obtain expressions for computing the amount of fundamental quantities such as helicity and angular momentum contained in static matter, given its charge and magnetization densities. In an exemplary application, we compute the helicity and angular momentum squared stored in a magnetic Hopfion.

Research in light-matter interactions benefits from theoretical tools whose generality allows one to treat light and matter in similar ways. In classical electrodynamics, light and matter are treated in a rather similar way: As continuous fields such as the electric and magnetic fields $\mathbf{E}(\mathbf{r},t)$ and $\mathbf{B}(\mathbf{r},t)$ representing radiation, and the densities of charge $\rho(\mathbf{r},t)$, current $\mathbf{J}(\mathbf{r},t)$, polarization $\mathbf{P}(\mathbf{r},t)$, and magnetization $\mathbf{M}(\mathbf{r},t)$, representing matter. In the case of the radiation fields, there exists a convenient and general way to compute the amount of fundamental quantities such as linear and angular momentum contained in a given dynamic electromagnetic field [1]. This approach exploits the tools of Hilbert spaces. The quantities are computed "à la Dirac" as sandwiches:

$$\langle f|\Gamma|f\rangle, \tag{1}$$

where $|f\rangle$ is the ket representing the field and Γ the Hermitian operator representing the quantity of interest, e.g. an angular momentum operator. The expression of the scalar product for the free radiation fields, which is used in particular for obtaining explicit expressions from Eq. (1), reads:

$$\langle f|g\rangle = \int_{\mathbb{R}^3} \frac{\mathrm{d}^3\mathbf{k}}{\hbar \mathrm{c}_0|\mathbf{k}|} \begin{bmatrix}\mathbf{F}_+(\mathbf{k})\\ \mathbf{F}_-(\mathbf{k})\end{bmatrix}^\dagger \begin{bmatrix}\mathbf{G}_+(\mathbf{k})\\ \mathbf{G}_-(\mathbf{k})\end{bmatrix}, \tag{2}$$

where $\mathrm{c}_0 = 1/\sqrt{\varepsilon_0\mu_0}$, and the two kets $|f\rangle$ and $g\rangle$ are represented by their plane wave components of well-defined helicity $\lambda = 1$ and $\lambda = -1$, corresponding to left- and right-handed circular polarizations, respectively:

$$\mathbf{F}_\pm(\mathbf{r},t) = \sqrt{\frac{\varepsilon_0}{2}}\left[\mathbf{E}(\mathbf{r},t) \pm \mathrm{i}\mathrm{c}_0\mathbf{B}(\mathbf{r},t)\right] = \int_{\mathbb{R}^3} \frac{\mathrm{d}^3\mathbf{k}}{\sqrt{(2\pi)^3}}\, \mathbf{F}_\lambda(\mathbf{k}) \exp(\mathrm{i}\mathbf{k}\cdot\mathbf{r} - \mathrm{i}\mathrm{c}_0|\mathbf{k}|t), \tag{3}$$

with $\mathbf{k}\cdot\mathbf{F}_\lambda(\mathbf{k}) = 0$, and the angular frequency is restricted to positive values $\omega = \mathrm{c}_0|\mathbf{k}| > 0$.

Together, Eq. (1) and Eq. (2) are a general and convenient way of computing the amount of any fundamental quantity in the field. This motivates the following question: *Can this algebraic approach be used for material objects?* The answer is *yes* [3]. The algebraic approach can be extended towards the matter side, resulting in particular in a way to obtain expressions for computing the amount of fundamental quantities contained in static material objects from their *static* charge and magnetization densities, $\rho(\mathbf{r})$ and $\mathbf{M}(\mathbf{r})$, which are assumed to be spatially confined. The expressions are again obtained as

$$\langle \Phi_{\omega=0}|\Gamma|\Phi_{\omega=0}\rangle, \tag{4}$$

where $|\Phi_{\omega=0}\rangle$ represents now the static ($\omega = 0$) charge and magnetization densities of matter, or, equivalently, the following Fourier transforms:

$$\mathbf{M}(\mathbf{k}) = \int_{\mathrm{V}} \frac{\mathrm{d}^3\mathbf{r}}{\sqrt{(2\pi)^3}}\, \mathbf{M}(\mathbf{r}) \exp(-\mathrm{i}\mathbf{k}\cdot\mathbf{r}),\ \mathbf{E}(\mathbf{k}) = \frac{-\mathrm{i}\hat{\mathbf{k}}}{\varepsilon_0|\mathbf{k}|} \int_{\mathrm{V}} \frac{\mathrm{d}^3\mathbf{r}}{\sqrt{(2\pi)^3}}\, \rho(\mathbf{r}) \exp(-\mathrm{i}\mathbf{k}\cdot\mathbf{r}), \tag{5}$$

where V is the finite volume occupied by $\rho(\mathbf{r})$ and $\mathbf{M}(\mathbf{r})$, and the definition of $\mathbf{E}(\mathbf{k})$ follows from $\nabla\cdot\mathbf{E}(\mathbf{r}) = \rho(\mathbf{r})/\varepsilon_0$. Crucially, the appropriate scalar product can be written as:

$$\langle\Phi^1_{\omega=0}|\Phi^2_{\omega=0}\rangle = \int_{\mathbb{R}^3} \frac{\mathrm{d}^3\mathbf{k}}{\hbar c_0|\mathbf{k}|} \begin{bmatrix} \sqrt{\varepsilon_0}\,\mathbf{E}^1(\mathbf{k}) \\ \sqrt{\mu_0}\,\mathbf{M}^1(\mathbf{k}) \end{bmatrix}^\dagger \begin{bmatrix} \sqrt{\varepsilon_0}\,\mathbf{E}^2(\mathbf{k}) \\ \sqrt{\mu_0}\,\mathbf{M}^2(\mathbf{k}) \end{bmatrix}. \tag{6}$$

The defining property of the scalar product in Eq. (2) is that it is conformally invariant [6]. That is, the value of $\langle f|g\rangle$ is identical to the scalar product between $\mathrm{X}|f\rangle$ and $\mathrm{X}|g\rangle$, for any transformation X in the 15-parameter conformal group in 3+1 Minkowski spacetime. Such group is the largest group of invariance of Maxwell equations *including sources as spacetime densities when these have the appropriate transformation properties*. After removing the transformations that do not preserve the static $\omega = 0$ condition, the remaining transformations also form a group: The 10-parameter conformal group in three-dimensional Euclidean space. The expression in Eq. (6) is invariant under such group.

In particular, with $\rho(\mathbf{r})$ and $\mathbf{M}(\mathbf{r})$ at hand, the expression in Eq. (6) allows explicit numerical computations of $\langle\Phi|\Gamma|\Phi\rangle$ for any Γ. Table 1 contains the values for the helicity and angular momentum squared stored in a magnetic Hopfion. A magnetic Hopfion is a twisted configuration of magnetization that can be hosted by some chiral magnetic materials [5]. The charge density $\rho(\mathbf{r})$ is ignored in this exemplary application.

$\langle\mathrm{M}\|\Lambda\|\mathrm{M}\rangle$	$\langle\mathrm{M}\|\mathrm{J}^2\|\mathrm{M}\rangle$
-129.1 $\hbar$	$1.30\times10^3\ \hbar^2$

Table 1: Helicity Λ, and angular momentum squared J^2 stored in a magnetic Hopfion. An analytical approximation to the magnetization $\mathbf{M}(\mathbf{r})$ of the Hopfion in a chiral FeGe magnet of cylindrical shape [5] was used in the calculations.

In the case of the Hopfion, the value of its helicity, equal to -129.1$\hbar$, implies a lower bound for the number of circularly polarized photons that would be needed in a helicity-dependent all optical switching of the Hopfion onto its mirror image of opposite helicity: $\lceil 129.1\times 2\rceil = 259$. Additionally, -129.1$\hbar$ also bounds the helicity that can be radiated by the Hopfion as it loses its chirality, for example by the action of a large magnetic bias aligning its magnetization density vector along the same direction at all points.

Off-resonance Spin-locked Metasurfaces based on Quasi-Bound States in the Continuum and Nonreciprocal Chiral Splitters

Abstract: We demonstrate off-resonance spin-locked metasurfaces inspired by quasi-bound states in the continuum, to achieve hybridized analog computing in two domains. High-quality resonance is excited in a broadband spin-locked scattering spectrum, providing frequency fliting in meta-splitters and meta-deflectors. We also discuss how nonreciprocal chiral splitting can be controlled in gyromagnetic metasufaces.

Given the merits of robust resonance and high quality (Q) factor, the bound state in the continuum (BIC) is attracting growing interest and experiencing a research upsurge in metasurfaces studies. Due to its high-Q characteristic at resonance, symmetry-protected BIC becomes an alternative approach widely used for high-Q metasurfaces in practice. While the twofold rotational symmetry (C2) of the structure is destroyed, the bound state leaks and true BICs will gradually transform into quasi-BIC status.

We propose and demonstrate a class of quasi-BIC assisted off-resonance metasurfaces that combine high-Q resonance and phase-modulation together [1]. The structure of the meta-atoms is evolved from symmetric split-ring (SSR) by engineering two asymmetric degrees, the radian of the semi-ring and the radius of the added ring, so that the C2 symmetry is broken. A single resonance model based on CMT is developed to analyze the high-Q resonance in a broadband spin-locked spectrum in ASR with symmetry-protected BIC, which has high robustness against circularly polarized scattering interference from environment. A phase-only resonance of linear polarization leads to a high-Q resonance of circular polarization with broadband helicity-preserving. PB phase is introduced to achieve broadband beam splitting and deflection with the phase modulation over the full 2π range. Then, we have proposed the concept of hybridized analog computing based on such off-resonance metasurfaces. Scalar multiplication in frequency spectrum and convolution in angular spectrum have been realized simultaneously by designer quasi-BIC assisted meta-splitter and quasi-BIC assisted meta-deflector.

Next, we study the nonreciprocal coupling effect between the resonant modes in absorbers and discover a chiral absorption behavior under asymmetric phase coupling [2]. A coupled-mode theory is established to quantitatively analyze the inherent nonreciprocal chiro-optical effects. Theoretical calculation on gyromagnetic metasurfaces points out that nonreciprocal coupling between inherent resonant modes cannot offer linear dichroism in reflection, yet is capable of providing circular dichroism. When the coupling strengths are tuned to opposite phases and equal amplitudes, an ideal perfect absorption of one circular polarization can be reached.

Broadband non-reciprocal transmission via a low-biased gyromagnetic metasurface will be further discussed. A triple-stacked structure broadens the isolation bandwidth utilizing multiple dipole resonances where the metallic disks act as photonic dopants, enhancing the slab's gyromagnetic and gyroelectric responses. The sign of gyromagnetic activity flips at two chiral modes, and the equivalent switching of the external biased revealed. Microwave measurement demonstrates that the bandwidth for an isolation ratio exceeding 10 dB is over 3 GHz. The broadband nonreciprocal performance maintains relatively stable, exhibiting strong robustness

against the bias disturbance.

Detecting the symmetry breaking of the quantum vacuum in a QED system

Tiefu Li[1*]

[1]School of Integrated Circuits, Tsinghua University, China
[*]corresponding author: litf@tsinghua.edu.cn

Abstract: In ultrastrong coupling regime, a qubit–resonator system has an entangled quantum vacuum with a nonzero average photon number. We experimentally observe the vacuum by the induced symmetry breaking of a dispersively coupled probe qubit. This result opens a way to experimentally explore the novel quantum-vacuum effects.

Hybrid quantum systems in the ultrastrong, and even more in the deep-strong, coupling regimes can exhibit exotic physical phenomena and promise new applications in quantum technologies. In these nonperturbative regimes, a qubit–resonator system has an entangled quantum vacuum with a nonzero average photon number in the resonator, where the photons are virtual and cannot be directly detected. The vacuum field, however, can induce the symmetry breaking of a dispersively coupled probe qubit. We experimentally observe this Higgs-like quantum-vacuum symmetry breaking induced by the field of a lumped-element superconducting resonator deep-strongly coupled with a flux qubit. The violation of the Xmon parity selection rule comes from virtual paths enabled by its interaction with an electromagnetic resonator whose parity symmetry is significantly broken by the deepstrong light–matter interaction with a flux qubit. The experimental results are in very good agreement with our theoretical analysis. The proposed setting offers a novel way to explore quantum-vacuum effects emerging in the light–matter ultra-strong and deep-strong coupling regimes and can be used as a tool to explore the coherence properties of quantum vacua in this exotic hybrid quantum system, and the occurrence of superradiant phase transitions in Dicke-like systems.

Abstract: Magneto-optical interactions in transparent materials are generally weak, making the devices bulky. Here, we discuss the design of a Si metasurface placed on a magneto-optical thin film. A 45° nonreciprocal polarization rotation at 1.5 μm was achieved by loading a 140-nm-thick Si metasurface on a 513-nm-thick Bi:YIG membrane.

Magneto-optical (MO) interactions in the optical regime are of technological importance for diverse applications including optical data communications. However, MO interactions are known to be weak in transparent optical materials, hampering downsizing of MO devices. Indeed, a typical Faraday rotator for optical isolation at telecommunication wavelengths has a thickness of ~ 0.3 mm, even using a family of yttrium iron garnets (YIGs), which are known as one of the best transparent MO materials in the optical domain at room temperature. To enhance the MO effects and miniaturizing the Faraday rotator, nanostructuring of YIG will be a promising approach, since it will allow for the use of metasurfaces for enhancing light matter interactions through resonant wave trapping [1]. However, it is widely recognized that nanopatterning of YIG is extremely difficult and has not been succeeded even after many trials over the years. This suggests that enhancing MO effects without nanopatterning of YIG itself will be a key challenge in the realization of ultracompact Faraday rotators [2].

In this talk, we will discuss the design of Si metasurface loaded on a thin YIG membrane [3]. We found a significant enhancement of Faraday rotation under the resonance with guided modes in the Si and YIG layers. A Faraday rotation of 45° was achieved at a wavelength of 1.5 μm by loading a 140-nm-thick Si metasurface on a 513-nm-thick unpatterned YIG membrane.

Figure 1 shows a schematic of the investigated photonic structure. A Si metasurface is placed on a 513-nm-thick Bi:YIG membrane prepared on glass. Magnetic field is vertically applied so that the Bi:YIG layer induces MO Faraday rotation. The metasurface is consisted of a square lattice of air holes in a 140-nm-thick Si slab. There are two air holes in the unit cell as shown in Fig. 1. The shapes of the airholes are slightly elliptic so that quasi-BIC (bound states in the continuum) resonance modes can be excited by vertical optical access. We carefully controlled the ellipticity of the airholes to attain a desired Q factor of the resonance, enabling arbitrary control over the light-matter interaction at the resonance. Moreover, by controlling the thickness of the Bi:YIG layer, the system can support dual resonance in the spectral domain, which induces electromagnetically-induced transparency for high light transmission. Figure 2 shows a resulting spectral response of Faraday rotation and optical transmission. We obtained a 45° polarization rotation at the resonance at 1.5 μm while maintaining 70% light transmittance. The value of polarization rotation is 800 times higher than that attainable in a plane Bi:YIG of the same thickness. Our design can significantly downsize the Faraday rotator and thus is of technological importance.

The details of the design will be discussed in the talk, in which we will also discuss other scenarios to increase MO interactions [4] and our recent effort for mitigating the effect of fabrication imperfections of MO metasurfaces as a Faraday rotator [5] and for enhancing MO interactions in photonic nanostructures.

Manifestation of crystal chirality in quasiparticles

T. Yokoyama[1*]

[1]Tokyo Institute of Technology, Japan

[*]corresponding author: yokoyama@stat.phys.titech.ac.jp

Abstract: I will talk about how crystal chirality is manifested in quasiparticles: Bogoliubov quasiparticles in superconductors and magnons in ferromagnets in the presence of chiral crystal structures.

We propose a mechanism of spin current generation under an external electric field due to chiral phonons in a chiral-structure superconductor based on the Bogoliubov de Gennes and the Boltzmann equations. We show that the spin current carried by quasiparticles flows along the screw axis and shows a quadratic dependence on the electric field at the low-field range, leading to a nonreciprocal spin transport. The spin current also shows a nonmonotonic temperature dependence and has a maximum at around the superconducting transition temperature.

We also investigate magnons in ferromagnets with chiral structures. The chirality of the crystal is manifested in orbital angular momentum of magnons. We discuss possible experimental setup to verify our predictions.

Pseudomagnetic fields in photonic crystals with synthetic strain: Observation of Landau levels and chiral edge states

R. Barczyk[1], L. Kuipers[2], and E. Verhagen[1*]

[1]Center for Nanophotonics, AMOLF, Amsterdam, The Netherlands
[2]Kavli Institute of Nanoscience, Delft University of Technology, Delft, The Netherlands
[*]corresponding author: verhagen@amolf.nl

Abstract: We experimentally demonstrate pseudomagnetic fields in photonic crystals with engineered synthetic strain, and investigate the resulting photonic Landau-levels and novel guided chiral edge states. This offers a design paradigm for optical confinement, radiation, and light-matter interaction.

Drawing inspiration from condensed matter physics has proven to be a rich resource for the emulation of topological phenomena in the photonic domain. It provides an especially interesting design paradigm for photonic crystals, which offer a versatile platform for control over on-chip routing and confinement of light, out-of-plane emission, and enhanced light-matter interactions. In contrast to electronic systems, photonic crystals allow for tailoring each unit cell individually, yielding enormous control over the properties of the states they host, and in particular over topological light confinement.

It is known for graphene that inhomogeneous *strain* of the crystal lattice can induce strong pseudomagnetic fields that lift the Dirac-point degeneracies and create discrete, highly degenerate Landau levels, analogous to those in quantum Hall systems subject to strong magnetic fields. As this mechanism does not require the breaking of time-reversal symmetry, it has high potential to be applied also to photons, which do not interact with real magnetic fields. It was recently predicted that engineered deformation in two-dimensional photonic crystals with Dirac-like dispersion acts as effective strain, and could generate synthetic pseudomagnetic fields for photons, leading to localization at flat bands, i.e., photonic Landau levels.[1] Realizing such states in photonic crystals is especially appealing because of the potential to enhance light-matter interactions due to high density of states of such flat bands. Moreover, the concept of synthetic strain engineering and pseudomagnetic fields provides a new design paradigm for on-chip photons with tailored spectral and spatial properties.

In this work, we experimentally demonstrate the realization of pseudomagnetic fields in photonic crystals through synthetic strain engineering.[2] We observe photonic Landau levels and characterize their spectral and localization properties. As an illustration of spatial tailoring of pseudomagnetic fields we create interfaces between opposing magnetic fields and observe novel chiral edge states that result.

We fabricate silicon photonic crystal membranes operating at telecom wavelengths with Dirac dispersion. We engineer synthetic strain that varies quadratically in one direction through perturbation of the unit cell (Fig. 1a). We probe the photonic crystal's modes in real- and momentum-space through Fourier spectroscopy. This reveals the formation of photonic Landau levels that are weakly coupled to the radiation continuum through an intentional breaking of unit cell symmetry. The states show characteristic square-root dependence of the mode spacing with the pseudomagnetic field strength (Fig. 1c-d). Interestingly, the Landau levels exhibit remarkably high quality factors. Moreover, we reveal that the states come in degenerate pairs with circular polarization linked to propagation direction, illustrating the relation to photonic spin-orbit coupling. Their localization properties are linked to long-range interactions, illustrating the difference between photonic and electronic

behaviour.

Finally, we fabricate a device that combines two domains of opposite pseudomagnetic field (Fig. 2). In analogy to the quantum Hall effect, domains of opposite magnetic field would have different topological order, meaning that chiral edge states are expected at their interface, connecting the bulk Landau levels.[3] We observe signatures of these novel photonic topological states in far-field spectroscopy (Fig. 2), and characterize their spatial and polarization properties. These states propagate within the radiation continuum, with theoretical quality factors approaching 10^7.

In conclusion, we have experimentally demonstrated synthetic strain engineering to induce pseudomagnetic fields in telecom-frequency photonic crystals. This provides intriguing prospects for the enhancement of light-matter interactions in highly degenerate flat bands, and the topological control of optical localization and radiation at the nanoscale.

Control of high harmonic generation and photo current in graphene by tuning laser polarization and combing two laser fields

Masahiro Sato[1*] **and Minoru Kanega**[1]

[1]Department of Physics, Chiba University, Inage, Chiba, Japan
[*]corresponding author: sato.phys@chiba-u.jp

Abstract: We theoretically study laser-driven high harmonic generation (HHG) and zeroth-order harmonics (photo-induced DC current) in graphene. It is shown that the HHG spectrum and photo current can be controlled by changing the laser polarization and the laser-field trajectory with two laser mixture.

Laser-driven high harmonic generation (HHG) is one of the simplest nonlinear optical response of materials. HHG refers to the optical phenomenon that when we apply an intense laser with frequency ω to a material, a radiated light including several waves with different frequencies $n\omega$ is generated (n is an arbitrary integer) through light-matter interaction [see Fig. 1(a)]. Over the last decade, HHG in solids [1] has been actively studied from both application and fundamental scientific viewpoints. In fact, second-order harmonic generation (SHG) with $n = 2$ has been often used as devices (such as laser pointer) and a probe of the inversion symmetry breaking in crystals. Moreover, the fundamental harmonics with $n = 1$, which corresponds to photo current (light induced rectification of electric current), is the basic optical phenomenon for solar cell [2].

In recent years, we have theoretically studied HHG in quantum many-body systems and developed the microscopic method of analyzing the HHG based on quantum master (GKSL) equation [3]. In this conference, we will report our recent theoretical result about HHG in graphene, honeycomb-lattice electron systems [see Fig. 1(b)] [4]. In particular, we consider what an effective way of controlling the HHG spectra (e.g., the presence or absence of nth-order harmonics generation) in solids is. We show that an application of DC current, tuning the polarization of incident light (from linear to circularly polarization) and use of two-color laser (mixture of two different light waves) provide powerful ways of controlling the HHG.

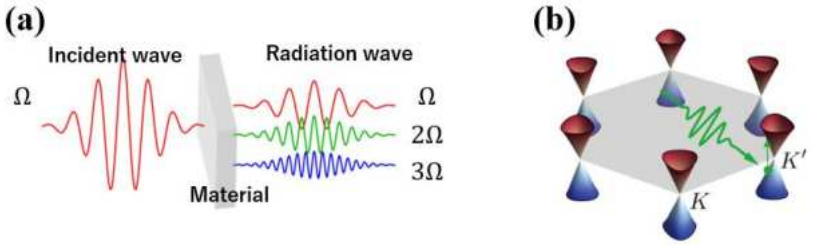

Figure 1: (a) Image of laser-driven HHG in solids. (b) Image of Dirac electron bands and laser irradiation in graphene.

Figure 2 shows the computed HHG spectra generated from laser-driven electric currents along the x and y directions, $J_x(\omega)$ and $J_y(\omega)$, in graphene models with different parameters. One finds from this figure that the spectra are drastically changed by tuning the laser polarization, the magnitude of applied DC current, and the staggered potential. We emphasize that the former two parameters of laser polarization and DC current can be accurately controlled in real experiments.

Figure 3 shows our numerical results of HHG spectra in graphene models under an irradiation of two-color laser, which consists of one laser with frequency Ω_1 and ellipticity ε_1 and another with Ω_2 and ε_2. Here we set $\Omega_2 = 2\Omega_1$ and $\varepsilon_1 = 0$ (± 1) corresponds to linear (circular) polarization. We find that the presence or

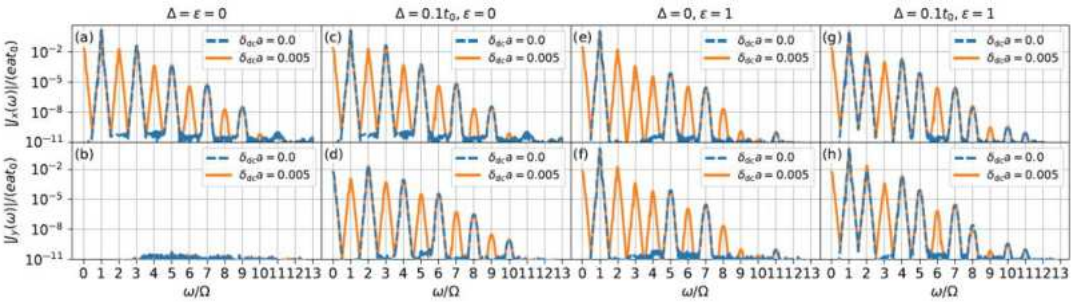

Figure 2: Computed HHG spectra of graphene models irradiated by laser pulses. Upper and lower panels respectively correspond to currents flowing along x and y directions. Parameters Δ, ε, and δ_{dc} are respectively a staggered potential, the ellipticity of laser ($\varepsilon = 0$ and $\varepsilon = 1$ are respectively linearly and circularly polarized lights) and an external DC electric field ($\propto$ external DC current).

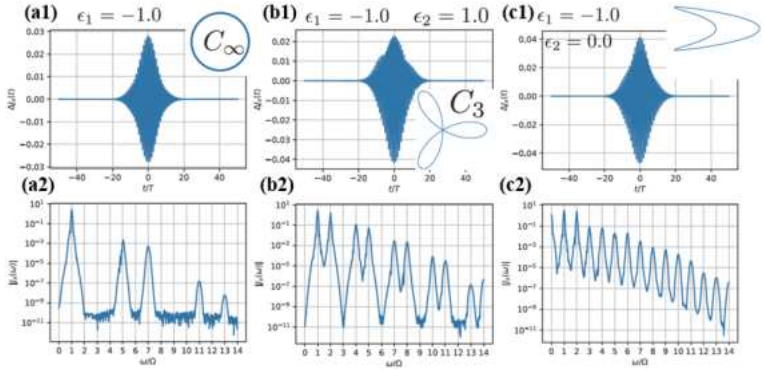

Figure 3: Calculated HHG spectra in graphene under the application of two-color laser. Upper and lower panels are respectively oscillating electric fields of applied laser pulses as a function of time and the corresponding HHG spectra. As a reference, we put the result of a single-color circularly polarized laser ($\varepsilon_1 = -1$) in panel (a). In Panels (b) and (c), the frequency is set to $\Omega_2 = 2\Omega_1$. Diagrams of circle (a1), mitsuba (b1), and boomerang (c1) represent the trajectories of the laser fields.

absence of nth-order harmonics strongly depends on the combination of $(\Omega_1, \varepsilon_1)$ and $(\Omega_2, \varepsilon_2)$. Namely, our result indicates that HHG spectra can be controlled by tuning parameters of two-color laser.

We show that the shapes of HHG spectra in Figs. 2 and 3 are well explained by the argument based on dynamical and static symmetries [3,4]. In addition, the numerical analysis based on the GKSL equation enables us to quantitatively estimate the HHG spectra in a broad parameter regime from a weak laser to an intense laser. In the conference, we would like to report the advantages of our analysis and it's results in more detail.

CP^2 triple-Q state in the SU(3) Kondo lattice model

Yutaka Akagi*

Department of Physics, University of Tokyo, Japan
*corresponding author: yutaka-akagi@g.ecc.u-tokyo.ac.jp

Abstract: This research details the CP^2 triple-Q state in the SU(3) ferromagnetic Kondo lattice model, highlighting its ground state phase diversity and topological magnetism at varying itinerant fermion filling and Kondo coupling strength.

Recent years have seen significant interest in quantum condensates with SU(N) symmetry (N≥3), such as SU(N) Mott insulator (SU(N) magnets), within cold atom frameworks [1,2]. Advances have also been made in the experimental realization of Kondo physics, where itinerant electrons and localized spins interact, using two "orbital" degrees of freedom in alkaline earth metal fermions [3,4]. The feasibility offered by cold atom systems has intensified the focus on SU(N) Kondo lattice systems. So far, their magnetism has been clarified, mainly in one dimension [5].

Ferromagnetic Kondo coupling is a natural occurrence when considering Kondo lattice systems with cold atoms. For instance, in the SU(3) ferromagnetic Kondo lattice model, itinerant fermions with three colors align their magnetic dipoles and quadrupoles with SU(3) localized moments at each lattice site. In this work, we investigate the SU(3) ferromagnetic Kondo lattice model on a triangular lattice, extending methods from Refs. [6, 7] to map out the ground state phase diagram as functions of itinerant fermion filling n (particle number density) and Kondo coupling strength J_K. We have identified that the smallest size CP^2 triple-Q state realizes at n = 1/4 [8], showcasing non-trivial topological magnetism with triple-Q peaks in both magnetic dipole and quadrupole structure factors [9]. Additional discovered phases include a CP^2 three-sublattice state at n = 1/3 and a CP^2 ferromagnetic state within areas of low-carrier density (refer to Ref. [5]). In this talk, we will discuss these phases in detail.

Non-Hermitian Aharonov-Bohm effect under imaginary magnetic fields

Tomoki Ozawa[1*]

[1]Advanced Institute for Materials Research, Tohoku University, Japan
[*] tomoki.ozawa.d8@tohoku.ac.jp

Abstract: We discuss the Aharonov-Bohm effect under imaginary magnetic fields. We find that the Aharonov-Bohm effect appears as amplification and/or decay of the norm of the wavefunction, reflecting the enclosed imaginary flux inside the trajectory we consider. We consider both real and parameter space versions of this non-Hermitian Aharonov-Bohm effect.

Following the recent development of non-Hermitian quantum mechanics, it is now possible to consider the effects of magnetic fields which take imaginary values, i.e. imaginary magnetic fields. As a manifestation of physics of imaginary magnetic fields, we consider how Aharonov-Bohm effect appears under the imaginary magnetic fields.

Aharonov-Bohm effect is the effect where the particle going through two different trajectories acquires a relative phase which is proportional to the magnetic flux enclosed by the two trajectories. Whcn the magnetic field takes an imaginary value, the magnetic flux enclosed by trajectories becomes imaginary. Then the relative phase in the Aharonov-Bohm effect becomes a relative number whose magnitude is different from one. As a result, the wavefunction of a particle going through one path would have its magnitude different from that of a particle going through another path.

We consider this non-Hermitian version of the Aharonov-Bohm effect both in real and parameter spaces. In the real space setup, we consider a two-dimensional lattice model with a perpendicular imaginary magnetic field. By preparing a wavepacket and making it go through a closed trajectory, we see that the norm of the final wavefunction is different from the initial wavefunction, and the difference can be precisely explained by the imaginary Aharonov-Bohm phase factor [1].

In a parameter space, we consider a wavefunction to be in one eigenstate of some non-Hermitian Hamiltonian which depends on a set of parameters. By making the parameter change adiabatically and forming a closed trajectory in the parameter space, we see that the final state wavefunction and the initial state wavefunction have different norms. This difference is again explained by the Aharonov-Bohm phase factor, where the role of the imaginary magnetic field is played by the imaginary Berry curvature [2,3].

Exploring magneto-optical and nonlinear processes using a polarimeter optical spectrum analyzer

Eyal Buks[1]

[1]Technion, Israel
[*]corresponding author: eyal@ee.technion.ac.il

Abstract: Two recently-discovered effects are explored. The first is an unequally spaced optical comb that occurs in a fiber loop operated at low temperatures. The second effect under study is single sideband modulation that is observed in an optical modulator based on a ferrimagnet. Both effects are explored using polarization measurements.

We integrate a coherent optical spectrum analyzer with a rotating quarterwave plate polarimeter. The combined polarimeter optical spectrum analyzer (POSA) allows the extraction of the state of polarization with high spectral resolution. In this work, POSA is used to study two optical systems. The first is an optical modulator based on a ferrimagnetic sphere resonator [1]. We explore the underlying magneto-optical mechanism that breaks time reversal symmetry, and consequently enables modulation having sideband asymmetry. The second system under study is a cryogenic fiber loop laser, which produces an unequally spaced optical comb [2]. Polarization measurements provide insights on the nonlinear processes responsible for comb creation. Characterizations extracted from POSA data provide guidelines for performance optimization of applications based on these systems under study.

Abstract: Metalens imaging suffers from a trade-off between broadband focusing efficiency and operating bandwidth of metalenses. We demonstrate a deep-learning-driven end-to-end image restoration framework to overcome the physical limitations of metalenses. The proposed framework achieves full-color imaging for a mass-produced 10-mm-diameter metalens and provides high image qualities comparable with ground truth images.

Metalenses, ultra-thin film lenses composed of subwavelength structures, have been spotlighted as a technology to overcome the limitations of conventional lenses, such as chromatic aberration, shadowing effect, bulky systems, and high manufacturing costs [1]. Consequently, they have been considered ideal replacements for conventional optical elements in optical sensors, smartphone cameras, unmanned aerial vehicle cameras and AR/VR devices. [1-2] However, recent studies suggest that the metalenses suffer from a fundamental trade-off between broadband focusing efficiency and operating bandwidth. [3-4] As a result, the large-area metalenses at present show chromatic aberration [10] or low focusing efficiency over a wide bandwidth [11-13], which hinders the commercialization of metalens-based compact imaging. In this study, we propose deep-learning-driven end-to-end metalens imaging (referred to as DRMI) to overcome the physical constraints of a mass-produced 10-mm-diameter metalens.

The metalens used in our imaging system is highly efficient but has strong chromatic aberration, which causes different types of image distortion than geometric lenses. The images captured from the metalens (referred to as 'metalens images') exhibit severe position-dependent distortion and high-frequency information loss. To restore the metalens images, we add two functionalities to a baseline image restoration model NAFNet: positional embedding and adversarial learning scheme in frequency domain. The positional embedding is applied to restore the position-dependent distortion of the images. Most image restoration models, including NAFNet, use randomly cropped patches of images for training to reduce computational complexities. However, these cropped patches have no information about the position-dependent distortions of images. Therefore, we embed the positional information of the pixels in the patches using a 1x1 convolution layer. Furthermore, to restore the high-frequency information, we apply the adversarial learning scheme, which comprises an auxiliary network that discriminates Fourier-transformed metalens images and ground truth images. [7-8]

Our results show the ground truth images, the metalens images, and the reconstructed images. The metalens images are severely blurred compared to the ground truth images, with more blur in the outer region than the inner region. On the other hand, the restored images show high image quality comparable with the ground truth images in both inner and outer regions.

Model	Image Quality Metric (Mean/Std)		
	PSNR	SSIM	LPIPS
Metalens Image	14.722/1.328	0.364/0.160	0.788/0.112
MIRNetV2	18.517/1.893	0.586/0.135	0.553/0.098
SFNet	18.231/1.727	0.597/0.129	0.520/0.095
HINet(Local)	21.300/2.333	0.674/0.117	0.449/0.097
NAFNet	21.731/2.382	0.676/0.116	0.436/0.097
DRMI	22.109/2.423	0.691/0.109	0.428/0.096

Table 1. Image quality metrics of DRMI and other image restoration models. (Best)

Table 1 shows quantitative comparisons of image quality metrics between DRMI and other restoration models. DRMI shows the greatest performance compared to those of metalens images.

Consequently, DRMI has significantly enhanced the resolution of metalens imaging systems, suggesting a potential to accelerate the commercialization of ultra-compact and ultra-light imaging systems.

Cavity quantum materials: Virtue photons, Real effects.

Qing-Dong Jiang[1*]

[1]Shanghai Jiao Tong University, China
[*]corresponding author: qingdong.jiang@sjtu.edu.cn

Abstract: A material with symmetry breaking inside can transmit the symmetry breaking to its vicinity by vacuum fluctuations. The vacuum in proximate to a symmetry-broken material is referred as its quantum atmosphere[1]. Here, we show that a symmetry-broken quantum atmosphere can induce a significant modification of the material or molecular properties.

Summary: In recent years quantum optics and quantum materials start to emerge together, leading to the new direction called cavity quantum materials. In this talk, we show that cavity symmetry-broken quantum fluctuations lead to many interesting modifications of the material's properties, such as band structure, topology, and magnetism.

In this paper[2], we propose an entirely new route to select chirality by using quantum fluctuations near parity-symmetry-broken materials. In this paper[3], we propose a new way to achieve flat band in twisted bilayer graphene, an essential issue in the field. In this paper[4], we show that chiral cavity can induce an angular-momentum dependent Lamb shift.

The vacuum in proximate to a symmetry-broken material is referred as its quantum atmosphere[1,2,3]. Using quantum atmosphere to select chirality is efficient yet dramatically different from previous proposals where real fields are needed. We show that parity-symmetry breaking and quantum fluctuations can induce a chirality-dependent shift of the molecular ground-state energy, leading to a chemical reaction process that favors producing one chirality over the other. Besides analytical analysis, we further perform the first-principle calculation to find specific examples, showing that our proposal gives significant chirality selectivity.

Dynamical control of topological solitons in ferroelectrics and dynamical multiferroicity via twisted light

Lingyuan Gao[1], Sergei Prokhorenko[1], Yousra Nahas[1], and Laurent Bellaiche[1*]

[1] Physics Department and Institute for Nanoscience and Engineering, University of Arkansas, Fayetteville, Arkansas, USA
[*]corresponding author: laurent@uark.edu

Abstract: Via the use of first-principle-based atomistic simulations, it is demonstrated that twisted light can induce emergent electrodynamic phenomena in ferroelectric systems. These include: (1) dynamical evolution of topology in ferroelectric skyrmions, (2) effective gyration of dipolar vortex arrays, and (3) orbital magnetic moments of ions and composed magnetic topological textures.

Twisted light carries a nonzero orbital angular momentum (OAM), that can be transferred from light to electrons and particles ranging from nanometers to micrometers. Up to now, the interplay between twisted light with dipolar systems has scarcely been explored, though the latter bear abundant forms of topologies and embrace strong light-matter coupling. Here, using first-principle-based simulations, we show that twisted light can excite and drive dynamical topological polar states with novel features in ferroelectric ultrathin films. For OAM of light equal to 1, a polar skyrmion is successively created and annihilated alternately at two interfaces, as well as experiences a periodic transition from a markedly "Bloch" to "Néel" character, accompanied with the emergence of a "Bloch point" topological defect with vanishing polarization. The dynamical evolution of skyrmions is connected to a constant jump of topological number between "0" and "1" over time. For higher OAM of light, local electric dipoles self-order and form a vortex array distributed along azimuthal directions. Owing to its intrinsic symmetry, the evolution of vortex array with time can be viewed as an effective spinning around the central axis, while its rotation speed is also connected to the OAM value. These intriguing phenomena are found to have an electrostatic origin.

Furthermore, electric dipoles follow the evolving pattern of the optical field and circular motions of rotating dipoles create strong on-site orbital magnetic moments of ions. By characterizing topology of orbital magnetic moments in each 2D layer, we identify the vortex type of magnetic topological texture—magnetic merons with a one-half topological charge and robust stability. Our study thus demonstrates that and explains why this unique light-matter interaction can be very powerful in creating and manipulating topological solitons in functional materials as well as generating magnetic fields and dynamical multiferroicity in nominally nonmagnetic materials.

Exploring chiral nanogap structures using inverse topology design

A. Taguchi[1*]

[1]Resaerch Institute for Electronic Science, Hokkaido University, Japan
[*]corresponding author: taguchi@es.hokudai.ac.jp

Abstract: Chiral nanostructures hold the potential for controlling chiral light-matter interactions at the nanoscale, yet the structure design poses challenges due to intricate near-field responses involving helically structured light. We present the inverse design of chiral nanostructures, demonstrating excellent chiroptical functionalities with a structural complexity that is unattainable by designing with human intuition.

Chiroptical light-matter interactions play a crucial role in various fields, such as circular dichroism (CD) spectroscopy, chiral chemistry, optical trapping and manipulation, spin quantum information technology, and so on. Extensive efforts have been devoted to enhancing chiroptical light-matter interaction using chiral metallic nanostructures and metamaterials [1]. However, the design of these structures has traditionally relied on heuristic approaches, largely dictated by a finite set of preassigned design parameters determined by humans. Considering the inherent complexity of chiral structured light, we explored crafting a high-performing chiral nanophotonic structure.

Topology optimization (TO), initially proposed for mechanical designs [2], uses gradient-based searches rooted in Maxwell's equations [3]. TO enables the handling of large-scale structure designs, comprising hundreds to potentially billions of dielectric values at each spatial point, offering a considerable degree of design freedom [4]. This allows for designing structures by passing through topologically discontinuous deformation, which is not possible using traditional design approaches that only optimize dimensional design parameters and the outer shape. Here, using TO, we show nanogap antennas with increased dissymmetry for improved CPL coupling [5].

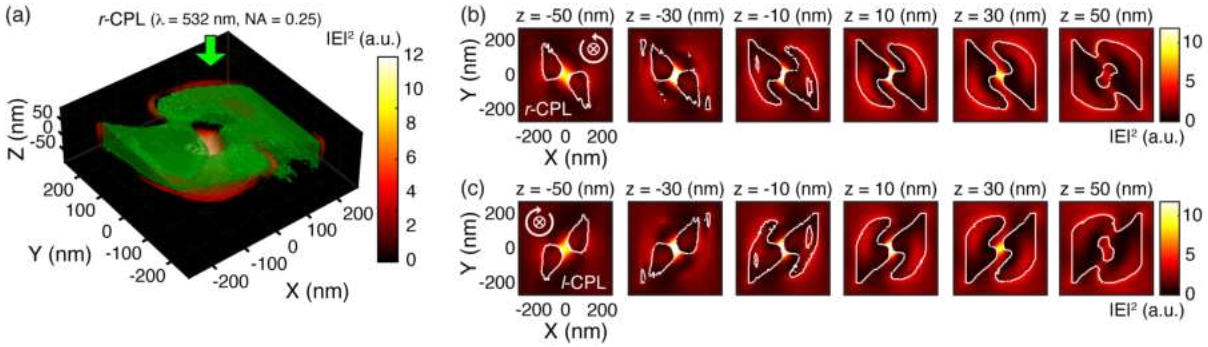

Fig. 1: Chiral gap antenna structure designed using topology optimization. (a) 3D rendering of the structure optimized for *r*-CPL and (b) the sectional view at various z positions. (c) Similar to (b) but optimized for incident *l*-CPL having reversed handedness.

A typical topology-optimized structure is represented in Figs. 1(a) and 1(b) along with the electric field intensity overlayed on the structure. The material is titanium dioxide (TiO_2) placed on a silicon dioxide (SiO_2) substrate. We configured TO to maximize the energy flow at the center of the TiO_2 slab, which had a size of 400 nm x 400 nm x 100 nm, upon being illuminated with right-handed circularly polarized light (*r*-CPL) at a

wavelength of 532 nm (Fig. 1(a)). As seen in the figure, the structure exhibits a spiral shape with an 8-nm-wide gap at the center of the body. Interestingly, the handedness of the spiral was reversed when we switched the handedness of the CPL from right to left (Fig. 1(c)). We calculated the field intensity enhancement for the structure optimized for *r*-CPL. The results are shown in Figs. 2(a) and 2(b) for both *r*-CPL and *l*-CPL excitations. The field intensities within the gap were much stronger when the excitation had the same handedness as the optimization (*r*-CPL). We evaluated the factor of enhancement as the electromagnetic field intensity within the gap divided by the value at the same position but calculated without the structure. The enhancement factors were 56 and 10 for *r*-CPL and *l*-CPL excitation, respectively. To evaluate the dissymmetry of the structure for the handedness of the circular polarization, we defined the dissymmetry factor $g = 2(I_R–I_L)/(I_R+I_L)$ and depicted in Fig. 2(c). The calculated value of the dissymmetry factor was –1.40 within the gap, which is sufficiently large [5].

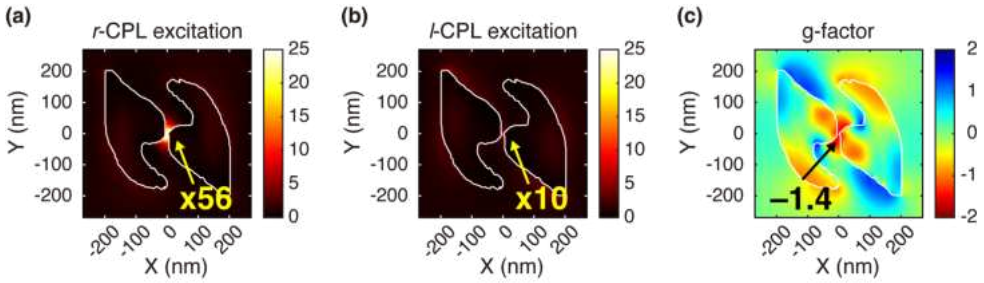

Fig. 2: (a,b) Distribution of the intensity enhancement factor for (a) *r*-CPL excitation (polarized co-circularly) and (b) *l*-CPL excitation (polarized cross-circularly), respectively. (c) Dissymmetry factor (g-factor) of the field intensity enhancement.

In the presentation, we show an in-depth analysis of the near-field polarization of the designed chiral nanogap structures. We then, based on the analysis, propose a CPL emission device using the chiral gap antenna. We also discuss how the structure impacts the spin angular momentum density of incoming light flowing inward the nanogap, which, we found, implies a profound design strategy of chiral nanostructures with enhanced optical chirality [6] at the nanoscale.

Emergent One-Dimensional Helical State on the Surface Opposite to a Step Edge in Higher-Order Topological Insulators

Akihiko Sekine[1*], Manabu Ohtomo[1], Kenichi Kawaguchi[1], and Mari Ohfuchi[1]

[1]Fujitsu Research, Fujitsu Limited, Japan
[*]corresponding author: akihiko.sekine@fujitsu.com

Abstract: We show theoretically that a one-dimensional conducting state with a helical spin structure, which also has a linear dispersion near the zero energy, emerges at a step edge and on the surface opposite to the step edge in three-dimensional higher-order topological insulators such as few-layer Td-WTe_2.

The spin-momentum-locked helical conducting states appearing at the boundaries between a topologically nontrivial phase and a topologically trivial phase have been studied intensively and extensively, pursuing practical technological applications. For example, topological quantum computation utilizing Majorana zero modes has low error rate because the qubits are robust against noises due to the topological nature of Majorana fermions. Also, possible ways to manipulate and utilize the two-dimensional (2D) helical states on the surfaces of 3D topological insulators have been investigated actively in spintronics.

In this work, we study theoretically the electronic structure of 3D higher-order (second-order) topological insulators such as few-layer Td-$X$$Te_2$ (X = Mo, W), which host the 1D helical states called the hinge states at their 1D edges. By diagonalizing the tight-binding model [1, 2] in a 3D geometry with a step edge [Fig. 1(a)], we find that a 1D helical conducting state emerges at a step edge and on the surface opposite to the step edge [3]. We also find that the 1D helical conducting state on the surface opposite to a step edge emerges when the electron hopping in the direction perpendicular to the step is weak. Such an existence of the emergent 1D helical conducting state on the surface opposite to a step edge in the weak coupling regime can be understood by considering an addition of different-sized independent blocks of 3D higher-order topological insulators [Fig. 1(b)]. On the other hand, when the electron hopping in the direction perpendicular to the step is strong, we find that the location of the emergent 1D helical conducting state moves from the surface opposite to the step edge to the dip (270° edge) below the step edge. In this case, the existence of the 1D helical conducting state at the dip below the step edge can be explained by that a gapless topological boundary state generically appears where a sign change in the mass of surface Dirac fermions occurs, as in the case of ordinary 1D topological hinge states. These two physical pictures are connected continuously without the bulk bandgap closing [Fig. 1(c)].

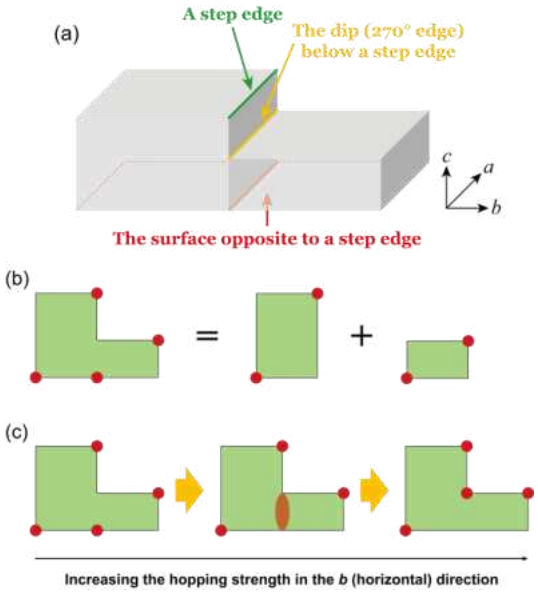

Fig. 1. Schematic illustration of (a) the geometry we consider, (b) the weak coupling regime in the b direction, and (c) the evolution of the location where the 1D helical conducting state emerges with respect to the decreasing hopping strength in the b direction. The filled red circles in (b) and (c) indicate the locations of 1D helical states.

Because one or more step edges can be created as desired by leveraging experimental processes commonly used in thin-film devices, our finding paves the way for on-demand creation of 1D helical conducting states from 3D higher-order topological insulators, which could lead to, e.g., a realization of high-density Majorana qubits.

Chirality-Induced Polarized Phenomena in Chiral Inorganic Materials

Y. Togawa[1, 2*]

[1] Department of Physics and Electronics, Osaka Metropolitan University, Japan
[2] Quantum Research Center for Chirality, Okazaki, Japan
[*]corresponding author: ytogawa@omu.ac.jp

Abstract: A role of chirality in materials is discussed with an emphasis on the emergence of macroscopic polarization of spin angular momenta and angular momenta in chiral inorganic materials.

A role of chirality in materials is discussed in terms of an emergence of macroscopic polarization response, being inspired by recent studies on chirality-induced selectivity of spin angular momenta and angular momenta with chiral materials. These viewpoints will bring us to a new frontier of chiral material science.

In this talk, we discuss the significance of experimental findings that chiral inorganic materials exhibit a spin-polarized state when the charge current is injected into them [1-6]. A spin-polarized transport occurs in a linear regime of the current-voltage characteristics. Importantly, a robust protection of the spin polarization enables a nonlocal spin transport over micrometers or longer [7]. Namely, spin transport occurs macroscopically in chiral materials. A comprehensive understanding of these nontrivial spin response remains an important issue and may clarify the interplay between structural and dynamical chirality. In this connection, controlling chirality in inorganic materials remains an important issue [5]. The influence of dynamical fluctuations, which are characteristic of chiral materials and known as chiral phonon [8, 9], is also argued in the viewpoint of polarization phenomena [10].

Three-dimensional topological spin textures in chiral magnets

Jiadong Zang[1]

[1]University of New Hampshire, USA
[*]corresponding author: jiadong.zang@unh.edu

Abstract: In this talk, I will discuss our recent attempts of generalizing topological spin textures in two-dimensions to those in three-dimensions.

Chiral magnets are a series of magnets with broken inversion symmetry. A new type of spin interaction therein, the Dzyaloshinskii-Moriya interaction, stimulates the formation of many novel topological spin textures. One important example is the emergence of magnetic skyrmion, whose nontrivial topology enables unique dynamical property and thermal stability, and gives rise to promising applications in future spintronic devices. However, skyrmion is just a two-dimensional texture. Its three-dimensional (3D) counterparts are widely unexplored. In this talk, I will discuss realization of 3D skyrmionic textures, including target skyrmion, skyrmion bundle, and skyrmionic vortices. I will also discuss the magnetic hopfion, a rigorously defined 3D topological texture. We propose the presence of zero-field hopfion in synthetic chiral magnetic multilayers. All these 3D textures exhibit novel dynamical properties that can be formulated in terms of collective coordinates. These works could stimulate the development of 3D spintronics.

Nonreciprocal Optical Responses and Diode Effect in Superconductors: Quantum Geometry, Topological Superconductivity, and Exotic Pairing

H. Tanaka[1], A. Daido[1*], H. Watanabe[2], N. Nunchot[1], K. Nakamura[1], S. Asano[1], and Y. Yanase[1]

[1]Department of Physics, Kyoto University, Japan
[2]Research Center for Advanced Science and Technology, University of Tokyo, Japan
[*]corresponding author: yanase@scphys.kyoto-u.ac.jp

Abstract: We present the theoretical framework of nonreciprocal transport and optical responses in superconductors. The optical second-harmonic generation, bulk photocurrent, superconducting diode effect, and nonreciprocal Meissner effect are discussed. Observation of exotic Cooper pairing and topological superconductivity is proposed.

First, we show that superconductors with the space-inversion symmetry breaking host unique nonreciprocal optical responses, such as the photocurrent generation and second-harmonic generation [1]. Unlike the normal state, the nonlinear optical conductivity shows divergence at low frequencies. The divergent behaviors are attributed to the nonreciprocal superfluid density and the Berry curvature derivative, characteristic of the space-inversion symmetry-breaking superconductors. These indicators quantify the performance of superconductors in nonlinear optics. We also formulate the shift current, injection current, and gyration current which show peaks around the superconducting gap frequency. The microscopic conditions for the nonreciprocal optical responses in noncentrosymmetric superconductors are clarified, and we find that the spin-triplet Cooper pairs are needed for the nonlinear optical responses in time-reversal symmetric single-band superconductors [2]. From this result, we propose the probe of spin-triplet Cooper pairs induced by the spin-orbit coupling in noncentrosymmetric superconductors, which was theoretically predicted but not yet verified experimentally. When the time-reversal symmetry is broken, conventional superconductors also show the nonreciprocal optical responses. We evaluate the nonlinear optical conductivity in noncentrosymmetric superconductors under the magnetic field and show that it is enhanced by quantum geometry in the band structure [3]. We also show the sign-reversal phenomenon associated with the emergence of topological superconductivity. Therefore, we propose the bulk probe of topological superconductivity, which has been awaited for a long time.

Second, stimulated by the recent discovery of the superconducting diode effect (SDE) [4], we propose an intrinsic mechanism to cause the SDE [5]. The SDE refers to the nonreciprocity of the critical current. We show that the SDE is caused by the nonreciprocity of the Landau critical momentum and propose that the crossover phenomenon in the helical superconducting state can be proved by the SDE. The intrinsic SDE unveils the rich phase diagram and functionalities of noncentrosymmetric superconductors.

The nonreciprocal correction to the superfluid density also leads to the nonreciprocal Meissner effect, namely, asymmetric screening of magnetic fields due to the nonreciprocal magnetic penetration depth. Performing a microscopic analysis of an exotic superconductor UTe_2, we show that the nonreciprocal Meissner effect is useful for probing parity-mixing properties and gap structures in superconductors [6].

Toroidal-assisted Metasurface for High-performance Nanophotonics

Pin Chieh Wu[1]

[1] Department of Photonics, National Cheng Kung University, Tainan 70101, Taiwan
*corresponding author: pcwu@gs.ncku.edu.tw

Abstract: We propose using toroidal-assisted responses to enhance the transmission efficiency of plasmonic metasurfaces. The Fano coupling between toroidal dipoles and quadrupoles enables a cross-polarization converter with 22.9% efficiency, and a hybrid meta-atom can achieve over 50% efficiency in the near-infrared region.

Plasmonic metasurfaces have been widely studied for their potential to create high-performance flat optical components and polarization converter devices[1-3]. However, these devices are often limited in efficiency due to the use of highly radiative electric and magnetic multipoles. As a result, they may not be suitable for real-world applications, especially when compared to dielectric metasurfaces which can have more limited interaction with incident light due to their high aspect ratio.

In this work, we propose a new strategy to enhance the transmission efficiency of plasmonic metasurfaces. We take advantage of the Fano coupling between toroidal dipoles and quadrupoles, which introduces minimal radiative loss and strong field confinement[4, 5]. By incorporating these low-loss toroidal multipoles, we have experimentally demonstrated a giant cross-polarization converter with a transmission efficiency of 22.9% in a single-layer plasmonic metasurface, which is close to the theoretical limit of 25%. Additionally, we have shown that a hybrid plasmonic meta-atom can achieve a transmission efficiency of over 50% in the near-infrared (NIR) region[6]. By integrating a solid nano-structure with its inverse complementary, we realized a plasmonic metasurface with a circular cross-polarization conversion efficiency higher than 50% in transmission at NIR wavelengths. Such high optical performance metasurface is achieved by simultaneously exciting the electric, magnetic, and toroidal multipolar modes, which satisfies the generalized Kerker condition and improves the transmission efficiency. These results open up new possibilities for the development of highly efficient plasmonic metasurface components and systems that could be used in real-world applications.

Abstract: The 4-sublattice tetrahedral order is the smallest topological spin texture with spatially uniform topological charge density. In this work, we study a minimal spin lattice model of the tetrahedral phase. We investigate the magnetic phase diagram when the Dzyaloshinskii–Moriya interaction is present.

Magnetic skyrmions exhibit topological spin structures in real space. Recently, nanosized skyrmions have been observed in various magnetic systems [1,2]. Ultrasmall skyrmions have a technological advantage for memory applications due to higher memory density. Furthermore, the discovery of ultrasmall skyrmions has stimulated many theoretical studies since a new mechanism is needed for stabilizing them. Itinerant electrons are now believed to play a fundamental role [3].

In this work, we consider the 4-sublattice tetrahedral order in triangular lattice. It consists of four spins pointing to the vertices of a tetrahedron. The positive biquadratic interaction stabilizes the tetrahedral order [4,5], which is a higher-order spin interaction beyond the Ruderman-Kittel-Kasuya-Yosida (RKKY) interaction. We study a minimal spin-lattice model, including the antiferromagnetic exchange, positive biquadratic interaction, and the Dzyaloshinskii–Moriya interaction. We find that the orientation of tetrahedral order is rotated in space when the Dzyaloshinskii–Moriya interaction is introduced. The twisted tetragonal order results in formation of multiple-Q states with a longer wavelength. Remarkably, we find that the antiferromagnetic skyrmion lattice (AFM-SkXs) is favored over the single-Q helical phase even without external fields. We discuss the magnetic excitations of AFM-SkXS and nontrivial magnon topology.

Abstract: Optical forces with opposite signs for enantiomeric versions of a molecule or nanoparticle can enable their separation, essential in chemistry and pharmaceutics. We analyze such forces in integrated dielectric waveguides with simulations, demonstrating separation within seconds for high and low chirality nanoparticles.

Enantiomeric separation, crucial in chemistry and pharmaceutics, conventionally relies on chemical methods like chiral High-Performance Liquid Chromatography, which are slow, expensive, and molecule-specific[1]. An alternative method using optical chiral forces[2] has recently gained attention. Recent theoretical works and experiments have explored optically-induced separation of microparticles, primarily with free-space beams[3]. However, using guided light in integrated waveguides presents a promising approach due to an enhanced chiroptical interaction, essential for sorting smaller particles, and due to the potential for large-scale integration. This study focuses on lossless dielectric waveguides, made of silicon Si or silicon nitride SiN, which offer low propagation loss and compatibility with telecom wavelengths[4]. By analyzing the chiral forces exerted by the optical field at different wavelengths on nanoparticles of various sizes, we show that integrated waveguides can effectively sort enantiomers, potentially enabling rapid enantiomeric separation in photonic integrated circuits.

From electromagnetic simulations we obtain the electric and magnetic fields of the mode supported in the waveguide cross-section for computing the optical force exerted by the mode on a nearby particle. The net optical force that the electromagnetic field ($\boldsymbol{E}$, $\boldsymbol{H}$) exerts on a dipolar particle is given by[2]:

$$\langle \boldsymbol{F} \rangle = \frac{1}{2}\Re\left[(\boldsymbol{\nabla}\otimes\boldsymbol{E})\boldsymbol{p}^* + \mu(\boldsymbol{\nabla}\otimes\boldsymbol{H})\boldsymbol{m}^* - \frac{k^4}{6\pi}\eta(\boldsymbol{p}^*\times\boldsymbol{m})\right] \quad (1)$$

where $\boldsymbol{p} = \alpha_e \varepsilon \boldsymbol{E} + i\alpha_c \boldsymbol{H}/c$ and $\boldsymbol{m} = \alpha_m \boldsymbol{H} - i\alpha_c \boldsymbol{E}/\eta$ are the electric and magnetic dipole moments obtained from the polarizabilities ($\alpha_e, \alpha_m, \alpha_c$) that model the particle's linear response to the electromagnetic field. The polarizability values are calculated with chiral Mie theory[5]. Further detail of each term of the different chiral and achiral forces arising from Equation 1 can be found in previous work[6,7]. Once the force field throughout the medium surrounding the waveguide is obtained, the trajectory of an individual particle is computed with a tracking algorithm that considers the stochastic nature of the Brownian motion of the particle in a fluid. We applied this algorithm to hundreds of particles, for both enantiomers, to do a statistical study on the probability of separation.

We explored different guided modes for separating both enantiomers of low or high chirality non-absorbing particles either transversally or longitudinally to the waveguide. We found that for high-chirality particles a quasi-TE mode at short wavelengths (λ=405 nm) can separate enantiomers transversally at each side of the waveguide due to a dominant magnetic-spin chiral force (see Figure 1(a)). At longer wavelengths (λ=1310 nm), a combination of quasi-TE and a 90º-delayed quasi-TM mode (with same mode index) generates a quasi-circularly polarized mode that enables an attractive/repulsive transversal sorting of smaller nanoparticles due to the transversal helicity

density gradient chiral force[7]. For low-chirality particles we found that a combination of a quasi-TE and a quasi-TM (with different mode index $\Delta n = n_{TE} - n_{TM}$, at λ=1310 nm) generates a beating pattern of alternating helicity, resulting in a longitudinal helicity density gradient along the waveguide that separates the enantiomers every $\lambda/(2\Delta n)$ distance (see Figure 1(b)). All the beforementioned sorting mechanisms successfully occur within seconds for nanoparticles suspended in fluid at room temperature. This study suggests that long Si and SiN waveguides present a viable path towards enantiomeric separation using guided light in photonic integrated circuits.

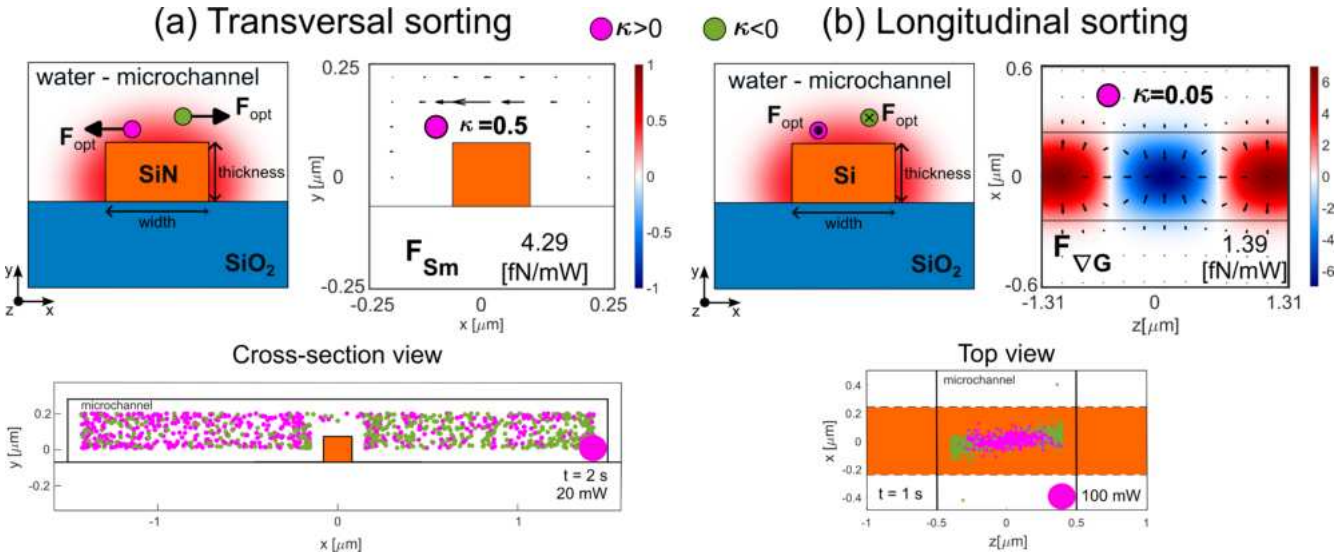

Figure 1 Schematic of each optical sorting configuration, together with the plot of the responsible chiral force, and results of the particle tracking simulations. **(a)** A quasi-TE guided mode in a SiN waveguide produces a dominant magnetic-spin chiral force ($\mathbf{F}_{Sm}$) responsible for the transversal sorting of high-chirality non-absorbing particles (radius = 80 nm, ε=2, μ=1, κ=0.5) at λ=405 nm. **(b)** A superposition of a quasi-TE and a quasi-TM mode (with different mode indices) in a Si waveguide produces a helicity density gradient chiral force ($\mathbf{F}_{\nabla G}$) responsible for the longitudinal sorting of low-chirality non-absorbing particles (radius = 100 nm, ε= 2, μ=1, κ=0.05) at λ=1310 nm.

Surface Lattice Resonance for Enhanced Magnetoplasmonic Activity

Terunori Kaihara[1*], Pablo Rodriguez-Suarez[1], and Paolo Vavassori[1,2]

Abstract: We investigate the magneto-optical effect enhancement in magnetoplasmonic metacrystals. Utilizing surface lattice resonance in periodic arrangements and noble/ferromagnetic metal hybridization, we achieve a ~4-fold enhancement over film counterparts without the need for correction by the fill factor. This underscores the importance of far-field coupling via surface lattice modes.

Magneto-optical (MO) effects are widely used in magnetic/spin detection/characterization, magnetic storage, and optical telecommunications technologies, extending their active areas from X-rays to THz in the wavelength domain and down to subpicoseconds in the time domain.[1] The enhancement of MO effects by magnetoplasmonics is of great interest for active nanophotonics, sensing, magnetic/spintronic dynamics, etc.[2] The MO enhancement in a magnetoplasmonic nanocavity is based on the fact that the orthogonal polarization resulting from spin-orbit interactions under spin polarization undergoes dual plasmon resonances, where the electric field of the incident polarization is amplified by the quality factor Q at the localized plasmon resonance (LPR) and again amplified by Q at the LPR in the orthogonal direction[3] though this Q^2 enhancement is limited to Q by the presence of the Q-fold initial polarization unless simultaneous control of both polarizations is implemented.[4] To make the best of the Q-factor, the hybridization of noble and ferromagnetic metals has often been employed. In addition, when a ferromagnetic film in contact with a noble metal becomes as thin as a few monolayers, the film exhibits perpendicular magnetic anisotropy (PMA) that makes the magnetic active control of the polarization easier.[5] In this work, we demonstrate an enhancement of the Polar MO Kerr (PMOKE) effect in periodic magnetoplasmonic nanodisk arrays consisting of noble and ferromagnetic metal multilayers that outperforms its film counterpart in the MO activity (MOA) with a high Q factor.

Figure 1(a) shows a schematic of a layered Au/Co disk array. The disk is composed of N alternating layers of 3 nm Au and 1 nm Co and is arrayed in a square lattice with a period of P on a glass substrate. In such a periodic arrangement, a surface lattice resonance (SLR) occurs, which is a Fano resonance between an LPR of each disk and a diffracted incident light to the surface mode and is characterized by intense sharp peaks in the reflectance spectra (see Fig. 1(b)). Since the LPR can only couple with the diffracted waves in its transverse direction, for x-polarized light incidence in the figure, the SLR arises depending on the array pitch in the y-direction. Under magnetization in the z-direction, the MO-induced LPR in the y-direction also exhibits the SLR depending on the pitch in the x-direction.[6] Figure 1(b) shows the reflectance spectra of the disk arrays of different diameters with P=500 nm and N=7. The comparison of the periodic and random arrays of D=180 nm demonstrates a strong amplification in resonance due to the SLR at a wavelength of λ = 750 nm. The MOA for D=180 nm exceeds the film counterpart by a factor of ~4 at the maximum at λ=900 nm as a result of the SLR in Fig. 1(c) even without taking the fill factor into account. From an application point of view, a figure of merit can be defined as FoM = reflectance × MOA as seen in Fig. 1(d). Although the reflectance of the film sample is as high as ~80% close to a pure Au film (~98%) thanks to the high Au content, the FoM for D=180 nm at λ=900 nm is comparably large with a much higher Q factor, which cannot be achievable without the SLR.

As has been seen, a Au/Co multilayered system with PMA and SLR can be a promising building block for high-performance magnetoplasmonic metacrystals and sensing applications. We would also like to discuss the arbitrary control of SLR by introducing angled incidence and sublattices,[7,8] and the lattice effect between multipolar plasmon modes in ring/disk nanocavities.

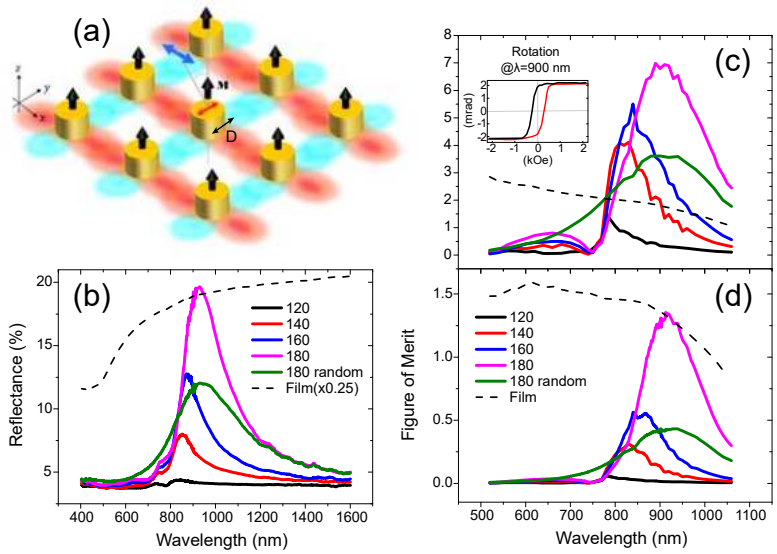

Figure 1. (a) A sketch of the Au/Co periodic multilayer array under study. (b)-(d) Experimentally observed reflectance, magneto-optical activity, and their figure of merit, respectively, measured in an index-matching liquid at normal incidence. The sample has P=500 nm, N=7, and diameters D given in the legend (nm). The inset in (c) is a representative hysteresis loop of the PMOKE rotation.

Correlation-enhanced interaction of a Bose–Einstein condensate with parametric magnon pairs and virtual magnons

A. A. Serga[1*]

[1]Fachbereich Physik and Landesforschungszentrum OPTIMAS,
Rheinland-Pfälzische Technische Universität Kaiserslautern-Landau, 67663 Kaiserslautern, Germany
[*]corresponding author: serha@rptu.de

Abstract: Nonlinear interactions in a magnetic medium excited by parametric pumping lead to Bose–Einstein condensation of spin-wave quanta—magnons. Using Brillouin light scattering spectroscopy, we have discovered a correlation-enhanced four-wave interaction process of the magnon condensate with fully correlated parametric magnon pairs, which results in off-resonant spin-wave excitations—virtual magnons.

Nonlinear wave interactions govern the behavior of various systems in nature. In the field of magnetism, the use of nonlinear phenomena opens promising prospects for applications of magnonics and spintronics in neuro-morphic computing, microwave data processing, and nanoscale wave logic circuits [1–3].

Traditionally, nonlinear-wave interactions are investigated via observation of real quasiparticles—quanta of freely propagating waves, i.e., eigenmodes of the nonlinear medium. In our experiments with highly populated magnon gases in ferromagnetic yttrium iron garnet (YIG) films probed by means of Brillouin light scattering (BLS) spectroscopy (see Fig. 1), we found several types of virtual magnons—quanta of off-resonant spin waves—driven by real magnons through the appropriate nonlinearity [4, 5]. These virtual magnons appear upon parametric pumping (this process is shown by orange arrows in Fig. 1) with the participation of a Bose–Einstein condensate (BEC) [5, 6] formed at the bottom of the spin-wave spectrum.

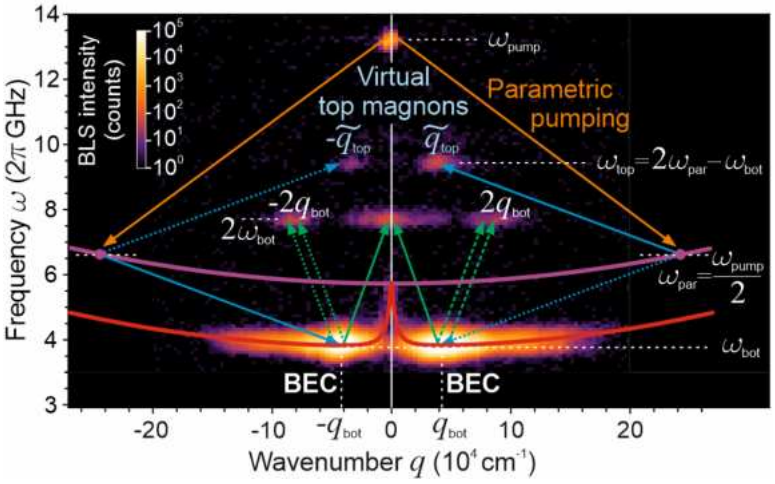

Figure 1: BLS intensity spectra of real and virtual magnons. The spectra were measured during the action of microwave pumping in the 6.7 μm-thick yttrium iron garnet (YIG, $Y_3Fe_5O_{12}$) film tangentially magnetized by the field of 1350 Oe. The experimental intensity spectra are shown together with the calculated magnon dispersion curves and diagrams representing the relevant quasiparticle scattering processes.

Some excitations outside the spin-wave dispersion range arise from the confluence of BEC magnons, as shown by the pairs of green arrows in Fig. 1. Others, named here as "virtual top magnons," are generated through four-magnon scattering processes involving the magnon condensate and parametric magnons (see the pairs of blue arrows). Theory shows that these scattering processes are correlation-enhanced due to the coherence of

parametrically generated magnon pairs, which have opposite wave vectors and fully correlated phases [7], and the coherence of BECs. This process is a classical analog of quantum mechanical correlation-enhanced scattering.

The study of interactions between virtual and real quasi-particles, both in the classical and quantum limits, is useful for their application in new information transfer and data processing technologies, including quantum magnonics and coherent quantum optics [8–12].

Chirality in optical manipulation via electronically resonant light-matter interactions

H. Ishihara

Department of Materials Engineering Science, Osaka University, Japan
*corresponding author: ishi@mp.es.osaka-u.ac.jp

Abstract: Particles ranging in size from the atomic scale to the micro scale can be mechanically manipulated by optical forces. This presentation delves into the effects of light-matter chiral interaction that appear in the optical force phenomena, which are discussed based on the electronically resonant linear and nonlinear optical response.

Photons carry momentum, and consequently, they exert force on matter systems when scattered or absorbed. This phenomenon serves as a mechanism for mechanically manipulating small materials ranging in size from the atomic scale to the micro scale. Optical manipulation of nanostructures poses particular challenges due to the extremely weak optical forces involved, in comparison to those acting on micro-particles, and the complex interactions with environmental materials such as solvents. Promising strategies involve the utilization of strongly localized and enhanced light electric fields resulting from localized surface plasmon resonance (LSPR) [1] and/or electronic resonance effects [2]. We have proposed the latter approaches employing both linear optical response [3] and nonlinear response [4], enabling not only the enhancement of force but also the selective manipulation based on the quantum mechanical characteristics of individual particles [5], along with the development of novel spectroscopies utilizing optical forces [6]. This presentation discusses following topics related to light-matter chiral interactions in resonance optical force phenomena.

< 1 > Peculiar physical effects arise when either light, targeted materials, or both exhibit chirality. Various schemes for chiral selective optical manipulations have been proposed [7]. However, studies based on the microscopic geometrical structures of targeted materials have been lacking. We have theoretically proposed chiral selective optical manipulation by utilizing resonant electronic resonance [8]. In this study, we calculated the chiral selective optical force exerted by circularly polarized light using a microscopic model of dimer molecules, specifically Tröger's base porphyrin, without resorting to any phenomenological parameters to represent chirality. We discussed the dynamics of molecules manipulated by counter-propagating beams to assess the feasibility of single molecular chiral selection. Recently, we have expanded these investigations to include chiral selective trapping of typical chiral molecules by LSPR [9]. In this work, calculations of optical force based on molecular electronic states obtained through first-principles calculations have revealed a variety of degrees of freedom for trapping single molecules, depending on the orientation of molecules and the sites of metallic structures sustaining LSPR.

< 2 > An optical vortex is known as a beam possessing orbital angular momentum, giving rise to rotational motion of particles. We have theoretically proposed some unique trapping mechanisms using optical vortices. For instance, the chiral formation of trapped nanoparticles can be achieved by employing counter-propagating optical vortices [10]. Furthermore, the resonant nonlinear response induced by optical vortices plays interesting roles in the formation of nanoparticles. As we proposed in Ref. [4], resonant nonlinearity can generate a stimulated recoil force, which acts as a negative dissipative force, pulling particles towards the light source. By

exploiting this mechanism, we can alter the direction of particle motion by pumping the excited states. Building upon this concept, we have suggested a super-resolution trapping method resembling stimulated emission depletion microscopy (STED) by combining Gaussian beams with vortex beams [11]. Moreover, it is noteworthy that by pumping rotating particles, the direction of rotation can be switched [12]. This implies that direction switching can occur not only for linear motion but also for rotational motion through induced stimulated emission. In this presentation, we will propose a theoretical scheme to achieve the switching of rotational direction using stimulated recoil force induced by optical vortices.

Twisted Cavity Resonators of Anyon Rotational Symmetry with Bulk Modes of Non-Zero Helicity

J. F. Bourhill[1], E. C. I. Paterson [1] , M. Goryachev and M. E. Tobar[1*]

[1]Quantum Technologies and Dark Matter Labs, Department of Physics, University of Western Australia, 35 Stirling Hwy, 6009 Crawley, Western Australia.
[*]corresponding author: michael.tobar@uwa.edu.au

Abstract: We present a new type of resonator through the formation of twisted hollow structures, which leads to the realization of a cavity with anyon rotational symmetry, and allows the existence of bulk resonant modes with non-zero electromagnetic helicity in vacuo. By constructing a stabilized oscillator from the resonator, we show that the modes couple to ultra-light dark matter axions by adding amplitude-modulated sidebands through the axion-photon chiral anomaly. This removes the typical requirement for an external magnetic field and therefore permits the use of superconducting materials to reduce surface losses and enhance sensitivity to axions.

Chirality is a fundamental property present in many physical systems, which exhibit asymmetry, ranging from particle physics, topological and quantum systems, complex molecules, and chiroptical phenomena. Many such systems that couple to electromagnetism occur as surface states, at high energy or frequency, or due to complex meta-structures or plasmonic systems, which inevitably add loss. In this work, we realize a new class of electromagnetic resonator, which we call the "anyon cavity resonator", based on twisted waveguide and "Möbius-like" structures [1]. Resonators based on Möbius strips have been shown to exhibit fermion rotational symmetry with respect to ring resonator with no twist, which in contrast exhibits boson rotational symmetry [2]. Here, our new type of resonators exhibits anyon rotational symmetry, realized through the formation of twisted hollow structures, optimized with an equilateral triangular cross-section (Fig. 1). Unlike other cavity resonators, resonant bulk modes reveal non-zero helicity [3-5], through a photonic magneto-electric coupling in vacuo. The normalized helicity in (1) can range between -1 and 1 and is tied to the conservation of Zilch [3], or photonic chirality [7] and is usually considered when photons interact with chiral molecules or materials. Here, $\mathbf{E}_p$ and $\mathbf{B}_p$ are the resonant modes electric and magnetic vector phasor amplitudes. Analogously, the axion is calculated to couple to photons through a chiral anomaly, whether in condensed matter physics or in quantum chromodynamics (QCD) and the introduction of the axion as a modification to Maxwell's equations introduces a non-zero Zilch to the equations of motion [1].

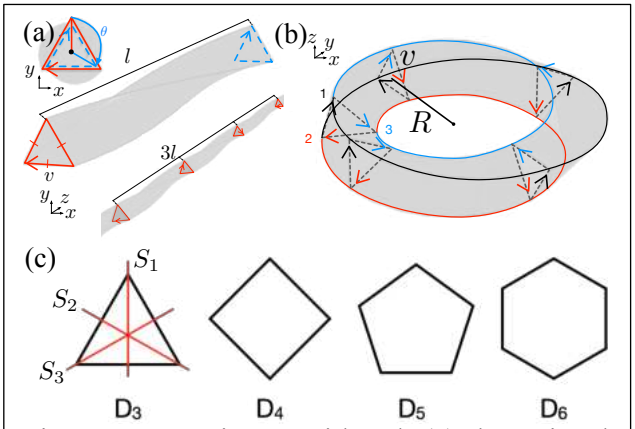

Fig 1. Geometries considered; (a) the twisted triangular waveguide resonator and (b) the triangular Möbius-like ring resonator. (c) The dihedral group of regular convex polygons, D_n, which have 2n symmetries, n rotational and n reflection.

$$\mathscr{H}_p = \frac{2\,\mathrm{Im}[\int \mathbf{E}_p(\vec{r}) \cdot \mathbf{B}_p^*(\vec{r})\ d\tau]}{\sqrt{\int \mathbf{E}_p(\vec{r}) \cdot \mathbf{E}_p^*(\vec{r})\ d\tau \int \mathbf{B}_p(\vec{r}) \cdot \mathbf{B}_p^*(\vec{r})\ d\tau}} \tag{1}$$

We show that the square of the magnitude of the helicity is equivalent to the form factor that couples low-mass axions to photons as an amplitude modulation of a single mode through a parametric interaction. Thus, we show the first sensitive ultra-light laboratory axion dark matter experiment through photon coupling may be realized by implementing such a resonator in an ultra-stable oscillator configuration and searching for signals in the Fourier spectrum of amplitude fluctuations. This removes the typical requirement for an external magnetic field and therefore permits the use of high-Q superconducting materials to reduce surface losses and enhance sensitivity to axions.

Polarization in inhomogeneous crystals and its relationship to quadrupole moments

Nobuhiro Arai[1], Yang Gao[2], Di Xiao[3,4], Shuichi Murakami[1*]

Abstract: We revisit the problem of a definition of the electric quadrupole moment as a bulk quantity. We calculate the polarization for inhomogeneous crystals, from which we derive the formula for the electric quadrupole moment. We show that the resulting formula cannot possess the property of bulk-boundary correspondence, i.e. it is not related to the quadrupole moment of a finite-sized crystal, but it is rather a hidden physical quantity which is manifest only when the crystal has inhomogeneity. Crystals under uniform electric or magnetic fields can be regarded as such example where the Hamiltonian is position dependent, and show that our result completely agree with previous works in such cases

The quantum formula of electric quadrupole moments has been previously discussed in previous literatures[1,2]. Nonetheless, unlike the quantum formula of polarization, which has been formulated as the modern theory of polarization, the definition of the electric quadrupole moment in crystals is still elusive. We revisit this problem by means of linear response theory[3]. We focus on an inhomogeneous crystal where the inhomogeneity is given by a perturbation linear in position. We calculate its polarization, and found that it consists of two contributions, one is due to the change of the local Hamiltonian, and the other is due to spatial inhomogeneity. The latter one should be related to the bulk quadrupole moment, since spatial variation of the quadrupole moment leads to polarization. We compare our results with the similar work[2] by the semiclassical theory. We also discuss the relationship with Ref. 1 where the quadrupole moment is calculated as a linear response to the spatial gradient of the electric field.

Ultracompact, controllable circular polarization laser based on chiral metamaterials

I. Katsantonis[1,2], A. Tasolamprou[1,3], Th. Koschny[4], and M. Kafesaki[1,2*]

Abstract: We demonstrate (theoretically) an ultracompact lasing structure formed by combining a bi-isotropic chiral metamaterial with a gain medium. The structure provides dynamically controllable polarization emission, ranging from left-handed circularly polarized (CP) to right-handed CP. The dynamic polarization control is achieved by changing the polarization of a linearly polarized pump wave.

Circularly polarized emission lasers constitute a topic of increasing interest in recent years, due to their involvement and high potential impact in many different phenomena and applications. These range from sensing and spectroscopy, in particular molecular chirality sensing, chemistry and biophysics to even quantum optics [1-4].

The most obvious way to achieve a circularly polarized emission laser is to combine a gain material with a chiral response. Chiral metamaterials, due to their huge chiral response (compared to natural chiral materials), constitute one of the most promising choices for the chiral response [5-6]. Indeed, recent studies demonstrated promising ultra-compact elliptically polarizing lasing configurations. Their relevant structures though were not able to give pure circularly polarized laser light, and even more importantly, could not provide a controllable polarization response.

The present study aims to remedy both those inefficiencies. In particular, we demonstrate here, through detailed numerical simulations, a bi-isotropic chiral metasurface structure able to provide almost pure circularly polarized emission lasing, being in parallel dynamically tunable through the pump-wave polarization [8]. Changing the linearly polarized pump wave polarization the laser emission can be transformed from almost pure left-handed circularly polarized to right-handed. Besides, the laser polarization can be also engineerable through the structure geometry [8].

Our proposed structure is formed from pairs of mutually twisted metallic crosses embedded in a gain-bearing dielectric host (of thickness 100 nm). The structure design is shown in Fig. 1(a). Fig. 1(b) demonstrates the lasing emission for two different structure geometries. The emission is maximized when the gain material resonance overlaps with the magnetic resonance of the structure, at ~207 GHz.

Our structure and results demonstrate the possibility to achieve ultra-compact and controllable circularly polarized emission lasing structures employing chiral metamaterials and metasurfaces. Such a possibility can open a great prospect in all applications based or affected by the chiral light-matter interactions.

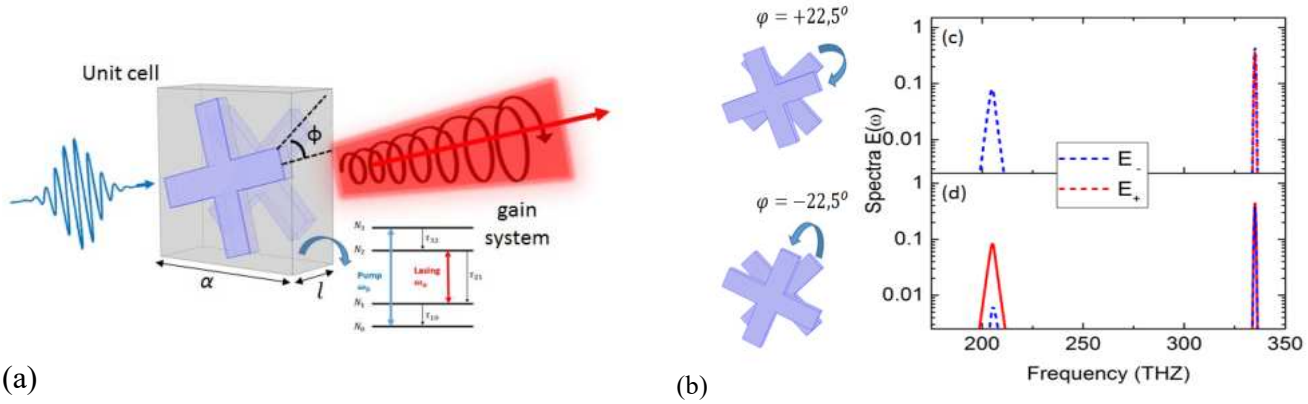

Figure 1: (a) The unit cell of the proposed structure: A pair of mutually twisted metallic crosses, embedded in a dielectric medium dopped with a gain material (dye molecules). The gain material is modelled as a 4-level atomic system [7], as shown also in the figure. The unit cell lateral size is α=300 nm and the thickness l=100 nm. (b) The spectral response of the structure for two opposite values of the twist angle, φ. The pump field (E) at ~330 THz is linearly polarized, while the output (laser) field is either left-handed circularly polarized (E_-; top case) or right-handed (E_+; bottom case).

Thermal Hall effect from chiral magnon-magnon many-body scattering

D. Chatzichrysafis[1], **A. Mook**[1*]

[1]Johannes Gutenberg University Mainz, Germany
[*]corresponding author: amook@uni-mainz.de

Abstract: We present a theory of thermal Hall transport caused by magnon-magnon skew scattering. In field-polarized chiral magnets, the Dzyaloshinskii-Moriya interaction causes three-magnon scattering, which interferes with four-magnon scattering to break the microscopic detailed balance. The resulting skew scattering produces a thermal Hall conductivity even without a magnon Berry curvature.

The thermal Hall effect has emerged as a promising probe of charge-neutral collective excitations in insulating materials. It is well known that quasiparticles such as phonons, magnons and other magnetic excitations can contribute to the thermal Hall conductivity. Typical microscopic mechanisms are scattering [1] and the intrinsic Berry curvature of quasiparticles, which leads to an anomalous velocity [2,3]. There also is increasing evidence that many-body scattering between quasiparticles must be taken into account for quantitative modeling of heat transport [4], since predictions based on the harmonic (non-interacting) theory are not supported by experimental data [5].

We consider a chiral magnet with Dzyaloshinskii-Moriya interaction (DMI) on the square lattice. In the field-polarized phase, i.e. in a magnetic field strong enough to overcome the formation of spin spirals, there is only a single magnon band and hence the magnon Berry curvature is zero. We perform a nonlinear spin wave theory and truncate it beyond four-magnon scattering. The DMI gives rise to three-magnon interactions that break the time-reversal symmetry and a thermal Hall effect can be expected. We evaluate the thermal Hall conductivity within a semiclassical transport theory and show that it is related to a broken microscopic detailed balance of the scattering events in the collision integral, as it appears due to the interference between three- and four-magnon scattering. We evaluate the longitudinal and transverse thermal conductivities and discuss how they change as a function of temperature and magnetic field. We find Hall angles on the order of 10^{-3}, a typical value showing that many-body scattering can be as important as other contributions to thermal Hall transport.

Giant electromagnetic nonreciprocity in magnetic epsilon-near-zero metamaterials

J. Qin[1], Y. Yang[1], S. Xia[1], L. Bi[1*]

Abstract: Magnetic epsilon-near-zero (ENZ) metamaterials present unique advantages of improving the electromagnetic nonreciprocity. Here, we report our recent progress on nonreciprocal electromagnetic wave manipulations via magnetic ENZ metamaterials, demonstrating strong nonreciprocal thermal absorption using InAs ENZ films, and significantly enhanced Cotton-Mouton effect in magnetic zero-index metamaterials based on $Y_3Fe_5O_{12}$ photonic crystals.

Magneto-optical (MO) materials can break Lorentz reciprocity and play an important application for nonreciprocal photonics devices. However, conventional MO materials show weak MO response, limiting the performance of the photonics devices. At optical frequencies, the MO response of magnetic materials depends on the degree of asymmetry of the permittivity tensor, which can be characterized by $\gamma = |a/\varepsilon_c|$, where a and ε_c are the off-diagonal and diagonal components of the permittivity tensor. Previous works have mostly focused on how to enhance the a, with little effort carried out to reduce the ε_c. The electromagnetic nonreciprocity in these magnetic ENZ metamaterials remains elusive. In this work, we report our recent progress on nonreciprocal electromagnetic wave manipulations based on MO ENZ metamaterials. We first report the observed broadband nonreciprocal thermal absorption in InAs ENZ films. Then we report a zero-index metamaterial based on a $Y_3Fe_5O_{12}$ (YIG) photonic crystal, which exhibits significantly enhanced Cotton-Mouton effect and nonreciprocal phase shift.

Experimentally realizing strong infrared nonreciprocal absorption remains an open challenge, and existing proposals of nonreciprocal absorbers are restricted to a narrow working waveband. Here, we report that strong infrared nonreciprocal absorption can be realized around the ENZ frequency of InAs thin films with film thickness of only λ/40, owing to the excitation of asymmetric Berreman mode. The nonreciprocal bandwidths can be improved by adding dielectric gratings sitting on the InAs film and designing multilayer composed of gradient-doped InAs films, potentially useful in thermophotovoltaic devices. [1]

(e) Simulated angle-resolved non-reciprocal absorption spectra of the sample and the measured non-reciprocal spectra at θ = 60° and B = 1.5 T. (f) Schematic of a magnetized ENZ multilayer with gradient doping. (g) Measured and simulated asymmetric absorption spectra of the 14-layer sample at θ = 60°.

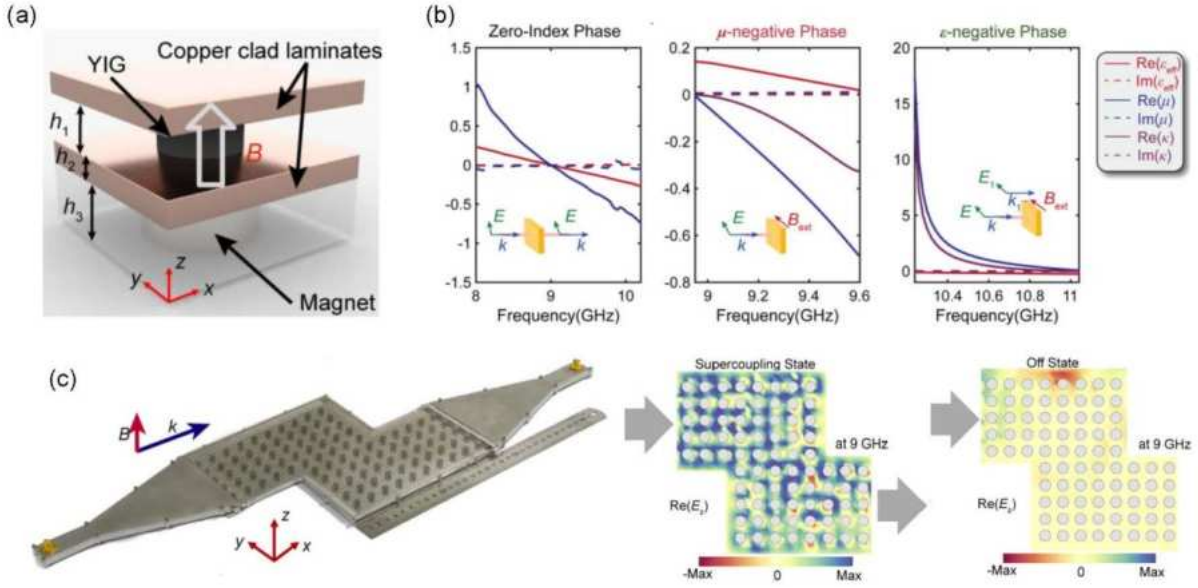

Fig. 2. Magnetically tunable zero-index metamaterial. (a) Schematic diagram of the active Dirac-like cone-based zero-index metamaterial. (b) Magnetic field-induced phase transition of active zero-index metamaterial. (c) Structure and characterization of a microwave switch based on active Dirac-like cone-based zero-index metamaterial.

Due to the large optical loss of InAs ENZ films, the materials are suitable only for reflection-based nonreciprocal systems. In a different work, we report a magnetic zero-index metamaterial (ZIM) based on low loss YIG photonic crystal, as shown in Fig. 2. The zero effective index is resulted from the Dirac-like cone dispersion formed by accidental degeneracy of two linear dispersion bands and a quadratic dispersion band. We observe significantly enhanced Cotton-Mouton effect and nonreciprocal phase shift in such metamaterials at the microwave frequency, realizing the magnetic field induced on-off switch of the supercoupling state. Based on this effect, we experimentally demonstrated a tunable microwave switch with a low intrinsic loss of 0.95 dB and a high extinction ratio of up to 30.63 dB at 9 GHz. [2] The ZIM metamaterials are attractive for applications such as compact nonreciprocal electromagnetic devices.

Abstract: We investigate the relationship between crossings in Spin-Orbital-texture and the Berry-curvature-flux, in terms of divergence and vorticity, on avoided-crossing-manifolds in the 3D-BZ of selected vdW-materials and TI/NI-superlattices. We identify hidden currents with topological charge and chirality in symmetry-subspaces, such as the inversion (anti)-symmetric states on adjacent sides of the interfaces.

While the topological classification of band structures has expanded rapidly, some of its foundations remained inconsistent: Could avoided crossings be the main sources of Berry curvature [1], rather than Dirac points ? Having a singularity at such, how do the textures of Spin/Orbital polarization translate to their Berry curvature counterpart ? And do these fields contain more than just scalar charges, possibly vorticity ?

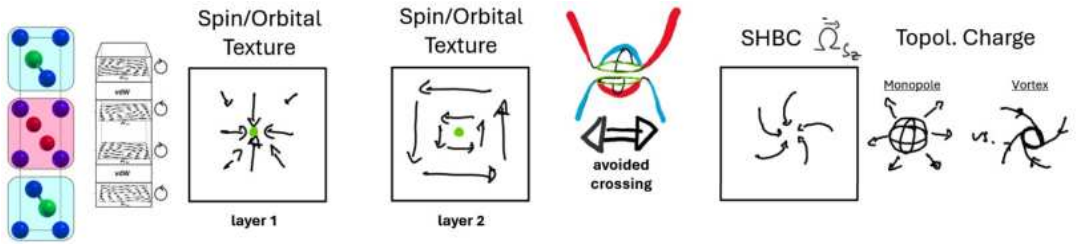

Figure 1. Left: Spin-Orbital texture. Middle: Band inversion from interface states. Right: BC texture and charges.

$$\Omega^{\mathrm{spin}\gamma}_{n,\alpha\beta}(\boldsymbol{k}) = \hbar^2 \sum_{m\neq n} \frac{-2\,\mathrm{Im}[\langle n\boldsymbol{k}|\frac{1}{2}\{\hat{\sigma}_\gamma, \hat{v}_\alpha\}|m\boldsymbol{k}\rangle\langle m\boldsymbol{k}|\hat{v}_\beta|n\boldsymbol{k}\rangle]}{(\epsilon_{n\boldsymbol{k}} - \epsilon_{m\boldsymbol{k}})^2 - (\hbar\omega + i\eta)^2} \qquad \text{(eq. 1)}$$

While the community has recognized Spin Weyl insulators (=3D Spin-Hall TIs) [2], in the broader study of pseudo-nodal line and -sphere semimetals [3] with segregated avoided crossing manifolds, it is necessary to employ Gauss+Stokes analysis of the fully vectorized BC around them and to account for the chiral spin texture with a modified gauge [4] of the perturbative spin current formula 1. As we pioneer such analysis for different materials, we observe via site-projection that hidden polarization textures and currents manifest in symmetry subspaces such as inversion (anti)symmetric bonds around vdW gaps, which can be understood as superposition of lower-dimensional semimetals, eg. Spin-Weyl states at the interfaces of TI+NI superlattices [5].

Photoacoustic spectroscopy and polarimetry spectroscopy for the chiro-optical characterization of nanostructures

A. Belardini[1*], E. Petronijevic[1], C. Skubisz[1], C. Sibilia[1]

[1]Sapienza Università di Roma, SBAI Department, Italy
[*]corresponding author: alessandro.belardini@uniroma1.it

Abstract: Chiro-optical characterization at nanoscale can be performed by using different techniques. The most used ones are the spectral extinction measurements in transmission, or in reflection where samples on opaque substrate were used. In addition to these techniques, there are other less conventional ones such as photoacoustic spectroscopy and spectral polarimetry.

The importance of chirality is crucial in nature as well as in applications ranging from drug synthesis to single molecule detection. For this reason, many types of metasurfaces have been created to increase the sensitivity of light to chirality. At the same time, several techniques for the optical characterization of circular dichroism have been developed. Chiro-optical characterization at nanoscale can be performed by using different techniques. The most used ones are the spectral extinction measurements, were left-handed circular polarized light (LCP) and right-handed circular polarized light (RCP) impinge on samples and were recollected in transmission or in reflection (in case of samples on opaque substrate). In addition to these techniques, there are other less conventional ones such as photoacoustic spectroscopy which is able to evaluate the absorption even from scattering samples or powders, and spectral polarimetry where the Stokes parameters are explored as a function of the wavelength [1].

Here we compare results obtained by measuring different self-assembled intrinsic and extrinsic chiral nanostructures [2] with all these techniques and also with nonlinear techniques such as the Second Harmonic Generation Circular Dichroism (SHD-CD) and Photothermal deflection techniques. Applications on organic materials and molecules are also described.

Abstract: We report the micromagnetic structure of screw dislocation line defects, within the 1-dimensional periodic spiral magnetic order in cubic chiral magnets. Using analytical and numerical techniques we show that the far field of these dislocations has the universal form found in general for lamellar order, with a non-trivial core structure.

The micromagnetic energy for cubic chiral magnets at leading order in spin-orbit coupling is,

$$\mathcal{E} = A(\partial_i \boldsymbol{n})^2 + D\boldsymbol{n}(\boldsymbol{\nabla} \times \boldsymbol{n}) - M_s \mu_0 H n_z. \tag{1}$$

where $\boldsymbol{n}$ is a unit vector oriented along the magnetization direction, A is the ferromagnetic exchange constant, D is the Dzyaloshinskii-Moriya interaction (DMI) constant, and an external magnetic field is applied along the z direction. The DMI stabilizes a helimagnetic order for a large range of temperatures and applied magnetic field. In this helimagnetic phase the magnetization varies only along the helix axis, that is aligned with the applied field, giving rise to a one-dimensional periodic magnetic texture. This texture shares many similarities with generic lamellar order like cholesteric liquid crystals, for example, it possesses disclination and dislocation defects [1].

Here, we investigate both analytically and numerically screw dislocations of helimagnetic order, in which the far field is universally determined by a topological index ν that quantizes the Burgers vector characterizing the dislocation. Whereas the far-field of these defects is universal, we find that various core structures can be realized even for the same Burgers vector of the screw dislocation [2] (see Figure 1).

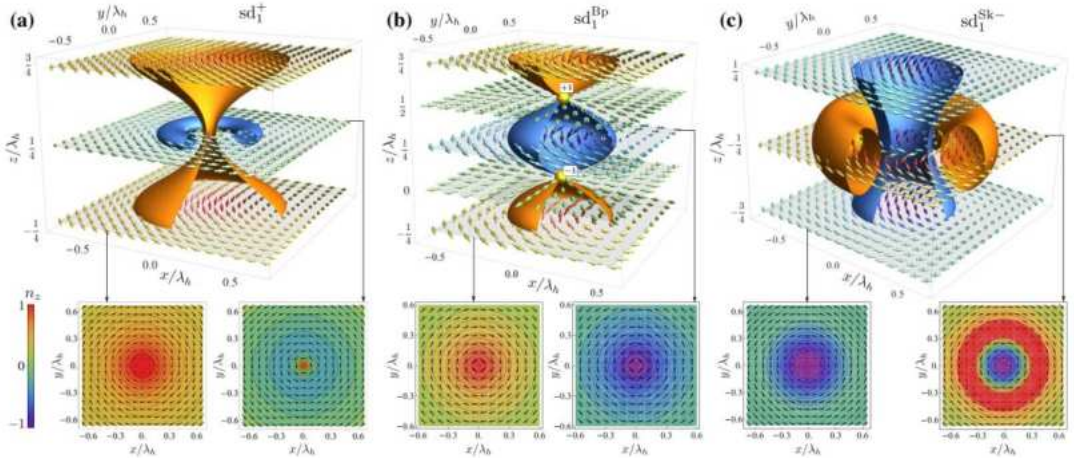

Figure 1 Micromagnetic texture of ν=+1 screw dislocation lines in chiral magnets.

Intriguingly, we identify screw dislocations with a smooth magnetic core and a simple screw structure ($\nu = +1$), that exist as vortex strings encircled by fractional Hopfion rings. The latter prediction has recently been experimentally confirmed by means of transmission electron microscopy [3]. Another astonishing spin structure that we predicted arise from a singular core comprising a chain of Bloch points with alternating topological charge.

Our findings enrich the portfolio of topological magnetic structures ubiquitously being present in bulk and thin-film helimagnets and will play a crucial role on the way to 3D nanomagnet and spintronics applications.

Making sense of the electron transport CISS effect properties and the spinterface model

A. Sharoni[1]*, R. Bornovski[1], S. Alwan[2] and Y. Dubi[2]

[1]Department of Physics & Institue of Nanosciene, Bar Ilan University, Ramat Gan 590002, Israel
[2]Department of Chemistry, Ben Gurion University of the Negev, Beer Sheva, Israel
*corresponding author: amos.sharoni@biu.ac.il

Abstract: Transport CISS effect is observed in metal-chiral-ferromagnet junctions, where current changes dramatically with magnetization of FM. Understanding different experimental findings and their origin is difficult. We show our spinterface model well explains effects such as magnitude of CISS signal and temperature dependence. We present recent experimental results supporting the model.

When electrons are injected through a chiral molecule, the resulting current may become spin polarized. This effect, known as the chirality-induced spin-selectivity (CISS) effect, has been suggested to emerge due to the interplay between spin–orbit interactions and the chirality within the molecule. However, such explanations require unrealistically large values for the molecular spin–orbit interaction without any physical justification. Put simply, to date, the physical origin of the CISS effect is unknown. Moreover, many of the reported results to date are surprising, and present a challenge for theory.

In this talk we will focus on the electron transport manifestation of the CISS effect, commonly observed in a metal - chiral molecule - ferromagnet junctions, where the total current is different when the ferromagnet is magnetized parallel or anti-parallel to the molecular chirality axis. This spin polarization (i.e., the percent difference between the two currents) may depend on different parameters, and was reported to show a variety of effects. These include such effects as: (1) The spin polarization measured to be close to 100% even though the polarization of the ferromagnetic (FM) detector electrode is much smaller. (2) The temperature dependence has been reported to decrease the magnitude of the CISS effect in some cases, while in other cases to increase it.

Here, we build upon the “spinterface” theory for the CISS effect[1] based on the interplay between spin–orbit interactions in the electrode, the chirality of the molecule (which induces a solenoid field), and spin-transfer torque at the molecule–electrode interface.

Using a mean-field calculation with simple models for the molecular junction, we show that our phenomenological theory can qualitatively account for all key experimental observations, most importantly the magnitude of the CISS with realistic parameters. We show analytically that experimental results indicate that the origin of the CISS effect must involve some interaction mechanism (as opposed to non-interacting electronic effects), since the observed CISS polarization can be much larger than the ferromagnetic electrode spin-polarization. Specifically, we show that a non-interacting single-level model cannot reproduce experimental data even if the molecular spin-filtering is perfect. On the other hand, we show that the spinterface mechanism can indeed lead to arbitrarily large CISS polarization.[2] We demonstrate this by showing excellent fit between the spinterface model and recent experiments where the effective magnetization of the ferromagnetic electrode was changed continuously. As a second example of the spinterface model we will show the temperature dependence of the CISS and the importance of correctly analyzing the experimental results. [3]

Finally, we will describe a set of experiments which can be used as a “smoking gun” for differentiating the

spinterface mechanisms from other theoretical explanations and show some of our recent experimental data that is aimed at testing these predictions.

Abstract: An internal mechanism of Chirality-Induced Spin Selectivity (CISS) is discussed based on a symmetry consideration in which electron's helicity is connected to molecular chirality and spin accumulation with a language of electronic multipoles.

Chirality-Induced Spin Selectivity (CISS) is attracting recent attention as a new source of spin polarized current [1]. With this effect, an electron spin is aligned parallel to or antiparallel to its velocity after passing through a chiral molecule. Here the electron acquires either positive or negative helicity (= $\boldsymbol{p}\cdot\boldsymbol{s}$ where $\boldsymbol{p}$ and $\boldsymbol{s}$ are linear and spin angular momentum, respectively) depending on the handedness of the molecule. This is a chiral information imprinting from molecular handedness to electron's helicity, both of which are parity(P)-odd and time-reversal(T)-even. We are now trying to identify a common language to describe molecular chirality and electron's helicity in a simple and convenient manner. For this purpose, electrical toroidal monopole (G_0) is ideal so that we need to quantify the molecular chirality in this terminology [2, 3].

It is also interesting to point out that, in a hypothetical consideration, an enhancement of spin polarization is associated with anti-parallel spin pair accumulation at two opposite ends of a chiral molecule in CISS. Note that such an anti-parallel spin pair is T-odd state, while the chiral molecular structure is T-even. We think symmetry conversion from T-even to T-odd quantities gives an essential clue to understand CISS effect that can generate huge spin polarization in a non-equilibrium condition. We have made such a symmetry consideration based on multipole basis and found that a T-odd chirality can emerge from an accumulation of spin current (= electrical toroidal monopole G_0) at reservoirs. In addition, we have experimentally shown that chiral organic superconductor can exhibit spin accumulation at two opposite crystal edges whose directions are anti-parallel to one another [4]. This can be regarded as a macroscopic-size emulation of chiral molecules that has T-odd spin accumulations at their opposite ends. A connection to falsely chiral influence [5] will be also discussed.

Abstract: The existence of polar vortex textures in strained nanoscale ferroelectric materials has been recently experimentally verified. As shown in this contribution, such materials offer a new route to study chiral, topological, and photonic systems. We show that, in the THz regime, the polar vortex lattice couples simultaneously to electric and magnetic field components leading to the formation of a photonic vortex lattice with particular dispersion. We discuss the spectral and mode properties of the formed photonic textures and discuss possible utilization in optoelectronics.

Materials with polar ordering are shown in [1]-[4] to exhibit chiral and vortex lattice textures (*e.g.*, as schematically depicted in Fig. 1a) that can be controlled by external stimuli, *e.g.*, by switching the underlying ferroelectric polarization [3]. We address in this contribution the characteristics of the photonic modes that are hosted in such dielectric structures. Analytical considerations, supported by rigorous self-contained material-specific numerical simulations [5] for the electromagnetic scattering, evidence the polarization-dependent optoelectronic modes and the emergence of photonic band-gaps (Fig.1b). In particular, we demonstrate how the ferroelectric vortex lattice enables a coupling to electric and magnetic fields simultaneously resulting in a novel type of photonic vortex lattice with particular dispersion that we analyze for a wide class of ferroelectric layered heterostructures. The proposed method based on the coupled differential equations presents an efficient numerical tool for the analysis of other types of structured ferroelectrics and gives a full picture of the coupling behavior of the electromagnetic waves with the vortex of electric dipole arrays.

(a) (b)

Figure 1: Schematics of ferroelectric vortex lattice which we use for the photonic simulations. The arrows show the local ferroelectric polarization direction that curl to form neighboring vortices with opposite chiralities. The equilibrium distances between the centers of the vortices along the *x*- and the *y*-axes are h and $2h$, respectively. The distribution of the local polarization along the *z* direction is uniform. The distance between the neighboring electric dipoles is a. We consider an electromagnetic wave incident with an inclined angle of φ. (b) Dispersion of the TM (H_z, E_x, E_y) modes calculated from the linear set of Bloch mode equations [5] where the wavevector is measured in units of $Q_x = 2\pi/h$ and $Q_y = \pi/h$. The frequency unit in this example is approximately $\kappa = 2\pi$ THz. More details can be found in [5].

Half Quantized Hall Effect

Shun-Qing Shen*

Department of Physics, The University of Hong Kong, Pokfulam, Hong Kong
*sshen@hku.hk

Abstract: A single gapless Dirac cone of fermions on a lattice gives rise to one half quantum Hall conductance while a gapped Dirac cone of fermions always has zero or one quantum Hall conductance. This effect can be realized in a semi-magnetic topological insulator film.

The quantum Hall effects refer to a series of peculiar quantum states of matter in the two-dimensional electron system in a strong magnetic field at a very low temperature. Similar phenomena in quasi-two-dimensional materials in the absence of a magnetic field are named the quantum anomalous Hall effect. So far, all the quantum Hall effects occur in insulating phases and are characterized by the TKNN number or Chern number for the band structure as a topological invariant. The longitudinal conductivity is zero and either the Hall resistivity or conductivity is quantized. The bulk-edge correspondence illustrates that the number corresponds to the number of the localized edge modes around the system boundary, which carries the dissipationless chiral charge current. Here we report a half-quantized Hall effect in a semi-magnetic topological insulator. The Hall conductance is half quantized and the longitudinal conductance is nonzero, but the Hall resistivity is not quantized. This effect is attributed to the existence of a single gapless Dirac cone of fermions on a lattice. More general, the half quantization occurs when the Fermi surface is invariant under the parity symmetry or time reversal symmetry while the symmetry is broken in the whole system. [1] [2]

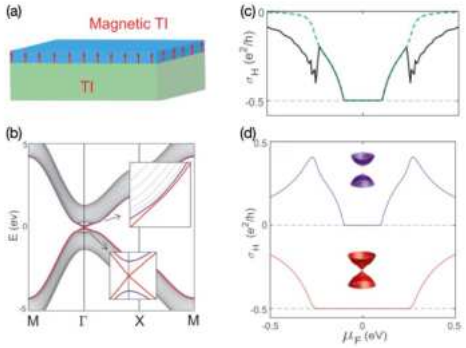

Figure 1: The Hall conductance for the gapless and gapped surface bands in a semi-magnetic topological insulator. (a). Schematic of a magnetic topological insulator film. (b) The band structure of a tight-binding model. (c) The total Hall conductance as a function of the chemical potential. (d) The Hall conductance of the gapped and gapless surface bands. (Adapted from Ref [3].)

We begin with a tight binding model for a three-dimensional topological insulator with finite thickness in the z-axis, incorporating the Zeeman field on the top layer to simulate magnetic ion doping. Periodic boundary conditions are performed in the x and y directions. The exact diagonalization method yields the energy dispersion and corresponding eigenstates explicitly, which are well defined the 2D first Brillouin zone. Numerical results corroborate the presence of gapped and gapless surface Dirac fermion cones in a semi-magnetic TI. The top surface Dirac cone is gapped due to the Zeeman field. However it is important to note the surface Dirac cones appear only near the Γ point, and are confined within the bulk gap Δ of the topological insulator, occupying only a small portion of the first Brillouin zone. Outside the regime, the wave functions of the energy eigenstates evolve into the bulk, and are no longer confined near the top and/or bottom surface. Using the TKNN formula, we calculated the Hall conductance for the bands associated with the top and bottom surface Dirac cones\. The Hall conductance for the gapless Dirac cone become half-quantized when the chemical potential is located within the bulk gap Δ while the

Hall conductance for the gapped Dirac cone exhibits a peak near the bulk band edge, which height is less than 0.5 and drops to zero when the chemical potential is located within the gap V of the top surface states. Consequently, the total Hall conductance is one half quantized when the chemical potential is situated within the gap V.

The observation of zero Hall conductance for the fully-filled top gapped Dirac cone aligns with the TKNN theorem and the Chern number. The gapped top surface states only arise within the bulk gap Δ of TI. While the nonzero Berry curvature of these states may contribute to a nonzero Hall conductance it is not expected to yield half-quantized value due to the finite ratio of V/Δ. A value of 0.5 can only be achieved when the ratio of V/Δ approaches zero. However, the first Brillouin zone is finite, and the remaining portion of the bands also contributes a nonzero Hall conductance, effectively cancelling out the contribution from the gapped surface states. This cancellation is dictated by the TKNN theorem in the presence of a nonzero V. In an open boundary condition, as there are no localized chiral edge states in the gapless and metallic system, we find that the chiral edge current is carried by the gapless surface states. The current density peaks at the edge and decays in a power law rather than the exponential decay as in the conventional quantum anomalous Hall effect [4]. We term the unexpected and nontrivial quantum phase as "parity anomalous semimetal" [1]. We also discovered a metallic quantum anomalous Hall effect without chiral edge states in a magnetic sandwich structure of topological insulators [5]. The set of works open the door to exploring novel topological states of matter with fractional topological invariants.

The half quantum Hall effect of a gapless Dirac cone is closely associated with the quantum anomaly in quantum field theory [1]. Quantum anomaly refers to the failure of a symmetry present in a theory's classical action to be a symmetry of any regulation of the fully quantum theory. Strictly speaking, there is no parity anomaly in a solid or on a lattice, as the lattice spacing in a solid crystal provides a natural cut-off for the wave vector, and both the first Brillouin zone and the band width are finite. In the case of the one-half quantum Hall conductance, it is believed to be closely related with the physics of parity anomaly. Near the Dirac crossing point or in the regime of the gapless surface states, electrons respect the parity symmetry, and the Berry curvature vanishes. However, the occupied electrons away from this regime break the symmetry, and contribute an exactly half-quantized Hall conductance.

Abstract: I will show our latest results in the control of the scattering and optical forces using modes of light with well-defined angular momentum and helicity. Traditionally, the roles of helicity and angular momentum are mixed. I will present the differential features of angular momentum and helicity of optical beams.

The angular momentum of light is a property that has been studied thoroughly in the last three decades. The ability of controlling the angular momentum of light through its spatial properties opened up the field of structured light with multiple applications in communications, quantum optics, optical trapping and the scattering of light by small particles.

Traditionally, the angular momentum of light is separated into spin and orbital parts. The spin is related with the circular polarization of optical fields, while the orbital is related with the azimuthal phase of a cylindrically symmetric field. While this separation may have its applications in the paraxial regime, it has encountered many problems when applied to focused beams and non-paraxial fields in general. On the other hand, another quantity also related to the circular polarization of optical fields, the helicity of light, has allowed to better interpret the interaction of light and matter both in the paraxial and non-paraxial regimes, with classical and quatum states of light. The key element is that angular momentum modes of light have a distinct relationship with rotational symmetries, while modes of well-defined helicity have a relationship with the duality symmetry between electric and magnetic parts of an optical field.

We have exploited these relationships to better understand the role of the angular momentum and the helicity in scattering experiments and, more recently in optical forces. In particular, we have experimentally used optical modes with well-defined angular momentum and helicity to trap particles in the Mie regime and showed that these particles can be stably trapped in the center of the beam as shown in Fig. 1

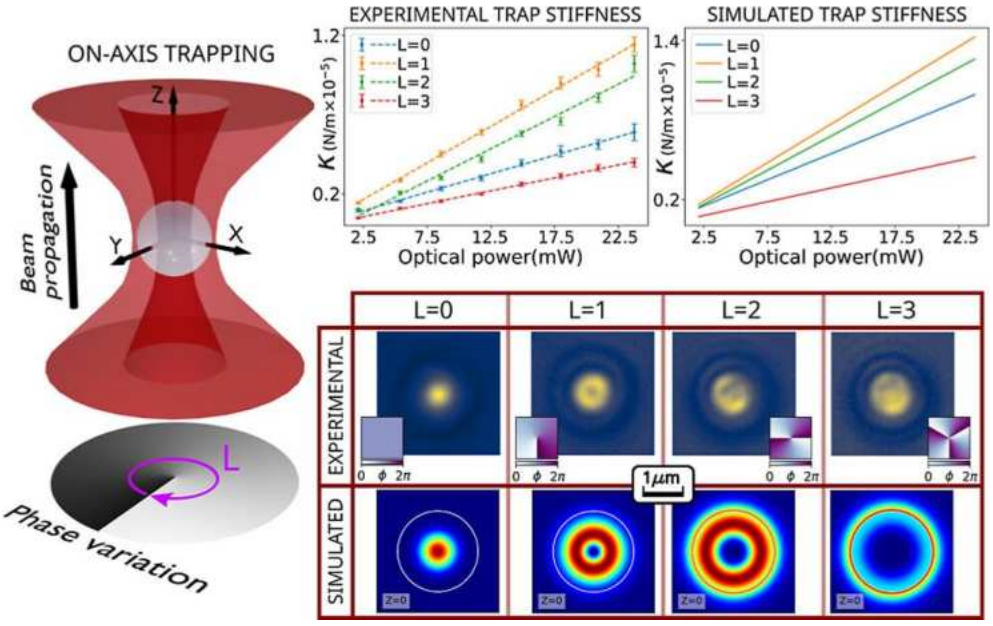

Figure 1: Comparison between experimental and experimental results of the optical trapping of silica particles in modes with well-defined angular momentum and helicity.

We have also developed numerical and theoretical techniques in order to elucidate the differential role of these quantities both in the scattering and the optical forces of optical beams.

Nonlinear topological magnon spin Hall effect

Peng Yan*

School of Physics and State Key Laboratory of Electronic Thin Films and Integrated Devices, University of Electronic Science and Technology of China, Chengdu 610054, China

*corresponding author: yan@uestc.edu.cn

Abstract: Nonlinear scattering of magnons and skyrmions in antiferromagnets leads to a spin Hall effect that emerges from real-space topology.

When a magnon passes through two-dimensional magnetic textures, it will experience a fictitious magnetic field originating from the 3×3 skew-symmetric gauge fields. To date, only one of the three independent components of the gauge fields has been found to play a role in generating the fictitious magnetic field while the rest two are perfectly hidden. In this work, we show that they are concealed in the nonlinear magnon transport in magnetic textures. Without loss of generality, we theoretically study the nonlinear magnon-skyrmion interaction in antiferromagnets. By analyzing the scattering features of three-magnon processes between the circularly polarized incident magnon and breathing skyrmion, we predict a giant Hall angle of both the confluence and splitting modes. Furthermore, we find that the Hall angle reverses its sign when one switches the handedness of the incident magnons. We dub it nonlinear topological magnon spin Hall effect. Our findings are deeply rooted in the bosonic nature of magnons that the particle number is not conserved, which has no counterpart in low-energy fermionic systems and may open the door for probing gauge fields by nonlinear means.

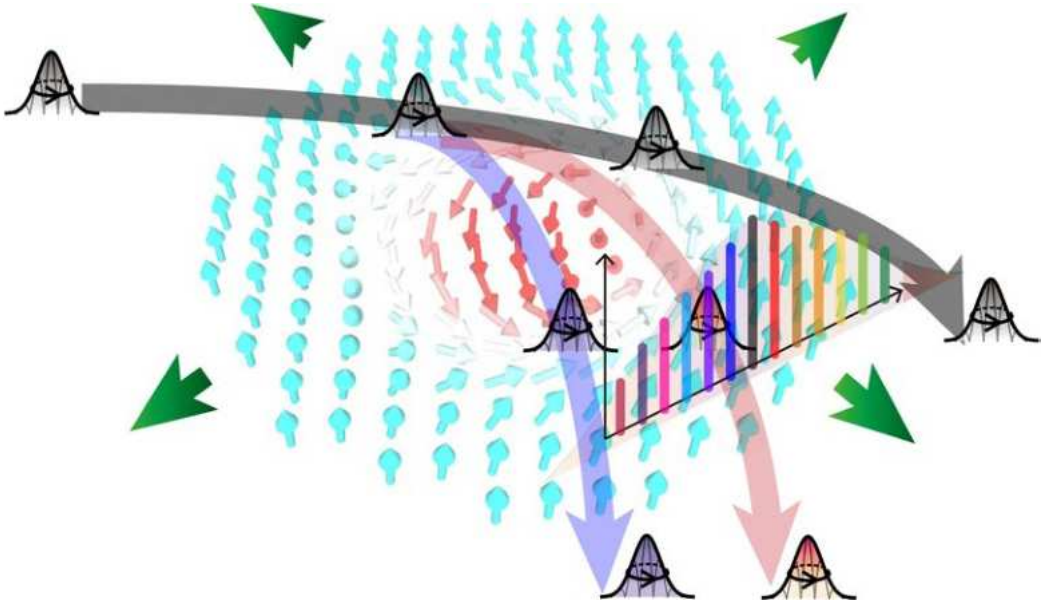

Fig. 1: Schematic of the giant spin Hall angle in the nonlinear scattering of magnons by skyrmion in antiferromagnets.

Chiral coherent control of electronic population transfer with femtosecond pulses: towards all-optical and highly enantioselective photochemistry

A. Ordóñez[1,2], P. Vindel-Zandbergen[3] and D. Ayuso[1,2,3*]

[1]School of Physical and Chemical Sciences, Queen Mary University of London, E1 4NS London, UK

Abstract: We provide a route to achieve highly enantioselective photochemistry via interference between two quantum pathways leading to an electronic excitation. Our simulations reveal differences of up to 19% in the excited state populations of R and S carvone, a major improvement over what is possible with circularly polarized light (~0.01%)

Enantioselective photochemistry relies on the ability to induce different electronic transitions in left-handed and right-handed versions (enantiomers) of a chiral molecule using light. This is usually a very challenging task, as opposite enantiomers share the same energy spectrum, and photoexcitation with circularly polarized light is barely enantioselective. As a result, highly enantioselective photochemistry remains an important milestone of photochemistry, which could enable laser-driven alternatives to traditional chemical methods for enantio-purification and enantioselective synthesis. These are tasks of immense importance in the chemical industry, where producing samples with only one of the two enantiomers of a chiral molecule starting from racemic (50% R – 50% L) mixtures is required in numerous applications. Whereas great progress has been recently achieved in the context of coherent control over *rotational* excitations [1,2], extending these achievements to *electronic* excitations and shorter timescales is extremely challenging.

Here we show how we can tailor light to induce highly enantioselective population transfer between electronic states using intense femtosecond pulses, which can trigger highly enantioselective photochemistry, see Fig. 1a,b. Our approach relies on driving and controlling an enantioselective interference between two quantum pathways leading to an electronic excitation, and it is supported by analytical modelling and ab-initio simulations which take into account the molecular orientation distribution and the variation of the field across the sample [3].

In the case of one- vs. two-photon interference (Fig. 1c,d), one of the dimensions of the interaction region must remain on the same order or smaller than the longest of the wavelengths. Otherwise, the enantioselectivity is washed out. While this is relatively easy to achieve when dealing with microwaves, it is a rather restricting condition for optical wavelengths and requires taking special measures, such as using carefully oriented ultrathin liquid microjets. In contrast, we can achieve highly enantioselective population transfer using a two- vs. three-photon interference (Fig. 1e,d). This scheme allows for interaction regions much larger than the longest wavelength. Our simulations show that it can lead to a 19% difference between the excited state populations of R and S enantiomers of carvone. This massive improvement over what is possible with circularly polarized light (~0.01%) brings all-optical enantioselective photochemistry within range for practical applications.

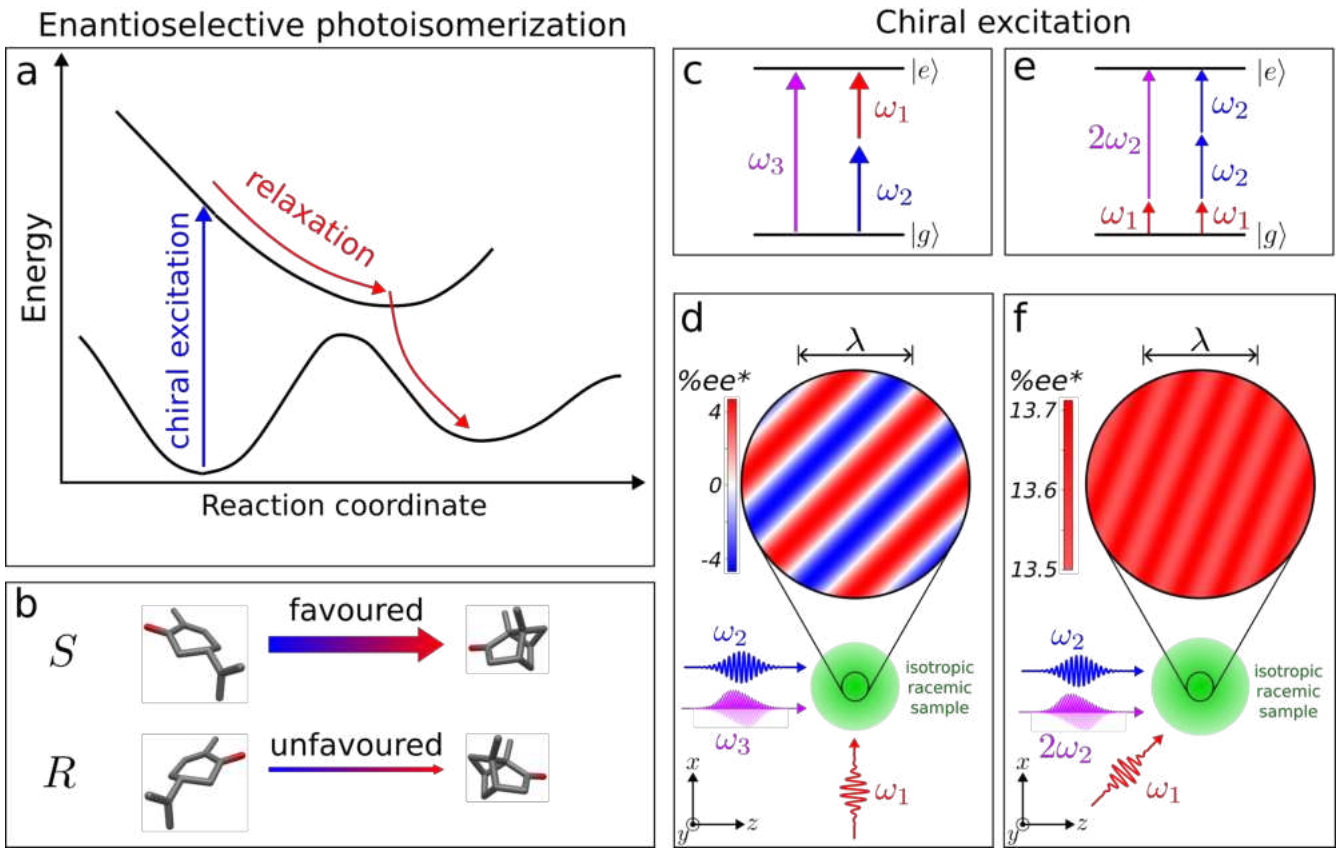

Fig. 1. a, Photochemistry is triggered by an electronic excitation, which often leads to chemical rearrangements (e.g. isomerization or dissociation). **b,** If the electronic excitation is driven by chiral light, the excitation becomes more likely in one of the two enantiomers. **c,** Enantioselective excitation can be achieved via coherent control. The microwave approach [1,2] relies on one-vs-two photon interference, and it leads to a subwavelength oscillation of the enantioselectivity across the interaction region. **d**, red and blue describe regions where more S and R enantiomers are excited, respectively, hindering applications in the optical domain. **e,f,** Such oscillations can be avoided by careful design in a two-vs-three photon interference scheme (**e**); note that the enantioselectivity is approximately constant (**f**).

Abstract: This study investigates chiral interactions and mode manipulation in quantum photonic circuits using topological photonic crystals and quantum dots. It features four pivotal advancements: tunable photon emission, efficient mode tapering, chiral multiport routing, and a comparative analysis of waveguides, with important implications for the design of efficient integrated quantum devices.

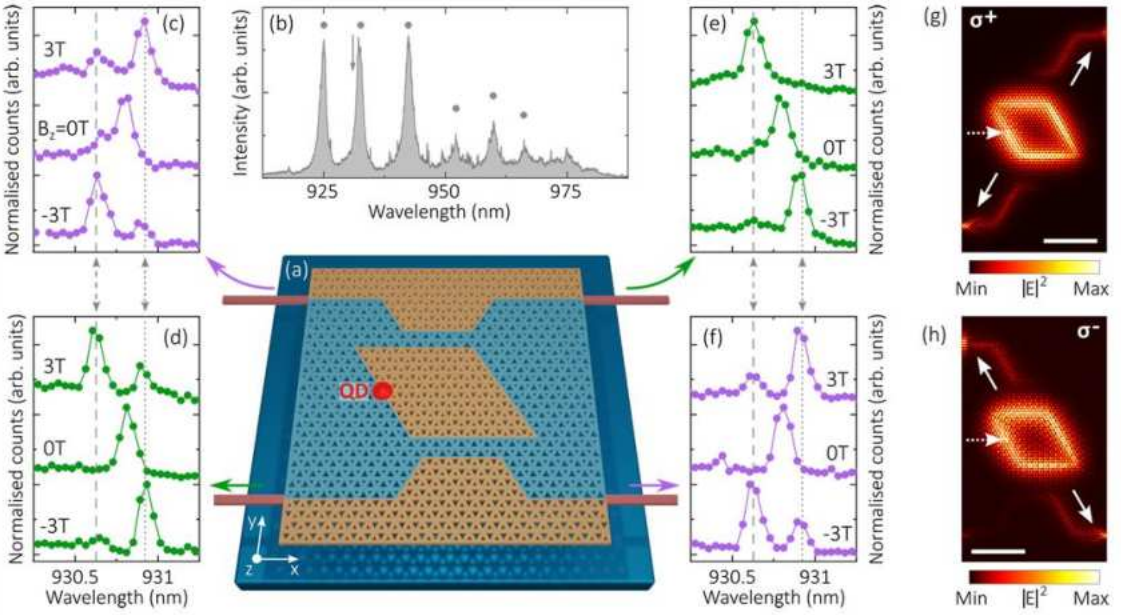

Figure 1: (a) Schematic of the topological photonic add-drop filter, with a quantum dot (QD) embedded at the resonator interface. Each of the four nanobeam waveguides is terminated with a grating out-coupler (OC), not shown. (b) PL spectrum acquired from an OC under high-power excitation of the resonator interface. The longitudinal resonator modes are marked by filled circles (c-f) Low power PL spectra for a single QD located at the resonator interface and with an optical transition near-resonant with a longitudinal mode (see arrow in (b)). The spectra are acquired from the OCs in the (c) top left, (d) lower left, (e) top right and (f) lower right of the device, respectively. Data is shown for three different magnetic field strengths, B_z =-3T, 0T and 3T, respectively. Dashed and dotted lines indicate the approximate wavelengths of the two QD transitions under non-zero magnetic field. (g-h) Simulated, time-averaged electric field intensity in the plane of the device, for a (g) σ^+ or (h) σ^- polarized dipole placed at a chiral point at the resonator interface (approximate location given by the dashed arrow). Solid arrows indicate the dominant coupling directions from of the resonator in each case. Scale bars 4μm.

Chiral Quantum Optical Interfaces: We experimentally integrate semiconductor quantum dots into a valley-Hall topological photonic crystal waveguide, forming a ring resonator that supports helical modes. We create an integrated topological add-drop filter within a valley-Hall photonic crystal membrane showcasing multiport chiral emission and wavelength-selective single photon routing, facilitated by resonator longitudinal modes. The device's inherent nonreciprocity at the single-photon level promotes advanced quantum optical devices like on-chip circulators and logic gates [1–2].

Comparative Study of Nano-Photonic Waveguides: Our analysis compares the chiral coupling of quantum emitters in topological versus conventional photonic waveguides, highlighting the current limitations of topological waveguides despite the potential advantages offered by state-of-the-art inverse design methods [3].

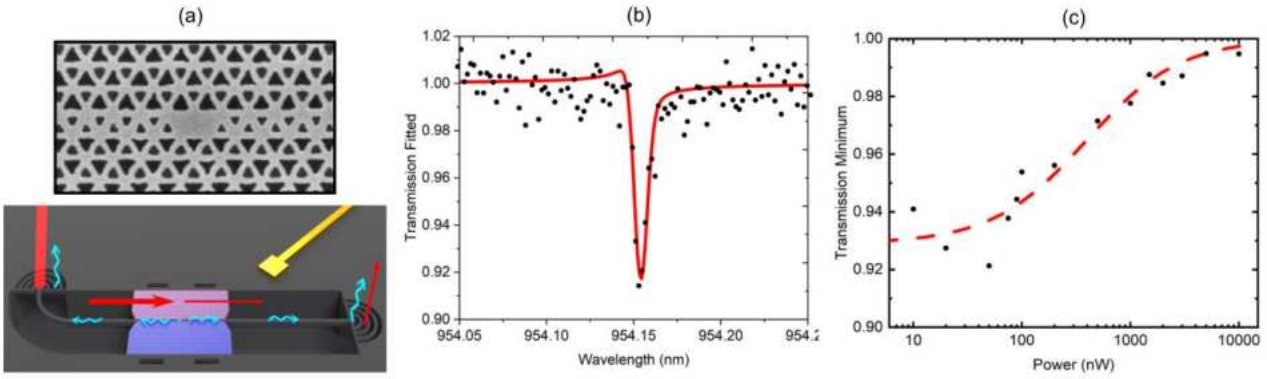

Figure 2: (a) SEM image of the valley-Hall waveguide defect, with a render of resonant transmission scheme positioning pump laser and far-field collection at separate out-couplers. (b) An example of transmission spectra observed at 50nW power at λ= 954.16nm with a fitted maximum dip of ~8%. (c) transmission dip from 10nW to 10μW, demonstrating non-linear power dependence. The dashed red line fits experimental data, showing saturation and plateau of transmission.

Non-Linear Quantum Optics at a Topological Interface: Addressing the integration challenges, we stabilize the charge environment for quantum dots within defects, achieving single-photon resonance fluorescence. We also develop an efficient interface for topological-conventional mode conversion, bridging the gap between novel topological designs and traditional photonics technologies. These collective works significantly advance the field of integrated quantum photonics, providing a robust framework for exploring non-linear optical phenomena and enhancing the design of next-generation photonic devices.

Abstract: Magnetic chirality, a material characteristic that originated from simultaneous time-reversal symmetry breaking and spatial inversion symmetry breaking. Here, we report an investigation on an artificially chiral magnet, which processes magnetic chirality and exhibits substantial magnon nonreciprocity at GHz frequencies at room temperatures.

Chirality, a characteristic of objects being nonsuperimposable mirror images of each other, plays a crucial role across various scientific disciplines and technology fields [1-2]. Magnetic chirality arises from broken spatial-inversion symmetry and time-reversal symmetry, which occur simultaneously in specific noncentrosymmetric crystals [3-4], and innately manifests nonreciprocal transmission of signal. Natural crystals possess the relevant magnetic ordering at low temperatures and require a complex fabrication process, consequently, leading to lack of room-temperature applications. In this study, we designed and created artificial chiral magnets (ACMs). By combining a mass production methodology, i.e., atomic layer deposition (ALD) of a ferromagnetic metal, and polymeric scaffolds produced by two-photon lithography (TPL) [5], we prepared screw-like tubular structures with left-handedness (LH) and right-handedness (RH) (Fig. 1a). The polymer (gray) had an outer diameter of 2 μm and was conformally coated with a 30 nm thick Nickel shell using ALD. The produced shell contains helical reliefs (helix regions) alongside a uniform tubular segment (tube region). When a magnetic field +H is applied parallel to ACMs, the magnetization in the tube region aligns longitudinally while aligning spirally in the helix region, forming screw-like (helical) spin textures. The handedness of the textures follows the corresponding structural chirality, generating opposite polarized toroidal moments $\mp\tau$ in LH and RH-ACMs, respectively (Fig. 1b). In the following we show that the different toroidal moments induce inverse nonreciprocities for magnons (Fig. 2).

The spin dynamics were investigated by μ-BLS with high spatial resolution. The samples were mounted on a piezostage and positive and negative external magnetic fields were applied in different orientations along the z-axis. The long axis of ACMs was positioned parallel to the z-axis. The green laser (wavelength: 532 nm) with a power of 3 mW was focused on the surface of the ACM using a 100x objective lens with a numerical aperture of 0.75. By analyzing Stokes and anti-Stokes scattering processes of thermal magnons with laser light, we identified asymmetries in resonance frequencies Δf and intensities of BLS peaks ΔI as shown in Fig. 2. In Fig. 2, the magnon spectrum obtained on the RH-ACM exhibits a stronger intensity of the Stokes peak compared to the anti-Stokes peak. The LH-ACM exhibits an opposite asymmetry. We attribute the observed nonreciprocity to asymmetric dispersion relations induced by the screw-like spin textures, which trigger mirrored nonreciprocities between LH and RH ACMs in Fig. 2.

We have successfully designed and synthesized ACMs. They showed asymmetric thermal magnon spectra attributed to the handedness-dependent magnon nonreciprocity. As evidenced in Fig. 2, by employing structures with mirrored handedness, a reversed asymmetric magnon spectrum is detected. We have observed that, in

spatial scanning spectra, the handedness and magnetic field polarity dependent asymmetries [6], which unveils the magnetic chirality of ACMs. The characteristics of the ACMs hence mimic reciprocities of intrinsic chiral magnets. The observed pronounced frequency shift (~ 1 GHz) and intensity difference (~ 50%), establishes its effectiveness for future high-frequency microwave electronics at room temperature and illuminates the potential of 3D assemblies of ferromagnetic materials.

Satisfaction of circular polarized Laguerre-Gaussian mode generation requirements by mid-infrared thermal emission metasurface

K. Sekiya[1*], and Y. Nishijima[1]

[1]Yokohama National University, Japan
[*]corresponding author: sekiya-kazuma-hx@ynu.jp

Abstract: We studied the design methodology for generating circularly polarized Laguerre-Gaussian beams using a metal-insulator-metal structured mid-infrared metasurface. As a result, it suggested that a two-layered meta-molecule with optimized three-dimensional chiral structure could control circular dichroism and geometric phase, indicating the potential realization of compact devices emitting ultra-narrowband mid-infrared radiation.

Introduction: The circularly polarized Laguerre-Gaussian (CP-LG) beam is a complex light mode that couples the orbital angular momentum (OAM) of a light vortex (or Laguerre-Gaussian beam) with the spin angular momentum (SAM). It has been demonstrated that due to the in-plane light-induced forces (IP-LIF) originating from the SAM spin direction, this light vortex exhibits circular dichroism and allows for velocity modulation of trapped particles[1]. The realization of a compact device emitting CP-LG beams is expected to bring significant progress in structural analysis and optical manipulation techniques.

The metal-insulator-metal nanostructures (MIM) multi layered mid infrared meta-surface we have proposed allows for microscale design and control of thermal radiation states by appropriately defining and adjusting the shape of meta-molecules placed on the meta-surface. To generate CP-LG beams, two requirements are necessary: spin selectivity and a 2π phase shift on the wavefront. It has been previously demonstrated that a three-dimensional chiral symmetric structure of meta-molecules exhibits circular dichroism[2]. Building upon this idea, we defined a chiral structure by stacking meta-molecules into two layers and applying orientation angles and aimed to improve circular dichroism and phase control through structural optimization.

FDTD Simulations: The two meta-molecules are designed both rectangular, and their shapes are determined by nine parameters (size of each meta-molecules, distance between meta-molecules, rotation angle of upper-layer meta-molecules relative to lower-layer meta-molecules, and meta-molecule periodicity). In the optimization process, we set the objective function to maximize extinction of right circularly polarized light (conversely, a maximized left circularly polarized metamolecule can be defined by taking the mirror symmetry of the optimized structure). This study was validated using electromagnetic field analysis simulations software based on the finite-difference time-domain (FDTD) method.

Results and discussions: As a result, the optimized meta-molecules exhibit different shape parameters between the upper and lower layers, demonstrating three-dimensional chirality. In wideband simulations, it achieved an absorption rate $\mathcal{A}$=0.86 and a circular dichroism absorbance CD=0.4 at wavelength λ=5.1 μm. This means the possibility of the emission of elliptically polarized light with an ellipticity of 0.4 and single-wavelength radiation. Additionally, π range rotation of meta-molecule about the radiation axis revealed a gradual 2π shift in radiation phase while maintaining the constant absorption wavelength. This result aligns with the theory of phase delay due to changes in polarization state indicated by the Pancharatnam-Berry (PB) phase[3]. By fitting the phase state to the rotation, it is practically feasible to achieve 100% phase coverage.

Conclusions: We designed meta-molecule structures that simultaneously satisfy the requirements of circular polarization and optical vortex properties, demonstrating the possibility of radiating CP-LG beams in the mid-infrared region by representing phase gradients based on geometric phase on the meta-surface. Future work will explore the feasibility of realizing CP-LG beams as small-scale devices through the observation of their topological charges and evaluation of physical prototypes.

Abstract: This study introduces a wavelength-multiplexed orbital angular momentum holographic device capable of encoding and reconstructing multiple holographic images using light of specific wavelengths and topological charges. The device, demonstrating significant storage potential, successfully encoded and reconstructed nine distinct images under defined conditions.

Metasurface is an advanced optical component characterized by its structure, which is composed of one- or two-dimensional array of nanostructures[1]. Metasurface plays the role of an exceptional platform for various optical applications. In particular, metasurface-based holograms have attracted significant attention due to their subwavelength pixel pitch, complex amplitude manipulation, and multiplexablity.

In this work, we introduce an orbital angular momentum (OAM) metasurface that employs wavelength and OAM multiplexing for the creation of holograms capable of preserving OAM properties within the image plane. When an OAM beam illuminates the hologram, holographic image is reconstructed through the convolution of the original image and Fourier transform of a helical wavefront, which is characterized by a doughnut-shaped intensity distribution and a spiral phase profile. The intensity profiles of pixels in the holographic image depend on the topological charges of the incident OAM beam, leading to a distinctive doughnut-shaped pixel intensity distribution as topological charges increase.

To encode these OAM-conserving holographic images onto a metasurface, precise sampled images are achieved through multiplication of object images with 2D Dirac comb function [2]. This technique effectively prevents interference between neighboring pixels in reconstructed holographic images. The sampling parameters are specifically chosen according to the largest radius of the kernel in the image plane, ensuring each pixel preserves the properties of the incident OAM beam. Additionally, OAM selectivity is accomplished by combining the hologram with a spiral phase profile of an opposite topological charge to the incident beam, allowing for the reconstruction of holographic images with peak intensity for specific OAM modes, as shown in Fig. 1(a).

We further explore the design and implementation of an OAM-selective and multiplexing meta-hologram, as shown in Fig. 1(b). By employing a modified Gerchberg-Saxton algorithm, the phase profile of the meta-hologram is optimized to facilitate holographic images. Moreover, we demonstrate the feasibility of multiplexing holographic images for various OAM modes on a single metasurface, considering wavelength dependencies to ensure consistent image sizes across different wavelengths (Fig. 1(c)). The proposed metasurface achieves full-color OAM holographic display capabilities, showcasing the potential for advanced holographic displays and

optical data storage solutions.

Abstract: In this study, we comprehensively investigate the resonant exceptional point (EP) in terahertz metasurfaces, which directly realize the singularity of complex frequency requiring one measurement only. Our approach not only provides a novel perspective to understanding EP in non-Hermitian terahertz metasurfaces but also offers alternative methods for terahertz high-sensitivity sensing.

Studies on EP in terahertz metasurfaces mostly focus on the scattering exceptional point (EP).[1] However, due to the highly sensitive characteristics of the EP itself, errors induced by multiple measurements are inevitable in practical sensing applications by this type of EP. Thus, our interest lies in exploring another form of EP in the terahertz region that requires one measurement only. As shown in Fig. 1, the resonant EP bilayer metasurface structure we designed consists of two layers of non-equal metal rods. Figure 1c and 1d visualize the variation of the Riemann surface consisting of the real and imaginary parts of the intrinsic complex frequency with respect to the longitudinal (*dy*) and transversal (*dx*) parameter space, and it can be clearly seen that the EP points at the crossings.

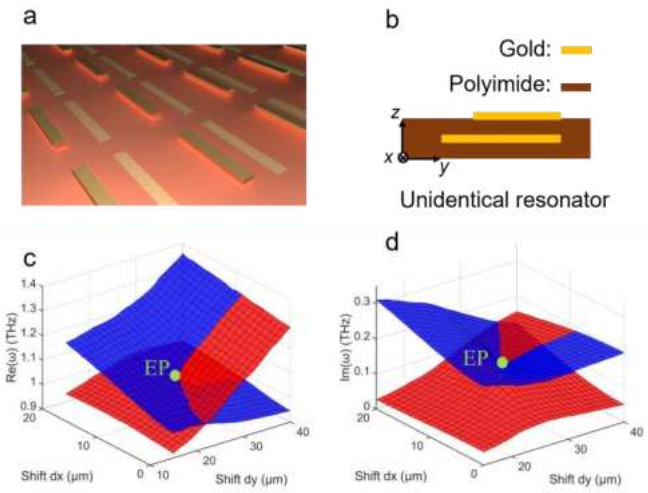

Fig. 1. (a) Schematic diagram of proposed bilayer metasurface structure with resonant EP. (b) Unit cell of unidentical resonators. (c) Real and (d) imaginary parts of the eigenmodes of the identical resonators.

In order to experimentally demonstrate the existence of EP, we characterized three groups of samples with four different values of *dy*. The frequency response spectral results of these metasurface samples were characterized by a fiber-based THz time-domain spectroscopy. Transmittance can be extracted from $T(\omega) = \left| E_{sam.} / E_{ref.} \right|^2$, in which $E_{sam.}$ and $E_{ref.}$ are the Fourier transforms of the time-domain electric field

measurements of the EP metasurface sample and reference, respectively.

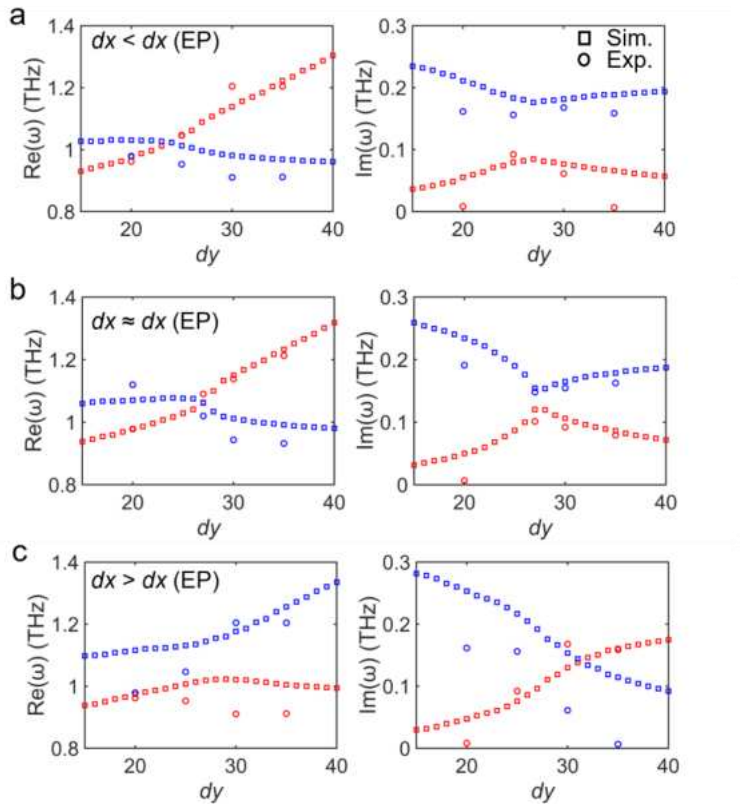

Fig. 2. Experimental observation of EP in metasurfaces. Experimental (circles) and simulated (squares) complex frequencies as a function of *dy* for (a) *dx* = 5 μm, (b) 9.5 μm, and (c) 15 μm. Blue and red distinguish two modes.

As shown in Fig. 2, the two-dimensional representation of the Riemann surface in Fig. 1 provides a more intuitive observation of the phase transition from PT symmetry to PT symmetry breaking. In Fig. 2a, we observe the intersection of real part of eigen-frequencies and the absence of intersection of imaginary part of eigen-frequencies at *dy* = 24 μm, indicating that the system is in the PT symmetry broken phase. In Fig. 2b, both real and imaginary part intersect at *dy* = 27 μm, indicating that the system is at EP. In Fig. 2c, we observe the absence of intersection of real part of eigen-frequencies and intersection of imaginary part of eigen-frequencies around *dy* = 32 μm, suggesting that the system is in the PT-symmetric phase. Thus, we demonstrate the ability to achieve a singularity of complex frequencies directly. Our EP proposal contributes to further understanding non-Hermitian physics in terahertz metamaterials/metasurfaces, as well as providing a novel approach for highly sensitive detection and biosensing and other functional devices.

Abstract: We propose Janus bound states in the continuum (BICs), a new topological defect with asymmetric topological charges for upward and downward radiation. Janus BICs enable the realization of chiral BICs and offer a novel approach to control momentum-space phase singularities and enhance direction- and spin-dependent asymmetric light-matter interactions.

We introduce the concept of Janus bound states in the continuum (BICs), which is a new type of topological defect featuring asymmetric topological charges in upward and downward radiation. By harnessing the unique topological property of Janus BICs, we achieve chiral BICs and gain additional freedom in controlling phase singularities. Specifically, Janus BICs are produced by introducing up-down mirror symmetry breaking to merge multiple circularly polarized states (C points) with the same topological charges into a symmetry-protected BIC on only the downward side. Consequently, the topological charge of the BIC on the downward side is modified, while the upward side remains unaffected, forming a Janus BIC. To achieve chiral BICs, we further introduce in-plane mirror symmetry breaking to tune two C points with the same topological charge and identical handedness on the upward side to the Janus BIC. This process ends in a Janus chiral BIC with large intrinsic chirality and an infinite Q factor. Janus BICs can induce distinct Pancharatnam–Berry phase singularities in momentum space for different incident channels, providing a new approach to control optical angular momentum. Janus chiral BICs hold promise in enhancing direction-dependent and spin-dependent asymmetric light-matter interaction, opening new pathways for improving chirality-dependent operation for on-chip devices.

Versatile Metaphotonic Singularities: Multidimensional, Optomechanical, and Topological Aspects

Tianyue Li[1], Shuming Wang[1], and Shining Zhu[1]
[1]National Laboratory of Solid-State Microstructures, Collaborative Innovation Center of Advanced Microstructures, School of Physics, Nanjing University, Nanjing, 210093, China
[*]corresponding author: leos4a@163.com

Abstract: This presentation highlights metaphotonic singularities in nanophotonics, emphasizing their multi-dimensional nature and optomechanics applications. Using spin-dependent metasurfaces and Jones matrix innovations, we show dynamic control and transformation of singular light beams, advancing nano-device development and on-chip optical manipulation in metaphotonic physics.

Photonic singularities refer to those undefined or discontinuous points in structured light fields or eigen-spectra in the periodic metastructures, and have been extensively studied across various nanophotonic systems. In the field of metaphotonics, investigating photonic singularities at sub-wavelength scales in localized near-fields or propagating into far-fields pave the way to enriched light-matter interactions, enabling multi-dimensional singular phenomena. This is further analyzed from a topological perspective and applied in the field of momentum transfer light-matter interactions, such as optomechanics. In this presentation, we will first discuss the multi-dimensional characteristics of phase singularities in the generalized spin-orbit conversion, caused by three-dimensional (3D) polarization field interference in non-paraxial light fields, as shown in Fig. 1a. This is dynamically observed through specially designed spin-dependent metasurfaces, enabling switchable Bessel beam generators[1]. Then, to further shape the form of singularities on metasurfaces, we not only developed the upper limit of the degrees of freedom of the Jones matrix but also proposed a local and global phase design method, theoretically and experimentally demonstrate the structural transformation of non-diffracting singular beams along optical trajectories, i.e., from circular Airy beam to Bessel beam, as depicted in Fig. 1b. Hence, we considered further methods for generating generalized singular beams, extracting and encoding the intensity profile of any figures onto the azimuthal phase gradient of a metasurface (Fig. 1c), creating a multifunctional generalized angular momentum plate for singular beam generation, representing a paradigm shift in phase singularity optical devices, extending beyond the conventional J-plate[2] and T-plate[3]. In its application in optomechanics, we focus on an integrated multifunctional optical tweezer-spanner, allowing for rotation and optical capture of nanoparticles, significantly reducing the volume through multi-dimensional characteristics. By combining the Mie scattering process with the birefringent properties of nanoantennas, we established a polarization multiplexing function capable of phase processing two independent dimensions of polarization, achieving simultaneous trapping and rotation of particles[4], as shown in Fig. 1d. This method is extended to generate programmable optical spanner and generalized vortex beams. Importantly, deformable metasurfaces can serve as artificial particles, enabling car-like motion or 'Metavehicles,' allowing arbitrary movement on a two-dimensional (2D) plane without the need for tightly focused structured light beams, anticipating to provide opportunities for developing on-chip optical manipulation (Fig. 1e)[5]. Meanwhile, the new ultrafast metavehicles reduce the need for additional incident fields, and their complete in-plane control heralds a new chapter in optical meta-manipulation. For singularities in the eigen-spectrum of metasurfaces, we focused on the Dirac singularity in 2D flat photonic structures, flexibly coupling six-folded rotation symmetric (C_6) honeycomb

lattices and C_3-symmetric triangular lattices with topological properties, as illustrated in Fig. 1f. These are combined into various domain wall photonic hybrid topological polycrystalline circuits, achieving multi-dimensional localized edge-corner modes at different frequencies and spins. These findings represent just the tip of the iceberg in the study of metamaterial photonic singularities. We believe that exploring the connections between photonic singularities will not only advance fundamental research in multi-dimensional light fields but also further promote the application of on-chip integrated optical devices and optical meta-manipulation.

Abstract: We study the topological feature of the momentum bandgap (PT-broken regime) with a simple 1D binary photonic crystal. Our theory shows that its momentum band (PT-exact regime) can exhibit nontrivial band topology, guaranteeing the existence of a robust temporal boundary state localized in time but extended in space.

Recently, many topological concepts have been extended and rebuilt in non-Hermitian system. However, most previous works are concerned with the topologies of energy/frequency bands and the associated in-gap spatial boundary states. From another perspective, PT-broken regimes in non-Hermitian band structure can be viewed as a momentum bandgap if we take Bloch k as the eigenvalue instead of energy/frequency. Here, we study the topological feature of the momentum bandgap (PT-broken regime) with a simple 1D binary photonic crystal as an example. Our theory shows that its momentum band (PT-exact regime) can exhibit nontrivial band topology, manifested as a local geometric phase. This guarantees the existence of a topological temporal boundary state localized in time but extended in space. The robustness against defects or disorders is numerically demonstrated by full-wave simulations. Although our idea is demonstrated in a simple 1D PT-symmetric photonic system, it can in principle apply to any PT-symmetric or pseudo-Hermitian system. Our findings would extend and supplement the current understanding of topological spatial edge states and provide a new perspective on topological physics in non-Hermitian systems.

Evanescent Wave Manipulation Based on Non-Hermitian Physics

Huanan Li*

MOE Key Laboratory of Weak-Light Nonlinear Photonics, School of Physics, Nankai University, Tianjin 300071, China
*corresponding author: hli01@nankai.edu.cn

Abstract: We present the concept of parity-time (PT) symmetry and spectral singularities as applied to evanescent waves, along with the first experimental verification of PT symmetry for evanescent waves using an acoustic platform. Our study sheds light on the opportunity to manipulate evanescent waves through non-Hermitian physics.

In the broad context of non-Hermitian physics, the concept of parity-time (PT) symmetry has unlocked remarkable possibilities for novel wave manipulations that are not unattainable within the confines of Hermitian systems [1]. In unbounded scattering systems with PT symmetry, the system response is characterized by a scattering matrix S which satisfies the fundamental relation $PTSPT = S^{-1}$ [2]. Traditionally, PT symmetry in scattering settings has been applied to propagating wave manipulation, enabling novel wave manipulations such as laser-absorber modes and anisotropic transmission resonances (ATRs). PT-symmetric systems operating in laser-absorber mode can simultaneously act as lasers and coherent perfect absorbers (CPAs), with this dual functionality experimentally confirmed in both optical and radio-frequency domains.

First, we propose an intriguing pathway to PT symmetry that leverages the incidence of evanescent waves on anti-PT-symmetric structures, which interestingly does not necessarily require the presence of gain [3]. Utilizing two exemplary anti-PT symmetric configurations, one integrating coupled resonators and the other photonic heterostructures [Fig. 1(a)], we demonstrate that PT-symmetric responses can be revealed via evanescent wave excitations. These excitations enable the generalized S matrix to adhere to the same fundamental relationship that govern conventional PT symmetric systems with balanced gain and loss when excited by propagating waves [Fig. 1 (b)]. In the system of anti-PT symmetric coupled resonators, the detuning of resonance frequencies between the dimer defect resonators functions as an effective mechanism of gain and loss. Then we introduce a versatile coupled-resonator acoustic waveguide (CRAW) system to observe evanescent wave within a bandgap [Fig. 1(c)], and demonstrate the PT-symmetric scattering response from an engineered anti-PT symmetric dimer defect under stationary-state evanescent wave incidence [4]. By examining the generalized scattering matrix in the evanescent wave regime, we observe hallmark PT phenomena—including phase transitions at an exceptional point, ATRs, and laser-absorber modes—in systems without the customary balanced gain and loss.

Finally, based on parity-time symmetry, we introduce the concept of spectral singularities (SSs) for evanescent waves, and explore their exotic features [5]. SSs emerge at isolated real frequencies when the scattering coefficients of a system diverge, producing scattering anomalies in non-Hermitian systems. So far, the emergence of these exotic SSs has been restricted to propagating waves. Here, we extend them to evanescent waves and show that, due to the decoupling between energy transport and scattering strength for evanescent waves, an evanescent wave SS with diverging scattering coefficients can support arbitrary magnitude (infinite or finite) and reversible energy flow [Fig. 1(d)], depending on how the evanescent wave SS is approached in parameter space. Our results shed light on the opportunity to manipulate structured waves for extreme wave-matter interactions based on non-Hermitian physics, which may be extended to nanophotonics.

Abstract: Directional light emission at subwavelength scale is key for quantum information processing and optical imaging in photonics and biology. Here, we present unidirectional emission of unpolarized luminescence in a spatially symmetric nanopillar lattice assisted by photonic orbital angular momenta (OAM), providing a tunable and large directional emission method for nanoscale optical control based on photonic OAM.

Directional light emission at subwavelength scale is key for quantum information processing and optical imaging in photonics and biology. Spin-orbit interaction of light is widely adopted for dynamically tuning the circularly polarized photoluminescence direction. However, the directional emission governed by spin mechanism is challenging for most luminescence materials, which typically generate unpolarized luminescence. Here, we present unidirectional emission of unpolarized luminescence in a spatially symmetric nanopillar lattice assisted by photonic OAM, providing a tunable and large directional emission method for nanoscale optical control based on photonic OAM as an additional degree of freedom.

Abstract: We introduce our recent works on chalcogenide phase change materials for tunable Tamm plasmonic response for bio-sensing, color coding, wide-angle perfect absorption and light beam switching, as well as van der Waals materials for electrically tuning of flat lens focusing, refractive index and near infrared plasmonic resonance.

Metaoptics constructed by sub-wavelength structures on a thin film has attracted tremendous interests for its great potentials over conventional refractive optics. Tunable metaoptics by employing active optical materials responding to external stimuli could further enhance the capability and adaptability of the optical system.[1] Chalcogenide alloys have phase changes between amorphous and crystalline with temperature changing across the phase transition temperature, which induce both refractive index and electrical conductivity changes and have been applied to diverse tunable micro-nano-optical devices across wide spectral range. [2-4] The unique properties of 2D materials such as the strong quantum confinement, bandgap tuning and flexible integration with different substrates bring many new opportunities to photonics and tunable metaoptics.[5] In this talk, I will give a brief review of tunable and reconfigurable metaoptics followed by introducing some of our recent works in this area using phase change and van der Waals materials.

We use low-loss Sb_2S_3 to construct a tunable Tamm plasmon polariton (TPP) cavity as a scalable sensing platform for surface enhanced resonance Raman spectroscopy (SERRS). By tuning the TPP resonance to match the laser excitation wavelength with the plasmonic resonance and the absorption peak of the biomolecules such as cardiac Troponin I protein, our SERRS is shown to be able to greatly reduce the detection limit.[6] Combining a broad-band and a narrow-band absorber made up of Sb_2S_3, we show tunable optical Fano resonance in the visible wavelength and a nano-optical coatings for optical steganography.[7] A wide-angle (0° to 70°) large spectral range tunable perfect absorption through critical coupling is achieved by utilizing a two-layer stack consisting of a high refractive index Sb_2S_3 on a reflecting silver layer. [8] We also demonstrate a transmission mode polarization-insensitive beam switching metasurface based on $Ge_2Sb_2Te_5$ at telecommunication wavelength with a switching angle of 15° and directivity of 82.4%. [9]

By manipulating the carrier density and interaction of excitons in 2D transition metal dichalcogenides, we show the large phase and refractive index tuning in a monolayer WS_2 assisted by optical cavity effect.[10] Electrostatically tunable near infrared plasmonic resonance around wavelength of ~1.67 μm in few-layer $NbSe_2$ is observed, which offers strong field confinement as compared to other near-IR plasmonic materials due to the atomic thickness.[11] A flat lens made of van der Waals ferroelectric material that can have its focusing been modulated by electrical bias through electro-optic effect will also be introduced.[12]

Machine-learning aided optimization for metasurfaces

Wei Ma[1*]

Abstract: We present an algorithm-driven strategy to automatically design metasurfaces for multi-dimensional light manipulation. Our metasurface design pipeline comprises iterative optimization steps, integrating gradient-based optimization or heuristic algorithms enhanced by machine learning models. This approach has been experimentally validated using multi-channel holograms, focusing lenses, and guided light control.

Recently, with the aid of intelligent algorithms, the nanophotonic community has witnessed tremendous development in the design, measurement and application of nanophotonic devices and systems. The core impetus is the prevalence of inverse design methods, which convert a design problem into an optimization problem, and solve it with various algorithms automatically 1.

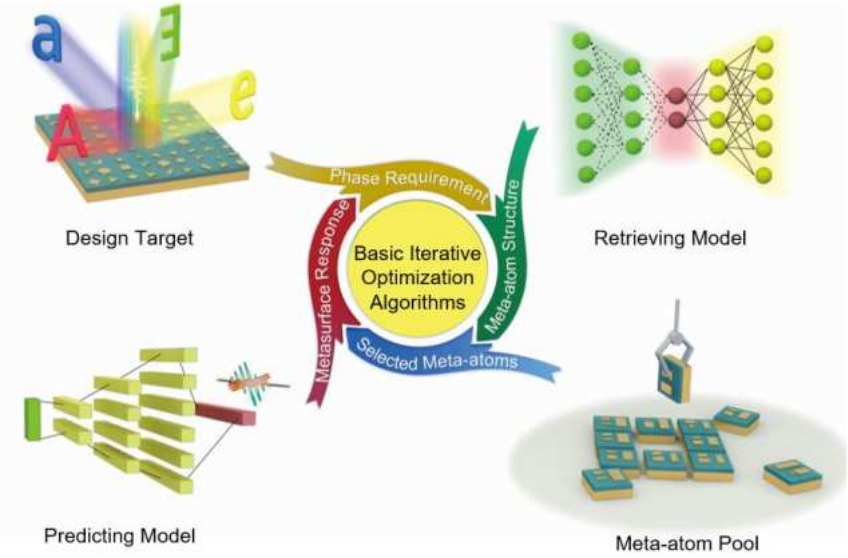

Figure 1 General end-to-end design pipeline for metasurface enhanced by machine learning

In this talk, we conceptually propose and experimentally demonstrate an end-to-end design pipeline with embedded statistical machine learning models for automatic design of metasurfaces. Instead of a two-step design routine including designing each meta-atom through a parameter sweep and then arrange them periodically, we resort to statistical machine learning as the bridge that directly links the structural parameters of each single meta-atom and the target metasurface performance. The machine learning model is composed of several probabilistic inverse retrieving models and a deterministic predicting model, which accurately capture and faithfully reproduce the statistical features of the high-dimensional joint distribution of meta-atom structures and their optical responses. Consequently, instead of artificially decoupling the complex optical response into independent sub-targets, a system-level multi-object optimization can be implemented to fully exploit the design space to push the design capacity to its physical limit. Under this design scheme, we experimentally demonstrated several design examples of metasurfaces including multi-channel holograms[2], wavelength-multiplexed light focusing[3], guided-wavefront manipulation[4], and ultra-compact fully etched grating

coupler.[5]

Abstract: Metasurfaces exhibit exceptional abilities to manipulate the amplitude, phase, polarization, and spectral properties of light fields. These mechanisms for light field control can be extended to other material systems like liquid crystals, facilitating the creation of novel functionalities and devices.

Metasurfaces are artificial planar structural materials with subwavelength-scale features, enabling precise and flexible control over various parameters of incident electromagnetic waves such as amplitude, phase, polarization, and spectral characteristics at subwavelength scales.[1] This capability has garnered significant attention in recent years, and one notable advantage of metasurfaces over traditional optical elements is their ability to simultaneously manipulate multiple optical parameters, allowing for the design of more complex optical components.

Liquid crystals (LCs) possess unique optical properties, including polarization control and sensitivity to external stimuli, making them widely applicable in displays, optical communications, biosensing, and spatial light modulations. Through the manipulation of LC directors' orientations using an external electric field, LCs exhibit electro-optic effects, resulting in the formation of pixels with varying optical amplitudes/intensities. In addition to intensity modulation, phase modulation in LCs is typically achieved through optical path differences and depends on the thickness of the LC layer. Recently, continuous phase modulation in LCs has been achieved via the Pancharatnam–Berry (PB) phase, stemming from the spin–orbit interaction of light in inhomogeneous anisotropic media.[2]

Given their similarities in light field control properties, metasurfaces and liquid crystals enable the development of novel functional devices with similar yet distinctive characteristics[3,4]. This report will introduce multi-channel image display devices, all-optical multi-order multiplexing differentiation, and LC-based spectral singlet techniques.

Metalens for Accelerated Optoelectronic Edge Detection under Ambient Illumination

Shuai Wang

Qingdao Innovation and Development Center, Harbin Engineering University, Qingdao, China
*corresponding author: swang@hrbeu.edu.cn

Abstract: Analog optical edge detection systems usually rely on coherent laser sources for illumination, which significantly restricts their use in imaging tasks with ambient illumination. Here, we demonstrated a metalens-assisted imaging system that can allow optoelectronic edge detection under ambient illumination. It holds great potential for image processing under ambient illumination.

Compact optical systems for edge detection have been realized using a metasurface or multilayer films to mimic spatial differentiation[1-4]. Nonetheless, one of the major challenges of most demonstrated optical edge detection systems is that they typically require coherent laser light for illumination. For a spatially incoherent imaging system[5], the relationship between the output image $I_{out}(k)$ and input object $I_{in}(k)$ in the spatial frequency domain is described as,

$$I_{out}(k) = T(k)I_{in}(k), \quad (1)$$

where $T(k)$ is the optical transfer function, serving as the autocorrelation function of the amplitude transfer function. It is noteworthy that $T(k)$ always reaches maxima at $k = 0$. This contradicts the requirement of a vanishing transfer function at the center of the spatial frequency for image differentiation[5].

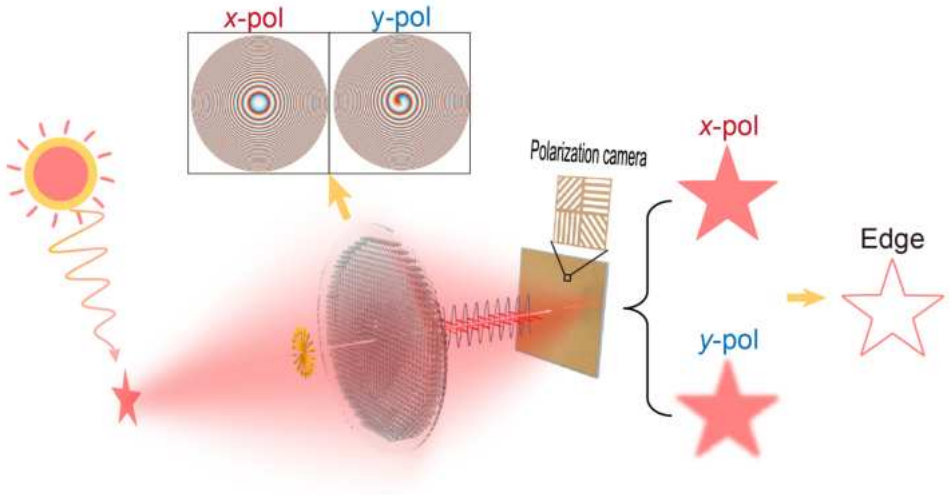

Figure 1. Schematic illustration of using polarization-multiplexed metalens for accelerated isotropic edge detection under ambient sunlight illumination.

Here, we proposed a polarization-multiplexed metalens for edge detection under ambient incoherent illumination shown in Fig.1. The metalens is designed to generate a pair of drastically different optical transfer functions (OTFs) for light with two orthogonal linear polarizations. Subsequently, an effective OTF can be synthesized via digital subtraction between the two OTFs, resulting in an isotropic high-pass filtering response. After multiplication between the polarization-dependent OTFs with the target object, the *x*- and *y*-polarized

images can be captured by a commercially available polarization camera in a single shot. For an image with $N\times N$ pixels, the computational complexity of the optoelectronic edge detection system with the point-by-point digital subtraction is $O(N^2)$. In contrast, for digital image processing using a convolution kernel with $a\times a$ pixels mimicking high-pass filtering response, it requires a point-by-point multiplication followed by a one-by-one summation, resulting in a computational complexity of $O(2a^2N^2)$. This reduction by a factor of $2a^2$ results in accelerated isotropic image differentiation. Therefore, the proposed system, while being extremely compact, can greatly reduce the computational complexity for edge detection under ambient incoherent illumination.

We integrated the polarization-multiplexed metalens with a polarization camera and experimentally demonstrated single-shot edge detection of indoor and outdoor scenes, including a flying airplane, under ambient sunlight illumination. The proposed system showcased the potential of using polarization multiplexing for the construction of complex optical convolution kernels towards accelerated machine vision tasks such as object detection and classification under ambient illumination.

Strong light-matter interactions in plasmonic/dielectric metasurfaces

Observation of Projective Embedded Topology and Trijunction-Induced Topological State in Acoustic Lattices

Abstract: Contrary to dimension increment for weak topology, we demonstrate dimension reduction in insulators with projective crystal symmetry to construct embedded topology. Based on the one-dimensional strong topology at interfaces between two-dimensional trivial insulators, we realize a trijunction-induced topological state on tight-binding and acoustic platforms, thus enriching band topology in subdimensions.

Dimension plays a significant role in topological classifications [1]: varying dimension without changing symmetry conditions can result in distinct topology. For instance, dimension-increment-induced weak topology is constructed by stacking strong topological insulators from low dimensions. On the contrary, dimension reduction can also induce new topology by constructing (n-1)-dimensional strong topological insulators, even from an n-dimensional trivial insulator [see Fig. 1(a)]. This topology is called "embedded topology" [2]. However, symmetries that support embedded topology is still unclear.

Projective crystal symmetry, arising from the time-reversal-invariant gauge field, has contributed to new topological phenomena like Möbius-twisted edge bands [3]. Although dimension still plays a crucial role in characterizing the resultant novel topological phases, there is no theoretical and experimental work on the effect of dimension reduction under projective crystal symmetry, particularly from the perspective of embedded topology.

In 2D insulators, we demonstrate embedded topology via dimension-reduction-induced 1D strong topological insulators protected by projective crystal symmetry. By restricting to projective mirror symmetry and time-reversal symmetry, 2D insulators are trivial according to the topological classification [1]. We realize the dimension reduction through the formation of the interface between two insulators using the tight-binding model in Fig. 1(b). We begin with insulators A and B whose edge bands form a gapless Möbius twist under projective translation symmetry [2]. After the dimension reduction by connecting to insulator C, the projective translation symmetry is broken, thus gapping out the Möbius edge bands as shown in Fig. 2(a). These two isolated edge bands form a strong 1D insulator protected by projective mirror symmetry and time-reversal symmetry [1], leading to an embedded topological insulator. After connecting two 1D topologically

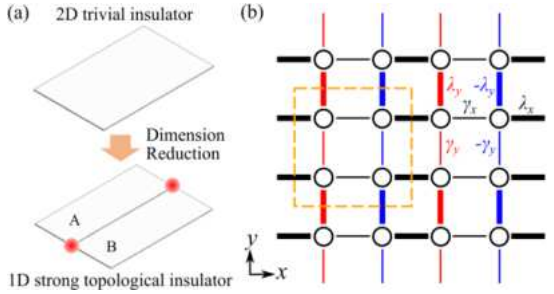

FIG. 1. (a) The effect of dimension reduction on the band topology at the interface. (b) Illustration of the lattice model. The colors and thickness of bonds indicate different real hopping strengths $\gamma_{x,y}$ and $\lambda_{x,y}$. The yellow dashed box denotes the unit cell. Insulators A, B, and C employ hoppings (γ_x, λ_x, γ_y, λ_y) = (1,1,1,10), (1,10,1,1), and (10,1,10,1), respectively.

distinct insulators based on dimension reduction, i.e., forming a trijunction [see Fig. 2(b)], a topological state emerges in the gap and localizes at the trijunction [see Figs. 2(c)-2(d)]. In acoustic lattices, we also perform the experimental observation of the trijunction-induced topological state with similar coupling distributions, as illustrated in Fig. 3.

Based on the projective crystal symmetry, similar constructions of embedded topology can be readily implemented in classical wave platforms and electric circuits. Furthermore, this novel idea can even be generalized to higher-dimensional systems, thus enriching topology in subdimensions.

Broadband sound attenuation under grazing flow via metamaterial-based acoustic liner

Sibo Huang[1], Yong Li[2], Jie Zhu[2], and Din Ping Tsai[1*]

[1]Department of Electrical Engineering, City University of Hong Kong, Hong Kong, China
[2]Institute of Acoustics, School of Physics Science and Engineering, Tongji University, Shanghai 200092, China
[*]corresponding author: dptsai@cityu.edu.hk

Abstract: This work presents a metamaterial-based acoustic liner consisting of a front perforated plate, an air interlayer, and an array of neck-embedded Helmholtz resonators. The presented liner experimentally achieves efficient sound attenuation within 800-3000 Hz in the presence of grazing flows with speeds from 10 m/s to 60 m/s.

Acoustic liners are widely used to attenuate the noise in aero-engines and exhaust mufflers [1-3]. Many conventional acoustic liners can effectively reduce noise for target modes in relatively narrow bands. However, on the one hand, broadband high-efficiency sound attenuation with thin structures remains challenging. On the other hand, in the presence of air flow, the acoustic impedances of the acoustic liners shift significantly along with the varying speeds of the flow, resulting in low tolerance to varying flow speeds and limiting the liners' overall performance in specific applications [1-3].

In this work, we present a metamaterial-based acoustic liner capable of effective broadband sound attenuation in the presence of grazing flow. The presented liner consists of a front perforated plate, an air interlayer, and an array of neck-embedded Helmholtz resonators (NEHRs) [4]. The NEHR array contributes to the thin thickness and provides the desired impedance condition in a wide frequency range. Besides, the front perforated plate maintains the aerodynamic flow smoother near the liner. With a suitable modulation of the acoustic impedance of the metamaterial-based liner in a broad frequency band, efficient broadband sound attenuation can be achieved under various speeds of grazing flows. In the experiment, we designed a sample having a thickness of 40.5 mm, and it can achieve remarkable sound attenuation within 800 Hz to 3000 Hz, both in the absence of air flow and in the presence of grazing flows with speeds from 10 m/s to 60 m/s [5].

Figure 1(a) depicts that the metamaterial-based acoustic liner is placed on one side of a rectangular flow duct to attenuate the sound energy. This situation is consistent with the most common practical application in aero-engines and exhaust mufflers. Figure 1(b) shows the sound-attenuation performance of the designed liner in the frequency band from 800 Hz to 3000 Hz under the condition of 130 dB of sound pressure level and without flow, where the peak value of transmission loss achieves 52.7 dB at 1600 Hz. Experiments were conducted in the flow duct test setup, as shown in Fig. 1(c).

Simulation results clearly demonstrate that the sound energy is strongly dissipated during the transmission along the designed liner. Based on the modulated impedance conditions, the sound-attenuation efficiency at 1600 Hz decreases as the flow speed increases but still remains at a high level, as shown in Fig. 2(a). The more comprehensive results of transmission losses are presented in Figs.2(b)-(c). On the whole, the thin meta-liner keeps high levels of transmission losses in a broad frequency range sustaining a relatively large variation of flow speeds.

Abstract: Acoustic nanocavities with high (above 10 GHz) resonance frequencies can be exploited in sensing and quantum devices. We demonstrate that for a sub-100-nm-thick van der Waals layer, the combination of exciton and Fabry-Pérot resonances, both tuned to the optical probe frequency, grants enhanced photoelastic response demanded in possible single-phonon applications.

Nanoacoustic devices, i.e., nanostructures supporting acoustic resonances, operating in the frequency range of 1-10 GHz, can serve as building blocks in quantum computing, optical cooling and sensing, filtering, and modulation of optical signals [1]. Along with Si-, GaAs-, and GaN-based systems, transition metal dichalcogenides (TMDs) represent a versatile platform for the realization of nanoacoustic devices with the resonances extended towards 0.01-1 THz frequency range characterized by high quality-factors above 10^3, see e.g. Ref. [2, 3]. Contrary to the previous studies, mainly aimed at the increase of acoustic mode eigenfrequency and lifetime, in this work, we focus on achieving highly efficient optical generation and detection of such high-frequency longitudinal acoustic (LA) phonons – breathing modes (BM) – in multilayer TMDs [4].

Here we study the optical generation and detection of high-frequency (10-200 GHz) coherent LA phonons in a WSe_2 nanolayer (Fig. 1a) as a function of its thickness. The sub-100-nm layers of TMD are deposited on top of an opal substrate, which acts as a firm mechanical insulator preventing the escape of high-frequency phonons from the TMDs into the substrate. We experimentally observe acoustically-induced relative changes in the relative reflectivity of more than 10^{-4}, an order of magnitude higher than previously reported in multilayer TMD-based systems [2, 3]. The comparison of the measured time-resolved pump-probe reflectivity signal with the one modeled theoretically reveals a strong dependence of the coherent signal amplitude on the complex photoelastic constant when probing with the wavelength in the vicinity of the exciton resonance in WSe_2. Moreover, bringing the thickness of the layer close to the lowest-order optical Bragg condition (thickness of 81 nm, Fig. 1(b, c)) grants an additional way to resonantly enhance the photoelastic response of such a nanoacoustic device. Our theoretical estimates show that such acoustic nanocavities combining exciton and Fabry-Pérot resonances, both tuned to the frequency of the optical probe, can be employed for operations with single phonons of high (above 10 GHz) frequencies at elevated temperatures.

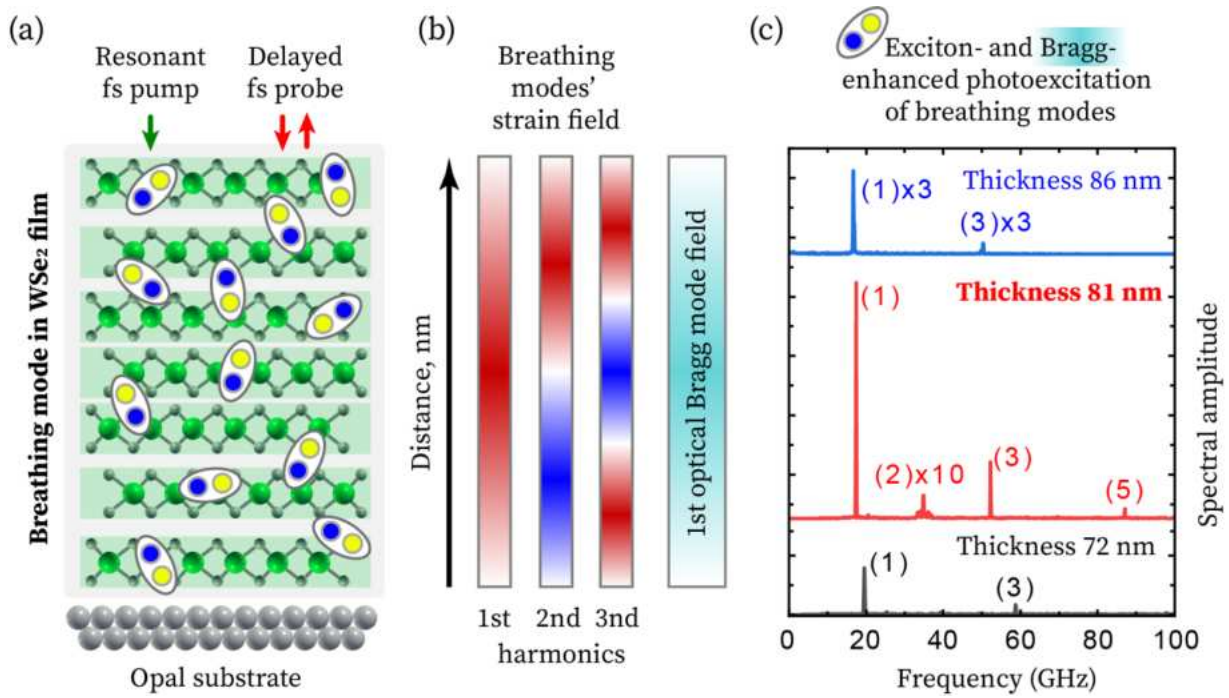

Figure 1. (a) Excitation and resonant detection of BMs in WSe2 film. (b) Distribution of strain field of the three lowest-order BMs. (c) Spectra of the optically detected coherent acoustic signals revealing BMs of the five lowest orders. The amplitudes of the spectral peaks get resonantly enhanced at the film thickness of 81 nm due to the lowest optical Fabry-Pérot mode, whose electric field is shown rightmost in panel (b).

Abstract: Slight variations in the critical dimensions of fabricated nano-opto-electro-mechanical systems (NOEMS) impact their performance by affecting the band gaps and dispersion relation. We study the effect of variability, using COMSOL simulations, on 1-dimensional hypersonic phononic and photonic crystals at telecom wavelength designed to operate at a mechanical frequency of 2 GHz.

The development of a scalable NOEMS device, based on the optomechanical (OM) interaction of GHz phononic and THz photonic elements within extremely small volumes, has received significant attention in recent years due to RF-optical conversion, frequency combs generation and the potential use in quantum technologies [1-3].

The variability of critical dimensions (CDs) resulting from state-of-the-art semiconductor micro- and nano-fabrication process of NOEMS devices is probably inevitable due to its statistical nature below and around 10 nm. Despite rigorous fabrication protocols, slight variations in the CDs during the fabrication process could potentially impact the performance of NOEMS devices. This is of crucial importance since the photon-phonon interactions within the combined unit cells affect the dispersion relations, and any deviation from the expected behaviour based on the design often results in the emergence of dissipation channels for both phonons and photons [4].

We perform a parametric study of subwavelength variability in CDs of 1-D hypersonic phononic and photonic crystals in which the simultaneous confinement of phonons and photons is achieved in a OM nanobeam [5, 6]. The devices are fabricated in nanocrystalline silicon (nc-Si). For this purpose, an amorphous silicon (Si) layer is deposited by low pressure chemical vapour deposition (LPCVD). The thickness control is in the range of 2-5 nm. The amorphous Si film is transformed to nc-Si by annealing, which also leads to stress changes from compressive to tensile in a highly reproducible manner. The most demanding step is the fabrication of the OM nanobeam, based on electron beam lithography and dry etching. An example of a fabricated nanobeam is shown in Figure 1 (a). The most important CDs for the OM operation of the nanobeam include the width of the beam, the diameter of the holes, the alignment of the holes with respect to the stubs, the stubs dimension and shape. Moreover, the slope and smoothness of the sidewalls also affect the OM coupling since the mirror symmetry at the mid-plane is broken. Finally, the nanobeams are released by HF dip or in HF vapour; this is a reproducible process once removal of polymer residuals is under control.

The device in Figure 1 (a) was designed so that each unit cell features a single hole at the center and two symmetric stubs on the sides. These strategically designed air holes within the nc-Si structure are responsible for the photonic gaps. Likewise, the stubs in the waveguide control the phononic band gaps and stubs design aims at realization of a full phononic bad gap at all the k-values. The band structures for photonic and phononic modes in the cavities of the nanobeams are computed by Finite-Element Method (FEM) via the COMSOL Multiphysics software. To facilitate this analysis, Bloch-Floquet periodic boundary conditions are applied to the sides of the

unit cell to determine the band structures. Parameter ranges used to obtain the effect of variability are: air holes diameters from 250 nm to 320 nm, stubs lengths from 450 nm to 550 nm, stubs widths from 200 nm to 300 nm, air hole position with off-centre deviations from 0 to 7 nm and sidewall angles from 90° to 74° on the hypersonic and photonic band gap.

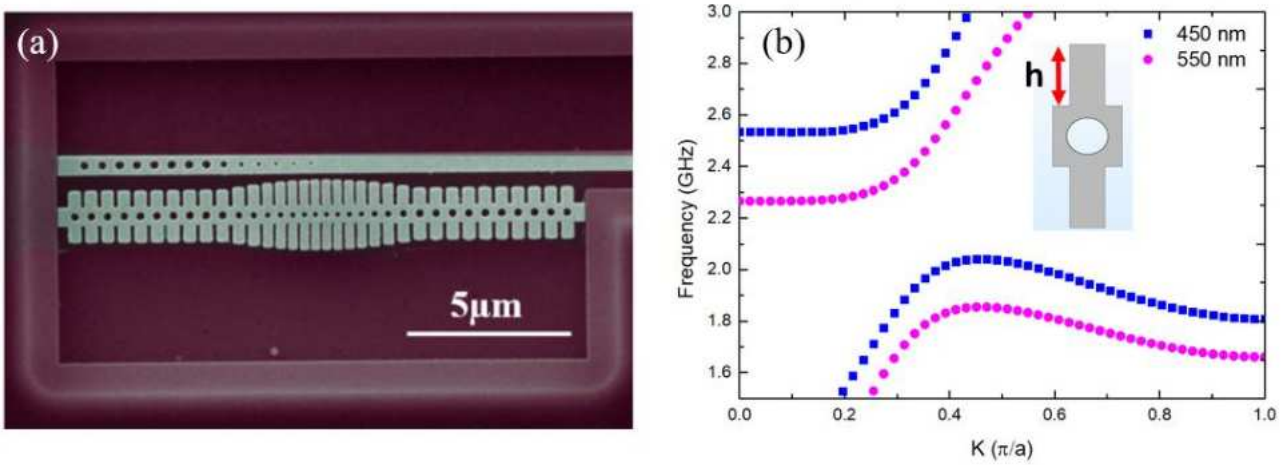

Figure 1: (a) SEM image of a nc-Si suspended optomechanical nanobeam and an integrated optical waveguide for 2 GHz operation. (b) Phononic band structure for stub lengths equal to 450 nm (blue squares (■)) and to 550 nm (magenta circles (●)). Inset: the unit cell with the red arrow showing the stub length.

We find that, for example,an increase of 100 nm in the stub length impacts the phononic band gap by shifting it to lower frequencies and reducing its width at the rate of -8.46×10^{-4} GHz/nm (Figure 1 (b)). Variations are also observed with respect to the sidewall angle; deviating it from 90°, the phononic band gap changes from 474 MHz to 566 MHz for sidewalls of 74°.

Abstract: This paper studied acoustic metamaterials that can control the phase of sound waves. Two types of microstructures were used to control proper phase delay for reflected and transmitted acoustic waves, respectively. By arranging the microstructures properly, thin-plane acoustic diffusers were designed, and specimens were fabricated to be tested in experiments.

Metamaterials are materials consisting of designed artificial microstructures that can manipulate waves, such as EM waves, elastic waves in solids, and acoustic waves in air. Acoustic metamaterials (AM) are currently studied to control the reflection, transmission, and absorption of sound[1-4]. In these studies, controlling the phase shift of sound by using metamaterials is a crucial topic. Controlling the phase shift of acoustic waves at each microstructure can be realized as rearranging the phase of point sources. Such AM can deflect the directions of the reflected or transmitted waves, and the corresponding sound field characteristics alter. For example, a Schroeder diffuser combines wells of different depths to have the non-uniform phases of the reflected wave[4]. Further, metamaterials that control the transmitted waves' phase were reported, but further applications are needed. Thus, in this paper, we report our studies on metamaterials for controlling phase shift of reflected and transmitted acoustic waves and their further application as diffusers.

Two types of microstructures were studied for control phase delay of reflected and transmitted acoustic waves, respectively. For the reflected waves, a Helmholtz-like cavity structure was proposed[2] to control the phase of reflected waves and was adapted in this study. On the transmitted waves, a channel is the fundamental part of the microstructure that allows sounds to pass through a solid structure. We used coiling channels introduced in reference 3 to control the phase delay. The finite-element method (COMSOL Multiphysics) was used to calculate the sound pressure fields of waves and study the designs of these microstructures. The geometric size of Helmholtz-like cavities affected the reconstruction of reflected waves and controlled the phase. The coil channels have different lengths, thus delaying the incident wave and shifting the output's relative phase. We used the finite-element method to calculate the sound pressure fields of waves reflected from a Helmholtz-like cavity and waves passing the coiling channel, respectively. Then, both the Helmholtz-like cavity and the coiling channel were designed to have a phase delay of 0, $\pi/8$, ..., and $15\pi/8$, respectively. These microstructures were used as the basic units for further applications.

Proper arrangments of the basic units constructed the functional metamaterials. For example, with different phase delays in space, an array of linear increasing phase delay units can steer the direction of the incident wave when it passes the metasurface. In this study, we designed acoustic diffusers based on the principle used in the Schroder diffusers to arrange the phase delay of units according to the quadratic residue sequences (QRS). Then, the sound pressure fields were simulated, and the diffusion coefficients of the diffusers were calculated. The AM diffusers for reflected and transmitted waves both showed that directional incident waves become diffusion. The

specimens of the AM diffuser were fabricated by 3D printing, and consistent results were obtained in experiments. These results showed that Helmholtz-like cavities controlled the reflective wave phases, and coiling channels controlled the transmitting wave phase efficiently. Functional AM diffusers can be easily applied to sound field control inside buildings and significantly contribute to architectural acoustics.

Abstract: In this work, we explore the use of active acoustic elements for the design of non-Hermitian topological systems. We experimentally observe the emergence of the non-Hermitian skin effect in a nonreciprocal acoustic network. Additionally, we discuss the transition from PBC to OBC and the associated boundary sensitivity.

Recently, we have witnessed a growing interest in the development of non-Hermitian topological systems. Such systems are characterized by complex eigenenergies resulting from the presence of losses/gains in the system, and offer promising new possibilities for wave control and the design of improved sensors [1-2]. A particularly striking effect of this type of system involves the emergence of the non-Hermitian skin effect, which occurs during the transition from a periodic boundary condition (PBC) to an open boundary condition (OBC). As a result of this transition, the eigenfrequencies can become real and the energy is exponentially localized at one edge of the system. These effects have been reported in many physical configurations, including acoustics and electronics [3-6].

Non-hermitian topological systems can be studied using simple models, such as the Hatano-Nelson or the Su-Schrieffer-Heeger, which are both among the most prominent in the field. The Hatano-Nelson model describes a one-dimensional lattice with an asymmetric coupling, whereas the Non-hermitian SSH describes a dimer with an asymmetric coupling. Both models can display complex eigenfrequencies for a periodic configuration, which becomes real when open boundaries are imposed. This transition leads to the localisation of all the eigenmodes of the Hatano-Nelson at one side of the system, whereas the Non-hermitian SSH can show different localisations depending on the parameter of the system.

In our work, we demonstrate theoretically that a transfer matrix approach can be used to map an acoustic problem to both the Hatano-Nelson model [6] and SSH. Our experimental setup consists of a series of cells. Each cell is made up of two coupling ducts and a cavity housing a loudspeaker. The loudspeaker is controlled through the use of a microphone facing the membrane which feeds back an amplified signal to the loudspeaker.
This allows a broadband nonreciprocal wave propagation. For the Hatano-Nelson model, we show that the acoustic system can be mapped using the transfer matrix M of a single cell following the expression,

$$u_{n+1} + t\,u_{n-1} = Eu_n \qquad \text{Eq. (1)}$$

where $t = det(M)$ and $E = Tr(M)$. This allows us to make a direct link between the eigenfrequencies of the HN model and the modes of the acoustic problem, in which the presence of losses enable us to obtain a stable system despite the complex closed loop spectrum.

Using a network of N=8 cells (see Fig.1), we experimentally demonstrate the emergence of the non-Hermitian skin effect in the acoustic equivalent of the Hatano-Nelson model. Moreover, by using diaphragm with different radii, we demonstrate the gradual transition from a looped to a line spectrum, highlighting the sensitivity of the system to variations in boundary conditions.

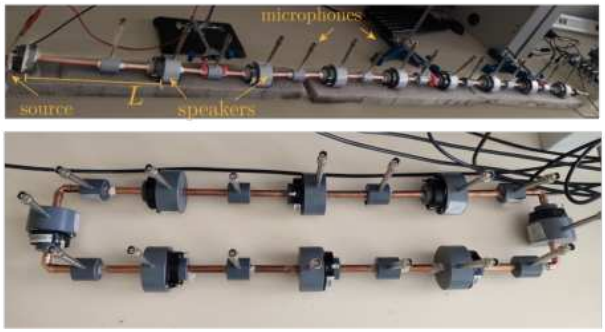

Figure 1 : Experimental setup for the Hatano-Nelson in OBC and PBC configuration .

The role of elastic interfaces in a reduced relaxed micromorphic formulation of finite-size mechanical metamaterials

L. A. Perez Ramirez[1*], J. Voss[1], G. Rizzi[1], S. Hermann[1], P. Demetriou[1] and A. Madeo[2]

[1]Faculty of Architecture and Civil Engineering, TU Dortmund, Germany
[2]Head of Chair of Continuum Mechanics, Faculty of Architecture and Civil Engineering, TU Dortmund, Germany
[*]corresponding author: leonardo.perez@tu-dortmund.de

Abstract: The surfaces and interfaces found in finite-size metamaterials are likely to trigger boundary effects. Introducing elastic interfaces in the micromorphic formulation of the problem captures this boundary-driven response in the simplified framework of generalized continuum mechanics. Finite-size specimens, identical almost everywhere except at their boundaries, may show different responses.

The mechanical properties of traditional materials, both in small geometrical dimensions and in bulk, are known to be subject to size-effects that can be controlled by the interfaces and surfaces of its microstructure [1]. Moreover, these effects dominate the mechanical response when the external dimensions of the material specimen approach the characteristic length scale of its microstructure [2]. This suggests that the architected nature of metamaterials can enable a similar phenomenon when considering finite-size metamaterial specimens.

We show that boundary-driven responses are present in finite-size metamaterials by running direct simulations of the microstructured domain. The lattice of the metamaterial is translated so that different samples are generated, while keeping the same bulk material. These have the same macro-size and the same bulk properties, but different geometries at their boundaries. We also use the reduced relaxed micromorphic model to simulate an equivalent system in view of its capacity to capture the dispersion, anisotropy and band-gaps of metamaterials [3], at a lower computational cost. The kinetic and strain energy of this model are shown in equations (1) and (2), respectively.

$$K\left(\dot{u}, \nabla\dot{u}, \dot{P}\right) = \frac{1}{2}\rho\langle\dot{u},\dot{u}\rangle + \frac{1}{2}\langle\, \mathbb{J}_{\mathrm{m}}\mathrm{sym}\,\dot{P}, \mathrm{sym}\,\dot{P}\,\rangle + \frac{1}{2}\langle\, \mathbb{J}_{\mathrm{c}}\mathrm{skew}\,\dot{P}, \mathrm{skew}\,\dot{P}\,\rangle + \frac{1}{2}\langle\, \mathbb{T}_{\mathrm{e}}\mathrm{sym}\,\nabla\dot{u}, \mathrm{sym}\,\nabla\dot{u}\,\rangle + \frac{1}{2}\langle\, \mathbb{T}_{\mathrm{c}}\mathrm{skew}\,\nabla\dot{u}, \mathrm{skew}\,\nabla\dot{u}\,\rangle \tag{1}$$

$$\mathrm{W}(\nabla u, P) = \frac{1}{2}\langle\, \mathbb{C}_{\mathrm{e}}\mathrm{sym}\,(\nabla u - P), \mathrm{sym}\,(\nabla u - P)\,\rangle + \frac{1}{2}\langle\, \mathbb{C}_{\mathrm{c}}\mathrm{skew}\,(\nabla u - P), \mathrm{skew}\,(\nabla u - P)\,\rangle + \frac{1}{2}\langle\, \mathbb{C}_{\mathrm{micro}}\mathrm{sym}\,P, \mathrm{sym}\,P\,\rangle \tag{2}$$

The results of the microstructured simulations show a distinct response of the displacement field when the lattice is translated, and consequently, the corresponding boundaries are different, see Figure 1. This suggests a boundary-driven phenomenon. Even though the reduced relaxed micromorphic model has been shown to adequately capture the dynamic response of metamaterial plates [4], it has also been observed that it cannot account for boundary effects when using perfect interfaces [5]. However, when the interface of the micromorphic domain is considered elastic (the tractions have non-vanishing jumps at the considered interfaces), it is possible to account for the boundary-driven effects of the finite-size metamaterials [6]. Therefore, we use imperfect interfaces in the micromorphic formulation to introduce a differentiated response attuned to the structure at the boundary. A

correlation between the shape of the surface tractions at the interface is observed when comparing the micromorphic and microstructured results.

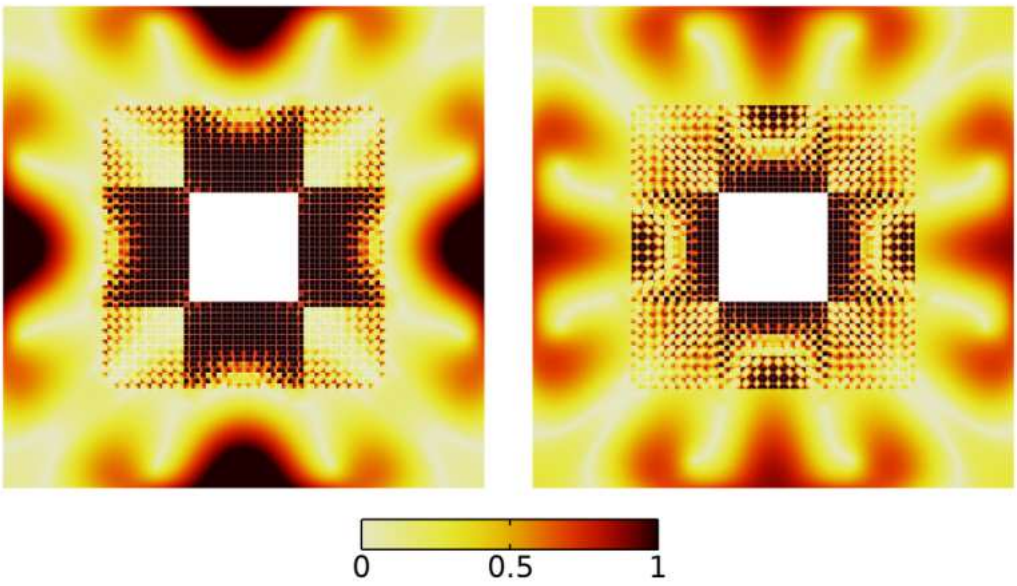

Figure 1. Normalized displacement field of a time-harmonic study at 1450 Hz of a plate subject to a radial expansion load. Two metamaterial cores are generated by the translation of its lattice while remaining surrounded by a classical linear elastic material.

Unified model for multiple scattering problems in one-dimensional elastic waveguides

M. Lázaro[1,2], V. Romero-García[1], L.M. García-Raffi[1*], R. V. Craster[2],

[1]Universitat Politècnica de València, Spain

[2]Imperial College London, UK

Abstract:. In this paper, a new model for the wave response of waveguides with an arbitrary number of scatterers is proposed. We consider two types of scatterers: resonator-type and inclusion-type, these latter as small properties perturbations (material and cross section). A resulting unified mathematical model results for both type of scatterers.

Studies focused on the scattering of elastic waves, there has been considerable attention on the interaction among point defects within clusters. Notably, this encompasses the seminal contributions of Foldy [1] and Lax [2], which established the theoretical underpinnings for representing defects as sources, either isotropic or otherwise, with undetermined intensities. A thorough examination of scattering theories, along with their relation to integral equations, is presented by Martin [3].

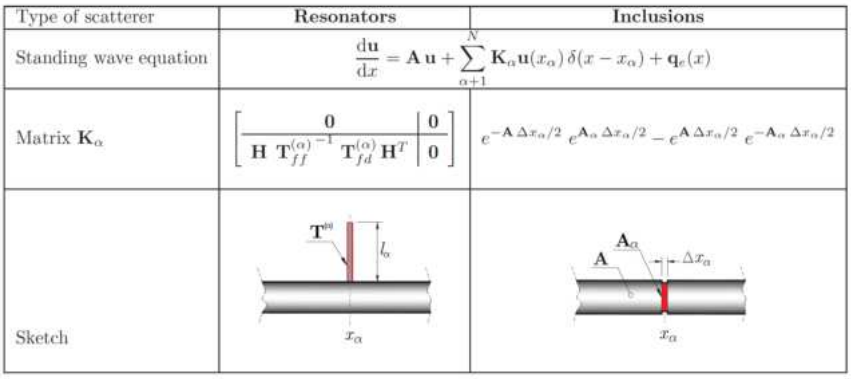

Figure 1. Sketch of the proposed unified model valid for all considered type of scatterers: resonator-type (left) and inclusion-type (right).

In the context of the present work, we consider as pointwise scatterers those substructures that are connected to a main elastic beam and have either internal resonances or local changes of properties (of material and/or section), in a very small length. In both cases, the propagating waves are affected in magnitude and phase by these obstacles. Furthermore, for the same number of scatterers, the correlation in the order of the scatterers positions also affects the wave response. The two situations are in essence different but produce wave effects of the same type. Our main objective is to unify the mathematical treatment of both scatterer models, something that is done in the current contribution in the context of elastic waves of any type (longitudinal, flexural, torsional or shear waves). The procedure is based on the multiple-scattering approach for 1D elastic waveguides. The wave field along the longitudinal direction verifies the equation of motion together with the kinematics relationships, gathered in the system of ordinary differential equations

$$\frac{d\boldsymbol{u}}{dx} = \boldsymbol{A}\,\boldsymbol{u} + \sum_{\alpha=1}^{N} \boldsymbol{K}_\alpha\,\boldsymbol{u}(x_\alpha)\cdot\delta(x-x_\alpha) + \boldsymbol{f}_e(x) \tag{1}$$

Where $\boldsymbol{u}(x)$ represents the state-vector (kinematics and generalized forces) of the waveguide. The matrix $\boldsymbol{A}$ includes all inertial and mechanical properties of the medium and $\boldsymbol{f}_e(x)$ stands the vector of external forces. We propose a common mathematical model based on the solution of Eq. (1) but with different scattering impedance matrices $\boldsymbol{K}_\alpha$ depending on the type of scatterer. The table shown in Fig. 1 summarizes the two approaches, depending on the type of scatterer: (1) resonator-type or (2) inclusion-type. The numerical results for resonator-type scatterer are considered exact since they are attached pointwise to the beam. On the other side, inclusion-type scatterer are modeled as simple pointwise source terms, which generates some error in the results. It is proved that the error depends on the wavelength and on the contrast of properties. In Fig. 2 some results for a rod with classical longitudinal waves are represented, showing the good agreement of the proposed model with the exact solution obtained with the Transfer Matrix Method.

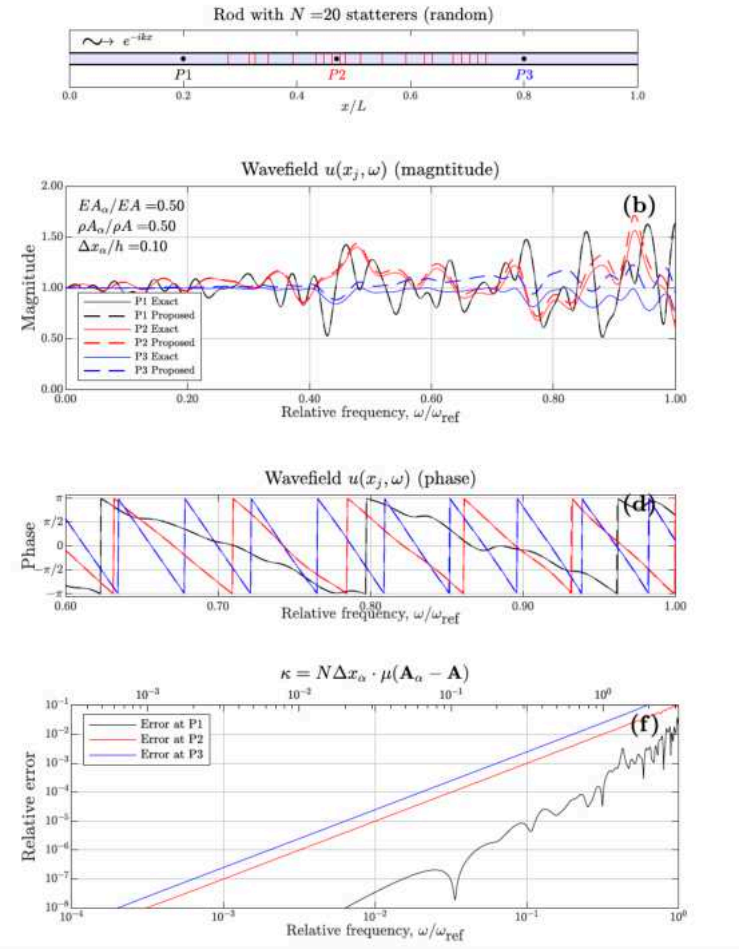

Figure 2. Numerical results of wave field of a rod. (b) and (d): magnitude and phase of wavefield. (f) relative error of the proposed method with relative frequency.

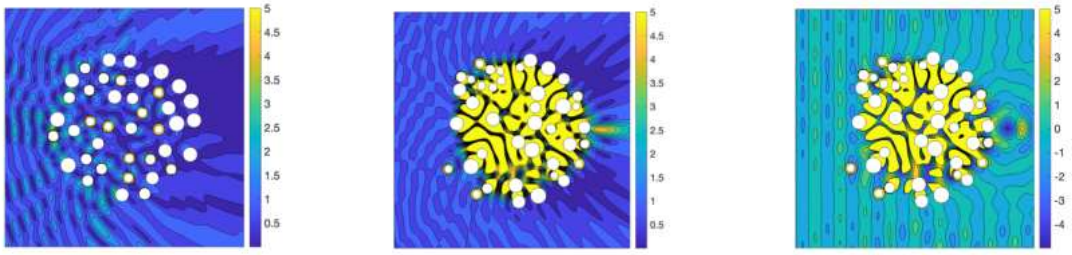
Inverse Design of Broadband Acoustic Lens using Gradient-Based Optimization

F. A. Amirkulova[1*], S. Gerges[1], and J. Samaniego[1]

[1]San José State University, USA
[*]corresponding author: feruza.amirkulova@sjsu.edu

Abstract: We design broadband acoustic lenses through gradient-based optimization. The root mean square of absolute pressure amplitudes at the focal point is maximized, considering a range of frequencies and incident angles amidst the nonuniform configuration of scatterers. We demonstrate how the analytical form of gradients enriches the modeling and solution accuracy.



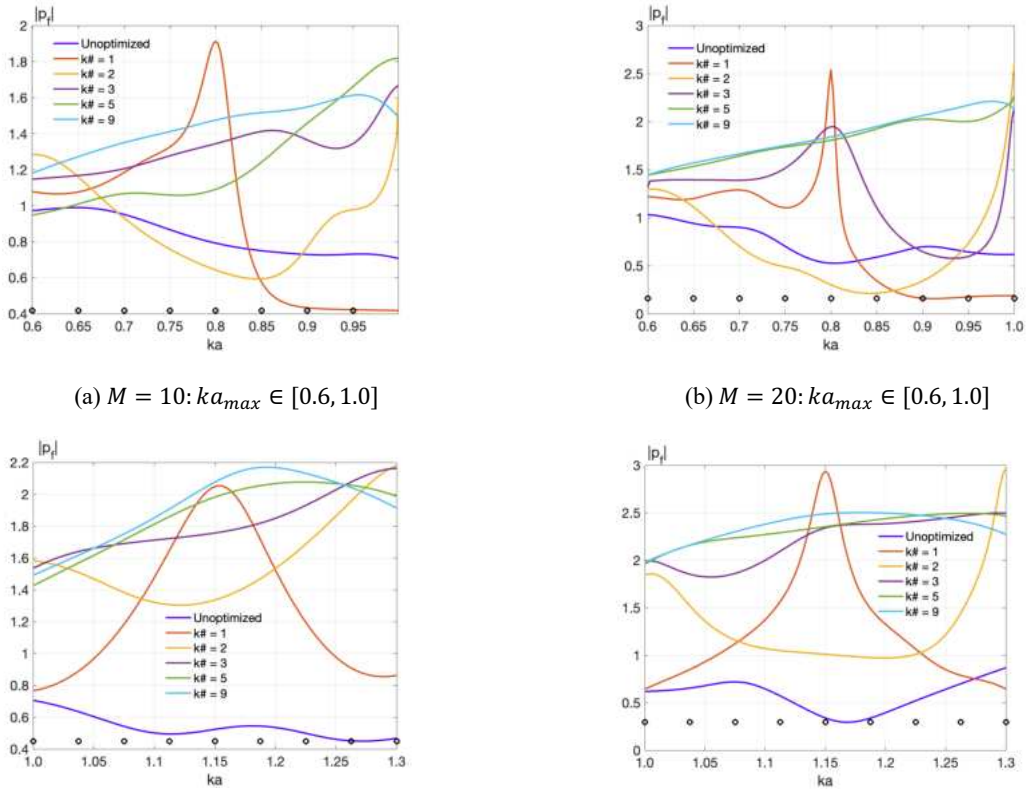
An acoustic Luneburg lens can focus the incident plane waves from any direction to a focal point on the opposite side of the lens configuration without aberrations [1, 2]. This work presents a semi-direct approach to broadband acoustic Luneburg lens design, employing gradient-based optimization algorithms and utilizing multiple scattering theory. Our method focuses on maximizing the absolute pressure amplitude at the focal point, achieved by incrementally adjusting the positions and radii of a set of cylinders so that they transform into an effective acoustic focusing apparatus. We obtained an analytical formula for the gradients of the absolute pressure amplitude at the focal point with respect to positions [3, 4] and radii [5] of a set of cylinders in closed form rather than relying on numerical evaluation of gradients through finite differences.

For a plane wave incidence, we define the objective function $|p_f(\{x_m\})|^{RMS}$ as the root mean square (RMS) of a set of the absolute pressure amplitudes $|p_f|$ at the focal point over some range of normalized wavenumbers $k_i a_{max}$ $(i = 1,2,\dots,N_k)$ and over a range of incident angles $\psi_l (l = 1,2,\dots,N_l)$ [3, 5]:

$$|p_f(\{x_m\})|^{RMS} = \left(\frac{1}{N_k}\frac{1}{N_\psi}\sum_{i=1}^{N_k}\sum_{l=1}^{N_\psi}|\,p_f(k_i a_{max},\psi_l,\{x_m\})|^2\right)^{1/2} \qquad (1)$$

where $\boldsymbol{x}_j = [\boldsymbol{r}, a_i]$, a_j and $\boldsymbol{r}_j$ are correspondingly the radius and position of the jth scatterer, $j = \overline{1,M}$, M is the total number of scatterers in the configuration, and $a_{max} = \max(a_i)$. The objective function is non-convex and highly non-linear, and has many local maxima and global maximum at infinity. Then, we define the broadband gradient vectors with respect to positions $\boldsymbol{r}_j$ and a_j [3, 5]:

$$[\boldsymbol{q}_j^{RMS}]_p = \frac{\partial |p_f(\{x_m\})|_p^{RMS}}{\partial \boldsymbol{x}_j}, j = 1,2,\dots M. \qquad (2)$$



(a) non-optimized: $|\,p\,|$ (b) optimized: $|\,p\,|$ (c) optimized: $Re(p)$

Figure 1. The absolute value of the total acoustic pressure field $|p|$ at normal plane wave incidence on the optimized configurations of $M = 40$ rigid cylinders at normalized wavenumber $ka_{max} = 2$.

We solve the non-convex optimization problems with non-linear constraints. To prevent cylinder overlapping, the distances between their centers are constrained to be greater than the minimal allowable distance, which is selected to be greater than the diameter of the cylinders. In addition, the cylinders are constrained to move inside a fixed circular region. Computations are performed on MATLAB using sequential quadratic programming (SQP) algorithms, *MultiStart* optimization solver to supply the gradients of p_f and gradients of RMS of p_f with respect to $\boldsymbol{x}_j$ vectors over a range of wavenumbers. We start with an initial random planar configuration of non-uniformly sized cylinders and employ the MATLAB build function *fmincon* alongside *MultiStart*. This approach harnesses the efficient local solvers within *MultiStart*, enabling simultaneous exploration of a wide variety of starting points.

Supplying analytical gradients of the function p_f enhances the optimized solution accuracy, reduces computational time, and enables parallel computing with *MultiStart*. Figure 1 illustrates the total acoustic pressure field at normal plane wave incidence for configurations of $M = 40$ rigid cylinders at normalized wavenumber $ka_{max} = 2$. Figure 1 (a) shows the total absolute pressure $|p|$ for nonoptimized configuration of $M = 40$ cylinders. Figures 1(b) and 1(c) clearly demonstrate the focusing effect for plane wave incidence on a optimized core of $M = 40$ cylinders.

(a) $M = 10$: $ka_{max} \in [0.6, 1.0]$ (b) $M = 20$: $ka_{max} \in [0.6, 1.0]$

(c) $M = 10$: $ka_{max} \in [1.0, 1.3]$ (d) $M = 20$: $ka_{max} \in [1.0, 1.3]$

Figure 2. The absolute value of the total acoustic pressure field $|p|$ versus wavenumber at normal plane wave incidence on the non-optimized (blue curve) and optimized configuration of M=10 and 20 rigid cylinders for a range of normalized wavenumbers ka_{max}. The pressure amplitude $|p|$ is optimized at *1,2, 3, 5, and 9* equidistant values of wavenumbers $ka_{max} \in [0.6, 1.0]$ and $ka_{max} \in [1.0, 1.3]$.

Figure 2 depicts the variation of the absolute value of the total acoustic pressure $|p|$ with wavenumber at normal plane wave incidence on the optimized configuration of $M = 10$ and $M = 20$ rigid cylinders for a range of normalized wavenumbers ka_{max}: $ka_{max} \in [0.6, 1.0]$ and $ka_{max} \in [1.0, 1.3]$. The absolute pressure $|p|$ is optimized at *1,2, 3, 5,* and *9* equidistant values of wavenumbers. The trade-off between the increase of the frequency band and focusing efficiency leads to the shift of peak performance for broadband focusing. Numerical results indicate that significant sound pressure amplification can be achieved by optimal scatterer rearrangement using this analytical-numerical technique. The method can be extended to design 3D lenses.

Robustness evaluation of merged topological bound states in the continuum

Jiamin Guo[1], Zhongming Gu[1,†], and Jie Zhu[1,‡]

[1] Institute of Acoustics, School of Physics Science and Engineering, Tongji University, Shanghai 200092, China

Abstract: We propose a theoretical model for realizing merged topological bound states in the continuum (TBICs), focusing on the investigations of system robustness through tight-binding calculations and numerical simulations. Our findings demonstrate that the topologically protected merged bound states exhibit remarkable robustness against various types of defects and perturbations.

Bound states in the continuum (BICs), a concept introduced by von Neumann and Wigner in 1929, represent unique bound states that exist within the bulk band without interacting with extended modes. Researches in BIC physics have surged due to its potential for advanced wave manipulation [1]. Apart from their topological notions [2], BICs also have been studied in the field of topological insulators, which are dubbed topological BICs (TBICs) [3]. The topological edge states in the continuum and topological corner states in the continuum have been successively verified by in many physical systems. Meanwhile, in recent years, there has been an increasing amount of research focusing on the robustness of TBICs. Yet, merging multiple TBICs remains an uncharted area.

In this work, we delve into this relatively unexplored domain, exploring the robustness of engineered merged topological corner states in the continuum. It is acknowledged that the robustness of a system can be inspected through various operations, including but not limited to the introduction of random perturbations, defect structures, or external sources of interference. Considering the random disorder of potential energy, for nontrivial systems, the eigenvalues and localized characteristics of trivial states will change, while nontrivial modes exhibit a certain degree of protection against perturbations [2].

To investigate this, we first perform calculations based on the tight-binding model, followed by full-wave simulations on the acoustic structure. In the tight-binding calculations, the disorder is introduced by changing the resonant frequencies, i.e., modifying the on-site terms in Hamiltonian. In the simulation, the disorder is introduced by placing a hard cylinder with random size inside the resonator. All numerical results indicate that for bulk disorder (perturbing cylinders on all sites except for corners), the merged topological corner states in the continuum remain stable, with the resonance peaks being unshifted. Conversely, under corner disorder, the corner states persist to exist but are no longer degenerate, with the resonance peaks still exist but shift to higher frequencies. These observations underscore the potential of merged topological bound states in the continuum in realizing devices with enhanced robustness, applicable across various wave systems.

Our conclusions highlight the successful realization of a bilayer lattice for merging TBICs in acoustics. This study not only paves the way for further exploration of merging BICs in higher-order topological materials but also opens avenues for the development of enhanced robust topological devices with minimal energy leakage. Through this research, we aim to inspire further investigations and applications leveraging the unique properties of merged TBICs to develop next-generation devices characterized by unprecedented performance metrics.

Abstract

Topological D-class phases (TDPs) are archetypes of the ten-fold classification of topological phases with particle-hole symmetry. Here, with a novel design scheme, we realize 2D TDPs in an acoustic crystal by synthesizing both the particle-hole and fermion-like time reversal symmetries for a wide range of frequencies.

Topological class	Time-reversal symmetry	Particle-hole symmetry	Chiral symmetry	Realization in 2D metamaterials
A	0	0	0	✓ [14,30]
D	0	+1	0	✗
DIII	-1	+1	1	✗
AII	-1	0	0	✓ [15,27]
C	0	-1	0	✗

[a]There are five nontrivial topological classes in 2D systems, characterized by combinations of time-reversal, particle-hole, and chiral symmetries. The number 0 in each column stands for absence of symmetry, while ± 1 indicate the presence of a symmetry together with the even or odd character of the symmetry operator relative to squaring. The check marks in the last column indicate whether the topological symmetry class has been realized in 2D metamaterials in the past, and citations to the relevant works are placed next to the marks.

Abstract: Anisotropy of 3D printing process is explored for design of a polarization rotator of shear waves. Due to strong anisotropy of elastic modulus of 3D printed sample the polarization of shear wave rotates following the gradual change in the direction of the infilled lines. The fabricated 90° rotator demonstrates high performance.

Usually, the mechanical properties of materials produced using the current additive manufacturing process are inferior to conventionally manufactured products. At the same time, manipulation of the various process parameters and mechanisms can produce structures with a very wide range of prescribed mechanical and physical properties from the same printing tool. Here we report a layered design of acoustic polarization rotator that can be easily fabricated using additive manufacturing process. We were motivated by a metamaterial-based polarization rotator for linearly polarized electromagnetic waves of the terahertz region [1]. It contains a tri-layer metasurface of thin metal plates with parallel narrow slits separated by a dielectric. The slits result in a strong anisotropy in transmitting electromagnetic waves with parallel or perpendicular polarization. In solids, rotation of a shear elastic wave oscillation plane can be realized by applying phased array systems and complex metamaterials [2]. The fabrication of these metamaterial designs is quite complex, making their practical use cost prohibitive.

The line-by-line 3D printed process provides high anisotropy of the shear modulus. The axis of anisotropy gradually rotates from layer to layer by an adjustment of the printing direction. The proposed in Ref. [4] cylindrical-shaped transverse acoustic 90° rotator shown schematically in Fig. 1. A stack of layers printed with a small angular shift, as shown in Fig. 1(c). It is known that the shear modulus in a straight-line infill FDM printed product has the maximum (minimum) value over the deformation along (across) the infilled line direction [3].

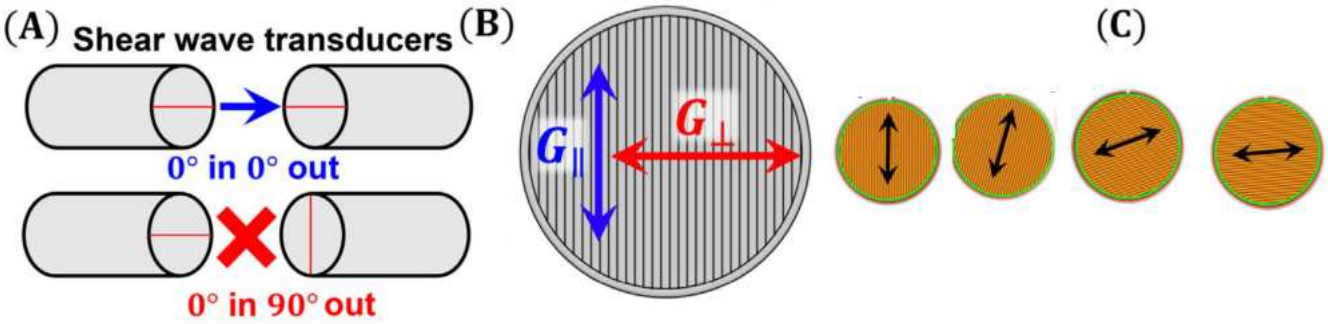

Figure 1. Principle scheme of polarization rotator. (A) Mutual orientation of emitting/detecting shear wave transducers. (B) Top view of the anisotropic pattern in a layer of 3D printed structure with line infill. The shear modulus is higher in the direction perpendicular to the infilled lines than in the parallel direction, $G_{\parallel} >> G_{\perp}$. (C) The infill line orientations were gradually rotated providing total rotation by 90°.

The performance of the FDM acoustic polarizer was characterized by measuring the transmission of the

shear wave propagating from left to right using a pair of shear-wave transducers shown in Fig 1(A). The polarizer samples were printed by PolyPrinter 229 single extruder FDM printer. We used black ABS (Acrylonitrile Butadiene Styrene) filament. The pattern of infilled straight lines is shown in Fig. 1(B). It corresponds to uniaxial anisotropy with significant contrast $G_{\parallel} >> G_{\perp}$ ($E_{\parallel} << E_{\perp}$).

In a bistatic configuration of two single-element shear transducers, an acoustic signal can hardly be detected when the emitting and receiving transducers are oriented mutually perpendicular. The transmission measurements through a practically uniform and isotropic molded ABS plastic slab are shown in Fig. 2(A) for parallel and perpendicular orientation of the transducers. The averaged over frequency amplitude ratio $A_{0°\to 90°}/A_{0°\to 0°}$ was as small as 0.008. The same transmission through polarization rotator with angle of rotation through a single layer $\alpha = 5°$ is shown in Fig. 2(B). A rotation of the anisotropy axis leads to about two orders of magnitude increase in the ratio $A_{0°\to 90°}/A_{0°\to 0°}$ = 0.66, as compared to a homogeneous plastic slab.

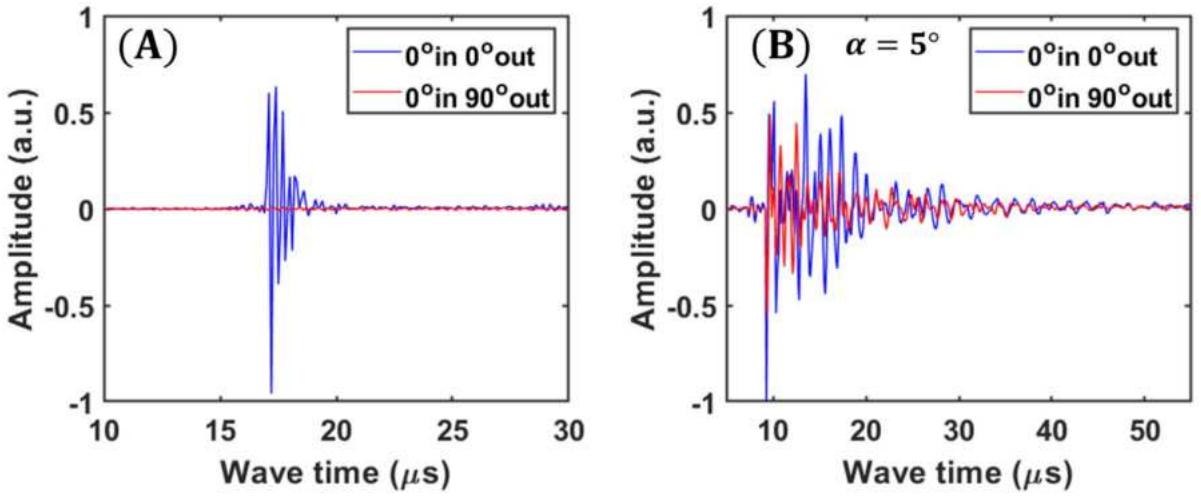

Figure 2. Transmission of shear wave pulses through different fabricated samples. (A) Transmissions through a uniform and isotropic ABS slab obtained by the molding process. (B) Transmissions through the printed PR with $\alpha = 5°$.

In our experiments we demonstrated even the higher efficiency of the proposed polarization rotator containing 90 printed layers, each rotated by 1°. Moreover, the efficiency can be improved by optimization with respect to the parameters of the 3D printing process.

Abstract: The study presents a theoretical analysis of the phononic and plasmonic modes of couples nanoantennas, their surface deformation field and electromagnetic field profiles.

Summary

Metallic nanoantennas have been studied as efficient coherent phonon generators and detectors, harnessing their characteristic optical absorption and polarization dependence of the optical modes [1-2]. The ability to control the excitation of phononic modes depends on the properties of the multiple optical resonances of the system. Lately, it has been made possible to optimally excite and detect phonon modes via plasmon resonances at the same optical frequency using chiral nanostructures and circularly polarized light [3]. However, torsional modes remain elusive in nanophononic studies. In this work we present a simple system composed of two coupled bars, where torsional mechanical modes can be excited using light with null angular momentum. The twisting of the phononic mode (Fig. 1) [4] is provided by the peculiar symmetry of the mechanical eigenmode due to the interaction of the bars via either the substrate or a central connector.

Acoustic Realization of Multiple Topological Corner Modes in a Coupling-inverted Phononic Crystal

Dongyi Wang[1*], Guancong Ma[1]
[1]Department of Physics, Hong Kong Baptist University, Kowloon Tong, Hong Kong, China
[*]corresponding author: phwang@hkbu.edu.hk

Abstract: Here, an unprecedented higher-order topological phase safeguarded by a larger-than-unity multipole chiral number (MCN) is experimentally realized with coupling inversion, i.e., long-range couplings stronger than the nearest-neighbour ones, in acoustic crystal. Sixteen topological corner modes are observed in the mid-gap (4 at each corner), protected by an MCN=4 phase.

The field of quantum and classical topological phases has been enriched recently with the development of higher-order topological band theory, localized modes like topological corner modes (TCMs) are thus observed. Numerous novel applications, including topological lasers, quantum optics and energy confinement, are correspondingly inspired by these 0D bound states. Yet, the generation of multiple TCMs at a single corner, which holds great potential for both scientific investigations and modern applications, remains highly desired but unachievable.

With the introduction of appropriate long-range couplings (LRCs), a winding number of a standard one-dimensional Su-Schrieffer-Heeger model can be integers larger than one. Analogically, with LRCs greater than nearest-neighbor couplings (NNCs) in magnitude (regarded as coupling inversion), the unconventionally generalized winding number in higher dimensions can be modulated. The topological invariants characterizing such lattice are referred to as the "multipole chiral numbers" (MCNs) [1], built from sublattice multipole moment operators. Greater-than-unity MCNs safeguard multiple mid-gap localized states at each corner, yet the requirement of coupling inversion is unrealizable in natural materials where couplings generally decay with the increase of distance.

Here, an acoustic wave system is leveraged to overcome the difficulties of coupling inversion [2]. Employing coupled acoustic cavities, we design and experimentally realize a multiple chiral topological phase (MCTP) possessing an MCN of 4. Specifically, a tight-binding Hamiltonian is used to describe the square lattice composed of 4-site unit cells:

$$H(\boldsymbol{k}) = \begin{bmatrix} 0 & h(\boldsymbol{k}) + g(\boldsymbol{k}) \\ h^{\dagger}(\boldsymbol{k}) + g^{\dagger}(\boldsymbol{k}) & 0 \end{bmatrix}, \tag{1}$$

where

$$h(\boldsymbol{k}) = \begin{pmatrix} u + ve^{-ik_x} & -u - ve^{-ik_y} \\ -u - ve^{ik_y} & -u - ve^{ik_x} \end{pmatrix}, \quad g(\boldsymbol{k}) = \begin{pmatrix} we^{-2ik_x} & -we^{-2ik_y} \\ -we^{2ik_y} & -we^{2ik_x} \end{pmatrix}, \tag{2}$$

u, v, w denoting the magnitudes of intra/intercell NNCs and LRCs, respectively. The formed lattice is shown in Fig. 1 (a). An additional synthetic magnetic field with π-flux threads, each plaquette in the lattice, induced by LRCs. When $w > v$, the system becomes an MCTP with an MCN of 4. Thus, 16 near-degenerate modes are protected and observed in the bulk gap of the spectrum as shown in Fig. 1(b), which are bound states localized around the four corners (four per corner, each possessing a different configuration as shown in Fig. 1(c).)

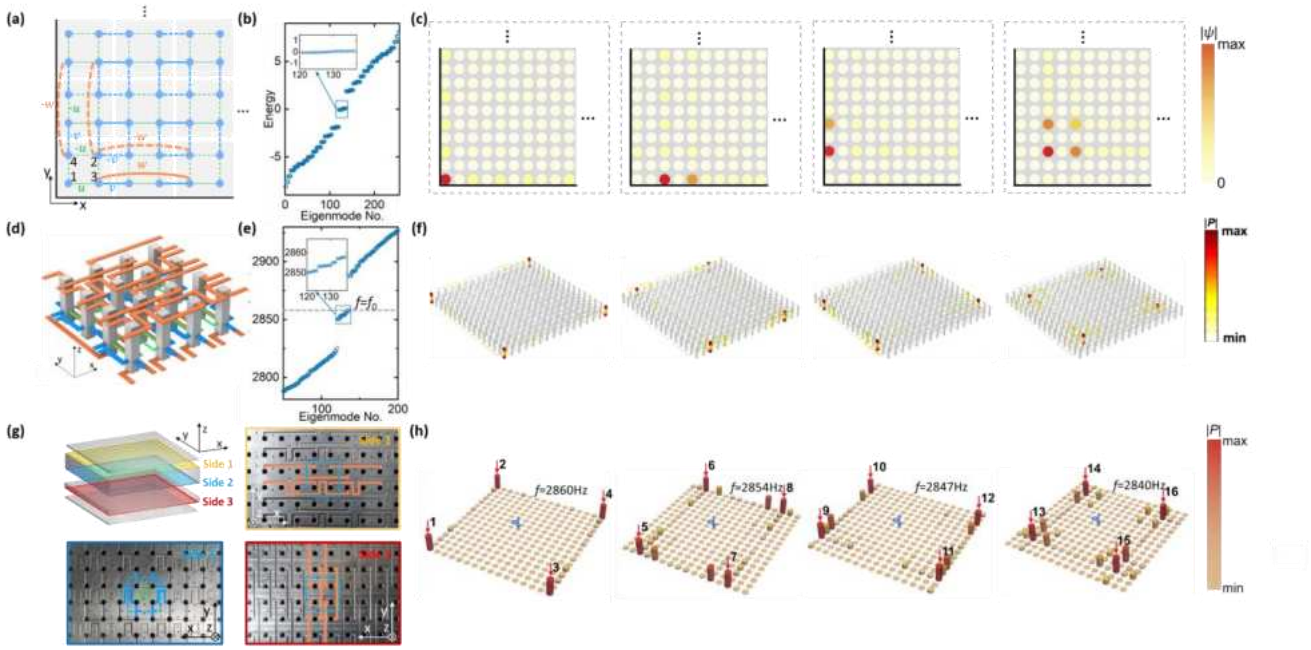

Figure. 1 Schematics, fabricated sample, and the corresponding TCM results obtained from the tight-binding model, simulation and experiment. Schematics of (a) the lattice model, (d) the acoustic lattice design, and (g) the fabricated acoustic lattice employed in experiments. Spectrums demonstrating 16 in-gap TCMs calculated by (b) TBM and (e) simulation. The amplitude distribution profiles of TCMs obtained from (c) TBM calculation, (f) simulation, and (h) experiment, categorized into four groups based on their spatial configurations.

Judiciously designing space-coiling air channels functioning as coupling terms by tuning their geometrical parameters, including channel length L_c, width D_c, and connecting position z_c on the cavity, NNC and LRC coefficients are precisely modulated and the coupling inversion is obtained. The acoustic crystal design is shown in Fig. 1 (d). Sixteen mid-gap TCMs can be identified in the corresponding finite-element simulation results illustrated in Fig. 1 (e,f), all of which are localized around corners and demonstrate four different kinds of intensity profiles compatible with a crystal in the MCN=4 phase. The fabricated sample is shown in Fig. 1 (g), and the experimentally measured spatial profiles of the TCMs are shown in Fig. 1 (h), well-consistent with their numerically calculated counterparts.

Overall, employing acoustic crystals, we experimentally demonstrate the existence of a chiral-symmetric higher-order topological phase with MCN>1 for the first time, and highlight the important role of LRCs in realizing novel topological phases. We also exemplify that classical-wave systems like the acoustic platform utilized in this work possess great potential for studying novel topological models. The proposed MCTP may benefit both further scientific research like investigation of non-Abelian physics, and realistic applications such as spatially multiplexed energy confinement and multi-mode corner-emitting topological lasers.

Abstract: In this work, a single-pixel imaging system, made of a homogeneous slab of material with time-dependent transmission properties, is employed for image reconstruction. We use the compressive sensing theory to optimize the recovery process and limit the number of coding sequences of the grating.

Imaging methods suffer a limitation dictated by the theory of diffraction which implies that only details of the order of the wavelength of the field can be coupled to the free space. Finer details are lost since they are carried by evanescent waves that decay quickly with increasing the distance from the object. Consequently, these details can be captured only very close to the object, i.e. in the near field [1]. Various methods, based on spatial coupling of the near-field waves to the free space, have been proposed to overcome these limitations [2].

In this work we employ an alternative approach for alleviating the above issues of the image reconstruction process, through application of a time-modulated metamaterial surface that couples the near-field waves to the free space. Analogously to a spatial grating generating diffracted modes, the proposed time grating excites waves at different frequencies, each carrying information about the Fourier transform of the image. We show that the reconstruction process can be carried out through the analysis of the temporal spectrum at a single point in space, hence indicating that time gratings can be used for fast and single-pixel imaging.

The model equation, without the loss of generality, is given as the scalar wave equation [3],

$$\nabla^2\psi = \frac{1}{c_0^2}\partial_{tt}\psi, \tag{1}$$

with ψ being the wavefield and c_0 the wave speed. The grating is introduced as an impedance boundary, hence

$$\partial_z\psi^+ - \partial_z\psi^- = \xi(t)\,\psi, \tag{2}$$

where $\xi(t)$ is the time-modulated impedance of the screen located at $z = 0$. The function $\xi(t)$ can be designed in way it is useful for the imaging process, hence it will be also referred to as a coding sequence.

For a wavefield of frequency ω_0 and wavevector **k** in the plane of the screen (i.e. in the x-y plane), the field generated at the modulated screen will be composed of the fundamental wave and a number of waves at frequencies other than ω_0. Assuming that multiple waves comprise the wavefield after this interaction, it is possible to derive formulas for their amplitude coefficients, once the form of $\xi(t)$ is known, from Eq. (2).

Now, let's assume the image to be reconstructed is placed in the x-y plane at $z = 0$ and given via its Fourier transform coefficients, $A_0(\boldsymbol{k})$. We illuminate the image with a plane wave of frequency ω_0, hence waves propagating along the z axis (with amplitudes given by $A_0(\boldsymbol{k})$), form the representation of the object. We note, however, that for waves which wavenumber is greater than k_0, i.e. $k > k_0$, their wavenumber component along the z axis will be complex, hence such a wave will be evanescent and will vanish after a small distance from the screen. The idea of inducing modulation of the screen is to ensure that for all **k**, there will be always a propagating

wave along z and, as a consequence, all information contained in $A_0(\boldsymbol{k})$ will be transferred to the detector. In other words, in this process, the modulated screen couples the evanescent waves to the free space ensuring their detection at (virtually) any point behind the grating.

In what follows we assume that the modulation pattern is time-periodic with frequency ν, hence the waves generated at the grating propagate at $\Omega_n = \omega_0 + 2n\pi\nu$, with n being integers. The proposed imaging process, apart from generating a set of harmonics at the grating (located at the same coordinate as the object, i.e. $z = 0$), consists of a second, receiving, screen which transmittance is inhomogeneous and given by $T_S(\boldsymbol{r})$ (no modulation at the receiving screen). We assume that the total field collected at this screen is integrated, hence the output of the system is a single time-dependent signal containing harmonics at Ω_n. The latter will, of course, depend on the coding sequence $\xi(t)$. The spectral content of the acquired signal ψ_I is given as

$$\psi_I(\Omega_n) = \iint T_S^*(\boldsymbol{k}) T_n(k, \omega_0) e^{iq_n l} A_0(\boldsymbol{k}) d^2\boldsymbol{k}, \tag{3}$$

where T_n is the nth transmission coefficient, q_n is the wavenumber along z and l is the distance between the receiving and modulated screens. Equation (3) can be seen as a system of equations, with $\psi_I(\Omega_n)$ representing the image through the harmonics at the receiving screen and $A_0(\boldsymbol{k})$ being the actual image in the Fourier space. The remaining portion of the equation is the coefficient matrix that depends on the coding sequence. The reconstruction process consists mathematically of inverting the coefficient matrix to recover $A_0(\boldsymbol{k})$ from the measurements $\psi_I(\Omega_n)$. The number of rows in the coefficient matrix depends on the number of harmonics excited by a given coding sequence. This number does not need to be very high though, as the experiment may be repeated with a new coding sequence and new rows can be added to the matrix until it becomes square and invertible.

We illustrate the proposed imaging approach by studying an image illuminated by a wave of $f_0 = 1$ Hz and $c_0 = 1$ m/s and applying a real-valued random modulation signal to the grating. The coding sequence allows for exciting a total of 16 harmonics (including the fundamental frequency, i.e. the 0th harmonic). Such a measurement contributes to 31 rows of the coefficient matrix (amplitudes and phases). The image under investigation is represented through its Fourier spectrum of 129 x 129 coefficients, i.e. 8385 unique complex coefficients. Consequently, a total of 560 measurements is required for the coefficient matrix to be square and invertible. This process allows for lossless image reconstruction.

It is widely known that images exhibit sparse representation in the spectral domain. Typically, only a few percent of coefficients are required for satisfactory reconstruction. This observation opens new possibilities of applying compressive sensing strategies to limit the number of measurements in the image recovery process. By applying the compressive sensing theory [4], we reduced the number of data necessary for satisfactory image reconstruction to approximately 20 % of the initial data.

Fast quasiadiabatic driving in controlling elastic wave propagations

Dong Liu[1], Yiran Hao[1] and Jensen Li[1*]

[1]Department of Physics, The Hong Kong University of Science and Technology, Kowloon, Hong Kong, China.

Abstract: Shortcuts to adiabaticity (STA) in quantum control allow fast evolving the state on the same band as if it is in the adiabatic regime. We simulate the fast quasiadiabatic driving (a STA) using a double elastic waveguide system, facilitating designs of metamaterials to manipulate elastic wave propagation with compact devices.

The adiabatic theorem [1] states that a quantum system follows an instantaneous eigenstate when the system is varied slowly enough in comparison with the energy scale between its eigenstates. In case the system is varied fast enough, adiabaticity is lifted and transitions between different eigenstates become much more favorable. This creates many difficulties in preparing quantum states, an increasingly important problem for quantum information processing, quantum computing and simulations. This problem has sparked recent interest in achieving shortcuts to adiabaticity (STA) [2], i.e., various algorithms to force a system to evolve to its final state as if it were undergoing adiabatic evolution, in a very short duration during which the adiabatic theorem breaks down in a conventional sense. There are several existing algorithms, including counterdiabatic driving, fast quasiadiabatic driving (FAQUAD), invariance-based engineering and non-Hermitian shortcuts.

The STA algorithms are closely related to the control of state evolution starting from a propagating equation, which implies that they can in practice be demonstrated using classical wave systems. This also indicates the feasibility of applications to other classical waves, providing a new mechanism to design more compact devices, especially in optics, such as polarization rotators, beam splitters, and other photonic integrated circuits. In this work, we establish a connection between STA algorithms and elastic systems. Compared with quantum or optical systems, which typically only permit the observation of the output state, the evolution of the state during the propagation of an elastic wave system can be readily probed with a laser scanning vibrometer, making the testing and development of STA algorithms much easier.

Here, we use flexural waves owing to their experimental convenience for field mapping and verification using a scanning laser vibrometer, where the experimental setup incorporates two waveguides coupled by bridges. In the propagation model, the "Hamiltonian" or propagation matrix is a 2-by-2 matrix,

$$\mathcal{H} = \begin{pmatrix} k_1 & \kappa \\ \kappa & k_2 \end{pmatrix}, \qquad (1)$$

where the diagonal elements represent the propagation constants of the two waveguides and the two off-diagonal terms represent the coupling between them. The thickness of waveguides can be used to tune the refractive indices, and hence the propagation constants k_1 and k_2, varying as $n \propto 1/h^{1/2}$ [3]; the cross-section of the bridges can be used to tune the coupling term κ. Then, as shown in Fig. $1(a)$, along the propagating direction of the flexural wave, we can construct position-dependent Hamiltonian from site to site and optimize possible k_1, k_2 and κ for intermediate sites (the first and last sites are fixed to predetermine the initial and final state) to change the character (relative amplitude between the two waveguides) of the state in an adiabatic process. We refer to this approach as FAQUAD, which is achieved by minimizing the so-called adiabaticity parameter. Without optimization (3D-printed resin sample in Fig. $1(a)$), the power flow cannot transfer from one waveguide to another (Fig. $1(b)$) but evenly distributed at the output (r.h.s.). In contrast, after optimization (another sample not shown), the power flow can adiabatically transfer from one waveguide to another, equivalently staying in the same band (Fig. $1(c)$). Our experimental results show that the FAQUAD successfully allows evolving the initial state to the final target state as if it were undergoing adiabatic evolution although the device length is very short (compact).

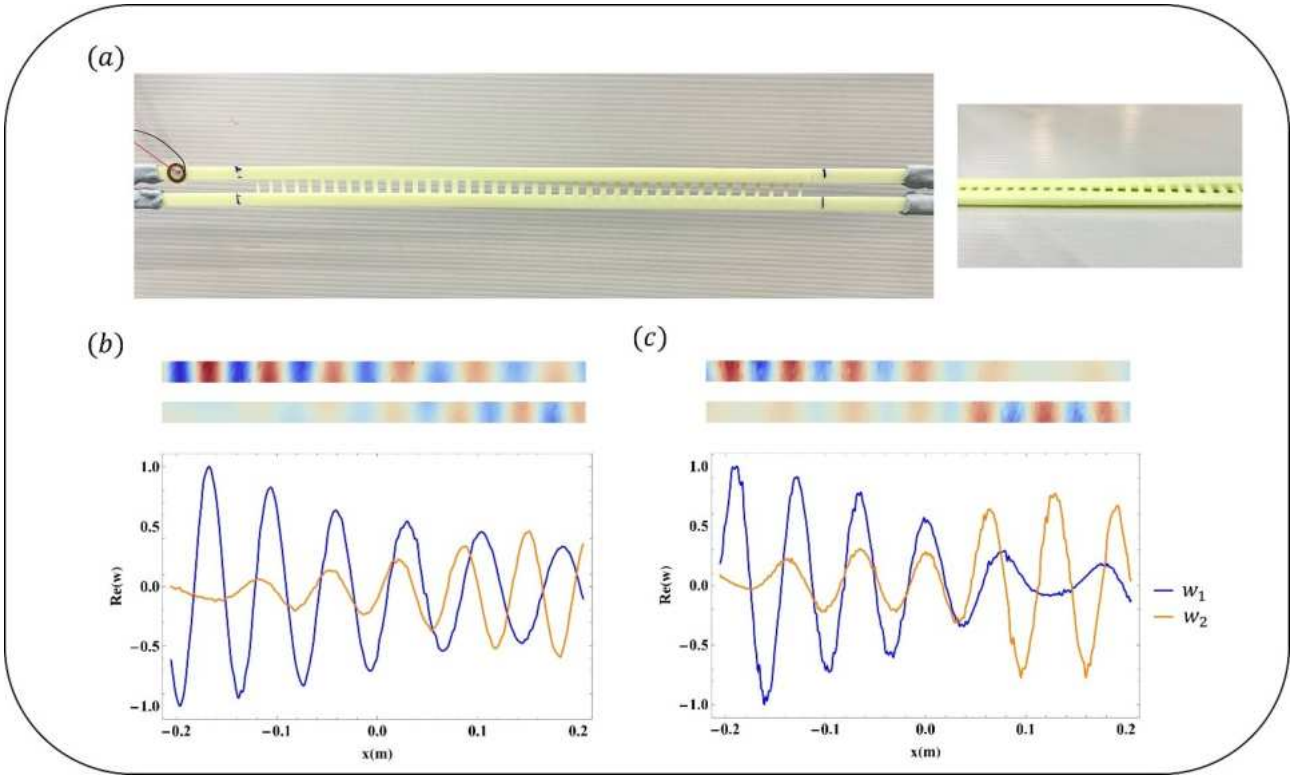

Figure. 1 (a) shows the experimental setup. The upper (lower) waveguide is waveguide 1 (2). (b) and (c) show the field pattern for the experimental results (real part of displacements) for the two samples before and after optimization. (b) is the result without optimization and the power transfers from waveguide 1 to both waveguides. (c) is the result after optimization (another sample) and the power transfers from waveguide 1 to 2 seemingly in the adiabatic regime.

Dispersion relationship of weakly scattered media

M. Lázaro[1,2*], V. Romero-García[1], L.M. García-Raffi[1], R. V. Craster[2],

Abstract:. In this paper periodic media with an arbitrary number of scatterers in the unit cell are considered. Our goal is to know analytically the propagation conditions outside the forbidden bands. By applying perturbative techniques we are able to find analytical solutions and the mathematical conditions under which our technique converges.

Periodic structures, also known as Phononic Crystals for sound and vibrations, have been exploited during the last decade to develop acoustic filters and waveguides for sound or vibrations [1], among other applications.

The introduction of subwavelength perturbations of the medium has allowed to manipulate and design metamaterials under disordered but correlated distributions in the long wavelength (hyperuniform media) achieving special properties and finding surprising transparency or absorption results [2,3]. In addition, metamaterials with a quasi-periodic pattern pattern in the scatterer distribution exhibit especially highly predictable correlation properties [4,5]. Designs of transparent metamaterials such as those based on stealth distributions require ensuring that scattering induced by perturbations is weak. Thus, our main objective is to find analytical solutions that allow us to find the dispersion relation in those frequency bands where propagation is guaranteed: i.e. outside the band-gaps. We have developed a methodology that allows us to find analytical relations of the dispersion relation of a medium, either 1D or 2D. We use procedures based on asymptotic perturbation, introduced here in a rigorous way assuming in the context of weak scattering. The developments are carried out in the context of elastic waves for beams and plates such as those shown in Fig. 1. We also deduce the closed-forms of propagation modes, expressionas that in turn relate the geometrical distribution of points in the medium with the wave propagation properties.

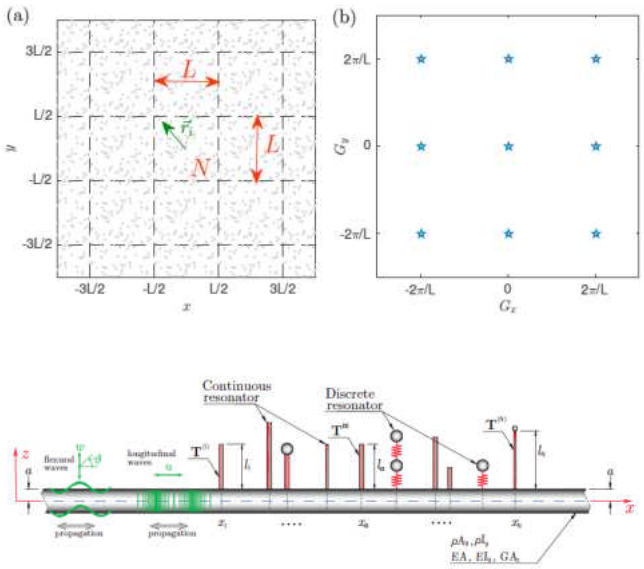

Figure 1. (a) and (b) direct and recirpocal space of a 2D distribution of points in 2D. Periodic replication of unit cello f size $L \times L$. (Bottom) Unit cell with N scatterers-resonators

We have obtained promising results for both beams and plates. Fig. 2 shows some results for a Timoshenko beam with multiple resonators at random positions within a unit cell. In both plots the dispersion relation with a set of scatterers is plotted in blue, computed using the exact approach of the Transfer Matrix Method (TMM).

In Fig. 2 (left) the red curve represents the dispersion relation of the homogeneous beam (without scatterers). This curve shows the typical classical relation predicting the occurrence of two modes from the shear frequency (bending and shear waves). Fig. 2 (right) shows in red the dispersion relation using the linear approximation of our method (first iteration). Closed analytical expression for this relation have been derived. It is remarkable how the wavenumbers are adjusted in those zones outside the bandgaps associated to the scatterer resonances in the whole frequency range.

Braiding of Bloch eigenmodes in a non-Abelian topological phase with quaternion charge

Xiaoming Wang[1,2*] Guancong Ma[1,2]

1 Department of Physics, Hong Kong Baptist University, Kowloon Tong, Hong Kong, China

Abstract: In this work, we show that non-Abelian quaternion charges can be realized by braiding its Bloch eigenmodes. An acoustic system with built-in synthetic dimensions is proposed for the realization of the non-Abelian topological phase and for the observation of the non-Abelian braiding of its eigenmodes.

The concept of braiding groups in relation to elementary particles is an interesting topic in physics. In a quantum mechanical system, e.g., a system with two indistinguishable particles has state $\psi_1\psi_2$ in Dirac notation. If the particles are bosons (fermions), then the exchange of the two particles yields $|\psi_1\psi_2\rangle = e^{i\theta}|\psi_2\psi_1\rangle$, where θ = 0 (θ = π) . When θ take values other than θ = 0 nor θ = π, the particles are called anyons. Remarkably, θ can also be a set of non-communicative matrixes, which correspond to the non-Abelian anyons braiding. In other words, the intrinsic property of elementary particles are encoded in θ .

Recently, non-Abelian topological phase has been proposed as a novel multiband topological phase. Its band topology is classified by a non-Abelian group, the quaternion group $Q_8 = \{\pm i, \pm j, \pm k, -1, 1\}$. The eight group elements obey the following relations as $ij = k, jk = i, ki = j$ and $i^2 = j^2 = k^2 = -1$. Different from Abelian topological band insulators, non-Abelian topological phases involve multiple bulk bandgaps and support nontrivial edge states even winding number is zero. Here, we show that non-Abelian quaternion charge can be realized by unique braiding its Bloch eigenmodes.

We consider a parity-time symmetric three-band Hamiltonian with

$$h(k) = \begin{bmatrix} s_a + 2v_a\cos k & 2u\sin k & 2w\sin k \\ 2u\sin k & s_b + 2v_b\cos k & 2v\sin k \\ 2w\sin k & 2v\sin k & s_c + 2v_c\cos k \end{bmatrix} \quad (1)$$

All parameters are real. Its eigenvectors are purely real vectors. The topological space of the above Hamiltonian is given as $M = \frac{O(3)}{O(1)\times O(1)\times O(1)}$, and the fundamental group is $\pi_1(M) = Q_8$. Consider the adiabatic evolution of all three eigenvectors $|u_k^n\rangle$ with m and n label different bands. The end states of the evolution is given by $|\psi(1,2,3),t\rangle = \int_0^t A_{3\times3}(k)dk\,|\psi(1,2,3),t=0\rangle$, where $[A_{3\times3}(k)]_n^m = \langle u_k^m|\partial_k|u_k^n\rangle$, $|\psi(1,2,3)\rangle$ is matrix and compose of all three eigenvectors. The same as

k, t vary from 0 to 2π. We find that the phase factor $\int_0^{2\pi} A_{3\times3}(k)dk$ can be always written as the combinations of the representations of Artin braid group B_3. An example is illustrated in Figure 1(b), where we braid the first two eigenmodes twice to obtain non-Abelian charge $Q_8 = i$. Thus the eigenvectors evolution of non-Abelian charge $Q_8 = i$ is expressed as

$$|\psi(1,2,3), t=\pi\rangle = b_{12}\,|\psi(1,2,3), t=0\rangle$$
$$|\psi(1,2,3), t=2\pi\rangle = (b_{12})^2\,|\psi(1,2,3), t=0\rangle$$

Where b_{12}, b_{23} denote the representation of Artin braid group B_3. The mapping between non-Abelian quaternion charges and braiding protocols are listed in Figure 1(c)-(i). Moreover, we also find that parity-time symmetry and spectral reciprocity together also ensure single-band Berry phase to be quantized in half Brillouin zone (BZ). Such a property can be characterized by defining a new topological invariant, we call a Half-BZ winding number. It is defined as $\mathrm{W}_{1/2} = \int_p^{p+\pi} i\langle\psi(k)|\partial_k|\psi(k)\rangle dk$ (p denotes start point).

Model (1) and the braiding of the bands therein can be demonstrated using an acoustic cavity system as shown in Figure1(a). We will show that the non-Abelian braiding process can be directly probed by measuring the acoustic pressure.

In summary, we reveal the intrinsic relations between non-Abelian quaternion charge and braiding group for the first time. We design an acoustic system to illustrate the non-Abelian properties of non-Abelian quaternion charge experimentally. A new topological invariant Half-BZ winding number is defined to distinguish all eight non-Abelian quaternion topological phases, while traditional winding number failed to distinguish some of them. Moreover, the above results can be also generalized for more than 3 bands. Our findings can deepen the understanding of the non-Abelian origin of non-Abelian topological phases.

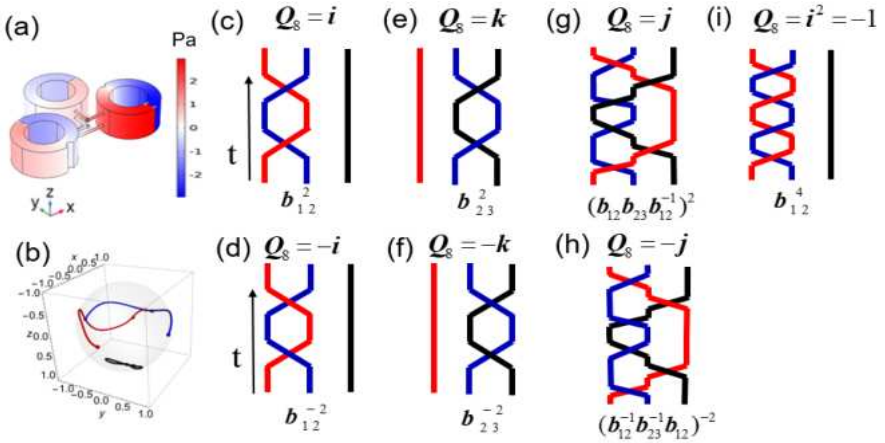

Figure 1. (a)Illustration of the structure of the acoustic cavities, color bar denotes acoustic pressure. (b)Eigenvectors evolution on a sphere. Three different colored trajectories represent the evolution of the three different eigenmodes. (c)-(i)Illustration of different braiding protocols to realize different non-Abelian charges. Those three different eigenmodes are marked with three different colors and considered as three strands. The braiding operations are represented by the crossing of the above colored strands.

Tunable magnetic lattices as a platform for controlling sound waves

Osama R. Bilal[1*]

[1]Department of Mechanical, Aerospace, and Manufacturing engineering, University of Connecticut, Storrs, Connecticut 06269, USA Affiliation, Country
[*]corresponding author: Osama.bilal@uconn.edu

Abstract: In this work, we realize metamaterials with programmable dynamical characteristics by combining analytical, numerical, and experimental analyses, to utilize tunable nonlinear magnetic lattices for sound wave manipulation.

Metamaterials can be defined as repeating geometric patterns in space, creating artificial lattices. Such lattices can be utilized as platforms to realize peculiar static and dynamic behavior (such as negative effective mass density, negative effective dynamical stiffness, and negative effective Poisson's ratio). These geometric patterns are usually fixed once the metamaterials are fabricated. While many theoretical and numerical studies of tunable metamaterials exist, realization of experimental platforms remain limited because of challenges in manufacturability, the destructive nature of reprogramming, and inherent nonlinearities. A valid path for functional tunability of matter is external stimuli, e.g., either static or dynamic load, which can effectively induce an external field to tune the materials. This, however, can translate to large shape change in the material with the potential rise of instabilities, phase transitions, degradation, and geometric frustration. This can hinder our ability to utilize programmable materials [1,2].

In this line of work, we realize metamaterials with programmable dynamical characteristics by combining analytical, numerical, and experimental analyses, to utilize tunable nonlinear magnetic lattices [3-6]. We create our lattices by confining self-aligned, free-floating disks of embedded permanent magnets in a range of symmetries within a fixed boundary and a pre-engineered magnetic field. The magnetic repulsive forces between the boundary magnets and the free-floating disks cause the disks to self-align and rest within their surrounding magnetic potential wells. Each disk or group of disks can act as a single building block, or a unit cell, of the lattice. These unit cells repeat in space, forming a one-dimensional or two-dimensional metamaterial with unique wave propagation characteristics. We design the geometry of the confining boundary, disk symmetry, and number of embedded magnets within each disk such that the tuning of the boundary's magnetic field controls the assembly of the disks. The relative positions and orientation angles between the disks define the corresponding metamaterial phase (ordered, quasi-ordered or random) and its stability conditions (mono-stable or multi-stable) (Figure 1). By changing the boundary geometry, number of disks, their symmetry, and therefore the resulting magnetic couplings within the unit cell, the transmittable frequencies through the metamaterial can be programmed. Figure 2 shows a few examples of the possible ordered lattices (crystalline), semi-ordered lattices (quasi-crystalline) or random (amorphous) assemblies that can self-assemble within the different boundaries.

The proposed platform can be utilized to engineer self-assembled metamaterials capable of manipulating low-frequency waves, within a relatively small volume, while utilizing negligible mass. Moreover, the nonlinear potentials between the disks and their boundaries can be harnessed to demonstrate phenomena with no linear parallel such as amplitude dependent response, bifurcation, chaos, non-reciprocity, and solitons. In addition, the self-assembly nature of the disks can be key in creating re-programmable materials with exceptional properties.

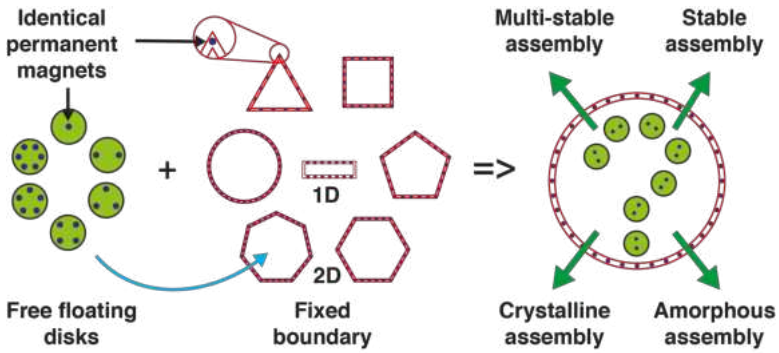

Figure 1: Schematic representation of the different symmetries of the disks confined within boundaries with embedded magnets of different shapes, resulting in a variety of lattice types and properties.

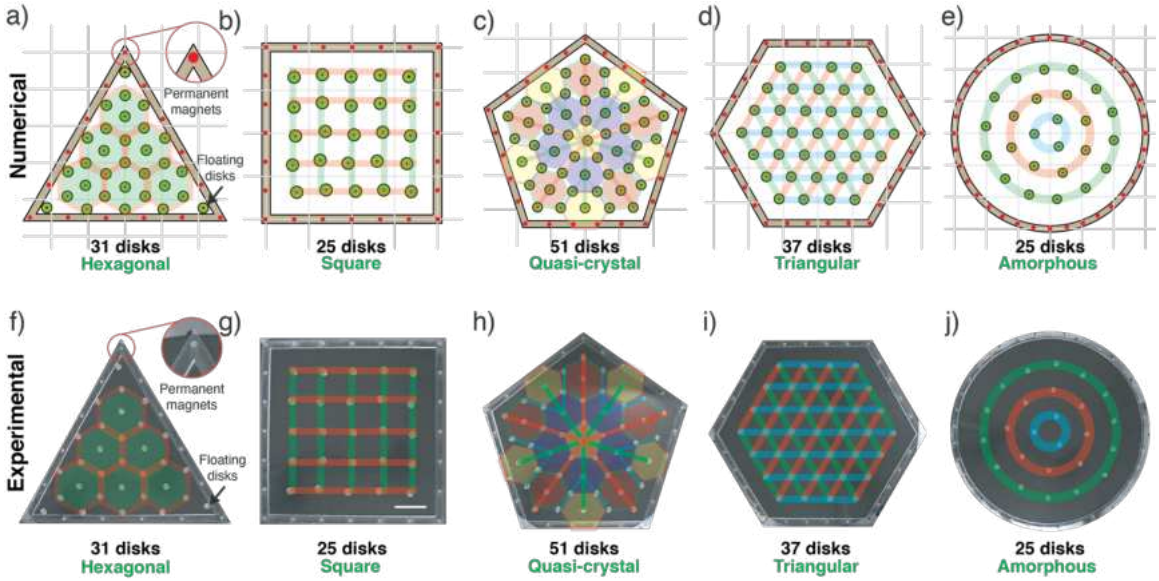

Figure 2: Example of numerical (top) and experimental (bottom) self-assembled lattices within two-dimensional magnetic boundaries with highly ordered, semi-ordered and random configurations.

Using Ping-Pong balls to reduce ambient noise

Y. Pennec[1*], E. Cochin[2], G. Lévêque[1] and B. Djafari-Rouhani[1]
[1]IEMN University of Lille, Cité Scientifique, 59650, Villeneuve d'Ascq, France

Abstract:
We study an acoustic metasurface using interconnected ping-pong balls as Helmholtz resonators (HR) for broad low-frequency spectral responses. We demonstrate how inter-unit coupling alters low-frequency acoustic insulation and introduce additional attenuation modes. Both numerical and experimental methods are employed for analysis.

Controlling the attenuation of acoustic waves in the sonic range represents one of the major challenges in our urbanized societies for the well-being of human life. One principal issue remains the narrowband response of and the difficult question of covering a large frequency spectrum, keeping a simple geometric arrangement of the metasurface. The coupling between elementary Helmholtz Resonators (HR) units appears as a key factor to cover this objective. We propose to investigate the case of coupled HR and showed that the degeneracy of the low-frequency resonance can be raised, leading to many absorptions peaks. Through a combination of numerical analysis and experimentation, we demonstrate that a metasurface made of interconnecting HR units offers new opportunities with multiple local resonances. The interaction between HRs can be manipulated by adjusting geometrical parameters, such as the number of holes and their orientations, the number of resonators, or the separation distance between units [1, 2].

To demonstrate the coupling property, we studied a finite system made up of 9 ping-pong balls, connected to each other by drilling the balls with openings of radius 2 mm. Each ball has, therefore, been pierced with four holes, allowing the connection in both *y* and *z* directions. We performed the eigenmode calculation of the system and found, as expected, 9 eigenmodes, shown in Fig. 1(a). We found three sets of modes, namely, two dipolar modes degenerated two times [(ii), (iii) and (vii), (viii)], two others which change sign under a $\pi/2$ rotation [(iv) and (vi)], and finally three modes totally symmetric [(i), (v), and (ix)]. The resonance properties of the 9-balls resonator structure have been tested under the excitation of an acoustic plane wave launched in the direction of propagation *x*. For the sake of experimental facilities, the pressure has been detected in the central ball, as shown in the inset of Fig. 1(c). Figure 1(b) presents the numerical calculation of the SPL, considering the lossless (dashed lines) system. Three peaks appear in the frequency spectrum, which can easily be associated with the eigenmodes (i), (v), and (ix) for which the pressure in the central ball is different from zero. Indeed, among all the modes, only the totally symmetric ones (i), (v), and (ix) are compatible with the symmetry of a normal acoustic excitation.

To fit the experimental results, we have considered the air dissipation, using a thermoviscous acoustic model where the air motion is described based on the momentum, continuity, and energy equations,

$$\omega\rho_0\overrightarrow{v_t} = -\nabla P_t\vec{I} + \nabla.\left(\mu[\nabla\overrightarrow{v_t} + (\nabla\overrightarrow{v_t})^T] - \left[\frac{2}{3}\mu - \mu_B\right][\nabla.\overrightarrow{v_t}]\vec{I}\right.$$

$$i\omega\rho_t = -\rho_0\nabla\overrightarrow{v_t}$$

$$i\omega(\rho_0 C_p T_t - T_0 \alpha_p P_t) = \nabla.(\kappa \nabla T_t)$$

$$\rho_t = \rho_0(\beta_T P_t - \alpha_p T_t)$$

where ρ_0 is the air density (1.2 kg/m^3) at the ambient temperature T_0 = 293 K, and P_t, v_t, T_t, and ρ_t are the values of the pressure, velocity, temperature, and density at the considered position in space and for the given acoustic frequency. The bulk and dynamic viscosities employed in the simulations are those of air, namely, $\mu_B = 1.09\ 10^{-5}$ Pa.s and $\mu = 1.81\ 10^{-5}$ Pa.s. C_p, κ, β_T, and α_p are the heat capacity at constant pressure, the coefficient of thermal conduction, the isothermal compressibility, and the coefficient of thermal expansion. I is the identity vector.

When the thermoviscous losses are taken into consideration, we found that the three peaks are shifted toward the low frequencies with a decrease in amplitude (dashed lines in fig 1(b)). The experimental demonstration was carried out by gluing 9 balls together, positioning the microphone in the middle of the central resonator. The experimental data, presented in Fig. 1(c), capture the 3 peaks obtained in the numerical calculation with a good agreement.

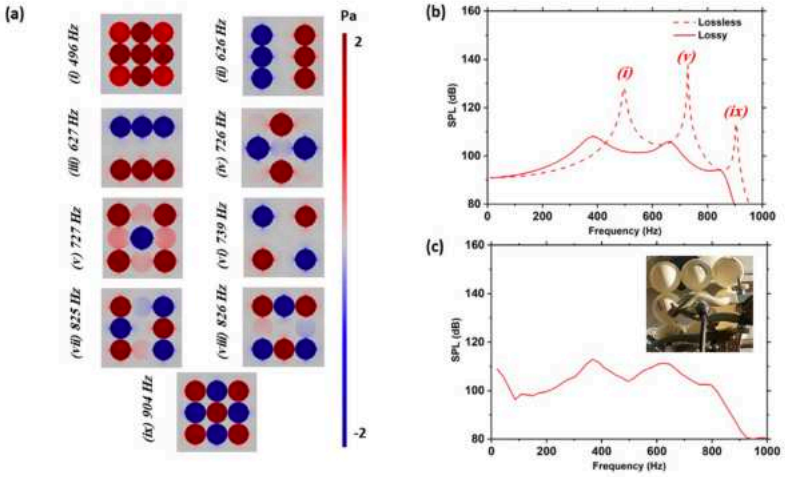

Figure 1 (a) Eigenmodes calculation of the nine-ball connected resonator. Numerical (b) and experimental (c) SPL recorded inside the central ball of a lossless (dashed lines) and lossy (solid line) system.

Abstract: The relaxed micromorphic model (RMM) is employed to investigate the elastic wave propagation of mechanical metamaterials. This model adeptly captures band gaps, restricting wave propagation at specific frequencies. Addressing finite-size blocks, we enrich the RMM framework to incorporate essential boundary effects, exemplifying this through the concept of boundary forces.

Exploring the dynamical response of mechanical metamaterials in the framework of elastic propagation has gathered increasing attention in the last decades. In order to describe elastic wave propagation in metamaterials, i.e. solids with heterogeneities or microstructure, it is necessary to consider non-local or enriched models. The relaxed micromorphic model (RMM) [1, 2, 3] proposed here can describe these effects as a continuous material with enriched kinematics. One of the most important micro-mechanical effects is the appearance of *band gaps* for which waves at given frequencies cannot propagate through the material.

We have shown in previous papers [1, 2, 3] that the relaxed micromorphic model can describe the bulk behavior of mechanical metamaterials. Things become more complicated when considering finite-size metamaterial blocks for which boundary effects may play a major role, e.g. due to the reduced size of the block itself. In these cases, the relaxed micromorphic model framework must be enriched to account for these boundary effects. We will show how the concept of *boundary forces* can be used to address the modeling of finite-size metamaterial specimens in the context of micromorphic elasticity.

Abstract: We present several topologies for phase-and-amplitude acoustic holograms based on metamaterial and phononic crystals. These approaches go beyond traditional phase holograms and produce sharper acoustic images for non-invasive and localized preclinical and clinical therapeutical applications like neuromodulation, drug delivery or surgery, or biomedical ultrasound imaging. Several application examples are provided.

Passive acoustic structures like metamaterials can be used to engineer wavefronts in many practical applications. By tuning its topology, the local refraction, scattering or inner resonances can be tailored for a particular functionality. Among them, acoustic holograms are emerging as a low-cost technology to focus therapeutic ultrasound beams [1-8]. These high-performance lenses can produce therapeutic acoustic images of arbitrary shape into biological tissues. In addition, by exploiting time-reversal symmetry of the wave equation acoustic holograms can encode complex wavefronts compensating the aberrations of stiff layers, enabling the focusing of ultrasound into the human brain. However, usually acoustic holograms are only designed to encode the phase of the beam, neglecting the amplitude information of the time-reversed wavefront. In addition, most of the design strategies for sound waves in air are not suitable for biomedical ultrasound applications, which are generally water-coupled.

In this work, we propose metasurfaces with internal resonances to encode the full-wave information in a 3D-printed structured material. In particular, we report the use of metasurfaces to synthesize wavefronts by tuning subwavelength 3D-printed elastic resonators for ultrasonic frequencies, as shown in Fig. 1. These structures are shown to be remarkably flexible for spatially-coding arbitrary phase-conjugated fields corresponding to the ones used for selected biomedical ultrasound applications.

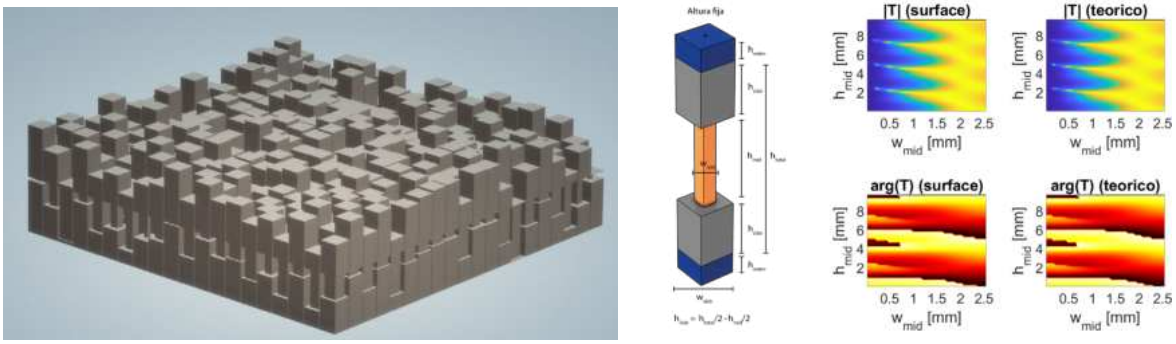

Figure 1. Topology of an acoustic hologram using a metamaterial as a building block. Phase and magnitude can be controlled locally to generate accurate acoustic images.

Then, by mimicking phase-and-amplitude information, these lenses can synthesize complex and arbitrary acoustic images with great accuracy. In this way, by tuning the hologram inner structure, we can synthesize

high-intensity acoustic images with unprecedent resolution, which are currently being applied to focus therapeutic ultrasound beams and treat several diseases in a non-invasive, non-ionizing, localized and low-cost manner. This approach improves the targeting of ultrasound and paves the road for low-cost biomedical ultrasound applications.

Abstract: In this contribution we focus on mechanical metamaterials and discuss how the lattice topology can influence stress localizations when uniaxial compression is applied. We discuss a theoretical model that faithfully can predict the shape and orientation of stress localizations, which appear in good agreement with experimental measurements.

Viscous phononic supercrystal

A. A. Krokhin[1*], M. A. Ibarias[2], and J. Sánchez-Dehesa[2]

Abstract: An effective medium theory and experimental study are proposed for a supercrystal of metallic rods in viscous background. Supercrystal (SC) is a combination of two phononic crystals with different periods imbedded in a viscous fluid. The decay coefficient of sound is calculated analytically at low frequencies when both lattices homogenize.

A monochromatic sound decays in a viscous fluid with the decay coefficient $\gamma_0 = \omega^2(\frac{4}{3}\eta_0 + \xi_0)/2\rho_0 c_0^3$, where ρ_0, c_0, η_0, and ξ_0 are the fluid density, speed of sound, and viscosity coefficients. If the wave meets a solid wall, dissipation is strongly enhanced due to formation of the boundary layer $\delta = \sqrt{2\eta_0/\omega\rho_0}$. A solid-fluid phononic crystal behaves in the low-frequency limit as a homogeneous medium. The effective elastic parameters of this medium, speed of sound c_{eff} and fluid density ρ_{eff}, are calculated using the homogenization procedures proposed in Ref. [1]. Dissipation in a phononic crystal occurs mainly within the boundary layers formed around each solid scatterer. Due to multiple scattering, the level of dissipation exceeds by orders of magnitude the viscous losses in the corresponding background fluid. The exact formula for the viscous decay coefficient in a 2D phononic crystal with arbitrary Bravais lattice was recently obtained in Ref. [2]

$$\gamma_{ph}(\hat{\mathbf{k}}) = \frac{L}{2A_c c_{eff}(\hat{\mathbf{k}})}\sqrt{\frac{\omega\eta_0}{2\rho_0}}N(\hat{\mathbf{k}}) \tag{1}$$

Here A_c is the area of the unit cell and $N(\hat{\boldsymbol{k}})$ is the direction-dependent numerical factor expressed through multiple series over reciprocal lattice vectors. This factor contains information about the microstructure of the lattice. It grows fast with the filling fraction reaching $\sim 10^3 - 10^5$ for the fillings near the close packing [2]. If the crystal lattice possesses the 3[d] or higher order axis of rotational symmetry, the effective medium is isotropic. Otherwise, it is an anisotropic metafluid where the effective parameters depend on the direction of propagation $\hat{\mathbf{k}}$. The effective viscosity for phononic crystal can be easily introduced from the equality $\gamma_{ph}(\hat{\mathbf{k}}) = \gamma_0$, that gives

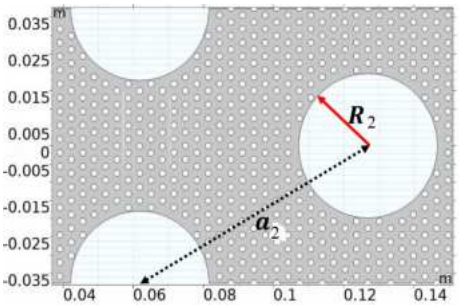

Figure 1. 2D phononic SC of solid cylinders in air. The cylinders of radii $R_1 = 0.88$ and $R_2 = 19.7$ mm are arranged in hexagonal lattices with periods $a_1 = 3.76$ mm and $a_2 = 20\,a_1 = 75.1$ mm. The filling fractions are $f_1 = 0.2$ and $f_2 = 0.25$.

$$\eta_{eff}(\hat{\mathbf{k}}) = \frac{3\rho_{eff}(\hat{\mathbf{k}})c_{eff}(\hat{\mathbf{k}})}{2\omega^2}\gamma_{ph}(\hat{\mathbf{k}}). \tag{2}$$

The effective viscosity is anisotropic in general case, and it scales as $\sim\omega^{-3/2}$ with frequency. For a phononic crystal of solid cylinders of radius $R_1 = 0.88$ mm arranged in a hexagonal lattice with period $a_1 = 3.76$ mm in air the effective viscosity calculated from Eq. (1) yields $\eta_{eff} = 0.365 \cdot 10^6/\omega^{3/2}$ g /s·cm. At frequency 1 kHz the effective viscosity is $3.2 \cdot 10^5$ times greater than the viscosity of air.

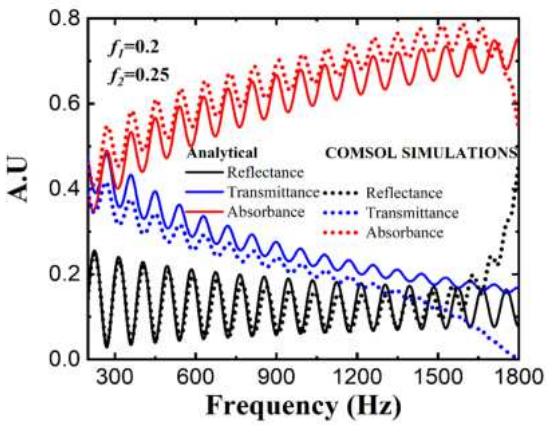

Figure 2. Transmission, reflection, and absorption spectra for SC slab of L=23a_2 length.

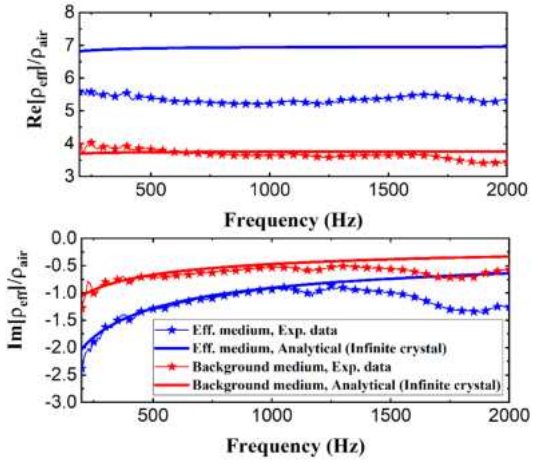

Figure 3. Normalized complex effective mass density.

Strongly enhanced effective viscosity of phononic crystal can serve as a viscous matrix for a phononic crystal with larger period. Such doubly periodic structure (Fig. 1) can be considered as strongly absorbing SC. Here we report analytical, numerical, and experimental results for sound transmission through a viscous SC. Note that it is assumed that sound wave weakly decays passing through a SC, i.e., $\gamma_{sc}^{-1} \gg \lambda \gg a_2$ and both lattices homogenize. Using the technique developed in Ref. [2], the decay coefficient γ_{sc} for 2D SC was calculated. For the SC shown in Fig. 1 the decay coefficient yields $\gamma_{sc} = 0.048\sqrt{\omega}$ m^{-1}. This leads to the effective viscosity $\eta_{sc} = \frac{0.51 \cdot 10^6}{\omega^{3/2}}$ $\frac{\text{g}}{\text{cm}\cdot\text{s}}$. To justify this result transmission through the SC slab of length $L = 23a_2 = 1.56$ was numerically modelled using COMSOL software. The spectra for the SC and for a homogeneous plate with the calculated effective parameters are shown in Fig. 2. There is a good agreement, which confirms the results of the homogenization theory for the viscous SC. All the spectra exhibit Fabry-Perot oscillations with period $2L/c_{sc} = 90$ Hz.

The experiment was performed with a 3D printed SC slab of ABS plastic placed in a standard ACUPRO impedance tube. The geometrical parameters of the SC are: $a_1 = 2.5$ mm, $R_1 = 1$ mm, $a_2 = 33.7$ mm, $R_2 = 9.7$ mm, and the length of the slab is $L = 30$ mm. Since the length of the slab fits only one row of big cylinders, the dispersive properties of the SC are not manifested well. At the same time, the slab contains enough periods a_1. Since the decay length of this SC is about 0.5 m, it is hard to measure it directly. Instead, the complex mass density was extracted experimentally [3] and compared to the analytical result $\rho_c = \lambda_{sc}/c_c^2$, where $\lambda_{sc} \approx \lambda_0/(1-f_1)(1-f_2) = 0.254$ Pa is the bulk modulus of the SC and $c_c = c_{sc}(1 - i\gamma_{sc}c_{sc}/\omega)^{-1}$ is the complex speed of sound. The plots in Fig. 3 demonstrate good agreement for the set of small cylinders with period a_1. For the SC the agreement is observed only for the $Im\,\rho_c$, which is responsible for viscous losses.

Abstract: Our study focuses on the elastic properties of gallium nitride (GaN) nanowires within a polymer matrix, vital for force sensor and artificial skin development. Utilizing picosecond acoustics, we investigate surface wave propagation, offering insight into the composite material's elasticity and resonant properties, crucial for advancing nanotechnology applications.

Here we present our work focusing on the study of the elastic properties of gallium nitride (GaN) nanowires integrated into a polymer matrix. This material is currently the most promising for the development of force sensors and is often cited in projects for creating artificial skin.

GaN nanowires exhibit exceptional elastic properties [1] and a very good piezoelectric response [2,3]. They have been studied individually, but their integration into a polymer matrix and the study of their properties as a whole pose a different experimental challenge from that of the previously used AFM technique.

In our work, we concentrate on studying the elasticity of this new composite material and examine the propagation of surface waves using picosecond acoustics technique. Picosecond acoustic technique enables the generation and detection of high-frequency elastic waves through ultrashort light pulses. Thanks to this non-destructive and contactless method, a picosecond acoustic pulse creates an acoustic wave on the surface of nanostructures. The behavior of the surface wave is studied in both time and space. Based on these elements, we analyze the elasticity of the entire ensemble of nanowires in the polymer layer. Drawing on our experience in the field of acoustic metamaterials, we compare these disordered structures with the latest ones by studying the resonant properties of the nanowires.

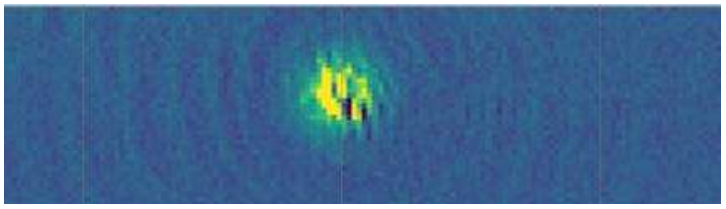

Figure 1. Spatial map (snapshot) of surface acoustic wave propagating on the surface of polymer including GaN nanowires.

Abstract: Energy transfer by Förster resonance (FRET) and the local density of states (LDOS) are both dependent on the electromagnetic environment. An analogy between direct measurements with a microwave antenna has been developed both theoretically and experimentally. A review of the work we have done on this subject will be presented.

FRET measurements in the optical regime are difficult because they require nanoscale control of the position and orientation of the molecules [1-5]. The idea of exploiting an analogy between optics and antenna measurements in the microwave domain has been used to measure the local density of photonic states [6,7]. Recently, we had proposed microwave antenna measurement analogy to improve spatial resolution and precise control of orientation [8-10]. However, the finite size of microwave antennas can affect energy transfer measurements, particularly over short distances. Thus, to obtain accurate results, the finite length of the antenna must be taken into account. In the presented work, we will take advantage of an analytical model that explicitly takes finite size of dipole antennas into account to get a more accurate understanding of dipole-dipole energy transfer in the microwave regime.

We compare our analytical model with experiments on energy transfer between antennas placed next to a perfect electrically conducting mirror. This allows us to establish criteria for the design of microwave experiments, distinguishing between regimes in which finite size effects can be neglected and those in which they must be taken into account.

In addition, present experiments carried out in the microwave domain which show that the excitation of surface waves on a dedicated metasurface can strongly modify near-field dipole-dipole interactions. While, it has been known for a long time that plasmonics can lead to a considerable modification of emission properties however, less is known about the role of surface modes such as surface plasmons on FRET. This makes it possible to envisage metasurfaces designed to control dipole-dipole energy transfer, with applications in many fields [11,12].

The work presented in the field of electromagnetism has natural extensions in acoustics and for mechanical waves in general, for instance for seismic waves.

Abstract: Acoustic metamaterials, which are engineered structures composed of sub-wavelength resonators, are designed to control sound propagation in ways not found in natural materials. Here we discuss the curious case of enhanced transmission through bare holes without resonance using the language of metamaterials.

Electromagnetic metamaterials, consisting of sub-wavelength oscillators that show effective negative permeability or permittivity have led to many applications over the last 20 years. In parallel, acoustic metamaterials showing effective negative density or modulus were introduced [1,2]. Curious phenomena such as acoustic negative refraction, superlensing and cloaking were demonstrated.

Following progress in electromagnetism, in the domain of acoustics metamaterial-related giant extraordinary transmission of kHz airborne waves has also been reported [3], that is, greatly enhanced resonant acoustic transmission through membrane-covered holes. Similar observations were documented for surface or bulk acoustic waves in solids [4,5].

Here we present recent kHz experiments on the extraordinary transmission of airborne sound through bare holes without the occurrence of any resonance [6]. Although resonances are essential in electromagnetism to overcome poor transmission through bare holes, this is not so in fluid acoustics. A plate perforated with bare holes can transmit nearly all the sound normally incident on it, which has practical applications in sound transparent screens. However, this phenomenon has not previously been systematically interpreted in terms of extraordinary transmission. Here we present such an analysis, and hope to make you appreciate, for example, how sound-transparent screens with holes at bank service counters work, and how to optimize them. Because of the enhanced acoustic energy density in the holes, we also propose applications in acoustic energy harvesting.

Static Loading Challenges of Three-Dimensional Ultrawide Phononic Crystals and Elastic Metamaterials

C. Yilmaz[1*]

[1] Department of Mechanical Engineering, Bogazici University, 34342 Bebek, Istanbul, Turkey
[*]corresponding author: cetin.yilmaz@bogazici.edu.tr

Abstract: Three-dimensional ultrawide phononic crystals and elastic metamaterials can ideally be applied for vibration isolation, elastic wave shielding and seismic protection. However, most designs in the literature are additively manufactured from polymers in small sizes. Challenges regarding production of these ultrawide designs in large sizes will be explained considering static loading.

When a periodic structure is excited within a vibration stop band or phononic band gap, transmission of vibrations or elastic waves can be eliminated. For broadband excitations, Bragg scattering [1,2] can be used by periodically varying mass (or density) and/or stiffness (or elastic modulus) values of the constituents of the structure. However, the lowest frequency Bragg gap is centered about the wave speed divided by the lattice constant. Hence, low elastic modulus and high density or large lattice constants are needed to generate band gaps at low frequencies, which are not practical for most engineering applications. If a structure is subject to narrowband excitation, then local resonance method [3-5] can be used by choosing local resonance frequency close to the excitation frequency. Local resonance method can generate band gaps below the Bragg limit. Yet, to obtain wide gaps at low frequencies heavy resonators are required [4,5]. Periodic structures that utilize Bragg scattering method are generally referred as phononic crystals, while the ones that use the local resonance method are usually referred as elastic metamaterials as band gaps can be generated below the Bragg limit. For elastic metamaterials and phononic crystals, obtaining wide band gaps at low frequencies is a major challenge.

Inertial amplification method was proposed [6-8] to circumvent the limitations of the Bragg scattering and local resonance methods for obtaining wide band gaps at low frequencies. In this method, effective mass of a periodic structure can be increased with embedded displacement amplification mechanisms so that band gaps below the Bragg limit can be obtained. Moreover, unlike the local resonance method, band gap formation does not rely on resonating substructures that are only effective around their resonance frequency. Instead, band gap forms due to inertial coupling, which yield broadband response [9]. Moreover, as another advantage over the local resonance method, periodic structures with wide low-frequency band gaps can be designed without necessitating large masses due to the increased effective inertia [6-7]. Since inertially amplified periodic structures can generate band gaps below the Bragg limit, they are considered as elastic metamaterials.

Three-dimensional (3D) ultrawide phononic crystals and elastic metamaterials can ideally be applied for vibration isolation, elastic wave shielding and seismic protection. However, 3D designs in the literature with arithmetic mean normalized bandwidth larger than 100% are generally produced from polymers via additive manufacturing in small sizes [10-16]. Furthermore, to achieve very large bandwidths, these designs involve thin ligaments or flexures joints. Consequently, their load carrying capacities are low. If these type of designs are scaled up to 1 meter or larger sizes, high stresses would be present on the ligaments and flexures due to large self-weight. Thus, additive manufacturing with polymers may not be feasible for large sizes. Although 3D ultrawide phononic crystals and elastic metamaterials are designed to function under dynamic excitations, their static load carrying capacities should also be critically evaluated (see for example [17]) if they are aimed to be used for load bearing applications such as vibration or seismic isolation.

In this invited talk, various 3D ultrawide phononic crystal and elastic metamaterial designs will be shown. Challenges regarding production of these designs in large sizes will be explained considering stress and deformation constraints under static loading. To overcome these challenges, a new design will be proposed.

Thermal rectification in graphite Tesla valve based on phonon hydrodynamics

Masahiro Nomura

Institute of Industrial Science, The University of Tokyo, Japan
corresponding author: nomura@iis.u-tokyo.ac.jp

Abstract: We demonstrate a phonon hydrodynamics approach to realize the rectification of heat conduction in isotopically enriched graphite crystals. We design a Tesla valve at the micrometer scale within a 90-nm-thick sample and experimentally observe a discernible 14% difference between the thermal conductivity in the opposite directions at 40 K.

The Tesla valve (TV) has found extensive application in the rectification of fluid flows without reliance on moving components [1]. The inherent asymmetry of the Tesla valve induces distinct fluid flow behaviors in opposing directions. In contrast to the rectification of fluid flows within microfluidic channels, the rectification of phonons presents a more formidable challenge, primarily attributable to the dearth of fluid-like phonon flows within the majority of microsolid systems. In this study, graphite was employed for thermal rectification, given its intrinsically robust hydrodynamic phonon behavior attributed to its strong lattice anharmonicity and elevated Debye temperature [2]. Asymmetric TV structures were fabricated within a 90-nm-thick graphite sample, as illustrated in Fig. 1(a-b). The graphite with a ^{12}C isotope content reaching 99.98% to minimize the defect scattering. The principal heat flow channel spanned a length of 26 μm and a width of 4.5 μm. Notably, the bend channel maintained an identical width to that of the main channel. The investigation of temperature-dependent thermal rectification effects was conducted utilizing microscale time-domain thermoreflectance (μ-TDTR). At 10 K, comparable thermal conductivity (κ) values were observed in both the forward and backward directions, suggesting that ballistic phonons exhibit a propensity to traverse the entire structures, primarily influenced by boundary scattering. Beyond 20 K, there was a discernible transition, with momentum-conserved normal scattering gradually assuming prominence. This transition is attributed to the collective flow of phonons through the graphite TV. In the forward case, as depicted in Fig. 1a, hydrodynamic phonons predominantly traverse from the heat source to the sink via the main channel. Conversely, in the backward case (Fig. 1b), two distinct hydrodynamic phonon flows diverge from the heat source. The convergence of these two flows leads to a loss of phonon momentum and introduces resistance to thermal transport. This phenomenon results in a notable disparity between κ_f and κ_b in the temperature range of 30 to 60 K, as illustrated in Fig. 1c. In Fig. 1d, we define the diodicity of the heat flow as the ratio of κ_f to κ_b. At 40 K, a pronounced establishment of phonon hydrodynamic flows occurs, with resistive Umklapp scattering remaining relatively scarce. Notably, the strongest rectification effect is observed, wherein κ_f surpasses κ_b by approximately 14%. This investigation elucidates thermal rectification in solid graphite TVs, thereby paving the way for novel approaches in thermal management leveraging phonon hydrodynamics.

Exploring Tunable Poisson's Ratio in Origami Metamaterials

D. Misseroni[1*]
[1]Department of Civil, Environmental and Mechanical Engineering, University of Trento, Trento, Italy

[*]corresponding author: diego.misseroni@unitn.it

Abstract: We present a triclinic metamaterial system of minimal symmetry derived from a Trimorph origami pattern. We investigate the Trimorph pattern through mathematical analyses, numerical simulations, and experimental validation. We developed a manufacturing technique and a testing device, named the Saint-Venant setup, to quantify its reversible auxeticity.

Testing origami metamaterials presents a challenge due to their high deployability in both transverse and longitudinal directions. Traditional uniaxial testing methods, which involve clamping the two ends of a sample to a testing machine, need to be revised since they lead to experimental inaccuracies. Moreover, the theoretical formulae describing the mechanical behavior of origami metamaterials are usually derived assuming two conflicting requirements: rigid and zero-thickness panels. To overcome these challenges, we developed a novel manufacturing process and a specific experimental platform, nicknamed Saint-Venant setup. This setup enables complete free deployment of the origami metamaterial, mimicking a proper periodic system in experiments without violating theoretical assumptions. The fabrication process, based on the use of a CNC milling machine, enables fine control of panels' stiffness and folding hinge properties. This manufacturing method is beneficial for creating multistable systems where each stable state is self-stressed, a feature difficult to achieve using paper models or 3D printing. This leads to programmable geometrically frustrated configurations. We demonstrated the effectiveness of our method by capturing the tunable auxeticity and tristable behavior of a triclinic metamaterial system with minimal symmetry originating from a Trimorph origami pattern. Our findings have important implications for designing and testing origami metamaterials with unique mechanical properties.

Twofold topological transition induced by third-nearest-neighbor hoppings in an artificial elastic polyacetylene

Abstract: An artificial elastic molecule, which emulates the electronic properties of the cis-polyacetylene with third-nearest-neighbor hoppings is introduced. The tight-binding band structure shows a transition between two topological phases with different winding numbers. The low frequency excitations obey the modified Dirac equation. The finite element numerical simulations agree with the theory.

The coupled-resonator phononic waveguides (CRPW) [1] are the analog of the well-known coupled-resonator optical [2] and acoustical waveguides [3]. The CRPW are formed coupling defects in an otherwise periodic structure. When a resonant frequency of the defects falls within a bandgap of the periodic structure a tight-binding (TB) regime, that emulates the TB regime of condensed matter physics, emerges. Generalizations to coupled-resonator phononic molecules (CRPMo) and metamaterials (CRPM) are straightforward.

One of the differences between the optical/acoustical structures and the phononic ones is that in the latter the hoppings to higher neighbors can be engineered *ad-hoc*. This kind of studies allow to study a new variety of phenomena and are almost impossible to realize in photonic and acoustic systems. Here we present a CRPMo that resembles the cis-polyacetylene, with third-nearest-neighbor hoppings [4] (See Fig. 1).

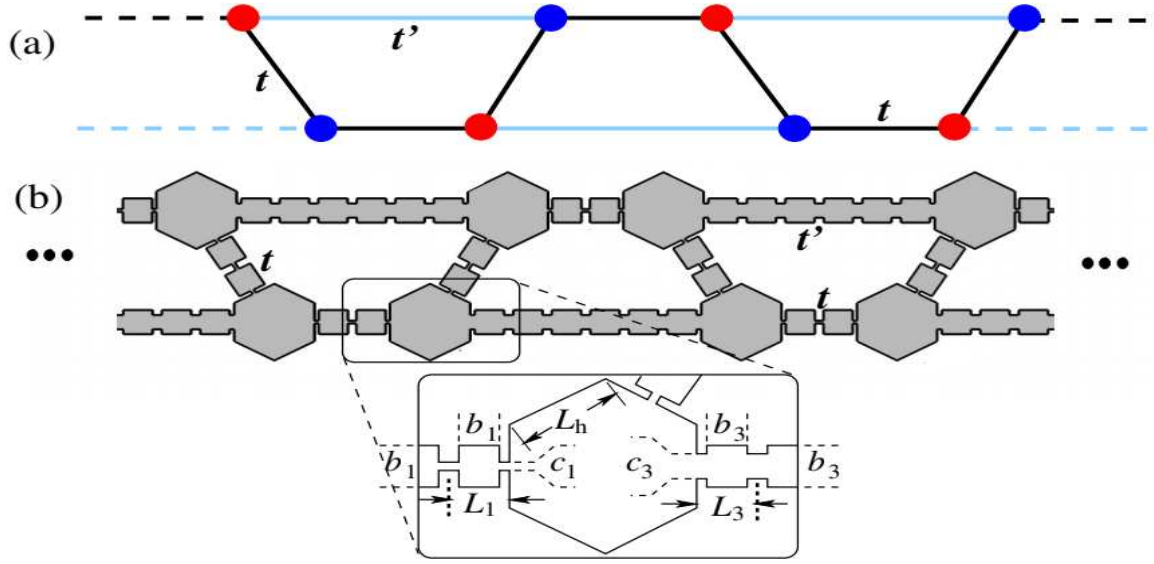

Figure 1: Cis-polyacetylene with first (t) and third (t') nearest-neighbor hopping: (a) tight-binding model, and (b) artificial elastic cis-polyacetylene molecule. The site frequency is governed by L_h and the hopping parameters by L_i and b_i, i=1,3.

The unit cell in the phononic cis-polyacetilene is composed by four meta-atoms; thus four bands are expected.

In Fig. 2 the band structures for the elastic structure of Fig. 2 (b), for different third nearest-neighbors hoppings (t'), and fixed nearest-neighbor hopping (t), are given. Those bands were obtained with finite elements. In case (a), when t'=0 a Dirac cone emerges. In case (b), when the t'<t, this cone disappears and a gap emerges. In case (c), when t'=t, two Dirac cones emerge. Finally, a new gap emerges when t'>t. Cases (b) and (d) correspond to topological phases with opposite winding numbers.

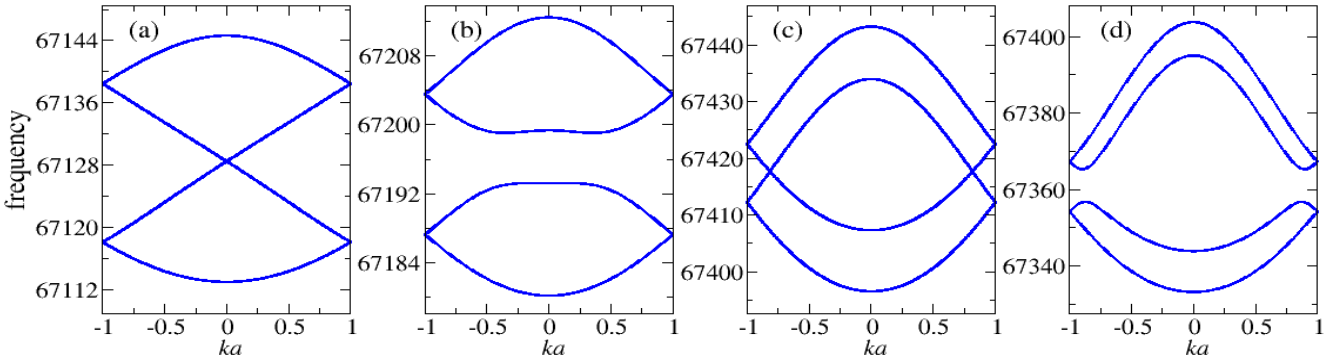

Figure 2: Band structures of the artificial elastic cis-poliacetilene of Fig. 1 L_h = 27 mm, L_1 = 22 mm, b_1 = 17 mm, c_1 = 2 mm, L_3 = 22.4608 mm, b_3 = 17 mm, and c_3 = 5, 7, 9, 10 mm for cases (a) to (d).

The TB Hamiltonian of the phononic cis-polyacetilene with third-nearest-neighbor hoppings is given by [4]

$$H = \begin{bmatrix} f_0 & g^*(k) & 0 & h^*(k) \\ g(k) & f_0 & h(k) & 0 \\ 0 & h^*(k) & f_0 & g^*(k) \\ h(k) & 0 & g(k) & f_0 \end{bmatrix},$$

where f_0 is the site frequency, $g(k) = t\exp(ika/6)$, $h(k) = t\exp(-ika/3) + t'\exp(2ika/3)$, with k the wave vector and a the lattice constant. The bands of the TB Hamiltonian agree with the FE simulations. Also, the low-energy excitations of the cys-polyacetylene TB-model with third-nearest-neighbor hoppings follow a modified Dirac equation instead of the common Dirac equation that satisfy the low-energy excitations in the trans-polyacetylene.

Non-Hermitian Metasurfaces for Extraordinary Elastic-wave Manipulations of Higher-order Diffractions

Bing Li[1*], Jiali Cheng[1], and Bochen Ren[1]

[1] School of Aeronautics, Northwestern Polytechnical University, Xi'an, Shaanxi, 710072, China
[*]corresponding author: bingli@nwpu.edu.cn

Abstract: Beyond the traditional paradigm of Hermitian physics, the concept of non-Hermiticity has recently inspired a surge of nontrivial principles and applications. In this work, we propose several active and passive non-Hermitian metasurfaces that enable unprecedented elastic-wave manipulations, including skin-like effects, asymmetric wave propagation, and perfect absorption.

The past decades have witnessed the remarkable development and explosive implications of meta-structures in elastic-wave steering under the Hermitian systems that disregard material loss. However, the reality of practical applications is inevitably intertwined with loss, leading to the dissipation of elastic wave energy. Traditionally, such losses were viewed as detrimental, potentially compromising the performance of elastic wave devices. Yet, a paradigm shift has emerged from recent groundbreaking research, which has uncovered the potential of strategically engineered loss/gain within non-Hermitian systems to facilitate remarkable wave steering phenomena[1-3]. Through the meticulous design of loss and gain media, complex wave-matter interactions can be realized, encompassing unidirectional wave propagation, band merging, and enhanced sensing capabilities. This novel perspective paves the way for innovative applications in acoustics, seismology, and materials science, where the judicious use of loss and gain can be harnessed to achieve unprecedented control over elastic waves[2-4].

The advent of non-Hermitian metasurfaces has opened new frontiers for elastic wave control, offering a reduced structure footprint in low-dimensional designs. Despite their promise, metasurfaces face inherent limitations stemming from their gradient index characteristics, which can constrain their capabilities. Achieving highly efficient wave manipulation in advanced artificial materials, with a focus on ultra-compact dimensions and easy fabrication, remains an open challenge. This work proposes a design strategy that leverages non-Hermitian modulation to surmount these obstacles. The proposed non-Hermitian metagratings (NHMGs)[4], characterized by their subwavelength unit cells, enable a suite of extraordinary elastic-wave manipulations, including the skin-like effect, asymmetric propagation, and perfect absorption. Building upon these capabilities, we have further engineered a cloaking device based on NHMG, as depicted in Fig. 1, which can effectively shield arbitrary-shaped targets from detection[4]. Our research not only expands the repertoire of elastic wave manipulation techniques in non-Hermitian materials but also offers an ultra-compact solution for wave control, holding significant potential for engineering applications.

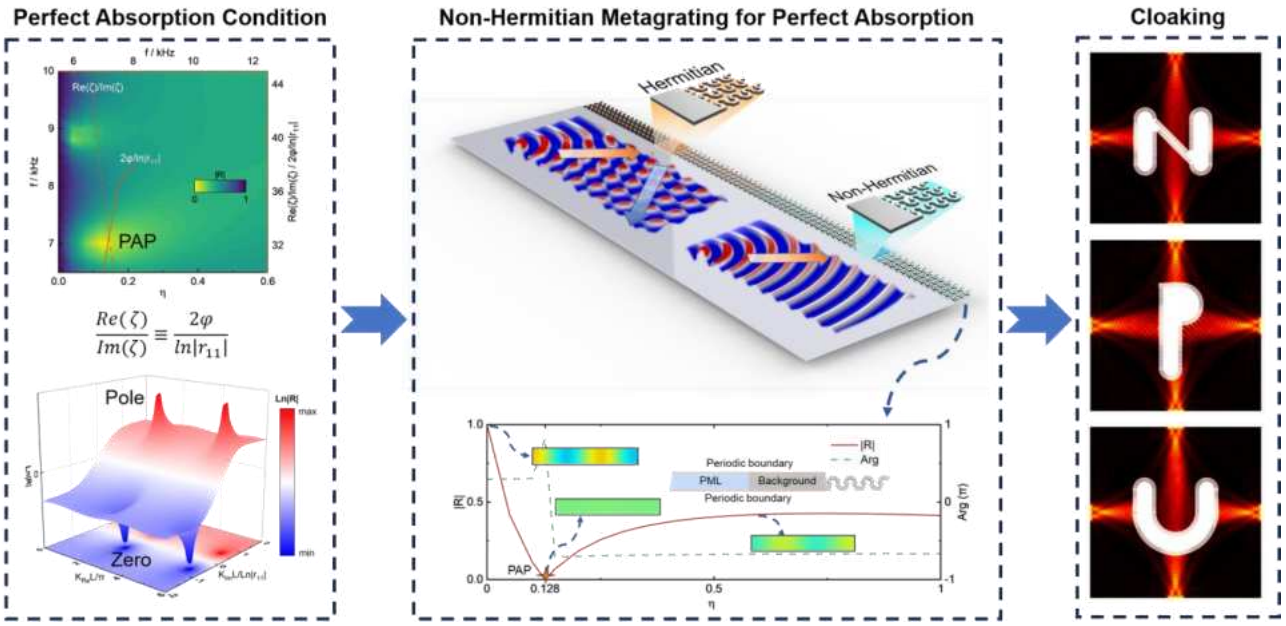

Fig.1 The proposed non-Hermitian metagrating for perfect absorption and arbitrary-shaped target cloaking

Non-adiabatic phononic control of polariton Bose-Einstein condensates

A. S. Kuznetsov[1], K. Biermann[1], and P. V. Santos*[1]

[1]Paul-Drude-Institut für Festkörperelektronik, Leibniz-Institut im Forschungsverbund Berlin e.V., Hausvogteiplatz 5-7, 10117 Berlin, Germany

Abstract:

Exciton-polariton Bose-Einstein condensates (BECs) with their long coherence times and high sensitivity to strain fields are excellent candidates for mediating the coherent interaction between photons, phonons, and electronic excitations in the solid state. We have recently demonstrated that polariton BECs modulated by high-frequency (i.e., GHz) acoustic waves provide a solid-state platform for optomechanics in the non-adiabatic regime, i.e., with polariton acoustic frequencies exceeding the BEC coherence rate [1,2]. Here, we investigate the non-adiabatic behavior of BECs modulated by sub-GHz surface acoustic waves (SAWs) in the regime of acoustic energy modulation amplitudes χhf_{SAW} far exceeding the modulation energy quantum, hf_{SAW}., i.e., for modulation indices $\chi>>1$, where f_{SAW} is the SAW frequency. We show that the large energy modulation reveals a novel regime of temporal coherence that is controlled by the acoustic modulation amplitude rather than just by the ratio between the modulation quantum and the BEC coherence.

The experiments were carried out on a polariton BEC confined within a 4x4 μm^2 intracavity trap formed in an (Al,Ga)As microcavity. The photoluminescence (PL) spectrum of these non-resonantly excited BECs was probed using a etalon with a frequency resolution of 0.3 GHz. Such a spectrum, as is displayed by the blue curve in Fig. 1(b), yields a linewidth $\gamma \sim 0.5$ GHz, corresponding to coherence times approaching 2 ns. The trap is placed in a field antinode of a SAW resonator consisting of two interdigital transducers operating at f_{SAW}=0.384 GHz. The red curve in Fig. 1(b) displays the PL spectrum of the trap when a nominal radio-frequency power P_{rf} = 10 dBm is applied to the SAW transducers. The strain field of the SAW modulates the energy of the confined BEC, leading to the appearance of non-adiabatic sidebands around the undisturbed BEC emission. By varying the acoustic power, we could show that the maximum frequency shifts of the sidebands are proportional to $\sqrt{P_{rf}}$ and, thus, to amplitude of the SAW strain field.

The high energy modulations amplitudes are expected to induce temporal coherences at time scales much shorter than the SAW period, $1/f_{SAW}$. The BEC coherence under acoustic excitation was probed in the time domain using the interferometric setup sketched in Fig. 1c. Here, the autocorrelation delay τ is controlled by the shifting the position of mirror M_2. In the absence of a SAW, the autocorrelation is characterized by short oscillations with period π/ω_{PL}, where $\hbar\omega_{PL}$ is the BEC emission energy (cf. upper panel of Fig. 1(d)). The acoustic energy modulation with amplitude χhf_{SAW} introduces a modulation of the envelope of the short-period oscillations with a periodicity $\tau_{ac} = 1/(2\,\chi\, hf_{SAW})$ controlled by the modulation index, as illustrated in the main panel of Fig. 1(d). This periodicity $\tau_{ac} = 30$ ps for the modulation index $\chi=44$ in this figure is almost two orders of magnitude smaller than the SAW period of 2600 ps.

The individual non-adiabatic sidebands cannot be clearly distinguished in Fig. 1(b) for small frequency shifts Δf, since their linewidths γ is comparable to the energy spacing hf_{SAW}. For large shifts, in contrast, one observes pronounced oscillations at the extrema of the modulation with frequency spacing far exceeding the SAW frequency (cf. dashed rectangle). These oscillations result from the bunching of the sidebands to form beats with the frequency spacing $\gg f_{SAW}$: they provide evidence to a novel regime of temporal coherences at time scales much

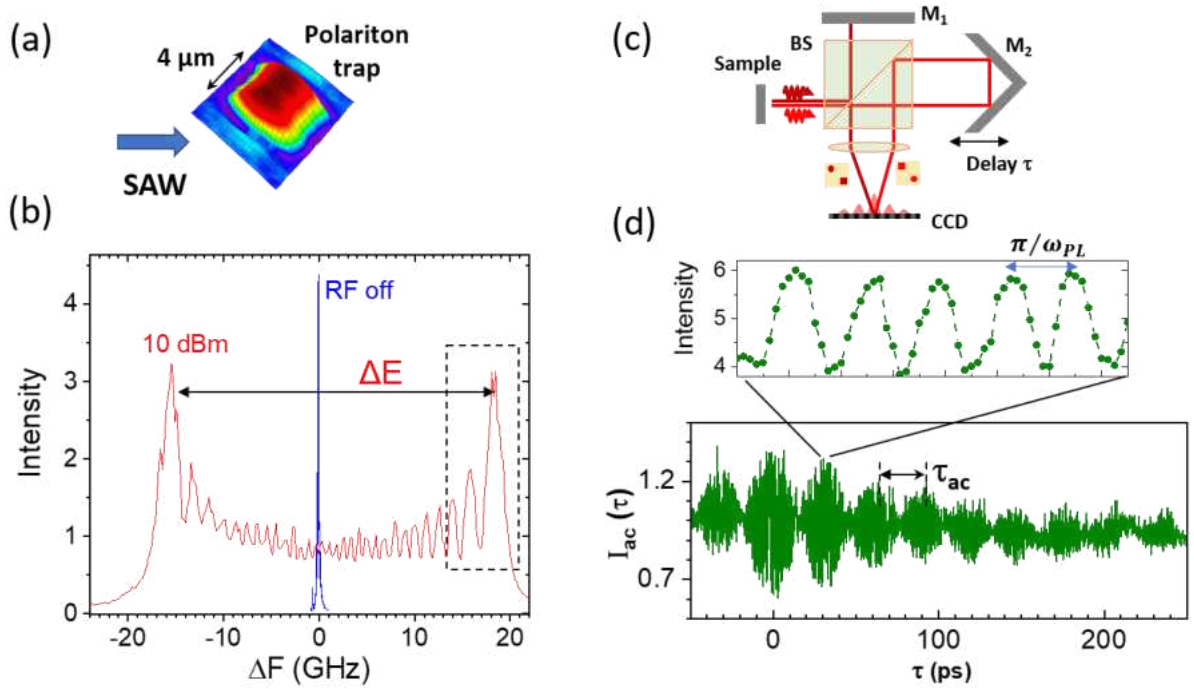

Figure 1. (a) Polariton BEC trap pumped by a surface acoustic wave (SAW). (b) (red curve) High-resolution photoluminescence (PL) spectra (spectral resolution of 0.3 GHz) displaying non-adiabatic sideband spectra recorded for a nominal rf-power Prf applied to the SAW transducer of 10 dBm (corresponding to χ=44). The blue curve shows the corresponding spectrum in the absence of acoustic excitation. The dashed rectangle indicates the region of acceleration beats. (c) Interferometric setup for temporal correlation measurements. (d) Autocorrelation traces of the PL emission under an energy modulation amplitude χhf_{SAW} with χ=44. The short-time autocorrelation oscillations associated with PL emission energy (with period π/ω_{PL}) is displayed in the inset. The acoustic modulation forms beats with time displaced by a period $\tau_{ac} = \pi/(\chi h\, f_{SAW})$ inversely proportional to the modulation amplitude χ.

shorter than the SAW period, which is induced at high amplitude modulation indices. In order to justify this assertion, we developed a model for the nonadiabatic modulation of the confined BECs, which reproduces very well the experimental spectral features in Fig. 1(b). The model shows that these spectral features, denoted as acceleration beats, arise from the bunching of the non-adiabatic sidebands induced by the accelerated energy changing rates close the extrema of the modulation [3]. The results presented here show that the strong interaction with vibrations together with the efficient optical and acousto-electrical control makes confined polariton BECs modulated by high-frequency acoustic waves excellent candidates for coherent information transfer between the GHz and near-infrared frequency domains..

Abstract: We control topologically protected states applying uniaxial prestrain in an auxetic metasurface, realized in a thin slab applying oriented cuts in a hexagonal lattice, where degeneracy is removed and topological band gaps opened by reducing the cut lengths. Scatter-free propagation can then be manipulated with the application of prestrain.

So far, most of the investigations on the properties of auxetic materials and metamaterials have focused on their static behaviour, but there are indications that many attractive features also appear in their dynamic properties. In particular, auxeticity enables large volumetric deformations at relatively low values of stress due to the small bulk modulus, while maintaining the shear modulus significantly large (as is typical of a solid), since the ratio between the bulk and the shear moduli tends to zero as the Poisson's ratio ν tends to the lowest limit of -1 (for an isotropic medium). This also applies to topological protection, which has recently emerged as a as a unique means to propagate waves through sharp corners or bends, being robust with respect to structural disorder, defects or backscattering [1]. In this context, it would be particularly important to introduce dynamic tunability (i.e. a means to modify in time the operational frequency of a given the device) employing an external field such as prestrain.
To do this, we use a phononic lattice whose unit cell design is based on the introduction of oriented cuts arranged in a hexagonal pattern within a thin sheet of material. This structure exhibits auxetic behaviour with an extremely negative Poisson's ratio [2]; at the same time, the band structure for both in-plane and out-of-plane modes admits various Dirac cones, which can be exploited for the creation of topological valley modes. The breaking of C6-symmetry of the unit cells to remove degeneracy is obtained by changing the length of alternate cuts, generating topologically protected modes in two frequency ranges. For the considered structure, this feature only occurs in the presence of cell auxeticity. In these frequency ranges, there is good wave localization at the interface and propagation at sharp edges with negligible backscattering.
The scatter-free waveguiding properties can now be manipulated by the simple application of unidirectional quasi-static pre-strains (Fig.1a) of moderate amplitudes (typically below 10%), in which geometrical nonlinearity can be activated. This allows a controlled variation of the unit cell dispersion properties, with the removal of the topological band gaps (Fig.1b), thus enabling the reversible transition from localized waveguiding to nonlocalized propagation (Figs. 1c,d,e,f). This modification can also be generated in limited portions of the propagation domain,

by applying strain that is variable in space or time.

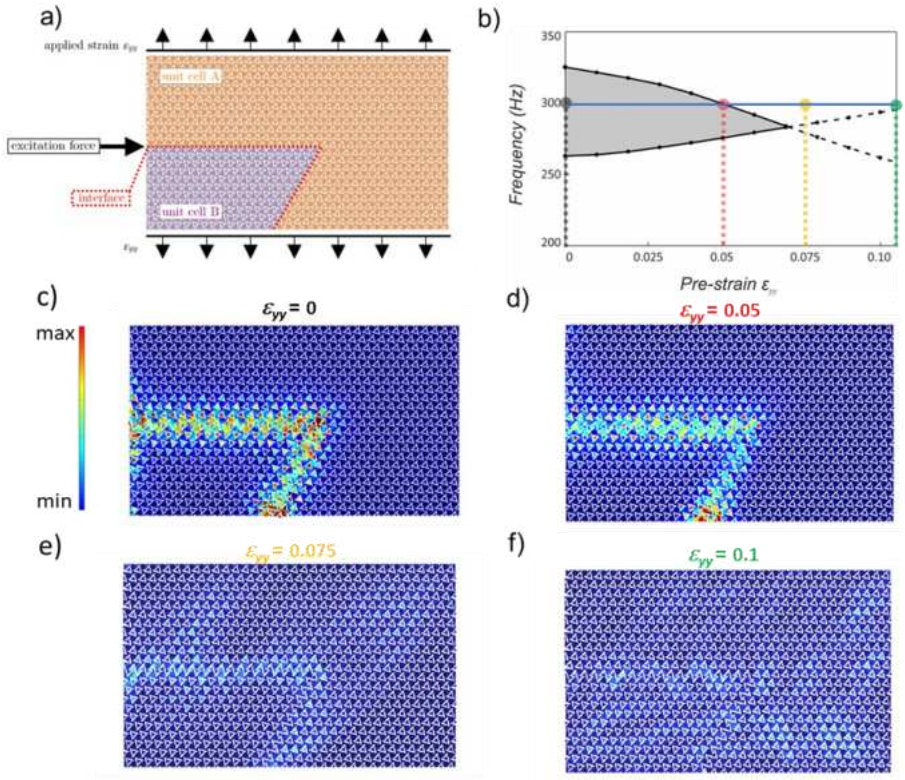

Figure 1: Tuning of waveguiding by applying an external pre-strain εyy. (a) Schematic of the FEM model for frequency domain simulations. b) Detail of the and gap as a function of pre-strain. Displacement fields for f=300 Hz and c) εyy =0, d) εyy =0.05, e) εyy =0.075, and f) ι yy =0.1, illustrating progressive loss of wave localization for increasing pre-strain.

Given the relative simplicity of the design, these auxetic tunable topological metamaterials should be amenable to fabrication in soft polymeric or elastomeric samples with standard techniques (e.g. molding and machining), and the required material/geometrical nonlinearity could be generated at relatively small applied pre-strain, allowing for an experimental realization of proof-of-concept experiments, and further extending the possibilities in the fast-growing field of tunable metamaterials.

Abstract:
This study explores the tunability of phononic crystals' topological properties, using photoresponsive azo-polymers based on the Su-Schrieffer-Heeger model. It demonstrates dynamic adjustment of edge mode frequencies in a one-dimensional SSH chain and the ability to induce topological phase changes in a two-dimensional SSH lattice through illumination.

The exploration of phononic crystals and their topological properties has opened fascinating avenues for manipulating wave propagation in materials. This study employs photoresponsive polymers in constructing phononic crystal systems, enabling the dynamic control of their topological properties through laser illumination, which alters the polymers' elastic properties upon exposure to light [1], thus facilitating the modification of the systems' topological characteristics under investigation. Within this context, we describe two systems based on Su-Schriffer-Heeger model. The first system explores a one-dimensional SSH chain implemented by aligning pairs of elements with varying coupling strengths, achieved through alternating "long" and "short" distances between them [2]. The basic structural unit consists of a polymeric slab (thickness $t = 1.5\,mm$ and width $a = 7\,mm$) upon which elastic rods, each $20\,mm$ tall and $0.5\,mm$ in radius, are periodically positioned within a unit cell (see Fig. 1a). These rods are placed at a distance s_i from one another, symmetrically around the center of the cell. We design two types of cells characterized by differing separation distances, s_1 and s_2, with s_2 being defined as $a - s_1$. Both cell types exhibit identical dispersion curves and share a common bandgap, interconnected by a mere shift of s_2. Two periodic structures are created by replicating 10 times these unit cells, which are subsequently joined to create a singular configuration that introduces a discontinuity in periodicity at the interface between the arrays. This disruption acts as a "defect", effectively serving as an interface between Zak phases and supporting a topologically protected edge mode. The photo-responsive characteristics of the material is exploited to decrease its Young's modulus through stimulation by a laser beam with a wavelength of $\lambda = 405\,nm$, targeting the sample's central region (interface) from the side. This was exploited to examine the effects of altering the elastic constants on the topological edge mode confined at the interface. Indeed, by enhancing the laser power directed at the central defect region, the peak associated with the localized mode moves to lower frequency values, as depicted in Fig. 1(b), observing a maximum shift of around $300\,Hz$ at $250\,mW$ from the initial frequency. This frequency shift, triggered by targeted illumination on the sample, exhibits a linear dependency on the laser power and can extend up to the edge of the band gap. Importantly, this adjustment is completely reversible upon the cessation of illumination.

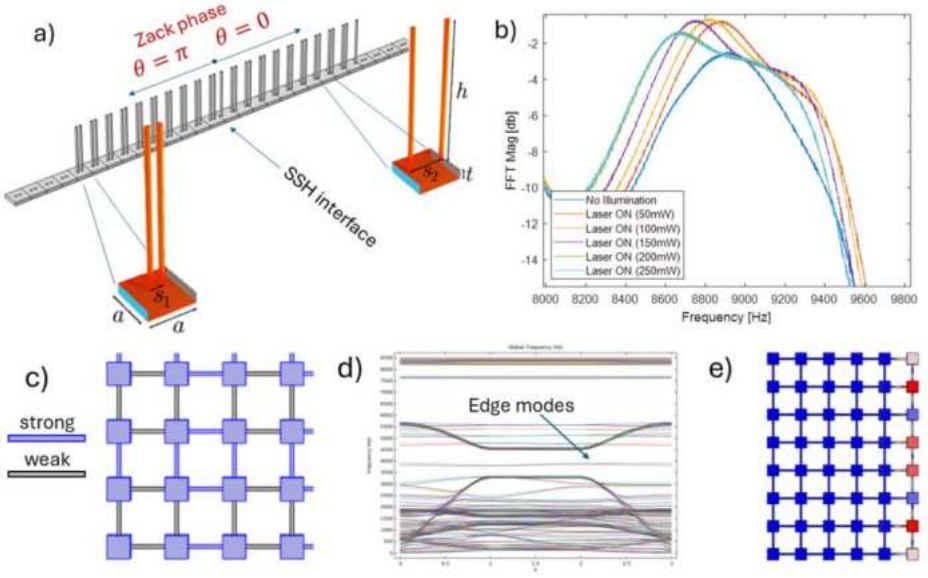

Figure 1:a) One-dimensional SSH based sample with zoom on the two unit cells of lateral dimension a and dstances between the pillars of s_i.b)Edge mode shift upon laser light illumination. c) Two-dimensional system with strong and weak bond depending on the young modulus value. d) Observation of the edge-mode in the band gap. e) Localized edge mode on the two-dimensional lattice

The second system extends these concepts to a two-dimensional lattice, composed of interconnected SSH chains. The SSH model's extension to 2D lattices has opened the door to a rich variety of topological states, including higher-order topological insulators, weak topological insulators, and Weyl semimetals [3].

Our investigation introduces a novel approach to engineering these topological phases by leveraging the unique properties of photoresponsive polymers. We commence with a uniformly connected 2D lattice, consisting of beams ($12\ mm$ in length and $1.25\ mm$ in square cross-section) linking mass nodes ($8\ mm$ cubes), fabricated from a photoresponsive polymer. This initial configuration represents a neutral state, with all links equivalent, thereby lacking any distinct topological character. The innovation lies in our method of inducing topological variation: by projecting a precise pattern of laser light onto the lattice, we selectively alter the mechanical properties of the polymer links. This selective illumination simulates the introduction of "strong" and "weak" bonds within the SSH model, thereby patterning the lattice into configurations that exhibit diverse topological phases. By changing the pattern of illumination, we can dynamically transition the lattice through various topological states, effectively “drawing” new topological properties onto the material with light.

Our work not only demonstrates a practical method for the manipulation of topological phases in 2D systems but also enriches our understanding of the interplay between material properties and topological physics, offering a versatile platform for the study and exploitation of topological phenomena.

Abstract: We report an ultrasonic hologram based on Quadratic Residue sequences encoded with resonant building blocks behaving as an ideal Lambertian scatterer from both sides, with spatial autocorrelation coefficients $\delta \approx 0.7$ each one, therefore diffusing waves in both transmission and reflection.

In this work, we present a bi-directional asymmetric ultrasonic hologram that can simultaneously control both the reflected and transmitted wave-fields. To do that we design a surface made of a discrete spatial distribution of monolithic elements with different properties than the surrounding medium. This allows to compress two identical or different wavefield scattering patterns (for transmission and reflection) into a single monolithic object. Depending on the applications, such hologram could be useful in situations where transmitted and reflected wavefields need to be controlled at the same time, such as a bi-directional diffusing system emitting and receiving equally in and from all directions (equivalent of perfect optical diffusers in optics [1]) or as a bi-directional beam directivity selector, e.g., focusing/collimating/decollimating beam switch. Such hologram could also be used directly in reflection situations for minimizing unwanted specular reflections, e.g., reflections from surgical instruments during ultrasound-guided medical procedures [2].

We consider the building block is made of a monolithic polymer block of length l surrounded by two water blocks of length d_1 and d_2 respectively (see Fig. 1(a)). The sound pressures, p, and normal particle velocities, v_z, at $z = 0$ and at $z = L$ can be modelled by means of the Transfer Matrix Method (TMM). We consider each building block is independent from each other in the structure and considered as an equivalent fluid. Such approximation can be made due to the low difference in impedance between the water and polymer media, with a polymer-to-water impedance ratio, coupled with the fact that shear waves can also be neglected due to the system being considered under normal incidence. Therefore, the scattering coefficients of each building block can be calculated

In order to design a lens that can behave as an ideal scatterer in both reflection and transmission directions, the latter must display a phase distribution coefficient at the surface, $\xi(x, y)$, such that the spatial Fourier transform of said distribution approximates a flat distribution. There are many number theoretic sequences that can help design such phase distribution, such as the maximum length or quadratic residue sequences [3]. Here, the quadratic residue (QR) sequence will be used. In order to determine the phase distribution coefficient at the surface, $\xi(x, y)$, we perform a data base of properties of the monolithic polymer block to produce the desired phase of the reflection and transmission coefficients.

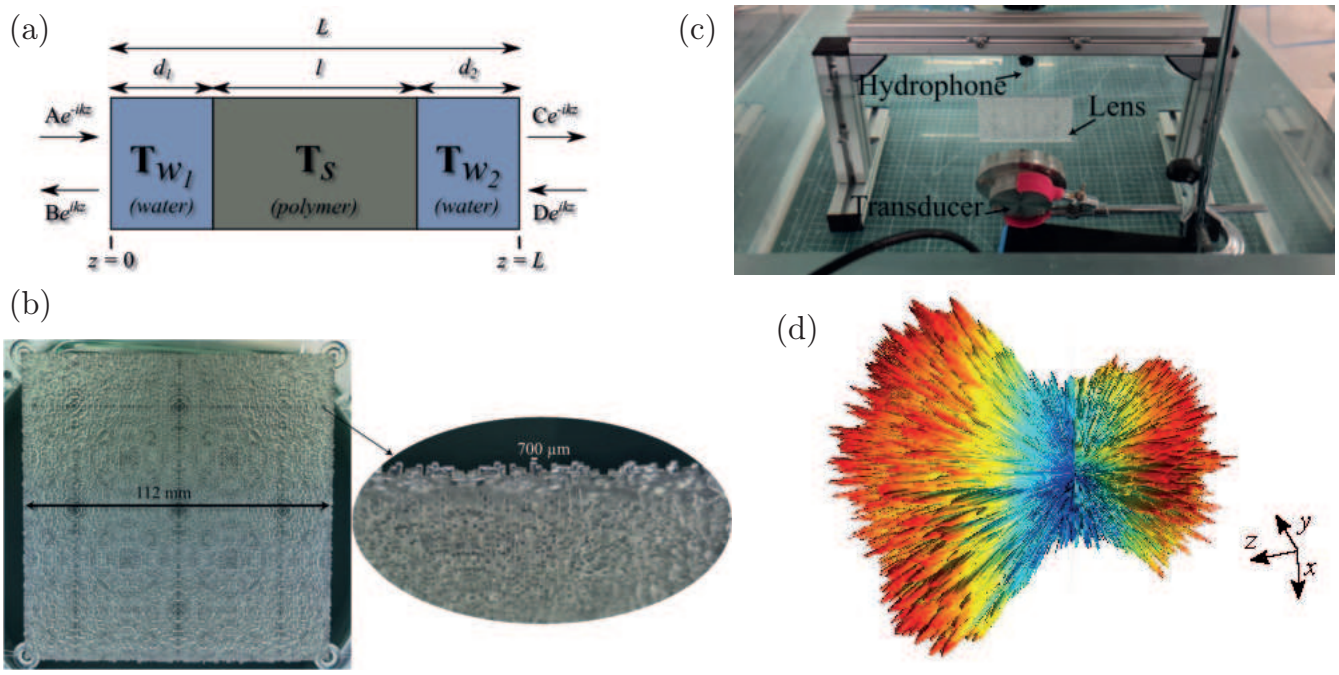

Figure 1. (a) Representative 1D Scattering Matrix diagram of a block of total length L composed of a polymer element and an exterior water medium. (b) Picture and detail of the fabricated sample. (c) Experimental setup. (d) 3D measured acoustic field at 1.1 MHz from both sides of the diffusing hologram.

A picture of the fabricated sample can be seen in Fig. 1(b). It has been experimentally tested for underwater acoustics in the water tank shown in Fig. 1(c). In this talk we will show the excellent agreement between the theoretical predictions and the experimental results, and we will discuss in details the main features of the system with a Physical insight of interest for the audience of the META conference.

Experimental study of sonic velocity modulations and time interfaces in a controllable piezoelectric phononic crystal

C. Croënne[1*], S. Tessier Brothelande[1], F. Allein[1], J. O. Vasseur[1] and B. Dubus[1]

Abstract: This communication concerns the experimental study of elastic wave propagation in a piezoelectric phononic crystal with controllable electrical conditions. The two control laws under study are (a) non-stop shifting conditions in the so-called sonic regime of modulation, and (b) global abrupt changes of conditions, i.e. time interfaces.

Phononic crystals made of piezoelectric materials exhibit the remarkable property that their dispersion can be modified by means of changes in their electrical boundary conditions. For instance, a stack of identical piezoelectric rings separated by thin electrodes (Fig. 1) presents different dispersion characteristics if these electrodes are grounded or left in floating potential[1]. The essential difference lies in the presence of a Bragg band gap of electrical origin in the former case, which is absent in the latter.

Figure 1 – Picture of the piezoelectric phononic crystal with its electrodes connected to a dedicated control system which consists in a chain of printed circuit boards supporting electrical switches whose state evolutions can be programmed through a digital signal processor (DSP).

Since the frequency of this gap is directly related to the distance between two grounded electrodes, this effect supplies an easy route to the realization of a space-time modulated propagation medium. In practice, a periodic subset of electrodes can be grounded, while the rest is left floating, and this subset can be spatially shifted as a function of time, resulting in an equivalent space-time modulated medium[2]. An important advantage of this type of system lies in the easiness to reach modulation speeds equal or even significantly greater than sound wave velocity, since the modulation is realized through sets of electronic circuits controlling the electrical conditions. In this communication, experimental results for these regimes are presented, discussed and confronted with theoretical predictions. The so-called *sonic* case (i.e. modulation speed exactly equal to sound wave velocity) is of special interest since analytical developments show that it results in an overlap (degeneracy, see Fig. 1) of dispersion branches[3] and possibly broadband parametric amplification effects[4].

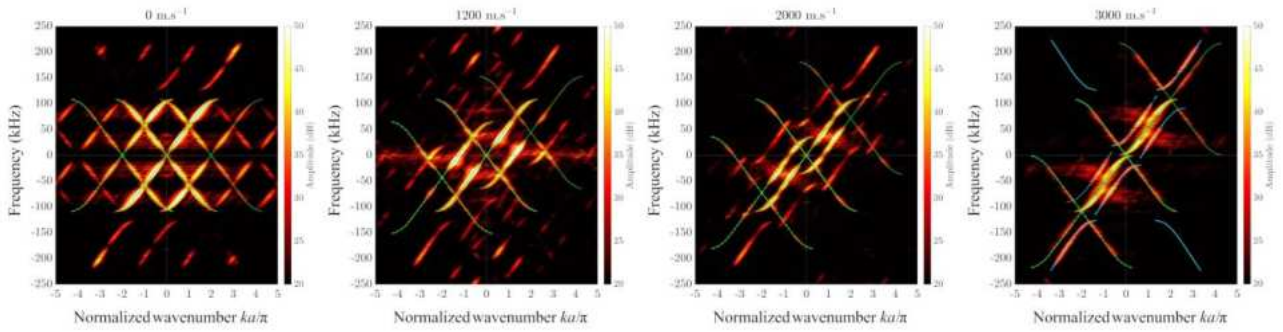

Figure 2 – Space-time Fourier transforms of measured electrical potentials inside the modulated phononic crystal for different modulation speeds c_m. Green and blue lines are guides for the eye, pointing out the general dispersion branch evolution as a function of c_m. The fourth case corresponds to the sonic regime, with branches in partial overlap.

In addition to modulation control laws (i.e. perpetually shifting electrical conditions), this type of device also enables the realization of time interfaces (i.e. global abrupt changes of conditions), turning them into members of the recently defined class of *Floquet metamaterials*[5]. Scattering of wave packets by one or several time interfaces of different types is experimentally investigated. In addition to the general effects related to time interfaces, piezoelectricity-related effects are discussed. In particular, the possibility of trapping elastic wave propagation-related electrical charges at each electrode is studied.

On the role of phase in nonreciprocal vibration transmission in passive and active phononic lattices

A. Kogani[1], J. Wu[1], and B. Yousefzadeh[1*]

[1]Department of Mechanical, Industrial and Aerospace Engineering, Concordia University, Montreal, QC, Canada
[*]corresponding author: behrooz.yousefzadeh@concordia.ca

Abstract: We highlight the contribution of phase to nonreciprocal vibration transmission in nonlinear (passive) and spatiotemporally modulated (active) phononic lattices of finite length. We showcase nonreciprocal response regimes characterized by equal energies transmitted in opposite directions. A nonreciprocal phase shift is the only contributor to breaking of reciprocity in this scenario.

Nonreciprocity is an important problem from a fundamental perspective and in terms of additional functionalities that it enables in mechanical devices [1]. Common realizations of nonreciprocal response rely on implementation of nonlinearity or time-varying properties within the mechanical system. In most cases, the focus is on maximizing the nonreciprocal energy transfer: the difference in the transmitted energies or amplitudes when the locations of the source and receiver are interchanged. Here, we emphasize the role of phase in nonreciprocal vibration transmission in both nonlinear and time-varying phononic lattices. We focus on response regimes that are characterized by nonreciprocal phase shifts: the transmitted energies are equal for the left-to-right (LR) and right-to-left (RL) directions, but the transmitted phases are not.

Fig. 1 shows the systems we study to demonstrate nonreciprocal phase shifts. Panels (a) and (b) show, respectively the representative units used for the lattices with spatiotemporal modulation and nonlinear stiffness. In each case, the steady-state response of the system to a harmonic excitation is computed. Excitation is first applied to the left end of the system and the response at the right end is monitored (left-to-right transmission, LR). The locations of source and receiver are then interchanged and the procedure is repeated (right-to-left transmission, RL). The response is reciprocal if and only if the two outputs are identical.

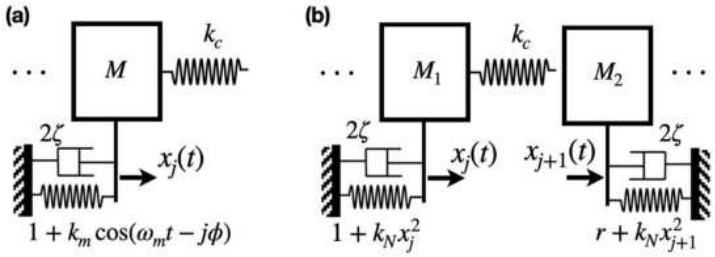

Figure 1: Representative units of the phononic lattice: (a) time-varying system, (b) nonlinear system.

In the nonlinear systems, nonreciprocal dynamics requires breaking the mirror symmetry of the system. This is enabled within the unit cell in Fig. 1(b) by the mass ratio (M_2/M_1) or stiffness ratio (r). Response regimes that exhibit nonreciprocal phase shifts ($\Delta\varphi$) can be computed for the unit cell or for the entire lattice using numerical continuation techniques [2,3]; see Fig. 2(a) for an example response. Computation of the nonreciprocal phase

shifts also allows obtaining reciprocal dynamic response in a nonlinear system with broken mirror symmetry [4].

In systems subject to spatiotemporal modulations, the definition of phase is not as straightforward because the response of the system is quasi-periodic. This is due to the presence of two incommensurate frequencies: external and parametric drive. The envelope of the response, however, remains periodic. It is therefore possible to search for nonreciprocal phase shifts in the modulated system by considering the response envelope instead. If the response envelope exhibits nonreciprocal phase shift, so does the original signal. Fig. 2(b) shows an example of a response computed in this manner that exhibits nonreciprocal phase shift [5].

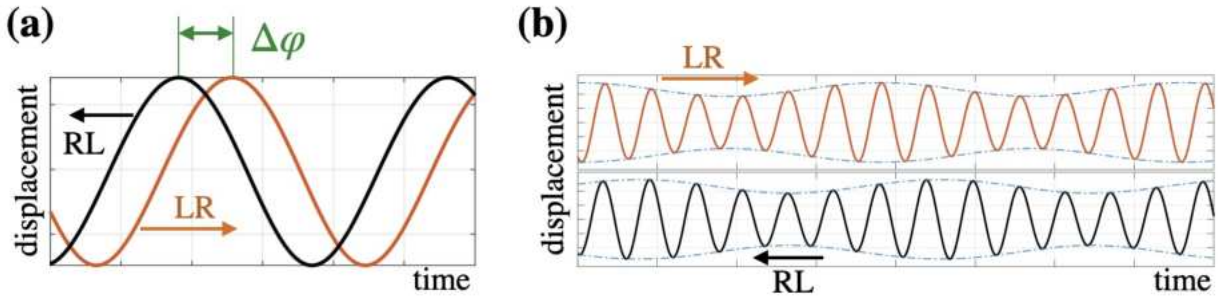

Figure 2: Response exhibiting nonreciprocal phase shift: (a) nonlinear system, (b) modulated system.

In summary, we showcased the contribution of nonreciprocal phase shifts in realizing nonreciprocal vibration transmission in short phononic lattices. To highlight the role of phase, we focused on nonreciprocal dynamics where the transmitted energies do not depend on the direction of travel but the transmitted phases do. For modulated systems, this became possible by formulating the response in terms of its response. We hope these findings contribute to enhancing the performance of devices that operate based on nonreciprocity.

Harnessing topology and nonlinearity for advanced elastic wave control

G. Theocharis[1]

[1]Laboratoire d'Acoustique de l'Université du Mans (LAUM), UMR 6613, Institut d'Acoustique - Graduate School (IA-GS), CNRS, Le Mans Université, France

Abstract: In this talk we will investigate structures for advanced control of elastic waves using concepts and tools from topological materials and nonlinear dynamics. This line of research has practical applications in the design of robust elastic wave devices and reconfiguration of flexible elastic materials.

The first part of the talk will focus on topological mechanics. The recent discovery of topological materials in condensed matter physics has led to the emergence of a new notion of topology associated with the intrinsic wave dispersion of a structure. As a result, numerous mechanical designs have been developed that exhibit non-trivial and robust energy localisation. This talk will give a brief overview of the different classes of topological mechanical metamaterials, and then present a new family of finite-frequency mechanical metamaterials that we have recently introduced [1]. Here, robust topological properties appear in deformation coordinates, while topological edge waves appear for free boundaries.

The second part of the talk will focus on the nonlinear dynamics of flexible elastic metamaterials. Flexible elastic metamaterials (flexEMs) are defined as engineered structures that can deform substantially, repeatedly and reversibly [2]. Although recent advances have improved our understanding of the quasi-static mechanical properties of flexEMs, there are not many studies on their nonlinear dynamic response. In this talk, two types of flexEMs will be presented. One consisting of (i) rotating rigid units (particles of different shapes) coupled with soft elastic elements [3] and (ii) a lattice of coupled buckled beams, a bistable mechanical metamaterial [4]. Using various analytical and numerical techniques, we were able to find several nonlinear wave solutions, including solitons, breathers and wave extreme events, that can be supported by these types of flexEMs.

We acknowledge the support from ANR project ExFLEM ANR-21-CE30-0003-01. This presentation is based on several works that have been done in collaboration with: Antoine Demiquel, Apostolos Paliovaios, Vassos Achilleos, Vincent Tournat, Florian Allein, Adamantios Anastasiadis, Rajesh Chaunsali, Ian Frankel, Nicholas Boechler and Fotis Diakonos.

Abstract: MetaVEH project, funded by the EU, pioneers in metamaterials for efficient vibration energy harvesting, enhancing frequency bandwidth and energy conversion. Achievements promise sustainable, battery-free solutions for autonomous devices, marking significant strides in self-powered electronics and sustainable energy solutions.

The EU-MetaVEH project represents a remarkable effort, to redefine the landscape of energy harvesting through the innovative application of metamaterials. This initiative has successfully designed, developed, and demonstrated novel metamaterials tailored for efficient vibration energy harvesting, targeting the broad frequency range of environmental vibrations. Our approach integrates cutting-edge research in resonant metamaterial structures with sophisticated energy conversion mechanisms, enabling the capture and conversion of vibrational energy from ambient sources into usable electrical energy.

The project's technical journey encompassed the exploration and optimization of multi-scale resonant structures, capable of enhancing energy harvesting from low-frequency vibrations, a challenging area for conventional materials. Through meticulous design and engineering, we achieved significant breakthroughs in increasing the bandwidth and efficiency of energy harvesters. These advancements were supported by rigorous computational modeling and experimental validation, leading to the development of prototypes with superior performance characteristics.

The insights gained from this project contribute significantly to the field of metamaterials, opening new avenues for research and application in energy harvesting and beyond. We believe our research will have profound implications for the future of autonomous sensors and devices, offering a sustainable alternative to battery-powered systems.

In this talk, I will present the most relevant results of the past 4 years of research and outline the challenges that still lies ahead.

The authors acknowledge support from the H2020 FET-proactive project METAVEH under the grant agreement 95203

Abstract: We study theoretically topological interface states in periodic and disordered pillared elastic metabeams. Using band inversion symmetry, we obtain interface states and through their coupling achieve a robust Fano mechanical resonance. Then, we show multiple topological interface states in hyperuniform disordered pillared metabeams. Finally, we consider topological Anderson insulators.

The emergence of topological materials has opened many avenues in various wave problems including elastic media. We have devoted several works to topological phononics in pillared structures consisting of an array of pillars on a plate. We demonstrated the analogs of valley-Hall and spin-Hall crystals[1], robust edge modes at the interface of two topologically different structures and various refraction phenomena at the edges' outlet[1], the existence of corner modes[2] as well as a topological vortex mode[3].

In this presentation, we focus on the case of a beam supporting an array of pillars. First, we present our results on periodic structures where the pairing between the beams allows us to construct the analog of the Su-Schrieffer-Heeger (SSH) model[4]. Considering each of the four types of waves that propagate along the beam (respectively symmetrical or antisymmetrical with respect to a horizontal and a vertical plane), we showed the existence of interface states at the boundary of two topologically different phases. Then, we made the superposition of the gaps associated with two types of modes, namely the symmetric and antisymmetric shear modes as shown in Figure 1. The coupling between their respectively low Q (dark) and high Q (bright) interface modes allows to achieve a robust topological Fano resonance[4].

Furthermore, we present topological interface modes between two SSH-like hyperuniform pillared metabeams with different Zak phases[5]. We demonstrate that this structure could open new bandgaps at low frequencies, of which some are nontrivial and can support topological interface modes, as shown in Figure 2. We further show that the number of low-frequency bandgaps supporting the topological modes increases with the level of randomness, hence providing a high number of interface modes in the same structure[5].

To extend these investigations to topological Anderson insulators driven by disordered non-Hermitian modulation, we have built a SSH type model with non-Hermitian on-site disorder and found that the disorder would drive a system from trivial to nontrivial. Based on this model, we expect to construct a topological insulator in the elastic beam where the non-hermiticity originates from the utilization of piezoelectric patches.

Our work offers a reliable platform for studying topological properties in elastic waves and designing novel and robust wave control devices. These findings pave the way for future research on disordered and hyperuniform systems for novel wave manipulation.

Abstract: We present a novel strategy to generate high-resolution photoacoustic images based on spatiotemporal encoding by combining a single-element detector and a reflecting cavity with attached acoustic metasurfaces designed to maximize sound diffusion in reflection. Numerical results demonstrate the potential of this concept to develop low-cost photoacoustic imaging systems.

Photoacoustic tomography is an emergent medical imaging modality that utilizes laser-generated ultrasonic waves to create images driven by optical absorption of tissues thanks to the photoacoustic effect [1]. It combines the high spatial resolution of ultrasound images with the high-contrast and spectroscopic character of optical imaging. Image reconstruction in photoacoustics is typically based on the time-of-flight reading of acoustic waves registered at multiple positions, normally via multi-element ultrasonic arrays distributed along a certain surface. Hence, spatial resolution is strongly dependent on the geometry and aperture of the acoustic detector. Generally, optimal resolution is achieved if all emitted photoacoustic waves are captured, i.e., if the sample is surrounded by the measurement surface. Typical ultrasound probe configurations (linear, planar, arc-shaped, etc.) do not fulfill such condition, affecting the resolution, as multiple angular components are lost. This is known as the "limited view problem" and implies that high resolution systems are generally associated to large multi-element detectors which require dedicated electronics per channel, resulting in high cost and complexity.

An alternative to spatial encoding consists in carrying out the reconstruction process by temporal encoding of the received data in a single waveform. Here, the lack of spatially variant data is compensated by enlarging the received angular spectrum through the generation of replicas of the original signal via scattering [2], randomized reflecting elements [3] or reflecting surfaces enclosing the imaging sample [4, 5]. Temporal encoding solves the limited view problem and suggests that the number of detectors could be drastically reduced, replacing multi-element arrays with smaller single-element detectors, paving the way for the realization of low-cost advanced imaging systems.

In this work, we propose a novel strategy to generate photoacoustic images based on temporal encoding. Our approach utilizes a single-element detector and an acoustically reflecting cavity enclosing the imaging sample. To obtain an efficient reconstruction with high spatial resolution, acoustic metasurfaces are designed to maximize sound diffusion and attached to the cavity walls.

Numerical simulations have been carried out using a pseudo-spectral time-domain method using the k-wave toolbox [6]. We consider three closed cavities (rectangular, chaotic and rectangular with metasurfaces), a single-element detector and a set of circular targets with an initial pressure distribution to solve the forward acoustic wave propagation problem. Image reconstruction is performed using time-reversal, i.e., the registered waveform at the detector is time-reversed and back-projected into the domain, where the reconstructed image corresponds to the pressure values at the last temporal sample. The designed acoustic metasurfaces are composed of a set of quarter-wavelength resonators whose depth is set to maximize sound diffusion in reflection. In this

way, we have chosen a quadratic residue sequence to define the depths, as it provides a flat response in the angular spectrum.

The lateral resolutions for increasing simulation times have been calculated for the three tested cavities, being averaged over the nine sources, as shown in Figure 1. The rectangular cavity incorporating diffusive acoustic metasurfaces outperforms both the rectangular and chaotic cavities in terms of lateral resolution values, but also showing a reduced standard deviation, indicating a high uniformity in the representation of the acoustic sources along the space, as shown in Figs. 1(c-e). Numerical results demonstrate a remarkable enhancement in the spatial resolution with respect to existing closed-cavity configurations based in rectangular and chaotic cavities, indicating the potential of diffusive acoustic metasurfaces to achieve a high-quality reconstruction using a simple and affordable photoacoustic imaging system.

[*]corresponding author: vincent.pagneux@univ-lemans.fr

Abstract: We present the design of an ultra-broadband, low-frequency and non-reciprocal absorber based on thermoacoustic effects using liquid nitrogen. It is shown that the system can achieve an absorption of up to 95% in the very low frequency range (10 Hz), with a broadband absorption above 80% over 6.3 octaves.

Acoustic wave damping at low frequencies is widely regarded as one of the most difficult challenges in the field of wave control, due to the fact that most materials have low absorption rates in this range. This is especially true when the system in question is much smaller than the typical wavelength [1-2]. It is well established that in a transmission problem, the maximum amount of absorption that can be achieved by a symmetrical point scatterer is only half of the incident energy [3]. To improve the performance of compact absorbers, one approach is to break the geometrical symmetry of the system, which has been shown to significantly increase absorption levels in various experiments. Another potential solution to this problem is to break the reciprocity of the system, which would allow for greater absorption of waves coming from one direction.There are several mechanisms that can be used to break the reciprocity in acoustics, one of which is the thermoacoustic effect. This effect describes the conversion of thermal or mechanical energy that occurs when gas parcels interact with the solid frame of a porous medium that is subjected to a temperature gradient. The thermoacoustic effect has been the subject of extensive research for several decades as an alternative to traditional heat engines and refrigeration technologies [4-5].

The aim of this work is to show that when an acoustic wave strikes a compact porous medium at a normal angle from one side, it is possible to significantly increase the absorption rate beyond the intrinsic limit of 50% by cooling the opposite side of the medium. This results in an efficient, broadband, subwavelength absorber [6] that can achieve near-total absorption as long as the temperature of the cold spot is sufficiently low.

Figure 1(left) shows the experimental setup for the liquid nitrogen broadband absorber. The setup includes two long ducts, each equipped with a microphone, that are connected to the absorber. The cross-sectional area of the waveguide used in the setup is 5 cm by 1 cm. The absorber used in the experiment consists of either one or two cells in series, depending on the chosen configuration. Each cell is equipped with a regenerator made of stacked stainless steel wire meshes, with a length of 1.6 cm, an estimated porosity of 0.8 (pore radius of 72 μm). A cold and an ambient heat exchanger are attached to each side of the regenerator, both made of honeycombed aluminum material with a length of 1.5 cm, a porosity of 0.945, and a pore radius of 450 μm. Heat can be added or removed from the system through these heat exchangers. The cold source consists of a pair of insulated aluminum reservoirs with an inner volume of 52 cm3, filled with liquid nitrogen (see Figure 1). During operation, liquid nitrogen is regularly added to the reservoirs to maintain their fullness. The hot source consists of cartridge heaters inserted into solid aluminum blocks, placed at the heat exchanger location on either side of

the waveguide. A thermocouple is placed near the hot source on the external face of the duct to monitor the hot temperature T0 and ensure that it stays close to room temperature by adjusting the power P supplied to the heater. On the left of Figure 1 is shown the absorption obtained with this system, with an absorption of up to 95% in the very low frequency range (10 Hz) and a broadband absorption above 80% over 6.3 octaves.

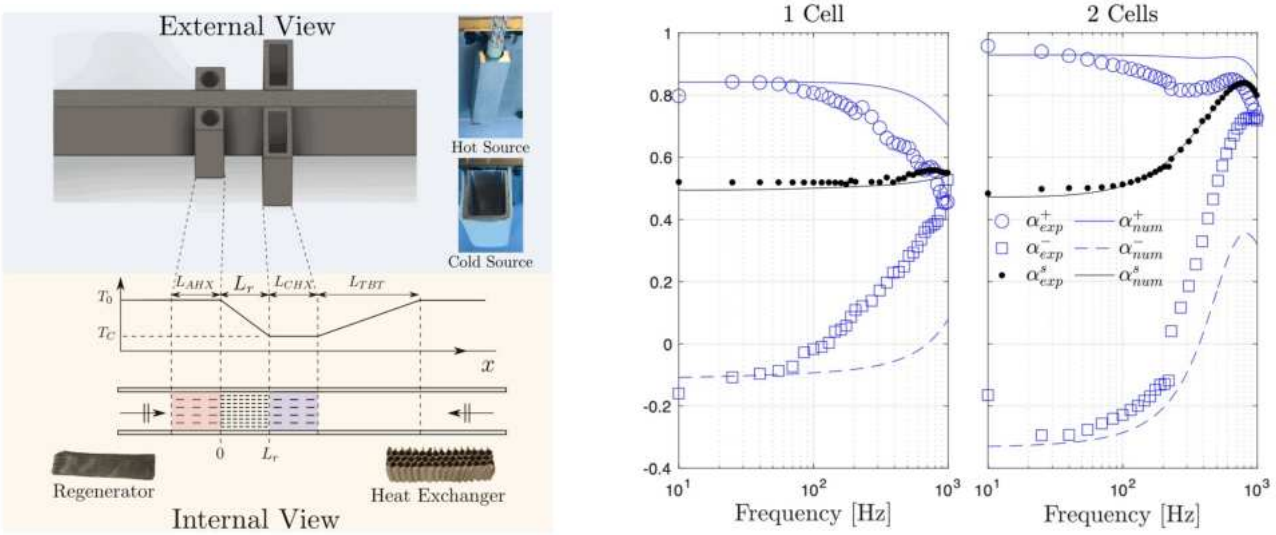

Figure 1: (**Left**): Sketch of the thermoacoustic cell used in the experiment The cell includes a regenerator surrounded by hot and cold heat exchangers and a thermal buffer tube. The regenerator is made up of a pile of ultrathin stainless steel mesh grids, and the heat exchangers are made of honeycombed aluminum material that is in thermal contact with heat sources placed outside the waveguide. The ambient heat source is an electric cartridge heater inserted into an aluminum block, while the cold heat source consists of a thermally insulated aluminum reservoir filled with liquid nitrogen. (**Right**): Absorption coefficients as a function of the frequency for one cell and two cells. Blue and black colors represent the configurations with and without the heat sources, respectively.

PT-latent symmetries

M. Röntgen[1], X. Chen[2], G. Gao[2], V Pagneux[1] and V. Achilleos[1*]

[1]Laboratoire d'Acoustique de l'Universit´e du Mans, Unite Mixte de Recherche 6613, Centre National de la Recherche Scientifique, Avenue O. Messiaen, F-72085 Le Mans Cedex 9, France

Abstract: In this work, we combine PT-symmetry with hidden symmetries, introducing the concept of latent PT -symmetry. We show how such systems can be designed, and experimentally confirm our theory. Moreover, we provide the means on how to keep the PT-unbroken phase of the system arbitrarily large.

Latent symmetries are those that aren't initially noticeable in the original system, but they emerge after a dimensional reduction process that is similar to an effective Hamiltonian [1,2]. These symmetries, initially rooted in graph theory, have been recently utilized in various physical configurations such as condensed matter systems, electric circuits[3], mechanical setups, and acoustic[4] and electromagnetic wave setups. In these applications, latent symmetries have been proven to significantly influence the underlying asymmetric system, leading to phenomena like spectral degeneracies or equireflectionality of the scattering matrix.

Here, we introduce the concept of latent symmetries into the domain of parity-time (PT) symmetry [3,4]. Specifically, we focus on the fundamental example of non-hermitian physics, the PT-symmetric dimer. Despite its simplicity, it encapsulates most of the intriguing phenomena of such systems, including the shift from real to complex spectra and the emergence of an exceptional point. This system has also been experimentally realized on various platforms, including photonics, acoustics, and electric circuits.

From a technical standpoint, a PT-symmetric dimer can be created by adding gain and loss, of equal strength, to a mirror-symmetric dimer. In this paper, we demonstrate how the original mirror-symmetric system can be replaced by an asymmetric one that possesses a latent mirror-symmetry. When gain and loss are introduced to this system, the result is a latently PT-symmetric system.

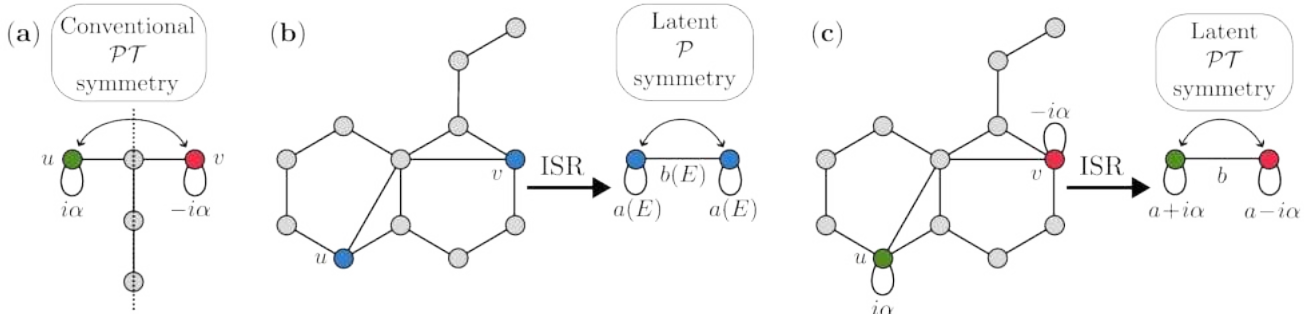

Figure 1. (a) A classic P T -symmetric system. (b) A latently reflection-symmetric system: Performing the isospectral reduction (ISR) over the two sites u, v yields a P-symmetric dimer (see text for details). (c) A latently P T -symmetric system (see text for details). In all three subfigures, a line between sites/nodes i, j corresponds to coupling of 1 between them. Loops correspond to diagonal terms in the underlying Hamiltonian.

The main idea is illustrated in Figure 1. The panel (a) shows a conventional discrete system composed of 5 coupled sites and two of them exhibit either loss (red circle) or gain (green circle). The system is clearly mirror symmetric around the axis denoted with dashed lines. This system was designed using the usual construction principle for PT-symmetry: Start from a reflection symmetric system and put complex on-site potentials ±iα (gain/loss) on one or more pairs of symmetric sites. However, while powerful, this principle is limited in the

sense of requiring a reflection-symmetric system as the starting point.
Our results drastically generalize this construction principle by using the concept of latent reflection symmetry. A latent symmetric setup is shown in Figure 1 (b), where although there is not clear symmetry in the system one can show that sites *u* and *v* are actually related with local mirror symmetry. As such combining the two concepts we can construct a system as the one shown in Figure 1 (c) which is non-Hermitian and at first look it has no symmetry, however we show that it is actually PT-symmetric. More specifically one can write an effective eigenvalue problem for this system of 12 sites in the form of a simple dimer which has an effective PT-symmetry as illustrated in the bottom right of Figure 1 (c).

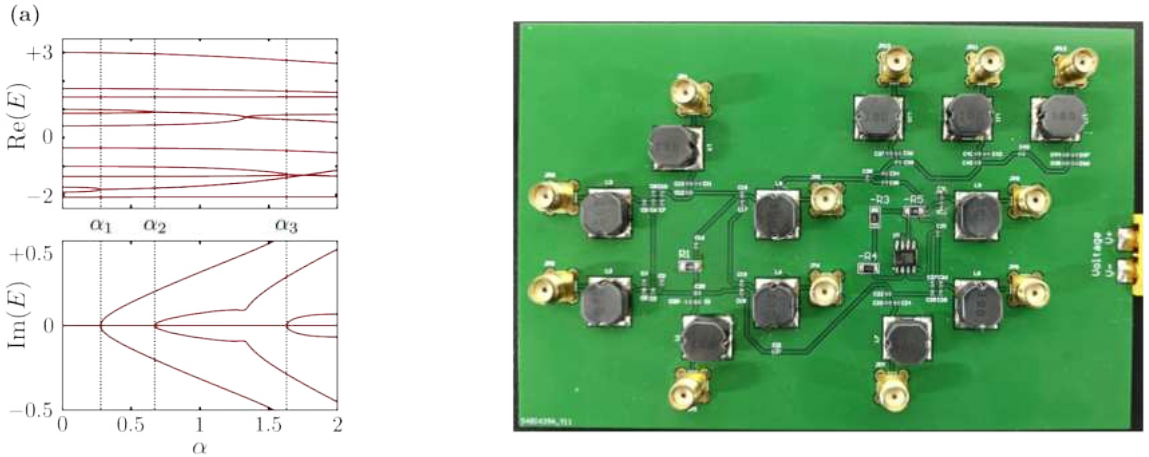

Figure 2. **Left**: Eigenvalue spectrum of the setup shown in Fig. 1(b), with the three exceptional point. **Right**: The electrical network used for experiments which simulates the same system as in Fig. 1(c).

To illustrate the fact that the proposed model shares the same properties as a typical PT-symmetric problem we plot the eigenvalues of the setup of Fig. 1 (c) as a function of the gain-loss parameter α which is shown in Fig 2 (a). Before the PT-symmetry breaking point the non-Hermitian problem has a fully stable (real) spectrum. However after a critical value of the gain/loss parameter, the eigenvalues collapse by pairs and unstable modes appear.

We note that such a setup could be realized in many different setups including acoustic waveguides [6] and optical fibers. Here as a prototype we performed experiments in an electric circuit shown in Fig 2 (b). Our results confirm the theoretical predictions and motivate further efforts on finding non-Hermitian systems with no obvious symmetries that share the same properties PT-symmetric ones.

Physically Interpretable Data-Driven Modeling and Control of Wave Dynamics

T. Shah[1], F. A. Amirkulova[1*], and S. Tiomkin[1]

[1]San José State University, USA

[*]corresponding author: feruza.amirkulova@sjsu.edu

Abstract: We present a novel machine learning method, based on deep neural networks, for efficiently learning the dynamics of an acoustic wave equation from samples. Our model is fully interpretable and maps physical constraints and intrinsic properties of the real acoustic environment into its latent representation of information.

In this talk, we present a novel machine learning method [1], based on deep neural networks and representation learning [2, 3], for efficiently learning the dynamics of an acoustic wave equation from samples and controlling the wave equation with Model Predictive Control. We have developed [1] an environment and algorithm that can serve as a basis for machine learning (ML) research in continuous dynamical systems governed by wave equations. Our environment is capable of simulating designs that can be manipulated in continuous time and influence complex PDE systems with physically realizable mechanisms. The novel algorithm we introduce operates on partial information from the environment and incorporates domain knowledge from acoustics to structure a latent representation of system dynamics. Our model is interpretable through physical properties; therefore, a level of meaning can be assigned to the evolution of its latent dynamics. With the interpretable structure of the latent space, we can apply a novel and trainable perfectly matched layer (PML) that actively dissipates energy. We discover that energy buildup in latent space is an important attribute and must be dissipated to allow the latent dynamics to maintain stability in the steady state. To our knowledge, a PML layer has not been incorporated into neural networks before. Furthermore, our work is the first to control acoustic waves in the time domain with ML enabling the efficient design of time-varying acoustic metamaterials. Time-varying metamaterials [4] can leverage the temporal dimension and drastically expand the range of degrees of freedom available for controlling wave dynamics.

We demonstrate the capabilities of our data-driven model on an important problem in acoustics, which is the minimization of total scattered energy. We consider a 2D planar motion and multiple scattering by fluid cylindrical structures embedded in acoustic media. Our environment and its implementation offer the technical tools required to further explore this area and establish stronger connections between acoustics and ML. We show that the prediction of scattered energy by our model generalizes in time and can be extended to long time horizons.

Any Dispersion You Want – Demystifying Roton, Maxon, Saddle Point, and Higher-order van Hove Singularities via Nonlocal Phononic Crystals

S. Paul[1], F. Chen[1], K. J. Deshmukh[2], B. Deng[3], A. Kazemi[1], X. Zhu[4], H. C. Fu[1], and P. Wang[1*]

Abstract: We first show precise inverse design of band structures via beyond-nearest-neighbor (BNN) interactions in discrete nonlocal phononic crystals of both 1D and 2D cases. Next, we focus on localized modes with vanishing group velocity and explain related concepts such as rotons, van Hove singularities, and bound states in continuum (BIC).

In this talk, we demonstrate the capability to completely and analytically customize the dispersion relations in phononic crystals by incorporating nonlocal springs [1]. We show dispersion curves with multiple critical points of the first (roton [2, 3] or maxon [4]) and second order (undulation point [1] – See Fig. 1) in one-dimensional case. We further study the wave packet dynamics at each of the critical points and illustrate how we can use them to create novel behaviors of localized modes. In addition, we investigate critical points such as the saddle point in 2D cases – See Fig. 2. Our studies enable future research on non-propagating elastic wave modes in terms of topology, scaling, and symmetry.

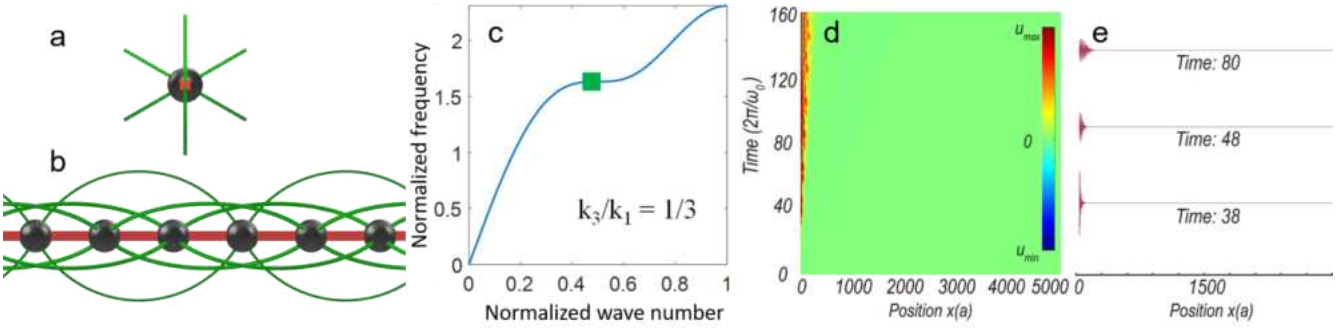

Figure 1: Non-local phononic crystals with second-order zero-group-velocity (ZGV) modes: (a)&(b) are the front and side views of the non-local 1D chain with stronger $k_3 = (1/3)\ k_1$. (c) shows the dispersion relations with a second-order ZGV mode at a stationary inflection point (undulation, green square). (d)&(e) show the time-domain simulation results on a finite chain of 5000 unit cells.

Next, we relate these phenomena to several popular concepts in condensed matter physics: (A) van Hove singularities in the density of states that arise directly from critical points of dispersion bands; and (B) Bound states in continuum, which are natural results of the strongly localized wave modes.

In addition, we also present experimental observations of two categories of van Hove singularities: The ordinary one with a vanishing group velocity and the high-order one with the simultaneous vanishing of both group velocity and spatial spreading rate.

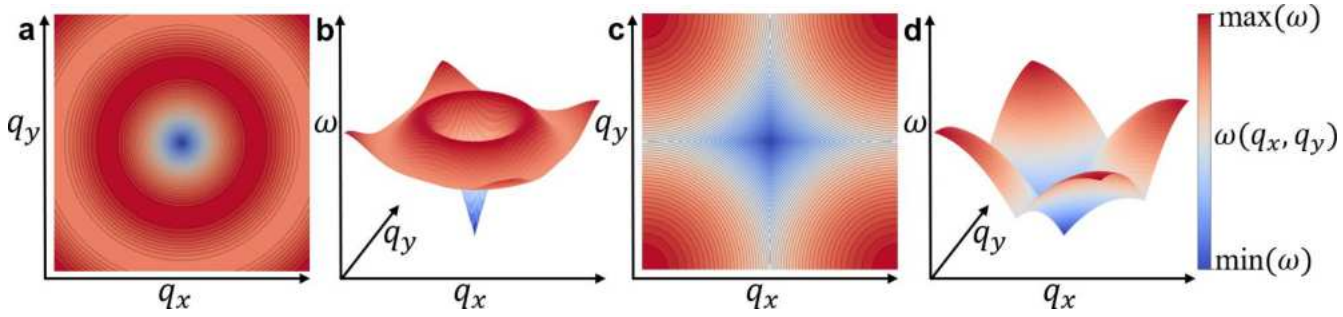

Figure 2: Dispersion contour plots of example 2D non-local phononic lattices.

Abstract: This study examines the band structure of a single-phase elastic metamaterial based on flexural resonances, employing two-scale asymptotic homogenization and Bloch–Floquet analysis. It reveals two frequency-dependent mass densities governing symmetric/antisymmetric flexural resonances, leading to low-frequency band-gaps and negative refraction in hyperbolic regions of the dispersion diagram.

Negative refraction (NR) and band-gaps (BG) are commonly observed phenomena in the wave band structure of photonic/phononic crystals, offering significant potential for applications in perfect lens design across various fields such as electromagnetism, acoustics, and elastodynamics. While NR crystals aim to overcome diffraction limits, BG crystals act as efficient insulators or defect-immune wave propagators. However, their practical utility is often constrained to high frequencies, limiting widespread application due to the necessity for comparable wavelength and crystal periodicity.

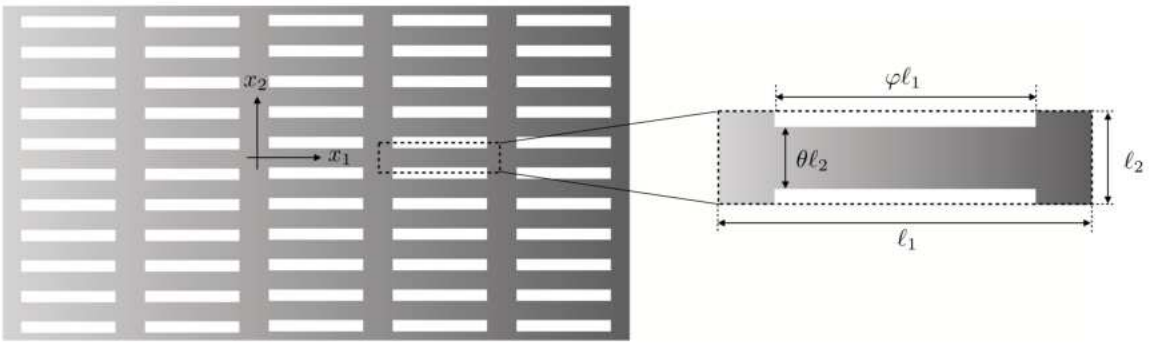

Figure 1: *Single-phase flexural metamaterial; the inset shows the unit cell containing a slender beam with flexural resonances*

Locally resonant metamaterials (LRM) have emerged as a solution to extend these properties to low frequencies over the past two decades. By incorporating subwavelength resonant mechanisms at the microstructural level, LRMs significantly impact macroscopic wave propagation. Despite their effectiveness in exhibiting BGs, achieving low-frequency NR remains challenging. Various strategies have been explored, including elastic LRMs based on single-phase materials, particularly elongated structures such as beams or plates with low bending stiffness, offering control over low-frequency flexural modes beneficial for seismic wave management.
The derivation of effective parameters for NR and BG materials from microstructures involves two primary approaches: discrete and homogenization methods. Discrete approaches model the system as discrete analogues of the continuous system, offering explicit dispersion relations through Bloch–Floquet analysis. However,

potential inadequacies between discrete and continuous systems pose risks. In contrast, homogenization approaches directly deal with the actual system, providing deductive effective parameters but are often limited to long wavelength regimes. This work proposes a combined approach leveraging the strengths of both methods.

This work deals with a a two-dimensional elastic structure made of a periodic collection of dumbbell-shaped specimens whose central elements consist in thin beams of length $\varphi\ell 1$ and thickness $\theta\ell 2$, see Figure 1(*Marigo et al. 2023*). By employing Bloch–Floquet analysis and two-scale asymptotics, the dispersion of elastic waves in flexural metamaterials is derived analytically,

$$(\rho_s - \rho_a)\omega^2 \sin^2 \frac{k_1 \ell_1}{2} + (1-\varphi)Ek_2^2 = \rho_s \omega^2$$

where (ρ_s, ρ_a) are frequency-dependent mass densities that can exhibit simultaneously negative values in some frequency range. Through exploration of the entire Brillouin zone, evidence of band-gaps due to resonances of symmetric and antisymmetric flexural modes is presented, each associated with a frequency-dependent effective mass density. The interplay between these densities yields elliptical or hyperbolic dispersion, facilitating the occurrence of negative refraction in the latter case, see Figure 2.

Abstract: We present a theoretical and numerical analysis of the diffraction of acoustic waves by space-time modulated gratings with rigid-type modulations. We report results exemplifying the non-reciprocal behavior of the grating, in relation with spatial and temporal harmonics.

Space-time metamaterials, refers to materials whose properties vary in the N + 1 dimensions, N in space and 1 in time. The term itself appeared around twenty years ago with the intuitive idea that the higher the dimensions, the more degrees of freedom we have to realize wave systems with the desired functionalities. There was pioneering work in the 1960s, mainly in electromagnetism, afterwards probably the most systematic description of these media was proposed by Lurie, who called them *dynamic materials*. Among these dynamic materials, he introduced the distinction between *kinetic material* when there is a mechanical movement of the material and *activated material* when the material does not move but its properties vary in space and time. In both cases, the most expected effects are non-reciprocity and the generation of temporal harmonics. Since then, there has been many theoretical and experimental studies for the two types of dynamic materials.

We have been interested in such activated material, namely a grating made of a periodic set of sound rigid blocks in a fluid, see figure 1.

Figure 1: Space-time modulated grating.

We consider the scattering problem leading to the solution, in reflection and transmission, of the form :

$$\varphi(x,y,t) = \begin{cases} e^{i(\alpha_0 x + \beta_0 y - \omega_0 t)} + \sum_n r_n e^{i(-\alpha_n x + \beta_n y + \omega_n t)}, \\ \sum_n t_n e^{i(\alpha_n x + \beta_n y - \omega_n t)}, \end{cases}$$

$$\omega_n = \omega_0 + \mathrm{M}\, c \frac{2n\pi}{h}, \quad k_n = \frac{\omega_n}{c}, \quad \beta_n = \beta_0 + \frac{2n\pi}{h}, \quad \alpha_n^2 + \beta_n^2 = k_n^2.$$

We shall discuss two particular behaviors of the modulated grating:

1) Perfect mode conversion and perfect transmission : Under specific condition, and when at least two modes are propagating (real value of αn), perfect transmission associated with perfect mode conversion

is observed, as illustrated in Figure 2. We stress that the non-reciprocity prevents in the reported case that the time reversed transmitted waves produces perfect mode conversion (unless the modulation is inverted).

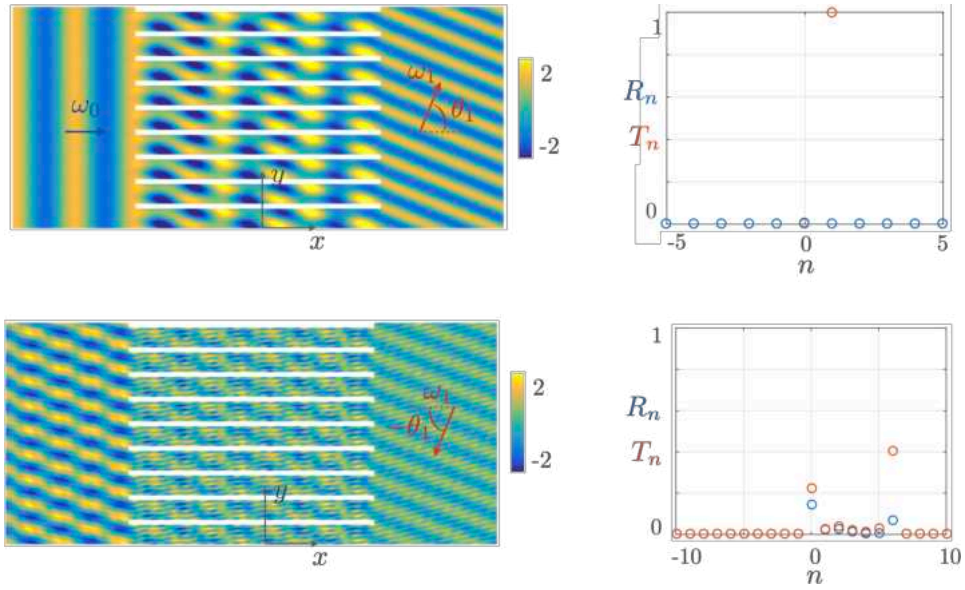

Figure 2: (top) Perfect transmission with perfect mode conversion for a wave at normal incidence , (bottom) evidence of non-reciprocal propagation.

2) Temporal Fano resonances associated with the excitation of the acoustic analog of quasi-spoof plasmons producing a succession of perfect transmission and perfect reflection, which is not possible at zero modulation due to symmetry.

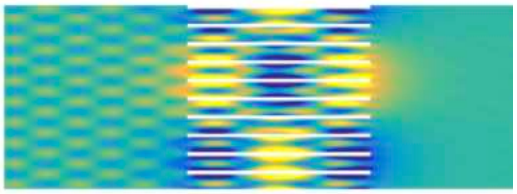

Figure 3: Quasi SPPs excitable through scattering and responsible of Fano resonance.

Theoretical Bound of Symmetric Metasurfaces

C. W. Park[1] **and Y. Y. Kim**[1,2*]

[1]Institute of Advanced Machines and Design, Seoul National University, 1 Gwanak-ro, Gwanak-gu, Seoul 08826, South Korea

[*]corresponding author: yykim@snu.ac.kr

Abstract: Symmetry may restrict the transmission and phase coverage of local scatterers of the metasurfaces. We investigate the theoretical limit of transmission coverage of the symmetric metasurface. We conduct numerical simulations of controlling acoustic wavefronts to validate our theoretical results.

We rigorously investigate the theoretical bound of a symmetric metasurface. Local responses of symmetric metasurfaces are identical, independent of incident direction. This condition can be written by the reflection coefficients as

$$\mathbf{r} = \mathbf{r}' \tag{1}$$

where the unprimed and primed symbols mean the forward and backward incident directions, respectively. Using Eq. (1) and assuming passive lossless metasurfaces, we derived two coupled equations of transmittance and phase information, which is expressed as For equations,

$$-\frac{1}{2}\sqrt{T}\left(\frac{1}{\sqrt{Z_r}}+\sqrt{Z_r}\right) \le \cos(\theta) \le \frac{1}{2}\sqrt{T}\left(\frac{1}{\sqrt{Z_r}}+\sqrt{Z_r}\right) \tag{2}$$

$$\frac{T^2\cos^2(\theta)}{\left[1/2T^{\frac{3}{2}}\left(1/\sqrt{Z_r}+\sqrt{Z_r}\right)\right]^2}+\frac{T^2\sin^2(\theta)}{\left(T^{\frac{3}{2}}\right)^2} \ge 1 \tag{3}$$

where, T is transmittance, θ is transmission phase, and Z_r is the impedance ratio of background medium.

Our theoretical analysis revealed that the maximum transmittance cannot be unity and also that only a finite number of phases can be selected to cover 2π phase change for the maximum efficiency, which is demonstrated by Fig. 1.

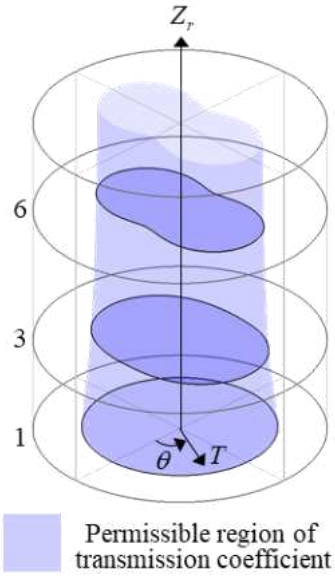

Figure 1. Permissible region of transmission coefficient for a symmetric metasurface.

To show the effect of limitations on transmission coefficients, we conduct numerical simulations of beam steering and focusing of acoustic waves by the symmetric metasurfaces. The transmission performance is significantly degraded due to the lack of possible transmission phases.

Abstract: In this talk, I will discuss some of our recent advances obtained by coalescing artificial Intelligence and acoustic artificial structures with extraordinary acoustic properties. Furthermore, I will also mention the applications of acoustic metamaterials in several important scenarios such as architectural acoustics and acoustic communication.

Simple and precise sound manipulation is of fundamental interest and practical significance in acoustics and many related fields, but is challenging due to the limitation in the acoustical properties of naturally available materials. The recent emergence of acoustic metamaterials which comprises a large number of subwavelength unit cells and behaves like a homogeneous medium with special acoustical properties overcomes the limitations of acoustical properties of naturally available materials and enables novel wave-steering phenomena, which would also open new applications in many diverse scenarios. Meanwhile, artificial intelligence is already impacting many other scientific disciplines and research fields. In this talk I will first briefly review some of our recent advances that provides acoustic metamaterials allowing novel unconventional sound manipulation such as wavefront manipulation, asymmetric transmission and production of acoustic orbital angular momentum. Then I will discuss what we can obtain by combining acoustic metamaterial with artificial intelligence. To go beyond the limitation in current acoustic metamaterials that only form sound waves form the desired fields, we build an acoustic "neuromorphic system" based on artificial structures, and proved that an array of unit cells following deep-learning-assisted design of parameters is endowed with the 'intelligence' to solve complicated tasks in a simple, precise, fast and passive manner. On the other hand, based on the unconventional wave-steering functionality and high design flexibility, we propose to inversely design acoustic metamaterials with the aid of machine learning technique and realize a series of acoustic functional devices with superb performance, whose applications in various scenarios such as absorption and isolation of low-frequency sound is also demonstrated.

Efficient electromechanical coupling to an optomechanical nanobeam

T. Makkonen[1], O. Ylivaara[1], S. Pourjamal[1], and J. Ahopelto[1*]

[1] VTT Technical Research Centre of Finland Ltd, Finland
[*]corresponding author: Jouni.ahopelto@vtt.fi

Abstract: We have developed a new approach for efficient electromechanical coupling into an optomechanical nanobeam. We exploit small bulk acoustic wave transducers integrated directly to the nanobeam. The transducers operate at GHz frequencies and at room temperature. Simulations suggest that in optimized structures, the conversion efficiency can approach 90 %.

Optomechanics provides an interesting alternative for low-power information technology[1]. Adding the possibility of electromechanical excitation in the system, further functionalities become available, including flexible modulation of the optical signal and direct readout. The most common way for electromechanical excitation is to use surface acoustic waves (SAW) generated by interdigitated transducers (IDT)[2]. The challenge of using IDTs is related to relatively low conversion efficiency of electrical signals to mechanical energy flow in the nanoscale beams[3], although high conversion efficiencies have been obtained by IDTs operating at low temperatures[4]. Another challenge is the typically large surface area required by the IDT electrodes. The latter can be tackled by using acoustic metasurfaces[5] to steer and focus the waves, but the coupling efficiency can still remain low.

In this work we have investigated the possibility to integrate small bulk acoustic wave (BAW) transducers directly in the optomechanical nanobeam to enhance the coupling efficiency and conversion of the electrical signal to the mechanical modes in the beam. The target is broadband operation at a few GHz range and at room temperature using a small footprint transducers. The simulated devices have transducers with a footprint of 10-30 μm^2, connected to a 220 nm thick and 800 nm wide silicon nanobeam. The main loss mechanisms include viscous losses and anchor losses, i.e., leakage into the substrate. By optimizing the anchoring, conversion efficiency approaching 90 % can be achieved, see Figure 1. In addition to simulations, we will tackle the challenges in fabrication and characterization of the devices.

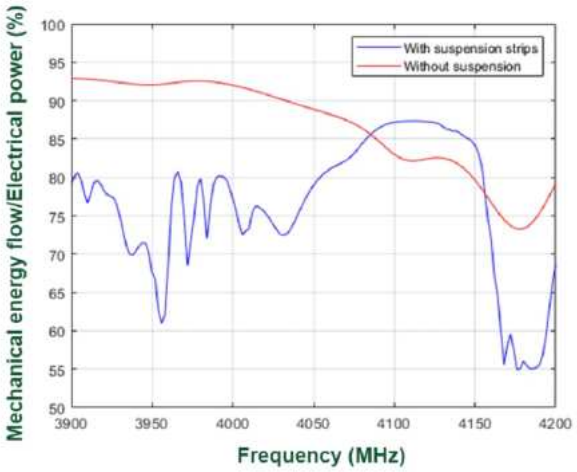

Figure 1. Simulated conversion efficiency of the electrical power fed to the device to mechanical energy flow in the nanobeam. Red: Ideal case with no connection from the transducer to the substrate (floating transducer). Blue: The transducer suspended by 1-dimensional phononic crystals with a band gap slightly above 4 GHz.

Abstract: We demonstrate experimentally dynamical acoustic and optical "drill" beams, presenting nonstationary intensity distributions that resemble the spinning mechanical drill. The drills appear as the spatiotemporal interference of two Bessel-vortex beams of different topological charges and different carrier frequencies. We explore material processing with such drills.

Exotic beams such acoustic vortices are emerging as tools for wave-matter interaction, including particle trapping and manipulation, mechanical torque transfer applications, or acoustic transceivers and underwater communications. Acoustic vortex beams are wave fields with phase singularities, and around these spots the phase of the beam rotates with the azimuthal coordinate. Therefore, in acoustic beams the phase is helical in the space. In this work we present acoustic drills, a new type of beam whose intensity distribution matches the shape of a helix, twisting around the beam axis. In addition, the intensity distribution rotates with time along the axis of the beam with a controlled direction and angular frequency, therefore resembling the shape of a rotating mechanical drill [1]. The acoustic drill which we present here is analogous to the recently demonstrated optical drill [2].

We synthesize two confocal and detuned Bessel beams of elongated focal spot and arbitrary topological charge using two concentric 3D-printed acoustic holograms. The outer beam is excited by a custom piezoelectric ring (84-mm external diameter, 50-mm internal diameter) and a concentric unfocused circular transducer (50-mm aperture). Each transducer is excited with a separate AWG and RF amplifier, with a pulsed burst of around 1 MHz central frequency. The frequency was slightly detuned, to about several Hertz. Field measurements were taken in water, k-space pseudospectral simulations were performed, and the field was calculated using the Rayleigh-Sommerfeld integral. Camera measurements were taken at the surface of the water.

We show that elongated drill beams are obtained using two high-order Bessel beams. Analytic, numeric, and experimental results are in good agreement, showing the helical structure of intensity distribution rotating with a controlled angular frequency. Acoustic drills emerge as the spatiotemporal interference of two confocal and detuned vortex beams. Analytical constraints for optimal beam overlapping were obtained. We show how the parameters of the helical beam are fully tuneable, their period, winding, rotation speed and direction, number of windings, and we link these parameters to the geometrical and detuning parameters of the primary vortex beams. This new wave structure opens novel avenues for wave-matter interaction, such as contactless particle manipulation, matter processing or biomedical applications.

Phonons, the vibrations of an atomic lattice, are responsible for heat and sound transport within materials. The ability to control and manipulate phonons is essential for effective thermal management. Engineering materials at the nanoscale are key to achieving this, demanding advanced fabrication or growth techniques. [1] Superlattices (SLs), characterized by periodic heterostructures, offer a means to explore novel phononic properties. [2] Especially, SL structures with nanoscale periodicities serve as a model system for studying the transition from coherent to incoherent phonon transport. [3] However, achieving smooth interfaces between layers, relative to the characteristic phonon wavelengths, remains challenging during the growth process, hindering the fabrication of nanoscale SL structures for phonon engineering. Nanowires (NWs), on the other hand, are quasi-one-dimensional structures that allow the growth of axial and radial heterostructures otherwise difficult in planar structures. [4] SL NWs are, therefore, a powerful platform to manipulate heat transport using coherent phonon effects.

In this study, we aim to showcase the remarkable adaptability of NWs as a platform for effective phonon engineering. Specifically, we focus on the investigation of SL NWs composed of group III-V semiconductors, namely GaAs/GaP and InAs/InP. [2,5] Group III-V semiconductor NWs are ideal material systems to explore nano-photonic and electronic properties. [6] However, their phononic properties remain unexplored. Using inelastic light scattering techniques such as Raman spectroscopy and Brillouin interferometry, we show that the phononic and electronic properties of SL NWs can be tuned by controlling the SL periodicity. Our results are also corroborated with the help of ab initio calculations.

Optomechanical measurement of liquids in unconventional regimes

Ivan Favero

Université Paris Cité, CNRS, Paris, France
*corresponding author: ivan.favero@u-paris.fr

We discuss our recent achievements using nano-optomechanical devices and concepts to measure liquid dynamics with increased temporal resolution and sensitivity. This has enabled access to previously unexplored temporal and spatial scales in the liquid state, leading to the observation of unconventional regimes. This is an example of the application of optomechanical technologies to probe complex matter.

Abstract: Mechanical and magneto-mechanical structures be engineered to generate a variety of nonlinear couplings and can even emulate orbital physics. In this talk I will discuss our team's experimental work to leverage such couplings for topological pumping, non-linearity induced spontaneous transitions, and new orbital-based topological states.

The coupling of mechanical resonators via magnetic fields is intrinsically nonlinear and can produce a variety of interesting coupling terms [1] that can also be dynamically modulated through non-contact means. Using this idea we have demonstrated [2] that it is possible to robustly transport states across 1-dimensional magneto-mechanical metamaterials using an analogue of the Thouless pump, even in the presence of severe spatial and temporal disorder. Such devices also readily enable the exploration of trapped states at dislocations in lattices [3].

We have also discovered that the amplitude-frequency nonlinearity intrinsic to magneto-mechanical materials can be used to self-tune the material locally based on excitation level. This has enabled our experimental research on self-induced boundary states, tunneling, and digitization effects [4] and could lead to smart responsive structures in the future.

Most recently, we are exploring how the parity representations of mechanical resonances can be considered as atomic orbitals. Using this new idea, we were able to demonstrate the first mono-atomic orbital-based 1D topological crystalline insulator [5].

X-ray Transient Gratings: Access to Nanoscale Acoustics, Magnonics, and More

Keith A. Nelson

Dept. of Chemistry, MIT, Cambridge, MA 02139, USA
*corresponding author: kanelson@mit.edu

Abstract: Transient grating (TG) measurements exploit interference between crossed excitation pulses to define a spatial period, and corresponding wavevector, for thermoelastic and other time-dependent dynamics that are measured. The TG method has been extended to extreme UV and hard x-ray spectral ranges, accessing nanometer periods for acoustic waves, thermal transport, magnons, and other high-wavevector responses. Recent results will be reviewed. Nondestructive excitation of nonlinear acoustic/shock waves will also be discussed.

Dielectric metasurfaces for nonlinear asymmetric imaging

D. Rocco[1,2], A. Locatelli[1,2*], L. Carletti[1,2], M. A. Vincenti[1,2], and C. De Angelis[1,2]

[1]Department of Information Engineering, University of Brescia, Italy
[2]National Institute of Optics - National Research Council (INO-CNR), Brescia, Italy
[*]corresponding author: andrea.locatelli@unibs.it

Abstract: We report nonlinear asymmetric generation of light from a dielectric metasurface via second-harmonic generation. In this platform, conversion efficiency is dramatically different when the metasurface is pumped from air and substrate. We exploit these findings to demonstrate that we can generate different images at second-harmonic depending on the illumination direction.

Dielectric metasurfaces are a promising platform employed in various research domains including sensing, lasing, all-optical modulation, and nonlinear optics, to name a few. Indeed, it is well known that nonlinear interactions between light and matter in metasurfaces offer a viable avenue for achieving miniaturized control over light. In this framework, asymmetric nonlinear metasurfaces have recently garnered increased attention, with particular emphasis on their application as optical isolators [1-3].

In this study, we demonstrate nonlinear asymmetric generation of light in a dielectric metasurface through second harmonic generation. The unit cell of the proposed metasurface is reported in Fig. 1(a). By reversing the illumination direction of the pump, we observe a variation of the power of the nonlinear emitted signal of more than one order of magnitude, see Figs. 1(b) and (c). In particular, we can identify three different operating points named A, B and C. Point A corresponds to a metasurface associated with a strongly emitted SH for the case of backward incidence (pump launched from the substrate). Contrarily, point B is related to a metasurface generating strong SH signal when the incidence light is propagating in the forward direction (pump impinging from the air side). Instead, by working at point C the SH power is poorly emitted for both pump directions.

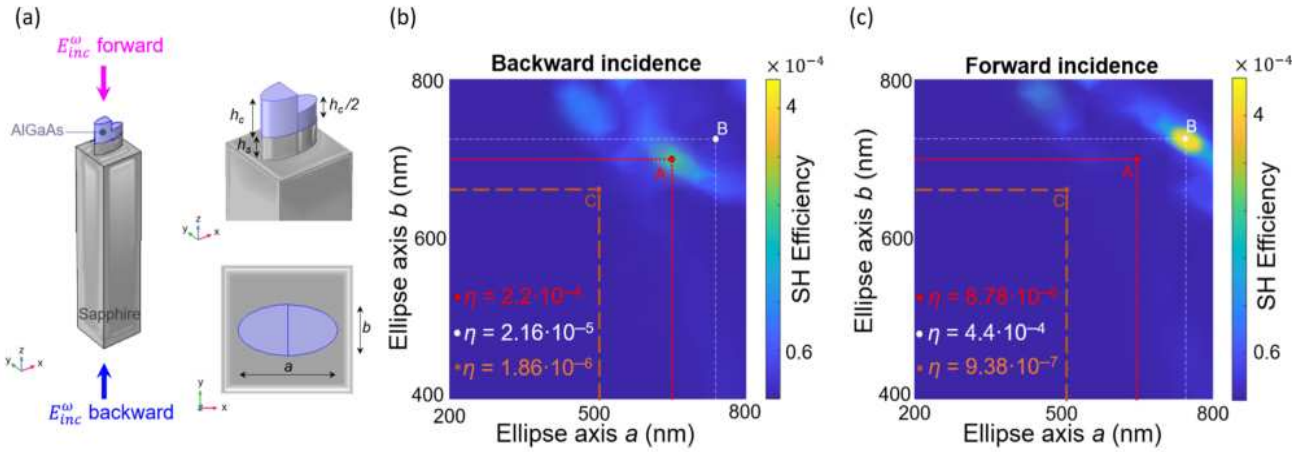

Figure 1. (a) Sketch of the proposed metasurface made of AlGaAs nano-chairs placed over a sapphire substrate with a sapphire pedestal in between them. Both nano-chair and pedestal are assumed to have an elliptical base with major and minor axes named *a* and *b*, respectively. The period is equal to 880 nm, the height of the pedestal is h_s = 250 nm and the

AlGaAs thickness is h_c = 400 nm. (b) Emitted SH efficiency as a function of the ellipse axes a and b for pump with backward or forward incidence, respectively.

Furthermore, we show how a properly designed metasurface composed of adjacent regions with geometrical parameters corresponding to points A, B and/or C can produce two distinct images at the second harmonic when the illumination direction is reversed, as displayed in Fig. 2. Notably, the conversion efficiency of the generated SH signal reaches 4.4×10^{-4} for a pump intensity of 1 GW/cm^2. We emphasize that our design does not need any external control bias and can be easily extended to different $\chi^{(2)}$ nonlinear phenomena.

As a matter of fact, dielectric metasurfaces characterized by a large asymmetric response based on nonlinear phenomena can find application in a plethora of research areas such as optical encryption, nonlinear multi-color imaging systems and QR code generation.

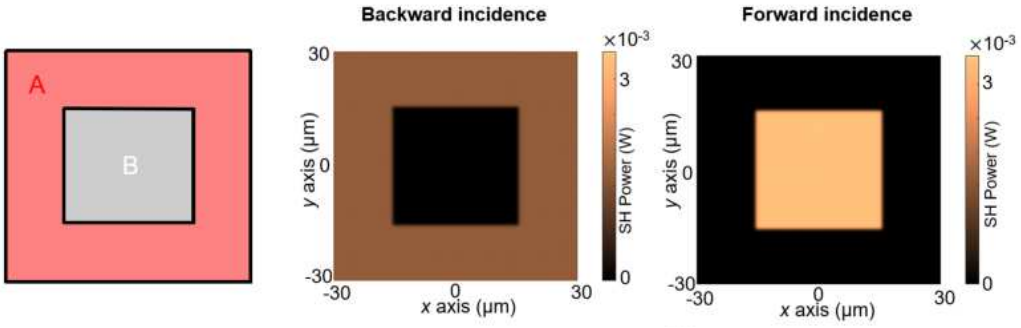

Figure 2. An example of generation of complementary SH images as a function of the pump direction when using regions with A and B geometry as building blocks.

Effect of Thermal Annealing on Surface Plasmon Properties of Gold and Silver Nanodisk Structures for Live Cell Imaging

K. Yamasaki[1], R. Hatsuoka[1], T. Matsuyama[1], K. Wada[1] and K. Okamoto[1*]

[1]Osaka Metropolitan University, Japan
[*]OkamoT@omu.ac.jp

Abstract: We investigate the effect of thermal annealing on Localized Surface Plasmon Resonance (LSPR) properties of gold and silver nanodisk structures. We found that gold structures showed blue-shifts and narrowing of peaks, while silver structures exhibited peak blue-shifts and reduction in intensity. These changes were analyzed using an electromagnetic field analysis.

Introduction

Blue light may potentially damage human bodies. However, assessing the impact of blue light on cells via fluorescence imaging is challenging due to the risk of damage by incident light. We aim to selectively enhance photoluminescence utilizing LSPR, thereby reducing cell damage from excitation light. In our previous study, we annealed nanodisk structures fabricated by Electron Beam Lithography to improve the plasmon properties [1]. In silver nanodisk structures, the LSPR peak shifted toward the short wavelength side while retaining its sharpness. Conversely, gold nanodisk structures exhibited peak narrowing accompanied by a blue-shift. In this research, we employed electromagnetic field analysis to accurately fit the LSPR peak shifts and to explore the differences in the annealing effects between silver and gold nanodisk structures.

Methods

Finite-Difference Time-Domain (FDTD) calculations were conducted using Fujitsu Poynting for Optics. We employed the dielectric function of the Drude model derived through fitting to that of the Lorentz Drude model [2] in a specific spectral region. The validity of the model was confirmed by simulating the LSPR peaks. Finally, we optimized the Oscillation Strength (OS) and the Damping Frequency (DF) to fit the LSPR peak shifts.

Results and discussions

Figure 1 (a) shows the dielectric function of silver approximated by the Lorentz Drude (LD) model and the Drude model. The relative instantaneous permittivity and the damping frequency in the Drude model were optimized in the visible spectrum region to fit the LD model. Figure 1 (b) and (c) respectively show the extinction spectra of silver nanodisk structures using the LD model and the Adjusted Drude model. The height of the disks was set to 30 nm with a radius of 50 to 90 nm. LSPR peaks calculated by using both the LD model and the adjusted Drude model exhibited remarkable similarity.

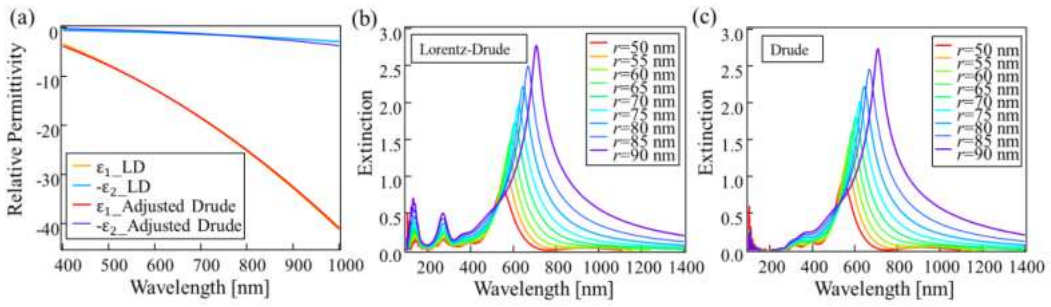

Figure 1. Dielectric function of silver and simulated spectra of silver nanodisk structures

Figure 2 shows the LSPR peak of silver nanodisk structures with a Ni height of 2nm and Ag height of 40 nm (a) in the experiment, (b) in the simulation by varying only the radius and (c) in the simulation by changing both the radius and the dielectric function. As shown in Figure 2 (a), the LSPR peak shifted while maintaining its intensity to some extent due to thermal annealing. While the radius decreased from 55 nm to 50 nm as the annealing temperature increased, this phenomenon was not reproducible in simulations that considered only the size or shape changes. Figure 2 (c) reveals an increase in OS due to thermal annealing. We posit that electrons trapped in the defects were enabled to oscillate due to thermal annealing.

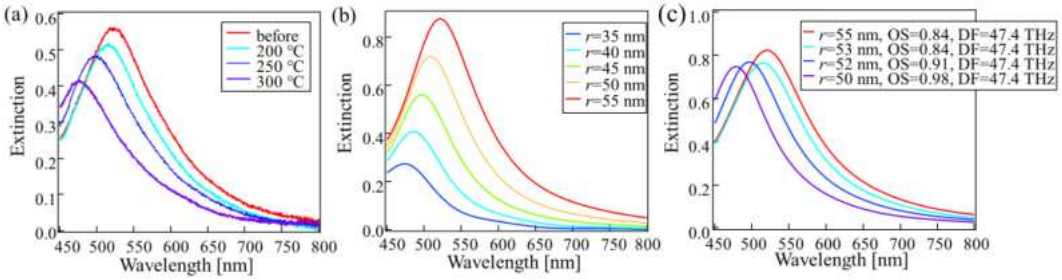

Figure 2. Extinction spectra of silver nanodisk structures

Figure 3 (a) and (b) respectively show the schematic diagram and extinction spectrum of silver nanodisk structures with ellipsoidal hemisphere. Extinction spectrum of silver nanodisk structures with height of 40 nm and radius of 50 nm is also included. The LSPR peak intensity decreases while the peak position and sharpness remained almost unchanged. The morphological changes account for the decrease in peak intensity in the experiment.

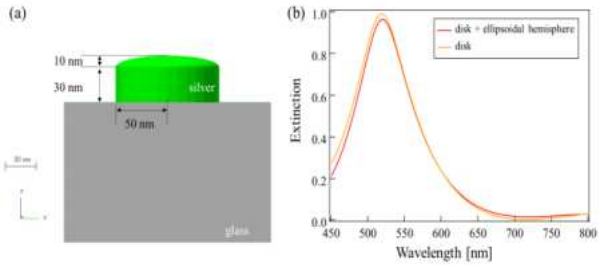

Figure 3. Silver nanodisk structures with ellipsoidal hemisphere

Figure 4 shows the LSPR peak of gold nanodisk structures with Ni height of 2 nm and Au height of 20 nm (a) in the experiment and (b) in the simulation by modifying the dielectric function. The radius of gold nanodisk structures was 83 nm and almost unchanged by thermal annealing. Figure 4 (b) demonstrates that OS increased as the annealing temperature increased. We attribute the decreased DF to an increase in mean free path due to the reduction of grain boundaries by thermal annealing.

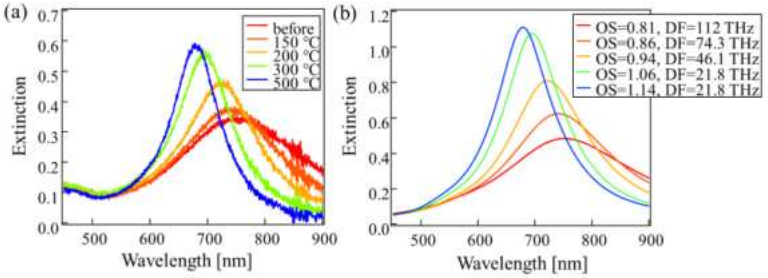

Figure 4. Extinction spectra of gold nanodisk structures

Abstract: In current work, we present detailed numerical investigation of high refractive index circular and square rings. We calculate scattering response, near-field, far-field radiation profiles of rings in infrared regime. We observe tunability, formation of certain modes as a function of thickness, liquid-crystal orientations with applications towards optically active metadevices, sensors.

Summary:

The control of light-matter interaction in metasurfaces offers an unprecedented potential for manipulation and tuning of light. Mie scattering occurs in dielectric structures made of high refractive index material. When metals are formed into specific geometries, such split-ring resonators (SRRs), they can generate magnetic resonant modes. However, displacement currents in the dielectric medium generate magnetic fields naturally for basic geometries like cubes and spherical particles, which excite the magnetic resonant modes [1-4]. All-dielectric metasurfaces have been gathering lot of interest in the recent years due to their intense localization of fields, excitation of magnetic modes as well as giving rise to novel resonant modes such as anapoles, quasi-BIC states, etc. [5-8]. Liquid crystals have attracted great attention due to the optical anisotropy and flexible control through optical, thermal, magnetic and electrical fields [9].

In this work, we investigate the effect of both the anisotropic properties of the medium and geometry of the dielectric structures on the electromagnetic response. A layer of periodic circular and square dielectric rings made of high refractive index materials such as Tellurium (Te, n~5.79) is taken in air as well as liquid crystal medium. The electromagnetic response of dielectric structures and electric and magnetic field profiles are studied in detail in near and far-field regions using numerical simulations based on CST. Further, we also investigate the effect of anisotropic medium on the electromagnetic response and exploit the tunability exhibited by the liquid crystals medium in which a surface of periodic high refractive index dielectric material is embedded. Electromagnetic waves of frequency in the range 10-70 THz are incident on the layer of Te rings of thickness 0.5um. The electromagnetic response of such dielectric structures and hence the electric and magnetic field profiles are studied in detail using FEM based numerical simulations. The circular and square dielectric structures are placed in the XY plane filled with air. Periodic boundary conditions are applied along X- and Y-directions. Plane electromagnetic wave is incident at one of the ports on the Z-axis with polarization along Y direction and magnetic field (H-field) is along X-direction. The periodicity of the unit cell is 2.5 um and the thickness of the cell along the Z-direction is 5um. The thickness of the rings is varied from 0.2um till 2.5um to

look at the effect of thickness on the field modes generated inside the materials. This rings when placed in birefringent liquid crystal medium orientation of liquid crystal molecules are observed to enhance certain modes over the other giving rise to tunable metasurfaces.

Conclusions:

In the present work, it is observed that effect of geometry and the refractive index of the dielectric rings play a significant role on the resonance characteristics. Typically square rings show sharper resonances (high Q-factors) and high field localization compared to the circular rings. Thinner rings support the electric modes predominantly while rings of thickness more than the radius exhibit only magnetic modes. Further, we also investigated the effect of anisotropic medium on the electromagnetic response and exploit the tunability exhibited by the liquid crystals medium. Te rings in liquid crystal medium give rise to novel toroidal-like magnetic modes and hybrid modes at certain frequencies. By carefully designing the dielectric rings in the liquid crystals one can find applications in optically active materials for opto-electronic devices and sensors.

Abstract: Au self-aligned nanoring doublets (SANDs) are introduced as a single-nanoparticle cavity at room temperature for strong coupling with randomly distributed chlorophyll-a molecules, without highly concentrated J-aggregates, mirrors, or any sophisticated effort to create dimers.

Achieving strong coupling in practical applications of cavity quantum electrodynamics often poses significant challenges due to the delicate conditions required. In particular, the realization of strong coupling with single nanoparticles has been predominantly demonstrated using J-aggregate dye molecules. In this work, we present a plasmonic cavity probe capable of transforming a nanocavity within a single nanoparticle. Our approach utilizes a plasmonic structure based on a gold self-aligned nanoring doublet (Au SAND) that incorporates an intraparticle nanogap (Fig. 1). Through dark-field scattering measurements on individual particles, we observe the emergence of exciton-plasmon polaritons, known as plexcitons, evidenced by the bifurcation of the scattering peak into two distinct resonances. Finite-element modeling is employed to elucidate the correlation between the Au SAND morphology and the cavity resonance wavelength relative to the exciton absorption, while temporal coupled-mode theory quantifies the strength of coupling. Verification of plexciton states is accomplished through photoluminescence measurements, which demonstrate light emission from the lower plexciton state. The proposed CQED nanocavity serves as a promising nanoprobe for the detection of small molecules within cells and offers a platform for groundbreaking biomolecular studies.

Abstract: We demonstrate cross-phase modulation of up to 17.5 mrad per polariton using laser beams attenuated to the average intensity of single photons, the highest amount achieved without using atom-like emitters. This advance opens new possibilities for quantum information processing and nonlinear quantum optics using strongly coupled light-matter systems.

The rapid development of quantum technologies is driving the implementation of novel photonic systems and spurring active research into new physical aspects within well-known photonic platforms. A key aspect of quantum photonics is the interaction of photons through optical nonlinearities, such as cross-phase modulation. In this study, we demonstrate that exciton-polaritons in an open cavity with embedded quantum wells can provide the necessary nonlinearity for the experimental observation of cross-phase modulation.

Our device is a tunable microcavity containing a single InGaAs quantum well (QW) (see Fig.1 (a)). The strong coupling between cavity modes and exciton resonances in the QW gives rise to exciton-polaritons. This strong nonlinear optical response in polariton systems enables the observation of various optical nonlinear phenomena [1-3], including single-photon-level nonlinear phase shifts [4].

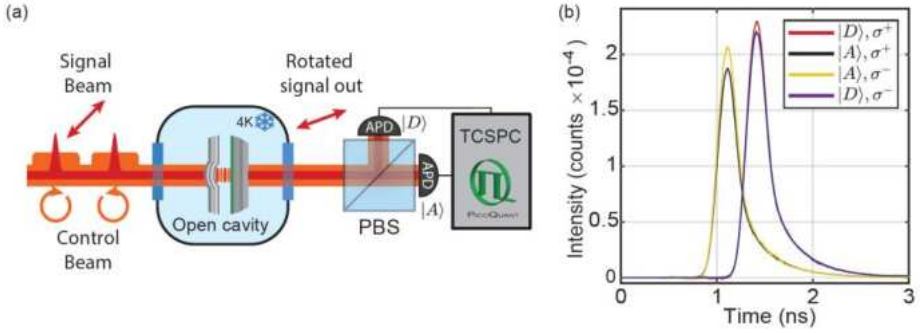

Fig.1 (a) Simplified schematic of the experimental setup. (b) Example of experimentally measured TCSPC curves for the signal beam after subtracting the background signal from the control beam.

To demonstrate the cross-phase shift, we resonantly excited the exciton-polariton state using a pulsed beam linearly polarized (signal beam) and a circularly polarized pulse beam with a longer duration (control beam). The linear polarization of the signal can be decomposed into two circularly polarized components. Polariton interactions strongly depend on the relative circular polarization [5]. As a result, the co-polarized signal component acquires a relative phase shift, leading to a rotation in the signal beam's linear polarization angle. Measuring this polarization change reveals the amount of the phase shift.

Examples of raw TCSPC curves recorded during a phase shift measurement are shown in Fig.1 (b). $|D\rangle$ and $|A\rangle$ denote the signals from avalanche photodiodes (APDs) measuring those polarization components while σ^+ and σ^- specify the control beam state. The phase shift ϕ is deduced from the difference in polarization degree with the

σ^+ and σ^- control beam, for relatively small nonlinear resonance shifts compared with the linewidth:

$$\phi \approx \frac{1}{2} \cdot \left(\frac{I_{|D\rangle}^{\sigma+} - I_{|A\rangle}^{\sigma+}}{I_{|D\rangle}^{\sigma+} + I_{|A\rangle}^{\sigma+}} \right) - \left(\frac{I_{|D\rangle}^{\sigma-} - I_{|A\rangle}^{\sigma-}}{I_{|D\rangle}^{\sigma-} + I_{|A\rangle}^{\sigma-}} \right)$$

Fig. 2 presents the relationship between the phase change and the number of polaritons $N_{Polaritons}$. These dependencies were measured for exciton-polariton states with an exciton fraction of approximately 35%. For the Sample A is 17.5 mrad per polariton, and for Sample B the phase shift is equal to 13 mrad per polariton. The main difference between the samples is the value of the observed Rabi splitting, which characterises the strong coupling between the excitons in a quantum well (QW) and the longitudinal mode LG_{00} in an open cavity. For Sample A, the Rabi splitting is equal to 2.66 meV, and for Sample B, it is 2.3 meV. One of the possible reasons for the observed difference is the lower oscillator strength of excitons in Sample B (as characterised in additional experiments). This not only affects the value of Rabi splitting but also can reduce the exciton nonlinearity, thereby reducing the observed optical phase shift.

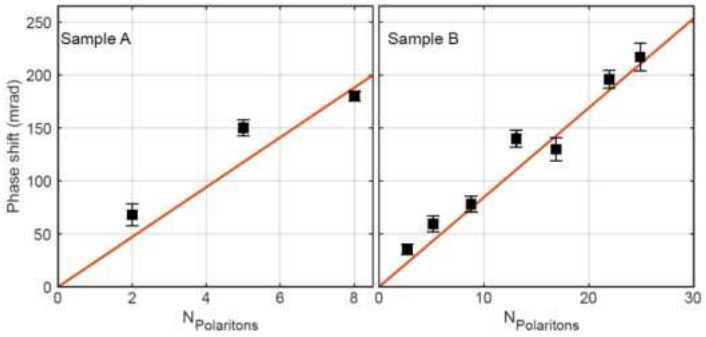

Fig.2 Phase shift measured on samples A and B as a function of the excited polariton number. The solid lines represent the best fits of straight lines passing through the origin to the data points.

For the first time, we have experimentally demonstrated an all-optical phase shift in a polariton system based on an open cavity, achieving a phase shift value of up to 17.5 mrad per polariton. In our experiment, we used laser beams that were synchronized in time and had the same wavelength. These beams were attenuated to an average intensity comparable to that of several photons. The optical phase shift demonstrated is five times larger than that observed in previous experiments with exciton-polaritons in semiconductor micropillars [4]. This marks the highest value achieved without the use of atom-like emitters, paving the way for new approaches in a wide class of nonlinear quantum optical phenomena and offering promising avenues for quantum information processing with polaritonic systems.
